Message from the USENIX ATC '22 Program Co-Chairs

Introduction

Welcome to the 2022 USENIX Annual Technical Conference (ATC). We are excited that, after two years of being virtual due to the COVID-19 pandemic, this year’s conference is held again in person. Because of the ongoing special circumstances, USENIX has adopted a hybrid model with some attendees and presenters connecting remotely.

Similar to last year, ATC 2022 is co-located with OSDI. Our 2021 predecessors have already written extensively about the opportunities and challenges of running two systems conferences at the same time (https://www.usenix.org/sites/default/files/atc21_message.pdf). This year brings the new challenge of running the two co-located events in a hybrid model. We very much look forward to meeting everyone in the systems community whether they attend ATC, OSDI, or both.

The rest of this document provides some insights into the submission and selection process that culminated in 64 accepted works that will be presented at the conference.

Submissions process

We have solicited full length and short papers presenting new and original computer systems work. We adopted a double-blind review process to minimize bias. To further the USENIX mission of bringing together researchers in academia and systems practitioners, we have designated a special Operational Systems Track (OST) category to solicit submissions describing the experiences from deployed systems at “production” scale with real-world data. OST submissions received the same rigorous review process but with different criteria. The submission’s novelty bar was lower, and system and organization names did not have to be blinded. Switching submission tracks after the deadline was forbidden.

Authors were requested to provide additional information with their submission. First, we asked whether the paper was a re-submission from prior ATC or some other conference. 65% of the papers were marked as first-time submissions and 45% of the accepted papers were first time submissions. In case of a resubmission, authors provided a description of what changes they made since the previous submission. The reviewers and the program committee (PC) had access to this information, but they did not know the venue where the paper was submitted or specific review comments (unless provided by the authors). Prior submission information had no bearing on assigning reviewers.

We also asked the authors to indicate whether they would make an artifact available. 70% of submissions indicated they would, if accepted. With all else being equal, the PC viewed more favorably submissions that would share an artifact over those that did not. As researchers, we need to ensure reproducibility of published works. As members of the USENIX community, we want to provide free and open access to data. The artifact evaluation process, which we instituted this year together with OSDI, provides this assurance.

We received 394 submissions, of which 21 (5%) were in OST and 23 (6%) were short papers. This was about 15% more submissions than in the previous two years. We rejected 5 submissions without a review due to violating one or more directives stated in the call for papers (CFP). The most popular submission topics were Distributed System (26%), Storage (24%), Machine Learning (21%), Operating Systems (15%), Networking (14%), Databases (13%) and Security (13%).

In the end, the PC accepted 64 submissions for an overall 16.5% acceptance rate. Acceptance was based on the quality of the submissions, while in-person conference constraints had no bearing on our decisions. Of the 64 accepted submissions, 7 (33% acceptance rate) were in Operational Systems Track and 2 (9% acceptance rate) were short papers.

Program Committee

We have assembled a program committee with many goals in mind: good coverage across diverse computer systems topics, balance between academia and industry, a mix of veterans of prior ATC PCs with individuals in early stages of their professional careers, geographic diversity, and adherence to the USENIX diversity and inclusion principles.

The assembled PC had 97 members from 15 countries, 52% from North America, 37% from EMEA and 10% from APAC. 60% of the PC were from academia and 40% from industry, though some PC members from academia were also affiliated with industry. 36% of the reviewers were early career researchers. Women were 64% more likely to decline an invitation to join the PC, which we find to be an alarming indication.

The main areas of expertise of PC members were Storage (22%), Distributed Systems (20%), Operating Systems (14%), Security (13%), Networking (12%) and Databases (9%). This was a good match to the submissions topics, given the PC was assembled in advance. As only 9% of PC members indicated that Machine Learning is their main expertise, a mismatch with 21% of submissions, we expanded the PC post submission deadline with more machine learning experts and recruited the help of a few expert external reviewers.

Reviewing Process

We proceeded with two double-blind review rounds with the authors’ response after round 2 and before the PC meeting. We sent early rejection notifications to 58% of papers 10 weeks after the initial submission to allow authors a quick turnaround on their resubmission. In the first round, we assigned 3 reviewers per paper, in the vast majority of cases, complementing the expertise with external reviewers as necessary. In the second round, we assigned at least two additional reviewers to the 162 submissions not rejected earlier.

After the authors’ response and an online discussion among the reviewers (with some papers receiving over 20 comments), we pre-accepted 48 papers. We identified additional 39 papers for discussion at the face-to-face (virtual) PC meeting, of which 42% of papers were accepted, and PC members had the opportunity to “revive” papers. Despite having PC members spanning a geographic area of 13 time zones, we conducted the virtual meeting “live”. While the day (and night) was long, with the usual logistical challenges of handling conflicts virtually in break-out rooms, we found that the ability to discuss and calibrate our acceptance criteria during the PC meeting was very important and proved very useful.

Artifact Evaluation Process

For the first time this year, ATC adopted an artifact evaluation process. The process ran jointly with OSDI, led by Anuj Kalia, Neeraja J. Yadwadkar, and Chengyu Zhang. The artifact evaluation committee chairs assembled a committee consisting of 118 members.

The authors of all accepted papers were invited to submit an artifact for an evaluation. 52 out of 64 papers (81%) had done so. 88% of artifacts received an “Available” badge, 76% received a “Functional” badge, and 61% received a “Reproduced” badge. 51% of papers received all three badges (some artifacts were reproduced, but are not available). Only one artifact received no badge.

Additional Observations

Strong papers easily stood out; 38% of the accepted papers received only positive reviews, and an additional 44% had only a single weak-reject initial recommendation. This is also why so many papers were accepted prior to the PC discussion.

The Operational System Track (OST) was intended only for operational systems, especially those deployed at scale. In particular, there was an interest in the experience using these operational systems. Some authors mistook a working prototype for an operational system. While all submissions to ATC are expected to describe working systems, a prototype implementation to gather experimental results is not the same. OST submissions required describing the experience of using the system.

Anonymization rules were not always followed. Only one paper was rejected immediately during post-submission checks for blinding authors names and affiliations. However, several papers were rejected following the first round of reviews, as authors had a technical report using a similar title or a similar system name. This, in turn, led to unblinding the papers to reviewers and violated the submission rules. Anonymization rules, especially when applied to technical reports, vary from year to year and between conferences. Authors should be extra vigilant when submitting blinded manuscripts.

Acknowledgements

More than 200 people have contributed to the organization of the USENIX ATC '22, most of them in a voluntary capacity. We would like to thank each and every one of them. We are tremendously grateful to the program committee members for a job extremely well done, and for their personal sacrifices. We thank the Artifact Evaluation committee and the Artifact Evaluation Committee Chairs for their work and contribution, which improves our community and enables future research. Last, we thank the USENIX organization, the USENIX ATC steering committee and OSDI '22 co-chairs. The amount of work and preparation that goes into organizing a conference is immense, and we were astounded by the help and support provided by everyone involved.

2022 USENIX Annual Technical Conference

July 11–13, 2022

Monday, July 11

Storage 1

ZNSwap: un-Block your Swap 1
Shai Bergman, *Technion*; Niklas Cassel and Matias Bjørling, *Western Digital*; Mark Silberstein, *Technion*

Building a High-performance Fine-grained Deduplication Framework for Backup Storage with High Deduplication Ratio 19
Xiangyu Zou and Wen Xia, *Harbin Institute of Technology, Shenzhen*; Philip Shilane, *Dell Technologies*; Haijun Zhang and Xuan Wang, *Harbin Institute of Technology, Shenzhen*

Secure and Lightweight Deduplicated Storage via Shielded Deduplication-Before-Encryption 37
Zuoru Yang, *The Chinese University of Hong Kong*; Jingwei Li, *University of Electronic Science and Technology of China*; Patrick P. C. Lee, *The Chinese University of Hong Kong*

Containers

RunD: A Lightweight Secure Container Runtime for High-density Deployment and High-concurrency Startup in Serverless Computing 53
Zijun Li, *Department of Computer Science and Engineering, Shanghai Jiao Tong University and Alibaba Group*; Jiagan Cheng, and Quan Chen, *Department of Computer Science and Engineering, Shanghai Jiao Tong University*; Eryu Guan, Zizheng Bian, Yi Tao, Bin Zha, Qiang Wang, and Weidong Han, *Alibaba Group*; Minyi Guo, *Department of Computer Science and Engineering, Shanghai Jiao Tong University*

Help Rather Than Recycle: Alleviating Cold Startup in Serverless Computing Through Inter-Function Container Sharing 69
Zijun Li, Linsong Guo, Quan Chen, Jiagan Cheng, and Chuhao Xu, *Shanghai Jiao Tong University*; Deze Zeng, *School of Computer Science, China University of Geosciences*; Zhuo Song, Tao Ma, and Yong Yang, *Alibaba Cloud*; Chao Li and Minyi Guo, *Department of Computer Science and Engineering, Shanghai Jiao Tong University*

RRC: Responsive Replicated Containers 85
Diyu Zhou, *UCLA and EPFL*; Yuval Tamir, *UCLA*

Distributed Systems 1

uKharon: A Membership Service for Microsecond Applications 101
Rachid Guerraoui and Antoine Murat, *École Polytechnique Fédérale de Lausanne (EPFL)*; Javier Picorel, *Huawei Technologies*; Athanasios Xygkis, *EPFL*; Huabing Yan and Pengfei Zuo, *Huawei Technologies*

KRCORE: A Microsecond-scale RDMA Control Plane for Elastic Computing 121
Xingda Wei, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University, and Shanghai AI Laboratory*; Fangming Lu, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; Rong Chen, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University, and Shanghai AI Laboratory*; Haibo Chen, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*

Zero-Change Object Transmission for Distributed Big Data Analytics 137
Mingyu Wu, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University and Shanghai AI Laboratory*; Shuaiwei Wang, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; Haibo Chen and Binyu Zang, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University and Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*

Sift: Using Refinement-guided Automation to Verify Complex Distributed Systems 151
Haojun Ma, Hammad Ahmad, Aman Goel, Eli Goldweber, Jean-Baptiste Jeannin, Manos Kapritsos, and Baris Kasikci, *University of Michigan*

Machine Learning 1

Faith: An Efficient Framework for Transformer Verification on GPUs 167
Boyuan Feng, Tianqi Tang, Yuke Wang, Zhaodong Chen, Zheng Wang, Shu Yang, Yuan Xie, and Yufei Ding, *University of California, Santa Barbara*

DVABatch: Diversity-aware Multi-Entry Multi-Exit Batching for Efficient Processing of DNN Services on GPUs . 183
Weihao Cui, Han Zhao, Quan Chen, Hao Wei, and Zirui Li, *Shanghai Jiao Tong University*; Deze Zeng, *China University of Geosciences*; Chao Li and Minyi Guo, *Shanghai Jiao Tong University*

Serving Heterogeneous Machine Learning Models on Multi-GPU Servers with Spatio-Temporal Sharing 199
Seungbeom Choi, Sunho Lee, Yeonjae Kim, Jongse Park, Youngjin Kwon, and Jaehyuk Huh, *KAIST*

PilotFish: Harvesting Free Cycles of Cloud Gaming with Deep Learning Training 217
Wei Zhang and Binghao Chen, *Shanghai Jiao Tong University*; Zhenhua Han, *Microsoft Research Asia*; Quan Chen, *Shanghai Jiao Tong University*; Peng Cheng, Fan Yang, Ran Shu, and Yuqing Yang, *Microsoft Research*; Minyi Guo, *Shanghai Jiao Tong University*

Operating Systems 1

Privbox: Faster System Calls Through Sandboxed Privileged Execution 233
Dmitry Kuznetsov and Adam Morrison, *Tel Aviv University*

BBQ: A Block-based Bounded Queue for Exchanging Data and Profiling 249
Jiawei Wang, *Huawei Dresden Research Center, Huawei OS Kernel Lab and Technische Universität Dresden*; Diogo Behrens, Ming Fu, Lilith Oberhauser, Jonas Oberhauser, and Jitang Lei, *Huawei Dresden Research Center, Huawei OS Kernel Lab*; Geng Chen, *Huawei OS Kernel Lab*; Hermann Härtig, *Technische Universität Dresden*; Haibo Chen, *Huawei OS Kernel Lab and Shanghai Jiao Tong University*

Disaggregated Systems

Sibylla: To Retry or Not To Retry on Deep Learning Job Failure 263
Taeyoon Kim, Suyeon Jeong, Jongseop Lee, Soobee Lee, and Myeongjae Jeon, *UNIST*

Speculative Recovery: Cheap, Highly Available Fault Tolerance with Disaggregated Storage 271
Nanqinqin Li, Anja Kalaba, Michael J. Freedman, Wyatt Lloyd, and Amit Levy, *Princeton University*

Direct Access, High-Performance Memory Disaggregation with DirectCXL 287
Donghyun Gouk, Sangwon Lee, Miryeong Kwon, and Myoungsoo Jung, *Computer Architecture and Memory Systems Laboratory, Korea Advanced Institute of Science and Technology (KAIST)*

Networking 1

Not that Simple: Email Delivery in the 21st Century 295
Florian Holzbauer, *SBA Research*; Johanna Ullrich, *University of Vienna*; Martina Lindorfer, *TU Wien*; Tobias Fiebig, *Max-Planck-Institut für Informatik*

AddrMiner: A Comprehensive Global Active IPv6 Address Discovery System 309
Guanglei Song, Jiahai Yang, Lin He, Zhiliang Wang, *Institute for Network Sciences and Cyberspace, BNRist, Tsinghua University and Quan Cheng Laboratory, Jinan, Shandong, China*; Guo Li and Chenxin Duan, *Institute for Network Sciences and Cyberspace, BNRist, Tsinghua University*; Yaozhong Liu, *Tsinghua University*; Zhongxiang Sun, *School of Computer and Information Technology, Beijing Jiaotong University*

Co-opting Linux Processes for High-Performance Network Simulation 327
Rob Jansen, *U.S. Naval Research Laboratory*; Jim Newsome, *Tor Project*; Ryan Wails, *Georgetown University, U.S. Naval Research Laboratory*

Finding Bugs

KSG: Augmenting Kernel Fuzzing with System Call Specification Generation 351
Hao Sun, Yuheng Shen, Jianzhong Liu, Yiru Xu, and Yu Jiang, *Tsinghua University*

DLOS: Effective Static Detection of Deadlocks in OS Kernels 367
Jia-Ju Bai, Tuo Li, and Shi-Min Hu, *Tsinghua University*

Modulo: Finding Convergence Failure Bugs in Distributed Systems with Divergence Resync Models 383
Beom Heyn Kim, *Samsung Research and University of Toronto*; Taesoo Kim, *Samsung Research and Georgia Institute of Technology*; David Lie, *University of Toronto*

Abstract

We introduce *ZNSwap*, a novel swap subsystem optimized for the recent Zoned Namespace (ZNS) SSDs. ZNSwap leverages ZNS’s explicit control over data management on the drive and introduces a space-efficient host-side Garbage Collector (GC) for swap storage co-designed with the OS swap logic. ZNSwap enables cross-layer optimizations, such as direct access to the in-kernel swap usage statistics by the GC to enable fine-grain swap storage management, and correct accounting of the GC bandwidth usage in the OS resource isolation mechanisms to improve performance isolation in multi-tenant environments. We evaluate ZNSwap using standard Linux swap benchmarks and two production key-value stores. ZNSwap shows significant performance benefits over the Linux swap on traditional SSDs, such as stable throughput for different memory access patterns, and $10\times$ lower 99th percentile latency and $5\times$ higher throughput for `memcached` key-value store under realistic usage scenarios.

1 Introduction

Swap is regaining interest from the academia, industry, and kernel communities [2, 3, 12–14, 42, 43, 53, 54] as SSDs are getting faster with both low-latency NAND and high-speed PCIe interfaces [5, 11, 51]. Swap on SSDs is no longer viewed as a last-resort memory-overflow mechanism, but as a crucial system component essential for effective memory reclamation and high system efficiency [3, 14, 18].

Unfortunately, the broader deployment of SSDs as swap devices is overshadowed by several notable performance issues. One of the key limitations is the system performance degradation as the SSD utilization increases. For example, [Figure 1](#) shows a drastic swap bandwidth drop as the device usage grows beyond 20%, forcing low space utilization to maintain high performance. In § 3 we thoroughly analyze this and other performance issues with swap on SSDs, such as bandwidth variations for different memory access patterns, and poor isolation in a multi-tenant setting.

These performance anomalies have no simple solution. They stem from the inherent mismatch between the easy-to-use block-interface abstraction and the intrinsic flash media

Figure 1: Swap-out bandwidth of random memory accesses (a common swap access pattern [43, 55]), with default Linux swap on Block SSD and ZNSwap on ZNS SSD. The two 1TB SSDs share the same hardware platform and media. WAF—Write Amplification Factor.

properties. In particular, this interface deliberately conceals the absence of in-place updates to flash-based media. Under the hood, updates are written out-of-place to a specifically allocated set of flash blocks (i.e., erase-block). To this end, SSD controllers implement a Flash Translation Layer (FTL), which translates the host-side random writes into sequential writes required by the media, and maintains logic-to-physical mapping for each block. It further entails a device-side Garbage Collection (GC) process to free up erase blocks and reclaim capacity for new writes.

More crucially, this interface decouples the media management from the host-side software stack, so neither the software using the SSD nor the SSD’s management logic have any visibility into each other activities. In the context of swap, this decoupling hinders the OS’s ability to optimize data placement on the device, and the device’s ability to leverage unique characteristics of the swap mechanisms and its usage of the device. For example, the performance degradation observed in [Figure 1](#) is caused by *Write Amplification (WA)*, i.e., the extra data movements performed by the GC. Notably, as we show in § 3, the Write Amplification Factor (WAF) ([Figure 1](#), right) could have been reduced if only the GC were aware of the OS-managed validity status of the stored blocks.

Zoned Storage interface for SSDs (ZNS) [4] aims to reestablish the host’s control over key aspects of the storage device management [25]. ZNS opens unique opportunities for cross-layer optimizations that allow novel storage-application co-design simultaneously tailored to the properties of the storage

media and its use by applications [25].

At a high level, ZNS introduces the concepts of zones. Zones disallow in-place updates and require their blocks to be written sequentially. To reclaim the space in a zone it needs to be reset, and new writes can be issued. One important benefit of the ZNS interface over prior attempts to expose flash media control to applications (i.e., raw flash or open-channel SSD [26]), is that it enables host-side storage control without having to deal with low-level media management such as wear-leveling or error correction.

In this work, we introduce **ZNSwap**, a novel swap subsystem for Linux that explores the advantages of the synergy between the SSD management and the OS swap logic, leveraging the ZNS interface to overcome the swap performance issues with block-interface SSDs. While prior works observed that the direct application control over SSDs can be beneficial in the context of file-systems and key-value stores [25, 26, 30, 59], ZNSwap is the first to leverage such control for the OS swap on SSDs.

ZNSwap provides a novel, space-efficient host-side mechanism for SSD space reclamation we call *ZNS Garbage Collector* (ZNGC). Unlike the device-side GC of traditional SSDs, ZNGC is tightly integrated with the OS and has direct access to OS data structures which it uses to optimize its operation.

ZNGC design poses a conceptual challenge, however. The space reclamation process naturally involves the migration of logical blocks on the device, without coordinating the block location changes with the applications that own the stored data. This is not a problem for an SSD-side GC because the user-visible Logical Block Addresses (LBA) remain intact. However, applying this solution to the host-side ZNGC would incur unacceptable space overheads in the host, requiring to maintain reverse mapping for every 4KiB block in TB-scale devices. ZNSwap avoids these overheads in the host by storing the reverse mapping information into the logical block metadata being written alongside the swapped-out page contents. The mapping is guaranteed to be correct during the page lifetime.

More specifically, ZNSwap brings the following benefits:

Fine-grain space management. ZNSwap obviates the need for TRIM commands, achieving higher performance and better space utilization. The OS uses TRIMs to hint to a Block SSD to deallocate specific LBAs, reducing the load on the SSD-side GC. Unfortunately, the use of TRIMs have been mostly disabled in the OS swap for their large overheads [35, 39, 50, 54], at the expense of significant bandwidth drop due to the artificial space bloat (§ 3.1.1). In ZNSwap, the ZNGC leverages the direct access to the OS internal page validity structures, without the costly overheads associated with TRIMs.

Dynamic ZNGC optimization. ZNSwap dynamically adjusts the number of swapped-in pages that are also stored in the swap device, improving the performance for read-mostly and mixed read-write workloads. The OS keeps a copy of unmodified swapped-in memory pages in the swap device

to avoid the swap-out penalty for those pages. The amount of disk space such pages may occupy is statically capped by the OS (50% in Linux, non-configurable). However, this static threshold does not fit all workloads: lower values degrade read-mostly workloads, whereas higher values affect mixed read-write workloads (§ 3.1.2). ZNSwap monitors the WAF and decreases the storage occupancy when necessary by reclaiming the SSD space from swapped-in pages.

Flexible data placement and space reclaim policies. ZNSwap allows easy customization of the disk space management policies to tailor the GC logic to the swap requirements of a specific system. For example, a policy may force co-location of data with similar lifetimes onto the same zone, which was shown to be useful before [28, 34, 44, 56], or achieve better performance isolation by dedicating a separate zone to handle swap from a specific tenant.

Accurate multi-tenancy accounting. As the ZNGC runs on the host, ZNSwap integrates with the cgroup accounting mechanisms to explicitly attribute GC overheads to different tenants, thus improving performance isolation between them.

To summarize, our main contributions are as follows:

- Thorough analysis of traditional Block SSDs' drawbacks when used as swap devices.
- A mechanism to enable ZNS SSDs to serve for swap, without resource-expensive redirection mechanisms in the host, by leveraging logical block metadata for efficient reverse-mapping.
- Custom swap-aware SSD storage management policies which reduce WA, improve performance, and achieve better isolation in multi-tenant environments.
- Extensive evaluation on standard benchmarks and real applications, demonstrating ZNSwap's performance gains, e.g., up to 10× lower 99th percentile latency and 5× higher throughput for `memcached`, with 2.5× lower WAF when compared to traditional swap on Block SSD.

2 Background

OS swap. When a system encounters memory pressure, it selects victim memory pages for eviction to a *swap device*. The OS unmaps the page chosen for eviction from the page-tables and *swaps-out* the page, writing it to the swap device.

Linux divides the space on a swap device into memory-page-sized blocks called *swap-slots*. The OS allocates a new slot for each page being swapped-out. When a page is swapped-in and the utilized swap device capacity is below 50%, Linux keeps the copy of the page both in memory and in the swap. Such pages belong to the *swap-cache*. The OS evicts swap-cache pages without writing them back to the swap. The swap-slot is freed upon the first write to a swap-cache page, and the page is removed from the swap-cache.

Block SSD space management. The SSD's FTL maps Logical Block Addresses (LBAs) to the physical data locations

within erase-blocks on the device. An update to a logical block is implemented by writing the new data to a separate erase-block, and then remapping the host-side LBA to the new block, followed by invalidating the old one. To free space for new writes, a *Garbage Collector* (GC), executed by the SSD controller, reclaims the invalidated blocks and consolidates the still-valid blocks from multiple erase-blocks to a new erase-block, and then erases the freed erase-blocks. This operation requires *over-provisioning* (OP) of the flash media in the drive in order to reduce the number of copies during the GC operation.

The device-side GC competes for bandwidth with the user I/O. The relative increase in the amount of data written due to GC vs. the external writes is called a *Write Amplification Factor* (WAF). The smaller the OP, the higher the WAF and the lower the user-visible performance of the device [34].

Zoned Namespace (ZNS) is a new storage interface for SSDs [25]. A ZNS SSD is organized as a set of logically-addressable *zones*. Each zone is physically aligned to an SSD's erase-block size. Reads inside a zone can be random, but writes must be *sequential*. Writing to a zone can be done via the common write command or through the *Zone Append* command. The latter works by the host specifying the zone, and the SSD returning the specific write location upon completion, which allows multiple in-flight requests to the same zone [24] (unlike the write command).

Each zone may be either `Empty` (initial state), `Open` (after the first write) or `Full` (no longer writable). The SSD maintains a write pointer to the next logical block for each `Open` zone. To rewrite a zone, it must be *reset*, which transitions it into an `Empty` state. There is a hardware limit on the number of simultaneously `Open` zones.

3 Motivation

Swap performance is important for data centers. The proliferation of fast flash-based storage revitalized the use of swap as a way to maximize memory utilization and reduce costs. Today, swapping does not serve for sustaining severe memory pressure alone. Rather, swap acts as a memory extension during moderate loads, e.g., to optimize the in-memory balance between file-backed and anonymous memory pages [3].

Thus, the swap performance is becoming increasingly important. Recent works propose to accelerate the swap with dedicated hardware [42]. Linux kernel added optimizations to its memory reclamation mechanism [13]. Alibaba Cloud added a per-cgroup background reclaim mechanism [12] to improve multi-tenancy support in data centers. Facebook introduced swap controls for the cgroupv2 mechanism and used it in the `fbtax2` project to improve system efficiency [10].

This trend highlights the importance of swap in modern systems. However, most of the current works focused on the

OS logic alone. Here we present a thorough analysis of the Linux swap performance focusing on the interplay between the swap logic and the SSD behavior.

3.1 Performance anomalies of swap on SSDs

3.1.1 GC is not aware of deallocated swap-slots

As shown in [Figure 1](#), the swap bandwidth decreases as the swapped-out data occupies a larger part of the device. In general, this behavior is expected because the GC overheads grow proportionally to the amount of actively updated data. However, the drop should not occur when a device is almost empty (occupied only 10% of its capacity).

The root cause is that the device-side GC is *not aware* that the OS discards some swapped-out pages and *invalidates* their respective swap-slots because the OS does not by default notify the SSD. Therefore, the *actual* occupancy of the swap device is much higher than the one visible to the OS, leading to higher GC overheads.

To cope with this issue, most SSDs implement a `TRIM` command that allows the OS to *hint* to the SSD to reclaim the storage of invalidated swap-slots. However, in practice, popular Linux distributions (e.g., Debian, Ubuntu) disable the use of `TRIM` command for swap [7, 9, 15, 21]. The reasons include `TRIM` dispatching overheads, the long latency of the `TRIM` command, and the complexity of supporting asynchronous `TRIMs` [35, 39, 50, 54, 54].

When `TRIMs` for swap are explicitly enabled, Linux issues the command *once* for a batch (*cluster*) of 512 invalidated swap-slots, to reduce the overheads. Notably, these swap-slots must be *contiguous* in the LBA address space [1].

To see the performance effect of `TRIMs`, we run the same random-write `vm-scalability` benchmark as in [Figure 1](#), but with `TRIMs` enabled (see § 6 for the setup). We measure the swap-out bandwidth and WAF over time as the device is being used to illustrate gradual performance degradation.

[Figure 2](#) shows that `TRIMs` (512-slot) have negligible effect. This is because the LBA contiguity requirement of `TRIM` clusters in Linux effectively prevents issuing `TRIMs` for the majority of the invalidated slots. These results corroborate the note in the `swapon` man page [20] that enabling `TRIMs` often does not improve swap performance.

Finer-grain `TRIMs` are not effective either. To demonstrate this, we develop a special mechanism that enables `TRIMs` for small contiguous clusters of eight swap-slots. This is not a practical approach, however, due to its high overheads (see § 6.1.1) [Figure 2](#) shows slight performance improvement, but still $2\times$ lower than the maximum bandwidth. Clusters smaller than 8 slots result in a prohibitively high rate of `TRIMs`, so the SSD cannot keep up with the swap-slot invalidation rate.

Observation 1: `TRIMs` are not effective at lowering GC overheads for swap.

Figure 2: Swap-out bandwidth over time. Random memory writes using 40% of swap capacity.

Figure 3: Swap-in bandwidth of random reads as a function of swap capacity utilization.

Figure 4: Swap-in and swap-out bandwidth for random reads and mixed reads and writes workloads respectively for different swap reclamation cutoffs.

3.1.2 Swap cache is not aware of GC

We execute the `vm-scalability` benchmark to perform uniform random reads on a large chunk of memory exceeding physical RAM and measure the swap performance for different values of the swap device utilization. Ideally, we expect the read performance to be independent of the utilization. Instead, Figure 3 shows a $6.9\times$ slowdown and $2.5\times$ WAF above 50% occupancy.

Our analysis shows that this problem occurs due to the way Linux implements its swap-cache. Recall that this cache is comprised of pages that are swapped into memory but the OS still maintains a copy in the swap. When the swap device’s utilization exceeds 50% – a hard-coded static parameter we call *swap reclamation cutoff*, Linux stops adding newly swapped-in pages to the swap-cache, invalidating their swap-slots immediately. As a result, the swap-out penalty for such pages incurs writing a page to the swap device, rather than discarding them from memory if they were in the swap-cache.

We suggest two possible reasons for this implementation. First, as the swap device gets full, the swap-slot allocation algorithm scans the swap-slot array linearly, which becomes slow [6]. Second, in the context of SSDs, deferring the swap-slot invalidation for in-memory pages effectively increases the device occupancy and eventually reduces performance due to the GC.

Unfortunately, the swap reclamation cutoff establishes a trade-off between the swap-out performance (preferring higher cutoff), and WAF (preferring lower cutoff). To illustrate, we measure the performance of two applications: one performing reads, and the other mixing both reads and writes. This setup aims to show that lower values of the reclamation cutoff are good for write-intensive workloads and bad for read-intensive ones. Higher values mirror this behavior.

We execute `vm-scalability` configured to use 80% of the swap device’s capacity. Half of the working set fits in RAM. Figure 4 shows the swap-in and swap-out bandwidth and WAF as a function of the swap reclamation cutoff. For random reads, the swap-in performance increases with the reclamation

cutoff, as fewer pages need to be written back upon eviction, with all the pages having copies both in the swap and in memory at the extreme. For the mixed workload, the effect of the cutoff is not visible with the default Linux configuration because the performance is low anyway. But with fine-grain TRIMs and higher baseline performance, smaller cutoff values are preferable.

Observation 2: The static reclamation cutoff strives to strike a balance between read and write performance, but instead aggressively prioritizes write workloads when the swap occupancy grows.

3.1.3 GC is not aware of page access pattern

We evaluate the performance of workloads with different memory access patterns using `pmbench`. We consider two write workloads: with uniform and with skewed access distributions (normal, $\sigma = \frac{1}{12}$ of the working set size, the default in `pmbench`). The swap-out bandwidth is 480MiB/sec (maximum for this SSD), and 195MiB/sec (WAF is 2.5) respectively, when using 5% of the swap capacity and 512-slot TRIMs enabled.

This difference stems from the different lifetimes of swapped-out pages. With the skewed distribution of memory writes, there are fewer opportunities for the swap subsystem to find large contiguous clusters of swap-slots to perform TRIMs, whereas uniformly distributed writes result in the swap-slots of similar lifetimes, increasing the chances of finding such clusters. 8-slot TRIMs are better, but the performance is still suboptimal: 324MiB/sec, with WAF of $1.5\times$.

Observation 3: Swap performance may vary significantly depending on the memory access pattern.

3.1.4 GC is not aware of OS’s performance isolation

Linux’s cgroup mechanism enforces resource isolation among different processes. In particular, it is possible to isolate swap bandwidth via `blk-throttle`. This is useful, e.g., in container-based virtualized environments to prevent performance interference between containers.

Figure 5: Swap-in bandwidth and WAF of 100%-random-read cgroup (A) and 50/50%-random-read/write cgroup (B) co-running together, each throttled to 300MiB/sec reads and 300MiB/sec writes.

We now evaluate the quality of the performance isolation in a scenario where we expect no interference. We run two processes, each in its own cgroup limited to 300MiB/sec reads and 300MiB/sec writes from/to the swap device. One process performs 100% reads and the other executes an equal mix of reads and writes, all uniformly distributed. To prevent any interference the processes are pinned to separate sets of cores, each with its own device queue. The aggregate bandwidth of the SSD does not reach its limit (1GiB/sec).

We expect both processes to achieve their maximum bandwidth allocation. In practice, during the first 20min of the execution (Figure 5) no GC is performed, thus the SSD sustains the cumulative request rate from both processes. When the GC is triggered, the swap-in bandwidth of *both* cgroups drops. Importantly, the first process performs only reads, and should not have been affected by the GC overheads caused only by the writes of the second process. This behavior stems from the GC’s inability to distinguish between the I/Os from different processes, and the OS’s inability to enforce bandwidth limits on the GC.

Observation 4: The GC impairs performance isolation dictated by the host OS.

3.2 Opportunities with swap on ZNS

ZNS SSDs provide better control over physical data placement, thereby enabling tighter coupling between the application logic and the device management, and have already been shown to offer new optimization opportunities for production Key-Value-Stores [25]. These results motivate a new GC-swap subsystem co-design that can leverage this coupling to mitigate the performance problems of traditional SSDs discussed above.

Is ZNS essential for performance? An important question is whether there is an inherent benefit to using ZNS SSDs over traditional ones, or one can redesign the swap subsystem alone to achieve the same outcome. In other words, can we achieve the performance of ZNS by emulating it on top of a Block SSD?

To answer, we run an experiment on a Block SSD while using a write access pattern that mimics the one enforced by ZNS zones. We run multiple threads, each performing

Figure 6: Write bandwidth and WA of sequential writes and TRIM operations to erase-block sized regions on Block SSD and ZNS SSD as a function of device utilization.

4KiB logically sequential writes with 1GiB-TRIMs (the size of an erase-block and a ZNS zone on our device). Each thread accesses its own part of a drive, and overwrites the available space, issuing a TRIM for the whole next 1GiB chunk. Multiple threads are used to emulate typical swap behavior.

We run the experiment for different values of device utilization. Figure 6 shows the results. We observe that the performance starts to decrease when a device is 30% full, drops to a half of the maximum bandwidth at 50%, and degrades down to a quarter at 80%. This is expected because the Block SSD cannot ensure that host-side TRIMs are aligned with physical erase-blocks as the writes from different threads get mixed in the device, even though the host strives to align them at the LBA level. In contrast, the same experiment on ZNS drives maintains full bandwidth no matter how full the device is.

We conclude that the *ZNS interface offers unique advantages that cannot be achieved with traditional Block SSDs.*

ZNS adoption. ZNS SSDs are expected to gain broader adoption in the near future. They hold the promise to reduce storage costs as they lower the internal DRAM size requirements, and might help reduce media overprovisioning via application-optimized software stack [25].

While the ZNS interface is not backward compatible with the in-place block interface, there is growing support for ZNS at the file system level. For example, F2FS and Btrfs in Linux can utilize ZNS drives.

These trends motivate us to tailor OS swap for ZNS SSDs.

4 Design

ZNSwap addresses three key design goals.

Resource-efficient Host-side GC. Reclaiming storage space in ZNS SSDs requires a host-side process akin to a GC that consolidates valid blocks from fragmented zones into new ones, subsequently erasing the freed zones. The primary challenge is in minimizing the memory and CPU overheads associated with the host-GC operation. This is because, unlike the device-side GC, the host-side GC directly competes for these host resources with regular applications. In essence, we need to *on-load* the GC to the CPU from the device with minimal costs, thereby enabling its tighter integration with the swap.

Figure 7: ZNSwap overview. Shaded shapes are internal ZN-Swap components.

These resource constraints preclude direct porting of existing host-side GC implementations. In particular, such implementations commonly maintain large translation tables (FTL) [32, 37], which consume about 1GiB for every TiB of data. The tables are frequently updated by writes and GC operations and accessed during reads. Given the typically poor locality of swap-induced I/O accesses [43, 55], these tables have to be resident in host memory. Maintaining the extra level of indirection between logical and physical block addresses appears to be inevitable to allow the host-side GC to move data without affecting the applications using it.

Our host-side GC, *znGC*, eliminates the need for the extra level of indirection entirely. It takes advantage of the fact that the swapped-out pages are still maintained in their owner’s page tables, and thus stores the relevant kernel reverse mapping metadata alongside the swapped-out page in the SSD. It also avoids I/O overheads to manage the reverse mappings by using the per-LBA metadata region available in NVMe devices as we describe in §§ 4.2 and 5.1.

ZNGC-OS integration. The key benefit of ZNGC over device-side GC is the ability to access the information exposed by the OS to optimize the swap I/O performance. For example, ZNGC may consult the OS-maintained swap-slot array to identify OS-invalidated swap-slots and avoid redundant copies without using TRIMs. We explain this and additional optimizations in § 4.3.

Swap data placement policies. Swap data placement may have a significant effect on the system performance, but the placement policy may depend on the specific execution environment. For example, a policy to achieve better resource isolation between a pair of processes might prefer storing all the pages of the same process in the same SSD zone. We strive to facilitate the implementation of such policies via a set of APIs that hide the complexity of zone management and ZNGC logic. We explain the API and the policies in § 4.3.

4.1 Overview

Figure 7 shows ZNSwap’s main design components. We explain each component and its role using the swap-out path as an example.

After a page to be swapped-out is selected by the OS, it is passed to the *ZNS page reclaim* ① which handles the page-table and swap-cache operations ②. In contrast to the original swap logic, it updates the destination location for the swapped-

Figure 8: Linux reverse mapping overview. Shaded shapes are data structures accessed during ZNGC reverse mapping.

out page *after* it has been written, as dictated by the ZNS zone-append interface. Before writing a page, the page reclaim module consults the *policy manager* ③ which determines the destination *zone* and may guide ZNGC to free certain zones on the device. The policy manager incorporates custom policies that can be tailored to specific system requirements. The *zone allocator* ④ seamlessly handles Full zones and allocates a new zone when necessary.

The page is then submitted to the *block layer* ⑤, which subsequently passes the page to ZNSwap’s *I/O manager* ⑥. The I/O manager merges zone-append operations whenever possible, and generates an I/O request containing the page’s data and reverse mapping information used by ZNGC. Finally, the I/O manager hands off the I/O requests to the NVMe driver ⑦ which writes to the ZNS SSD ⑧, and updates the reclaim module with the page location on the SSD ⑨.

4.2 ZNGC

ZNSwap’s reclamation mechanism, ZNGC, is tightly integrated with the kernel virtual memory (VM) subsystem. ZNGC runs as a daemon in the kernel and is triggered either when the number of `Empty` zones is low, or via explicit requests by the ZNSwap policy.

Contrary to Block SSDs, a page moved by ZNGC is assigned a new host-visible address. Without an additional translation layer, ZNGC must update the page tables holding the original page swap-slot to reflect the new location. To this end, ZNGC stores the relevant reverse-mapping metadata alongside the data in the ZNS SSD’s per-LBA metadata region to assist later in updating the page tables. The storage interface (i.e., NVMe) allows to retrieve the metadata together with the respective data block in a single I/O operation. Thus, ZNGC retrieves the metadata to perform the reverse lookup of a given page and then updates the page table(s) that own it.

An important question remains: *which information* needs to be stored in the page metadata to guarantee that the reverse mapping remains correct during its lifetime?

To answer it, we leverage the same main data structures and procedures in the Linux kernel used to implement its reverse mapping scheme (Figure 8).

Background: Linux memory mapping structures. Recall that virtual memory pages in a process’ address space belong to virtual memory areas (vmas) that represent virtual memory allocations. vmas belong to a process’ virtual memory

address spaces (`mm_structs`), which hold the page table directory (`pgd`). The physical page descriptor (`struct page`) holds metadata enabling the reverse mapping. ZNGC stores the same metadata fields in the logical block’s metadata on the SSD.

To locate *all* page table entries associated with a physical page, the reverse mapping procedure accesses the `anon_vma` data structure, which is present between each physical page and the virtual memory area (`vma`) structures that map it¹. The `anon_vma` structure holds a list of `vmas` which may map the page and accounts for changes to the virtual mappings of the physical page. The physical page’s descriptor (`struct page`) does not directly account virtual mapping changes, rather, the descriptor holds a pointer to the `anon_vma` in its mapping field.

The `mm_structs` of each of the `vmas` that may map the page are accessed, and their page tables are walked to locate the page table entries. To calculate the virtual address used to walk the page tables, the `index` metadata value along with the `vma`’s start virtual memory address are used. The physical address corresponding to the physical page we have initialized the reverse mapping procedure is located in the last level page table entries and subsequently returned. Since swapped-out pages do not have a valid physical address in their page table entry, ZNGC returns the entries that hold the swapped-out location of the swap-slot we were performing the reverse mapping procedure.

Since the `anon_vma` structure is freed when there are no more `vmas` which may map the page and the `anon_vma` pointer in the `struct page` does not change, storing the pointer to the `anon_vma` as well as the mapping’s offset (`index`) within the logical block’s metadata on the SSD enables the same functionality as reverse mapping within the kernel.

4.3 ZNGC-swap integration

Physical zone information. Each zone is associated with a map of swap-slots. The map holds information on the use of each swap-slot, and whether it is valid, or swap-cached (similar to Linux’s `swap_map`). This information is used by ZNGC during the space reclamation. Note that a swap-slot can be discarded by the OS and ZNGC becomes immediately aware of the change, without using TRIMs as in Block SSDs. ZNGC may decide to reclaim some zones that are mostly free but hold some of the swap cache pages if it runs out of free storage space, making the swap reclamation cutoff parameter in Linux unnecessary.

Swap-zone abstraction. Active zones that can be used for swap-slot allocation are exposed via a *swap-zone* abstraction. A swap-zone is a virtual entity used to hide the complexity of managing physical SSD zones. Swap-zones are backed by Open zones. When an underlying physical zone transitions

Table 1: ZNGC policy API.

to the Full state, it is seamlessly replaced by another Open physical zone. The total number of swap-zones is determined by the limit on the number of Open zones in the device.

ZNSwap policies. ZNSwap provides an API to facilitate the development of custom data placement and zone reclamation policies. A policy is invoked when the OS swaps-out a page, and its primary goal is to determine which swap-zone the page is written to. If there is a need to reclaim some of the zones, the policy may (asynchronously) invoke ZNGC to do so for a specific set of zones. The policies are implemented in a kernel module. Note that the swap-slot allocation policy operates at the granularity of swap-zones rather than swap-slots to conform to the ZNS interface.

API. A policy receives the page frame number (`pfn`) of the page being swapped-out and returns the `swap_zone_id` of the swap-zone where the swap-slot should be allocated. Table 1 lists the functions that can be invoked by the policy.

We define three sample policies:

per-core policy Attempts to assign a swap-zone per-CPU-core. If there are more cores than Open zones, the swap-zones are multiplexed. This mimics Linux’s swap-cluster per core policy and reduces contention on swap-zones.

hot/cold policy Utilizes a per-page access history bit-vector maintained by the OS and assigns hot and cold pages to different swap-zones.

cgroup policy Attempts to assign a swap-zone per-cgroup. If more cgroups are available, the swap-zones are multiplexed. If cgroup swap limits are set (max number of swap-slots), the policy will reclaim a zone used by the cgroup whose number of used zones exceeds the limit the most (as zones may contain invalidated swap-slots).

Example policy. We use cgroup policy to illustrate the use of the policy API. When invoked, the policy:

1. Selects the destination swap-zone for the cgroup (using

the `cgroup_id` from `pg_inf()`).

2. If the number of free physical zones is below a predefined low watermark (`swap_inf()`):
 - 2.1. Selects a victim cgroup whose number of utilized physical zones exceed its allocated swap-slot capacity the most.
 - 2.2. Iterates over the cgroup's physical zones (obtained via `swap_zone_id` from `zn_inf()` corresponding to the swap-zone allocation of the cgroup) and selects the zone with the least amount of valid slots.
 - 2.3. Triggers an asynchronous explicit reclaim on the victim zone (`rec_zn()`).
 - 2.4. Repeats the procedure until enough zones have been reclaimed (step 2.1).
3. Returns the destination swap-zone.

cgroup accounting. When a cgroup's swapped-out data is copied during the ZNGC operation, ZNGC's bandwidth is accounted as part of the cgroup's total bandwidth to the device. We do not yet implement the CPU accounting, but this is not critical as ZNGC's CPU overhead is low as we show in § 6.1.1.

4.4 Discussion

ZNSwap introduces the zoned namespace interface to core kernel mechanisms which used to support only traditional block devices. The ZNSwap's design is driven by the fundamental characteristics of ZNS SSDs, that are unattainable with traditional Block SSD, and which dictate the following design choices:

- **Zoned interface:** ZNSwap fully adheres to the zoned storage specification, therefore it inherits the specification's integral benefits. For example, ZNSwap utilizes zone-append operations to enable concurrent writes to sequential-write-only zones, accelerating the swap-out procedure to ZNS SSD by sequentially appending page data.
- **ZNS-related host responsibilities as opportunities:** ZNS requires implementing host-side GC, which present new opportunities for WA mitigation, better utilization of the SSD's capacity for swap-cache pages, and for improving performance isolation.
- **Tight integration of ZNSwap with kernel mechanisms:** utilizing fine granularity information the OS attains per swap-slot enables better synergy between the OS and ZNS SSD.

Hardware limitations. The number of possible destination zones for swapped-out pages in ZNSwap's data placement policies are limited by the number of `Open` zones the ZNS SSD supports, which is device specific. The limit affects the granularity of the policies' classifications. ZNSwap is designed to support ZNS SSDs with varying number of `Open` zones and zone sizes, and abstracts the intricacies of zone management via the swap-zone abstraction (§ 4.3).

ZNSwap also requires the use of the ZNS SSD's per-block metadata (64B). While per-block metadata is currently sup-

ported primarily in enterprise NVMe-SSDs, we believe that it will be a common feature among ZNS-SSDs.

5 Implementation

ZNSwap adds support for the zoned-interface model to key kernel mechanisms located in several subsystems. We implemented ZNSwap in Linux 5.12 with 4K LOC² (CLOC [8]).

5.1 ZNS page reclaim

Linux's reclamation algorithm is incompatible with the zone-append interface because it assumes that the write location of the swapped-out data is known before the write completion. Specifically, the algorithm uses the swap-slot as the key in the swap-cache for the page currently undergoing reclamation. If a page is accessed while it is being written to the swap device, a page-fault is raised, and the kernel locates the page in the swap-cache using the swap-slot entry to remap it.

ZNSwap redesigns the swap-out mechanism not to rely on the pre-acquired swap-slot entry. The main idea is to utilize the dirty bit of the page's page-table entry to indicate whether the page has been dirtied during the data transfer to the swap device. Write access to such a page does not raise a page-fault since the page is *still mapped* in the page-table. Rather, we check the dirty bit in the page-table when unmapping it. We provide more details in Appendix A.

5.2 ZNGC

We now describe the zone reclamation process in detail. ZNGC first selects a candidate zone from a preselected set of zones supplied by the policy. Given a zone, ZNGC scans through batches of pages until a whole zone is reclaimed. Figure 9 depicts the main stages:

Gather. ZNGC checks the swap-slots in the candidate zone. Swap-slots of the pages currently cached by the swap-cache are removed from the swap-cache and their swap-slots are invalidated. Occupied valid swap-slots are gathered into a pre-allocated array of block IOs to perform device reads. This stage completes when the block IO array is full, or until it reaches the end of the zone.

Read. The occupied blocks IOs containing the read operations are dispatched as a batch of requests to the device. The destination of each read operation corresponds to a page from a pre-allocated page pool. The metadata for each swap-slot is read from the device into a buffer.

Write. Once all read operations are complete, each occupied page from the page pool is examined and assigned a destination zone based on the ZNGC-swap policy. The block IO array is subsequently reused to hold all the pending write requests, which are dispatched as a batch.

²<https://github.com/acsl-technion/znszap>

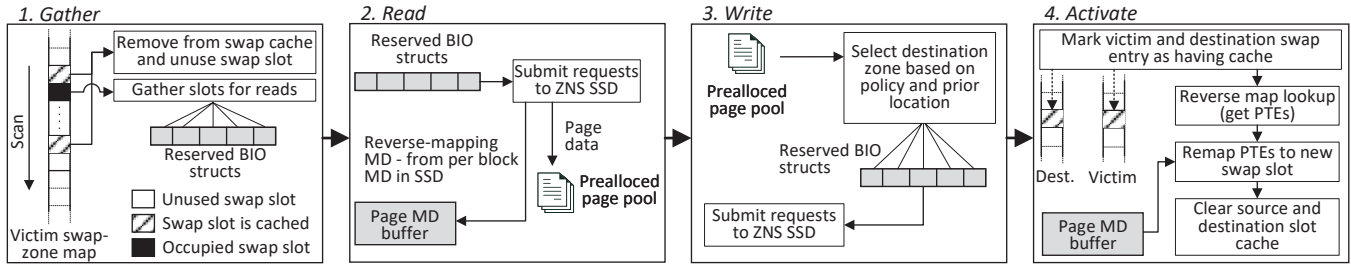

Figure 9: ZNGC: main stages in garbage-collecting a victim zone.

Activate. After the write operations complete, the corresponding swap-slots in the victim’s zone are re-examined. If a swap-slot is still valid and occupied, it is marked as if it resides in swap-cache in both victim and destination zones, to indicate to other kernel procedures that these swap-slots are currently in use. The page-table entries corresponding to the victim swap-slots are subsequently remapped to hold the destination swap-slots with the help of the reverse mapping information obtained from the metadata (`mapping` and `index`). Finally, the victim swap-slots are cleared. After ZNGC traversal over a zone is complete, the zone is reset.

Concurrent accesses to swapped-out pages undergoing migration trigger a regular swap-in operation. ZNGC will skip the corresponding swap-slot’s migration as the page resides in memory, and will continue with the reclamation of the zone.

ZNGC does not perform dynamic memory allocations and is designed to occupy a minimal amount of physical memory (up to 5MiB).

5.3 I/O manager

ZNSwap’s I/O manager adds support for zone-append merges and seamlessly stores the per-page reverse-mapping information into the metadata region of each written LBA.

Zone append merges. ZNGC and the page-out procedures take advantage of the `blk_plug` mechanism to batch together zone-append operations destined to the same zone. We add support for zone-append merges in the block layer by identifying block IOs destined towards the same zone that are waiting to be drained and merge the page-list of each block IO, creating a single block IO request. Once the request has been completed, we iterate over the pages in the request and generate an independent completion notification to each of the merged block IOs with their respective write location, calculated from their offset within the merged block IO and its final location.

Reverse mapping metadata. The I/O manager allocates a DMA-mapped physical page pool for metadata associated operations. The pages serve as a host buffer for the per-page metadata, and act either as a source or target location for append and read I/Os, respectively. The DMA address of the pages is supplied as part of the per-LBA metadata for each command. When serving a swap-out append operation, each

LBA stores 16 bytes of metadata for the reverse mapping information of the page (`mapping` and `index`).

6 Evaluation

Our evaluation demonstrates the benefits of ZNSwap using ZNS SSDs over the Linux swap using Block SSDs. In particular, we focus on the benefits of integrating the ZNGC with the host OS and the usefulness of ZNGC policies. We note that all our benchmarks perform direct *memory* accesses only, and impose SSD accesses due to the swap activity. Thus, the actual SSD access pattern might differ from the memory access pattern in the benchmark.

Can ZNS drives be used via compatibility layers? Linux swap does not work on top of ZNS drives, either as a swap-file or a swap partition. Existing Linux device-mappers such as `dm-zoned` [49] and `dm-zap` [33] aim to expose zoned devices as regular block devices without any write-pattern constraints but require large mapping structures for indirection. However, they do not currently support ZNS SSDs. Therefore, the only plausible baseline is Linux swap with block SSDs.

Hardware. We use a server with 2× Intel Xeon Silver 4216 CPU and 512 GiB of memory (2× 256 GiB DDR4 2933 Hz), with Ubuntu 20.04, Linux 5.12.0. HyperThreading is disabled, the frequency governor is "performance", and "turbo" is disabled to achieve stable results. We use a 1 TB production-grade Western Digital ZN540 ZNS SSD and an equivalent 1TB conventional Block SSD (with 7% OP) that uses the same hardware platform and media. Both SSD’s maximum sequential read and write bandwidth is 3.2 GiB/sec and 1 GiB/sec respectively. Random 4 KiB reads and writes reach 1.4 GiB/sec and 1 GiB/sec respectively. For the ZNS SSD, the writeable capacity of each zone is 1077 MiB, and is formatted with the ability to store 64 B of metadata per LBA.

Setup. We configure the swap size to be the size of the system memory (512 GiB) according to the common practice [19]. The remaining capacity on the drives is filled with data. The resulting effective OP of the swap partition in the Block SSD is 12%, therefore we configure ZNSwap to use the same OP.

Before each experiment, the SSD is formatted, followed by a ramp-up until the workload has reached its steady state [17]. Bandwidth and WAF measurements are sampled at 10 min

Figure 10: Swap-out bandwidth of `vm-scalability` with random memory writes. As expected, higher device utilization results in higher GC load.

intervals. The Block SSD’s WAF is measured through the device’s internal host- and media-writes counters, and the ZNS SSD’s WAF is measured by recording the number of writes performed by ZNGC.

Performance metrics and optimal performance. We primarily focus on the swap-out bandwidth as the main performance metric. The rationale is that under write-intensive memory access pattern, swap-in operations trigger the eviction of an equal amount of dirty pages to the drive. Hence, the resulting SSD access pattern is an equal mixture of 4KiB random reads and mostly random writes for Block SSD, and random reads and sequential writes for ZNS SSD.

The maximum write bandwidth for such a 50%/50% access pattern on both Block SSD and ZNS SSD drives is measured to be 488 MiB/sec. Therefore, we claim that the ZNSwap’s performance benefits over the Linux swap baseline presented in this section *stem primarily from ZNSwap design rather than from the performance differences among the drives or the difference in the access patterns.*

6.1 Synthetic benchmarks

We use the standard swap performance benchmarks, `vm-scalability` [22] and `pmbench` [58] which allow evaluating the performance of the swap subsystem and the swap device under different memory access patterns.

We rerun several experiments from the Motivation section on ZNSwap, to show how it recovers the system performance for the cases where the standard Linux swap on Block SSDs suffers from the performance anomalies.

6.1.1 Benefits of ZNGC-swap subsystem integration

Swapping without TRIMs. We execute `vm-scalability` in a 2 GiB memory-limited cgroup. In each experiment, we pre-allocate different amounts of memory to evaluate different levels of the swap device’s capacity utilization. We then perform random writes to that memory (`case-anon-w-rand-mt`), resulting in random read/writes from/to the swap device. To maximize throughput, we execute 64 threads ($2\times$ the number of available cores). This is the same experiment as in § 3.1.1.

Figure 10 shows the results. ZNSwap immediately observes the OS-managed swap-slot allocation without using TRIMs, and as such only moves the valid pages when running ZNGC. While ZNGC adds overheads to the host, ZNSwap outperforms the Linux swap in all cases but at 10% utilization due to the device WA being lower.

CPU overheads of ZNGC vs. fine-grain TRIMs with Block SSD. We measure the maximum CPU overhead of ZNGC under 80% swap device utilization in Figure 10. We observe that ZNGC occupies 15% of a single CPU core. At 10% swap device utilization, the overhead drops to a negligible 0.3%. In contrast, the CPU overhead for dispatching 8-slot TRIMs is 32% of a single CPU core with lower swap performance compared to ZNSwap.

Swapping without swap reclamation cutoff. We run the same experiment with read-only and mixed read-write benchmarks as in § 3.1.2 where we established the performance degradation due to the static swap reclamation cutoff in the standard swap. When invoked with ZNSwap, the performance matches the “ideal” line in Figure 4.

6.1.2 Skewed workloads

We run `pmbench` configured to allocate 320 GiB of memory and perform skewed memory writes with the default normal distribution parameters ($\sigma = \frac{1}{12}$ of the allocated memory). The distribution directs 80% of the memory accesses to 20% of the allocated memory considered “hot”. The other 80% of the allocated “cold” memory occupies 50% of the swap capacity. The “hot” pages’ lifetime in swap tends to be shorter than for other pages. In each experiment, we modify the amount of RAM available to `pmbench` thus varying the proportion of the working set swapped-out from 50% to 90%. This allows to vary the swap device utilization without changing the working set size and page access pattern across the experiments.

We compare the baseline with ZNSwap with the per-core policy that ignores the page access frequency, and ZNSwap with the hot/cold policy that strives to group pages with similar access frequencies into the same zone (see § 4.3).

We make two observations. First, ZNSwap achieves the same performance regardless of the access pattern up to $2\times$ higher bandwidth compared to the baseline for both ZNSwap policies. Second, the hot/cold policy exhibits 15-20% lower WA compared to the naive policy, even though this benefit is not reflected in the swap-out bandwidth in this workload. Reducing WA is important on its own to achieve a higher device lifetime [31].

6.1.3 Swap performance isolation in cgroups

We execute two instances of the `vm-scalability` benchmark, each in a different cgroup. Both cgroup A (CG. A) and cgroup B (CG. B) run with 16 threads. CG. A utilizes 30% of the swap capacity, and performs random *writes*, whereas

Figure 11: Bandwidth distribution among different cgroups, one reading and another writing data.

CG. B utilizes 10% of the swap capacity and performs only random *reads*. In addition, A’s and B’s swap bandwidth is limited via `blk-throttle` to 300 MiB/sec. This is the same experiment as in § 3.1.4.

Figure 11 shows the swap-in bandwidth for each cgroup under different configurations. If the swap performance isolation was perfect, each cgroup would behave as if it runs with its own SSD, reaching its target bandwidth (red line). With Block SSD, however, the target bandwidth cannot be attained. Figure 5 shows that without the device-GC overhead, the upper bound is reached, implying that in this experiment this overhead indeed causes performance degradation. Similar to Block SSD, ZNS SSD with ZNSwap’s per-core placement policy fails to provide swap isolation.

In contrast, with ZNSwap’s cgroup policy, the bandwidth of the writer process (CG. A) fully absorbs the ZNGC bandwidth overheads because only the data attributed to that cgroup is moved by ZNGC. Note that the sum of the bandwidth used by the swap and ZNGC operations in that cgroup does not exceed the predefined limit. CG. B attains full bandwidth, and it is not affected by the ZNGC bandwidth overheads.

6.1.4 Raw swap performance

We stress-test the raw swap-out performance of ZNSwap and its multi-core scaling. We execute `vm-scalability` to sequentially write (`case-anon-w-seq-mt`) 500 GiB of data in a contiguous memory region, while limiting the memory size to 2 GiB via cgroup. By choosing the sequential access pattern, not reusing the same pages, and limiting the number of writes to not surpass the device’s capacity, we force the system to avoid reusing swap-slots thus preventing device-side GC and swap-in operations. This is done to achieve the highest performance, stressing the swap software mechanisms.

ZNSwap exhibits the same performance as the traditional Linux swap, achieving 740 MiB/sec swap-out bandwidth for a single core, and the maximum device bandwidth of 1 GiB/sec with 4 cores (no graph shown).

6.2 End-to-end application Benchmarks

We evaluate two popular key-value store servers, demonstrating the benefits of ZNSwap to run large-memory produc-

tion applications. The throughput and latency we obtain are consistent with those reported for other flash-assisted KVS works [36, 46, 57].

We execute the KV servers on one NUMA node, and the client on the other; hence we set the affinity of both NUMA nodes’ `kswapd` threads as well as the `kznsd` thread that executes ZNGC to run on the first NUMA node to co-locate them with the application. Thus, both ZNSwap and traditional Linux swap are allocated *the same* amount of compute resources which they share with the application threads.

6.2.1 memcached-ETC

We run a `memcached` key-value store [29] using the `mutilate` client [45] and Facebook’s ETC benchmark [23]. We evaluate a random-skewed access pattern with 90% of requests accounting for 10% of the keys. Despite this skewness, the distribution of popular keys in the *memory* is mostly uniformly random because they are scattered across different memory pages. This also dictates random access to the SSD.

We configure `memcached` to use 32 threads on one NUMA node, and invoke 32 `mutilate` client threads on the other NUMA node. We load the data to the server until we reach the target swap device capacity utilization. We do not limit the amount of memory available to the server, thus utilizing all memory (from both NUMA nodes) for the workload. For example, 10% swap utilization (51 GiB) implies the total working set of 563GB. We report the 99p latency of the KV store, maximum throughput, as well as the WAF of the SSD.

Figure 12 shows that ZNSwap consistently outperforms Block SSD-based swap in all performance metrics under the evaluated swap device utilization: under 10% swap device utilization ZNSwap exhibits 10× lower 99p latency and 5× higher maximum QPS while not experiencing any WA, as opposed to Block SSD which suffers from a 2.5× WAF. With the added 8 blk. TRIM support for Block SSD, ZNSwap achieves 5× lower 99p, 1.6× higher QPS and 1.1× lower WAF.

6.2.2 redis-YCSB

We use an in-memory `redis` data store [16] with the `YCSB` client [27] configured with 50% reads and 50% updates (update-heavy configuration) in a 20-80 hotspot distribution (80% of accesses target 20% of the working set) which is one of the standard options. This memory access pattern induces the same distribution of accesses as we evaluated in § 6.1.2, thereby allowing us to show the application performance impact of the hot/cold placement policy.

`redis` is executed in cluster-mode consisting of 32 server-threads, running on one NUMA node in a RAM-limited cgroup. It loads a 320 GiB dataset to the cluster. 64 client threads are spawned on the other NUMA node. Similar to the microbenchmark in § 6.1.2, we vary the amount of available RAM while keeping the working set size constant.

Figure 12: memcached Facebook ETC 99 percentile latency at the highest throughput

Figure 13: redis 20-80 hotspot distribution 50/50 read/write, 99p latency at maximum throughput

Figure 13 shows the 99p latency, throughput and WA for ZNSwap’s per-core and hot-cold policies, as well as Block SSD. Both ZNSwap’s policies outperform Block SSD in all performance metrics. We observe a $1.27\times$ speedup in throughput and $1.4\times$ drop in latency with $1.1\times$ lower WA for ZNSwap’s hot/cold policy compared to the per-core policy.

7 Related work

SSD-friendly swap support. SSDs’ unique characteristics warranted a body of works [48, 54] that aim to optimize swap on Block SSDs. These works modify Linux’s page reclaim policy (similar to CFLRU [52]) to prioritize reclamation of clean pages and reduce device-side GC overheads without modifying the GC itself. In contrast, ZNSwap offers a novel co-design of the host-side GC and the swap mechanisms and achieves its benefits via tighter coupling between them.

Swap on raw flash. Several early works proposed swap to raw flash [38, 41, 47] thereby avoiding GC overheads due to copying blocks of discarded swap-slots. These papers predated the introduction of native TRIM support in SSDs, which was supposed to achieve the same effect. ZNSwap shows that even fine-grain TRIMs are not sufficient, and demonstrates other benefits of the tight coupling with the OS enabled by the host-side GC.

Open-channel SSDs [26] expose a low-level storage management interface, similarly to ZNS. ZNSwap’s main contribution is its study of the benefits of host-side SSD management and swap co-design, not considered in prior works. Further, unlike ZNS, the adoption of OC-SSDs so far has been limited due to poor portability and the complexity of the host-side media control they require, such as media wear-levelling.

Stream-SSDs [40] expose a traditional block interface, and can reduce WA by utilizing hints so the device may attempt

to co-locate data with similar lifetimes onto the same erase-blocks. However, Stream-SSDs’ block-interface hinders support for cross-layer optimizations introduced by ZNSwap on ZNS-SSDs, which are key to ZNSwap’s performance gains.

Implementing swap data placement support for Stream-SSDs, akin to ZNSwap’s swap policies, will offer certain benefits in the scenarios where data lifetime can be predicted and data consolidated into a set number of streams, such as hot/cold access patterns (as noted in § 6.1.2). However, under random access patterns, Stream-SSDs would perform similarly to traditional Block SSDs. The performance gains pertaining to ZNSwap’s cross-layer optimizations that aren’t related to data-placement policies (i.e., the elimination of TRIMs) exhibit higher performance gains than data-placement policies, as shown in Figure 10.

8 Conclusion

ZNSwap leverages the recent ZNS SSD interface to enable tight integration of the storage management mechanisms with the swap subsystem. ZNSwap introduces a host-side ZNGC that is co-designed with the swap logic to reduce garbage-collection overheads and improve system performance, while also leveraging the tight coupling with the OS and NVMe metadata interface to avoid the costly flash translation layer in the host. ZNSwap demonstrates significant performance advantages of using ZNS for swap in realist scenarios, paving the way to broader adoption of this new technology.

A Pageout process

Figure 14 illustrates the operations performed during the pageout process in detail.

Traditional page-out. A candidate anonymous memory page from the inactive-list [1] is selected to be evicted (not recently accessed [2]) and is not in the swap cache [3], it is assigned a swap-slot entry [4]. The swap-slot entry is used both as the destination of the page in the swap device, as well as its identifier within the swap-cache. After the page has been inserted into the swap-cache and subsequently unmapped from the page tables [6], the swap-slot entry value is inserted instead. If the page is dirty [7], it is unmarked as such, the write operation to the swap device initiates [8], and the page is reinserted into the head of the inactive list [9].

After the page has been successfully written to the swap device, it is moved to the tail of the inactive list [10], where it is then removed for the second time [11] and passes through the same conditions as in the first iteration. Finally, the page is freed along with its swap-cache entry [16].

If the page is accessed during the write to the swap device, it is located in the swap-cache using the swap-slot entry, and will subsequently fail one of the conditions in [12-15].

ZNSwap page-out. Apart from sampling the accessed bit in [2], the dirty bit is sampled, cleared, and stored in the `PG_dirty` flag of the `struct page`. The page is then assigned a zone per the defined policy [4] and the append operation to the swap device initiated [5]; the page is then reinserted to the inactive-list [6]. Once the append operation has been completed and the location of the written data retrieved, the page is inserted into the swap-cache. The `PG_dirty` flag is cleared and the page is moved to the tail of the inactive-list [7]. The page then traverses through [8-11] and is unmapped from the page tables [13]. If the page has been dirtied since the append operation has initiated [14-15], the page-out operation is aborted. The page is finally freed at [16].

Unlike the traditional page-out algorithm, an access to the page while it is undergoing write-back to the swap device will not raise a page-fault and subsequently be remapped since it is *still mapped* in the page-tables. Rather, the dirty bit in the page tables is evaluated during the unmapping process [14], which indicates whether it is safe to free the page or not.

Building a High-performance Fine-grained Deduplication Framework for Backup Storage with High Deduplication Ratio

Abstract

Fine-grained deduplication, which first removes identical chunks and then eliminates redundancies between similar but non-identical chunks (i.e., delta compression), could exploit workloads' compressibility to achieve a very high deduplication ratio but suffers from poor backup/restore performance. This makes it not as popular as chunk-level deduplication thus far. This is because allowing workloads to share more references among similar chunks further reduces spatial/temporal locality, causes more I/O overhead, and leads to worse backup/restore performance.

In this paper, we address issues for different forms of poor locality with several techniques, and propose MeGA, which achieves backup and restore speed close to chunk-level deduplication while preserving fine-grained deduplication's significant deduplication ratio advantage. Specifically, MeGA applies ① a backup-workflow-oriented delta selector to address poor locality when reading base chunks, and ② a delta-friendly data layout and "Always-Forward-Reference" traversing in the restore workflow to deal with the poor spatial/temporal locality of deduplicated data.

Evaluations on four datasets show that MeGA achieves a better performance than other fine-grained deduplication approaches. In particular, compared with the traditional greedy approach, MeGA achieves a 4.47–34.45 \times higher backup performance and a 30–105 \times higher restore performance while maintaining a very high deduplication ratio.

1 Introduction

Chunk-level deduplication [2, 7, 18, 20, 27, 28, 40, 45, 54] has been widely used in backup storage systems to reduce storage costs, but it is limited by its coarse-grained processing granularity (i.e., file/chunk level) and can not completely exploit data workloads' compressibility. To achieve a higher deduplication ratio, fine-grained deduplication [22, 38, 47] is proposed.

Fine-grained deduplication, sometimes previously called "delta compression," not only focuses on duplicate chunks but also removes sub-chunk-level redundancies existing in

Figure 1: Performance of MeGA (our approach), FG Dedup (a typical fine-grained deduplication approach similar to SDC [53]), CL Dedup (a typical chunk-level deduplication approach [23]), and MF Dedup (a special chunk-level deduplication approach [58]) on a website snapshot dataset.

similar but non-identical chunks, and it has been studied in several use cases [15, 37, 38, 51]. Typically, fine-grained deduplication first deduplicates identical chunks, then finds similar base chunks (among non-duplicates), and finally runs delta encoding between the new and base chunks to only store their differences (a.k.a., delta chunks) for space-saving. As a result, fine-grained deduplication could achieve a much higher deduplication ratio than chunk-level deduplication [37]. We use the term fine-grained deduplication, though some previous literature uses the term delta compression to refer to this entire process.

However, fine-grained deduplication's performance is usually much worse than that of chunk-level deduplication because of further reducing data locality. Chunk-level deduplication usually suffers from the poor locality of deduplicated data, which has been mentioned in several previous works [12, 23, 58]. For example, when deduplicating a workload, we only store unique chunks and "share" chunks that appear in stored workloads as duplicates. Because chunks are stored in chronological order, this kind of "sharing" results in duplicate chunks and other unique chunks of this workload being scattered across the storage media, which leads to poor performance when restoring this workload. This problem is aggravated by fine-grained deduplication. It is because fine-grained deduplication introduces delta compression to exploit more compressibility among workloads, so workloads "share"

more data, decreasing locality, increasing I/O overheads, and leading to worse backup/restore performance.

Generally, different forms of the poor locality caused by delta compression impact backup and restore workflows. In the backup workflow, reading base chunks for delta encoding suffers from poor locality of base chunks (denoted by **Reading Base Issue**). Specifically, this issue is related to local compression, since consecutive chunks are compressed and must be decompressed together, which makes the compression unit become the I/O unit [6, 25, 44]. Thus, we have to read a compression unit even when only one or a few base chunks are needed, which leads to huge I/O amplification. In the restore workflow, the **Fragmentation Issue** [12, 23, 53] (that also exists in chunk-level deduplication) is exacerbated by the more complex dependencies in fine-grained deduplicated data. It is caused by a new kind of reference relationship between delta and base chunks, and this new kind of reference relationship further breaks spatial locality in fine-grained deduplicated data. Meanwhile, additional reference relationships between delta and base chunks also lead to a poor temporal locality in fine-grained deduplicated data. During delta decoding, base chunks and delta chunks must both be read, unlike restoring deduplicated data that only requires a single I/O read for a needed chunk, which makes the restore workflow repeatedly access containers to gather delta-base pairs (denoted by the **Repeatedly Accessing Issue**).

In this paper, we aim to improve these locality issues based on several observations and techniques.

For the *Reading Base Issue*, we apply a backup-workflow-oriented delta selector to improve the efficiency of reading base chunks in the backup workflow. It is based on an observation that most base chunks are located in a few containers (e.g., 64.1% containers only include 8.31% of the base chunks when running a backup workflow in a studied dataset). According to this observation, our delta selector skips delta compression when base chunks are located in those “base-sparse containers”. Without reading these “inefficient” containers, the efficiency of reading base chunks will be improved.

For the *Fragmentation Issue*, we propose a delta-friendly data layout, which covers the two-level reference relationships in fine-grained deduplicated data: the chunks–workloads reference relationship (also exists in chunk-level deduplication) and the additional delta–base reference relationship (caused by delta compression). The delta-friendly data layout handles the new dependencies and improves the spatial locality in fine-grained deduplicated data.

For the *Repeatedly Accessing Issue*, we observe the existence of “Always-Forward-Reference” traversing. It is a special path to traverse restore-involved containers, in which delta chunks always appear before their base chunks. By using this feature and exploiting the asymmetry of the I/O characteristics of storage media, we design a delta prewriting mechanism to deal with the poor temporal locality in deduplicated data, which first prewrites delta chunks to their

location in the to-be-restored workload and then reloads them for decoding when later accessing their base chunks.

We propose MeGA, a fine-grained deduplication framework, by using the above techniques to address the *Reading Base Issue*, *Fragmentation Issue*, and *Repeatedly Accessing Issue*. As shown in Fig. 1, MeGA achieves performance close to chunk-level deduplication while preserving fine-grained deduplication’s significant deduplication ratio advantage. The contributions of this paper are threefold:

- We analyzed several forms of poor locality caused by fine-grained deduplication, which leads to additional I/O overhead and poor backup/restore performance.
- We proposed techniques (i.e., the backup-workflow-oriented delta selector, the delta-friendly data layout, the “Always-Forward-Reference” traversing, and delta prewriting) to deal with these different issues caused by the poor locality.
- We proposed MeGA with these techniques to achieve performance close to chunk-level deduplication while preserving fine-grained deduplication’s significant deduplication ratio advantage. Especially, compared with the traditional greedy approach [53], MeGA achieves a 4.47–34.45 \times higher backup performance and a 30–105 \times higher restore performance, while maintaining a very high deduplication ratio.

2 Background and Related Works

2.1 Fine-grained Deduplication

Fine-grained deduplication [10, 15, 37, 38, 44, 51] could achieve a much higher deduplication ratio than deduplication alone [9, 11, 17, 19, 21, 32–34, 39]. It focuses on redundancies not only between duplicate chunks but also between similar but non-identical chunks, and finally achieves sub-chunk-level detection as well as byte/string-level elimination.

However, fine-grained deduplication achieves a higher deduplication ratio while introducing additional computation and I/O overhead when applying delta compression between similar chunks. To address these challenges, many previous works have been proposed, and the additional computation overhead has been hugely reduced. For example, Zhang et al. [52] and Zou et al. [57] proposed much faster sketch methods by exploiting the locality in backup streams and content-based sampling, respectively. MacDonald [26] proposed Xdelta for fast delta encoding. Xia et al. [48, 49] and Tan et al. [41] presented chunking-inspired methods to further improve delta encoding/decoding speeds. Zhang et al. [53] extended the rewriting techniques [12, 23] from chunk-level deduplication to fine-grained deduplication to reduce the additional I/O overhead only in fine-grained deduplication’s restore workflow.

Fine-grained deduplication has been employed in many other works. Xu et al. [50] introduced fine-grained deduplication for databases to reduce storage cost. Jain et al. [16] applied the idea of fine-grained deduplication in replica syn-

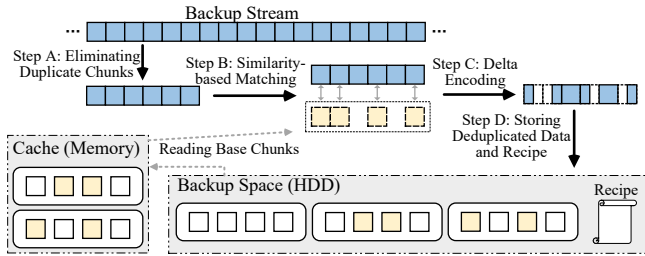

Figure 2: The backup workflow of fine-grained deduplication.

chronization. Pucha et al. [35], Mogul et al. [30], and Zhou et al. [55] designed a detection mechanism for p2p system, which finds both identical and similar sources to accelerate downloads.

Fig. 2 shows a standard workflow for fine-grained deduplication: ① Split backup streams into chunks and calculate a fingerprint for each chunk. ② Check and eliminate duplicate chunks using the fingerprint index. ③ Calculate each unique chunk’s sketches. Super Feature [5, 22, 24, 37] is a typical kind of sketch. It first generates multiple local-sensitive hashes with rolling hashes and linear transformations, and then packs these local-sensitive hashes together into fewer Super Features to detect highly similar chunks. ④ Find similar candidates for unique chunks using a sketch index or cache. ⑤ If a similar candidate exists, read it as a base chunk, and delta encode the incoming chunk relative to the base, often generating a much smaller delta chunk. ⑥ All deduplicated chunks are stored in containers in order, and then each container will be compressed. ⑦ Generate a recipe for a backup stream by recording fingerprints of all needed chunks, including indirectly referenced base chunks.

2.2 Backup Workloads

In backup storage systems [29], workloads usually are a series of backups (i.e., successive snapshots of the primary data), and consecutive backups are usually similar, which has been reported and exploited in many existing studies [13, 47, 52]. Thus, due to the highly redundant nature of the data, backup storage often leverages data deduplication to greatly reduce the size of backups and save hardware costs.

Deduplicated data (i.e., chunks) are usually locally compressed and stored in immutable and fixed-size containers (e.g., 4MB). Containers are compatible with striping across multiple drives in a RAID configuration, and writing in large units achieves the maximum sequential throughput [23].

3 Observation and Motivation

3.1 Challenges

Fine-grained deduplication obtains a higher deduplication ratio than chunk-level deduplication with much worse backup/restore performance, but further fragments data locality. As mentioned in several previous works [12, 23, 58], chunk-level deduplication usually suffers from poor locality because chunks from a workload that are logically consecu-

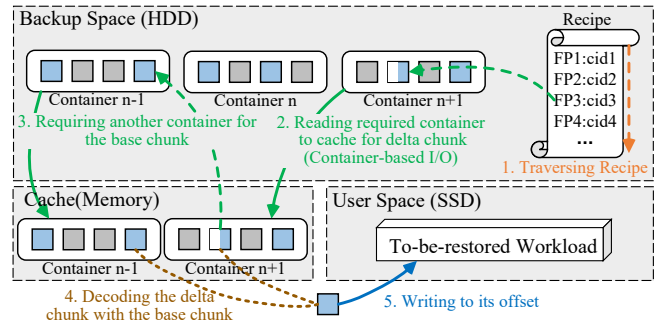

Figure 3: Restoring a delta chunk in the restore workflow of fine-grained deduplication.

Figure 4: I/O overheads in backup and restore workflow.

tive may refer to previously written chunks scattered across the disks. However, fine-grained deduplication has more serious locality issues. Specifically, fine-grained deduplication eliminates redundancies among similar chunks by creating more references to previously written chunks, which increases fragmentation. Meanwhile, this observation also means that as more space is saved, locality becomes worse. Poor locality harms both backup and restore performance.

Fig. 2 demonstrates the poor locality involved in reading base chunks for fine-grained deduplication. Specifically, this issue is related to the local compression, since consecutive chunks must be decompressed entirely according to the compression unit (that also becomes the I/O unit) [6, 25, 44], which could be containers or compression regions (i.e., containers’ sub-unit). Therefore, reading a compression unit when only one or a few base chunks are needed leads to I/O amplification. Generally, a larger I/O unit (e.g., containers) may cause a larger I/O amplification, but it also could opportunistically prefetch more base chunks and reduce costly random accesses on HDDs (due to locality of backup stream [38, 52]). Even with a smaller I/O unit (e.g., 128KB container regions), reading bases remains a bottleneck [38]. Though it may cause less I/O amplification, reading some base chunks having locality with a small I/O unit can be disrupted by write tasks and result in more random seeks, because the backup workflow of fine-grained deduplication mixes reads and writes (i.e., reading base chunks and writing deduplicated data). Thus, we learn **Challenge 1**: Poor locality in the backup workflow causes inefficient I/O when reading base chunks.

In the restore workflow (like Fig. 3), there are two challenges. The first challenge in the restore workflow is the fragmentation problem, which is caused by poor spatial locality in

deduplicated data. It also exists in chunk-level deduplication, but it becomes more serious in fine-grained deduplication. It is because fine-grained deduplication allows workloads to share more similar chunks, but it also produces more references to previously written chunks. Therefore, fine-grained deduplication introduces another kind of reference relationship (i.e., between the base and delta chunks) and no longer only has one kind of reference relationship (i.e., between chunks and workloads). This makes the fragmentation problem more complex since the dependencies of each workload are distributed more widely. Thus, there exists **Challenge 2: Delta-base relationships lead to more complex fragmentation problems than deduplication alone.** The restore workflow also has **Challenge 3: Delta-base dependencies cause poor temporal locality during delta decoding and causes repeated container reads.** Without fine-grained deduplication, individual chunks can be read as needed to restore a file, but for fine-grained deduplication, base chunks and delta chunks must both be read. When chunks in a container are used (for unique or base chunks) across long time intervals, the restore workflow needs to alternately and repeatedly access containers to gather delta-base pairs for delta decoding.

Finally, Fig. 4 suggests the seriousness of these challenges. It studies the I/O overheads of a basic fine-grained deduplication system with container I/O when backing up and restoring backup workloads from a WEB dataset (detailed in §5.1), which consists of 100 snapshots of a website. “WriteDeduplicatedData” means I/O for writing deduplicated data in the backup workflow, and “NeededChunks” means I/O for reading needed chunks. “ReadBase”, “Fragmentation”, and “RepeatedlyAccess” map to the above three challenges, respectively. We learn that these three challenges cause huge I/O overheads, and even “WriteDeduplicated” and “NeededChunks” only take about 0.3% and 1.12% of the total I/O in backup and restore workflows.

3.2 Selective Delta Compression

As Challenge 1 mentioned, poor locality in reading base chunks causes large I/O overheads in the backup workflow.

To this end, we studied datasets and observed that base chunks are not distributed evenly. For example, Fig. 5 gives the distribution of base chunks when backing up the 100th backup in the WEB dataset. Fig. 5(a) suggests that 64.1% of containers include fewer than 30 base chunks, and Fig. 5(b) demonstrates that these containers only hold 8.31% of the total base chunks. We call these containers “base-sparse containers”. Though there are only a few base chunks in these base-sparse containers, when requiring base chunks in one of them, we have to load the whole container from the disk, which causes a significant read amplification.

Thus, these observations motivate us to design a **backup-workflow-oriented delta selector**, which skips delta compression whose base chunks are located in “base-sparse containers” to avoid reading these “inefficient” containers. Thus,

(a) 64.1% of containers contain only ~30 base chunks. (b) These 64.1% containers only include 8.31% of the total base chunks.

Figure 5: Base chunks are not distributed evenly.

(a) An example of three backup streams before deduplication.

(b) The order-based data layout after fine-grained deduplicated.

(c) The delta-friendly data layout for fine-grained deduplication.

Figure 6: An example of the order-based data layout versus the delta-friendly data layout.

it could reduce the I/O overheads in the backup workflow, and finally greatly improve the backup speed in fine-grained deduplication, which will be evaluated in §5.2.

3.3 Delta-friendly Data Layout

For Challenge 2, we use the example in Fig. 6 to discuss the fragmentation problem in fine-grained deduplicated data. Fig. 6(a) lists three backup streams, and Fig. 6(b) suggests the order-based data layout after fine-grained deduplicating these three backup streams. The order-based data layout allocates chunks in containers according to their written order and is widely used in previous works [12, 23, 37, 52]. When restoring a backup, the needed and unneeded chunks are always mixed in this data layout. Consider Container 2 in Fig. 6(b) for example: when restoring the 3rd backup, chunk *F* is needed while chunks *D* and *E* are unneeded, but all of them will be read as a whole container due to container I/O, which causes extra I/O overheads.

Rewriting-like defragmentation approaches could be extended to fine-grained deduplication to alleviate the fragmentation problem [53]. Their mechanisms can be summarised as skipping deduplicating chunks already in sparse containers, but this cannot stop the locality of deduplicated data becoming increasingly poorer as the number of backups increases, which thus makes the restore speed continually decrease [13, 23, 53].

MFDedup [58] introduces a lifecycle-based data layout and eliminates the fragmentation problem in chunk-level deduplication. The lifecycle-based data layout classifies chunks into categories according to whether they are always referenced by the same set of consecutive backup workloads (i.e., **lifecycles**), and stores chunks in the same category together. Lifecycle-based classification of chunks ensures whichever backup workload is to be restored, chunks in any categories are always either all needed together or all not needed together. Thus, reading needed chunks in the unit of categories will never cause unneeded chunks to be read. Generally, MFDedup only considers **one-level** simple reference relationships (between chunks and backup workloads), which is the only type of reference relationship in chunk-level deduplication.

However, directly applying this lifecycle-based data layout to fine-grained deduplication is not feasible since fine-grained deduplication introduces an additional kind of reference relationship between delta and base chunks and causes new fragmentation. In the 2nd backup stream, there are **two-level** reference relationships:

- Between workloads and chunks.
i.e., the 2nd backup stream $\Leftrightarrow \{A, B', C', H, I, F', G\}$
- Between base chunks and delta chunks.
i.e., $B \Leftrightarrow \Delta(B)$; $C \Leftrightarrow \Delta(C)$; $F \Leftrightarrow \Delta(F)$

Therefore, we need a new data layout that considers both kinds of reference relationships to eliminate the fragmentation problem in fine-grained deduplicated data.

We first need a new way to describe chunks' lifecycles with the additional introduced reference relationship's impacts. Here we define the **Necessary Chunks** (denoted by **NC**) of a backup workload as the combination of its directly referenced chunks (i.e., the 1st level) and its indirectly referenced chunks (i.e., the 2nd level). Accordingly, we redefine a chunk's lifecycle in fine-grained deduplication as which backup workloads' NCs refer to this chunk, which could cover the two-level reference relationships. In Fig. 6, we can list the NCs for the three backups:

- NC_Backup1: A, B, C, D, E, F, G
- NC_Backup2: A, B, $\Delta(B')$, C, $\Delta(C')$, H, I, F, $\Delta(F')$, G
- NC_Backup3: A, J, C, H, $\Delta(H')$, I, F, $\Delta(F')$, G, $\Delta(G')$

In this example, the lifecycle of chunk *G* is from *NC_Backup1* to *NC_Backup3*, since *G* is used as a unique chunk for *NC_Backup1* & *NC_Backup2* and then as a base for *NC_Backup3*.

After that, we could build a **delta-friendly data layout** by integrating the second level of reference relationship into the lifecycle management as well. As shown in Fig. 6(c), the delta-friendly data layout consists of categories, which includes several chunks. To clearly present them, we use **Cat.(X,Y)** to indicate the category, which includes all chunks whose lifecycles are only from *NC_BackupX* to *NC_BackupY*. All deduplicated data are classified and sequentially stored in categories according to their lifecycles, which hugely benefits the restore workflow. In this example, *NC_Backup1* is composed of

Figure 7: The delta prewriting mechanism. Here the half shaded chunk is a delta chunk.

Cat.(1,1), *Cat.(1,2)* and *Cat.(1,3)*; *NC_Backup2* is composed of *Cat.(1,2)*, *Cat.(2,2)*, *Cat.(1,3)* and *Cat.(2,3)*; *NC_Backup3* is composed of *Cat.(1,3)*, *Cat.(2,3)* and *Cat.(3,3)*. When restoring any of these three backups, we can select categories according to the above lists, and all chunks in selected categories are all needed. In this way, the restore workflow never needs to read any unneeded chunks, and the *Fragmentation Issue* in Challenge 2 could be eliminated.

To simplify the implementation of the delta-friendly data layout, we only deduplicate redundancies between adjacent backups to ensure that chunks' lifecycles are always consecutive (composed of successive backup streams' *Necessary Chunks*), similar to the approach in MFDedup [58]. This strategy may reduce the total deduplication ratio, but it will not be significant according to several previous works [38, 44, 58], which will be also further studied in §5.4.

3.4 Forward Reference and Delta Prewriting

For Challenge 3, we design a delta prewriting mechanism. It relies on two things: ① The storage media's I/O characteristics between User Space and Backup Space are asymmetric. Backup Space usually uses HDDs as storage media due to its lower price, while User Space usually uses SSDs or NVMs since better I/O performance is essential for business [58]. ② When performing a restore, delta-encoded chunks are always accessed before their base chunks, which we call "**Forward Reference.**"

Fig. 7 shows the basic idea of the delta prewriting mechanism. For each delta chunk, the prewriting mechanism will prewrite it to the offset where it should be after delta decoding in the to-be-restored backup workload (in User Space). And then, when meeting its base chunk later, the prewriting mechanism will read the delta chunk from the prewritten position, decode the delta chunk with the base, and finally write back the decoded chunk to its offset. Through this mechanism, we ensure that when restoring, all restore-involved containers only need to be read only once, which hugely reduces the I/O overheads on Backup Space.

The next issue is how to make the assumption always hold. By studying the data layout proposed in §3.3, we find it is possible to design a special path for traversing restore-involved containers when restoring, in which delta chunks always appear in front of their base chunks. We call it "**Always-Forward-Reference**" **traversing** (shortened to

AFR traversing), whose details will be introduced in §4.4.

Due to improved spatial locality (delta-friendly data layout in §3.3) and temporal locality (the AFR traversing and delta prewriting in §3.4) in deduplicated data, the I/O overheads in the restore workflow are hugely reduced. Meanwhile, there exists only sequential I/O to the Backup Space when restoring, which is optimized for HDDs. Finally, the restore speed could be greatly improved, which we evaluate in §5.3.

4 Design and Implementation

4.1 General Description

The overall framework of MeGA is shown in Fig. 8. In general, ① For the backup workflow, MeGA first runs *Chunk-level Deduplication* to remove duplicate chunks according to *Local-based FP Index*, and then, it finds similar matches for unique chunks according to *Local-based Sketch Index* and selectively applies delta compression using *Delta Selector*. ② For the storage organization, MeGA stores and manages the deduplicated and delta compressed data in the *Delta-Friendly Data Layout*. ③ For the restore workflow, MeGA generates an *Offset Hash Table* according to the recipe of a to-be-restored workload; then, MeGA accesses all restore-involved containers with *AFR Traversing* and *Delta Prewriting*.

Specifically, there are several modules in MeGA:

- *Local-based FP Index* and *Local-based Sketch Index* maintain fingerprints and sketches of each backup workload’s chunks in separate hash tables per backup. They only retain the current and last backup’s tables (similar to some previous works [44, 58]), because MeGA only deduplicates a backup within itself and the previous backup (mentioned in §3.3).
- *Chunk-level Deduplication* first splits the backup stream into chunks with Content-Defined Chunking [31, 46] and then calculates a fingerprint (i.e., SHA1 digest) for each chunk. After that, it detects and eliminates identical chunks with a Local-based FP index.
- *Delta Selector* first generates sketches with the resemblance detection approaches [4, 5, 37, 52, 57] for unique chunks and identifies similar candidates according to the Local-based Sketch index for further delta compression. Then, it delta-encodes chunks unless the referenced bases are in base-sparse containers.
- *Base Cache* holds cached containers to provide base chunks for delta compression in the backup workflow.
- *Delta-Friendly data layout* manages fine-grained deduplicated chunks according to their lifecycles, reflecting which backup workloads require these chunks. As a result, the delta-friendly data layout promises to eliminate the fragmentation problem in fine-grained deduplicated data and reduce I/O overheads in the restore workflow.
- *AFR Traversing* applies “Always-Forward-Reference” traversing on fine-grained deduplicated data in a restore workflow, which guarantees that delta chunks are always accessed before their base chunks and provides the pre-

Figure 8: An overview of MeGA framework.

condition for Delta Prewriting.

- *Delta Prewriting* transfers the random operations from Backup Space to User Space, exploiting the asymmetry of storage media characteristics between the two spaces. This also avoids repeatedly accessing containers when restoring files.
- *Offset Hash Table* is built according to a to-be-restored backup workload’s recipe and provides offsets of chunks (three kinds of chunks: unique, base, and delta) in the to-be-restored backup workload.

Details of each workflow using our proposed key techniques will be introduced in the following §4.2–§4.4.

4.2 Backup Workflow

The backup workflow runs *Chunk-level Deduplication* and *Delta Selector* to eliminate duplicate chunks and redundancies among similar chunks, respectively.

Chunk-level Deduplication. The chunk-level deduplication step splits the backup stream into chunks with Content-Defined Chunking [31, 46] and then calculates a fingerprint (i.e., SHA1 digest) for each chunk. After that, MeGA detects and removes duplicate chunks according to the Local-based FP Index, as we introduced in §4.1.

Delta Selector. Then, the backup workflow runs *Delta Selector* with the following steps. ① *Delta Selector* first combines several successive chunks (from *Chunk-level Deduplication*) into fix-sized segments (e.g., 20MB). ② In each segment, *Delta Selector* generates sketches (i.e., Super Features [22]) for each (unique) chunk, and then tries to find for each chunk a similar chunk as its base chunk with the Local-based Sketch Index. ③ For chunks that have a potential base chunk, *Delta Selector* records their base chunk’s container ID in a ‘selector table’, which counts the times each container is referenced for base chunks within a segment. ④ Then, *Delta Selector* observes which containers are rarely referenced (with a **threshold**) in the ‘selector table’ and considers these containers as ‘sparse-base containers’, which are inefficient to read for base chunks. ⑤ Finally, for chunks having a similar chunk that is not in sparse-base containers, *Delta Selector* will run delta compression to calculate and store their differences (i.e., delta chunk) for saving space; For the remaining chunks, they will be directly stored as unique chunks. Base chunks in delta compression are acquired from the base cache, and if a cache miss occurs, the base cache will read related containers

Figure 9: An example of maintaining data layout after storing the 3rd backup. Chunks, which are duplicate to the 3rd backup and referenced as base chunks in the 3rd backup, will be migrated to new categories. *Cat.(1,3)* and *Cat.(2,3)* do not exist before migrations.

from disks and add them to the cache.

As a result, Delta Selector could improve the efficiency of reading base chunks and then accelerate the backup workflow. Next, we will introduce how to store these deduplicated data.

4.3 Maintaining Delta-Friendly Data Layout

In this subsection, we will introduce how to locate the deduplicated data in the delta-friendly data layout. There are two steps: ① Store the incoming deduplicated data of a new backup in the delta-friendly data layout. ② Process the incoming and previous backups’ deduplicated data to ensure each chunk’s location is consistent with the principle of our delta-friendly data layout.

Storing New Fine-grained Deduplicated Data and Data Organization. For storing fine-grained deduplicated data, we first consider their lifecycles. After running the backup workflow (introduced in §4.2), the fine-grained deduplicated data consists of the latest backup workload’s unique and delta chunks. Since these chunks are only referenced by the latest backup, they should have the same lifecycle, and their lifecycle should be different from previously stored chunks.

Then, considering the definition of the lifecycle and the naming style of categories (**shorten to Cat.**) introduced in §3.3, these chunks (assuming they are from the n^{th} Backup) should be classified into a new category *Cat.(n,n)*.

Considering the sizes of categories are usually variable, we design a two-level storage organization: fix-sized Containers (e.g., 4MB) and variable-sized Categories. Containers directly hold chunks, and categories hold containers whose chunks have the same lifecycle. For example, *Cat.(1,2)* could include one or several containers, and each container holds chunks whose lifecycle is from *NC_Backup1* to *NC_Backup2*.

Data Migration. After storing fine-grained deduplicated data of the latest backup workload, we should consider updating the data layout to handle the issue that some chunks’ lifecycles are changed. In general, storing a new backup in the delta-friendly data layout only changes the lifecycles of its adjacent backups’ chunks, because MeGA only allows adjacent backups to share common chunks (i.e., MeGA deduplicates a backup within itself and its previous backup). Therefore,

these shared chunks’ lifecycles should be extended to the latest backup. Thus, we need to migrate these shared chunks into new categories to match their updated lifecycles, and we call these migrations the maintenance workflow.

An example of the maintenance workflow is shown in Fig. 9. It shows a situation that the 1st and 2nd backups have been stored in the data layout, and the 3rd backup is the latest one, whose fine-grained deduplicated data have been stored in *Cat.(3,3)*, as discussed earlier in this subsection. At this time, some chunks located in *Cat.(1,2)* and *Cat.(2,2)* are referenced by the 3rd backup (as duplicate or base chunks). Thus, these chunks’ lifecycles newly include *NC_Backup3* and they should be migrated into new categories. In this example, chunks in *Cat.(1,2)* and *Cat.(2,2)* will be traversed, and duplicate/base chunks will be migrated into new categories *Cat.(1,3)* and *Cat.(2,3)*, respectively.

Note that the **maintenance workflow (i.e., data migration) only works on related categories and does not involve all categories.** As the example in Fig. 9 shows, a maintenance workflow after storing the 3rd backup only impacts Column 2. Similarly, the maintenance workflow always runs on one column, and its overhead is also limited (will be studied in §5.6). With support of the maintenance workflow, the delta-friendly data layout is preserved, which benefits restore performance.

Features in Migration. There exist two interesting features when the maintenance workflow involves delta and base chunks. For clarity, here we say *Cat.(X,Y)* is in Row X, and Column Y, as shown in Fig. 9.

Feature 1: base chunks are always in the same or an earlier Row than their delta chunks. It could be easily explained by the example in Fig. 9. For delta chunks of the 3rd backup (must be in *Cat.(3,3)*), their base chunks can only be from two sources: ① from the 3rd backup itself. In this case, the bases are also in *Cat.(3,3)*, the same Row as the delta. ② from the 2nd backup. In this case, the bases must be migrated into *Cat.(1,3)* or *Cat.(2,3)*, the earlier Row than the delta.

Feature 2: base chunks are always in the same or a later Column than their delta chunks. Here we also take Fig. 9 as an example: When the duplicate chunks in Fig. 9 contain base or delta chunks, there are two cases: ① If a delta chunk is a duplicate of another delta chunk (i.e., its “original” chunk is a duplicate of delta-encoded chunk) to the 3rd backup and should be migrated, its base must be also migrated as the delta’s dependency, since both of them should be included in *NC_Backup3*. Therefore, in this case, they will be migrated into the same Column (Column 3). ② If a base chunk is duplicate (i.e., is itself a duplicate) to the 3rd backup and should be migrated, its delta will not be migrated, since the 3rd backup does not require this delta chunk. In this case, the base (migrated to Column 3) will be in a later Column than the delta (left in Column 2).

These two features will help to achieve “Always-Forward-Reference” traversing, which will be further used in §4.4.

Table 1: Possible category locations of the corresponding base chunks for the delta chunks in the 2nd backup.

Delta Chunks' Positions	Corresponding Base Chunks' Possible Positions
Cat.(1,2) ⇒	Cat.(1,2), Cat.(1,3)
Cat.(2,2) ⇒	Cat.(1,2), Cat.(2,2), Cat.(1,3), Cat.(2,3)
Cat.(1,3) ⇒	Cat.(1,3)
Cat.(2,3) ⇒	Cat.(1,3), Cat.(2,3)

4.4 Restore Workflow

As introduced in §4.1, the restore workflow of MeGA relies on AFR traversing and Delta Prewriting. In the beginning, the restore workflow needs to determine which containers are needed for restoring the required backup workload.

Identifying All Required Containers. All the required containers could be simply calculated in a delta-friendly data layout. For example, there are n backup workloads stored, and we want to restore a backup B_k . According to the naming style of categories (mentioned in §3.3), all categories whose lifecycles include NC_Backup_k are required, and they are $\bigcup_{j=k}^n \bigcup_{i=1}^j Cat.(i, j)$, where $1 \leq i \leq k \leq j \leq n$. For example, when restoring the 2nd backup in Fig. 9, $Cat.(1,2)$, $Cat.(2,2)$, $Cat.(1,3)$, $Cat.(2,3)$ are required.

Then all containers in these categories are the restore-required ones. Benefiting from the delta-friendly data layout, all chunks in these containers are exactly what we need, which avoids reading unneeded chunks when restoring. Next, we present how to traverse them for restoring a workload.

AFR Traversing. As mentioned in §4.1, AFR traversing promises that when traversing the restore-involved containers, delta chunks always appear in front of their base chunks. For the example in Fig. 6(c), when restoring the 2nd backup, restore-involved categories are $Cat.(1,2)$, $Cat.(2,2)$, $Cat.(1,3)$ and $Cat.(2,3)$ (according to “Identifying All Required Containers”). In this case, we can achieve AFR traversing with the following order: $Cat.(2,2) \Rightarrow Cat.(1,2) \Rightarrow Cat.(2,3) \Rightarrow Cat.(1,3)$, in which we always meet the delta chunks before their base chunks.

Next, we explore how and why MeGA can achieve AFR traversing, also with the example of restoring the 2nd backup in Fig. 6(c). Consider the two key Features about the relative positional relationship (i.e., the located categories' Rows and Columns) between the delta and base chunks (learned from §4.3). We can get Table 1, listing all possible positions (i.e., located categories) of delta and based chunks of the 2nd backup. To achieve AFR traversing (accessing delta chunks and then their bases), $Cat.(2,2)$ must be first accessed, which is because the base chunks of $Cat.(2,2)$'s delta chunks could be in all four categories as shown in Table 1. With similar analysis, we could finally get the previous example path: $Cat.(2,2) \Rightarrow Cat.(1,2) \Rightarrow Cat.(2,3) \Rightarrow Cat.(1,3)$. Additionally, AFR traversing should go through chunks and also containers of each category in reverse order in case there are delta and base chunks in the same category or container, since the delta

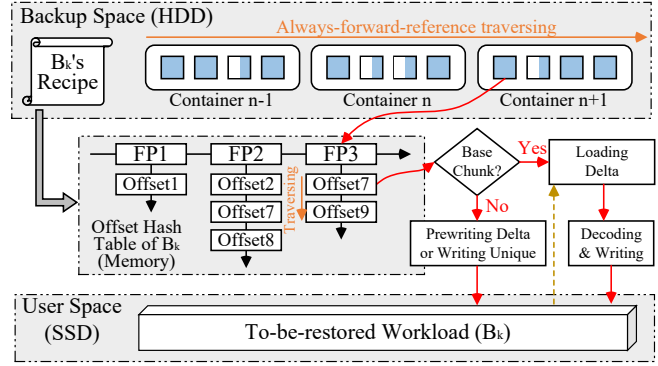

Figure 10: An example of the restore workflow.

must be generated and then appear after its base in the backup workflow.

To this end, we can summarize **three rules to achieve AFR traversing** on our delta-friendly data layout in general cases:

- Between columns, access columns in positive order. This is deduced from Feature 2 (in Section 4.3).
- In the same column, access categories in reverse order. This follows from Feature 1 (in Section 4.3).
- In a category, access containers in each category and chunks in each container in reverse order. This is because delta chunks can only reference earlier chunks by design.

Delta Prewriting. As shown in Fig. 10, *Delta Prewriting* requires an *Offset Hash Table*, which is generated according to the to-be-restored backup's recipe. The Offset Hash Table records key/value pairs: **each chunk's offset** (in the to-be-restored backup) and **whether it is a base chunk** (i.e., <offset, base tag>). For unique chunks in the recipe, we only insert its offset into its FP's entry list and tag this record as not a base (e.g., <offsetUniqueK, false>). For a delta chunk in the recipe, we first process it as a unique chunk (e.g., insert <offsetDeltaN, false> in its FP's entry list) and then additionally insert a record into the entry list of its base's FP and tag this record as a base chunk (e.g., <offsetDeltaN, true>).

Then, we apply AFR traversing on restore-involved containers. For each chunk, we acquire its entry list according to its fingerprint. We check each record in the entry list: If it is not a base chunk record, we directly write the chunk (it may be a delta or unique chunk) to the offset in the record; If it is a base chunk, we read the delta chunk from the offset in the record (the delta should already be written before), decode the delta chunk with the base chunk, and then write back the decoded chunk to the offset in the record.

Finally, MeGA could achieve a much higher restore speed with the benefits of the delta-friendly data layout, AFR traversing and delta prewriting, since it no longer reads unneeded chunks and repeatedly accesses restore-involved containers.

4.5 Discussion

In this subsection, we discuss several features and issues.

Deletion. Different from the order-based data layout, the delta-friendly data layout supports direct deletions without GC. Because MeGA allows workloads to share chunks as duplicate chunks or base chunks, deleting the n^{th} backup only needs to remove its unique chunks. According to the category naming rule, $Cat.(n,n)$ only contains chunks unique to backup n . Thus, deleting the n^{th} backup could be achieved by directly removing this category, instead of the way in the order-based data layout, which first runs logical deletion and later runs garbage collection to reclaim storage space [3, 9, 14].

Delta Prewriting. This mechanism introduces additional I/O on User Space, including prewriting and reading delta chunks. Our observations suggest these issues cause about 5%-10% additional I/O overheads on User Space. Moreover, since delta chunks are usually much smaller than unique ones, we could also introduce a delta cache in memory and prewrite delta chunks into the cache as an alternative solution.

Memory Overhead. Since the size of the base chunk cache (in a backup workflow) is configurable, the other memory overhead of MeGA is mainly from the local-based indexes (in backup workflow) and the offset hash table (in restore workflow). ① Instead of putting the whole index in memory, MeGA only maintains the index of the last two backups and thus costs less memory, which is similar to some previous work [44, 58]. Moreover, a stream-informed index [56] could also be applied to our local-based index to further reduce memory overhead. ② The overhead of the offset hash table is related to the number of chunks in a single backup. Some previous works [1, 43] suggest that the majority of single backups were 4–128GB, and for these cases, RAM usage for the Offset Hash Table could be 12.9–445.6MB, which is feasible for a server. To reduce this RAM usage for large backups, we could keep the offset hash table in an on-disk key-value store, but it would require indexing time.

Maintenance's (i.e., Migrations) Overheads. The Maintenance process in MeGA replaces Garbage Collection (GC) in previous works, and its overhead could be offset since both techniques are offline processes, which will be evaluated in §5.6. Through the Maintenance process, MeGA could achieve direct deletion (to immediately reclaim storage space) instead of logical deletion followed by GC. Besides, the Maintenance process also addresses two interesting issues [36]: knowing how much space will be freed after deletion and estimating the remaining logical space of a fine-grained deduplication system.

Incremental Backups. Although MeGA focuses on full backups (i.e., a full snapshot of primary storage), we present a plan to support incremental backups by generating “virtual” full backups.

When handling an incremental backups, we generate a “virtual” full backup according to the previous full backup’s recipe, and then process the “differences” included in the incremental backup. Specifically, ① non-modified (i.e., not listed in the incremental backup) parts of the “virtual” full

backup are duplicates, and we can directly copy corresponding records from the previous full backup’s recipe to the “virtual” full backup’s recipe; ② modified (i.e., listed in the incremental backup) parts have potentially new content, and we need to apply fine-grained deduplication. Chunk boundaries need to be recalculated due to the modified data regions, so we could combine the new data with their surrounding duplicate chunks to make up a local stream and run content-defined chunking on this stream to determine new chunks. Then, MeGA could process these chunks normally, and finally record these “modifications” in the “virtual” full backup’s recipe.

5 Evaluation

5.1 Configuration

We perform our experiments on a workstation running Ubuntu 18.04 with an Intel Core i7-8700 @ 3.2GHz CPU, 64GB memory, and a 7200rpm HDD. To better evaluate MeGA, the following five approaches are considered:

- **Greedy:** applying the greedy strategy for fine-grained deduplication, often evaluated as the baseline [44, 53].
- **FGD:** Fine-Grained Deduplication with the Capping rewriting technique [23], which skips some deduplication and delta compression whose duplicate chunks or base chunks are located in a few referenced containers. This is similar to a recent work called SDC [53].
- **CLD:** Chunk-Level Deduplication with the Capping rewriting technique [23], considered as a typical approach of chunk-level deduplication defragmentation.
- **MFD:** Chunk-level deduplication with the previous lifecycle-based data layout, which only deduplicates chunks between adjacent backups [58].

These approaches are implemented according to related papers, and they all follow these common configurations:

- Chunking backups uses FastCDC [46] with the minimum, average, and maximum chunk sizes set to 2KB, 8KB, and 64KB; SHA1 is used for chunk identification.
- Their resemblance detection generates 12 features and 3 super-features as sketches for each unique chunk, as suggested in previous works [22, 24, 37].
- Consecutive chunks are compressed together with ZSTD and stored in containers.
- The delta encoding stage uses Xdelta to calculate differences between unique chunks and its similar candidates, as configuration in previous works [52, 57].
- MeGA only requires a container cache in the backup workflow, and the other four non-trivial approaches require two container caches in both backup and restore workflows. The cache of each workflow totals 512MB. When loading base chunks into the cache, all approaches apply container I/O for fair comparison.

To focus on testing the performance of the deduplication storage side (i.e., running deduplication on HDD media), tested datasets are backed up from User Space (i.e., a

Figure 11: Backup speed of five deduplication approaches on four datasets.

Table 2: Four backup datasets used in evaluation.

Name	Original Size	Versions	Workload Descriptions
WEB	269 GB	100	Backups of website: news.sina.com, captured from Jun. to Sep. in 2016.
CHM	279 GB	100	Source codes of Chromium project from v82.0.4066 to v85.0.4165
SYN	1.38 TB	200	Synthetic backups by simulating file create/delete/modify operations [42]
VMS	1.55 TB	100	Backups of an Ubuntu 12.04 Virtual Machine

RamDisk) to Backup Space (i.e., a 7200rpm HDD) one by one while the restore runs in the reverse direction. For speed of backup and restore in our evaluation, we present the average results of five runs.

Four backup datasets are used for evaluation, as shown in Table 2. These datasets represent various typical backup workloads, including website snapshots, an open-source code project, virtual machine images, and a synthetic dataset. They have been used in several deduplication studies [8, 46, 53].

5.2 Backup Speed

The backup speed of five approaches are evaluated and shown in Fig. 11, and the results vary by 5.2% on average in multiple runs. FGD# and MG# represent FGD and MeGA with different parameters (the capping level in FGD and the delta selector threshold in MeGA). The capping level L indicates that when processing a backup stream segment, containers will be considered as sparse containers except for the L most referenced (for duplicate or base chunks). Chunks in the segment, whose duplicate or base chunks are in sparse containers, will be processed as unique chunks. A delta selector threshold T means that when processing a backup stream segment, containers, which are referenced for base chunks less than T times, will be considered as base-sparse containers. Delta compression in the segment, whose base chunks are in base-sparse containers, will be skipped. Considering that datasets

have different characteristics and require different parameters, we optimized the parameters for each dataset. The backup speed is calculated by $\frac{\text{The-Size-of-Backup-or-Restore-Workload}}{\text{Backup-or-Restore-Time-Cost}}$. Because deduplicated and compressed data is much smaller than their original size and writing to disk takes less time, the backup speed could exceed the disk speed.

With the benefits of the delta selector, MeGA outperforms other fine-grained deduplication approaches (i.e., Greedy and FGD). On the SYN dataset, MeGA reads increasingly fewer containers when processing later backups, which makes MeGA’s backup speed increase. VMS is a virtual machine dataset and its modification style (i.e., trending to change the same region in each backup) makes distribution of base chunks uneven, which makes MeGA’s performance jittery. Generally, MeGA achieves a 4.47–34.45 \times higher backup speed than Greedy.

Fig. 11 also suggests a stricter (smaller) capping level in FGD and a stricter (bigger) delta selector threshold in MeGA both accelerate backup speed, due to skipping some potential delta compression and the need to read more base chunks. Note that if delta selector threshold and capping level were strict enough, all delta compression would be skipped. Though the delta selector and the capping rewriting have similar mechanisms, their results are much different due to their different views on container utilization. The capping rewriting is restore-workflow-oriented and focuses on how many needed chunks (all kinds of chunks) are in containers. But the delta selector is backup-workflow-oriented, and only concerns how many base chunks are in containers.

Fig. 12 further studies why MeGA could achieve a much higher backup speed than FGD, which lists the disk access times for acquiring base chunks (within the unit of containers) and average access time cost when storing backup. On the one hand, MeGA has much lower disk access time due to skipping reading “inefficient” containers. On the other hand, MeGA has a lower average access time cost, since it only finds base chunks in adjacent backups and its accessed containers will be located closer. These two efforts ensures MeGA’s better performance.

Note that MeGA achieves similar results with chunk-level deduplication approaches (CLD and MFD) on most datasets. It is because the additional I/O and computation overhead both have been hugely limited by our delta selector and previous computation optimization works, respectively. Besides, SYN is a synthetic dataset and its modified parts are distributed ran-

Figure 13: Restore speed of five deduplication approaches on four datasets.

Figure 14: Number of restore-involved containers and actually read containers in MeGA, FGD and CLD. Only WEB and CHM are shown due to the space limit.

domly instead of having more typical locality, which makes MeGA slightly slower than CLD and MFD.

5.3 Restore Speed

Fig. 13 shows the restore speed of all five approaches, and the results vary by 2.6% on average in multiple runs. Among all approaches, MeGA consistently achieves a better restore performance than other approaches, which reflects MeGA’s restore techniques (i.e., the delta-friendly data layout, delta prewriting and AFR traversing). MeGA solves the *Fragmentation Issue* and *Repeatedly Accessing Issue* and improves the spatial and temporal locality in fine-grained deduplicated data. It also ensures that MeGA’s restore performance is more consistent, while FGD, CLD and Greedy all have a decreasing restore speed. Note that the local compression ratio increases when storing more backups on SYN, which makes the restore speed faster. Generally, MeGA achieves a 30–105× higher restore speed than Greedy.

Fig. 14 shows the number of restore-involved containers (i.e., containers with restore-required chunks) and containers read from disk during restore of MeGA, FGD, and CLD. These two metrics reflect the seriousness of the *Fragmentation Issue* and *Repeatedly Accessing Issue*, respectively. Compared with FGD and CLD, MeGA has lower results on both of the metrics due to applying our data layout and AFT traversing with delta prewriting. Consequently, MeGA achieves a much higher restore performance, as shown in Fig. 13.

5.4 Deduplication Ratio

Fig. 15 studies deduplication ratios of five approaches with different parameters mentioned in the above subsections. All three fine-grained deduplication approaches (i.e., Greedy, FGD, and MeGA) have higher deduplication ratios than chunk-level deduplication approaches (i.e., CLD and MFD), since they can exploit compressibility among similar chunks.

Greedy always achieves the highest deduplication ratio, and MeGA achieves similar results. For FGD and MeGA, a stricter capping level in FGD or threshold in MeGA will lower the deduplication ratio but lead to a better backup or restore speed, as reported in the above subsections.

MeGA’s advantage is relatively smaller on the VMS and SYN datasets. For VMS, its modification style (i.e., trending to change the same region in each backup) leads to fewer similar chunks, which limits the benefits of fine-grained deduplication, regardless of the approach. For SYN, its modifications are completely random because it is a synthetic dataset, and the locality of base chunks is not as strong as that of other datasets. Therefore, MeGA’s delta selector causes more reduction in the compression ratio.

Generally, MeGA preserves fine-grained deduplication’s significant advantage by achieving a 1.18–8.73× higher deduplication ratio than chunk-level approaches.

5.5 Overall Performance

The three metrics discussed above are of the most interest to users. Fig. 16 shows the overall performance with different parameters (used in Fig. 11 and 13) from the above section. It is obvious that MeGA significantly improves over other fine-grained deduplication approaches (i.e., FGD and Greedy) on both backup and restore speed while preserving the deduplication ratio advantage of fine-grained deduplication. It reflects the performance improvement that our proposed technology brings. MeGA’s advantage is relatively smaller on SYN and VMS datasets. As we mentioned in § 5.4, it is because VMS does not have many similar chunks, and SYN lacks natural locality, which is unfriendly for our delta selector.

5.6 I/O Overhead in Maintaining Data Layout

In this subsection, we evaluate I/O overheads of maintaining the delta-friendly data layout (shortened to "Maintenance") compared with traditional garbage collection (GC).

Our experiments are based on MeGA and FGD using the median parameters as in Fig. 11 and 13, and MeGA runs maintenance while FGD runs GC. For GC, a container liveness threshold is usually considered to make a tradeoff between more storage space cost and more GC overheads. Here we use three liveness thresholds: 0%, 25%, and 50%, mapping to toleration up to 0%, 25%, 50% invalid chunks in each container, respectively. In order to make the results among different datasets comparable, we measure their time costs. Both approaches retain the last 20 backups; thus GC would

Figure 15: Deduplication ratio achieved by the ten approaches on four datasets.

Figure 16: A general view of five approaches. MeGA and FGD use three different parameters as used in Fig. 11, 13 and 15. The results of backup and restore speed are from the average performance on each dataset’s last 10 backups.

Figure 17: The delta-friendly data layout’s maintenance vs. the order-based data layout’s garbage collection.

not run for the first 20 backups, though the maintenance does.

Fig. 17 compares time cost of maintenance and GC. For GC, a bigger threshold does not always lead to a lower I/O overhead, since tolerating invalid chunks will make the next GC need to clean more containers, which causes additional I/Os. In general, maintenance and GC have similar I/O overheads, and compared with the best version of GC (“GC:25%”), maintenance costs about 0.32–1.92× the GC I/O overheads, which suggests maintenance and GC’s overhead have different characteristics and have an overall similar impact.

Note that in maintenance of MeGA, if all chunks in a container are needed to be migrated to a new category, we can directly let this container belong to that new category without any chunk migration. It is interesting to observe that about 25.13% (WEB), 14.57% (CHM), 59.13% (SYN), and 72.95% (VMS) of containers do not need chunk migrations.

6 Conclusion

This paper proposes MeGA, a fine-grained deduplication framework, with three techniques: backup-workflow-oriented delta selector, delta-friendly data layout, and AFR traversing with delta prewriting, to address the three issues for different forms of poor locality caused by the introduction of delta

compression: reading base chunks, fragmentation, and repeatedly accessing containers, respectively. Evaluations show that MeGA achieves performance close to chunk-level deduplication while preserving fine-grained deduplication’s significant deduplication ratio advantage.

Acknowledgments

We are grateful to our shepherd and the anonymous reviewers for their insightful comments. This work was supported in part by NSFC under Grant 61972441, 61972112 and 61832004, in part by Shenzhen Science and Technology Program under Grants RCYX20210609104510007, JCYJ20210324131203009, JCYJ20200109113427092, and GXWD20201230155427003-20200821172511002, in part by Guangdong Basic and Applied Basic Research Foundation under Grant 2021A1515012634, 2021B1515020088 and in part by the HITSZ-J&A Joint Laboratory of Digital Design and Intelligent Fabrication under Grant no. HITSZ-J&A-2021A01.

A Artifact Appendix

Abstract

The artifact is source code of a prototype deduplication system for backups that follows the ideas in the paper.

Scope

It could suggest the details and effectiveness of the delta selector, the delta-friendly data layout, the "Always-Forward-Reference" traversing, and the delta prewriting mechanism.

Contents

The artifact is source code of a prototype deduplication system for backups that follows the ideas in the paper. It mainly supports two main operations: (1) deduplicating and storing backup workloads and (2) restoring stored backup workloads.

Detailed manuals are introduced in our GitHub repository. In brief, the artifact supports the two operations with the following two commands.

```
=====  
# deduplicating and storing a new backup  
./MeGA --ConfigFile=[config file path] --task=write --InputFile=[backup work-  
load] --DeltaSelectorThreshold=[Delta Selector Threshold]  
  
# restoring a stored backup  
./MeGA --ConfigFile=[config file path] --task=restore --RestorePath=[path  
to restore] --RestoreRecipe=[which backup to restore (1 ~ n)]  
=====
```

MeGA generates several outputs when executing. Note that:

① MeGA includes chunk-level deduplication, delta compression, and local compression. The "total reduction ratio" suggests the benefits from all these parts on a single backup.

② The "total reduction ratio" simply indicates how many times the size of a single backup has been reduced. For the entire dataset, the user needs to add up the original size of all backups in a dataset and divide it by the "After Compression" of all backups to get the general "Dedup ratio" of the dataset, which is suggested in Figure 15.

③ The backup speed is related to the results in Figure 11.

④ The cache misses and average time cost are related to the results in Figure 12.

⑥ The arrangement duration is related to the results in Figure 17.

⑦ The restore speed is related to the results in Figure 13.

⑤ Figure 16 is just a general view, and it does not have new results.

Hosting

The source code is available at <https://github.com/Borelset/MeGA> (the "ContainerBased" branch).

Requirements

The Artifact has the following requirements.

Hardware Requirement:

- CPUs supporting AVX2 instructions.
- 32GB or larger RAM
- 7200rpm HDD drives for experiments.
- Another storage device for datasets. (400GB for full evaluations or 100GB for partly evaluations)

Software Requirement:

- `isal_crypto` [https://github.com/intel/isa-l_crypto]
- `jemalloc` [<https://github.com/jemalloc/jemalloc>]
- `openssl` [<https://github.com/openssl/openssl>]
- `zstd` [<https://github.com/facebook/zstd>]
- Reformat your HDD and deploy an XFS file system, as fragmentation of the file system will affect performance.

Secure and Lightweight Deduplicated Storage via Shielded Deduplication-Before-Encryption

Zuoru Yang[†], Jingwei Li^{‡,*}, and Patrick P. C. Lee[†]

[†]*The Chinese University of Hong Kong* [‡]*University of Electronic Science and Technology of China*

Abstract

Outsourced storage should fulfill confidentiality and storage efficiency for large-scale data management. Conventional approaches often combine encryption and deduplication based on deduplication-after-encryption (DaE), which first performs encryption followed by deduplication on encrypted data. We argue that DaE has fundamental limitations that lead to various drawbacks in performance, storage savings, and security in secure deduplication systems. In this paper, we study an unexplored paradigm called deduplication-before-encryption (DbE), which first performs deduplication and encrypts only non-duplicate data. DbE has the benefits of mitigating the performance and storage penalties caused by the management of duplicate data, but its deduplication process is no longer protected by encryption. To this end, we design DEBE, a shielded DbE-based deduplicated storage system that protects deduplication via Intel SGX. DEBE builds on frequency-based deduplication that first removes duplicates of frequent data in a space-constrained SGX enclave and then removes all remaining duplicates outside the enclave. Experiments show that DEBE outperforms state-of-the-art DaE approaches.

1 Introduction

Data outsourcing to public cloud storage provides a plausible solution for low-cost, large-scale data storage management in the face of explosive data growths [71]. To defend against data privacy leakage [57], clients require end-to-end encryption, such that their outsourced data be encrypted before being stored in (untrusted) public cloud storage. However, traditional symmetric encryption prohibits cross-user deduplication (i.e., removing duplicate data from multiple clients), since each client encrypts its own outsourced data with a distinct secret key, implying that the encrypted outputs from multiple clients are also distinct.

The literature has numerous studies (e.g., [3, 7, 8, 18, 23, 72, 74, 79]) on how to seamlessly combine encryption and deduplication for secure deduplicated storage in data outsourcing, which we collectively refer to as *deduplication-after-encryption (DaE)*. DaE first performs encryption on the outsourced data on the client side for confidentiality, followed by applying cross-user deduplication in the cloud to remove duplicate encrypted data for storage savings. To preserve the identical content after encryption, DaE encrypts data using a

symmetric key derived from the content of each *chunk* (the basic unit of deduplication), such that duplicate original chunks (called *plaintext chunks*) are always encrypted by the same key into duplicate encrypted chunks (called *ciphertext chunks*) that are later removed by deduplication.

Despite its popularity, we argue that DaE has fundamental limitations including high key management overhead, incompatibility with compression, and security risks (see §2.1 for details). Since DaE always manages a key for each chunk for encryption before deduplication, it not only unnecessarily generates a huge number of keys for duplicate chunks that will later be removed by deduplication, but also incurs high storage overhead for managing a huge number of keys for all duplicate and non-duplicate chunks [47]. In addition, DaE stores non-duplicate encrypted chunks, whose contents look randomized and have limited room for further space reduction from compression. Furthermore, DaE necessitates deterministic encryption to preserve the deduplication capability on ciphertext chunks. Such a deterministic nature is vulnerable to information leakage through frequency analysis [48, 49].

The limitations of DaE motivate us to explore a simple but unexplored paradigm called *deduplication-before-encryption (DbE)*, which first performs deduplication on the plaintext chunks and then encrypts the remaining non-duplicate plaintext chunks with any key that is independent of the chunk content. A major distinction from DaE is that DbE does not need to manage per-chunk keys for encryption/decryption, and we argue that DbE addresses the limitations of DaE (§2.2). However, DbE remains unexplored in secure deduplicated storage, mainly because the chunks are no longer protected by encryption in deduplication processing, which is carried out in the cloud for cross-user deduplication.

Our insight is that the deduplication process in DbE can be protected with *shielded execution* [4, 37]. To this end, we present DEBE, a shielded DbE-based deduplicated storage system with performance, storage savings, and security in mind. DEBE builds on Intel Software Guard Extensions (SGX) [41], which provides a shielded execution environment, called an *enclave*, for secure deduplication processing. A key challenge of realizing DEBE in SGX is the limited enclave space (e.g., up to 128 MiB [36]). Thus, we propose *frequency-based deduplication*, a two-phase deduplication scheme that can realize secure and lightweight deduplication with the space-constrained enclave. Specifically, DEBE first performs deduplication on the most frequent chunks inside an enclave,

*Corresponding author: Jingwei Li (jwli@uestc.edu.cn)

motivated by our observation that the most frequent chunks often contribute to a large fraction of duplicates in real-world backup workloads (§4.1). It then performs deduplication on the remaining less frequent chunks outside the enclave. With frequency-based deduplication, DEBE has the key advantages of: (i) high performance, as it removes most duplicates in the first-phase deduplication and incurs limited performance overhead for the second-phase deduplication outside the enclave; (ii) high storage savings via both deduplication and compression; and (iii) security, as it protects the most frequent chunks (which are more vulnerable to frequency analysis attacks [48]) inside the enclave.

We evaluate our DEBE prototype in a LAN testbed. DEBE achieves significant speedups over state-of-the-art DaE approaches (e.g., 10.09× and 13.08× speedups over DupLESS [7] in uploading non-duplicate and duplicate data, respectively). In our technical report [81], we also show that DEBE achieves high storage savings (e.g., 93.8% of key metadata storage savings compared with DaE) and reduces information leakage without compromising storage savings (e.g., by 87.7% of the relative entropy over TED [49], while TED incurs a storage blowup). The source code of our DEBE prototype is at: <https://github.com/yzr95924/DEBE>.

2 Background and Motivation

2.1 Limitations of Deduplication-after-Encryption

Deduplication is a widely deployed data reduction technique in modern storage [26, 27, 59, 77, 85]. We focus on *chunk-based deduplication*, which removes duplicates at the granularity of a *chunk*. Specifically, a deduplicated storage system partitions input file data into chunks. It identifies each chunk by a cryptographic hash (e.g., SHA-256), called a *fingerprint*, of the chunk content (assuming that fingerprint collisions of distinct chunks are practically impossible [10]). It maintains a key-value store, called the *fingerprint index*, to track the fingerprints of all existing stored chunks, and stores only the non-duplicate chunks. It also stores a manifest file, called the *file recipe*, for each file to track all chunks of the file in storage for file reconstruction. In addition, it may further apply *compression* to remove byte-level duplicates within the non-duplicate chunks for more storage savings [27, 73, 85].

Deduplication-after-encryption (DaE) combines deduplication and encryption for both confidentiality and storage savings. In DaE, a client locally encrypts the plaintext chunks and uploads the ciphertext chunks to the cloud, which then performs deduplication on the ciphertext chunks. One popular cryptographic primitive for DaE is *message-locked encryption (MLE)* [8], which formalizes that the key for chunk encryption/decryption is derived from the content of each chunk, so that identical plaintext chunks are always encrypted into identical ciphertext chunks for deduplication. An instantiation of MLE is *convergent encryption (CE)* [3, 18, 23, 72, 74, 79], which derives each chunk’s key based on its fingerprint.

CE is vulnerable to *offline brute-force attacks* [7], in which an adversary enumerates all possible plaintext chunks to derive their secret keys, attempts to decrypt a ciphertext chunk using each key, and deduces the plaintext chunk if the decryption succeeds. DupLESS [7] defends against offline brute-force attacks in CE via server-aided key management, by deploying a *key server* that generates the key of each chunk based on a global secret (securely owned by the key server) and the chunk fingerprint. Also, DupLESS implements key generation based on an oblivious pseudorandom function (OPRF) [63] to prevent the key server from learning the chunks or the keys during key generation, and rate-limits the key generation requests from clients to defend against *online brute-force attacks*, in which a malicious client aggressively issues key generation requests for different plaintext chunks to the key server.

Limitations. DaE is the state-of-the-art paradigm for building secure deduplicated storage systems. However, we argue that DaE suffers from three fundamental limitations.

- *L1 (High key management overhead).* DaE generates one key per chunk, leading to huge overheads for maintaining all chunk-based keys. Also, each client needs to encrypt its chunk-based keys via its own master secret key for protection. Thus, the key storage overhead increases proportionally with the numbers of chunks and clients, and is particularly significant for the workloads with high content redundancy (e.g., backups [77]) as they store only small amounts of non-duplicate data after deduplication. Also, DupLESS [7], which realizes server-aided key management, generates a key for the encryption of each chunk before the chunk is uploaded to the cloud, even though the chunk is a duplicate and is later removed by deduplication. As DupLESS employs OPRF and rate-limiting in key generation (see above), its key generation is shown to be expensive [70]. In short, DaE incurs high key management overhead, both in terms of key storage and key generation.
- *L2 (Incompatibility with compression).* In DaE, the cloud cannot further save additional storage space of non-duplicate encrypted chunks via compression, as encrypted chunks have high-entropy (almost random) contents. While a client may apply compression to the plaintext chunks before encryption and upload the encrypted compressed chunks, this leaks the compressed chunk lengths and introduces security risks [13].
- *L3 (Security risks).* Server-aided key management in DupLESS [7] makes the key server a single point-of-attack. If an adversary compromises the key server and has access to the global secret, it can infer the secret keys of chunks via offline brute-force attacks as in CE. Also, DaE is deterministic by nature and realizes one-to-one mappings between plaintext chunks and ciphertext chunks. An adversary can launch frequency analysis to infer the original plaintext chunks from the frequency distribution of ciphertext chunks in deduplicated storage [48].

2.2 Moving to Deduplication-before-Encryption

Given the limitations of DaE (§2.1), we study an unexplored paradigm, namely *deduplication-before-encryption (DbE)*, for secure deduplicated storage. Its idea is to first perform deduplication on the plaintext chunks to remove duplicates, followed by encrypting the non-duplicate plaintext chunks into ciphertext chunks for storage.

DbE naturally offers several benefits over DaE. First, since deduplication is applied first, DbE can encrypt each non-duplicate plaintext chunk with a content-independent key as in traditional symmetric encryption (§1) without compromising deduplication. This avoids generating and storing per-chunk content-derived keys and reduces the key management overhead (i.e., L1 addressed). Second, DbE can apply compression to the non-duplicate plaintext chunks after deduplication for further storage savings, followed by encrypting the compressed non-duplicate plaintext chunks (i.e., L2 addressed). Finally, since DbE can perform encryption with a content-independent key, it no longer needs a key server for per-chunk key generation as in DupLESS. This removes the single point-of-attack in the key server (i.e., L3 addressed).

The major challenge of DbE, however, is to decide whether clients or the cloud should perform deduplication, which is no longer protected by encryption. We consider three scenarios:

- Each client maintains a local fingerprint index for its own plaintext chunks. It encrypts the non-duplicate plaintext chunks and uploads the ciphertext chunks to the cloud. However, this approach prohibits cross-user deduplication.
- The cloud maintains a global fingerprint index to track the stored chunks of all clients. Each client first submits the fingerprints of its own plaintext chunks to the cloud to query if they can be deduplicated. It encrypts the non-duplicate plaintext chunks identified by the cloud, and uploads the ciphertext chunks to the cloud. This approach, also referred to as *source-based deduplication* [35], is vulnerable to *side-channel attacks* [35,62] since any malicious client can infer if some target chunk has already been stored by querying if the target chunk can be deduplicated.
- Each client uploads all chunks to the cloud. The cloud performs deduplication based on its global fingerprint index that tracks the stored chunks of all clients, followed by encrypting the non-duplicate chunks. This approach, also referred to as *target-based deduplication* [35], hides the deduplication pattern from the clients and is secure against side-channel attacks. However, each client inevitably exposes its plaintext chunks to the cloud.

Thus, DbE remains unexplored in the literature, while existing studies mostly focus on DaE for secure deduplicated storage.

2.3 Intel SGX

In this work, we realize DbE with target-based deduplication and show how we protect DbE via *shielded execution*. We implement shielded execution using Intel SGX [41]. As our

major requirement is to provide a secure memory region for data processing in the untrusted cloud, we conjecture that our design can be supported with other shielded execution technologies (e.g., ARM TrustZone [67] and AMD SEV [2]).

SGX basics. SGX is a set of extended instructions for Intel CPUs to realize a shielded execution environment, called an *enclave*, in an encrypted and integrity-protected memory region called the *enclave page cache (EPC)*. It ensures confidentiality and integrity for in-enclave contents with hardware protection. It provides two interfaces to interact with untrusted applications outside the enclave: (i) *enclave calls (ECalls)*, which permit applications to safely access in-enclave contents, and (ii) *outside calls (OCalls)*, which allow in-enclave code to issue function calls in applications.

Challenges. Realizing DbE in SGX is non-trivial due to the resource constraints of an enclave. First, the EPC size is limited (e.g., up to 128 MiB [36]). When an enclave has memory usage exceeding the EPC size, it encrypts and evicts the unused memory pages to the unprotected main memory, and decrypts and verifies the integrity of the evicted pages when loading them back to the EPC. This incurs expensive EPC paging overhead [5, 21]. Although recent SGX designs support a large EPC size of up to 1 TiB [44], they provide weaker security guarantees due to the loss of integrity tree protection [28]. Second, both ECalls and OCalls involve expensive hardware operations (e.g., flushing TLB entries [5]) that lead to significant context switching overhead (e.g., around 8,000 CPU cycles per call [66, 78]).

3 Design Overview

3.1 DEBE Architecture

We make a case for DbE by designing DEBE, a shielded DbE-based deduplicated storage system based on Intel SGX [41]. Figure 1 presents the architecture of DEBE; note that DEBE does not maintain a key server as in DupLESS [7] (§2.1). We consider a *multi-tenant* scenario, in which the clients from different organizations store outsourced data to a cloud storage service (or the cloud in short). DEBE performs target-based deduplication [35] (§2.2) to remove the duplicate data of multiple clients in the cloud. Currently, each DEBE client uploads all its data to the cloud for deduplication. Although a client may apply deduplication to its own data to save upload bandwidth without introducing side-channel attacks [50], our design does not make this assumption.

To prevent the cloud from accessing any plaintext chunks during deduplication processing, DEBE hosts an enclave in the cloud and performs deduplication inside the enclave. To support the multi-tenant scenario, we assume that a trusted third party (e.g., a certificate authority in the public key infrastructure (PKI) [56]) is responsible for the enclave setup. Specifically, the trusted third party compiles the enclave code into a shared object (as a .so file). It distributes the shared object to the cloud, along with its signature for integrity ver-

Figure 1: DEBE architecture.

ification. The cloud loads the shared object to bootstrap the enclave. The trusted third party can initiate *remote attestation* [41] to ensure that the correct code is loaded into the enclave, and it can go offline after the enclave is bootstrapped.

After the enclave is bootstrapped, each client sets up two secure communication channels: (i) the *control channel* with the cloud for transmitting the commands of storage operations and (ii) the *data channel* with the enclave for transmitting the plaintext chunks originated by the client. Currently, DEBE sets up the control channel between a client and the cloud using traditional SSL/TLS authentication. To set up the data channel between a client and the enclave, since the enclave cannot directly access the network socket of the cloud [41], DEBE implements the Diffie-Hellman key exchange to agree on a session key between a client and the enclave (§4.2), and the session key is used to protect the data channel. Note that other key exchange algorithms can be used for session key establishment.

To upload a file to the cloud, a client divides the file data into fixed-size or variable-size plaintext chunks as in traditional chunk-based deduplication (§2.1). It issues an upload request to the cloud through the control channel, and sends all plaintext chunks to the enclave through the data channel. The enclave deduplicates and compresses the received plaintext chunks on a per-batch basis (§4.1), encrypts the remaining non-duplicate compressed chunks into ciphertext chunks, and emits the ciphertext chunks and the file recipe to the storage pool.

To download a file, the client issues a download request to the cloud through the control channel. The enclave then retrieves the file’s recipe and the corresponding ciphertext chunks. Finally, it decrypts the ciphertext chunks, and decompresses and returns the plaintext chunks to the client through the data channel.

Practical relevance of DEBE. DEBE focuses on multi-tenant deduplication, which is widely deployed in practice (e.g., Dropbox [24], Druva [25], Cohesity [14], and Memopal [58]) and is shown to achieve higher storage savings than single-tenant deduplication by removing the duplicate data from multiple clients [50,59,83]. Existing DaE approaches are also designed for multi-tenant deduplication, while DEBE addresses the limitations of DaE (§2.1). Although DEBE incurs costs due to shielded execution (e.g., the enclave verification fee from a trusted third party), its improvements over DaE approaches (in terms of performance, storage savings, and robustness; see §3.3) provide incentives for a cloud storage provider to use DEBE to provide secure and cost-effective cloud storage services for customers.

3.2 Threat Model

We consider an honest-but-curious adversary that does not modify the system protocol but aims to compromise data confidentiality by identifying the original content of the out-sourced data stored in the cloud. The adversary can tap into the cloud and gain access to any data stored in the unprotected main memory of the cloud as well as the ciphertext chunks in the storage pool. It can also eavesdrop on the content of OCalls issued to the unprotected main memory (e.g., the parameters and untrusted functions used by OCalls).

Our threat model assumes that the enclave is trusted and reliable; its authenticity is verified by remote attestation [41] when it is created (§3.1). Any denial-of-service or side-channel attack against SGX is protected by existing solutions [64, 76]. Also, if the adversary has access to a compromised client, then it can access all the plaintext chunks of the client. However, since DEBE performs target-based deduplication (§3.1), the adversary cannot access or infer the plaintext chunks of other non-compromised clients.

3.3 Design Goals

DEBE is designed for clients from multiple tenants (§3.1) to securely outsource their storage management to public cloud storage services. It targets storage workloads with high content redundancy (e.g., backups [77] and file system snapshots [59]) that can be effectively removed by deduplication and compression. DEBE has the following design goals:

- *High performance.* DEBE has significantly lower key management overhead than DaE approaches. It also incurs limited overhead in SGX.
- *High storage savings.* DEBE supports *exact* deduplication (§4.4), i.e., all duplicates from multiple clients can be removed. It also applies compression to the non-duplicate chunks after deduplication for extra storage savings.
- *Confidentiality.* DEBE preserves the security of DaE by enforcing end-to-end encryption for the plaintext chunks between each client and the enclave, and the plaintext chunks are inaccessible by the cloud provided that the enclave is trusted and reliable (§3.2). DEBE remains secure against offline brute-force attacks in CE (§2.1), without the need of server-aided key management as in DupLESS [7].
- *Robustness over DaE.* DEBE mitigates the single point-of-attack of DaE by eliminating the key server. It also mitigates the information leakage caused by frequency analysis against DaE [48, 49].

4 Detailed Design

4.1 Main Idea

DEBE’s core idea is to perform deduplication inside the enclave (hosted in the cloud), so as to provide confidentiality guarantees for the plaintext chunks during the deduplication process. Keeping a full fingerprint index (or the *full index* in short) inside the enclave can track the fingerprints of all

Figure 2: Duplicate rate versus top-percentage of frequent chunks in five real-world traces.

non-duplicate chunks being stored, but incurs significant EPC paging overhead due to the limited EPC size (§2.3). Alternatively, managing the full index outside the enclave saves the EPC usage, but incurs expensive context switching due to excessive OCalls for querying the full index (§2.3).

We propose *frequency-based deduplication*, which performs secure deduplication subject to the resource constraints of the enclave. Our insight is that the frequencies (i.e., numbers of duplicates) of chunks are highly skewed in practical backup workloads, such that *a small fraction of chunks can contribute to a large fraction of duplicates*. To justify, we conduct trace analysis on five real-world backup traces (see §6.1 for the trace details). We measure the *duplicate rate* for a subset of input chunks, defined as the ratio between the total size of duplicate chunks derived from the subset of chunks and the total size of duplicate chunks in the whole trace (note that a chunk is said to be a duplicate chunk if its identical copy has already been stored and it can be removed by deduplication). Figure 2 shows the duplicate rate versus the top-percentage of frequent chunks (ranked by their frequencies in descending order). For example, in the VM trace, the top-5% of frequent chunks contribute to a duplicate rate of around 97%. This implies that if we maintain a small fingerprint index to track the top-5% of frequent chunks, we can remove around 97% of duplicate data and achieve high storage savings.

The idea of frequency-based deduplication is to separate the deduplication process based on chunk frequencies. It manages a small fingerprint index inside the enclave to remove the duplicates from the most frequent chunks. It also maintains the full index outside the enclave to remove the remaining duplicates for the less frequent chunks. Frequency-based deduplication addresses both performance and security concerns. For performance, it only manages a small fingerprint index for the most frequent chunks inside the enclave to remove a large fraction of duplicate chunks. Thus, it mitigates the EPC paging overhead. It also reduces the context switching overhead as it only queries the full index outside the enclave via OCalls for a limited fraction of less frequent chunks. For security, since the most frequent chunks are more vulnerable to frequency analysis [48], we remove the duplicates of the most frequent chunks with in-enclave processing only. Thus, an adversary in the cloud cannot readily learn the frequencies of the most frequent chunks, and hence the information

Figure 3: Architecture of the enclave.

leakage caused by frequency analysis is limited.

Enclave architecture and design roadmap. Figure 3 depicts the architecture of the enclave in DEBE. Initially, the enclave is bootstrapped with a set of keys and establishes secure data channels with each client (§4.2). Then the enclave tracks the frequency of each plaintext chunk received from the data channel of a client (§4.3). Based on the chunk frequencies, frequency-based deduplication removes the duplicates of the most frequent plaintext chunks and interacts with the full index outside the enclave to remove the duplicates of the remaining less frequent plaintext chunks (§4.4). The enclave performs compression on the non-duplicate plaintext chunks and encrypts the compressed plaintext chunks. Finally, the enclave stores the ciphertext chunks in the storage pool (§4.5).

4.2 Key Management

The enclave maintains a set of keys for the secure storage of chunks after deduplication and compression as well as for secure communication with clients.

Data key and query key. The enclave maintains two long-term keys, which remain valid throughout the lifetime of the enclave (i.e., the whole duration when DEBE is running): (i) the *data key* for encrypting and decrypting the compressed non-duplicate plaintext chunks in secure storage, and (ii) the *query key* for protecting the information of plaintext chunks when querying the full index outside the enclave (§4.4). When the enclave is bootstrapped, it initializes both the data key and the query key via the on-chip hardware random number generator (i.e., `sgx_read_rand` [42]). Both keys can be periodically renewed via existing approaches (e.g., key regression [30]), without compromising deduplication as DEBE performs deduplication before encryption.

Session key. Recall that each client maintains a data channel with the enclave for secure data communication (while maintaining a control channel with the cloud for securely issuing storage operations) (§3.1). Each data channel protects its communication using a short-term *session key*, which remains valid for a single communication session. It establishes a session key for the data channel using Diffie-Hellman key exchange through the control channel. The session key is kept in the enclave during the communication session of the client, and will be freed after the session is completed (both the control and data channels will be released as well).

Per-client master key. The enclave requires each client to

submit a *master key* through the data channel for each storage request. It uses the master key to protect the file recipes for the client’s files and enforces the client’s ownership of the files. Similar to the session keys, the enclave only keeps the master key of the client for a single communication session and will destroy the master key at the end of the session, so the storage overhead for the master keys is also limited.

4.3 Frequency Tracking

The enclave needs to track the frequencies of plaintext chunks to identify the most frequent and less frequent chunks for frequency-based deduplication. To mitigate the EPC usage (§2.3), the enclave uses a *Count-Min Sketch (CM-Sketch)* [16] to track the *approximate* frequency of each chunk with fixed-size space and small errors.

The CM-Sketch is a two-dimensional array with r rows of w counters each. One key design here is to limit the computational overhead of mapping the plaintext chunks to the counters. To do so, our insight is that the chunk fingerprint is computed as a cryptographic hash (e.g., SHA-256 in our case), so we can treat the chunk fingerprint as a random input value and map it directly to a counter without compromising the accuracy of the CM-Sketch. Specifically, for each plaintext chunk M , the enclave partitions the fingerprint of M into r pieces. It takes the i -th piece modulo w to find one of the w counters, indexed from 0 to $w - 1$, in row i ($1 \leq i \leq r$) and increments each of the mapped counters by one; this is in contrast to the traditional CM-Sketch, which maps the input to the counters of different rows using pairwise independent hash functions [16] and hence has extra computational overhead. To estimate the frequency of a chunk, the enclave uses the minimum value of the r mapped counters of the chunk. By default, we configure $r = 4$, $w = 256$ K, and 4-byte counters, so the overall EPC usage of the CM-Sketch is only 4 MiB.

4.4 Frequency-based Deduplication

We present the design of frequency-based deduplication, which removes all duplicate plaintext chunks in two phases based on their estimated frequencies (§4.3).

First-phase deduplication. The enclave maintains a small fingerprint index, called the *top- k index*, to deduplicate the k most frequent plaintext chunks. We implement the top- k index as a combination of a min-heap and a hash table, as shown in Figure 4. The min-heap differentiates the top- k -frequent and less frequent plaintext chunks. It tracks top- k estimated frequencies of the plaintext chunks, such that the root heap entry corresponds to the plaintext chunk with the minimum frequency in the current top- k estimated frequencies. Each heap entry in the min-heap stores a pointer to a hash entry in the hash table. On the other hand, the hash table is used for duplicate detection, as in conventional deduplication. Each hash entry stores a mapping from the chunk fingerprint to a tuple of elements: (i) the pointer to the heap entry (i.e., both the heap entry and the hash entry reference each other), (ii)

Figure 4: Overview of the top- k index.

the estimated frequency of the chunk, (iii) the chunk address (including the container ID and the internal offset within the container; see §4.5), and (iv) the compressed chunk size (i.e., the size of the chunk after compression).

Given a plaintext chunk, to perform the first-phase deduplication, the enclave takes the estimated frequency of the plaintext chunk obtained from the CM-Sketch (§4.3) and the chunk fingerprint as inputs. It first checks against the root heap entry of the min-heap. If the input frequency is smaller than the minimum frequency of the min-heap (i.e., the chunk is a less frequent chunk), the enclave skips querying the hash table for the chunk and proceeds to the second-phase deduplication (see below); otherwise (i.e., the chunk is a top- k -frequent chunk), the enclave uses the input fingerprint to look up the hash table. We have the following two cases:

- If the fingerprint is found in the hash table (i.e., the chunk is a duplicate), the enclave updates the frequency in the hash table and adds both the chunk address and the compressed chunk size to the file recipe (§4.5). Since the frequency is updated, it also adjusts the min-heap based on the pointer to the heap entry in the min-heap.
- If the fingerprint is not found in the hash table (i.e., the chunk is a new top- k -frequent chunk), the enclave creates a new hash entry in the hash table and inserts a new heap entry containing the pointer to the new hash entry into the min-heap. If the min-heap has already stored k heap entries, the enclave deletes the current root heap entry of the min-heap (with the minimum frequency) and also deletes the corresponding hash entry in the hash table via the pointer stored in the root heap entry. Since the chunk may have already been stored (but not tracked by the top- k index as its frequency is low), the enclave also runs the second-phase deduplication on the chunk and updates the chunk address and the compressed chunk size according to the result of the second-phase deduplication.

We show that the top- k index has low space usage. Suppose that the chunk fingerprint has 32 bytes (a SHA-256 hash), the chunk address has 12 bytes (an 8-byte container ID and a 4-byte internal offset; see §4.5), and the compressed chunk size has 4 bytes. For each top- k -frequent chunk, the hash entry additionally stores a 4-byte frequency and a pointer to a heap entry. Since we implement the min-heap as an array, the pointer to a heap entry can be represented as a 4-byte integer array index. Also, the heap entry keeps an 8-byte pointer to a hash entry. Overall, each top- k -frequent chunk uses 64 bytes

in the top- k index (excluding the internal pointers of the hash table, which we now implement as an `unordered_map` of the C++ standard library). For example, to track 512 K most frequent chunks, the EPC usage of the top- k index is 32 MiB.

We further show that the top- k index has low time complexity. For each plaintext chunk, the top- k index can return the minimum frequency (from the root heap entry) in the current min-heap in constant time. For a top- k -frequent chunk, the top- k index needs to further check the hash table (in constant time) and update the min-heap. Since we store the pointer to the heap entry in the hash entry, we can directly update the corresponding heap entry when the frequency is changed, without searching the whole min-heap for its location. Thus, the time complexity of updating the min-heap is $\mathcal{O}(\log k)$.

Second-phase deduplication. The second-phase deduplication is performed on the plaintext chunks that are not removed by the first-phase deduplication, including the less frequent chunks and the fresh new top- k -frequent chunks whose fingerprints are new to the top- k index. DEBE manages a full index outside the enclave as the EPC size is limited (§2.3). We implement the full index as a hash table, in which each entry stores the mapping from the *encrypted fingerprint* of a plaintext chunk to the *encrypted chunk information* (i.e., the chunk address and the compressed chunk size, both of which are encrypted by the query key) of the corresponding ciphertext chunk. Our rationale of encrypting both the fingerprint and the chunk information is to prevent any adversary in the cloud from inferring the plaintext chunks, since the full index is not protected by the enclave.

Given a plaintext chunk, to perform the second-phase deduplication, the enclave *deterministically* encrypts the fingerprint of the plaintext chunk (not removed by the first-phase deduplication) with the query key (§4.2), so that duplicate plaintext chunks from different clients are always mapped to duplicate encrypted fingerprints for cross-user deduplication. It then queries the full index based on the encrypted fingerprint via an OCall. If the encrypted fingerprint is found in the full index, the OCall returns the encrypted chunk information that will be decrypted by the query key inside the enclave. Then the enclave will update the address and the compressed chunk size into the file recipe (§4.5). Otherwise, if the encrypted fingerprint is new to the full index, the enclave identifies this chunk as a non-duplicate chunk, assigns the chunk an address, compresses the chunk to obtain its compressed chunk size, and encrypts both the address and the compressed chunk size with the query key. It then updates the encrypted fingerprint and the corresponding encrypted chunk information in the full index. Note that the context switching overhead due to OCalls is limited, as a large fraction of duplicates are expected to have been removed by the first-phase deduplication.

Remarks. Traditional efficient indexing techniques for deduplication, such as similarity-based [9] and locality-based deduplication [52] approaches, can also address the limited EPC size by loading only a portion of the full index into the en-

clave. However, they only achieve *near-exact* deduplication (i.e., some duplicates cannot be removed), while DEBE can achieve exact deduplication (§3.3).

Note that the CM-Sketch may overestimate the chunk frequencies as multiple chunks can be mapped to the same counters (§4.3). Thus, the enclave may track some less frequent chunks in the top- k index. Nevertheless, it does not affect the storage savings from deduplication, as the full index still tracks all currently stored non-duplicate chunks.

4.5 Storage Management

Container storage. DEBE manages physical chunks in fixed-size *containers* to mitigate disk I/O costs [51]. The enclave performs compression on the non-duplicate plaintext chunks after deduplication, and encrypts the compressed non-duplicate plaintext chunks into ciphertext chunks with the data key. It writes each ciphertext chunk, together with an initialization vector (IV) (§5), into an in-memory container inside the enclave. When the in-memory container is full, the enclave emits it to persistent storage in the cloud. Note that DEBE only stores an IV (of size 16 bytes in AES-256) for each non-duplicate ciphertext chunk *after* deduplication, while DaE approaches store an encrypted key (of size 32 bytes in AES-256) for each ciphertext chunk *before* deduplication and incurs substantial key storage overhead when there exist many duplicate chunks (§2.1).

Also, the enclave creates and manages the file recipe for each uploaded file. Each entry in the file recipe keeps the chunk address and the compressed chunk size of each ciphertext chunk of the file. Note that when the enclave adds entries to the file recipe, it does not need to perform compression for the duplicate chunk to obtain its compressed chunk size, since the compressed chunk size has been stored in both the top- k index and the full index. To guarantee the ownership of the file, the enclave encrypts the file recipe by the client's master key and stores the encrypted file recipe as a regular file. Since the enclave treats containers (each of which contains multiple ciphertext chunks) as the basic I/O units and the chunk size is stored in the file recipe (protected by the per-user master key), DEBE preserves the security of compression as it avoids leaking the lengths of compressed chunks [13].

Downloads. To download a file, the client issues a download request and its master key to the enclave through the secure data channel. The enclave retrieves the file recipe and decrypts the file recipe with the given master key. It then parses the decrypted file recipe to obtain the chunk addresses and compressed chunk sizes. To restore all chunks, the enclave exposes the container IDs of the requested chunks to the cloud to perform I/Os via OCalls. Once the cloud fetches the corresponding containers into the unprotected main memory, the enclave accesses the ciphertext chunks based on their internal offsets and decrypts the ciphertext chunks by the data key. Finally, it decompresses and sends the plaintext chunks to the client through the data channel.

4.6 Security Discussion

We discuss the security of DEBE in response to our threat model (§3.2). We focus on two cases.

Case 1: A snapshot adversary gains one-time access to contents in unprotected memory and storage pool. DEBE enforces end-to-end encryption for the plaintext chunks between each client and the enclave, and provides *semantic security* [33] for the ciphertext chunks stored in the cloud. Specifically, it sets up a secure data channel that encrypts all plaintext chunks exchanged between a client and the enclave by a session key. It performs deduplication inside the enclave (that is oblivious to the adversary), and encrypts the non-duplicate plaintext chunks into ciphertext chunks by the data key before the ciphertext chunks are stored. Note that both data-in-transit and data-at-rest encryption operations are based on traditional symmetric encryption, and semantic security is achieved.

Case 2: A persistent adversary eavesdrops on OCalls in deduplication. DEBE encrypts both chunk fingerprints and chunk information by the query key inside the enclave before it includes them as the inputs of OCalls for accessing the full index outside the enclave. Thus, even though an adversary can eavesdrop on the OCalls, it cannot infer the original inputs from the OCalls.

One potential information leakage is that a persistent adversary (that stays in the cloud for a long time) can learn the chunk frequencies in the deduplication process, as the enclave maps duplicate plaintext chunks into duplicate encrypted fingerprints when querying the full index. Specifically, the adversary can track the frequency distribution of encrypted fingerprints by monitoring the OCalls, and launch frequency analysis to infer the plaintext chunks. However, DEBE limits such information leakage to the less frequent chunks, which are relatively robust against frequency analysis [48] (for comparisons, DaE leaks the frequencies of *all* chunks since it is deterministic by nature; see §2.1). Our evaluation shows that DEBE mitigates information leakage more effectively than TED [49], a state-of-the-art approach that trades storage savings for security (see our technical report [81]).

Remarks. A powerful adversary may launch frequency-based side-channel attacks by simultaneously compromising a client and the cloud. If it proactively lets the compromised client upload artificial chunks to the cloud and monitors OCalls in the cloud, the adversary could infer chunk frequencies and even identify the most frequent chunks among the clients. While the practical damage caused by such side-channel attacks remains an open question, we can obfuscate the chunk frequency information by perturbing the OCalls patterns (e.g., adding dummy OCalls), at the expense of incurring extra performance overhead.

5 Implementation

We have implemented a prototype of DEBE in C++ on Linux based on Intel SGX SDK Linux 2.7 [42]. It uses OpenSSL-

1.1.1 [65] and Intel SGX SSL [43] for cryptographic operations. Our current prototype contains 17.5 K LoC.

Each client implements FastCDC [80] to realize content-defined chunking, where the minimum, average, and maximum chunk sizes are configured at 4 KiB, 8 KiB, and 16 KiB, respectively. The container size is 4 MiB. We implement Diffie-Hellman key exchange based on NIST P-256 elliptic curve for session key management of the data channel between the client and the enclave. The enclave computes the fingerprints of plaintext chunks via SHA-256 and encrypts each unique plaintext chunk via AES-256 in GCM mode with a random 16-byte IV. Also, it encrypts the fingerprint of each plaintext chunk via AES-256 in CMC mode with a 16-byte zero IV to support queries over encrypted fingerprints (as in CryptDB [68]). Both SHA-256 and AES-256 are configured to use (via OpenSSL EVP API) the Intel New Instructions Set for hardware-accelerated operations [39, 40]. We also implement LZ4 [15] for lossless stream-based compression in the enclave for chunk compression after deduplication.

To mitigate context switching overhead of the enclave, DEBE transmits and processes chunks on a per-batch basis (the default batch size is 128 chunks). Also, to speed up downloads, the cloud keeps an in-memory least-recently-used cache (256 MiB by default) to hold the recently accessed containers. For each container access request issued by the enclave (§4.5), the cloud first checks the cache and retrieves the containers from local storage only if they are not in cache. **Limitations.** DEBE currently does not address crash consistency. We now discuss how to extend DEBE with crash consistency, and pose the implementation as future work.

When a system crash occurs, DEBE would lose its in-enclave contents (i.e., the query key, the data key, the CM-Sketch, the top-*k* index, and the in-memory container pending to be persisted into the storage pool). We can extend DEBE to recover the query and data keys, the CM-Sketch, and the top-*k* index via *sealing*, an SGX feature that encrypts in-enclave content for secure out-enclave storage on disk [41]. When the enclave is bootstrapped (§3.1), DEBE stores a persistent copy of both the query key and data key by sealing. Also, it makes periodic snapshots of the CM-Sketch and top-*k* index by sealing. To restore the enclave states from a system crash, the cloud re-initializes the enclave by unsealing the keys and snapshots back to the enclave.

To realize crash consistency, we can augment DEBE with write-ahead logging [61] to record updates in on-disk logs before updating the in-memory CM-Sketch and top-*k* index. To recover from the data loss of the in-memory container, the enclave can log the IDs of the persisted containers for the currently uploaded file in on-disk logs. If a system crash occurs during the current upload, DEBE can roll back to the state before the upload starts based on the logs. It finally notifies the client to re-upload the file. Note that logging the changes into on-disk logs would incur extra OCalls. To mitigate the context switching overhead of logging, we can

batch multiple logging operations in a single OCall.

We can initialize a new CM-Sketch and a new top- k index after enclave recovery. This would not affect the storage savings from deduplication, provided that the full index is crash-consistent (e.g., via its implementation in a persistent key-value store) and tracks all currently stored non-duplicate chunks. However, DEBE incurs extra performance overhead, as it cannot learn frequent chunks and hence incurs more OCalls to build the top- k index from scratch.

6 Evaluation

We deploy DEBE in a local cluster of 11 machines connected with 10 GbE. Each machine has a quad-core 3.4 GHz Intel Core i5-7500 CPU and 32 GiB RAM, and is installed with Ubuntu 16.04. We deploy one or multiple clients, a key server (for DaE only), or a cloud storage backend on distinct machines. The machine for the cloud storage backend is attached with a TOSHIBA DT01ACA 1 TiB 7200 rpm SATA hard disk. By default, DEBE sets $k=512$ K for the top- k index and configures the CM-Sketch with $r=4$ and $w=256$ K, so as to keep the overall EPC usage within 64 MiB to limit the paging overhead in SGX. Note that we can tune the parameters based on the available EPC size.

We evaluate DEBE using both synthetic and real-world datasets. We summarize our evaluation results as follows.

- DEBE accelerates the uploads of non-duplicate and duplicate data of state-of-the-art DaE approaches by up to $10.09\times$ and $13.08\times$, respectively (Exp#1). Its frequency-based deduplication only takes 5.8-18.4% of the overall upload time (Exp#2). It preserves high performance for multi-client uploads/downloads (Exp#3) and various synthetic workloads (Exp#4).
- For real-world workloads, DEBE achieves 1.17 - $2.76\times$ speedups over state-of-the-art deduplication alternatives (Exp#5), and preserves high performance in long-term uploads and downloads (Exp#6).

In our technical report [81], we present additional evaluation results and show that DEBE achieves high storage savings and preserves security against frequency analysis.

6.1 Datasets

Synthetic datasets. We consider two synthetic datasets for our evaluation. The first dataset, namely *SYN-Unique*, includes non-duplicate and individually compressible chunks. Specifically, we generate SYN-Unique as a set of 2 GiB compressible files via the LZ data generator [38], which generates synthetic data based on SDGen [34]. The LZ data generator takes two parameters as inputs: (i) a compression ratio, which specifies the compressibility of the generated data, and (ii) a random seed for data generation. We configure the compression ratio as 2 to resemble real-world backup workloads [77], and vary the random seeds to generate distinct synthetic files. We perform chunking on each synthetic file

to ensure that its chunks are globally unique over all files. We use the dataset for stress-testing different schemes with non-duplicate chunks.

The second dataset, namely *SYN-Freq*, includes the original chunks (before deduplication) following a target frequency distribution. We build a synthetic file generator that generates files whose chunk frequencies follow a Zipf distribution as shown by prior work [83, 84]. Our generator takes three parameters as inputs: (i) the number of original chunks, (ii) the deduplication ratio (i.e., the ratio between the original data size and the non-duplicate data size), and (iii) the Zipfian constant (a larger constant implies higher skewness). To generate a synthetic file, we prepare a set of non-duplicate 48-bit fingerprints based on the expected number of non-duplicate chunks (i.e., the number of original chunks divided by the deduplication ratio). We assign each fingerprint with a compression ratio based on the normal distribution with a mean of 2 and a variance of 0.25 [46, 77]. To generate each original chunk, we sample its fingerprint from the fingerprint set based on the target Zipf distribution, and construct its content using the LZ data generator [38] with the compression ratio and fingerprint (as the random seed) as inputs. Finally, we generate the SYN-Freq dataset as a set of synthetic files, each of which contains 13,107,200 8-KiB original chunks (i.e., 100 GiB) and a deduplication ratio of $5\times$. The number of non-duplicate chunks is large enough that only a subset of non-duplicate chunks can be tracked by the top- k index.

Real-world datasets. We consider five real-world datasets of backup workloads, which are also used in previous studies for trace-driven evaluation [49, 50, 69, 70, 80, 86]:

- *DOCKER*: docker snapshots (from v4.1.0 to v7.0.0) of Couchbase [17] from Docker Hub [22];
- *LINUX*: snapshots (from stable versions between v2.6.13 and v5.9) of Linux source code [54], in which each snapshot is stored in the *mtar* format [53];
- *FSL*: home directory snapshots [29], among which we select 42 snapshots from nine users in 2013;
- *MS*: Windows file system snapshots [59], among which we select 30 snapshots of size around 100 GiB each; and
- *VM*: virtual machine snapshots [50] collected by ourself.

Table 1 shows the statistics of the five real-world datasets. Previous studies have shown that multi-tenant deduplication can achieve higher storage savings than single-tenant deduplication in FSL, MS, and VM [50, 59, 75]. Given the limited available disk space in our testbed, we sample a subset of snapshots from the original datasets [29, 59] for FSL and MS as in [49]. As FSL, MS, and VM only contain fingerprints, we generate compressible chunk contents as in SYN-Freq.

6.2 Evaluation on Synthetic Data

To examine the maximum achievable performance without disk I/O overhead, we load the synthetic files into each client's memory before each test and let the cloud store all post-

Dataset	Raw size	Snapshots	Dedup Ratio	Compress Ratio
DOCKER	70.2 GiB	94	4.2	1.7
LINUX	44.6 GiB	82	2.8	2.3
VM	3.0 TiB	660	33.4	2.0
FSL	3.0 TiB	42	8.2	2.0
MS	3.9 TiB	30	4.1	2.0

Table 1: Characteristics of real-world datasets.

deduplicated data in memory (we include the disk I/O overhead in the evaluation in §6.3). We report the average results over five runs and include the 95% confidence intervals based on student’s t-distribution (except for line graphs).

Exp#1 (Overall performance). We evaluate the upload (download) performance of overall systems. We consider a single client that successively uploads the same 2 GiB file from SYN-Unique *twice*. The client then downloads the same file. We measure the upload (download) speed of each operation. Our goal is to examine the maximum achievable performance of all schemes for storing all non-duplicate data and all duplicate data. Note that the file size is small here, such that all fingerprints can be tracked in the top- k index in DEBE (we consider large-scale datasets in §6.3).

We compare DEBE with three DaE approaches: (i) *DupLESS* [7], which implements server-aided key management based on OPRF (§2.1); (ii) *TED* [49], which generates the key of each chunk based on lightweight hash computations in the key server; and (iii) *CE* [23], the convergent encryption scheme (§2.1). To study the security overhead of DEBE, we include plain deduplication (*Plain*), in which the client uploads the plaintext chunks to the cloud for deduplication and compression through a communication channel protected by SSL/TLS. Unlike DEBE and Plain, the DaE schemes (i.e., DupLESS, TED, and CE) do not realize compression due to incompatibility (§2.1). For fair comparisons, we re-implement all baselines based on their original papers under the same implementation setting (§5) in C++.

Figure 5(a) shows the upload speeds. DEBE outperforms all DaE schemes. When uploading non-duplicate data, DEBE achieves 10.09 \times , 1.42 \times , and 1.25 \times speedups over DupLESS, TED, and CE, respectively, by avoiding the generation of chunk-based keys (note that DupLESS has very low upload speeds due to the expensive OPRF operations). Even though DEBE applies compression, its compression overhead is masked by the performance gain over the key generation overhead of DaE. When uploading duplicate data, DEBE becomes more efficient. Its speedups increase to 13.08 \times , 1.88 \times , and 1.65 \times over DupLESS, TED, and CE, respectively, since it avoids performing encryption and compression on the duplicate chunks. Compared with plain deduplication, DEBE only incurs 21.6% and 7.4% performance overhead for the uploads of non-duplicate and duplicate data, respectively.

Figure 5(b) shows the download speeds. All DaE schemes follow the same download paradigm, in which the client retrieves both ciphertext chunks and encrypted chunk-based keys from the cloud, decrypts each key and the corresponding

Figure 5: (Exp#1) Overall performance.

Steps	1st upload	2nd upload
Chunking	0.61 \pm 0.01 ms	
Transmission Protection	0.37 \pm 0.01 ms	
Fingerprinting	2.27 \pm 0.04 ms	
Frequency tracking	0.06 \pm 0.01 ms	
First-phase dedup	0.10 \pm 0.01 ms	0.14 \pm 0.01 ms
Second-phase dedup	0.80 \pm 0.02 ms	-
Compression	0.67 \pm 0.01 ms	-
Encryption	0.33 \pm 0.01 ms	-

Table 2: (Exp#2) Breakdown of computational time per processing 1 MiB data in two successive uploads.

chunk, and reconstructs the original file. Compared with DaE, DEBE incurs 8.5% download speed drop due to the OCalls for moving chunks into the enclave for decryption and decompression (§4.5). Also, DEBE and DaE have 17.7% and 10.1% download speed drops compared with Plain, respectively, since they perform decryption on retrieved chunks.

Exp#2 (Upload breakdown). We study the breakdown of the upload performance. We consider the same scenario as Exp#1 (i.e., a client successively uploads the same 2 GiB file from SYN-Unique twice) and measure the computational time of the client and the enclave in different steps in uploads: (i) *chunking*, in which the client partitions the input file into plaintext chunks; (ii) *transmission protection*, in which the enclave exchanges a session key with the client and decrypts received ciphertext chunks; (iii) *fingerprinting*, in which the enclave computes the fingerprint of each plaintext chunk; (iv) *frequency tracking*, in which the enclave estimates the frequency of each plaintext chunk via the CM-Sketch; (v) *first-phase deduplication*, in which the enclave removes duplicate plaintext chunks via the top- k index; (vi) *second-phase deduplication*, in which the enclave queries the full index via OCalls to remove remaining duplicates; (vii) *compression*, in which the enclave compresses the non-duplicate chunks; and (viii) *encryption*, in which the enclave encrypts the compressed chunks with the data key.

Table 2 shows the results (measured by the computational time per 1 MiB of uploads). In the first upload (i.e., uploading non-duplicate data), fingerprinting is the most time-consuming step since it performs expensive computations on all chunks. On the other hand, frequency-based deduplication (including frequency tracking plus first-phase and second-phase deduplication) takes only 18.4% of the overall time. Note that since the storage is empty before the upload, each non-duplicate chunk is treated as a frequent chunk and examined by both the first-phase and second-phase deduplication.

Figure 6: (Exp#3) Multi-client uploads and downloads. **Figure 7:** (Exp#4) Impact of frequency distribution.

In the second upload (i.e., uploading duplicate data), all duplicate chunks are removed by the first-phase deduplication and hence the second-phase deduplication is skipped. In this case, frequency-based deduplication takes only 5.8% of the overall upload time.

Exp#3 (Multi-client uploads and downloads). We evaluate DEBE when multiple clients issue upload/download requests concurrently. In addition to the cloud, we deploy 10 machines, with two client instances each, so as to simulate the concurrent uploads/downloads by up to 20 clients. Each client uploads a 2 GiB synthetic file from SYN-Unique to the cloud, and then downloads the same 2 GiB file. We measure the *aggregate* upload (download) speed as the ratio of the total uploaded (downloaded) data size to the total time all clients complete the uploads (downloads).

Figure 6 shows the results versus the number of clients. The aggregate upload speed first increases with the number of clients and reaches 791.1 MiB/s for 10 clients, followed by dropping to 755.8 MiB/s for 20 clients due to the resource contention in the enclave. The aggregate download speed has a similar trend, and first increases to 870.0 MiB/s and finally drops to 835.7 MiB/s.

Exp#4 (Impact of frequency distribution). We evaluate DEBE on processing the chunks from different frequency distributions. We configure a single client to upload each original chunk of SYN-Freq without chunking, and measure the *computational speed* of the enclave (i.e., including the steps of Table 2 except chunking).

Figure 7 shows the results for different k in the top- k index versus the Zipfian constant. A larger k implies lower performance for all Zipfian constants, since SGX incurs significant paging overhead when the size of enclave contents is greater than 64 MiB [45]. For example, when the Zipfian constant is 0.8, the computational speeds for $k = 512$ K and $k = 1$ M are 282.5 MiB/s and 147.3 MiB/s, respectively. In addition, the computational speed of the enclave increases in more skewed distribution (i.e., a larger Zipfian constant), since the most frequent chunks contribute more duplicates. This mitigates the OCall overhead of querying the full index.

6.3 Evaluation on Real-world Traces

Exp#5 (Performance of deduplication approaches). DEBE’s key design is frequency-based deduplication, and we compare it with other design alternatives. We consider two state-of-the-art memory-efficient deduplication approaches,

namely *similarity-based deduplication* [9] and *locality-based deduplication* [52]. Both approaches store a small in-enclave fingerprint index based on the *feature* of each segment of chunks and perform deduplication by loading a portion of the full index (outside the enclave) into the enclave based on the matched feature. Similarity-based deduplication derives the feature based on the minimum chunk fingerprint of each segment of chunks, while locality-based deduplication generates it by sampling a few fingerprints. As in [9, 52], we choose the segment size as 10 MiB, and the sampling rate of locality-based deduplication as 1/64. While both approaches aim to mitigate disk I/O in plain deduplication, our idea is that they can also be applied to reduce EPC usage, but can only support near-exact deduplication (§4.4).

In addition to the above near-exact deduplication approaches, we include the naïve but exact deduplication baselines for comparisons. Specifically, *in-enclave deduplication* attempts to manage the full index in the enclave; when the full index increases in size and cannot fit into the EPC, it triggers page swapping to evict unused EPC pages to memory. *Out-enclave deduplication* manages the full index in memory, and detects duplicates by issuing OCalls to the full index. For fair comparisons, we include compression over non-duplicate chunks into all baseline approaches. We upload the snapshots of each real-world backup dataset (§6.1) in the order of their creation times. We measure the computational speed of the enclave as in Exp#4.

Figure 8 shows the results. DEBE generally outperforms all approaches. For example, in FSL, it achieves 1.17 \times , 1.20 \times , 1.25 \times , and 2.76 \times average speedups over the similarity-based, locality-based, out-enclave, and in-enclave approaches, respectively. The reason is that DEBE avoids the extra computational overhead of compressing and encrypting some duplicate chunks in both similarity-based and locality-based approaches (which perform near-exact deduplication). Also, it performs the first-phase deduplication and filters out many queries to the full index, thereby mitigating the OCall overhead of the out-enclave deduplication. Although in-enclave deduplication outperforms DEBE when the workload size is small (e.g., the first few snapshots in DOCKER and LINUX), its performance drops dramatically in subsequent snapshots due to expensive paging overhead. DEBE manages lightweight data structures (a CM-Sketch and the small top- k index) in the enclave and mitigates the paging overhead.

Exp#6 (Trace-driven upload and download). Unlike in Exp#1, we evaluate the upload and download performance of DEBE based on real-world data. We enable cloud-side disk I/O, upload all snapshots of each dataset, and finally let the client download them on disk. Here, we only compare DEBE with CE, which is the fastest DaE approach. Since FSL, VM, and MS only include the compressible chunks (§6.1), we let the client machine directly upload chunks without chunking.

Figure 9 shows the speeds for uploading and downloading each snapshot in DEBE and CE. The upload speed of

Figure 8: (Exp#5) Performance comparison of different deduplication approaches.

Figure 9: (Exp#6) Trace-driven upload and download performance.

DEBE gradually increases in subsequent snapshots, which include more duplicate plaintext chunks, so DEBE does not need to perform compression and encryption on the duplicate plaintext chunks (removed by deduplication). In contrast, CE is consistently slower than DEBE in uploads, as it performs key generation and encryption for all duplicate plaintext chunks. For example, in FSL, the upload speed of DEBE is 246.5 MiB/s for the first snapshot, and reaches 277.5 MiB/s for the last snapshot. In contrast, the upload speed of CE is 163.5-179.1 MiB/s across all snapshots.

The download speeds of both DEBE and CE are almost the same, since they are throttled by disk I/O. Also, their download speeds decrease across snapshots due to chunk fragmentation [51] (i.e., the chunks of subsequent snapshots become scattered after deduplication), which increases I/O overhead. For example, the download speed of DEBE in FSL is 131.4 MiB/s for the first snapshot, and drops to 95.1 MiB/s for the last snapshot (the download speed of CE is almost the same). Chunk fragmentation can be mitigated via existing approaches [11, 12, 31, 51, 86] and we pose the integration of such approaches into DEBE as future work.

7 Related Work

DaE approaches. Several approaches realize secure deduplication via DaE. In addition to those described in §2.1, some approaches are designed from the security perspectives. Random MLE [1] and iMLE [6] apply non-deterministic encryption to prevent frequency leakage, but they use expensive primitives (e.g., non-interactive zero-knowledge proofs [1], fully homomorphic encryption [6]) that are not ready to be implemented. Liu *et al.* [55] propose to share keys via a decentralized agreement protocol without relying on a dedicated key server, but it introduces expensive performance overhead of interactions among different clients. TED [49] mitigates frequency leakage with a configurable storage blowup. In contrast, DEBE realizes DbE to address both key management overhead and security issues simultaneously.

SGX meets secure deduplication. SGX has been used in secure deduplication. Dang *et al.* [20] employ SGX as a trusted proxy to save network bandwidth for secure deduplication. SPEED [19] performs deduplication for computations inside the enclave to improve resource utilization. You *et al.* [82] leverage SGX to verify the ownership of deduplicated data for secure deduplication. SeGShare [32] builds on a server-side enclave for file-based deduplication, but does not consider fingerprint indexing for chunk-based deduplication. S2Dedup [60] uses a server-side enclave to eliminate a trusted key server for key generation, and it performs deduplication outside the enclave via re-encrypting chunks; in contrast, DEBE directly performs deduplication inside the enclave to protect plaintext chunks. SGXDedup [70] leverages SGX to improve the performance of client-side secure deduplication under DaE. Note that the above SGX-based deduplication approaches are still based on DaE.

8 Conclusion

DEBE realizes an unexplored paradigm, deduplication-before-encryption (DbE), for secure deduplicated storage. It builds on SGX and applies frequency-based deduplication to manage a small fingerprint index for most frequent chunks in the enclave. We show that DEBE outperforms conventional deduplication-after-encryption (DaE) approaches in performance, storage savings, and security.

A Artifact Appendix

Abstract

Our artifact consists of the prototypes of DEBE and all baseline approaches, a trace analysis tool for frequency leakage measurement, and the scripts to run all our experiments in §6. The DEBE prototype is a shielded DbE-based deduplicated storage system that supports secure deduplication via Intel SGX. It supports upload/download operations to allow multiple clients to securely outsource their data storage to the cloud. It applies frequency-based deduplication and implements the designs described in §4.

Scope

Our artifact can be used to validate our main claim that DEBE outperforms conventional DaE approaches in performance, storage efficiency, and security. Specifically, our artifact can be used to validate the results shown in the figures and tables

in §6 to support our main claim. In addition, our artifact can be used to run the workloads independent of our evaluation in §6.

Contents

The artifact comprises the following sub-directories:

- `./Prototype`, which includes the implementation of the DEBE prototype.
- `./Baseline`, which includes the implementation of all baseline approaches (e.g., DupLESS, TED, CE, and Plain) used in Exp#1 and Exp#6.
- `./Sim`, which includes a trace analysis tool to measure frequency leakage of CE, TED, and DEBE (see Exp#9 in our technical report [81]).

Also, each sub-directory has a separate README file to introduce the build instructions and usage.

Hosting

Our artifact is available on GitHub. Users can obtain the artifact from the repository <https://github.com/yzr95924/DEBE>. The version we provided for the artifact evaluation is marked with the `atc22ae` tag. We encourage the users to use the latest version of the repository, since it may include bug fixes. We also release the traces used in §6. The README file (<https://github.com/yzr95924/DEBE/blob/master/README.md>) describes the detailed instructions to collect the traces.

Requirements

We developed and evaluated our artifact on a local cluster of 11 machines connected with 10 GbE. Each machine has a quad-core 3.4 GHz Intel Core i5-7500 CPU and 32 GiB RAM running Ubuntu 16.04. We implement DEBE based on Intel SGX SDK Linux 2.7 [42], OpenSSL 1.1.1 [65], and Intel SGX SSL 1.1.1 [43]. The DEBE prototype is written in C++ and compiled by Clang 3.8.0. To validate the basic upload/download operations of DEBE, users need to prepare at least two machines, one of which needs to support Intel SGX to run as the cloud. We recommend users to check the SGX-supported device in <https://github.com/ayeks/SGX-hardware>.

Note that if the user's OS version is higher than Ubuntu 16.04 LTS (e.g., Ubuntu 20.04 LTS), it might not be able to install the packages with the same versions as in our paper. Nevertheless, we expect that the impact of using the packages with newer versions would be limited and our prototype can still run correctly.

Workflow

To reproduce the experiments in §6, users can refer to `./Prototype/ae_instruction.md` for the detailed instructions.

RunD: A Lightweight Secure Container Runtime for High-density Deployment and High-concurrency Startup in Serverless Computing

Abstract

The secure container that hosts a single container in a micro virtual machine (VM) is now used in serverless computing, as the containers are isolated through the microVMs. There are high demands on the high-density container deployment and high-concurrency container startup to improve both the resource utilization and user experience, as user functions are fine-grained in serverless platforms. Our investigation shows that the entire software stacks, containing the cgroups in the host operating system, the guest operating system, and the container *rootfs* for the function workload, together result in low deployment density and slow startup performance at high-concurrency. We propose and implement a lightweight secure container runtime, named **RunD**, to resolve the above problems through a holistic guest-to-host solution. With RunD, over 200 secure containers can be started in a second, and over 2,500 secure containers can be deployed on a node with 384GB of memory. RunD is adopted as Alibaba serverless container runtime to support high-density deployment and high-concurrency startup.

1 Introduction

With serverless computing (Function-as-a-Service), tenants submit functions directly to the Cloud without renting virtual machines, and the cloud provider uses containers to host invocations on-demand [26, 31, 35, 48, 48, 56]. Most cloud providers publish the serverless computing services with the pay-for-use pricing model, such as Amazon Lambda [4], Google Cloud Function [11], Microsoft Azure Functions [13], and Alibaba Function Compute [2].

When hosting function invocations, traditional containers (e.g., Docker, LXC) only provide process level isolation [22, 38], as they are implemented based on *Namespace* and *Cgroup*. They cannot prevent privilege escalation, information disclosure side channels, and covert channel communication [20]. To this end, secure containers that achieve the same isolation with the traditional virtual machines are

Figure 1: The state-of-the-art secure container model, and several bottlenecks in the architecture stacks.

often preferred. MicroVM is for isolation, and the container is for abstraction [30]. Secure container often creates a normal container within the lightweight microVM as shown in Figure 1(a). In such way users can build serverless services based on existing container infrastructure and ecosystem. It ensures compatibility with the container runtime in the MicroVM. Kata Containers [19] and FireCracker [20] provide practical experience in implementing such secure containers.

Figure 1(b) shows the architecture hierarchy of a secure container. In general, the guest operating system (GuestOS) in the microVM and resource scheduling on the host are off-loaded to the cloud provider. The *rootfs* is a filesystem and acts as the execution environment of user code. It is created by the host and passed to the container runtime in the microVM. On the host side, cgroups are used to allocate resources to secure containers, and the CPU scheduler manages the resource allocation. The complex hierarchy of secure containers brings extra overhead.

The lightweight and short-term features of functions make high-density container deployment and high-concurrency container startup essential for serverless computing. For instance, 47% of Lambdas run with the minimum memory specification of 128MB [5] in AWS, about 90% of the applications never consume more than 400MB in Microsoft Azure [49]. Since a physical node often has large memory space (e.g., 384GB), it should be able to host many func-

tions. Meanwhile, a large number of function invocations may arrive in a short time. However, the overhead of secure containers significantly reduces the deployment density of functions, and the concurrency of starting containers.

Our investigation identifies two key factors in secure containers that result in low concurrent startup. First of all, *rootfs* either results in unacceptable long latency for writable device provisioning or high CPU overhead under considerable I/O stress, when many containers are started concurrently. Secondly, concurrently starting multiple containers brings a large number of cgroups operations on the host side. However, the cgroup-related operations are serialized in the operating systems. The serialization is due to several mutex locks introduced in the kernel to handle a complex hierarchy of cgroup subsystems. The serial operations slow down cgroups creation for microVMs.

Meanwhile, secure containers amplify the resource overhead of each function, multiply host-side resource consumption with more microVMs, and lower the deployment density. Firstly, for microVMs, the standard Linux kernel is heavyweight for a small-sized memory specification. Secondly, the mainstream block-based solution for container *rootfs* in microVM generates the same page cache in both host and guest, resulting in a duplicated memory overhead. Lastly, CFS (Completely Fair Scheduler) in the host operating system traverses all the cgroups (containers) for balancing the processes, resulting in a significant scheduling overhead at high-density deployment.

We propose and implement a lightweight secure container runtime, named **RunD**, to resolve the above problems through a holistic guest-to-host solution. According to our evaluation, RunD boots to application code in *88ms*, and can launch 200 secure containers per second on a node. On a node with 384GB memory, over 2,500 secure containers can be deployed with RunD.

The main contributions of this paper are as follows.

1. **Bottlenecks identification in high-density deployment and high-concurrency startup of secure containers in serverless.** We analyze the shortcomings and bottlenecks through a holistic guest-to-host solution, in terms of container *rootfs* storage, the microVM memory footprint, and the overhead of cgroups.
2. **A guest-to-host solution to secure containers for high-density and high-concurrency targets in serverless.** The practice including: 1) a better container *rootfs* implementation based on read/write splitting for serverless; 2) the method to condense the guest kernel and improve kernel sharing by a pre-patched kernel image; 3) the host-side lightweight cgroup design and the rename-based cgroup pool management.
3. **A lightweight serverless runtime RunD for serverless architecture.** We design and open-source RunD based on Kata-runtime, and it shows much higher de-

Figure 2: Two practices of the secure container model.

ployment density and startup concurrency compared with the state-of-the-arts.

RunD is adopted as Alibaba serverless container runtime serving more than 1 million functions and almost 4 billion invocations daily. The online statistics demonstrate that RunD enables the maximum deployment density of over 2,000 containers per node and supports booting at most 200 containers concurrently with a quick end-to-end response.

2 Background

In this section, we will discuss the current secure container design, and concerning problems motivating this work.

2.1 Secure Container Models

Based on different levels of security/isolation requirements, there are generally two categories of secure containers in the production environments.

Figure 2(a) shows the *multi-container-per-VM* secure container model that only isolates functions. In the model, a virtual machine (VM) hosts the containers for the invocations of the same function. The containers in the same VM share the guest operating system of the VM. In this case, the invocations to different functions are isolated, but the invocations to the same function are not isolated. Since the number of required containers for each function varies, this model results in memory fragmentations [34]. Though the memory fragmentations can be reclaimed at runtime, it may significantly affect the function performance, and even crash the VM when the memory hot-unplug fails.

Figure 2(b) shows the *single-container-per-VM* secure container model that isolates each function invocation. Current serverless computing providers [1, 20] mainly use this secure container model. In this model, each invocation is served with a container in a microVM. This model does not introduce memory fragmentations, but the microVMs themselves show heavy memory overhead. It is obvious that each microVM needs to run its exclusive guest operating system, multiplying the memory footprints.

The secure container depends on the security model of hardware virtualization and VMM, explicitly treating the guest kernel as untrusted through syscall inspections. With the prerequisite of isolation and security, this work targets the *single-container-per-VM* secure container model.

2.2 Problems with Secure Containers

In production serverless platforms, achieving high container startup concurrency, and high container deployment density are the two key requirements [20]. With the *single-container-per-VM* secure container model, there are problems in achieving the two purposes.

Requirement on high-concurrency container startup.

In serverless platforms, each function invocation is short, and a large number of function invocations may arrive in a short time. For example, in Alibaba serverless platform, more than 200 container-launch requests arrive nearly simultaneously on a node. The latency until all containers have entered *main()* can swell super-proportionally due to resource contention among the simultaneously launching VMs. Meanwhile, emerging internet services often show a diurnal load pattern and have bursty loads [18]. A large number of containers are required to be created when the load bursts. Some techniques, such as prewarming containers [31, 42, 49], are able to alleviate container cold startups.

However, bursty loads are inevitable can easily exhaust the limited prewarmed containers. The ability to startup containers at high-concurrency is crucial for serverless platforms.

Requirement on high-density container deployment.

The small container specification in a serverless computing platform brings the requirement to deploy containers densely on a node. For instance, 47% of lambda functions run with the minimum memory specification of 128MB in AWS [5]. The actual memory usage of a container may also be smaller than its specifications. As Azure reports [49], about 90% of the applications never consume more than 400MB of memory. A node with 256GB of memory can host $8 \times 256 = 2048$ containers if there is no other overhead. In Alibaba serverless platform, over 2,500 secure containers that 128MB-sized can be deployed on a node with 384GB memory.

Without proactive customizations, secure containers incur extra memory overhead, reducing deployment density in serverless computing. Increasing deployment density greatly improves resource utilization and multi-tenant serving efficiency with the same infrastructure.

3 Problem Analysis and Insights

In this section, we analyze the problems of achieving high-concurrency startup and high-density deployment with secure containers. We use Kata container [19] as the representative secure container to perform the following studies.

Figure 3: The steps of starting up multiple Kata containers concurrently. The concurrency bottleneck results from creating *rootfs* (step ① in red block) and creating *cgrouops* (step ③ in red flowline). The density bottlenecks result from the memory footprint of the microVM (step ② in blue block) and the scheduling of massive *cgrouops* (step ③ in blue block).

Figure 3 shows the steps of starting Kata containers. First, *containerd* concurrently creates the container runtime *Kata-runtime* and prepares *runc*-container *rootfs*. Second, the hypervisor loads the GuestOS and the prepared *rootfs* to launch a *runc*-container in the microVM. Third, the function workload is downloaded into the container and may start to run.

Comparing with starting traditional containers [53], we have two observations when starting up secure containers.

- When starting 100 or more Kata containers concurrently, there is a distinct performance degradation of creating *rootfs* and *cgrouops*, during the *Kata-runtime* preparation. The degradation results in the low concurrency of starting containers.
- When deploying more than 1,000 Kata containers with 128MB memory specification on a single node with 384GB memory and 104 cores, the microVMs' memory footprint (due to the guest kernel and *rootfs*) already occupies most of the memory space. Meanwhile, the containers' I/O performance is also seriously degraded.

Figure 3 also shows three bottlenecks we found that result in the above two observations. In general, the inefficiency of creating *rootfs* and *cgrouops* results in low container startup concurrency. The high memory footprint and scheduling overhead result in low container deployment density. We analyze the bottlenecks in the following subsections.

3.1 Bottleneck of Container Rootfs Storage

In general, *rootfs* can be exposed to the container runtimes in the microVMs through two interfaces to construct the image layers: filesystem sharing (e.g. *9pfs* [45], *virtio-fs* [16]) and block device (e.g. *virtio-blk* [46]). Filesystem sharing enables microVMs to access a directory tree on the host directly. When the block device is used, the host creates block devices through the device-mapper [8] and passes them to the microVMs, so that containers can access data at the block level, rather than the file level.

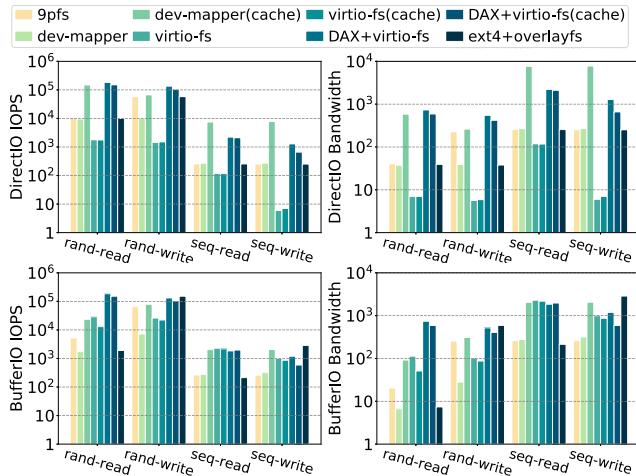

Figure 4: The IOPS/bandwidth performance of rand/seq directIO/BufferIO read/write when using different *rootfs* mapping in Kata-runtime (dev-mapper represents that *virtio-blk* is used, *ext4+overlaysfs* represent the baseline of default runc-container *rootfs* implementation).

Figure 4 shows the IOPS (IO-Per-Second) and IO bandwidth of the random/sequential read and random/sequential write, when Kata uses *9pfs*, *virtio-fs*, and *virtio-blk*, respectively. We also measure the metrics of using *ext4* file system and *overlaysfs* file access interface on the host node, to denote the case of the traditional containers [50, 51]. As observed, microVMs should not use *9pfs* as *rootfs* storage interface due to the poor performance.

With the default configuration (cache enabled), *virtio-blk* performs best at random/sequential writing. However, the device-mapper who prepares the block device in the host cannot meet the high-concurrency requirement [59]. According to our measurement, it takes as high as 10 seconds to prepare a *rootfs* when 200 containers are started concurrently, while it only takes about 30 milliseconds for a single container startup. In this case, the operation of preparing *rootfs* timeouts, resulting in the container breakdown. Moreover, *virtio-blk* inherently does not support the page cache sharing between host and guest operating systems. When *virtio-blk* backend reads *rootfs* files into the host page cache, the mapped content reproduces the same page cache in the guest. The issue of duplicated page cache brings a high memory footprint overhead.

Virtio-fs resolves the problem of duplicating page cache. When *DAX* is enabled in *virtio-fs*, it allows bypassing guest page cache and mapping host page cache directly in guest address space [16]. However, *virtio-fs* results in poor random/sequential write performance (Figure 4). In addition, each container has to employ a client daemon to support *virtio-fs* I/O operations, leading to excessive CPU usage when enormous containers colocate. Things get worse for

Figure 5: The memory overhead of a secure container.

either large I/O stress under high-concurrency or massive operations of metadata processing.

The above investigation shows that either *virtio-fs* or *virtio-blk* can compromise either deployment density or startup concurrency of secure containers. An exploratory alternative would be: using *virtio-fs* to support the read-only part of *rootfs* for sharing page cache between host and guests, and using *virtio-blk* to support the writeable part of *rootfs* for high I/O performance. A solution is also required to further reduce the duplicated writable part for *rootfs*.

3.2 High Memory Overhead Per Container

Except for the memory used by the user function, the memory footprint of other components in the secure container is the memory overhead. The 5MB memory overhead reported in FireCracker [52] is the overhead of the FireCracker VMM itself. In the microVM of a secure container, the guest operating system, the struct page for memory management, and other components (e.g., baseOS, shimv2, agent) also consume additional memory space [52].

Figure 5 shows the per-container memory overhead of secure containers with different memory specifications and at different deployment densities. In the figure, *Kata-qemu* is the secure container that uses *qemu* as the hypervisor, and *Kata-FireCracker* uses *FireCracker* as the hypervisor. As observed in Figure 5(a), the memory overheads of a 128MB container are 94MB and 168MB with *Kata-FireCracker* and *Kata-qemu*, respectively. The overhead increases with the memory specification of the container.

The average memory footprint of a single microVM can be reduced by sharing the text/rodata segment among multiple microVMs. Mainstream MicroVMs achieve it by mapping the kernel file to the guest memory directly using *mmap*. As shown in Figure 5(b), the per-microVM memory overhead of *kata-qemu* and *kata-FireCracker* reduce to 145MB and 71MB when 1,000 VMs are deployed on a node. However, the overhead is still too large for a serverless container with only 128MB memory specification.

MicroVM template (e.g., Kata template) [17, 29, 52] is a popular method to further reduce the per-microVM memory overhead, while preserving microVM consistency. The

template serves as a primary image for a microVM copy that includes disks, devices, and settings. New microVMs are created by on-demand forking from a pre-created template microVM, and text/rodata segments are also shared among multiple microVMs [54] in read-only mode. The unaccessed kernel files of the template will not consume the physical memory, reducing the memory overhead.

However, the template technique is not as efficient as we thought, due to the self-modifying codes in the operating system kernel [24, 25]. The self-modifying code technique alters the instructions on-demand as it runs, and the Linux kernel relies heavily on self-modification code to improve performance on boot and during runtime. We start a clean microVM with CentOS 4.19 guest kernel from a template to investigate the impact of self-modifying codes. The investigation shows that 10,012KB of the code and the read-only data is accessed in the memory, but 7,928KB of them were modified during boot. This case in point reveals that the self-modifying codes degrade the efficiency when using *mmap* for less memory consumption of kernel image files.

The code self-modifying reduces the shareable memory when using microVM template. Reducing the self-modifying codes in the guest kernel is worth investigating if they are not necessary for the serverless computing scenario.

3.3 High Host-side Overhead of Cgroups

Cgroup is designed for resource control and abstraction of processes. In serverless computing, the frequency of function invocations shows high variation. In this case, the corresponding secure containers are frequently created and recycled. For instance, in our serverless platform, at most 200 containers would be created and recycled on a physical node concurrently in a second. The frequent creating and recycling challenge the cgroup mechanism on the host.

We measure the performance of cgroup operations when creating 2,000 containers concurrently. In the experiment, we use different numbers of threads to perform cgroup operations. Figure 6(a) shows the cumulative distribution of container creating latencies. Counter-intuitively, the latency increases when more threads are used, even if each thread needs to create fewer containers.

The reason behind the above fact is that the Linux kernel introduces several global locks (e.g., *cgroup_mutex*, *css_set_lock*, *freezer_mutex*) to serialize cgroup operations. The global locks are used to coordinate more than 10 resource subsystems (aka. the cgroup subsys) involved in cgroup. Figure 6(b) shows the flame graph of creating 2,000 cgroups using 10 threads concurrently. In the figure, the red parts show the case that “mutex locks” are active. When the cgroup mutex uses the optimistic spinning by default, the spinner cgroups experience the optimistic spinning if they fail to acquire the lock. It will lead to heavy CPU consumption and belated exiting of the critical section in the multi-

Figure 6: The performance of cgroup operations when creating 2,000 containers concurrently. Due to the mutex lock, the cgroup operations have higher latencies as the concurrency increases.

threaded scenarios. *Therefore, the locks serialize the operations of cgroups and drag down the latencies.*

Besides, a common observation is that there are often more than 10,000 cgroups with thousands of containers on a compute node. The PELT (Per-Entity Load Tracking) for load balancing in CFS will iterate over all cgroups and processes when scheduling these containers. In this scenario, the frequent context switching and hotspot functions that involve high-precision calculation in the scheduler become a bottleneck, accounting for 7.6% of the CPU cycles of the physical node, according to our measurement.

The host-side overhead of cgroups prohibits the high-density deployment and high-concurrency startup in serverless computing. Simplifying the cgroup design, and reducing the critical section introduced by the mutex locks, are fundamental solutions to eliminate the high host-side overhead.

4 Methodology of RunD

The above analysis reveals the bottlenecks in the host, the microVM, and the guest in achieving the high-concurrency startup and high-density deployment. We propose **RunD**, a holistic secure container solution that resolves the problem of duplicated data across containers, high memory footprint per VM, and high host-side cgroup overhead.

In this section, we first show a general design overview of RunD, and then present the design of each component to resolve the corresponding problem.

4.1 Design Overview

When designing RunD, we have a key implication for serverless runtime. The negligible host-side overhead in a traditional VM can cause amplification effects in the FaaS scenario with high-density and high-concurrency, and any trivial optimization can bring significant benefits. Utilizing the

Figure 7: The lightweight serverless runtime of RunD. The condensed kernel and pre-patched image land in the guest domain, while read/write splitting-based *rootfs* and a lightweight cgroup pool land in the host domain.

features of read-only data/runtime and non-persistent storage in serverless, RunD proposes guest-to-host solutions.

Figure 7 shows the RunD design and summarizes our methodologies. RunD runtime makes a read/write splitting by providing the read-only layer to *virtio-fs*, using the built-in storage file to create a volatile writeable layer to *virtio-blk*, and mounting the former and latter as the final container *rootfs* using *overlaysfs*. RunD leverages the microVM template that integrates the condensed kernel and adopts the pre-patched image to create a new microVM, further amortizing the overhead across different microVMs. RunD renames and attaches a lightweight cgroup from the cgroup pool for management when a secure container is created.

Based on the above optimizations, a secure container (referred to as a “sandbox”) is started in the following steps, when RunD is used as the secure container runtime.

- In the first step, once *containerd* receives a user invocation, it forwards the request to RunD runtime.
- Second, RunD prepares the runc-container *rootfs* for the virtual machine hypervisor. The *rootfs* is separated into read-only layer and writable layer. (Section 4.2).
- Third, the hypervisor uses the microVM template to create the required sandbox (Section 4.3), and mount the runc-container *rootfs* into the sandbox by *overlaysfs*.
- Lastly, a lightweight *cgroup* is attached to the sandbox (Section 4.4), to manage the resource allocation for this sandbox in the host.

4.2 Efficient Container Rootfs Mapping

Section 3.1 examines the challenges in the high-density and high-concurrency scenario for container *rootfs*. The current secure container fails to discriminate between serverless platforms and traditional infrastructure-as-a-service environments. The mainstream solutions are designed for persistent

Figure 8: The read/write splitting of container *rootfs*. *Virtio-fs* is used to handle the read-only layer and *virtio-blk* is used to handle the volatile writable layer.

data storage, and it is the key point why container *rootfs* storage imposes restrictions on our goals.

We investigate the data in a sandbox in the serverless computing scenario, and find that **user-provided code/data is read-only for the operating system, and the system-provided runtime files are also read-only for user functions**. Meanwhile, the data in the local memory or storage generated in a sandbox will not be used by subsequent function invocations, due to the stateless feature of serverless computing. The temporary and intermediate data generated during the function execution is not required to be persisted.

Based on the above finding, it is possible to split the *rootfs* into a read-only layer and a writable layer, and then handle them in different ways [32]. The sandboxes can share the read-only layer on the same node, and the writable layer has to be prepared separately for each sandbox.

Figure 8 shows the way to split *rootfs* into a read-only layer and a volatile writable layer. According to the investigation in Section 3.1, *virtio-fs* is used to handle the read-only layer, and *virtio-blk* is used to handle the volatile writable layer for better performance. The read-only layer is stored in the host and can be prepared in negligible time when using the overlay snapshotter provided by the container runtime. However, it is challenging to handle the volatile writable layer efficiently. By default, the host operating system needs to prepare a logic storage volume for the sandbox. This operation is time-consuming and is one of the most important reasons that result in the long latency of preparing *rootfs*.

We propose the volatile block device as the volatile writable layer, considering the volatile feature of the writable layer in serverless platforms. The volatile block device will not persist temporary data from user functions to the disk, unlike the logic storage volume. A *storage image template* is pre-created in the host as the base file. When creating a volatile block device for a new sandbox, a *build-in storage image* is created and linked to the *storage image template*, using *reflink* [60]. *reflink* enables *storage image template* to

share data with *build-in storage images* in a CoW (Copy-on-Write) fashion. Then a volatile block device is created associated with the *build-in storage image*. Once the hypervisor opens the device, the *build-in storage image* will be deleted. The volatile block device ensures that user functions can perform writing as usual without persisting data on the local disk.

We compare our solution with the traditional ones in which the entire *rootfs* is created by the device-mapper as a block device. When 200 sandboxes are started concurrently, traditional solutions incur 4,500 IOPS and use 100MB/s IO bandwidth. On the contrary, our solution incurs only 1,500 IOPS and uses 8MB/s IO bandwidth. Better, the time needed to prepare the *rootfs* decreases from 207ms to only a negligible 0.2ms, and the writing performance of our solution is the same as that of the mainstream transmission.

4.3 Condensed and Pre-patched Guest Kernel

In this subsection, we present two techniques used to reduce the memory used by each sandbox, so that the deployment density can be significantly increased.

4.3.1 Reducing the guest kernel size

Following the abstraction premise in current serverless platforms, the guest environment management for serverless containers is offloaded to the cloud provider. Meanwhile, RunD depends on the security model of hardware virtualization and VMM, explicitly treating the guest kernel as untrusted through syscall inspections. Based on this fact, there is an opportunity to condense the guest kernel for the lightweight characteristic of serverless functions. Considering that several features in the guest kernel are redundant and memory intensive in the serverless context, RunD condenses these features at compile-time. When customizing the condensed guest kernel, the principles behind it are as follows:

- Minimize kernel memory footprint and image size.
- Retain features required in the serverless context.
- Without runtime performance degradation.

Following the above principles, we build the condensed kernel for the guest operating system based on Linux kernel, by disabling features:

- Do not pre-create loop device (2.2MB Mem reduced).
- Disable *acpi* and *ftrace* (2MB and 6MB Mem reduced).
- Disable *graphics*-related items (2MB Mem reduced).
- Disable *i2c* and *ceph* (3MB Mem reduced, and 4MB reduced of kernel image size).
- Kernel files (560K Mem and 571K image size reduced).

Validating all features at compile-time case by case, RunD effectively reduces the memory footprint of a CentOS 4.19 Linux kernel by about 16MB and condenses the kernel image by about 4MB. Based on this condensed guest kernel, we

review several investigations of the self-modifying code and propose our solution to reduce the memory overhead further.

4.3.2 Alleviating code self-modification

As mentioned before, cloud providers manage and maintain the underlying hardware and execution runtimes in serverless context, standing for that all microVMs on the same node generally use the same guest kernel. In this scenario, the sandboxes on the same node generate the same patched kernel code, even if they execute the self-modification patch logic. This is because **the self-modifying code of kernel text segments only occurs at the startup phase, after which the kernel code area becomes “read-only after initialization”**. In this case, sandboxes experience the same initialization phase and generate predictable self-modifying code segments.

Based on the above observation, there is an opportunity to generate a pre-patch guest kernel image file already patched with self-modified code segments. The MicroVM template technique discussed in Section 3.2 may work efficiently without self-modifying code.

Adapting to this optimization, we also resolve the potential kernel panic issues when loading the pre-patched kernel image for higher stability. RunD tries to share as many kernel files as possible across different secure containers. With a pre-patched microVM template, RunD not only reduces the memory footprint of a single container for higher-density deployment, but also allows to quickly fork multiple instances [29, 52].

4.4 Lightweight Cgroup and Cgroup Pool

In Section 3.3, we analyze that serialized cgroups operations in the host become one of the bottlenecks of secure containers with high-density deployment and high-concurrency startup. The intuitions are to efficiently handle synchronization access on mutex structures and reduce the number of cgroups with a better design.

Our further investigations reveal the optimization opportunities in two aspects. Firstly, creating containers involves multiple cgroup subsystems (e.g. *cpu*, *cpuacct*, *cpuset*, *memory*, and *blkio*). Because the Linux kernel cannot parallelize these cgroup-related operations, creating these groups for each sandbox is time-consuming. Secondly, **pre-creating and maintaining cgroups in a pool can effectively reduce the creation overhead, since afterward only the cgroup rename is used**. The cgroup rename, as a special case, is a lightweight operation without acquiring any global lock. Following these two observations, we propose a lightweight cgroup and the cgroup pool, as shown in Figure 9.

The lightweight cgroup decreases the total number of cgroups and system calls. Rather than creating the cgroup for each subsystem, we aggregate necessary cgroup subsystems

Figure 9: The lightweight Cgroup aggregates all subsystems, eliminating the time-consuming creation by renaming from the Cgroup pool.

(aka the *cpu*, *cpuacct*, *cpuset*, *memory*, and *blkio*) into one single dedicated lightweight cgroup. The implementation of the joint cgroup controller helps RunD reduce the redundant cgroup operations when a container is started, significantly decreasing the total number of cgroups and system calls.

The cgroup pool with renaming mechanism eliminates the time-consuming cgroup creation and initialization. RunD pre-creates corresponding lightweight cgroups and maintains them in a cgroup pool based on the pre-defined node capacity. These cgroups are marked idle when initialized, and are protected in a linked list. For each created container, RunD simply allocates an idle cgroup, updates the state to busy, performs the `cgroup rename` operation, and then attaches the container to this renamed cgroup when a container is started. If a container triggers recycling, RunD will take the cgroup back to the pool, kill the corresponding instance process, and then update the returned cgroup state to idle for subsequent allocating and renaming.

Adopting the above optimizations in kernel mode, we replay the evaluation in Section 3.3. The cgroups creation only consumes 0.09s (1 thread), 0.1s (50 threads), and 0.14s (200 threads), respectively. Compared with the default mechanism, the lightweight cgroup and the rename-based cgroup pool reduce 94% of the cgroups creation time.

5 Evaluation

In this section, we evaluate the performance of RunD in supporting high-concurrency startup and high-density deployment of secure containers, and introduce the performance of RunD in production usage.

5.1 Evaluation Setup

We have implemented and open-sourced RunD with Rust, a more memory-efficient and thread-safe programming language. RunD runtime involves four main modules: Containerd-shim (21k LOC), Device (4.4k LOC), Hypervisor (5.6k LOC), and Lightweight-cgroup (20k LOC).

Table 1: Experiment setup in our evaluation.

Configuration		
Hardware	CPU: 104 vCPUs (Intel Xeon Platinum 8269CY) Memory: 384GB, two SSD drives: 100GB, 500GB	
Software	OS: CentOS7, kernel: Linux kernel 4.19.91	
Container	kata-qemu	containerd 1.3.10, kata 1.12.1
	kata-FC	containerd 1.5.8, kata 2.2.3
	kata-template	containerd 1.3.10, kata 1.12.1
	RunD	containerd 1.3.10

Baselines: we compare RunD with the state-of-the-art secure container, Kata Containers [19]. Specifically, we use three popular configurations of Kata containers: *Kata-qemu*, *Kata-template*, and *Kata-FC*. *Kata-qemu* uses QEMU [15, 23] as the microVM hypervisor, *Kata-template* uses QEMU while integrating container template, *Kata-FC* uses lightweight FireCracker [20] as the microVM hypervisor. *Kata-qemu* and *kata-template* use an old version of Kata Containers, as the new version has some bugs that result in poor performance. Table 1 shows the detailed setups.

Testbed: we run the experiments on a node with 104 virtual cores, 384GB memory, and two SSD drives of 100GB and 500GB. Such specification is widely-used in production clouds. The 100GB drive is used as the root filesystem of the host operating system, and the 500GB drive is used by the secure containers. We use Alibaba Cloud Linux 2 for RunD and Alpine Linux [3] for others, as the guest operating systems in the microVM for a low memory footprint.

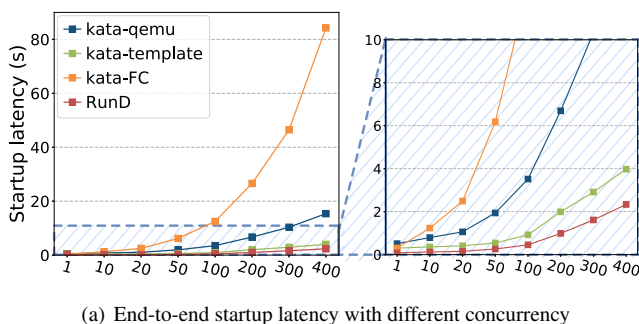

Measurement: in the CRI specification [6], a pod sandbox refers to a microVM with a lightweight pause container [12]. In all the tests, we only create the pod sandboxes without other containers inside, through the `crictl` command. In the following evaluations, the memory specification of a container denotes the size of memory that can be used by itself. The actual memory usage of a container is collected using the `smem` command.

As RunD is proposed to maximize the supported container startup concurrency and deployment density, in the experiment, we start empty secure containers without user codes or data considering that it is a common practice in FaaS to start empty containers concurrently for prewarming. The in-production results show the performance of RunD for actual workloads with all the steps involved.

5.2 Concurrent Startup Measurement

In this experiment, we focus on three critical metrics related to user experience: (1) the time needed to start a large number of sandboxes concurrently, (2) the startup latency distribution of the sandboxes, and (3) the CPU overhead on the host. The first metric reveals the throughput of starting sandboxes, and the second metric reveals the experience of every user.

As for the first metric, Figure 10(a) shows the time needed to start a large number of sandboxes concurrently. In the fig-

(a) End-to-end startup latency with different concurrency

(b) Latency distribution

(c) CPU time

Figure 10: The startup metrics with different runtime and concurrency: (a) The end-to-end latency of concurrent startups. The right figure is an enlargement of the left one ($y \in [0, 10]$). (b) The CDF of startup latencies from a 200-way concurrent launch. (c) The CPU usage of concurrent startups.

ure, the x -axis shows the number of sandboxes to be started concurrently, the y -axis shows the overall time needed to startup all the sandboxes.

As shown in the figure, RunD uses the shortest time to start a large number of sandboxes for all concurrency levels. When 200 containers are created concurrently (we already observe such high-concurrency in Alibaba serverless platform), Kata-FC, kata-qemu, kata-template, and RunD needs 47.6s, 6.85s and 2.98s and 1s to create them. Kata-FC requires a much longer time to startup the sandboxes when the concurrency is high. This is because Kata-FC uses *virtio-blk* to create *rootfs*, and the performance is poor at high-concurrency, as we measured in Section 3. There is no such bottleneck in Kata-template and Kata-qemu. Kata-template simply uses template to reduce the overhead of guest kernel and *rootfs* loading, but the inefficient *rootfs* mapping, code self-modification and high host-side overhead of the cgroup operations still exists. As a result, it performs worse than RunD at high startup concurrency. The overall optimizations suggest that RunD provides the performance improvement of about 40% over its nearest baseline, Kata-template, at high-concurrency (e.g., 400-way) startup.

As for the second metric, Figure 10(b) shows the latency distribution of starting each sandbox, when 200 sandboxes are started concurrently. RunD and Kata-template are able to start sandboxes in a stable short time, but the latencies of starting sandboxes with others are out of expected. Users can have identical good experiences with RunD.

As for the CPU overhead, Figure 10(c) shows the CPU time needed on the host to startup sandboxes. When the concurrency is high, RunD greatly reduces the CPU overhead. For instance, when 200 sandboxes are started concurrently, RunD reduces 89.3%, 74.5% and 62.1% CPU overhead compared with Kata-qemu, Kata-template, and Kata-FC, respectively. In addition, the CPU overhead of RunD only increases slightly, when the concurrency increases. This is due to the read/write split policy and the reduction of compute-intensive operations in cgroups. Therefore, RunD

Figure 11: The memory overhead of Kata-qemu, Kata-template, Kata-FC, and RunD (100 sandboxes are deployed).

is scalable in starting more sandboxes concurrently.

In summary, RunD is able to start a single sandbox in 88ms and launch 200 sandboxes simultaneously within 1s, with minor latency fluctuation and CPU overhead.

5.3 Deployment Density

In this experiment, we evaluate the effectiveness of RunD in increasing the sandbox deployment density. In general, the memory used by each container determines the deployment density, while the CPU time needed by each function invocation is minor in the serverless platform. Figure 11 shows the memory overhead when 100 sandboxes are deployed on the experimental node. In the figure, the x -axis shows the memory specification of each sandbox.

As observed, RunD has the least memory overhead among four runtimes, and does not increase with the memory specification. The memory overhead is less than 20MB per sandbox with RunD. Compared to kata-qemu, kata-template and kata-FC, the overhead of RunD is reduced by 54.9%, 27.2%, and 18.9%, respectively, even when the memory specification is 128MB. The memory overhead does not increase, because the microVM template technique uses the on-demand memory loading for the containers. Therefore, the page table required for memory management is determined by the actually used memory space. On the contrary, the memory overheads introduced by Kata-qemu and Kata-FC increase

Figure 12: The memory overhead and the amortization by multiple secure containers. The missing point around 2,000 indicates the over-subscription for physical memory space.

Figure 13: The end-to-end startup latency at different deployment densities. (10c/200c means a 10/200-way concurrent startup, and the Delta means the overhead increment compared with a 10-way concurrent startup).

with larger memory specifications, as the page table is built for all available memory. In addition, the pre-patched kernel image in RunD further reduces memory overhead.

Figure 12 shows the average memory overhead of the sandboxes when different numbers of sandboxes are deployed on a node. The x -axis shows the deployment density. As observed, the average memory overhead reduces with the deployment density, as the sandboxes share the mapped code/data segments. RunD reduces the memory overhead by 87.7%, 82.4%, and 75.1% when 1,000 sandboxes are deployed, respectively, compared with kata-qemu, kata-template, and kata-FC.

RunD supports to deploy over 2,500 sandboxes of 128MB memory specification on the node with 384GB memory.

5.4 Impact of Deployment Density on Startup Latency and Concurrency

When some sandboxes are already deployed on a node, the performance of starting sandboxes concurrently is affected. Figure 13 shows the time needed to boot 10 and 200 sandboxes, when some sandboxes are already deployed on the node. The x -axis shows the number of already deployed sandboxes. The y -axis is in the log10 scale.

When 1,000 sandboxes are already deployed, the time needed to startup 10 containers increases by 1.69s, 0.41s,

Figure 14: The startup latency and concurrency tracing of RunD in Alibaba serverless platform.

10.8s, and 0.22s compared with the cases in Figure 10(a) with Kata-qemu, Kata-template, Kata-FC, and RunD. In addition, the time needed already increases with the number of already deployed sandboxes.

We can also observe that, the time needed to start 200 sandboxes is at least 10 times as much as that needed to start 10 sandboxes at a 1,000-density deployment in all the tests. The significant increase originates from a large number of cgroups in the host operating system. Scheduling and managing containers with these cgroups consume more CPU cycles, thus resulting in CPU bottlenecks appearing earlier than a low-density deployment. The increased time is the smallest with RunD, because it already eliminates many time-consuming cgroup operations.

RunD shows better performance and stability in supporting high-concurrency startups at high-density deployment.

5.5 In-Production Usage for Serverless

Currently, Alibaba serverless computing platform has adopted RunD. The platform serves almost 4 billion invocations from more than 1 million different functions per day.

Figure 14 reports the sandbox startup concurrency and the corresponding startup latency from six nodes. The specification of each node is the same as our experimental setup in Table 1. The data is collected between 08:00 and 18:00 of Jan 10th, 2022. There are about 800 active sandboxes on each node, when the concurrency data is collected. The in-production startup latency of sandboxes at high-concurrency is consistent with that reported in Section 5.4.

As observed from the figure, the startup concurrency bursts at the beginning of each hour. At most 191 sandboxes are started concurrently around 10:00. RunD starts the 191 sandboxes in 1.6 seconds. We look into the function invocation logs, and find that the periodic burst is caused by the an-hour time trigger and cluster-level load balancing. The periodical burst is pervasive, as the Azure serverless platform traces [14] show the same pattern. In the figure, the sandbox startup latency occasionally increases when the concurrency is low. The long time results from the operation in loading large-scale workloads from the tenants. Although the startup

Figure 15: The deployment density and concurrency of RunD in 1 minute intervals, from Alibaba production traces.

concurrency is not always high, it is crucial to ensure a quick startup for a good user experience.

Figure 15 shows the deployment density of the sandboxes on each node. We collect the density statistics of the six nodes between 18:00 of Jan 10th to 10:00 of Jan 11th, 2022. As observed, more than 2,000 sandboxes are deployed on a node at most. We can also find that the high-density deployment happens at the same time as high concurrent startups. This is because many tasks are triggered at the beginning of each hour. The deployment density does not achieve the theoretical upper limit of $384GB/(128+20)MB=2656$ containers, as some functions use more than 128MB memory, and the workloads are also balanced to other nodes.

RunD is production-verified to meet the high-concurrency startup and high-density deployment requirements.

5.6 Lessons Learned from Production Usage

Besides the RunD secure container, we have some insights about designing secure containers for serverless systems.

Lesson-1: the CRI specification designed for Kubernetes is not suitable for serverless system. In CRI, multiple related containers can co-locate in the same sandbox, and a lightweight pause container is started first to prepare the cgroups for the remaining containers. This pause container-based solution is negative for serverless computing, as each sandbox only has a single container for security and privacy.

Lesson-2: Functions tend to use the same standard guest environment provided by the serverless platform. In this case, the language environment (e.g., JVM) can also be integrated into the microVM template. However, the language-level template will invalidate the on-demand memory loading in the guest because some language runtimes need to pre-allocate the available memory. There are tradeoffs between higher memory utilization and less startup time, and the decision should be made based on how often the functions share the language environment.

Lesson-3: The memory usage of user functions is the key aspect determining the upper limit of the deployment density. Most functions are lightweight. When 2,000 sandboxes are deployed on a node of our serverless platform, the CPU

utilization does not achieve 50%, and there is no complaint on the poor performance from users. One reason for the low CPU utilization is that many sandboxes are actually idle and “kept-alive” after its function invocation is completed in a serverless scenario.

6 Related Work

The most closely related work to RunD is FireCracker [20], which proposes a lightweight VMM for serverless runtime. It provides fast startup within 125ms, allowing 150 VMs to start concurrently per second per node, with less than 5MB footprint per VM. However, FireCracker only serves as the hypervisor stack in the Security Container model, without other complex related processes, e.g., *rootfs* [52]. By contrast, RunD investigates the guest-to-host solution through all stacks and provides higher concurrency and density.

Higher-density deployment. Regarding serverless computing, in the space of higher function deployment density of Secure Containers and VMs [57], the key is designing a more lightweight container runtime both in guest and host. Unikernel [36, 37, 43, 47] runs as a built-in GuestOS without necessary add-ons, demonstrating great potential for deploying containers with less overhead. Kuo [33] Explores lightweight guest kernel configurations for use in Unikernel environments, which has similarity to the approach towards reducing guest kernel size. However, Unikernel is hard to be changed once after compilation with the application. Its compile-time invariance results in poor flexibility in practice. SAND [21] adopts the *multi-container-per-VM* model to amortize the memory footprint of sandboxing. However, they do not further investigate the utilization impact of memory fragmentations in a real-system with high-density deployment. Gsight [61] observes that fine-grained function-level profiling can expose more predictability system-level features in the partial interference. With a more accurate interference predicting [27, 44], the function density can get improved with QoS guaranteed.

The above studies make sense in improving the effective density with less interference for serverless. They are orthogonal to our work, because RunD is motivated to improve the maximum deployment density on a single node.

Higher-concurrency startup. In the space of higher function startup concurrency, recent approaches leverage the container prewarm pool [9, 40, 49, 58]. The state-of-the-art on container prewarming, SOCK [42], uses a benefit-to-cost model to select packages pre-installed in zygotes, and builds a tree cache to ensure that the forked zygote container does not import any additional packages other than the private ones the handler specifies. The C/R (Checkpoint/Restore) [7, 31, 39] supporting the VM snapshotting [10, 28, 29, 41, 54] captures the state of a running instance as a checkpoint, and then restores it once cold startup. Observing that most functions only access a small fraction of the files and mem-

ory loaded in the initialization stage, Catalyzer [29] and Replayable Execution [55] extend the C/R mechanism to achieve a faster on-demand recovery and paging when start containers. REAP [52] identifies the guest-side page when loading a VM snapshot and records the metadata during the record phase. Then, for subsequent invocations, REAP proactively prefetches and load the recorded pages into the guest memory for faster and higher-concurrency startup.

The above studies reduce the startup and recovery phases to partially improve the capability of higher-concurrency startup. From a different angle, RunD holistically focuses on prominent bottlenecks through a guest-to-host investigation when start secure containers with high-concurrency. We also proposes a lightweight serverless runtime that production-verified in practice.

7 Conclusion

In serverless computing, the lightweight and short-term functions leads to the requirement of high-density container deployment and high-concurrency container startup. This work dives into the bottlenecks from the entire software stack and proposes RunD, a lightweight secure container runtime for serverless through a holistic guest-to-host solution. The evaluation results and in-production usage prove the efficiency of RunD to launch 200 secure containers in one second, and deploy over 2,500 secure containers per node. RunD is used in Alibaba production serverless platform, and shows good performance in terms of high-density deployment and high-concurrency startup.

A Artifact Appendix

A.1 Abstract

We choose Kata containers and its three configurations *kata-gemu*, *kata-FC*, *kata-template* as baselines for comparison with RunD. For measuring the startup latency, we use the

crictl command to start pod sandboxes and measure the time between the first *crictl runp* invocation and the last ready pod sandbox. For measuring the memory footprint, we use the *smem* command and the PSS column of its output. All the tests are run on a machine with 104 vCPUs and 384GB of memory running CentOS7.

A.2 Artifact Check-list (Meta-information)

- **Run-time environment:** Alibaba ECS instance;
- **Hardware:** Intel Xeon(Cascade Lake) Platinum 8269CY, CPU and Memory: 104 cores and 384GiB, Storage: Two ESSDs (100GB + 500GB);
- **Software:** Aliyun Cloud OS 2, with Linux kernel 4.19.91, Kata container 1.12.1 and 2.2.3, containerd 1.3.10, smem 1.4;
- **Metrics:** average latency and average memory footprint;
- **Time is needed to complete experiments:** 10 hours;
- **Available:** https://github.com/chengjiagan/RunD_ATC22
- **Code Licenses:** Apache-2.0 license

A.3 How to Access and Installation

Github Link: https://github.com/chengjiagan/RunD_ATC22. Then you should follow the *README* instructions to get installation.

A.4 Experiment Workflow

A.4.1 High-concurrency Experiment (Section 5.2)

Scripts are provided to run the high-concurrency test for kata-qemu, kata-fc and kata-template. To run high-concurrency tests:

```
$ ./script/time_kata_test.sh
$ ./script/time_katafc_test.sh
$ ./script/time_katemplate_test.sh
```

They may take several hours to finish. Some concurrency tests can be removed by removing the corresponding concurrency setting in file *time_test.conf* to shorten the time. The scripts will create a directory (e.g., named like *time_kata_05120948*) to store the logs.

We provide python scripts to analyze logs from the tests:

```
$ python3 data/time.py
$ python3 data/cpu.py
```

The python script will create two .csv files in the result directory: *time.csv* and *cpu.csv*. Each line in the csv file indicates the average cold-start latency and cpu time of a container runtime.

A.4.2 High-density Experiment (Section 5.3)

Scripts are provided to run the high-density test for kata-qemu, kata-fc and kata-template. To run high-density tests:

```
$ ./script/mem_kata_test.sh
$ ./script/mem_katafc_test.sh
$ ./script/mem_katemplate_test.sh
```

Density and memory capacity of containers in the tests can be changed in the file *mem_test.conf*. The scripts will create a directory named like *mem_kata_05120948* to store the logs.

We provide a python script to analyze logs from the tests:

```
$ python3 data/mem.py
```

The python script will create a csv file for each runtime, named like *mem_kata.csv*, containing the average memory consumption of containers with different memory capacity in different density.

A.4.3 Density Impact on Concurrency (Section 5.4)

Scripts are provided to run the high-density test for kata-qemu, kata-fc and kata-template. To run tests:

```
$ ./script/density_kata_test.sh
$ ./script/density_katafc_test.sh
$ ./script/density_katemplate_test.sh
```

The background density and the concurrency of the tests can be changed in the file *density_test.conf*. The scripts will create a directory (e.g., named like *density_kata_05120948*) to store the logs.

We provide a python script to analyze logs from the tests:

```
$ python3 data/density.py
```

The python script will create a csv file for each runtime, named like *density_kata.csv*, containing the average cold-start latency under different background densities and concurrencies.

A.5 Expected Results and Notes

The expect results are all stored in *ae_data* directory. Considering that some related binary packages are tightly integrated with our internal system, we provide a screencast *ATC_RunD_AE.mp4* of the tool along with the results. You can also find RunD-related performance and execution logs in our artifact..

Help Rather Than Recycle: Alleviating Cold Startup in Serverless Computing Through Inter-Function Container Sharing

Abstract

In serverless computing, each function invocation is executed in a container (or a Virtual Machine), and container cold startup results in long response latency. We observe that some functions suffer from cold container startup, while the warm containers of other functions are idle. Based on the observation, other than booting a new container for a function from scratch, we propose to alleviate the cold startup by re-purposing a warm but idle container from another function. We implement a container management scheme, named **Pagurus**, to achieve the purpose. Pagurus comprises an intra-function manager for replacing an idle warm container to be a container that other functions can use without introducing additional security issues, an inter-function scheduler for scheduling containers between functions, and a sharing-aware function balancer at the cluster-level for balancing the workload across different nodes. Experiments using Azure serverless traces show that Pagurus alleviates 84.6% of the cold startup, and the cold startup latency is reduced from hundreds of milliseconds to 16 milliseconds if alleviated.

1 Introduction

Owing advantages of high maintainability and testability, serverless computing is suitable for the ever-growing Internet services (the tenants are charged per invocation). As a result, hyperscalers now provide serverless computing services (e.g., Amazon Lambda [5], Google Cloud Function [11], Microsoft Azure Functions [12], and Alibaba Function Compute [1]). Meanwhile, some open-source serverless computing solutions like Apache OpenWhisk [3] and Fission [9] have also been developed and released.

In serverless computing, user functions run in containers (or Virtual Machines), and the containers are specialized for a function (a container is not allowed to run different user functions). Warm containers refer to the keep-alive containers that serve subsequent invocations (*warm startup*). If there is no warm container for a function invocation, a new container is started from scratch (*cold startup*). The cold startup

Figure 1: “Fork” an idle container of Function A for Function B to alleviate its cold startups.

latency is more than $10\times$ of the warm startup latency due to the container creation, software environment setup, and code initialization [40, 44, 47, 49, 59, 61]. It is ideal if all functions can run in warm containers. However, keep-alive containers are recycled to save resources once no new invocation arrives during the lifetime.

Many efforts have been devoted to speeding up the container cold startup [7, 28, 31, 32, 45, 46, 54–56, 58]. The prewarm-based methods create containers and runtime in advance, one method of which is prewarming customized containers for each function that includes all its required software packages [8, 15, 27, 28, 60]. However, it brings heavy memory consumption. Another method of prewarming containers is only installing common packages, and all functions share the prewarmed container pool [14, 45, 46]. This method is more memory space-efficient, but generating customized containers for a function from the prewarmed containers suffers from package download and installing latency overhead. Current solutions mainly adopt the second method [14, 46].

To alleviate the memory waste and minimize the function response time, instead of prewarming containers, we propose to alleviate the cold container startup through container sharing. For instance, if function A in Figure 1 can “fork or lend” the runtime checkpoint from its idle warm containers for function B, the cold startup of B is eliminated. By such means, we can leverage a function’s idle warm containers before being recycled to help others that tend to experience cold container startup.

Figure 2: The container sharing logic and challenging steps.

Analyzing the container sharing procedure, we find three challenges in achieving such goal. **1) The function invocation loads are not stable [51].** It is difficult to identify whether function A’s warm containers are actually idle or not. If the warm containers of A are always used to help B, A’s invocation may not be able to get a warm container and may even suffer from Quality-of-Service (QoS) violation. **2) Functions rely on different software packages.** When function A “forks” a warm container for function B, the warm container has to install extra packages. Installing and importing these packages may take longer than the cold container startup. Worse still, greedy re-packaging for excessive functions can also lead to huge image size or incur package version contradictions. **3) “Forking” an idle container from other functions may introduce security vulnerabilities.** While a function’s code or data are stored privately, sharing the container with other functions is risky.

We propose a container management system, named **Pagurus** to tackle these challenges. Figure 2 shows the steps of using function A’s idle warm containers to alleviate the cold container startup of other functions. The key idea is to replace its idle containers with new containers that other functions can safely use. The new container is created through a new image that already installs the required software packages of other functions, without including the code/data of the original function A. In this way, the warm containers of a function are classified into three categories: *private containers*, *zygote containers*, and *helper containers*. A function’s private containers can only be used by itself. Its zygote containers are the new containers that other functions can use. Its helper containers are the containers forked from other functions’ zygotes. A helper container already loads its user code for future invocations. By using privilege control in the operating system, a function that uses a helper container cannot obtain any code, data, or package information of other functions.

Pagurus uses an *intra-function container manager* for each function to manage its containers, an *inter-function scheduler* on each node to manage the “fork” action between functions, and a *sharing-aware function balancer* to schedule functions across the nodes. For a function, the

intra-function manager monitors the status of each container, identifies idle warm containers, and re-purposes an idle container based on a QoS-based timer. The inter-function scheduler, acting as an orchestrator, determines the to-be-helped functions of each function. We design a Similarity Filtered Weighted Random Sampling (SF-WRS) algorithm to find an appropriate set of to-be-helped functions. Besides, the sharing-aware function balancer distributes function invocations to different nodes to achieve efficient inter-function container sharing.

Pagurus requires no offline analysis or profile on the functions, thus can be easily adopted in production. The main contributions of this paper are as follows.

- **A resource-friendly design of zygote and helper container.** Zygote container enables resource-saving through package and function reclamation, without incurring any additional security issues meanwhile.
- **The design of a SF-WRS re-packing policy.** Based on the package similarity between functions and the frequency of function cold startups, SF-WRS policy reduces the number of packages to-be-installed, thus minimizing the memory needed and the overhead of creating zygote containers.
- **The design of an efficient container sharing mechanism.** Pagurus divides the warm containers of a function into three types and manages the three types of containers in different ways. The mechanism efficiently alleviates the cold container startup.

We evaluate Pagurus using both best-practice AWS serverless functions [6] and Azure traces [50]. Experiments show that Pagurus alleviates 84.6% of cold startups on average in Azure traces, and the cold startup latency is reduced from hundreds of milliseconds to 16 milliseconds if alleviated.

2 Background and Related Work

If a function is invoked for the first time or there is no alive (or warm) container for it, the serverless system starts a new container to encapsulate its function runtime, initializes the software environment, loads application-specific code, and runs the function. All these steps make up a *cold startup* and may even take several seconds [21, 36, 59]. The cold startup significantly increases queries’ end-to-end latency [23, 33, 47, 49]. The long latency problem worsens when the function invocation is short (e.g., hundreds of milliseconds).

Prewarm startup spawns template containers that are already initialized with the software environment. Though it skips the container startup and users only need to perform application-specific code initialization [2, 3, 32, 46], its pre-loaded packages can either make the image size too large [20, 32, 53], or cause more memory consumption for the prewarm container [24, 46, 50].

Many prior studies have been conducted to reduce the container startup latency [19, 28, 34, 48, 52, 54]. However, existing works mainly focused on seeking lightweight virtualization technologies to pursue lower overhead [17] or optimizing prewarm strategies for more accurate prediction models and less initialization cost []. A common optimization is to pause the container when idle to save resources consumed by function codes and packages, and then reload it for reusing when invoked [34, 44, 45, 57].

SAND [19] separated applications via containers while allowing functions of one application to run in the same container by different processes. FaasCache [31] took the caching model for objects into serverless context, and implemented the Greedy-Dual keep-alive caching mechanism to reduce the resource requirement and keep containers warm. Shahrad *et al.* [50] proposed to dynamically change the instance lifetime of the recycling and provisioning instances according to the time series prediction. Some researchers use C/R (Checkpoint and Restore) [7, 55, 56, 58] that restores container images from checkpoints to speed up the cold startup. For example, Catalyzer [28] utilized C/R to realize on-demand recovery. However, it still incurs long latency compared with a warm startup. The above technologies are orthogonal to us, and Pagurus can be combined with them to reduce the cold startup latency further. SOCK [46] introduced a tree cache and uses the benefit-to-cost model to update packages in the prewarmed containers dynamically, but the zygote design consumes more memory when maintaining packages by a cache-tree. Moreover, the cache-tree does not work if functions require conflicted package versions.

Pagurus resolves the problems through inter-function container sharing with conflict concerns, and needs neither pool-size tradeoffs nor time-consuming model training.

3 Investigation and Motivations

In this section, we discuss the current prewarm-based mechanism for alleviating the cold container startups, and show the possibility of eliminating the cold container startup with inter-function container sharing.

3.1 Latencies of Cold and Prewarm Startups

A cold container startup is done in three time-consuming steps: *create container from the image*, *initialize software environment*, and *initialize application-specific code*. With the prewarm mechanism (used in OpenWhisk [3] and production platforms), several containers that already import common libs/packages are hatched in a container pool. A function invocation with no warm container can specialize the prewarmed container by installing the extra packages.

We use prewarm-enabled OpenWhisk with local cache as the serverless platform, and use the best practice serverless

Figure 3: The cold startup latency and prewarm startup latency of the benchmarks in OpenWhisk.

applications in AWS [6] as the benchmarks, to investigate the impacts of cold and prewarm startup on the end-to-end latency of a function invocation. A benchmark may have several functions [41]. As for the hardware, we use one node to perform the computation and one node to generate function invocations. The benchmarks, software, and hardware setups are described in Section 8.

Figure 3 shows the time of generating a container when it is started from the image, or is specialized from a common prewarmed container. As shown, the cold container startup takes about 500 milliseconds. The prewarm startup takes 15 milliseconds in the best case, but takes more than 1500 milliseconds in the worst case (e.g., function *union* in the benchmark *ddns*). This is because *union* requires to load/install many additional packages in the prewarmed containers, and the package loading is time-consuming.

Intuitively, a prewarmed container may install all the software packages required by all the functions on a physical node to speed up the prewarm startup. It is possible because for most serverless systems, the packages needed by a function (besides the private ones) are usually given by its user in a *requirements.txt*, and are publicly accessible for FaaS providers. However, many functions require software packages of contradicting versions. In addition, such a solution may expose the package information of other functions. The pre-imported requirements will implicitly embody user privacy. *Due to the software conflict and privacy concerns, it is not a good option to install packages for all functions in the prewarmed containers.*

3.2 Limitations of Prewarm Schemes

We then explore the effectiveness of the prewarm schemes in alleviating the cold startup. In this experiment, we run all the benchmarks on a single node, and the invocation patterns of the functions are the same as the patterns in the Azure serverless traces. The invocation patterns actually follow the Pareto distribution (most of the invocations are for a small part of the functions) [15]. By default, a prewarm container pool has two prewarmed containers on a node [2].

Figure 4 shows the percentage of the remaining cold startups with the prewarm mechanism. Many cold startups are not eliminated (e.g., functions in *eco* and *cart*). This phe-

Figure 4: The remained cold startup in prewarm-enabled OpenWhisk compared with the disabled one.

nomenon attributes to the inappropriate pool size of the prewarm container pool. For *eco* and *cart*, their functions are invoked simultaneously/or in short intervals to satisfy complex business logic, such as workflows [18, 22, 25]. For instance, five functions are triggered simultaneously by a caller in *eco*. These functions contend for the prewarmed containers.

It is nontrivial to appropriately configure the prewarm scheme due to two considerations. **1) Pool-size and memory overhead trade-off.** If we prewarm more containers, larger additional memory space is used. In our experiment, the prewarmed containers use more than 1GB of memory (on a node with 16GB memory) to eliminate 80% of the cold startup. The prewarm mechanism is not able to effectively eliminate the cold startup with reasonable memory overhead.

2) User experience and system efficiency contradiction. As discussed, most of the invocations are from a small part of the functions [15], and a prewarmed container can only cache a small number of packages for the low memory overhead. Caching packages for frequently invoked functions improves the system efficiency (frequent invocations have low startup time), but results in poor user experience (invocations of most functions tend to suffer from the long package installation time), and vice versa.

The current container prewarm scheme is not efficient due to several inevitable trade-offs. It is beneficial to alleviate cold startups without trapping in the same dilemmas.

3.3 Opportunity of Reusing Idle Containers

We therefore propose to alleviate cold startup without relying on prewarming containers. The key idea is leveraging the warm but idle containers of some functions to alleviate the cold startups. A function invocation that requires cold startup may “steal” an idle warm container from other functions.

The proposed scheme is effective only when there are idle warm containers in some functions when an invocation tends to suffer from the cold container startup. In principle, only underutilized warm containers that are active due to the keep-alive strategy can be used by other functions. Otherwise, always stealing a warm container directly may result in the cold container startup of the victim function.

We analyze the *day07* trace of Azure serverless platform [50] (the trace contains invocations of over 44,000

Figure 5: The number of container cold startups and idle containers from 400 randomly selected functions.

functions) to verify the above requirement. If a container triggers recycling, it must be an idle warm container because of no new invocation during its lifetime. By replaying the trace, we find that the warm containers for some functions are idle (no invocation is received during this idle time), while some other functions suffer from cold startup. We refer to idle warm containers as idle containers.

Figure 5 shows the number of idle containers and cold startups when replaying the trace. As observed, the time that idle containers and cold startup happen are similar, and there are more idle containers than the cold startups. If the time does not match, the functions that suffer from cold startup cannot find idle containers from other functions.

The time matches because many containers are prepared and invoked to serve the high load, and they become inactive when the load drops. We can observe a significant discontinuity at the beginning of each hour as there is a certain number of functions with a 1-hour timer trigger, and they are invoked once and will keep idle during the rest of their lifetime. In this case, excessive idle containers are pervasive.

In summary, serverless computing systems usually adopt a keep-alive strategy (e.g., 15 minutes) to reduce the cold startup. The kept-alive containers are idle before they are recycled. The widely-existed diurnal load pattern also makes containers over-provisioned at the high load. These containers will become idle when the load drops as well.

Based on the investigation, we observe the opportunity to leverage the idle containers of some functions to help others that suffer from cold startup on the same node.

4 Design of Pagurus

There are two prerequisites to alleviate the cold container startup with the warm containers of other functions. First, the container manager has to identify the actual idle warm containers. Otherwise, the “steal” results in the container cold startup of the victim function. Second, the proposed strategy should not expose any information of a function (e.g., data, code, package requirements) to other functions from the consideration of security.

We propose and implement **Pagurus**, a container management system that fulfills the two prerequisites. Figure 6

Figure 6: Design of Pagurus.

shows the design of Pagurus. It comprises an *intra-function container manager* for each function, an *inter-function container scheduler* on each node, and a *sharing-aware function balancer* at the cluster level. The intra-function container manager of a function manages its three types of containers (private containers, zygote containers, and helper containers) (Section 5). The inter-function scheduler manages the zygotes sharing between functions (Section 6). The sharing-aware function balancer maps the functions across multiple nodes to minimize the system-wide cold startup (Section 7).

Based on runtime statistics, a function’s idle warm containers are replaced with its zygote containers that are newly created from its zygote image (② in Figure 6). The zygote image does not include the code or data of any functions. Pagurus uses the inter-function container scheduler on each node to generate the zygote image of each function (① in Figure 6). Creating zygote images does not introduce extra runtime latency overhead, as it is done asynchronously before replacing the idle container with a zygote container. The inter-function container scheduler determines the possible to-be-helped functions of each function based on Similarity-Filtered Weighted Random Sampling (SF-WRS) policy, which will be detailed in Section 6.1. A function’s zygote container additionally installs the required packages of its to-be-helped functions in an anonymous fashion. Based on the privilege control of the Linux operating system, a function is only able to access its own packages.

Specifically, when an invocation of a function f arrives, it obtains a container to host the invocation in four steps.

1) It first tries to obtain an idle warm private container from its own private container pool directly. Then, if its private container pool is empty, it checks whether its helper container pool has containers for queries.

2) If both the private pool and the helper pool are empty, it will further check whether its zygote container pool has some containers already adapted for other functions. If not

empty, a zygote container can be used to host the invocation.

3) If its zygote container pool is also empty, Pagurus tries to find a container that includes the required packages of f from other functions’ zygote container pool. The forked zygote then joins the helper container pool of f (③ in Figure 6).

4) If all the above steps fail, the invocation of f would suffer from a cold container startup.

5 Intra-function Container Management

The key points of the intra-function manager are identifying the actual idle containers, and designing an efficient sharing mechanism.

5.1 Identifying Idle Containers

In principle, a container is idle when it does not host function invocations for a long time. For a function f , we introduce a timer in each of its containers to measure the free time. A warm container is treated to be idle if its timer exceeds threshold $T_{idle}(f)$. The timer is reset once the container receives an invocation.

The design principle here is that most function invocations can still get warm containers, even when a container is identified to be idle and “stolen” by other functions. Different functions should have different idle thresholds because of their diverse invocation patterns. We explore the runtime invocation arrival pattern to determine the value of $T_{idle}(f)$ for a function f . Specifically, we use all the m invocations during the container lifetime, and let T_1, T_2, \dots, T_m represent the time intervals between the adjacent invocations (the time interval is sorted in the ascending order). Equation (1) calculates the idle threshold $T_{idle}(f)$ for the function f in the next time period.

$$T_{idle}(f) = \begin{cases} T_{[0.95m]}, & m \geq 30, \\ T_{default}, & m < 30. \end{cases} \quad (1)$$

In the equation, $T_{[0.95m]}$ is the 95%-ile time interval of the m samples. In this case, for frequent invoked functions ($m \geq 30$), more than 95% invocations of f tend to get warm containers, if the invocation arrival patterns remain. We use 30 to be the sampling target for stability considerations. For occasionally invoked functions, $T_{idle}(f)$ is set to be $T_{default}$, and almost all the invocations get warm containers. $T_{default}$ may impact the overall efficiency for idle identification, and Section 8.4.3 evaluates the sensitivity of Pagurus to it.

5.2 Replacing Idle Containers with Zygotes

A function’s idle containers cannot be used by other functions directly, as the data and code of the function may still reside in the memory of the idle containers. To this end, Pagurus creates a zygote container that does not include any

Figure 7: Security assurance of a zygote container.

data or code of the owner function, and uses the zygote container to replace the original idle warm container. The zygote container is created from an image that installs the shared packages of all the to-be-helped functions. Section 6 discusses the policies used to determine the to-be-helped functions and generate the zygote image of a function.

One may be concerned about the security and privacy of the zygote container for re-purposing. Figure 7 shows the way to avoid package information leakage in zygote containers. All the functions run as non-root users [4, 10, 16]. In the figure, f_B and f_C are the to-be-helped functions in f_A 's zygote container. In general, the common intersectant packages required by all functions are installed as a shared domain (pkg_m, pkg_n) in the zygote container, and the additional complementary and private packages of to-be-helped functions are cached in different directories of the host. These directories are mounted anonymously into the zygote, thus ensuring that others cannot identify a function.

Each function that may use the zygote container is given a privilege domain and is only allowed to access its corresponding package directory. The privilege domain and privilege control are provided by Linux operating system and different non-root users. For instance, in Figure 7, when function f_B obtains the zygote container, it can only enter its own privilege domain for f_B 's packages (private packages and pkg_y) to specialize its software runtime. In this way, the zygote container serves as a safety checkpoint. Because it does not import any user-related code and data, the function privacy of the software environment is also protected.

6 Inter-function Container Scheduling

The inter-function container scheduler selects to-be-helped functions for zygotes, re-packs zygote images, and manages the fork operation for helper containers.

6.1 Selecting To-be-helped Functions

A straightforward approach is to treat all the other co-located functions as the candidate to-be-helped functions, and install all the required packages into a zygote image. However, this approach suffers from extremely high re-packing overhead, in terms of both time and resource consumption. When

re-packing a zygote image, we have two important observations. On the one hand, if the set of to-be-installed packages is large, it is time-consuming and resource-unfriendly to create a giant zygote image. On the other hand, some functions tend to have more cold startups than others (as observed from Azure traces [12]), inappropriate selection of to-be-helped functions is inefficient in alleviating the system-wide cold startups. Taking the above challenges into consideration, we propose **SF-WRS** (Similarity Filtered Weighted Random Sampling) algorithm, which contains:

- A Similarity-based Filter to find out to-be-helped candidates based on the similarity of functions' packages. In this way, a zygote installs fewer complementary packages, thereby lowering the re-packing overhead.
- A WRS (Weighted Random Sampling) strategy [29] to select K to-be-helped functions based on the cold startup frequency of each function on the node. Pagurus tends to prepare zygote images for the functions that suffer from more cold startups with high possibility.

Similarity-based Filter. Focusing on the package information, a function f can be viewed as a set of packages, i.e., $f = \{pkg_1, pkg_2, \dots\}$, where pkg_i is assigned in the *requirements.txt* and refers to the required package in f 's runtime environment. Let $\mathbb{F}_n = \{f'_1, f'_2, \dots\}, \forall f'_i \neq f$ represent the set of functions on node n when function f triggers re-packing. The package difference between f and $f'_i \in \mathbb{F}_n$ imposes a deep influence on the re-packing overhead. Let us denote the containment relationship of a package pkg in f_A and another function f_B as

$$con(pkg, f_A) = \begin{cases} 1, & \text{if } pkg \in f_A, \forall pkg \in f_A \cup f_B. \\ 0, & \text{others,} \end{cases} \quad (2)$$

We can then derive the containment relationship vector of f and $f'_i \in \mathbb{F}_n$ as $\vec{f} = \{con(pkg, f) | \forall pkg \in f \cup f'_i\}$ and $\vec{f}'_i = \{con(pkg, f'_i) | \forall pkg \in f \cup f'_i\}$, respectively. The similarity between f and f'_i thus can be calculated as their cosine distance by

$$Cos(\vec{f}, \vec{f}'_i) = \begin{cases} \frac{\vec{f} \cdot \vec{f}'_i}{\|\vec{f}\| \|\vec{f}'_i\|}, & \|\vec{f}\| \|\vec{f}'_i\| \neq 0, \forall f'_i \in \mathbb{F}_n. \\ 1, & \|\vec{f}\| \|\vec{f}'_i\| = 0. \end{cases} \quad (3)$$

Thereafter, we can obtain an initial f 's to-be-helped function candidate set \mathbb{C}_n^f by removing those functions with similarity lower than *TargetSimilarity* from \mathbb{F}_n . *TargetSimilarity* can be set as the median similarity in default.

Note that, as discussed before, a package may be specified in different versions, and a zygote image with version conflict (i.e., the same package but different versions) could not be re-purposed by another function. Denoting the version of a package pkg in function f as $V(pkg, f)$, we can express the version conflict relationship between f and f' as

$$Conflict(f, f') = \begin{cases} 1, & \exists pkg \in f, V(pkg, f) \neq V(pkg, f'), \\ 0, & \text{others.} \end{cases} \quad (4)$$

Then, we first ensure that there is no conflict between function f and its candidates, by removing the functions with version conflict from the candidate set. However, it is still possible that some candidates conflict with each other. For instance, candidates f'_1 and f'_2 do not conflict with f , but f'_1 conflicts with f'_2 . In this case, they cannot be packed into a single zygote image either. The candidate set \mathbb{C}_n^f should be further updated by Equation (5), where $\mathbb{C}_n^f \setminus f'_i$ represents the complement of f'_i in \mathbb{C}_n^f .

$$\begin{aligned} \mathbb{C}_n^f &= \{f'_i | \text{Conflict}(f, f'_i) = 0, \\ &\text{Conflict}(f'_i, \mathbb{C}_n^f \setminus f'_i) = 0, \forall f'_i \in \mathbb{C}_n^f, \} \end{aligned} \quad (5)$$

Take the package conflict in AWS application benchmarks as an example, function `tcp_check_transcribe` requires the package `aws_requests_auth` with version 0.4.1, while function `ep_delivery_on_package_created` requires that with version 0.4.3. It denotes that applications have various package similarities, and two functions may rely on conflicted packages. By selecting the to-be-helped functions based on package similarity, a zygote image installs fewer packages for zygote images with less re-packing overhead.

WRS selection. After the similarity filter and conflict recognition, the to-be-helped function candidates can be significantly reduced. However, it is still nontrivial for the inter-function scheduler to determine the appropriate number of to-be-helped functions without resulting in too large image size, too long image generation time, or failing to eliminate most cold startups. Therefore, we should choose an appropriate number, say K , of functions from candidates \mathbb{C}_n^f that tends to eliminate the cold startups with high probability.

Therefore, we first remove the functions never re-invoked from \mathbb{C}_n^f . Let I be the number of remaining functions that have been invoked more than once. We can calculate K as

$$K = \frac{\sum_{n=1}^I K_n}{I} = \sum_{n=1}^I \left[\frac{\sum_{n=1}^I \text{Cold}(f'_n) + \sum_{n=1}^I \text{Zygote}(f'_n)}{(\text{Cold}(f'_n) + \text{Zygote}(f'_n)) \text{Num}(\text{Zygote})} \right] / I, \quad (6)$$

K_i is the expected number of to-be-helped functions for f'_i , $\text{Num}(\text{Zygote})$ is the average number of active zygotes in the system, $\text{Zygote}(f'_i)$ and $\text{Cold}(f'_i)$ indicate the times a function experiences zygote-based invocation and cold startups of f'_i , respectively. K_i ensures that each to-be-helped function f'_i can be re-packed into a zygote container at least once.

Algorithm 1 summarizes the SF-WRS algorithm. First, the inter-function scheduler filters out the candidate functions with low similarity values (lines 1-3), recognizes the package conflicts (lines 4-6), and then selects K to-be-helped ones by the A-ExpJ algorithm, which is a variation of WRS (Weighted Random Sampling) algorithm [29] (lines 9-12). Compared with naive WRS, A-ExpJ shows much lower time complexity. The time complexity of selecting K functions is $O(K \log(\frac{n}{K}))$ with A-ExpJ, and the time complexity of naive WRS is $O(n)$.

Algorithm 1 SF-WRS Selection Algorithm

Require: To-be-helped function candidates \mathbb{C}_n^f
Require: $\text{Cold}(f'_i)$ and $\text{Zygote}(f'_i)$ of function f'_i in last hour

- 1: $\mathbb{C}_n^f = \text{Sample.init}(\mathbb{F}_n)$
- 2: **for** f'_i **in** \mathbb{C}_n^f **do**
- 3: **if** $\text{Cos}(\vec{f}, f'_i) < \text{TargetSimilarity}$ **then:** $\mathbb{C}_n^f.\text{delete}(f'_i)$
- 4: **for** f'_j **in** \mathbb{C}_n^f **do**
- 5: **if** $\text{Conflict}(f, f'_j) = 1$ **or** $\text{Conflict}(f'_j, \mathbb{C}_n^f \setminus f'_j) = 1$ **then**
- 6: $\mathbb{C}_n^f.\text{delete}(f'_j)$
- 7: **if** $\mathbb{C}_n^f \neq \text{Null}$ **then**
- 8: $\text{Total} = \sum_{n=1}^K \text{Cold}(f'_i) + \sum_{n=1}^K \text{Zygote}(f'_i)$

- 12: $A\text{-ExpJ}(\text{Sample}, K)$

Figure 8: The key steps (represented in green) of re-packing a zygote image for the first time.

6.2 Re-packing a Zygote Image

Figure 8 shows the steps of re-packing the zygote image for a function f . When the intra-function container manager of f identifies an idle container, it informs the inter-function scheduler, then selects the to-be-helped functions of f based on the SF-WRS algorithm. After that, the inter-function scheduler triggers the re-packing operation, obtains the packages, and re-packs the zygote image. Only the packages shared by all the to-be-helped functions are installed in the shared domain. Finally, the re-packed zygote image is returned to the intra-function container manager of f for building zygote containers to replace f 's idle containers.

The inter-function container manager has an advantage compared with the traditional building method, where the image is built through the network from the container repository. Pagurus omits the downloading of the required packages in a zygote image through the network again, benefiting from the locally cached packages, when creating the private container images [26, 39]. By reusing cached packages, re-packing a zygote image takes a much shorter time.

Besides, the zygote image of a function is asynchronously re-packed before its to-be-helped functions actually meet in cold startups. Re-packing a zygote image does not result in long response latencies of to-be-helped function invocations.

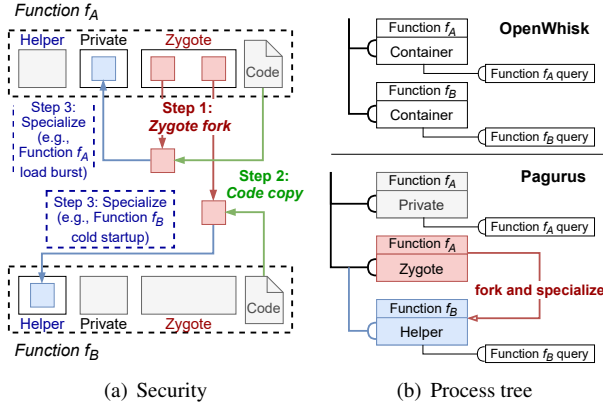

Figure 9: Security guarantee when forking a zygote.

6.3 Forking a Zygote Container

The rest undertaking is to safely and efficiently share zygote containers for other functions. To provide higher availability for multiple to-be-helped functions getting zygote containers, we fork the zygote container to be helper containers, rather than directly specializing it. The zygote container remains there for other to-be-helped functions. The forked containers also ensure software security by the anonymous mounting and privilege domain as zygote containers do.

When a zygote container is forked from function f_A to be f_B 's helper container, the code of f_B is copied into the forked one. We implement two plugins *Zygote fork* and *Code copy*, in the inter-function scheduler. The *Zygote fork* plugin forks a container asynchronously, un-mounts the package directories of functions other than f_B , and transfers the control access to f_B 's corresponding privilege domain. The *Code copy* plugin copies the code of f_B to the helper container.

Figure 9(a) shows the steps of f_B forking a zygote container of function f_A . In Step 1, a zygote container of f_A is forked through the *Zygote fork* plugin. Then, the *Code copy* plugin copies the code of f_B into the forked zygote (Step 2). Lastly, the forked container joins the helper container pool of f_B (Step 3). It also provides process-level isolation for queries, as shown in Figure 9(b).

7 Sharing-aware Function Balancing

In existing serverless computing clusters, hash-based methods or resource usage-based methods are often used to route user queries [13, 30, 35, 37, 38, 42, 43]. It is possible that the functions on a node do not share many packages. In this case, the host node needs to create many private directories with many packages, resulting in poor resource efficiency. To address such a problem, a straightforward solution is checking the package similarities of all the active functions, and assigning the functions that share more packages to the same

node. However, it is not always a good solution, as the functions sharing many packages may not have idle containers.

To resolve the problems above, we propose a function balancing strategy based on the statistics of zygote containers and the available resources $\mathbb{U}_n = \{U_{CPU}, U_{IO}, U_{net}, \dots\}_n$ on every node. The function balancer is implemented on the head node of the cluster, to obtain the statistics from all the nodes. For a function f_B that requires package pkg_a and pkg_b , if it fails to find a zygote container during its invocation on a node, its future invocations should be redirected to another node with potential zygote images.

To this end, Pagurus runs the sharing-aware function balancer on the head node based on the resource usage \mathbb{U}_n , and the similarity between the redirected f_A and functions with idle containers on node n . Let $\mathbb{N} = \{n | \max \mathbb{U}_n \leq T_{res}\}$ represent the set of nodes where the resource utilization is under the threshold T_{res} (80% by default). The head node will select a new node with the most zygote containers from \mathbb{N} and inform the API gateway accordingly. After that, the queries of f_B will be routed to this new node.

8 Evaluation of Pagurus

In this section, we evaluate Pagurus in reducing the cold startups and end-to-end latencies when a function does not have warm containers. Then, we evaluate Pagurus by a large-scale evaluation with Azure trace. After that, we show the integration with other techniques and overhead.

8.1 Experimental Setup

We use 10 best-practice applications with the most GitHub stars from Amazon AWS samples as the benchmarks [6]. We use these applications for revealing the performance of Pagurus for real applications. Experiments with small scale benchmarks in serverless benchmark suites, e.g., FaaS-Profiler [49] and ServerlessBench [61] show similar results. We run the benchmarks on a 6-node cluster. A node generates function invocations, and the other 5 nodes serve invocations. Table 1 shows the configurations of each node.

Pagurus does not rely on the function invocation arrival distribution. In Section 8.2-8.3, we send queries to each application following a Poisson distribution by randomly sampling λ between 0 and 5 queries per second. We co-locate all the benchmarks, and run 20 tests with different samples to avoid randomness. More experiments are done with the Pareto distribution-based invocation pattern of the Azure serverless trace in Section 8.4.

We compare Pagurus, prewarm-disabled OpenWhisk, prewarm-enabled OpenWhisk (OpenWhisk-Prewarm), and SOCK [46]. SOCK also prewarms containers by dynamically updating packages in the prewarmed containers to alleviate cold startups. When a function obtains a prewarmed

Figure 10: Remained cold startups of OpenWhisk-Prewarm, SOCK and Pagurus, compared with prewarm-disabled OpenWhisk. The left figure shows the remained cold startups (all bars are normalized to the number of cold startups of OpenWhisk Prewarm-Disabled) of each function, while the right figure shows the remained cold startups of all functions in the system.

Table 1: Hardware, software, and benchmark setups

	Configuration
Node	CPU: Intel Xeon(Ice Lake) Platinum 8369B @3.5GHz Cores: 8, DRAM: 16GB, Disk: 100GB SSD (3000 IOPS)
Software	Operating system: Linux with kernel 4.15.7, Docker: 20.10.6 Nginx version: nginx/1.10.3, Database: Couchdb:3.1.1 runc version: 1.0.0-rc93, containerd version: 1.4.4
Container	Container runtime: Python-3.7.0, Linux with kernel 4.15.7 Resource limit and Lifetime: 1-core with 256MB, 600s Function container limit: 10 for each function on each node prewarm pool size in OpenWhisk: 2 on each node
Benchmarks (38 functions in 10 AWS Lambda best practice applications)	serverless-e-commerce-platform (eco), etl-orchestrator (etl) cost-explorer-report (rep), serverless-tokenization (tok) transcribe-comprehend-podcast (pod), serverless-chatbot (bot) serverless-shopping-cart (cart), refarch-fileprocessing (file) finding-missing-persons-using-rekognition (rek), ddns

container, SOCK and OpenWhisk-Prewarm copy the missing packages into the prewarmed container for its invocation.

8.2 Alleviating Container Cold Startups

Figure 10 shows the percentages of the cold startups not eliminated by Pagurus, SOCK, and OpenWhisk-Prewarm, compared with prewarm disabled OpenWhisk. On average, Pagurus alleviate 83.1% of the cold startups, while OpenWhisk-Prewarm and SOCK alleviate 68.9% and 64.4% of that. Meanwhile, as Pagurus does not need to prewarm containers, there is no extra memory overhead introduced by the prewarm container pool with Pagurus.

As observed, SOCK and OpenWhisk-Prewarm only reduce a small percentage of cold startups for many functions (e.g., functions of *eco* and *cart*). This is because the functions tend to contend for the limited prewarmed containers. On the contrary, Pagurus alleviates the cold startups by forking other functions' zygote containers, without trapping in the same dilemmas. We can also find that Pagurus alleviates slightly fewer container cold startups for several functions, compared with SOCK and OpenWhisk-Prewarm. This is because these functions have low cold startup frequency by default, and SF-WRS policy does not tend to re-pack them into zygotes for achieving higher system-level cold startup alle-

Figure 11: The latency of starting up a prewarmed container in OpenWhisk-Prewarm and SOCK, and the latency of forking a zygote container in Pagurus.

viation. The percentage looks large when the original cold startup frequency is low, even if a small number of cold container startup is not eliminated.

In our experiment, 27.8% of the warm containers are turned into zygote containers, then are forked by other functions. When a function does not have a warm container for its queries, 60.5% of the obtained containers are forked.

8.3 Reducing Startup and E2E Latency

Figure 11 shows the latencies of starting a container from a prewarmed one (OpenWhisk-Prewarm and SOCK), and forking a zygote container (Pagurus). As observed, all the benchmarks have the shortest startup latencies with Pagurus.

If a function invocation is hosted by a helper container with Pagurus, the packages are ready beforehand, and only the user-specific code initialization is needed. Pagurus is able to fork a zygote container in 11ms, and completes the code initialization in 5ms.

With OpenWhisk-Prewarm, starting from prewarmed containers takes longer than directly cold startup a container from the image (e.g., functions in *ddns*, *pod*, and *rep*). SOCK reduces the latency of the prewarm startup leveraging the packages cached with higher benefit-to-cost.

Figure 12 shows the average end-to-end latency of each function normalized to its latency with prewarm-disabled

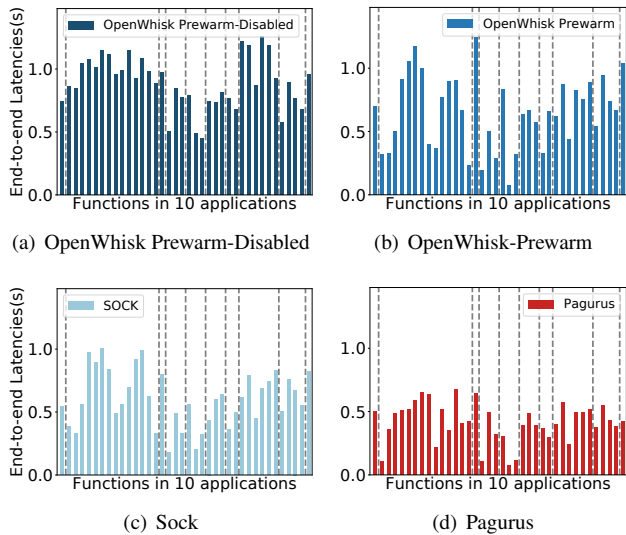

Figure 12: The end-to-end latencies of Prewarm-Disabled OpenWhisk, OpenWhisk Prewarm, SOCK and Pagurus.

OpenWhisk. Pagurus reduces the end-to-end latency of the benchmark functions by 475ms and 479ms on average, while OpenWhisk-Prewarm and SOCK reduce the end-to-end latency by 237ms and 286ms.

By mounting packages beforehand with privilege control, zygote containers can better reduce the startup latency, thus the end-to-end latency.

8.4 Large-scale Evaluation with Azure Trace

In this subsection, we evaluate Pagurus by replaying the Azure serverless trace [50] on a 31-node cluster. The software and hardware configuration of each node is the same as Table 1. We use all the 40,000 functions from the *day07* trace [12], generate function invocations, and randomly route the invocations to the 30 nodes.

The Package similarity in Pagurus is used to shrink the searching space for identifying to-be-helped candidates and reducing the re-packing overhead. However, the Azure trace does not provide package information for the functions, but only the function duration and invocation arrival time. Lacking the package information, it is impossible to evaluate the similarity-filtered WRS selection policy in Pagurus, nor OpenWhisk-Prewarm or SOCK. With no package information and similarity-filtered re-packing for Azure trace, Pagurus identifies to-be-helped candidates based on the basic WRS policy. We therefore only compare similarity-disabled Pagurus, with the prewarm-disabled OpenWhisk for the large-scale evaluation, to show the effectiveness of alleviating cold startups by simply replacing idle containers with zygotes.

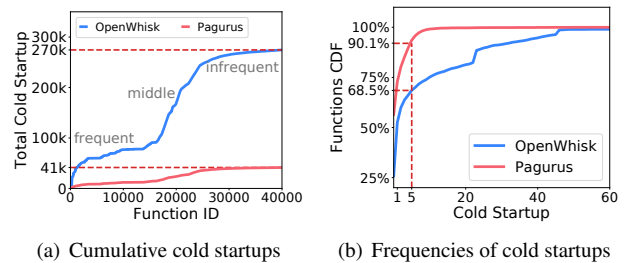

Figure 13: The effect of alleviating cold startup, and the CDF that functions suffer from different cold startup frequencies.

8.4.1 Alleviating Cold Startup

We report two user experience-related metrics in this experiment. First, how many cold startups are alleviated by Pagurus? Second, how many functions seldom experience cold startups (e.g., one cold startup) in one day with Pagurus?

Figure 13(a) shows the total number of cold startups with Pagurus and prewarm-disabled OpenWhisk (denoted by “OpenWhisk” for short in this subsection). In the figure, the functions are sorted in the descending order of their invocation frequencies. The smaller the function ID, the more frequent the function is invoked. As shown in the figure, Pagurus reduces the number of cold startups by 84.6%. We can also find that OpenWhisk results in the frequent cold startup for the functions of middle-popularity. It is because the warm containers of these middle-popularity functions tend to be recycled due to the relatively low invocation frequencies. Pagurus efficiently alleviates the cold startups for the middle-popularity functions through zygote containers.

Figure 13(b) shows the cumulative distribution of the functions with different container cold startup frequencies. As observed, 73.4% and 52.1% of all functions experience cold startup less than once in a day with Pagurus and OpenWhisk, respectively. Meanwhile, 90.1% of the functions experience cold startups less than 5 times daily with Pagurus. In the figure, sudden jumps happen around 24 and 48 cold startups for OpenWhisk. The jumps are caused by functions with a 1-hour or 30-minutes trigger in the trace.

Pagurus effectively alleviates the cold container startup, especially for middle-popularity and low-popularity functions in production. It greatly improves the user experience.

8.4.2 Reducing Tail Latency

Figure 14 shows the 95%-ile latencies of the 40,000 functions with Pagurus and OpenWhisk. The left y-axis shows the 95%-ile latencies of functions with Pagurus, and the right y-axis shows that with OpenWhisk normalized to the former. OpenWhisk results in longer 95%-ile latencies for most functions than Pagurus (the right y-axis is larger than 1).

We can also observe that popular functions (functions

Figure 14: The end-to-end 95%-ile latency of 40,000 functions with Pagurus and OpenWhisk.

Figure 15: The convergency and the percentages of cold startups alleviated by Pagurus with different $T_{default}$.

with ID smaller than 15,000) have similar 95%-ile latency with OpenWhisk and Pagurus. This is because the slowest 95%-ile invocations of these functions still experience warm startup, as these functions are frequently invoked. For the middle-popularity and low-popularity functions, their 95%-ile latencies are the latency of the function invocation that suffers from the cold container startup with OpenWhisk.

8.4.3 Impacts of Hyperparameters

In this experiment, we evaluate the impact of $T_{default}$ (the value is set as 60s by default), and the number of to-be-helped functions K , on Pagurus. Figure 15 shows the percentages of cold startups alleviated by Pagurus with different $T_{default}$ and different K . As observed, the performance of Pagurus is stable when $T_{default}$ varies. The performance of Pagurus is not sensitive to $T_{default}$.

We also find the number of to-be-helped functions, K , gradually converges to 8. Moreover, the appropriate value of K is not affected by $T_{default}$. For Azure workloads, Pagurus should generate a zygote for 8 to-be-helped functions on average. It is consistent with the calculated one in Equation 6. We also measure the impact of larger prewarm pool size in OpenWhisk, and find that the improvement becomes marginal but with significant resource waste.

8.5 Integrating with Orthogonal Techniques

The decoupled hierarchy design of Pagurus provides easy-to-use APIs for container orchestrators. Pagurus can be integrated with prior work on speeding up the cold startup.

Table 2: Overheads of the components in Pagurus

Sources	Type	Overheads (each node)
Intra-container manager	CPU overhead	0.345 core
	Memory overhead	228MB
	Storage overhead	485MB for each zygote image
Inter-function scheduler	CPU overhead	0.66 core (re-packing included)
	Memory overhead	315MB

Pagurus brings shorter end-to-end latency when it is integrated with Checkpoint/Restore [7] (denoted by C/R) and Catalyzer [28], respectively. With C/R, a container is recovered from a checkpoint image. With Catalyzer, more data are already loaded in the image stored in memory. By replaying the evaluation, we find that C/R+Pagurus reduces the cold startup time of the benchmarks by 78.9% on average compared with C/R; Catalyzer+Pagurus reduces the cold startup time by 15.1% on average compared with Catalyzer. Even if no appropriate forked zygote container returns, Pagurus does not slow down the container startup.

8.6 Overheads of Pagurus Components

In Pagurus, *packing zygote images, generating zygote containers from the images, and determining the to-be-helped functions* for each function introduce runtime overhead.

According to our measurement, each container in Pagurus uses smaller memory on average than OpenWhisk. The reduction originates from the design of the zygote container. Although packages are pre-installed in zygote containers, they are imported into memory only when a zygote container is forked. On the contrary, warm containers (private containers) always keep the packages in memory for low latency. The reduction of memory usage is not affected by the number of to-be-helped functions.

Table 2 shows the CPU, memory, and storage overhead caused by the intra-container managers and the inter-function schedulers when replaying the Azure trace. As reported, less than one core is required to run all the intra-container managers and the inter-function scheduler on a node. If fewer functions are executed on a node, the overhead will be smaller.

9 Conclusion

Pagurus alleviates cold startups with inter-function container sharing rather than popular prewarm-based methods. It comprises an intra-function manager for idle container identification and management, an inter-function scheduler for safe container scheduling, and a sharing-aware function balancer for resource-aware workload balancing. Our experimental results based on both real system benchmarks and Azure trace show that Pagurus significantly alleviates the cold container startup. The cold startup latency is reduced from hundreds of milliseconds to 16ms if Pagurus alleviates it.

Acknowledgment

We would thank our anonymous reviewers and shepherd, for their helpful comments and suggestions. A Artifact Appendix

A.1 Abstract

Our artifact includes the prototype implementation of Zygote-based mechanism in Pagurus, 10 masked applications (including 38 functions) benchmarks, and mapped functions from Azure Trace. The artifact provides experiment workflow scripts to perform the measurement.

A.2 Artifact Check-list (Meta-information)

- **Run-time Environment:** Ubuntu 18.04, Docker 20.10.6, CouchDB 3.2.2 and Python are required.
- **Data set:** The artifact uses 10 masked application benchmarks from AWS samples and Azure traces.
- **Execution workflows:** For reproducing our paper’s results, we provide the corresponding scripts for each evaluation section (from Section 8.2 to Section 8.4) to send queries, collect the execution metrics, and draw the comparison plots.
- **Time needed to complete:** see the instruction of each Exp.
- **Publicly available:** <https://github.com/lzjzx1122/Pagurus>
- **Code Licenses:** Apache-2.0 license

A.3 Hardware and Software Dependencies

- **Hardware:** The hardware is configured by {CPU: Intel Xeon(Ice Lake) Platinum 8369B @3.5GHz, Cores: 8, DRAM: 16GB, Disk: 200GB SSD with 4200 IOPS.}
- **Software environment:** Operating system: {Linux with kernel 4.15.0, Docker: {20.10.15}, Container runtime: {Python-3.6.9, Linux with kernel 4.15.7}, Nginx version: {nginx/1.10.3}, Database: {Couchdb with version 3.2.2}, runc version: {1.0.0-rc93}, containerd version: {1.4.4}, and Pagurus. Detailed software dependencies are all listed and scripted in the artifact.

A.4 How to Access and Install

GitHub link: <https://github.com/lzjzx1122/Pagurus>. Clone the GitHub repository and then run the quick setup script to deploy Pagurus.

A.5 Experiment and Expected Results

A.5.1 AWS applications (Section 8.2 and 8.3)

Under the path `Pagurus/aws/trace`, there are 18 different sampling test results for AWS applications, and the expected test results for each sampling are stored in the directory `aws/expected_result`. You can directly run `aws/plot.py` to generate the plots, or replay the trace using a testing script to run the AWS experiment:

```
$ python3 aws/run_experiments.py 1
```

Experiment customization: The above script performs the 1st sampling test with Openwhisk, Pagurus, OpenWhisk-Prewarm and SOCK. Other sampling tests can also be performed by changing "1" to other test numbers. To fully reproduce our result, it additionally takes at least 160-hours (20 tests with different sampling parameters) to generate the execution logs for 4 platforms. To ensure that the zygote repackaging mechanism and prewarm works efficiently, the running time should be at least 2-hours for both 4 platforms (8 hours for each test number).

After running the sampling tests under four platforms, the script will generate the results under `aws/result`. Run the following script to generate three .csv files:

```
$ python3 aws/summary_from_results.py
```

- `cold_start.csv` shows the remained cold startups of OpenWhisk, SOCK and Pagurus, compared with prewarm-disabled OpenWhisk (Figure 11).
- `startup_time.csv` shows latencies of starting up containers in prewarm-disabled OpenWhisk, OpenWhisk and SOCK, respectively. It also contains latencies of forking zygote containers in Pagurus (Figure 12).

- `e2e_latency.csv` shows e2e latencies of benchmarks in Pagurus, SOCK, OpenWhisk, and prewarm-disabled OpenWhisk, respectively. (Figure 13).

Then run the following script to generate the plots:

```
$ python3 aws/plot_from_results.py
```

A.5.2 Azure Trace mapping (Section 8.4)

In the Azure trace experiment (Day07), invoke more than 40,000 functions will take 24 hours and more than 800 vCPUs by default. To reduce the computation resources needed, we randomly select about 4,000 functions to generate several small-scale Azure traces under the path `Pagurus/azure/trace`. The functions in each small-scale trace are all different from each other. A larger trace with more functions can be replayed if only more computation resources or nodes are provided.

Considering that the experiment will take about 24 hours, we already pre-run each small-scale Azure trace and save their execution results. You can directly run `azure/plot.py` to generate the plots, or replay the trace using the following script:

```
$ python3 azure/run_experients.py 1
```

Experiment customization: Each small-scale Azure trace can be replayed by changing "1" to other trace numbers. The script will replay the trace in Openwhisk and Pagurus, respectively, and then generate results under `azure/result`. Run the following script to generate two `.csv` files:

```
$ python3 azure/summary_from_results.py
```

- `cold_start.csv` shows the remained cold startups of OpenWhisk and Pagurus, respectively (Figure 14).
- `e2e_latency.csv` shows end-to-end 95%-ile latencies of benchmarks in Openwhisk and Pagurus, respectively (Figure 15).

Then run the following script to generate the plots:

```
$ python3 azure/plot_from_results.py
```

RRC: Responsive Replicated Containers

Diyu Zhou
UCLA and EPFL

Yuval Tamir
UCLA

Abstract

Replication is the basic mechanism for providing application-transparent reliability through fault tolerance. The design and implementation of replication mechanisms is particularly challenging for general multithreaded services, where high latency overhead is not acceptable. Most of the existing replication mechanisms fail to meet this challenge.

RRC is a fully-operational fault tolerance mechanism for multiprocessor workloads, based on container replication. It minimizes the latency overhead during normal operation by addressing two key sources of this overhead: (1) it decouples the latency overhead from checkpointing frequency using a hybrid of checkpointing and replay, and (2) it minimizes the pause time for checkpointing by forking a clone of the container to be checkpointed, thus allowing execution to proceed in parallel with checkpointing. The fact that *RRC* is based on checkpointing makes it inherently less vulnerable to data races than active replication. In addition, *RRC* includes mechanisms that further reduce the vulnerability to data races, resulting in high recovery rates, as long as the rate of manifested data races is low. The evaluation includes measurement of the recovery rate and recovery latency based on thousands of fault injections. On average, *RRC* delays responses to clients by less than 400 μ s and recovers in less than 1s. The average pause latency is less than 3.3ms. For a set of eight real-world benchmarks, if data races are eliminated, the performance overhead of *RRC* is under 48%.

1 Introduction

For many applications hosted in data centers, high reliability is a key requirement, demanding fault tolerance. The key desirable properties of a fault tolerance mechanism, especially for server applications, are: A) Low throughput and latency overheads; B) Support for multithreaded applications; and C) Application transparency. Replication, has long been used to implement application-transparent fault tolerance, especially for server applications.

The two main approaches to replication, specifically, duplication, are: (1) high-frequency checkpointing of the primary replica state to a passive backup [33], and (2) active replication, where the primary and backup both execute the application [38, 47]. A key disadvantage of the first approach is that, for consistency between server applications and their clients after failover, outputs must be delayed before being released to the client, typically for tens of milliseconds. Such delays are unacceptable for many server applications.

To support active replication of multiprocessor workloads,

where there are many sources of nondeterminism, active replication is implemented using a leader-follower algorithm. With this algorithm, the outcomes of identified nondeterministic events on the primary, namely synchronization operations and certain system calls, are recorded and sent to the backup. This allows the backup to deterministically replay their outcomes [38, 47]. A disadvantage of this approach is that it is vulnerable to even rare replay failures due to untracked nondeterministic events, such as those caused by data races. Another disadvantage is that, for application with a high rate of synchronization operations, the replay on the backup may be significantly slower than the execution on the primary, resulting in high throughput overhead [38]. This is due to the interaction between thread scheduling by the OS and the need to mirror on the backup the execution on the primary.

This paper presents a fault tolerance scheme, based on container replication, called *RRC* (Responsive Replicated Containers). *RRC* targets server applications and is thus optimized to minimize response latency overhead. *RRC* overcomes the disadvantages of existing approaches using a combination of periodic checkpointing [33, 62] and externally-deterministic replay [29]. The primary sends periodic checkpoints to the passive backup. While executing, the primary logs to the backup the outcomes of nondeterministic events. Upon failure, the backup restores the latest checkpoint and deterministically replays the execution up to the last external output. Hence, external outputs only need to be delayed by the short amount of time it takes to send and commit the relevant portion of the nondeterministic event log to the backup.

RRC minimizes request-reply latency overhead, not only for the average case, but also the tail latency overhead. To that end, *RRC* had to overcome a key challenge, namely, that while the state of the primary is collected for transmission to the backup, execution has to be paused. Even with various optimizations, this latency is often tens of milliseconds, largely due to the cost of retrieving in-kernel state associated with the container, such as the state of open file descriptors [62]. To meet this challenge, *RRC* introduces a new kernel primitive: container fork. For checkpointing, *RRC* pauses the primary container, forks a shadow container, and resumes execution. This results in pause times of less than 3.5ms. The checkpoint is obtained from the shadow container.

RRC decouples the response latency from the checkpointing duration. This enables high performance by allowing the tuning of epoch duration to trade off performance and resource overheads with recovery latency and vulnerability to untracked nondeterministic events. The latter is important

since applications may contain data races (§3, §6.3). *RRC* is focused on dealing with data races that rarely manifest and are thus more likely to remain undetected (§3). Since *RRC* only requires replay during recovery and for the short interval since the last checkpoint, it is inherently more resilient to data races than active replication schemes that rely on replay of the entire execution [38]. Furthermore, *RRC* includes timing adjustment mechanisms that result in a high recovery rate even for applications that include data races, as long as their rate of unsynchronized writes is low (§4.7).

RRC also decouples the performance on the primary from the backup. Thus, unlike active replication schemes [38], the backup is not a performance bottleneck (§6.1).

Replication can be at the level of VMs [27, 33, 35, 53, 58], processes [32, 38, 47], or containers [62]. Containers have advantages over VMs due to smaller memory and storage footprints, faster startup, and avoiding the need to manage updates of multiple VMs [25, 45]. Furthermore, containers are the best fit for mechanisms such as *RRC*. Applying *RRC*'s approach to VMs would be complicated since there would be a need to track and replay nondeterministic events in the kernel. On the other hand, with processes, it is difficult to avoid potential name conflicts (e.g., process IDs) upon failover. While such name conflicts can be solved, the existing container mechanism already solves them efficiently.

The implementation of *RRC* involved developing solutions to implementation challenges that have not been addressed by prior works. The most important of these is dealing with the integration of timer-triggered checkpointing, that is not synchronized with the application, and user-level recording of nondeterministic events (§4.2). *RRC* also efficiently handles the failover of TCP connections through checkpoint restoration, a replay phase, and finally resumption of live execution (§4.3, §4.4). *RRC* is application-transparent and does not require any changes to the application code.

We have implemented a prototype of *RRC* and evaluated its performance and reliability. With 1s epochs, *RRC*'s throughput and average latency overheads were less than 49% and 230 μ s, respectively, for all eight benchmarks. With 100ms epochs, the corresponding overheads were less than 53% and 291 μ s for seven benchmarks, 86% and 264 μ s for the eighth. *RRC* is designed to recover from fail-stop faults. We used thousands of fault injections to validate and evaluate *RRC*'s recovery mechanism. For all eight benchmarks, after data races identified by ThreadSanitizer [6] were resolved, *RRC*'s recovery rate was 100% for 100ms and 1s epochs. Three of the benchmarks originally included data races. For two of these, without any modifications, with 100ms epochs and *RRC*'s timing adjustments, the recovery rate was over 99.1%.

RRC achieves both low response latency overhead and resilience to infrequently-manifested data races. This combination provides a fundamental advance over both Remus-based techniques [33] and active replication [38, 47], respectively. Specifically, we make the following contributions: 1) a

fault tolerance scheme based on container replication, using a unique combination of periodic checkpointing, deterministic replay, and an optimized scheme for failover of network connections; 2) a new system call, container fork, used to minimize tail latency overhead; 3) a replication mechanism with inherent resilience to untracked nondeterministic events, further enhanced by mechanisms that increase recovery success rate in the presence of data races; 4) a thorough evaluation of *RRC* with respect to performance overhead, resource overhead, and recovery rate, demonstrating the lowest reported external output delay compared to competitive mechanisms.

Section 2 presents two key building blocks for *RRC*: NiLiCon [62] and deterministic replay [21, 29, 44, 50, 57]. An overview of *RRC* is presented in §3. *RRC*'s implementation is described in §4, with a focus on key challenges. The experimental setup and evaluation are presented in §5, and §6, respectively. Limitation of *RRC* and of our prototype implementation are described in §7. §8 provides a brief overview of related work.

2 Background

RRC integrates container replication based on periodic checkpointing [33, 62], described in §2.1, and deterministic replay of multithreaded applications, described in §2.2.

2.1 NiLiCon

Remus [33] introduced a practical application-transparent fault tolerance scheme based on VM replication using high-frequency checkpointing. NiLiCon [62] is an implementation of the Remus mechanism for containers. A key challenge faced by NiLiCon is that, compared to VMs, there is much tighter coupling between the container state and the state of the underlying platform. NiLiCon meets this challenge, based on a tool called CRIU (Checkpoint/Restore in User Space) [4], with novel optimizations that significantly reduce overhead. CRIU checkpoints and restores the user-level and kernel-level state of a container, except for disk state. NiLiCon handles disk state by adding system calls to checkpoint and restore the page cache and a modified version of the DRBD module [8]. NiLiCon relies on CRIU to preserve established TCP connections across failover, using a special repair mode of the socket provided by the Linux kernel [18].

2.2 Deterministic Replay on Multiprocessors

Deterministic replay is the reproduction of some original execution in a subsequent execution. During the original execution, the results of nondeterministic events/actions are recorded in a log. This log is used in the subsequent execution [29]. With a uniprocessor, nondeterministic events include: asynchronous events, such as interrupts; system calls, such as *gettimeofday()*; and inputs from the external world.

With shared-memory multiprocessors, there is a higher frequency of nondeterministic events related to the order of

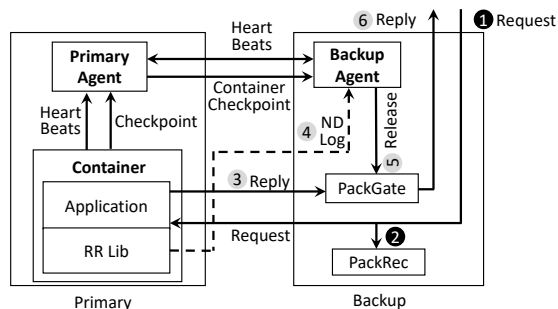

Figure 1: Architecture and workflow of *RRC*.

accesses to the same memory location by different processors. For such systems, a common approach is to support deterministic replay only for programs that are data-race-free [49]. For such programs, as long as the results of synchronization operations are deterministically replayed, the ordering of shared memory accesses are preserved. The recording of nondeterministic events can occur at different levels: hardware [40,59], hypervisor [36,37,41], OS [39,43], or library [49,54]. Without dedicated hardware support, it is advantageous to record the events at the user level, thus avoiding the overhead for entering the kernel or hypervisor [44].

To support seamless failover with replication, it is sufficient to provide *externally deterministic replay* [44]. This means that, with respect to what is visible to external clients, the replayed execution is identical to the original execution. Furthermore, the internal state at the end of replay must be a state that corresponds to a possible original execution that could result in the same external behavior. This latter requirement is needed so that the replayed execution can transition to consistent live execution at the end of the replay phase.

3 Overview of *RRC*

RRC provides fault tolerance by maintaining a primary-backup pair with an inactive backup that takes over when the primary fails. Execution on the primary is divided into epochs and the primary state is checkpointed to an inactive backup at the end of each epoch [33,62]. Upon failure of the primary, the backup begins execution from the last primary checkpoint and then deterministically replays the primary's execution of its last partial epoch, up to the last external output. The backup then proceeds with live execution. To support the backup's deterministic replay, *RRC* ensures that, before an external output is released, the backup has the log of nondeterministic events on the primary since the last checkpoint. Thus, external outputs are delayed only by the time it takes to commit the relevant last portion of the log to the backup.

Figure 1 shows the overall architecture of *RRC*. The primary records nondeterministic events: operations on locks and nondeterministic system calls. The record and replay are done at the user level, by instrumentation of glibc source code. When the primary executes, the instrumented code invokes functions in a dedicated RR (Record and Replay) library that create logs used for replay. There is a separate log for each

Figure 2: Timeline of an epoch on the primary replica.

lock. For each thread, there is a log of the nondeterministic system calls it invoked, with their arguments and return values. Details are presented in §4.1.

Figure 1 shows the processing of requests and replies for server applications. (1) Client requests are sent to the backup. (2) To support TCP failover, the backup records incoming packets and forwards them to the primary. (3) Replies from the primary are forwarded to the backup and blocked by the *PackGate* queueing discipline kernel module. (4) The primary sends the nondeterministic event log to the backup. (5) Upon receiving the log, *PackGate* releases the corresponding replies.

Figure 2 shows a timeline of each epoch on the primary replica. First, the container is paused and a container fork is performed. Execution is then resumed. The first write to a page results in a Copy On Write (COW) so that the state of the forked shadow container is maintained. Concurrently, the pages modified since the last checkpoint are copied to a staging buffer (*MEM COPY*). Once this copy is completed, the original container ceases to perform the COW operations. A container checkpoint includes in-kernel state associated with the container, such as the state of open file descriptors [62]. This state is obtained from the shadow container and written to the staging buffer (*Other COPY*). The entire checkpoint is then sent from the primary to the backup.

RRC is based on having the ability to identify all sources of nondeterminism that are potentially externally visible, record their outcomes, and replay them when needed. Thus, unsynchronized accesses to shared memory during the epoch in which the primary fails may cause replay on the backup to fail to correctly reproduce the primary's execution, leading the backup to proactively terminate. This implies that applications are expected to be free of data races. However, not all multithreaded programs meet this expectation. Furthermore, precise race detection is NP-hard [48]. Hence, it is not possible to ensure that all data races are detected and eliminated. Fortunately, frequently-manifested data races are detectable using tools such as ThreadSanitizer [6]. Hence, only rarely-manifested data races are likely to remain in applications.

Since *RRC* only requires replay of short intervals (up to one epoch), it is inherently more tolerant to rarely-manifested data races than schemes that rely on accurate replay of the entire execution [38]. As an addition to this inherent advantage of *RRC*, *RRC* includes optional mechanisms that significantly increase the probability of correct recovery despite data races, as long as the manifestation rate is low (§4.7). During execution on the primary, these mechanisms record the order and timing of returns from nondeterministic system calls by *all* the threads. During replay, the recorded order and relative

timing are enforced.

If the primary fails, network connections must be maintained and migrated to the backup [19, 20, 22, 60]. Like CoRAL [19, 20], requests are routed through backup by advertising the service IP address in the backup. Unlike FT-TCP [22, 60] or CoRAL, replies are also routed through the backup, resulting in lower latency (§4.3).

As with most other state replication work [33, 53, 58, 62], *RRC* assumes fail-stop faults. Either the primary or the backup may fail. Heartbeats are exchanged between the primary and backup so failures are detected as missing heartbeats. Thus, *RRC* relies in the synchrony assumption [34] with respect to both the hosts and the network. If the backup fails, the primary configures its network, advertises the service IP address, and communicates with the clients directly. To maintain redundancy, a new backup needs to be instantiated and take over the service IP address.

4 Implementation

This section presents the implementation of *RRC*, focusing on the mechanisms used to overcome key challenges. *RRC* is implemented mostly at the user level but also includes small modifications to the kernel. At the user level, the implementation includes: agent processes on the primary and backup hosts that run outside the replicated container; a special version of the glibc library (that includes Pthreads), where some of the functions are instrumented (wrapped), used by the application in the container; and a dedicated RR (record and replay) library, that provides functions that actually perform the record and replay of nondeterministic events, used by the application in the container.

The kernel modifications include: an ability to record and enforce the order of access to key data structures (§4.1); support for a few variables shared between the kernel and RR library, used to coordinate checkpointing with record and replay (§4.2); a new queueing discipline kernel module used to pause and release network traffic (§4.3); and container fork (§4.6).

In the rest of this section, §4.1 presents the basic record and replay scheme. §4.2 deals with the challenge of integrating checkpointing with record and replay. §4.3 presents the handling of network traffic. The transition from replay to live execution is discussed in §4.4. The performance-critical operation of transmitting the nondeterministic event log to the backup is explained in §4.5. Container fork is presented in §4.6. §4.7 presents our best-effort mechanism for increasing the probability of correct replay in the presence of infrequently-manifested data races.

4.1 Nondeterministic Events Record/Replay

To minimize overhead and implementation complexity, *RRC* records synchronization operations and system calls at the user level. This is done by code added in glibc before (*before*

hook) and after (*after hook*) the original code. Recording is done in the after hook, replay is in the before hook.

For each lock, there is a log of lock operations in the order of returns from those operations. The log entry includes the ID of the invoking thread and the return value. The return values are recorded to handle the *trylock* variants as well as errors. During replay, synchronization operations must actually be performed in order to properly enforce the correct semantics. For each lock, the ordering of successful lock acquires is enforced. Since there is no need to enforce ordering among different locks, it is sufficient to maintain a separate log for each lock.

For each thread, there is a log of invoked system calls. The log entry includes the parameters and return values. During replay, the recorded parameters are used to detect divergence (replay failure). For some functions, such as *gettimeofday()*, replay does not involve the execution of the function and the recorded return values are returned. However, as discussed in §4.4, functions, such as *open()*, that involve the manipulation of kernel state, are actually executed during replay.

There can be dependencies among system calls, even if they are invoked by different threads. For example, this is the case for system calls whose execution involve writes and reads from kernel data structures, such as the file descriptor table. Hence, simply maintaining a separate log for each thread is not sufficient. To handle such cases, the kernel was modified to maintain an access sequence number for each such shared kernel resource. Each thread registers the address of a per-thread variable with the kernel. When the thread executes a system call accessing a shared resource, the kernel increments the sequence number and copies its value to the registered address. At the user level, this sequence number is attached to the corresponding system call log entry. During replay, the before and after hooks enforces the recorded execution order.

4.2 Integrating Checkpointing with Record/Replay

Checkpointing is triggered by a timer external to the container [62], and is thus not synchronized with the recording of nondeterministic events on the primary. This has the potential of resulting in a checkpoint and log contents on the backup from which correct replay cannot proceed. One example is that the checkpoint may include a thread in the middle of executing code in the RR library, resulting in the backup, during replay, attempting to send the nondeterministic event log to the backup. A second example is that there may be ambiguity at the backup as to whether a particular system call, such as *open()*, was executed after the checkpoint and thus needs to be reexecuted during replay, or executed before the checkpoint and thus should not be reexecuted during replay.

A naive solution to the above problem would be to delay the checkpointing of a thread if it is in execution anywhere between the beginning of the before hook and the end of

the after hook. However, this could delay checkpointing for arbitrarily long time if a thread is blocked on a system call, such as *read()*.

The actual solution in *RRC* has two properties: (I) checkpointing of a thread is delayed if the thread is *within* the before hook or *within* the after hook, and (II) checkpointing of a thread can occur even if the thread is between the end of the before hook and the beginning of the after hook.

To enforce property (I), each thread registers with the kernel the address of a per-thread *in_rr* variable. In user mode, the RR library sets/clears the *in_rr* when it respectively enters/leaves the hook function. An addition to the kernel code prevents the thread from being paused if the thread's *in_rr* flag is set.

To deal with property (II), *RRC* includes mechanisms to: (A) detect that this scenario has occurred, and (B) eliminate the potential ambiguities, such as the one mentioned above and take appropriate actions during replay. To implement the required mechanisms, *RRC* uses three variables: two per-thread flags – *in_hook* and *syscall_skipped*, as well as a global *current_phase* variable [63]. These variables are shared between the user level and the kernel. In the record phase, *in_hook* is set in the before hook and cleared in the after hook – this is mechanism (A) above.

For mechanism (B), *syscall_skipped* is used, during the replay phase, to determine whether, during the record phase, the checkpoint was taken before or after executing the system call. During the record phase, this flag is cleared during initialization and is not otherwise read or written. With CRIU (§2.1), if a checkpoint is triggered while a thread is executing a system call, before that call performs any state changes, the system call is retried after the checkpoint is restored. In the replay phase, at an early point in the kernel code executing a system call, if *in_hook* is set, the system call is skipped and *syscall_skipped* is set. Thus, if the system call was not executed before the checkpoint, it will be initially skipped during replay. During replay, if the after hook finds that *in_hook* and *syscall_skipped* are set, it passes control back to the before hook and the system call is then replayed or re-executed.

The handling of lock operations is similar to the handling of system calls. In the after hook, if *in_hook* is set, the lock is released and control is passed to the before hook, thus allowing enforcement of the order of lock acquires.

4.3 Handling Network Traffic

The current *RRC* implementation assumes that all network traffic is via TCP. To ensure failure transparency with respect to clients, there are three requirements that must be met: (1) client packets that have been acknowledged must not be lost; (2) packets to the clients that have not been acknowledged may need to be resent; (3) packets to the clients must not be released until the backup is able to recover the primary state past the point of sending those packets.

Requirements (1) and (2) have been handled in connection with other mechanisms, such as [20, 60]. With *RRC*, this is done by routing incoming and outgoing packets through the backup (§3). Incoming packets are recorded by the PackRec thread in the agent. Outgoing packets are sent to the backup as part of the nondeterministic event log.

The PackGate kernel module on the backup is used to meet requirement (3). PackGate maintains a release sequence number (*RSN*) for each TCP stream. When the primary container sends an outgoing message, the nondeterministic event log it sends to the backup (§3) includes a release request that updates the stream's *RSN*. The outgoing packets with sequence numbers lower than the *RSN* are then released.

PackGate is implemented in the kernel since it operates frequently and must thus be efficient. PackGate maintains fairness among the TCP streams using a FIFO queue of release requests ordered by the order of sends.

4.4 Transition to Live Execution

As with [38, 43] and unlike the deterministic replay tools for debugging [44, 55–57], *RRC* needs to transition from replay mode to live mode. This occurs when the backup replica finishes replaying the nondeterministic event log, specifically, when the last system call that generated an external output during the original execution is replayed. To identify this last call, after the checkpoint is restored, the RR library scans the nondeterministic event log and counts the number of system calls that generated an external output. Once replay starts, this count is atomically decremented and the transition to live execution is triggered when the count reaches 0.

To support live execution, after replay, the kernel state must be consistent with the state of the container and with the state of the external world. For most kernel state, this is achieved by actually executing during replay system calls that change kernel state. For example, this is done for system calls that change the file descriptor table, such as *open()*, or change the memory allocation, such as *mmap()*. However, this approach does not work for system calls that interact with the external world. Specifically, in the context of *RRC*, these are reads and writes on sockets associated with a connection to an external client. As discussed in §4.1, such calls are replayed from the nondeterministic event log. However, there is still a requirement of ensuring that, before the transition to live execution, the state of the socket, e.g., sequence numbers, must be consistent with the state of the container and with the state of external clients.

To overcome the above challenge, when replaying system calls that affect socket state, *RRC* records the state changes on the sockets based on the nondeterministic event logs. When the replay phase completes, *RRC* updates all the sockets based on the recorded state. Specifically, the relevant components of socket state are: the last sent sequence number, the last acknowledged (by the client) sequence number, the last re-

ceived (from the client) sequence number, the receive queue, and the write queue. The initial socket state is obtained from the checkpoint. The updates to the sent sequence number and the write queue contents are determined based on writes and sends in the nondeterministic event log. For the rest of the socket state, *RRC* cannot rely on the event log since some packets received and acknowledged by the kernel may not have been read by the application. Instead, *RRC* uses information obtained from PackRec (§4.3).

With respect to incoming packets, once the container transitions to live execution, *RRC* must provide to the container all the packets that were acknowledged by the primary but were not read by applications. During normal operation, on the backup host, PackRec keeps copies of incoming packets while PackGate extracts the acknowledgment numbers on each outgoing stream. If the primary fails, PackGate stops releasing outgoing packets and it thus has the last acknowledged sequence number of each incoming stream. PackRec obtains the last acknowledged sequence number of each stream from PackGate and stops recording when it has all the required (acknowledged) incoming packets. Before the container is restored on the backup, PackRec copies the recorded incoming packets to a log. Using the information from the nondeterministic event log and PackRec, before the transition to live execution, the packet repair mode (§2.1) is used to restore the socket state so that it is consistent with the state of the container and the external world.

4.5 Transferring the Event Logs

Whenever the container on the primary sends a message to an external client, it must collect the corresponding entries from the multiple nondeterministic event logs (§4.1) and send them to the backup (§3). Hence, the collection and sending of the log is a frequent activity, which is thus performance critical. Specifically, with our initial implementation, with the *Memcached* benchmark under maximum load, the throughput overhead was approximately 300%.

To address the performance challenge above, *RRC* offloads the transfer of the nondeterministic event log from the application threads to a dedicated *logging thread* added by the RR library to the application process (as in [47]). With available CPU cycles, such as additional cores, this minimizes the overhead for the application threads. Furthermore, if multiple application threads generate external messages at approximately the same time, the corresponding multiple transfers of the logs are batched together, further reducing the overhead. When an application thread sends an external message, it notifies the logging thread via a shared ring buffer. The logging thread continuously collects all the notifications in the ring buffer and then collects and sends the nondeterministic logs to the backup. To reduce CPU usage and enable more batching, the logging thread sleeps for the minimum time allowed by the kernel between scans of the buffer.

To maximize performance, *RRC* allows concurrent access to different logs. One application thread may log a lock operation concurrently with another thread that is logging a system call, while the logging thread is collecting log entries from a third log for transfer to the backup. This enables the logging thread to collect entries from different logs out of execution order. Thus, there is the potential for the log transferred to the backup for a particular outgoing message to be incomplete – missing an entry for an event on which the outgoing message depends. This can lead to replay failure.

There are two key properties of *RRC* that help address the correctness challenge above: (A) there is no need to replay the nondeterministic event log beyond the last system call that outputs to the external world, and (B) when an application thread logs a system call that outputs to the external world, all nondeterministic events on which this system call may depend are already logged in nondeterministic event logs.

To exploit the two properties above, the RR library maintains two corresponding global sequence numbers: *primary batch sequence number* (PBSN) and *backup batch sequence number* (BBSN) in the primary and backup, respectively. They are both initialized to 0. Application threads attach the PBSN to the entries they log for nondeterministic events. When the logging thread picks up an entry from the aforementioned ring buffer, that is a request to collect and send the current event log. Before taking any other action, the logging thread scans the ring buffer to determine the number of pending requests. It then increments the PBSN by that number. Thus, every event log entry that is created after the logging thread begins collecting the log, has a higher PBSN tag. After the logging thread sends the log, it sends to the backup a message that directs the backup to increment the BBSN by the most recent increment of the PBSN. If the primary fails, before replay is initiated on the backup, all the nondeterministic event logs collected during the current epoch are scanned and the entries for system calls that output to the external world are counted *if* their attached sequence number is not greater than the BBSN. During replay, this count is decremented for each such system call replayed. When it reaches 0, replay terminates and live execution commences.

4.6 Container Fork

The new container fork (*cfork*) system call is based on the existing process *fork*. Given a process ID in a container, *cfork* duplicates the container state shared among its processes and threads: namespaces (e.g., mount points, network interfaces) and control groups. *Cfork* then duplicates all the processes and their threads in the container and assigns them to the new container. *Fork* duplicates the file descriptor state, but does not duplicate the underlying state, such as socket state or pipe state. However, *cfork* does duplicate this underlying state.

The implementation of *cfork* for *RRC* includes optimizations to minimize the container fork time. We identified two

major sources of overhead: (1) duplicating the namespaces and control groups, and (2) page table copy. To minimize (1), *RRC* exploits the fact that most namespace and control group state rarely changes after initialization [62]. Thus, at the first checkpoint, *RRC* creates a staging container with an idle process. *Cfork* assigns the forked container to the namespace and control group of the staging container instead of creating new ones. To ensure correctness, *RRC* detects state changes of the namespaces and control groups of the service container using hooks, added with *ftrace* to the kernel functions that can change the namespace and cgroup state. *Cfork* updates those changes to the staging container. *Ftrace* only incurs overhead if a hooked function is invoked. Since the namespace and cgroup states rarely change, such functions are rarely invoked and *ftrace* does not incur high overhead.

To minimize the latency of the page table copy, *RRC* avoids copying the page table of the data region of the RR library, whose size can be up to several gigabytes and thus takes tens of milliseconds to copy. Specifically, the RR library tags the VMA of the data region with a new special flag and thus informs the *cfork* to skip copying its page table. This optimization is correct because *RRC* does not need to checkpoint the data region of the RR library; its state is initialized upon replay by reading the saved nondeterministic logs in the backup.

4.7 Mitigating the Impact of Data Races

As discussed in §3, *RRC* includes mechanisms that significantly increase the probability of successful recovery in the presence of rarely-manifested data races. Specifically, *RRC* mitigates the impact of data races by adjusting the relative timing of the application threads during replay to approximately match the timing during the original execution. As a first step, in the record phase, the RR library records the order and the TSC (time stamp counter) value when a thread leaves the after hook of a system call. In the replay phase, the RR library enforces the recorded order on threads before they leave the after hook. As a second step, during replay, the RR library maintains the TSC value corresponding to the time when the after hook of the last-replayed system call was exited. When a thread is about to leave a system call after hook, the RR library delays the thread until the difference between the current TSC and the TSC of that last-replayed system call is larger than the corresponding difference in the original execution. System calls are used as the basis for the timing adjustments since they are replayed (not executed) and are thus likely to cause the timing difference. This mechanism is evaluated in §6.3.

5 Experimental Setup

All the experiments were hosted on Fedora 29 with the 4.18.16 Linux kernel. The containers were hosted using runC [12] (version 1.0.1), a popular container runtime used in Docker. The primary and backup replicas were hosted on different

36-core servers, using modern Xeon chips. These hosts were connected to each other through a dedicated 10Gb Ethernet link. The clients were hosted on a 10-core server, based on a similar Xeon chip. The client host was in a different building, interconnected through a Cisco switch, using 1Gb Ethernet.

Five benchmarks were in-memory databases handling short requests: *Redis* [13], *Memcached* [10], *SSDB* [15], *Tarantool* [16] and *Aerospike* [2]. These benchmarks were evaluated with 50% read and 50% write requests to 100,000 100B records, driven by *YCSB* [31] clients. The number of user client threads ranged from 60 to 480. The evaluation also included a web server, *Lighttpd* [7], and two batch PARSEC [26] benchmarks: *Swaptions* and *Streamcluster*. *Lighttpd* was evaluated using 20-40 clients retrieving a 1KB static page. For *Lighttpd*, benchmarking tools SIEGE [14], ab [1] and wget [5] were used to evaluate, respectively, the performance overhead, response latency, and recovery rate. *Swaptions* and *Streamcluster* were evaluated using the native input test suites. We evaluated only two benchmarks from the PARSEC suite since *RRC* targets server applications and its design is thus focused on low latency overhead. Low latency overhead is not relevant for the batch applications, such as those included in the PARSEC suite. Nonetheless, we show that such applications can be handled by *RRC* with very low throughput overhead.

We used fault injection to evaluate *RRC*'s recovery mechanism. Since fail-stop failures are assumed, a simple failure detector was sufficient. Failures were detected based on heart beats exchanged every 30ms between the primary and backup hosts. The side not receiving heart beats for 90ms identified the failure of the other side and initiates recovery.

For *Swaptions* and *Streamcluster*, recovery was “successful” if the output was identical to the golden copy. For *Lighttpd*, we used multiple wget instances that concurrently fetched a static page. Recovery was “successful” if all the fetched pages were identical to the golden copy. For the in-memory database benchmarks, we developed customized clients, using existing client libraries [3, 9, 11, 17], that spawn multiple threads and let each thread work on separate set of database records. Each thread records the value it stores with each key, compares that value with the value returned by the corresponding get operation and flags an error if there is a mismatch. Recovery was considered successful if no errors were reported.

For the fault injection experiments, for server programs, the clients were configured to run for at least 30 seconds and drive the server program to consume around 50% of the CPU cycles. A fail stop failure was injected at a random time within the middle 80% of the execution time, using the *sch_plug* module to block network traffic on all the interfaces of a host. To emulate a real world cloud computing environments, while also stressing the recovery mechanism, we used a *perturb* program to compete for CPU resources on the primary host. The *perturb* program busy loops for a random time between 20 to 80 ms and sleeps for a random time between 20 to 120ms. During fault injection, a *perturb* program instance

was pinned to each core executing the benchmark.

6 Evaluation

This section presents *RRC*'s performance overhead and CPU usage overhead (§6.1), the added latency for server responses (§6.2), as well as the recovery rate and recovery latency (§6.3). Two configurations of *RRC* are evaluated: *RRC-SE* (short epoch) and *RRC-LE* (long epoch), with epoch durations of 100ms and 1s, respectively. Setting the epoch duration is a tradeoff between the lower overhead with long epochs and the lower susceptibility to data races and lower recovery time with short epochs. Hence, *RRC-LE* may be used if there is high confidence that the applications are free of data races. Thus, with the *RRC-SE* configuration, the data race mitigation mechanism described in §4.7 is turned on, while it is turned off for *RRC-LE*.

RRC is compared to NiLiCon (§2.1) with respect to the performance overhead under maximum CPU utilization and the server response latency. NiLiCon is configured to run with an epoch interval of 30ms, as in [62]. The short epochs of NiLiCon are required since, unlike *RRC*, the epoch duration with NiLiCon determines the added latency in replying to client requests (§2.1). Thus, for many server applications, even with 30ms epochs, NiLiCon provides unacceptably long response latencies. In all cases, the “stock setup” is the application running in an unreplicated container.

Some server applications can be configured to enable their own custom fault tolerance mechanisms. However, developing and validating such mechanisms is time consuming and error prone. Hence, mechanisms, such as *RRC*, that can be deployed for many applications, are likely to be of higher quality (reliability) and incur lower total development cost. Table 1 compares the overhead of *RRC* with the custom mechanisms of three of our benchmarks (§5). The custom mechanisms are all configured to provide *strong consistency* (outputs are not released until the changes are reflected in the backup), which *RRC* also provides. The results show that *RRC-LE* actually has lower throughput overhead. On average, the custom mechanisms do result in lower response latency. This is mainly due to their ability to release the outputs of read requests without waiting for acknowledgments from the backup. However, on average, the overall results are comparable.

6.1 Overheads: Performance, CPU Utilization

Two key overhead measures of *RRC* are: for a fixed amount of work, the increase in execution time and the increase in the utilization of CPU cycles. These measures are distinct

Figure 3: Performance overheads: NiLiCon, *RRC-SE*, *RRC-LE*.

since many of the actions of *RRC* are in parallel with the main computation threads.

For the six server benchmarks, the measurements reported in this subsection were done with workloads that resulted in maximum CPU utilization for the cores running the application worker threads¹ with the stock setup.

With four of the server benchmarks, the number of the worker threads cannot be configured (*Lighttpd*, *Redis*: 1, *Tarantool*: 2, *SSDB*: 12). The remaining four benchmarks were configured to run with four worker threads.

For each benchmark, the workload that saturates the cores in the stock setup was used for the stock, *RRC*, and NiLiCon setups. With NiLiCon, due to its large latency overhead (§6.2), it is impossible to saturate the server with this setup. Hence, for the NiLiCon measurements in this subsection, the buffering of the server responses was removed. This is not a valid NiLiCon configuration, but it provides a comparison of the overheads excluding buffering of external outputs.

Performance overhead. The performance overhead is reported as the percentage increase in the execution time for a fixed amount of work compared to the stock setup. Figure 3 shows the performance overheads of NiLiCon, *RRC-SE*, and *RRC-LE*, with the breakdown of the sources of overhead. Each benchmark was executed 50 times. The margin of error of the 95% confidence interval was less than 2%.

The record overhead is caused by the RR library recording nondeterministic events. The pause overhead is due to the time the container is paused during the container fork. The COW overhead is caused by the time to copy the pages after the container fork. The page fault overhead is caused by the page fault exceptions that track the memory state changes of each epoch (§2.1).

With *RRC-SE*, the average incremental checkpoint size per epoch was 0.2MB for *Swaptions*, 15.6MB for *Redis*, and 41.2MB for *Aerospike*. With *RRC-SE*, the average number of

logged lock operations plus system calls per epoch was 9 with *Streamcluster*, 907 with *Tarantool*, and 2137 with *Aerospike*, partially explaining the differences in record overhead. However, the overhead of logging system calls is much higher than for lock operations. *Memcached* is comparable to *Aerospike* in terms of the rate of logged system calls plus lock operations, but has 341 compared to 881 logged system calls per epoch and thus lower record overhead.

The number of pages modified during an epoch determines the rate of page faults and COW operations, as well as the size of the incremental checkpoint that is transferred to the backup (§3). Hence, this write working set size (WWSS) impacts the performance overhead. Table 2 shows the performance overhead of *RRC-SE* with four of our benchmarks as the WWSS is increased to 2x and 3x of the WWSS used in Figure 3. These measurements were obtained by increasing the number of records and then, with a fixed number of records, varying the ratio of writes to reads to obtain the different WWSS values. As expected, the checkpointing component of the overhead (“COW” plus “Others” in Figure 3) increases approximately linearly with the WWSS. As shown in Figure 3, as the epoch duration is increased, the checkpointing component of the overhead is decreased and thus the impact of the WWSS becomes less significant. It should be noted that the number of pages read during an epoch has no impact on the performance overhead. The footprint of the application has only negligible impact that is due to the time to scan the page table to identify the modified pages.

CPU utilization overhead. The CPU utilization (Table 3) is the product of the average numbers of CPUs (cores) used and the total execution time. The CPU utilization overhead is the percentage increase in utilization with *RRC* compared to with the stock setup. The breakdown of the overhead into its components was obtained by incrementally enabling each component and measuring the corresponding increase in CPU

overhead. A significant factor in the CPU utilization overhead is for packet handling in the backup kernel needed to support TCP failover. This overhead is mostly due to routing. Techniques for optimizing software routing [42] can be used to reduce this overhead.

The overheads shown in Table 3 should be evaluated in the context of comparable alternative techniques. The only alternatives that can achieve low latency overheads necessary for many server applications are based on active replication [38, 47]. Such techniques have CPU overheads comparable to *RRC*’s for recording nondeterministic events and handling TCP failover. They do not have the overhead for checkpointing but instead have 100% overhead for execution on the backup. Table 3 shows the with *RRC-SE* the overhead for checkpointing is 4%-56%. Hence, *RRC*’s CPU overhead is significantly smaller than the comparable alternatives’.

Performance decoupling. An important property of *RRC* is that, unlike active replication, it decouples the performance of the application on the primary host from the performance on the backup. To illustrate the impact of this, we selected two representative benchmarks: *Redis* and *Aerospike*, which incur a significant CPU usage on the backup host, and ran them with *RRC-SE*. We ran the perturb program (§5), which consumes 40% of a CPU, first on all the cores of the primary and then the backup. When the perturb program runs on the primary, the performance overhead increases from 46% to 71% and 85% to 116% for *Redis* and *Aerospike*, respectively. However, when the perturb program runs on the backup, the execution time remains the same.

6.2 Response Latency

Table 4 shows the response latencies with the stock setup, *RRC-SE* and NiLiCon. The numbers of client threads for stock and *RRC-SE* are adjusted so that the CPU load on the cores running application worker threads is 50%. For NiLiCon, the number of client threads is the same as with *RRC-SE*, resulting in CPU utilization of less than 5%, thus favoring NiLiCon. To evaluate the impact of response size, *Lighttpd* is evaluated serving both 1KB as well as 100KB files.

With *RRC*, there are three potential sources for the increase in response latency: forwarding packets through the backup, the need to delay packet release until the corresponding event log is received by the backup, and increased request processing time on the primary. With *RRC-SE*, the increase

Table 6: The average time (ms) between resuming container execution and the stop of COW.

Figure 4: Average response latency and the number of COW since container fork.

in average latency is only $144\mu s$ to $290\mu s$. The worst case is with *Aerospike*, which has the highest checkpointing overhead (COW+Others in Figure 3) and a high rate of nondeterministic events and thus long logs that have to be transferred to the backup. The increase in 99th percentile latency is $235\mu s$ to $959\mu s$. The worst case is with *Memcached*. As shown in Table 4, in terms of increase in response latency, NiLiCon is not competitive, as also indicated by the results in [62].

With *RRC-LE*, the increase in the average response latency is from $42\mu s$ to only $229\mu s$, due to the the lower checkpointing overhead. The increase in the 99th percentile latency is under $510\mu s$ since the container fork are much less frequent and thus less likely to interrupt the processing of a request.

The impact of container fork. The tail response time latency overhead is determined by the time the primary is paused for checkpointing. Table 5 shows *RRC*'s pause time with and without the container fork. Without the container fork, the container has to be paused during the entire checkpointing process, leading to a pause time between 5.9ms to 45.8ms. The pause time with the container fork is only from 0.5ms to 3.5ms. Most of the container fork time is spent on copying page tables and thus can be further reduced with recent techniques on optimizing *fork()* [61].

Due to the reduction in the pause time, with the SE setup, the container fork reduces the average response latency overhead from $156\mu s$ - $581\mu s$ to $144\mu s$ - $290\mu s$, and the worst-case 99% response latency overhead from 6ms to $959\mu s$. The throughput overhead is reduced from 8%-145% to 4%-85%.

Immediately after the container fork there is a period during which there is additional overhead due to COW of pages on the primary (§3). Table 6 shows that this period terminates at an early stage of each epoch. To evaluate the impact of the COW on response latency, we obtained fine grained measurements with *Memcached*. Figure 4 shows the results.

		Recovery Rate		Replay Time	
		Mem\$	Aero	Mem\$	Aero
100ms	stock	94.3%	84.5%	20	28
	+ Total order of syscalls	94.3%	92.7%	131	299
	+ Timing adjustment	99.2%	99.8%	234	383
1s	stock	51.4%	34.8%	249	373
	+ Total order of syscalls	51.6%	76.5%	1122	1345
	+ Timing adjustment	99.0%	99.4%	1230	1460

Table 7: Recovery rate and replay time (in ms). *RRC* with different levels of mitigation of data race impact.

Immediately after the container fork, due to the pause and a high rate of page copies, the response latency is around 3.5ms. However, the response latency almost immediately drops to around 1.5ms and then to $700\mu s$, where it remains for the rest of the epoch.

6.3 Recovery Rate and Latency

This subsection presents an evaluation of the recovery mechanism and the data race mitigation mechanism. The service interruption time is obtained by measuring, at the client, the increase in response latency when a fault occurs. The service interruption time is the sum of the recovery latency plus the detection time. With *RRC*, the average detection time is 90ms (§5). Hence, since our focus is not on detection mechanisms, the average recovery latency reported is the average service interruption time minus 90ms.

Backup failure. 50 fault injection runs are performed for each benchmark. Recovery is always successful. The service interruption duration is dominated by the Linux TCP retransmission timeout, which is 200ms. The other recovery events, such as detector timeout and broadcasting the ARP requests to update the service IP address, occur concurrently with this 200ms. Thus, the measured service interruption duration is between 203ms and 208ms.

Primary failure recovery rate. Three of our benchmarks contain data races that may cause recovery failure: *Memcached*, *Aerospike*, and *Tarantool*. Running *Tarantool* with *RRC-SE*, through 50 runs of fault injection in the primary, we find that, due to data races, in all cases replay fails and thus recovery fails. Due to the high rate of data race manifestation, this is the case even with the mechanism described in §4.7. Thus, we use a version of *Tarantool* in which the data races are eliminated by manually adding locks.

We divide the benchmarks into two sets. The first set consists of the five data-race-free benchmarks and a modified version of *Tarantool*. For these, 50 fault injections are performed for each benchmark. Recovery is always successful.

The second set of benchmarks, *Memcached* and *Aerospike*, is used to evaluate the the data race mitigation mechanisms (§4.7). For these, to ensure statistically significant results, 1000 fault injection runs are performed with each benchmark with each setup. The results are presented in Table 7. For both the recovery rate and replay time, the 95% confidence interval

Figure 5: Recovery latency (ms) breakdown with *RRC-SE* and *RRC-LE*.

is less than 1%. Without the §4.7 mechanism, the recovery rate for *RRC-LE* is much lower than with *RRC-SE*, demonstrating the benefit of short epochs and thus shorter replay times. Enforcing a total order of the recorded system calls in the after hook is not effective for *Memcached* but increases the recovery rate of *Aerospike* for both *RRC* setups. However, with the timing adjustments, both benchmarks achieve high recovery rates, even with *RRC-LE*. The total order of the system calls is the main factor that increase the replay time. Thus, there is no reason to not also enable the timing adjustments.

We measured the rate of racy memory accesses in *Tarantool*, *Memcached* and *Aerospike*. To identify “racy memory accesses”, we first fixed all the identified data races by protecting certain memory access with locks. We then removed the added locks and added instrumentation to count the corresponding memory accesses. For *Tarantool*, the rates of racy memory writes and reads are, respectively, 328,000 and 274,000 per second. For *Memcached* the respective rates are 1 and 131,000 per second and for *Aerospike* they are 250 and 372,000 per second. These results demonstrate that, when the rate of accesses potentially affected by data races is high, our mitigation scheme is not effective. Fortunately, in such cases, data races are unlikely to remain undetected.

Primary failure recovery latency. Figure 5 shows a breakdown of the factors that make up the recovery latency for the server benchmarks with *RRC-SE* and *RRC-LE*. With *RRC-SE*, the data race mitigation scheme is enabled, while with *RRC-LE* it is disabled. The 95% confidence interval margin of error is less than 5%. *Restore* is the time to restore the checkpoint, mostly for restoring the in-kernel states of the container (e.g., mount points and namespaces). *Read log* is the time to process the stored logs in preparation for replay. *Others* include the time to send ARP requests and connect the backup container network interface to the bridge.

The recovery latency differences among the benchmarks are due mainly to the replay time. It might be expected that the average replay time would be approximately half an epoch duration. However, replay time is increased due to different thread scheduling by the kernel that causes some threads to wait to match the order of the original execution. This increase is more likely when the data race impact mitigation mechanism is enabled since it enforces more strict adherence

footprint	Redis	Taran	SSDB	Mem\$	Aero
1x	409 (1.00)	425 (1.00)	442 (1.00)	573 (1.00)	763 (1.00)
2x	424 (1.04)	460 (1.08)	479 (1.08)	583 (1.02)	836 (1.10)
3x	463 (1.13)	493 (1.16)	524 (1.18)	609 (1.06)	917 (1.20)

Table 8: The impact of the footprint size, relative to the footprint size used in Figure 5, on the primary recovery latency (in ms) with *RRC-SE*. The latencies relative to the 1x case are in parentheses.

to the original execution. A second factor that impact the replay time is a decrease due to system calls that are replayed from the log and not executed.

With the current *RRC* implementation, the total memory occupancy of the application, i.e., its footprint, has an impact on the recovery latency. Specifically, during recovery on the backup host, all the pages are copied from the memory area where they are saved during prior checkpointing to new locations. Hence, as shown in Table 8, as the footprint is increased, there is a small increase in the recovery latency. In these measurements, the footprint was determined by the final checkpoint size. It should be noted that the impact of the footprint on recovery latency is a limitation of the current implementation. An optimization with kernel support would avoid copying the pages from one memory location to another by simply updating the page table.

7 Limitations

An inherent limitation is that the mechanism used for mitigating the impact of data races (§4.7) is incapable of handling a high rate of racy accesses (§6.3). However, as discussed in §3, such data races are easily detectable and are thus easy to eliminate, even in legacy applications.

The prototype implementation of *RRC* is restricted to single-process containers. This is not a major restriction since, in most cases, containers are used to run only a single process. Cito et al. [30] analyzed 38,079 Docker projects on Github and concluded that only 4% of the projects involved multi-process containers. This is reinforced by Internet searches regarding this issue that yield numerous hits on pages, such as [23], that suggest that running single-process containers is best practice. To overcome this limitation, the *RR* library would need to support inter-process communications via shared memory. Techniques presented in [24] may be applicable.

RRC also does not handle asynchronous signals. This can be resolved by techniques used in [43], that delay signal delivery until a system call or certain page faults.

The current implementation of *RRC* only supports C/C++ applications. Adding support for non-C/C++ applications would require instrumenting their runtimes to track nondeterministic events. *RRC* does not handle C atomic types, functions, intrinsics and inline assembly code that performs atomic operations transparently. In this work, such cases were handled by protecting such operations with locks.

8 Related Work

RRC is related to prior fault-tolerance works on replication based on high-frequency checkpointing, replication based on deterministic replay, and network connection failover.

Early work on VM replication is based on leader-follower active replication using deterministic replay [27]. This is combined with periodic checkpointing in [28], based on use of this technique for debugging [41]. These works focused on uniprocessor systems. Extending them to multiprocessors is impractical, due to the overhead of recording shared memory access order for a VM [37, 52]. Remus [33] (§2.1) and its follow-on works [46, 53, 62] focus on multiprocessor workloads and implement replication using high-frequency checkpointing. Plover [58] optimizes Remus by using an active replica to reduce the size of transferred state and by performing state synchronization adaptively, when VMs are idle. All the Remus-based mechanisms release outputs only after the primary and backup synchronize their states. Hence, outputs are delayed by multiple (often, tens of) milliseconds. COLO [35] compares outputs from two active VM replicas and synchronizes their states on a mismatch, resulting in high throughput and latency overheads for applications with significant nondeterminism.

For process-level checkpointing, libckpt [51] implements “forked checkpointing,” where the unmodified *fork()* system call is used to minimize the pause time for checkpointing.

To handle nondeterminism in parallel applications, as with *RRC*, some works rely on replaying the order of synchronization operations [32, 38, 47]. Rex [38] and Crane [32] cannot handle state divergences caused by data races and require manual modifications of the application source code. Castor [47] handles data races by buffering outputs until the backup finishes replaying the associated logs. If divergence due to data races occurs, the two replicas synchronize their state.

Comparing *RRC* with Rex, Crane, and Castor, for data-race-free applications, *RRC* is likely to have a smaller throughput overhead. Specifically, Rex reports that under heavy load, replay may be slower than the original execution and thus the active replica is a performance bottleneck. With a data-race-free setup, both Rex and *RRC* are evaluated with *Memcached*, and the performance overheads are 40% vs. 17%.

For applications that have data races, the only relevant comparison is with Castor. Castor is likely to have higher response delays since outputs cannot be released until the backup finishes replaying the associated log. Additionally, a data race can also cause Castor to fail. Specifically, if the primary fails in the middle of state synchronization caused by a data race, the system fails. Hence, for an application with a high rate of racy memory accesses, such as *Tarantool* (§6.3), Castor would be frequently synchronizing the state and thus have low recovery rate (like *RRC*) and also high performance overhead. For applications with a lower rate of racy memory accesses, such as *Memcached* and *Aerospike*, Castor also has lower recovery rate. For example, for *Memcached*, based on Table 7, the probability of execution divergence in 50ms is 0.059. Hence,

execution diverges approximately every 0.85s. With our setup, the time it takes to create and transfer the checkpoint for *Memcached* is 48ms. Hence, an upper bound on the recovery rate with Castor is expected to be 94.7% versus 99.2% with *RRC* (Table 7). A similar calculation for *Aerospike*, taking into account 76ms to create and transfer the checkpoint, results in a recovery rate for Castor of 79.8% versus 99.8% for *RRC*.

9 Conclusion

RRC is a unique point in the design space of application-transparent fault tolerance schemes for multiprocessor workloads. By combining checkpointing, with externally deterministic replay, and container fork, it provides all the desirable properties of a fault tolerance scheme listed in §1, with specific emphasis on low latency overhead, which is critical for server applications. *RRC* facilitates trading off performance and resource overheads with vulnerability to data races and recovery latency. Critically, the response latency is decoupled from the frequency of checkpointing, and sub-millisecond added delay is achieved with all our server applications. *RRC* is a full fault tolerance mechanism. It can recover from primary or backup host failure and includes transparent failover of TCP connections.

As we have found (§6.3), legacy applications may have data races. *RRC* targets data races that are most likely to remain undetected and uncorrected, namely, rarely-manifested data races. Unlike mechanism based strictly on active replication and deterministic replay [38], *RRC* is not affected by data races that manifest during normal operation, long before failure. For data races that manifest right before failure, *RRC* introduces simple mechanisms that significantly reduce the probability of the data races causing recovery failure.

This paper describes key implementation challenges encountered in the development of *RRC* and outlines their resolution. The extensive evaluation of *RRC*, based on eight benchmarks, included performance and resource overheads, impact on response latency, as well as recovery rate and latency. The recovery rate evaluation, based on fault injection, subjected *RRC* to particularly harsh conditions by intentionally perturbing the scheduling on the primary, thus challenging the deterministic replay mechanism (§5). With high checkpointing frequency (*RRC-SE*), *RRC*’s throughput overhead is less than 53% for seven of our benchmarks and 85% for the eighth. If the applications are known to be data-race-free, with a lower checkpointing frequency (*RRC-LE*), the overhead is less than 49% for all benchmarks, significantly outperforming NiLiCon [62]. With data-race-free applications, *RRC* recovers from all fail-stop failures. With two applications with infrequently-manifested data races, the recovery rate is over 99% with *RRC-SE*.

Abstract

Modern data center fabrics open the possibility of microsecond distributed applications, such as data stores and message queues. A challenging aspect of their development is to ensure that, besides being fast in the common case, these applications react fast to changes in their membership, e.g., due to reconfiguration and failures. This is especially important as they form the backbone of numerous cloud-powered services, such as analytics and trading systems, trying to meet ever-stringent tail latency requirements. As the microservices-oriented architecture is the de facto standard for building cloud services, a single user request translates to a wide fan-out of microservices interactions sitting on the critical path. The outcome is implacable: the traditionally uncommon events of reconfiguration and failures are exacerbated by the fan-out of communication, making user requests commonly experience such events and quickly impacting the tail latency of the service.

We present uKharon, a microsecond-scale membership service that detects changes in the membership of applications and lets them failover in as little as 50 μ s. uKharon consists of (1) a multi-level failure detector, (2) a consensus engine that relies on one-sided RDMA CAS, and (3) minimal-overhead membership leases, all exploiting RDMA to operate at the microsecond scale. We showcase the power of uKharon by building uKharon-KV, a replicated Key-Value cache based on HERD [24]. uKharon-KV processes PUT requests as fast as the state-of-the-art and improves upon it by (1) removing the need for replicating GET requests and (2) bringing the end-to-end failover down to 53 μ s, a 10 \times improvement.

1 Introduction

State-of-the-art data centers form the backbone of today's online services, including social networks, search engines, video streaming, e-commerce and banking platforms. The ever-increasing popularity of online services and their pervasive role manifest in both huge-scale requirements as well as stringent tail latency to guarantee smooth user interaction.

The tail of a cloud service refers to the latency of the slowest requests, and thus provides a limit to the maximum latency experienced by the end user. Despite substantial efforts in both hardware (e.g., InfiniBand/RDMA [40], RoCE [4], FPGA [6], Gen-Z [28], CXL [50]) and hardware-accelerated software [15, 21–23, 38, 52, 53, 55], keeping the tail short at large scale is one of the most important challenges in the cloud computing industry.

Dean *et al.* [9] shed light on the challenge of building tail-tolerant software at data center scale. This challenge mainly stems from the architecture of modern online services, which are composed of a plethora of layers that communicate frequently. Despite the scalability and cost benefits of such architectures, each end-user request results in a wide fan-out of interaction across tiers, each of which lies in the critical path between the service and its reply to the user. The probability of the traditionally rare reconfiguration and failure events is thus multiplied by the fan-out of the communication. As a result, user requests encounter such events more frequently, which quickly impacts the tail latency of the services.

Existing systems are not capable of handling failures within microseconds. Key-Value stores like Hermes [26], state machine replication [44] systems like Mu [2] and Hovercraft [29], and transactional systems like FaRM [12], process requests in a few microseconds in failure-free scenarios, but miss the microsecond envelope when handling failures. Mu and Hovercraft take 0.5ms and 10ms respectively to failover. Aguilera *et al.* [2] reported that Hermes has a failover of 150ms, while FaRM mentioned ZooKeeper [20], a widely used distributed coordination service that offers at-best millisecond failover, for its membership management.

This paper builds on the observation that a crucial step in making tail-tolerant microsecond applications is reacting fast to failures. We thus propose uKharon¹, a membership service tailored to the microsecond scale. Apart from acting as a distributed membership storage for (distributed) applications, uKharon monitors their nodes, detects their failures and

¹“u” stands for microsecond, and Kharon is the carrier of the souls of the dead in Greek mythology. It is pronounced ma · ka · ron.

changes their membership within 50 μ s. When uKharon itself experiences a failure, it recovers within 64 μ s. uKharon particularly benefits applications with efficient state transfer which can swap a faulty replica with a hot one in microseconds, for example via shadow replication. It targets cloud services that require seamless reconfiguration for fault tolerance and scalability, such as indexes, datastores and transactional systems.

The key to the performance of uKharon is the careful design of three fundamental components, all of which leverage RDMA to operate at the microsecond scale. *First*, uKharon achieves microsecond failure detection by employing a multi-level failure detector. It distinguishes the failures related to the application (e.g., segmentation faults), from those related to the kernel (e.g., driver faults), and failures related to the hardware (e.g., RDMA NIC faults), employing for each a different failure detector. *Second*, uKharon decides on memberships using a consensus engine which solely relies on one-sided RDMA verbs. This engine takes advantage of RDMA Compare-and-Swap (CAS) to handle leader changes within 10 μ s. *Third*, uKharon provides membership leases that add minimal overhead to the end application and last \sim 20 μ s. As a result, our membership service combines typically opposing forces: having applications with low-overhead dynamicity in failure-free scenarios and very fast failover upon failures.

We showcase the benefits of our membership service by building uKharon-KV, a replicated in-memory KV-cache based on HERD [24]. It uses uKharon to track the set of nodes and react to node failures. We compare uKharon-KV against HERD+Mu [2] (i.e., HERD replicated by Mu), a system which—to the best of our knowledge—achieved the lowest replication latency to date. Our evaluation shows that uKharon-KV processes PUT requests as fast as HERD+Mu in failure-free periods. Moreover, thanks to its leasing mechanism, uKharon-KV manages to spare the replication of GET requests, an optimization that is algorithmically impossible in HERD+Mu. As a result, uKharon-KV GETs are 31.8% faster than HERD+Mu’s. uKharon-KV, though, shines in the event of failures, achieving an end-to-end failover of 53 μ s, improving on HERD+Mu’s failover of 531 μ s by up to a factor of 10.

In a nutshell, we present uKharon, the first ever membership service suitable for the needs of tail-tolerant microsecond applications. We make the following contributions:

- A multi-level failure detector for the microsecond scale.
- A consensus engine that relies on one-sided RDMA CAS to change leader within microseconds.
- Microsecond leases that have minimal impact on the performance of the end application.
- uKharon-KV, a replicated KV-cache which outperforms the previous state of the art.
- The source code of uKharon is available at <https://github.com/LPD-EPFL/ukharon>.

The rest of this paper is organized as follows: Section 2 introduces background concepts. Section 3 gives an overview of uKharon’s design. Sections 4, 5 and 6 discuss the failure detection, consensus and leasing components, respectively. Section 7 reports on the performance of uKharon. Finally, Section 8 discusses related work and Section 9 concludes.

2 Background

2.1 Membership Service

To achieve resilience, long-lived distributed systems must be dynamic. Many systems [30, 31, 39, 45, 47] achieve dynamicity by relying on a coordination substrate, such as ZooKeeper [20] or etcd [14]. Among the various services (e.g., atomic locks, registers) these substrates offer, dynamicity is fundamentally addressed via their *membership service*.

A membership services offers dynamicity both in graceful executions and upon failures. In the former case, it serves join and leave requests issued by processes that want to become part of a distributed application or exit it. In the latter, it detects process failures and reacts to them. All these events are reflected through new configurations (called views or simply memberships). Essentially, a membership service acts as a storage of configuration information, keeping track of how the set of processes evolves, and exposes this information.

Typically, membership services rely on consensus [16] to establish a totally ordered sequence of views. Such services, including Zookeeper and etcd, offer strong semantics as all processes using the membership service transition through the same sequence of views.

Consensus-based membership services also offer real-time semantics. Apart from knowing the sequence of memberships, it is also important to know which is the (single) *active* membership. To understand why this real-time property is useful, consider the following example that incorrectly builds a cache storage solely relying on the sequence of memberships: The cache serves READ and WRITE requests. Initially, membership $M_1 = \{S_1\}$ designates server S_1 as responsible for the cache (i.e., S_1 stores it and serves requests). Eventually, a second membership $M_2 = \{S_2\}$ replaces S_1 with S_2 . S_2 , being part of M_2 , proceeds with serving clients’ requests and updates the content of the cache. At the same time, S_1 is unaware of M_2 and continues serving clients’ requests as well. As a result, a client that is also unaware of M_2 and reads from S_1 will get stale data. This example demonstrates a violation of consistency. It shows that total order of memberships does not provide any real-time guarantees by itself.

Membership services provide real-timeness by making outdated memberships nonoperational. A commonly used mechanism to achieve this property is the use of a distributed invalidation protocol. Another solution is to rely on leases. With leases, processes are forced to periodically check the active membership, execute operations in this membership,

and abort operations that span over multiple memberships. uKharon provides real-timeness via leases.

2.2 RDMA

Remote Direct Memory Access (RDMA) [49] is a networking technology that allows processes to access the memory of a remote machine without involving the CPU of the latter. By implementing several layers of the networking stack in hardware and relying on kernel bypass, RDMA achieves microsecond inter-machine communication. It allows applications within the data center to communicate in as little as $0.9\mu\text{s}$ [25]. This technology is supported by different fabrics such as InfiniBand [49] and commodity Ethernet via RoCE [4].

Applications communicate over RDMA by relying on primitives called *verbs*. There exist *one-sided verbs* that include READ, WRITE and Compare and Swap (CAS) verbs and *two-sided verbs*, such as SEND and RECV verbs. One-sided verbs let a process read, write and apply atomic transformations to a remote machine’s memory without involving its CPU. Two-sided verbs are similar to message passing and involve both communicating sides. They let processes send and receive memory buffers. Communication in RDMA can notably occur over established *Reliable Connections (RCs)* or over *Unreliable Datagrams (UDs)*. While the former provide FIFO semantics, the latter trade reliability for better performance and support for message multicast [49].

2.3 Communication Model

uKharon is designed for data centers. It is safe under asynchrony and live under partial synchrony [13]. That is, to make progress, uKharon assumes a Global Stabilization Time (GST), unknown to the processes, such that from GST onwards there is a bound Δ on communication and processing delays. This is a realistic assumption, as data center fabrics are not asynchronous in practice [3, 35, 54]. Additionally, our system relies on bounded clock drift for safety, i.e., durations are approximately the same across all processes. uKharon also assumes *crash-stop* failures: processes may fail by crashing, after which they stop executing. Finally, we assume that network partitions, which affect uKharon’s liveness, are eventually resolved by the data center administrators.

3 Design Overview

3.1 Architecture

Figure 1 gives an overview of uKharon. Our system, as a membership service, runs on application nodes as well as a set of dedicated nodes called *coordinators*.

Central to uKharon is uKharon Core, a single-threaded library that hosts monitoring functionalities of the membership service. This includes detecting failures of member nodes

Figure 1: Overview of uKharon

(including coordinators), listening for failures and new memberships, as well as renewing leases. The application receives these events via thread-safe accessors: a stream of failures, a stream of memberships and a method `Active(M) → bool` which checks whether a given membership M is active.

The generation and storage of memberships is delegated to coordinators. Coordinators achieve fault tolerance through consensus. One of them is the leader, which processes join/leave requests from both application nodes and coordinators, proposes new memberships and broadcasts decided memberships which are picked up by the uKharon Core instance running on every node. The rest of coordinators help the leader decide and replicate the sequence of memberships. Finally, coordinators assign each member a unique identifier.

Running uKharon Core on both application nodes and coordinators helps bootstrap the membership service. uKharon Core learns about the new memberships from coordinators, but coordinators require the membership service to learn about each other. Similarly, coordinators rely on uKharon Core to detect failures of application nodes or themselves.

Part of uKharon’s failure detection logic resides in the kernel, outside of uKharon Core. It consists of a kernel module hooked to Linux’s process cleanup routine. This module can be enabled by the application logic and broadcasts a failure notification (called *heartbeat*) when the application crashes.

New memberships are merely broadcast by coordinators, putting the burden of detecting the active membership to the application nodes. uKharon Core is responsible for bringing real-timeness to applications. It reads the RDMA-exposed memberships at a majority of coordinators to determine whether a membership has been superseded by a new one or whether it is still active. The active membership is leased for a limited amount of time, in our case $\sim 20\mu\text{s}$.

3.2 Communication

uKharon relies extensively on the performance of today’s RDMA-enabled fabrics to achieve its microsecond latency target. It leverages one-sided RDMA verbs, two-sided ones (i.e., HERD-style RPC [24]), as well as RDMA Multicast. Coordinators run consensus using RDMA Reliable Connections

(RCs). In particular, coordinators establish all-to-all connections among themselves and communicate using RDMA READ, WRITE and CAS. Additionally, coordinators use RDMA Multicast, which is backed by RDMA Unreliable Datagrams (UDs), to notify all nodes about new memberships. uKharon also uses RDMA Multicast to emit failure notifications. uKharon Core relies on RDMA READs over RCs to retrieve the active membership from coordinators and to detect the failure of remote nodes. Finally, processes send *join* and *leave* requests to the coordinator leader using RPC.

3.3 Challenges

Our system is designed for applications that operate and failover at the microsecond scale. To do so, uKharon meets two important design goals. First, it itself operates at the microsecond scale, meaning that it is able of changing the active membership within as few as 50 μ s. Second, we ensure that uKharon Core has minimal performance overhead on the end application it is bundled with. To meet these goals, uKharon is structured around three major components:

Failure detection. Efficient failure detection is the first step towards fast failover. Conventional wisdom suggests that there is a trade-off between the speed and accuracy of a failure detector. We work around this limitation by building a hierarchy of RDMA-tailored failure detectors suited for the microsecond scale. Our hierarchy detects failures within a few tens of microseconds, as we explain in Section 4.

Consensus engine. The second step of failover is agreeing on the new membership. Existing leader-based consensus engines, although optimized for the microsecond scale, struggle to change their leader at this time scale. In Section 5, we explain how our microsecond consensus engine changes leader in microseconds. This gives our design the unique property that a coordinator failure—especially failure of the coordinator leader—has negligible effect on the failover time.

Leases. As far as the membership service is concerned, the last step towards failover is updating the active membership. However, the new membership cannot become active before leases on previous memberships have expired. Thus, the longer the leases, the higher the failover time. On the other hand, short leases can result in application overhead, as they have to be checked in the application’s critical path and renewed in time before expiring. In section 6, we explain how uKharon manages to have $\sim 20\mu$ s leases with virtually no cost for the end application and how leases can scale to hundreds of machines for an extra $\sim 20\mu$ s.

4 Microsecond Failure Detection

uKharon relies on microsecond failure detection to notify nodes about member failures and to trigger the generation of

new memberships. In this section, we describe uKharon’s failure detection scheme.

4.1 Multi-level Failure Detection

A practical failure detector aims at being as complete and as accurate as possible. A complete and accurate failure detector is able to detect all failures and not have false positives, respectively. Completeness without accuracy causes problems in practice, as false positives trigger new memberships which require distributed applications to take further action (e.g., rebalancing data among nodes).

Commonly, failure detectors rely on timeouts for their operation. However, timeouts are hard to set correctly: if they are too low, the failure detector may experience instability (e.g., oscillating behaviors). That explains why most systems set the timeouts to a safe high-enough value. In the microsecond scale this problem is magnified, as small execution delays (e.g., kernel jitter) can take several microseconds.

Our failure detector follows a pragmatic approach: it avoids timeouts when possible. To achieve this, we are inspired by Falcon [35], and identify four levels of failures: (1) *userspace failures* (e.g., segmentation faults, out of memory errors, uncaught exceptions) that cause the application to abort, (2) *kernel failures* (e.g., cores hanging in the kernel, kernel oops caused by driver crashes) that impede the application’s execution, (3) *catastrophic failures* (e.g., power failures, RDMA NIC failures) that prevent communication with the application’s host, and (4) *byzantine failures* (e.g., stack overflows, mercurial cores [19]) that affect the application state. Each of the first three levels is handled by uKharon via a specialized failure detector. We do not address Byzantine failures.

4.2 uKharon’s Failure Detectors

We now explain how uKharon’s specialized failure detectors work, depending on the type of failure.

Userspace failures. They are handled by the Linux kernel. The application registers to the kernel to enable a *deadbeat*, which is a failure notification broadcast by the kernel upon the death of the process. This registration happens by means of the `prctl` system call that the application calls early in its execution. The system call includes the node’s identifier and modifies the process descriptor (Linux’s `task_struct`) with a flag that the kernel checks during the *cleaning routine* of the process. In Linux, when a process crashes, control is transferred to the kernel which starts executing the process cleaning routine. If the flag is set, the kernel broadcasts a failure notification that includes the specified identifier. To achieve this functionality, we extend the `prctl` system call and modify the process cleaning routine that is part of the kernel’s `exit` system call. The task of broadcasting the crash notification is delegated to a kernel module. This module uses the kernelspace RDMA driver to broadcast crash notifications

which are polled by all instances of uKharon Core. As this failure detector does not use timeouts, it has no false positives.

Kernel failures. To detect application failures caused by the kernel, we rely on the way RDMA is handled in userspace. An application registers memory to an RDMA device by issuing `ioctl` system calls on a file descriptor. By design, the Linux kernel destroys that file descriptor and thus disables remote access to this memory at the end of the process' cleaning routine. If this cleaning routine runs, the failure is caught by the previous failure detector. Otherwise, the memory will remain remotely accessible while the execution of the application is suspended (and the kernel is dying).

For the operation of this failure detector, processes are arranged in a logical ring where every process monitors its successor. Our system uses a local heartbeat counter in a similar fashion to Mu's detector [2]. uKharon Core increments this counter to indicate that the process is alive. This counter is read by the predecessor process. If a process RDMA-reads the same value twice, it reports its successor as having failed.

A process would be wrongly detected if it were unable to increment its counter between two consecutive reads. Thus, we take special care to ensure that processes always increment their counters faster than the time delay between two consecutive reads. Importantly, we deploy (the single-threaded) uKharon Core in its own dedicated physical core. We resort to a custom kernel compiled with the `NO_HZ_FULL` option, which disables regular timer interrupts [37] on the dedicated core and thus reduces the kernel jitter towards uKharon Core. Additionally, we boot this kernel with the `isolcpus` parameter, which prevents other userspace processes from sharing the dedicated core with uKharon Core. In experiments, the interval we observed between two counter increments under heavy load was $5\mu\text{s}$ most of the time and never more than $15\mu\text{s}$. To account for unexpected jitter (e.g., thermal throttling), we make processes wait $30\mu\text{s}$ after the completion of an RDMA READ before issuing the next one. As RDMA READs are issued sequentially, network delays do not negatively impact the accuracy of this failure detector.

Catastrophic failures. uKharon relies on a timeout-based scheme to detect failures that prevent machines from communicating. We set the timeout to 1ms, which is 2 – 3 orders of magnitude higher than the common case latency of modern data center fabrics. As reported by Li *et al.* [36], 1ms is safe even in case of network congestion.

The detector works by having processes periodically broadcast a heartbeat and poll for heartbeats from others. Processes keep track of the set of processes they recently received a heartbeat from. They compare this set with the current membership and report which processes they consider failed to the coordinator leader. Then, the leader constructs a connectivity graph based on the reported link states and changes the membership to approximately match the maximum clique in which it is included. Thus, our membership service en-

forces all-to-all connectivity among the members and does not expose any information regarding network partitions. A systematic treatment of network partitions is out of our scope.

The first two detectors broadcast failure notifications over RDMA-multicast, which offers better scalability than broadcasting using Reliable Connections. Nevertheless, RDMA-multicast is backed by Unreliable Datagrams, thus failure notifications can be lost under high network load. Dropping these notifications is safe, as uKharon-Core rebroadcasts a failure notification until a new membership excludes the failed node.

5 Microsecond Consensus

In this section, we present a state-of-the-art consensus engine that is tailored for the needs of uKharon and powers its coordinators. Our engine is efficient regardless of failures: in the absence of failures, it decides in one RDMA delay (by issuing an operation to a majority of processes in parallel), while it decides in one additional RDMA delay in the event of a failure. It uses a slightly modified version of Paxos based on the observation that the original algorithm contains RPCs that can be emulated with RDMA CAS operations. In the rest of the section, we intuitively describe our consensus algorithm and discuss implementation details. Appendix A provides its pseudocode and a proof of its correctness.

5.1 Consensus and Paxos

Consensus is a fundamental problem in distributed computing. Informally, each process proposes a value and eventually all processes irrevocably agree on one of the proposed values. Processes agree on a sequence of values and totally order them by running multiple instances of consensus.

Several algorithms solve consensus in the partially synchronous model. Many are variants of Paxos [32]. In Paxos, processes are divided in two groups: *proposers* and *acceptors*. Proposers *propose* a value for decision and acceptors *accept* some proposed values. Once a value has been accepted by a majority of acceptors, it is decided by its proposer.

Intuitively, Paxos is split in two phases: the *Prepare* phase and the *Accept* phase. During these phases, messages from the proposer are identified by a unique *proposal number*. The Prepare phase serves two purposes. First, the proposer gets a promise from a majority of acceptors that another proposer with a lower proposal number will fail to decide. Second, the proposer updates its proposed value using the accepted values stored in the acceptors. This way, if a value has been decided, the proposer will adopt it. The prepare phase can also *abort* if any acceptor in the majority previously made a promise to a higher proposal number. If the proposer manages to complete the Prepare phase without aborting, it proceeds to the Accept phase. In this phase, the proposer tries to store its value in a

```

1 # Paxos's RPCs pattern
2 def rpc(x):
3     if compare(x, state):
4         state = f(state, x)
5         return proj(state)
6
7 def cas_rpc(x):
8     expected = fetch_state()
9     if not compare(x, expected):
10        return proj(expected)
11    move_to = f(expected, x)
12    old = state.cas(expected,
13                  ↪ move_to)
14    if old == expected:
15        return proj(move_to)
16    abort

```

Algorithm 1: Paxos's RPCs turned into CAS-based RPCs.

majority of acceptors. If it succeeds (i.e., a majority accepted the value), it decides on that value.

5.2 One-sided Paxos

Paxos uses RPC in a very specific form. The acceptors' state consists of only three variables: `min_proposal`, `accepted_proposal` and `accepted_value`. In both phases, acceptors atomically update these values based on the proposer's input and return some of them.

Algorithm 1 proposes an obstruction-free transformation to turn Paxos's RPCs into purely one-sided conditional writes using RDMA CAS. Paxos's RPCs follow the pattern seen in `rpc`. The acceptor executing the RPC compares the received value `x` to its state (stored in `state`). If the comparison is successful, the acceptor updates its state (shown with function `f`) using the provided value `x`. Finally, the acceptor unconditionally returns part of its state (shown with function `proj`).

The pattern presented in `cas_rpc` allows RDMA to emulate `rpc` while solely relying on one-sided verbs. Opposite to `rpc`, which is executed on the acceptor's side, `cas_rpc` is executed on the proposer's side. To execute the one-sided RPC, the proposer first needs to know the `state` that is stored in the memory of the acceptor. This value can either be guessed (e.g., using a previous value of `state`) or fetched (e.g., using RDMA READ, as shown in line 2). Then, the proposer executes the comparison locally (line 3) and decides whether to continue or terminate. If the comparison succeeds, the proposer proceeds with updating the state of the acceptor. It is this update that utilizes CAS². In line 7, if the CAS succeeds, the acceptor's `state` has been updated successfully with the value of `move_to`. Otherwise, `state` remains unchanged.

When the RDMA CAS succeeds, i.e., in the absence of contention, both `rpc` and `cas_rpc` are equivalent (see Appendix A.2). However, if the RDMA CAS fails, `cas_rpc` will abort while `rpc` would not. In this case, `rpc` and `cas_rpc` are not equivalent, but this does not violate the correctness of Paxos. The reason is that Paxos tolerates an arbitrary number of proposer failures and that aborting the RPC and starting over is indistinguishable from such a failure.

²As a reminder, `variable.cas(expected, new)` atomically checks if `variable` equals `expected` and sets `variable` to `new` if this is the case. The operation always returns the initial value of `variable`.

Figure 2: uKharon's Consensus Engine with its RDMA-exposed memory for multiple instances of consensus (left) and a state machine for a single instance of consensus (right).

5.3 uKharon's Consensus Engine

We now explain how to make the variant of Paxos described in Section 5.2 practical and compare it with Mu [2], a state-of-the-art consensus engine.

5.3.1 Practical Considerations

Leader election. To avoid the contention rising from multiple concurrent proposers, our consensus engine adopts the same leader election scheme as Mu. The process with the lowest identifier among the coordinators considered alive is elected as the leader. In the event of a partial network partition, this scheme can elect multiple leaders. For example, if coordinator C₂ is the only one unable to reach C₁, it will think of itself as the leader, while other coordinators will consider C₁ as their leader. Having multiple leaders cannot lead to multiple values being decided, i.e. safety is always preserved. Leader contention can, however, prevent the engine from being live. Thus, a leaders that fails to decide uses a randomized backoff before proposing until the partition is resolved.

Pre-preparation. Coordinators decide on a sequence of values by running consensus on a sequence of *slots*, as shown in Figure 2. It requires two RDMA delays for each slot: one for the Prepare and another for the Accept phase (shown with horizontal arrows in the figure). A stable leader can prepare slots in advance and only run the Accept phase to decide. In this case, the leader decides in a single RDMA delay. The leader uses the time spent waiting for the Accept phase to complete on a slot to run the Prepare phase for the next one. Thus, it always maintains one pre-prepared slot (depicted in the second consensus slot of Figure 2), with no latency overhead. Switching to the new leader requires re-preparing the next slot. As an optimization, the new leader predicts that the last slot had been prepared by the previous leader and uses this prediction as the expected value of the RDMA CAS. With this approach, the new leader manages to re-prepare the next slot in a single RDMA delay instead of two.

CAS size limitation. Algorithm 1 assumes that the consensus state fits within a single CAS. Current RDMA NICs only

support CAS up to 8 bytes. We set both `min_proposal` and `accepted_proposal` to be 2 bytes each³. The remaining 6 bytes are dedicated to the `accepted_value`.

Our consensus engine uses indirection to overcome the limited size of the `accepted_value` and store uKharon's memberships. Instead of deciding on the membership itself, coordinators decide on its location in memory. First, the proposer RDMA-writes the membership to a part of acceptors' memory dedicated to membership proposals (see Figure 2) to which it has exclusive write access. Then, the proposer runs the Accept phase where it proposes its own identifier (C_1 in the figure). If the Accept phase succeeds at a majority of acceptors, then the proposer decides. Thanks to the FIFO semantics of RDMA RCs, if the last RDMA operation (i.e., the Accept phase CAS) succeeds, the previous RDMA operation (i.e., storing the membership with an RDMA WRITE) also succeeded. The two RDMA operations combined do not execute atomically, yet a coordinator cannot have accepted an identifier without knowing its associated membership.

5.3.2 Comparison with the State-of-the-art

Many systems, such as Mu [2], DARE [41] and APUS [51] study consensus over RDMA. They primarily focus on improving the throughput and latency of common case executions, thus achieving consensus in a few microseconds. However, these systems have failovers ranging from 0.5ms (in Mu) to 10s or 100s of ms (in DARE and APUS, respectively).

Mu has the best performance in failure-free executions among competition as it solves consensus in $\sim 1.4\mu\text{s}$. It relies extensively on RDMA permissions. During its Prepare phase, a proposer asks acceptors for the exclusive write permission to their memory and waits for a majority of replies. This step guarantees that only one proposer can write to an acceptor at a time. In the Accept phase, the proposer decides by merely writing to a majority of acceptors. As acceptors give write permissions to a single proposer at a time, no two concurrent proposers can successfully write to a majority of acceptors and decide on different values. Since WRITE is the most efficient RDMA verb and the Prepare phase runs only once per leader change, Mu is optimal in failure-free executions.

The Accept phase of our algorithm relies on a WRITE followed by a CAS. Importantly, these one-sided operations have lower tail latency compared with the two-sided verbs present in DARE and APUS. The CAS increases the decision time from $1.4\mu\text{s}$ to $2.9\mu\text{s}$ compared with Mu. When it comes to a leader change, Mu's permission change mechanism requires approximately $250\mu\text{s}$, since it constitutes a control path operation that involves a system call and a reconfiguration of the NIC. In our consensus engine, the additional CAS lets coordinators change leader in under $10\mu\text{s}$. Thus, our algorithm is designed for short tail latency and makes the failure of the

³Appendix A.6 discusses how to prevent overflows after 2^{16} failed attempts to decide on a slot by switching from CAS-based to two-sided RPCs.

coordinators' leader no more important (latency-wise) than the failure of any other node.

6 Microsecond Real-timeness

In addition to reacting to failures and deciding on views, uKharon lets applications track the active membership via the `Active` method. While this information is essential for consistency, it must not burden the end application. In this section, we describe the challenge of making `Active`'s overhead negligible while preserving microsecond view changes.

6.1 The Active Method

uKharon exposes real-timeness to end applications via the `Active(Membership) → bool` method. If `Active(M)` returns `true`, we say that M is *active* at some point between the call and return of the method. `Active` satisfies three important properties. First, there are no two overlapping active memberships. Second, after a membership M is active, no memberships older than M become active. Third, the active membership converges to the latest decided membership.

Intuitively, processes use the `Active` method to determine the membership they should be executing operations in. When coordinators decide on a new membership M' , a process p may stay in an older membership M due to a delay in receiving M' . Calling `Active(M)` will eventually return `false` at p , thus letting it realize that it misses the latest membership M' . To ensure consistency, an application typically calls `Active` once before starting an operation and a second time before committing it, only committing if both calls return `true`.

6.2 Leases

uKharon uses leases for efficiency. We proceed incrementally, first describing an implementation of `Active` without leases, before moving to a more efficient lease-powered scheme.

The basic implementation of `Active` requires communication in every invocation. Let M be the k -th membership decided by the coordinators and assume a process p invokes `Active(M)`. In essence, `Active` declares that M is active if it can conclude that no newer membership M' has been decided. To this end, the process RDMA-reads the $k + 1$ -th consensus slots at coordinators and waits for a majority of replies. If all replies are empty, then the $k + 1$ -th membership has not been decided, meaning that M is (still) active at some point between the invocation and return of the method. If, on the other hand, at least one of the replies is non-empty it is inconclusive whether M has been superseded by M' . In case M' has been decided before p issues the READs, then at least one of the replies must be non-empty, but the opposite is not always true. For safety, `Active` returns `false` if at least one of the READs on the next consensus slot is non-empty.

```

1 leased_membership = ⊥; t_start = 0; t_end = 0
3 def Active(M) → bool: # M is always a decided membership
4   t = hw_timestamp()
5   if leased_membership != M: # First-time lease on M
6     if majority_active(M):
7       leased_membership = M; t_start = t + δ; t_end = t_start
8   else: # Check/extend lease on M
9     if t in [t_start, t_end): return True
10    if majority_active(M):
11      t_end = t + δ
12    return t > t_start
13 return False

```

Algorithm 2: Leased active membership.

A lease refers to a membership and has a start and an expiration date. A lease guarantees its holder that its associated membership will remain active until it expires. In our system, leases are created by uKharon Core and last $\delta \approx 20\mu\text{s}$.

Algorithm 2 provides an efficient alternative implementation of `Active` that relies on leases to reduce communication. It starts by taking a hardware timestamp t (line 4) and then checks if a lease on M already exists (line 5). If no lease exists (lines 6-7), the method checks for a newly decided membership by contacting a majority of coordinators. If no membership newer than M could have been decided (i.e., all replies are empty), it creates a lease on M (line 7) that starts at $t + \delta$ and has no duration. This prevents overlapping active memberships since any lease that processes could hold on a previous membership $M' < M$ will have expired before M becomes active. In case a lease on M already exists, the method tries to use it in order to avoid reaching the coordinators (line 9). If it cannot use it, it tries to extend the lease (line 11) by checking the coordinators. It returns `True` only if leases on previous memberships have expired (line 12), which takes—in the worst case— δ to happen. As a result, leases affect the speed at which memberships can change, justifying the desire for a small lease duration. Section 7 demonstrates that leases of $\delta \approx 20\mu\text{s}$ are feasible in practice.

This efficient implementation of `Active` renews its lease on demand. As long as its lease is valid, the method merely takes a hardware timestamp—which takes a few tens of nanoseconds—and returns immediately without reaching the coordinators. The latency overhead of `Active` to the application that invokes it is thus very low. Communication with the coordinators is only necessary when leases expire and have to be renewed, which results in a spike in `Active`'s latency. In practice, uKharon Core renews leases in the background to ensure that—when the membership remains unchanged—`Active` is not delayed by the calls to `majority_active`.

uKharon does not rely on operational leases for either liveness or safety. Timely renewal of leases is only a way to reduce the latency of `Active` as Algorithm 2 would work even with zero-duration leases. uKharon relies on bounded clock drifts for safety, as opposed to clock synchronization. This ensures that durations are approximately the same across

all processes, thus preventing overlapping memberships. Appendix C includes a microbenchmark evaluating the clock drift of actual hardware and gives an overestimated drift that is no more than 0.001% of the lease duration. Thus, clock drift is accounted for by making leases last a few nanoseconds less than their nominal value. As drift is reset on each lease renewal, it does not accumulate over time. Therefore, no matter how long a system is up for, its operation remains unaffected by the clock drift. A proof of correctness of uKharon's leases is given in Appendix B.

6.3 Extensions

Adaptive leases. So far, we have assumed a fixed lease duration δ . Network delays greater than δ render leases useless as, every time the lease is extended (line 11), t_{end} is always in the past. In this case, `Active` always contacts the coordinators. In order to work under partial synchrony and avoid this scenario, we extend the leasing mechanism as follows: Coordinators store the lease duration for a given membership along with the membership itself. An application node that wants to increase the lease duration contacts the coordinator leader. This results in a new *compatible* membership that is identical to the previous one apart from the lease duration. Compatible memberships receive special handling by uKharon Core in order to ensure that—when going from one compatible membership to another—`Active` does not wait for leases on the previous membership to expire. Also, if the latest membership M is not compatible with the previous one, invocations to `Active(M)` return false until all possibly ongoing leases on previous memberships have expired.

Lease caches. `Active` reaches a majority of coordinators to renew its lease, which scales badly as the number of application nodes increases. uKharon solves this issue with an intermediate lease renewal layer, the *lease caches*. These caches use the `Active` method to lease memberships for Δ (by reading from a majority of coordinators). In turn, application nodes use leases that last for δ and a modified version of `Active`. This version differs from the one presented in Algorithm 2 in the `majority_check` calls, which are replaced with RPCs to a *single* lease cache. As a result, application nodes reduce the communication cost required to renew their lease by a factor of—at least—3 (the typical number of coordinators). However, lease caches increase the failover time of applications by at least Δ . The reason is that when the coordinators change the membership, the `Active` method of caches waits Δ before making the new membership active. At the same time, the `Active` method of application nodes that is directed to some lease cache, waits δ before making the new membership active. Thus, the overall time from the moment a new membership is decided until application nodes start using it jumps from (at least) δ to (at least) $\Delta + \delta$.

7 Evaluation

We evaluate the various performance traits of uKharon and verify its suitability as a membership service for microsecond applications. We aim to answer the following:

- How much does uKharon increase the latency of end applications and what is its impact on their throughput?
- How fast does uKharon respond to failures?
- How can uKharon be leveraged to build replication protocols and what performance can they achieve?

CPU	2x Intel Xeon Gold 6244 CPU @ 3.60GHz (8 cores/16 threads per socket)

RDMA Driver	Mellanox OFED 5.3-1.0.0.1

Table 1: Hardware details of machines.

We evaluate uKharon in a 8-node cluster, the details of which are given in Table 1. The custom kernel sets the `NO_HZ_FULL` option and uses the `isocpus` boot parameter, as explained in Section 4.2. Our dual-socket machines are NUMA and their RDMA NIC lies on the first socket. For this reason, we ensure that all threads during our experiments execute on cores of the first socket. We also make all threads exclusively use the memory bank closest to this socket.

Our implementation measures time durations using the `clock_gettime` function with the `CLOCK_MONOTONIC` parameter. The function uses the TSC clocksource of the Linux kernel, which offers efficient and accurate timestamping [43]. Appendix C discusses details regarding the drift and synchrony of TSC in symmetric multiprocessing (SMP) systems.

Finally, in all experiments we deploy 3 coordinators.

Applications. We integrate uKharon with HERD [24]. HERD is a non-replicated microsecond-scale RDMA-based KV-cache. Clients send requests to a HERD server by RDMA-writing to a dedicated buffer that the server has allocated for them. Requests contain an 8-byte key and are either PUTs or GETs. PUTs additionally contain the value to be stored for the specified key. The server discovers new client requests by polling its local memory, executes the requests locally and then replies to the clients using RDMA UD. We also leverage uKharon to build uKharon-KV, an extended version of HERD which supports replication. We compare our solution with HERD replicated by Mu (HERD+Mu) [2] which—as far as we know—offers the lowest replication latency to date.

Implementation effort. We implemented uKharon on top of our own RDMA framework. uKharon Core and the consensus engine span 4448 and 1324 lines of C++, respectively. The

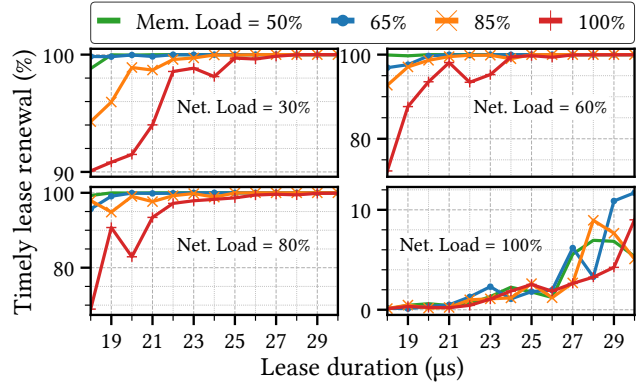

Figure 3: Percentage of timely lease renewal depending on the lease duration, network load and memory load.

kernel module of the deadbeat failure detector is 404 lines of C. uKharon-KV extends HERD by 1498 lines of C++. The only unimplemented features are clique-based memberships (Section 4.2) and adaptive leases (Section 6.3).

7.1 Overhead Induced by uKharon

Latency Overhead. Applications bundled with uKharon Core rely heavily on its `Active` method. As long as (the background running) uKharon Core renews the lease on the active membership in time, the `Active` method adds negligible latency overhead to the application. We experimentally determine that the 99th percentile latency for invoking `Active` is 38ns when the lease is renewed in time, which is the time it takes to fetch the hardware timestamp and compare it with the expiration date of the lease. Fluctuations in the network’s latency or execution delays when uKharon Core renews the lease (e.g., due to cache misses) induces additional latency to the application, as explained in Section 6.2.

Figure 3 shows how the duration of leases affects their timely renewal. We run 1-minute experiments under a steady membership with 32 lease renewers contacting coordinators directly and lease durations ranging from 18 to 30 μ s. Each machine has a maximum memory bandwidth of 480Gbps and a maximum network bandwidth of 100Gbps. We apply variable network and memory load by running `stress-ng` [27] and `perftest` [42] on the first socket of our machines.

When the network load is maximum (bottom right figure), less than 12% of the calls to `Active` return immediately, irrespective of the memory load. For network loads of 30–80% (other figures), the memory load progressively affects lease renewal. Maximum memory load causes expired leases when lease duration is shorter than 27 μ s. For most other configurations, a duration greater than 23 μ s suffices. For example, with 80% network and 50% memory load, lease renewal fails 0.0011% of the time, which corresponds to `Active` inducing latency every 300 out of 1.5 billion invocations. In other

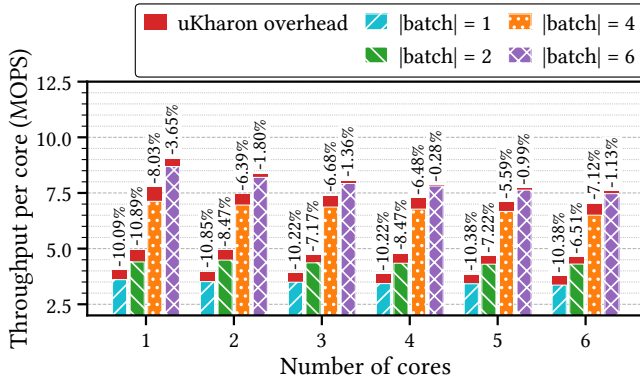

Figure 4: Impact of uKharon on HERD’s throughput for different batch sizes and numbers of cores. Full bar shows the throughput w/o uKharon; labels show uKharon’s overhead.

words, the 99.999th percentile of Active’s latency is 2 μ s.

We get similar (omitted) results when an application renews its leases through lease caches. In fact, RPC-based renewal requires at most 2 μ s longer leases (compared with reading from coordinators) to achieve the same percentages of timely lease renewal. We attribute this difference to RPC, which involves the CPU of both the application and the lease cache.

From this experiment we select the lease duration that we use for the rest of our evaluation. We pick the lease duration when renewing from coordinators (δ) to be 23 μ s, and the lease duration when renewing from lease caches (Δ) to be 25 μ s.

Throughput Reduction. We use uKharon to make HERD dynamic. The original HERD assumes a static set of servers, each of which serves a shard of the key space. Clients are aware of this sharding and use the key of a request to determine the appropriate server. The lack of dynamicity affects HERD’s flexibility in two ways. First, if a server fails, its shard becomes unavailable forever. Second, the system is unable to re-balance the load among the servers. Importantly, the use of a static set of servers ensures consistency of clients’ requests: GETs return the value of the most recent PUT.

In our implementation, each server dedicates up to 6 cores to the KV-cache and each core is responsible for a part of the key space. Every core processes clients’ requests and invokes the Active method before replying to avoid inconsistencies. If Active returns true, the core executes the request (if the key belongs to its shard) and replies to the client. Otherwise, the core rejects the request. Given that every core invokes Active in the critical path of serving requests, the latency of requests increases (by \sim 38ns) and the throughput decreases.

Figure 4 shows the per-core throughput of a static deployment of HERD, along with the drop in performance caused by the integration of the Active method. The workload is 80% GETs and 20% PUTs with 32 byte-long values. We vary the number of cores from 1 up to 6 as well as the batch size (i.e., the number of clients’ requests processed at once). Typically,

static HERD issues a reply every 350ns. Without batching, having Active in the critical path raises the reply time to 388ns, an increase of 11%. Batching has a positive impact on Active’s overhead as a single call to the method is used to serve all the requests in a batch. Thus, for batches of 6 replies, Active effectively takes 38/6 = 6.3ns per reply, an increase of just 1.8%. Finally, the overhead of Active does not increase with the number of cores, even though they invoke the method concurrently. This indicates good multicore scalability, which implies that a single uKharon Core instance per server is sufficient to serve all applications running on it.

Bandwidth overhead. uKharon Core reduces the bandwidth available to applications. Lease renewal requires 240 bytes when contacting 3 coordinators and 132 bytes when contacting a lease cache, which translates to (assuming renewal every 10 μ s) 192Mbps and 105Mbps, respectively. This bandwidth requirement accounts for 0.1 – 0.2% of a 100Gbps link, thus the bandwidth of application nodes is marginally impacted. Failure detection has similar bandwidth requirement.

7.2 Failover Time

We study uKharon’s failover time considering userspace and kernel failures. We do not further evaluate catastrophic failures, as 95% of the failover is for their 1ms-long detection, making microsecond-scale agreement and leases insignificant.

Table 2 summarizes the median failover (over 100 measurements) for various failure scenarios. We consider the failure of a single application node optionally combined with the failure of the coordinator leader or/and a lease cache. We emulate simultaneous failures by relying on RDMA Multicast. An auxiliary program executes alongside the program which we emulate the failure of. When the auxiliary program receives the multicast message, it uses SIGKILL to kill the targeted program. We assume the worst scenario, i.e., the failure of the application node results in global unavailability that is resolved only by a new (active) membership that excludes it.

In every entry of Table 2, we present the failover time when detecting the failure using the deadbeat mechanism (left) and the RDMA-based heartbeat mechanism (right). We now discuss the failover time when using the deadbeat, first considering the case when the lease caches are absent. For a single application failure, uKharon is able to failover in 50 μ s using the deadbeat. If the coordinator leader crashes at the same time as the application, the failover time increases by around 15 μ s. We attribute this increase to (1) the leader switch mechanism of the consensus engine (\sim 10 μ s) and (2) the imperfect synchronization of SIGKILL among the failed nodes (\sim 5 μ s). When lease caches are part of uKharon, the failover times for the same failure scenarios increase (as expected) by 20 – 25 μ s, which is about the lease duration of the cache. Failure of a cache has no impact on the failover time (bottom entries of the first and third columns). This is because (1) the application node receives the broadcast failure

L exists?	A	A + C	A + L	A + L + C
No	50\96	64\114	-	-
Yes	74\108	96\138	75\113	101\139

Table 2: Failover time (in μs) for failures in App, Coordinator leader and Lease caches; using the `deadbeat\heartbeat`.

notification and switches lease cache before the membership changes and (2) the new membership is compatible with the previous one. The simultaneous failure of all three types of nodes has a downtime of $101\mu\text{s}$, instead of $96\mu\text{s}$. Again, the failure of the cache does not affect the failover time, but with three nodes the imperfect synchronization of failures adds up. Finally, the same failures when using the RDMA-based heartbeat mechanism range from 96 to $139\mu\text{s}$. This mechanism adds $\sim 45\mu\text{s}$ of failover compared to the deadbeat. The reason is that reading the same value twice upon failure takes 1.5 delays on expectation and READs are issued every $30\mu\text{s}$.

7.3 uKharon-KV

Both uKharon-KV and HERD+Mu follow a primary-backup replication scheme. All requests are served by the primary, which replicates them to backups. Backups are only used for fault tolerance. All replicas (primary and backups) execute requests in the same order, but only the primary replies to clients. In the event of a failure of the primary, one of the backups becomes the new primary and continues serving clients' requests. All replicas execute all requests in the same total order, thus replicas are an exact copy of the failed primary. This means that when a replica becomes the new primary, it can respond to clients without breaking consistency.

One problem these systems have to deal with is multiple nodes trying to replicate clients' requests simultaneously. This happens when the primary fails and multiple nodes, believing they are the new primary, try to handle clients' requests. Mu avoids this problem by relying on RDMA permissions (see §5.3.2). On the other hand, uKharon-KV relies exclusively on the membership service to address it. Each membership determines a single primary. When the primary fails, a new membership is emitted that determines the new primary. Since only one membership is active at a time, no two replicas can believe to be the primary simultaneously.

The replication protocol of uKharon-KV works as follows: The primary P replicates all clients' requests to a single backup B by RDMA-writing them to a dedicated buffer on the latter. In parallel, P *speculatively* executes the requests. Upon completion of the RDMA WRITE, the primary checks that the membership in which P is the primary is still active. If that is the case, P replies to the client. Otherwise, P drops the request. Upon membership change, B waits for the new membership—in which it is the primary—to become active. Then, B scans the local buffer that was dedicated to P and applies all unprocessed requests in it. Only then B starts pro-

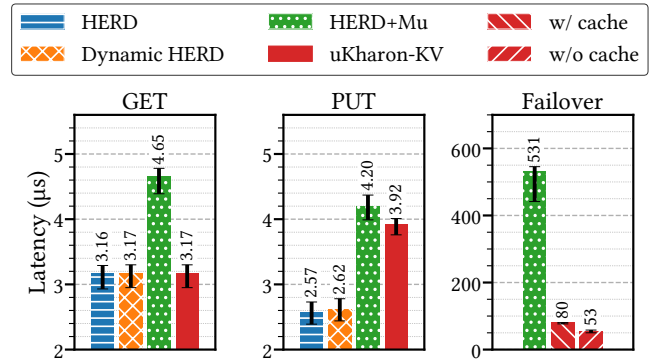

Figure 5: Latency comparison (left) of vanilla HERD, Dynamic HERD, HERD+Mu, uKharon-KV. Failover time comparison (right) of HERD+Mu and uKharon-KV. HERD+Mu uses 3-way replication; uKharon-KV uses its deadbeat. Bar height shows 95th %-ile latency; numerical label shows the 95th %-ile; error bars show the median and 99th %-ile.

cessing clients' requests. The client's failover time is the time interval between the client's last successful request to P and its first successful request to B (as the new primary).

If P 's speculative execution turns out to be incorrect, its state may diverge from the one of the new primary B . uKharon-KV, however, does not follow the common practice of rolling back unsuccessful speculations, because our prototype adopts a simple design: when a node is removed from the membership, it is not allowed to re-enter the system. Thus, the state of the old primary P is no longer used when B takes over, hence skipping the rollback.

Replication latency. We compare the latency of HERD, HERD+Mu and uKharon-KV. For HERD, we deploy a single node. For HERD+Mu, we deploy three nodes, a primary and two backups, all of which execute an instance of HERD and Mu. For uKharon-KV, we deploy a primary and a backup, both running uKharon-KV, as well as three coordinators. For these experiments, a HERD client connects to the primary and issues PUT and GET requests. We measure the time it takes for a client to complete a request and compute the median, the 95th and the 99th percentiles over 10 million requests.

Figure 5 shows the end-to-end latency of vanilla HERD and of both replication approaches. In vanilla HERD, PUTs are more efficient than GETs by 23%, due to the way HERD handles the two types of requests. Briefly, PUTs rely mostly on RDMA WRITES, which is the most efficient RDMA verb [25], while GETs rely mostly on RDMA SENDS. For reference, we also show the latency of Dynamic HERD, which uses uKharon's `Active` method in the critical path of executing clients' requests, as explained in section 7.1. We verify, once again, the efficiency of the `Active` method. At the 95th percentile, Dynamic HERD's requests are delayed by 10ns (for GETs) and 50ns (for PUTs), compared with vanilla HERD.

The two replicated solutions exhibit different costs.

HERD+Mu replicates all requests, regardless of whether they are PUTs or GETs, while uKharon-KV replicates only PUTs. HERD+Mu does not distinguish between PUTs and GETs, because in Mu the primary uses the result of replication (whether it is successful or not) to determine if it is still the primary or not. If Mu were to skip the replication of GETs, inconsistency would occur (see §2.1). On the other hand, uKharon-KV executes GETs locally, without replicating them, since the primary relies on the `Active` method to determine if its data is stale or not. Also, observe that uKharon-KV replicates PUTs approximately 300ns faster than Mu. This improvement is merely attributed to the speculative approach adopted by uKharon-KV. In HERD+Mu, the primary executes the request *after* it has been replicated to a majority. On the other hand, the primary in uKharon-KV executes the request in *parallel* to the replication to the backup. Thus, our solution hides the cost of executing the request, which is approximately 300ns, as shown by the difference of the two rightmost bars in the middle plot of Fig. 5. Regardless, uKharon-KV provides the same fault tolerance as Mu, even with one less replica: if a single replica crashes in either HERD+Mu or uKharon-KV, the system remains operational but cannot tolerate another failure. Fundamentally, both HERD+Mu and uKharon-KV assume a majority of correct nodes, the former among the replicas and the latter among the coordinators.

Failover. We compare the failover latency of uKharon-KV with HERD+Mu in the event of userspace failures. We run uKharon-KV in two configurations. In the first one, clients directly RDMA-read from coordinators to renew their lease. In the second one, clients go to lease caches. The third graph of Figure 5 shows that HERD+Mu has a 95th-percentile failover time of 531 μ s. This number is almost half of what Mu’s authors report since we fine-tuned their failure detector for our own setup. At the same time, uKharon-KV without cache (resp. with) achieves a 10 \times improvement (resp. 6.5 \times) at 53 μ s (resp. 80 μ s) of end-to-end failover time.

8 Related Work

Membership services in general. They are widely used in the data center. Distributed data processing apps (e.g., Kafka [30], MapReduce [10]), storage systems (e.g., Cassandra [31], HDFS [46]) and orchestration tools (e.g., Mesos [18]) rely on Zookeeper [20] for leader election, membership management, locks, watches, etc. uKharon focuses on membership management, yet it can be extended to support Zookeeper’s features. Indeed, uKharon-KV (excluding the lack of durability) offers similar guarantees to the strongly consistent KV-store of Zookeeper, which comprises its basic building block. ZooKeeper’s strongly consistent KV-store that forms its basis. For instance, locks can be implemented on top of uKharon-KV by extending its interface with `CompareAndSwap`. Watches, being an unreplicated pub/sub sys-

tem, only require modifying uKharon-KV’s primary. The important difference is that Zookeeper is not suitable for the microsecond scale and does not exploit RDMA.

Failure detection in the data center. A common approach to detect failures is to use end-to-end timeouts, which are hard to set. Falcon [35] proposes to use inside information in order to build faster and more accurate failure detectors by relying on hierarchies of specialized detectors. It maximizes accuracy by killing suspected processes. Albatross [34] is slightly more forgiving and isolates suspected processes so that they cannot affect the state of the system. Pigeon [33] provides fine-grained reports that end applications use to act accordingly. We embrace Falcon’s philosophy and use RDMA-tailored failure detectors to operate at the microsecond scale.

Time-bound leases. Time-bound leases are widely used to implement consistent distributed applications at the price of some synchrony assumptions. They are often provided by a distributed coordination framework such as ZooKeeper [20] or etcd [14]. Leases are used for leader election [48], as well as for guarding memberships (e.g., in FaRM [12] and Hermes [26]). uKharon guards memberships with purely client-side leases. As a result, uKharon brings leases down to a few tens of microseconds and only assumes bounded clock drift instead of loosely synchronized clocks as in Hermes.

9 Conclusion

Continuous breakthroughs in data center fabrics have paved the way for microsecond applications. A key challenge for building tail-tolerant software at scale is for applications to react fast to events such as reconfigurations and failures. Yet, existing microsecond applications lack an equally fast membership service to provide microsecond dynamicity. This lack is counter-intuitive, as the vast ecosystem built around ZooKeeper showcases the usefulness of membership services. uKharon fills this gap by being the first membership service tailored to microsecond scale applications. To achieve this demanding target, uKharon relies on (1) a multi-level failure detector, (2) a consensus engine that takes advantage of RDMA CAS, as well as (3) leases, all of which have been carefully designed to operate in the microsecond envelope. We used uKharon to implement uKharon-KV, a replicated KV-cache which outperforms the state of the art in latency while improving its failover time by up to 10 \times .

A One-sided Paxos

A.1 Assumptions

In the next subsections, we consider the M&M model [1]. It allows processes to both pass messages and share memory.

We assume that communication channels are lossless and have FIFO semantics, which is ensured by InfiniBand’s Reliable Connections. The system has n processes $\Pi = \{p_1, \dots, p_n\}$ that can attain the roles of *proposer* or *acceptor*. There are p proposers and n acceptors. Up to $p - 1$ proposers and $\lfloor \frac{n-1}{2} \rfloor$ acceptors may fail by crashing. As long as a process is alive, its memory is remotely accessible. When a process crashes, subsequent operations to its memory hang forever. We assume partial synchrony for consensus’s liveness [17].

A.2 One-sided RPC

In this section, we prove that the one-sided RPCs of Algorithm 1 are equivalent to two-sided RPCs when not obstructed. Moreover, we prove that when equivalence is violated (due to obstruction), one-sided RPCs have no side effects. We assume that both `compare` and `f` are deterministic.

Lemma A.1. *If `cas-rpc` does not abort, `rpc` and `cas-rpc` are equivalent.*

Proof. An execution of `rpc` solely depends on the value of `state` and the input value x . We denote such execution of `rpc` as $\langle state, x \rangle_{rpc}$. If an execution of `cas-rpc` does not abort, it solely depends on the value of `expected` fetched at line 2 and the input value x . We denote such execution of `cas-rpc` as $\langle expected, x \rangle_{cas-rpc}$.

We show that any execution $\langle s, x \rangle_{rpc}$ is equivalent to the execution $\langle s, x \rangle_{cas-rpc}$ in the sense that both `rpc` and `cas-rpc` will have the same `state` value and return the same projection at the end of their execution.

If an execution $\langle s_1, x \rangle_{rpc}$ makes the comparison at line 3 fail, then `state` is not modified and `proj(s1)` is returned. In the execution $\langle s_1, x \rangle_{cas-rpc}$, the comparison at line 3 will also fail and `proj(s1)` is also returned without modifying the remote state. In this case, both executions are equivalent.

If an execution $\langle s_2, x \rangle_{rpc}$ makes the comparison at line 3 succeed, then `state` is modified to `f(s2, x)` and `proj(f(s2, x))` is returned. In the execution $\langle s_2, x \rangle_{cas-rpc}$, the comparison at line 3 will also succeed. As the execution is assumed not to abort, the CAS will succeed. Thus the remote state will atomically be updated from s_2 to `f(s2, x)` and `proj(f(s2, x))` is also returned. In this case, both executions are also equivalent. \square

Lemma A.2. *If `cas-rpc` aborts, it has no side effects.*

Proof. If `cas-rpc` aborts, the comparison at line 7 has failed. This implies that the CAS failed and thus that `state` is unaffected by the execution. \square

From lemmas A.1 and A.2, `cas-rpc` exhibits all-or-nothing atomicity. We now prove that such a transformation is obstruction-free.

Lemma A.3. *If `cas-rpc` runs alone, it does not abort.*

Proof. Let's assume by contradiction that `cas-rpc` runs alone and aborts. For `cas-rpc` to abort, the comparison at line 7 must have failed. This implies that the CAS at line 6 failed due to state not matching expected. `state` must thus have been updated between lines 2 and 6. This implies a concurrent execution, hence a contradiction. \square

A.3 Consensus and Abortable Consensus

In the consensus problem, processes *propose* individual values and eventually irrevocably *decide* on one of them. Formally, consensus has the following properties:

Termination Every correct process eventually decides once.

Uniform agreement If v and v' are decided on, then $v = v'$.

Validity If v is decided on, v is the input of some process.

We implement consensus by composing two abstractions:

- *Abortable consensus* [5], an abstraction weaker than consensus that is solvable in the asynchronous model,
- *Eventually perfect leader election* [7], the weakest failure detector required to solve consensus.

Abortable consensus is identical to consensus except for:

Termination Every correct process eventually decides once or aborts.

Decision If a single process proposes infinitely many times, it eventually decides.

A.4 One-sided Abortable Consensus

Algorithm 3 appears in [5] and implements abortable consensus. Algorithm 4 transforms algorithm 3 by replacing its RPCs with CAS-based RPCs. This transformation causes it to abort strictly more than the original algorithm. To see why, consider the following execution: Let proposers P_1 and P_2 concurrently initiate the Prepare phase with respective proposals 1 and 2. Both fetch the remote state and get $\langle 0, 0, \perp \rangle$. Then, P_1 succeeds in writing its proposal to acceptor A_1 . Later on, the CAS of P_2 fails at A_1 as the value is now $\langle 1, 0, \perp \rangle$ instead of the expected $\langle 0, 0, \perp \rangle$. Thus, P_2 aborts even if it had a larger proposal number than P_1 . The more relaxed comparison in the original algorithm would not have caused P_2 to abort.

Lemma A.4. *Algorithm 4 preserves Decision.*

Proof. If a single process proposes infinitely many times, it will eventually run the one-sided RPCs obstruction-free. By Lemma A.3, this guarantees that the one-sided RPCs will eventually terminate without aborting. In such case, Lemma A.1 guarantees the execution to be equivalent to one of the original algorithm. Thus, the transformation preserves the decision property of Algorithm 3. \square

Algorithm 3: Paxos's Abortable Core

```

1  Proposers execute:
2  decided = False
3  proposal = id
4  proposed_value =  $\perp$ 

6  def propose(value):
7      proposed_value = value
8      prepare()
9      accept()

11 def prepare():
12     proposal = proposal + | $\Pi$ |
13     broadcast (Prepare | proposal)
14     wait for a majority of (Prepared | ack, ap, av)
15     adopt av with highest ap as proposed_value
16     if any not ack: abort

18 def accept():
19     broadcast (Accept | proposal, proposed_value)
20     wait for a majority of (Accepted | mp)
21     if any mp > proposal: abort
22     trigger once (Decide | proposed_value)

24 Acceptors execute:
25 min_proposal = 0
26 accepted_proposal = 0
27 accepted_value =  $\perp$ 

29 upon (Prepare | proposal):
30     if proposal > min_proposal: min_proposal = n
31     reply (Prepared | min_proposal == n, accepted_proposal,
            $\hookrightarrow$  accepted_value)

33 upon (Accept | proposal, value):
34     if proposal  $\geq$  min_proposal:
35         accepted_proposal = min_proposal = n
36         accepted_value = value
37     reply (Accepted | min_proposal)

```

Lemma A.5. *Algorithm 4 preserves Termination.*

Proof. Assuming a majority of correct acceptors, CASes will eventually complete at a majority. Due to the absence of loops or blocking operations inside `prepare`, `accept`, `cas_prepare` and `cas_accept` in algorithm 4 (apart from waiting for the completion of CASes at a majority), a proposer that invokes `propose` will either abort or decide. \square

Algorithms 3 and 4 differ only in some executions where the transformed algorithm aborts whereas the original does not. Nevertheless, aborting does not violate safety, as we show next.

Lemma A.6. *Algorithm 4 preserves the safety properties.*

Proof. Assume, by contradiction, that adding superfluous abortions in Algorithm 3 violates safety. Consider an execution E_1 , where processes $\{P_1, \dots, P_n\}$ deviate from the algorithm and abort at times $\{t_1, \dots, t_n\}$ after which the global state is $\{S_1, \dots, S_n\}$ and safety is violated. Also, consider another execution E_2 , where processes $\{P_1, \dots, P_n\}$ crash at times $\{t_1, \dots, t_n\}$ after which the global state is $\{S_1, \dots, S_n\}$. In execution E_1 , safety is violated. On the other hand, execution E_2 preserves safety, since Algorithm 3 tolerates arbitrarily many proposer crashing. The two executions, however, are

Algorithm 4: One-sided Abortable Consensus

```

1  Acceptors execute:
2  state = { min_proposal: 0, accepted_proposal: 0,
           ↪ accepted_value: ⊥}

4  Proposers execute:
5  proposal = id
6  proposed_value = ⊥

8  def propose(value):
9    proposed_value = value
10   prepare()
11   accept()

13 def prepare():
14   proposal = proposal + |Π|
15   async cas_prepare(p) for p in Acceptors
16   wait for a majority to return ⟨ack, ap, av⟩
17   if any not ack: abort
18   adopt av with highest ap as proposed_value

20 def accept():
21   async cas_accept(p) for p in Acceptors
22   wait for a majority to return mp
23   if any mp > proposal: abort
24   trigger once (Decide | proposed_value)

26 def cas_prepare(p):
27   expected = fetch_state(p)
28   if not proposal > expected.min_proposal:
29     return (False, expected.accepted_proposal, expected,
           ↪ accepted_value)
30   move_to = expected
31   move_to.min_proposal = proposal
32   read = statep.cas(expected, move_to)
33   if read == expected:
34     return (True, expected.accepted_proposal, expected,
           ↪ accepted_value)
35   abort

37 def cas_accept(p):
38   expected = fetch_state(p)
39   if not proposal ≥ expected.min_proposal:
40     return expected.min_proposal
41   move_to = expected
42   move_to.min_proposal = proposal
43   move_to.accepted_proposal = proposal
44   move_to.accepted_value = proposed_value
45   read = statep.cas(expected, move_to)
46   if read == expected:
47     return expected.min_proposal
48   abort

```

indistinguishable, hence a contradiction. Thus, Algorithm 4 preserves safety regardless of how often it aborts. \square

Theorem A.7. *Algorithm 4 implements abortable consensus.*

Proof. The result follows directly by composing lemmas A.4, A.5 and A.6. \square

A.5 Streamlined One-sided Algorithm

In this section, we make Algorithm 4 efficient in order to increase its practicality.

First, it is not required to fetch the remote state at the start of each RPC. As it is safe to have stale `expected` states, it is safe to use states deduced from previous CASes. Predicted states can thus be initialized to $\langle 0, 0, \perp \rangle$ and updated each time a CAS completes (either succeeding or not). Moreover,

wrongly predicting states can only result in superfluous aborts which have been proven to be safe by Lemma A.6. Thus, it is safe to optimistically assume that onflight CASes will succeed. Second, in the Prepare phase, the `proposal` variable can be increased upfront to value higher than any predicted remote `min_proposal` to reduce predictable aborts.

Algorithm 5: Streamlined One-sided Abortable Consensus

```

1  Acceptors execute:
2  state = { min_proposal: 0, accepted_proposal: 0,
           ↪ accepted_value: ⊥}

4  Proposers execute:
5  predicted[] = { 0, 0, ⊥}
6  proposal = id
7  proposed_value = ⊥

9  def propose(value):
10   proposed_value = value
11   prepare()
12   accept()

14 def prepare():
15   while any predicted[.].min_proposal ≥ proposal:
16     proposal = proposal + |Π|
17   for p in Acceptors:
18     move_to[p] = {min_proposal: proposal, ..predicted[p]}
19     reads[p] = async statep.cas(predicted[p], move_to[p])
20   wait until majority of states are read
21   for p in Acceptors:
22     if reads[p] ∈ {predicted[p], ⊥}:
23       predicted[p] = move_to[p]
24     else:
25       predicted[p] = reads[p]
26   if any CAS failed: abort
27   adopt proposed_value from predicted accepted_values with
           ↪ highest accepted_proposal if any

29 def accept():
30   reads = ⊥|Acceptors|
31   move_to = (proposal, proposal, proposed_value)
32   for p in Acceptors:
33     reads[p] = async statep.cas(predicted[p], move_to)
34   wait until majority of states are read
35   if any CAS failed:
36     for p in Acceptors:
37       if reads[p] ∈ {predicted[p], ⊥}:
38         predicted[p] = move_to
39     else:
40       predicted[p] = reads[p]
41   abort
42   trigger once (Decide | proposed_value)

```

With the aforementioned optimisations, Algorithm 4 is transformed into Algorithm 5. Notably, the liveness of the resulting algorithm is preserved: Let's assume that a *single* proposer runs infinitely many times. Eventually, it will run obstruction-free. In the worst case, each time it will abort at line 26 or 41 because of a single wrong guess and update its prediction. The optimistic update of expected states at lines 23 and 38 and the FIFO semantics of communication links provide that, once a remote state is correctly guessed, any later CAS will succeed. Thus, after at most n runs, all CASes will succeed and the proposer will decide.

A.6 Overcoming Limited CAS Size

As explained in Section 5.3.1, the RDMA hardware limits the size of CASes. Thus, proposal fields will overflow after 2^{16} attempts. In such an unlikely scenario, our consensus engine falls back to traditional RPC: Once the RDMA-exposed `min_proposal` of an acceptor reaches $2^{16} - |\Pi|$, proposers switch to RPC to communicate with this specific acceptor. Acceptors check `state` and, if it is above the threshold, initiate the standard RPC version of Paxos with the `min_proposal`, `accepted_proposal` and `accepted_value` variables initialized to match `state`.

B Active Method Correctness

In this section, we provide a formal definition and a proof of correctness of the `Active` method described in Section 6.

B.1 Formal Definition

`Active(Membership) → bool` has the following properties:

Monotonicity If `Active(M')` returns `true` at any process, future calls `Active(M)` with $M < M'$ will return `false`.

Convergence If M is the last membership to be decided (if any), invoking `Active(M)` will eventually return `true` at all correct processes.

Definition 1. If `Active(M)` returns `true`, then M is considered active at the linearization point of the call.

Definition 2. If M is active at times t and t' , then it is considered active in the interval $[t, t']$.

From these simple properties and definitions, it follows that no two active memberships can overlap.

Theorem B.1. Only one membership can be active at a time.

Proof. Assume by contradiction that M and M' ($M < M'$) are simultaneously active. By definition, `Active(M)` must have returned `true` after `Active(M')` returned `true`. This breaks Monotonicity, hence a contradiction. \square

B.2 Non-leased Active Membership

We prove the correctness of uKharon's implementation of `Active`. We assume no gaps in the sequence of decided memberships. This is enforced by coordinators by not proposing the $(k+1)$ -th membership until the k -th is decided.

Lemma B.2. Algorithm 6 ensures Monotonicity.

Proof. `Active` can only be called on decided memberships. Let M and M' be two decided memberships with $M < M'$. If `Active(M')` returned `true`, by the no-gap assumption, all

Algorithm 6: Active built on top of the consensus engine

```
1 def Active(M) → bool:
2   reads =  $\perp_{|\text{Acceptors}|}$ 
3   for p in Acceptors:
4     reads[p] = async paxos[M.id + 1].slotp.read()
5   wait until majority of slots are read
6   if all slots are not accepted:
7     return true
8   propose_membership(M.id + 1, first accepted value)
9   return false
```

memberships between M and M' have been decided. Because M' 's successor has been decided, a majority of acceptors' slots $M.id + 1$ have been written. Thus, `Active(M)` will read at least one non-empty slot and return `false`. \square

Lemma B.3. Algorithm 6 ensures Convergence.

Proof. Assume by contradiction that M is the last decided membership and `Active(M)` never returns `true` at some correct process. Thus, this process executes line 8, which means that it proposes a new membership. Given that the process is correct, some membership with $id\ M.id + 1$ will eventually be decided. Therefore, M is not the last membership, hence a contradiction. \square

Theorem B.4. Algorithm 6 implements `Active`.

Proof. Follows directly from Lemmas B.2 and B.3. \square

B.3 Leased Active Membership

Algorithm 2 reduces communication by leasing the output of Algorithm 6. We prove that it preserves `Active`'s properties.

Lemma B.5. Algorithm 2 preserves Monotonicity.

Proof. Let e be an execution of `Active(M)` that returned `true`. e either returned at line 9 or at line 12 with $t > t_{start}$. We denote the former case *leased(M)* and the latter *checked(M)*. Assume by contradiction that `Active(M')` returned `true` in an execution e_1 and then `Active(M)` returned `true` in an execution e_2 with $M < M'$. Either:

- *leased(M)*: In e_2 , `majority_active(M)` returned `true` at most δ before `Active(M)` returned `true`. In e_1 , lines 5–7 ensure that M' was decided at least δ before `Active(M')` returned `true`. Thus, `majority_active(M)` returned `true` after M' was decided. However, because M' has been decided, a majority of acceptors' slots $M'.id = M.id + 1$ must have been written. Thus, `majority_active(M)` should have read at least one non-empty slot and returned `false`. Hence, a contradiction.
- *checked(M)*: `majority_active(M)` returned `true` after `majority_active(M')` returned `true`. This breaks `majority_active`'s Monotonicity, hence a contradiction.

□

Lemma B.6. *Algorithm 2 preserves Convergence.*

Proof. Assume that M is the last membership to be decided. Thus, `majority_active(M)` will eventually always return `true`. At most δ after `Active(M)` returns for the first time, t_{start} will be in the past and `leased_membership` set to M . Thus, eventually, the `else` branch at line 8 will always be visited and either return `true` via line 9 or 12. □

Theorem B.7. *Algorithm 2 implements Active.*

Proof. Follows directly from Lemmas B.5 and B.6. □

C Clocks

uKharon relies on hardware timestamps to check if a membership is `Active`. When using modern Intel processors, Linux has three available clocksources: `tsc`, `hpet` and `acpi_pm`. The `tsc` clocksource is the most efficient and requires 20-25ns to take a timestamp [11].

Architectural considerations. The `tsc` clocksource uses Intel's TSC hardware to measure time accurately. TSC stores the number of cycles executed by the CPU after the latest reset. Traditionally, TSC is considered an unreliable way to take timestamps. The reason is that Intel processors have variable clock speed, thus the number of cycles does not correspond to wallclock time. However, modern Intel processors have three features [8]: *Constant TSC*, *Nonstop TSC* and *Invariant TSC* which solve this problem. The combination of these features results in a TSC that is incremented at a constant rate regardless of the power state of the processor. As a result, it is safe to use this counter for efficient timestamping.

TSC synchrony. In Intel processors, every core has its own TSC. All processors in the same socket start the TSC hardware using the same `RESET` signal, thus the absolute values of the TSC across cores of the same socket match. This means that one can compare safely the values of TSC across different cores, assuming that all TSCs run at the same frequency. Because this assumption does not always hold, Linux determines the base frequency of every core during boot and uses this frequency to convert clock cycles to wallclock time. To accomplish it, Linux uses the more accurate (and more expensive) `hpet`.

uKharon takes further care to deal with TSC synchrony. More precisely, it checks for the synchronization of TSC between cores using a ping-pong test. In this test, core A takes a timestamp t_1 and signals core B to do the same. Core A signals core B by writing to a lock-free Single-Producer Single-Consumer (SPSC) queue that is polled by B. When B receives the signal it also takes a timestamp t_2 and sends it back to A (using another SPSC queue). Upon reception of the timestamp from B, core A takes the last timestamp t_3 . In

our test we confirm that always $t_1 < t_2 < t_3$. Additionally, in our hardware, the minimum difference between t_1 and t_2 is $\epsilon = \min(t_2 - t_1)$ is 64ns. uKharon takes ϵ into consideration by incorporating into the leases as follows: Suppose a lease is valid for a duration of δ starting at time t . uKharon considers that the lease starts at time $t + \epsilon$ and has a duration of $t + d - 2\epsilon$.

Inter-machine clock drift. In order to ensure that active memberships do not overlap, uKharon assumes that clock drift is bounded, i.e., that time passes approximately at the same speed on different machines. This assumption is necessary to enable client-side leases. It guarantees that after a lease duration period, leases across all clients will have to be renewed. Our system is built to tolerate clock drift, as long as this drift is bounded. We experimentally determine an upper bound for the clock drift with a simple test. In this test, machine A takes a timestamp t_1 and pings machine B to wait for 1 minute before replying back to it. Upon reception of B's response, A takes another timestamp t_2 . It then computes $t_2 - t_1$ and compares it to the expected 1 minute measured by B (after removing the communication delay). We repeat this test several times and determine that the clock drift between machines differs by at most 0.001%. uKharon incorporates inter-machine clock drift by waiting $1.01 \times \delta$ upon membership discovery, ensuring that when leases become active on a new membership, everyone's leases on the previous membership will have expired.

D Artifact

Abstract

The evaluated artifact is provided as a git repository and contains the source code of uKharon, build instructions and deployment scripts to run the experiments presented in this paper.

Scope

The artifact contains code and steps to reproduce results obtained in Figure 3, Figure 4, Figure 5 and Table 2.

Contents

The artifact contains the source code of uKharon, including the custom kernel modules. It also contains the patches to create the custom Linux kernel, as well as the patches required for HERD [24] and Mu [2]. The artifact describes how to build everything presented in the paper, including the custom Linux kernel and the solutions we compare against. It also describes how to deploy the built binaries.

Hosting

The artifact source code for uKharon is available at <https://github.com/LPD-EPFL/ukharon>. All the necessary instructions are provided in the README.md file.

Requirements

Building uKharon requires an x86-64 system set-up with Ubuntu 20.04 LTS. Executing uKharon requires 8 machines equipped with Ubuntu 20.04 LTS, RDMA over InfiniBand, ability to install a custom kernel and custom kernel modules, as well as ability to configure and use InfiniBand multicast groups.

KRCORE: A Microsecond-scale RDMA Control Plane for Elastic Computing

Xingda Wei^{1,2}, Fangming Lu¹, Rong Chen^{*1,2}, and Haibo Chen¹

¹Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University

²Shanghai AI Laboratory

Abstract

We present KRCORE, an RDMA library with a microsecond-scale control plane on commodity RDMA hardware for elastic computing. KRCORE can establish a full-fledged RDMA connection within $10\mu s$ (hundreds or thousands of times faster than verbs), while only maintaining a (small) fixed-sized connection metadata at each node, regardless of the cluster scale. The key ideas include virtualizing pre-initialized kernel-space RDMA connections instead of creating one from scratch, and retrofitting advanced RDMA dynamic connected transport with static transport for both low connection overhead and high networking speed. Under load spikes, KRCORE can shorten the worker bootstrap time of an existing disaggregated key-value store (namely RACE Hashing) by 83%. In serverless computing (namely Fn), KRCORE can also reduce the latency for transferring data through RDMA by 99%.

1 Introduction

The desire for high resource utilization has led to the development of elastic applications such as disaggregated storage systems [52, 16, 67]. Elasticity provides a quick increase or decrease of computing resources (e.g., processors or containers) based on application demands. Since the resources are dynamically launched and destroyed, minimizing the control path overheads—including process startup and creating network connections—is vital to applications, especially those with ephemeral execution time. Elastic applications typically have networking requirements. For instance, computing nodes in a disaggregated storage system access the data stored at the storage nodes across the network.

RDMA is a fast networking feature widely adopted in datacenters [53, 19, 13]. Unfortunately, RDMA has a slow control path: the latency of creating an RDMA connection (15.7ms) is 15,700X higher than its data path operation (see Figure 1(b)). As the latency of typical RDMA-enabled applications that require elasticity has reached to microsecond-scale (see Figure 1(a)), this high connection time may significantly decrease the application efficiency, e.g., increasing latency when expanding resources to handle load spikes. The cost is challenging to reduce because it not only includes software data structure initialization costs but also involves extensive hardware resource configurations, as RDMA offloads network processing to the network card (§2.3.1).

*Rong Chen is the corresponding author (rongchen@sjtu.edu.cn)

Fig. 1. (a) The execution time (**Data**) of typical elastic RDMA-enabled applications, and (b) the breakdown of control path costs. RACE [67] is a disaggregated key-value store. FaRM-v2 [46] is a database that can accelerate serverless transactions [63]. YCSB-C [11] and TPC-C [50] are representative benchmarks for each system. The serverless platform evaluated is Fn [43].

A common approach to avoiding the control path cost is to cache connections and share them with different applications. However, user-space RDMA connections can not be directly shared by different applications, because each app has its own exclusive driver data structure and dedicated hardware resources. Nevertheless, sharing a kernel-space RDMA connection is possible since applications share the same kernel (LITE [53]). However, LITE has performance and resource inefficiency issues (§2.3.2) in elastic computing, because it doesn't target this scenario. First, it still pays the initialization cost under cache misses. Second, caching all RDMA connections to all nodes is resource inefficient (e.g., taking several GBs of memory), especially when a production RDMA-capable cluster has reached a scale of more than 10,000 nodes [34]. Finally, sharing RDMA connections complicates the preservation of the low-level verbs interfaces, which is important to apply RDMA-aware optimizations [67, 55, 14, 57, 24, 25]. LITE only provides a high-level API.

We continue the line of reusing connections to boost the RDMA control path, and further overcome the issues mentioned above. We present **KRCORE**, a networking library with an ultra-fast control plane. KRCORE can establish a full-fledged RDMA-capable connection within $10\mu s$, only 0.05% and 0.22% of the verbs and LITE under cache misses, respectively. More importantly, KRCORE only needs a small amount of fixed-sized memory for the connection pool (e.g., 64MB), irrelevant to the cluster scale. Finally, KRCORE supports low-level RDMA interfaces compatible with existing RDMA-aware optimizations.

Supporting such a fast control plane seems to contradict our promise of a small fixed-sized connection pool. To achieve this, KRCORE makes a key innovation: we *retrofit* a less-studied yet widely supported advanced RDMA hardware feature—*dynamic connected transport* (DCT) [1]—to the kernel. DCT allows a single RDMA connection to communicate with different hosts. Its connection and re-connection are offloaded to the hardware and thus, are extremely fast (less than $1\mu s$). Our observation is that when virtualizing an established kernel-space DCT connection to different applications, they no longer pay the control path cost and memory consumption of ordinary RDMA connections.

In designing KRCORE, we found virtualizing DCT with a low-level API brings several new challenges, and we propose several techniques to address them (§3.1). First, DCT requires querying a piece of metadata to establish a new connection. Using RPC can not achieve a stable and low latency. Further, RPC needs extra CPU resources to handle DCT-related queries. Observing the small memory footprint of DCT metadata, we propose an architecture that deploys RDMA-based key-value stores to offload the metadata queries to one-sided RDMA READ (§4.2). Second, DCT has a lower data path performance than normal RDMA transport (RC) due to its dynamic connecting feature. The performance is mostly affected when a node keeps a long-term communication with another. Therefore, we introduce a hybrid connection pool that retains a few RC connections connected to frequently communicated nodes to improve the overall performance. KRCORE further adopts a transfer protocol that can transparently switch a virtualized connection from DCT to RC (§4.6). Finally, we propose algorithms to safely virtualize a shared physical QP to multiple applications with a low-level API (§4.4).

We implement KRCORE as a loadable Linux kernel module in Rust. We also extended an existing kernel-space RDMA driver (mlx-ofed-4.9) to bring DCT to the kernel. To the best of our knowledge, KRCORE is the first to achieve a microsecond-scale RDMA control plane. Although KRCORE is a general-purpose RDMA library, it really shines with elastic computing applications. Our experiments demonstrated that KRCORE can reduce the computing node startup time of a state-of-the-art production RDMA-enabled disaggregated key-value store (RACE [67]) by 83%, from 1.4s to 244ms (§5.3.1). For serverless computing—another popular elastic application, KRCORE can shorten the data transfer time over RDMA by 99%, from 33.3ms to $0.12\mu s$ (§5.3.2).

Our source code and experiments are available at <https://github.com/SJTU-IPADS/krcore-artifacts>.

2 Background and Motivation

2.1 The case for fast control path in elastic computing

KRCORE targets systems that require elasticity: the ability to automatically scale according to application demands. One such case is disaggregated storage systems where the computing nodes and storage nodes are separated and connected

by the network [52, 16, 67]. Under high loads, the system can dynamically add computing nodes for better performance: and they need to establish connections to the storage nodes on-the-fly. Another important case is serverless computing [22] where the platforms instantaneously launch short-lived tasks with containers¹. The launch time typically includes network connections [51].

Unlike long-running tasks (e.g., web servers), the control path (e.g., network creation) is typically on the critical path of elastic applications. For example, before executing the application code, a serverless function that issues database transactions must first establish network connections to remote storage nodes [63, 21]. With RDMA, the transaction latency has reached 10-100 μs [14, 57]. Reducing the control path costs—including launching a container and creating network connections—is therefore vital to the end-to-end execution time or tail latency of elastic applications (see Figure 1).

Much research has focused on reducing other control path costs, e.g., the container launch time to about 10ms [40] and even sub-millisecond [15]. However, only a few considered accelerating network connection creation [51], especially for RDMA. The control path of RDMA is indeed several orders of magnitude slower than its data path (e.g., 22ms vs. $2\mu s$ in §2.3). It is also orders of magnitude slower than the execution time of common elastic RDMA-enabled applications, or other control path costs (see Figure 1).

2.2 RDMA and queue pair (QP)

RDMA is a high bandwidth and low latency networking feature widely adopted in modern datacenters [53, 19]. It has two well-known primitives: *two-sided* provides a message passing primitive while *one-sided* provides a remote memory abstraction—the RDMA-capable network card (RNIC) can directly read/write server memory in a CPU-bypassing way.

Although RDMA is commonly used in the user-space, the kernel adopts the same *verbs* API (verbs), which exposes network connections as queue pairs (QPs). Each QP has a send queue (*sq*), a completion queue (*comp_queue*), and a receive queue (*recv_queue*). Both primitives follow a similar execution flow. To send a request (or a batch of requests), the CPU uses `post_send` to post it (or them) to the *send queue*. If the request is marked as *signaled*, the completion can be polled from the *completion queue* via `poll_cq`. For two-sided primitive, the CPU can further receive messages with `poll_cq` over the *receive queue*. Before receiving, one should use `post_recv` to post message buffers to the QP. Note that the CPU needs to register memory through `reg_mr` to give RNIC memory access permissions.

QP has several kinds of transport each with different capabilities. We focus on improving the control path performance of *reliable connected* QP (RCQP), as it is the most commonly used one that supports both RDMA primitives and is reliable.

¹Serverless platforms may use virtual machine (VM)s to run tasks, which is not the focus of our paper. §6 discusses how KRCORE can apply to VMs.

Fig. 2. The execution flow of a client (CL) communicating with two nodes (S0 and S1) using user-space verbs. `change_rtr` changes the QP to ready to receive status while `change_rts` changes the QP to ready to send status.

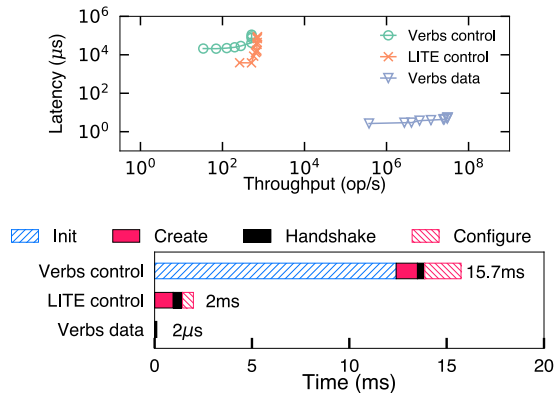

Fig. 3. (a) Huge performance gap btw. RDMA's control path and data path (issuing 8B READ) when connecting and communicating with one node. (b) A breakdown of RDMA control path time.

2.3 Analysis of RDMA control path costs

2.3.1 User-space control path costs

Consider the example in Figure 2 where a client sends RDMA requests to two nodes. The control path includes first initializing the driver context (**Init**)², creating the QPs (**Create**), exchanging the QP information to the remote peer with a **handshake** protocol and configuring the QPs to ready states (**Configure**). Figure 3(a) reports its latency, which is 7,850X higher than the data path (Verbs control vs. Verbs data).

Issue: High hardware setup cost. To quantify the costs in detail, Figure 3 breakdowns the control path time. We carefully optimize the connection handshake with RDMA's connectionless datagram [26], which is orders of magnitude faster than using TCP/UDP. Contradicting the common wisdom, exchanging the connection information through the network (**Handshake**) is **not** the dominant factor: **Handshake** only contributes 2.4% of the total time. The cost is dominated by communicating with the RNIC hardware for the connection setups. Consider the `create_qp` in **Create**: we found 87% of the `create_qp` time (361μs vs. 413μs) is waiting for the RNIC to create the hardware queues.

2.3.2 Existing kernel-space solution is insufficient

LITE [53] is the only kernel-space RDMA solution and is the closest to our work. It provides high-level remote memory *read*, *write* and *RPC* interfaces over the low-level verbs API (§2.2). LITE maintains an in-kernel connection pool that

²Including creating the protection domain and registering the memory.

Fig. 4. The execution flow of a client (CL) communicating with two nodes (S0 and S1) with the kernel-space RDMA assuming that CL has cached a QP to S0 in its connection pool.

caches RCQPs connected to all nodes, which avoids the user-space **Init** (Figure 2) costs because applications share the same kernel-space driver data structures. However, it still has the following **issues** for elastic applications:

Issue#1: High cost connecting to a new node. If the RCQP of the target node is not cached, LITE must follow the same **Create** and **Configure** as user-space RDMA, e.g., S1 in Figure 4, which are non-trivial (2ms for each connection). Note that we have carefully optimized LITE's control path: LITE originally adopts a centralized cluster manager to create connections, which can only establish tens of QPs per second. We optimize it with a decentralized connection scheme using RDMA's connectionless datagram. The optimization achieves a 2ms per-connection latency and 712 QPs/second per node throughput (Figure 3), bottlenecked by the RNIC (see §2.3.1).

Issue#2: Huge memory consumption. Caching RCQPs connected to all other nodes can mitigate Issue#1. However, this strategy has huge per-machine memory consumption since the number of RCQPs needed scales linearly with the cluster size. In LITE, each QP consumes at least 159KB memory³, excluding the message buffers and receive queues (may share between different QPs via shared receive queue). Therefore, LITE would consume at least 1.52 GB memory per node for fast connection on a modern RDMA-capable cluster with more than 10,000 nodes[17].

Issue#3: Inflexible interface. LITE exposes a high-level RDMA API (e.g., a synchronous remote memory read), which simplifies sharing the same QP to different applications. However, it is inflexible to apply RDMA-aware optimizations widely adopted in the literature [67, 55, 14, 57, 24, 25], e.g., sending different read/write requests within a batch asynchronously. To utilize these optimizations, applications need verbs low-level API (§2.2). Unfortunately, directly executing the low-level API on a shared QP can easily corrupt the QP states (see §3.1), and interrupt application running. We carefully design the QP virtualization algorithms to correctly virtualize a shared QP with verbs's low-level API (§4.4).

³It configures the QP with 292 *sq* and 257 *comp_queue* entries, a common setup in RDMA-based systems. Each *sq* entry takes 448B while *cq* takes 64B. The driver would further round queues to fit the hardware granularity.

3 Approach and Overview

Opportunity: advanced RDMA transport (DCT). Dynamically Connected Transport (DCT) [1] is an advanced RDMA feature widely supported in commodity RNICs (e.g., from Mellanox Connect-IB [37] to ConnectX-7 [35]). DCT preserves the functionalities of RC and further supports dynamic connecting: a DCT QP (DCQP) can communicate to different nodes without user-initiated connections: RNIC can create DCT connections on-the-fly by piggybacking control plane messages with data plane ones. Since the connections are only processed in the hardware, DCT re-connection is extremely fast: our measured overhead is less than $1\mu s$. When using DC-QPs, the host only needs to specify the target node’s RDMA address and its DCT metadata (i.e., DCT number and DCT key) in each request.

Basic approach: virtualized kernel-space DCQP. The goal is to achieve an ultra-fast control plane for the applications. Our basic approach is to virtualize kernel-space DCQPs (as VQPs) to user-space applications. The observation is that DCT naturally addresses the costly creation overhead (**Issue#1**) and the huge memory consumption (**Issue#2**) of RCQPs (§2.3.2). A kernel-space solution further mitigates the user-space driver loading costs (§2.3.1).

VQP also supports low-level RDMA interfaces (e.g., `ibv_post_send`) with the necessary extended API suitable for elastic computing (§4.1). Therefore, users can flexibly apply existing RDMA-aware optimizations [24, 25, 57] (**Issue #3** in §2.3.2). Note that different VQPs can share the same physical QP in the kernel. Nevertheless, KRCORE provides an exclusively owned QP abstraction to the applications.

3.1 Challenges and solutions

#1. Efficient DCT metadata query. DCQP needs to query the DCT metadata before sending requests. Specifically, to allow communicating with DCT, the server must first create a *DCT target* identified by a key and number (DCT metadata). Afterward, the clients can piggyback the metadata in their requests to communicate with the created target.

A viable solution is to send an RPC to the target node to query the metadata using RDMA’s connectionless datagram (UD)⁴, which prevents control plane costs as UD is connectionless. However, it is inefficient in performance and CPU usage. First, the latency of RPC may vibrate to tens of milliseconds due to the scheduling and queuing overhead of the CPU. Second, KRCORE must deploy extra kernel threads to handle the queries.

Solution: RDMA-based meta server. We replicate the DCT metadata at a few global meta servers backed by RDMA-enabled key-value stores (KVS) [67, 58, 55, 13], meaning each node can query it with one-sided RDMA bypassing the CPU. To support one-sided RDMA while preventing QP over-

⁴It only supports two-sided RDMA.

Fig. 5. The execution flow of a client (CL) communicating with two nodes (S0 and S1) with KRCORE. MS: meta server. Note that KRCORE always put the hardware control path (i.e., creating RC-QPs) in the background.

provisions, KRCORE only maintains a few RCQPs connected to nearby meta servers. Replicating the DCT metadata is practical because it is small: 12B is sufficient for one node to handle all requests from others.

#2. Performance issues of DCT. DCT is slower than RC in peak throughput and may incur high tail latency due to re-connection (§5.2). The performance is mostly affected when a node frequently sends requests to the same node.

Solution: virtualized hybrid QP. KRCORE manages a hybrid QP pool that stores both RC and DC QPs. A VQP can transparently switch between DC and RCQP (§4.6), allowing us to create RCQPs in the background on-the-fly without exposing the creations overhead to the applications.

#3. QP state protection. If we directly forward the VQP request (from `ibv_post_send`) from different applications to the (same) shared physical QP, QP’s physical states can easily be corrupted due to malformed requests or queue overflow, because verbs API assumes an exclusively owned QP. Bringing the QP back to a normal state is costly because it requires reconfiguration (the **Configure** in Figure 3 (b)).

Solution: pre-check. KRCORE carefully checks the physical queue capacity and request integrity before forwarding the requests to the physical QP. The overhead of these checks is negligible as they only involve simple calculations. Thus, we can avoid QP corruption while preserving the RDMA-aware optimizations (§4.4) of using low-level interfaces.

3.2 Execution flow and architecture

Execution flow. Applications can use KRCORE to create RDMA-capable connections in a few microseconds. Figure 5 presents its execution flow when communicating to two nodes. First, we find available RCQPs in the hybrid pool (1). If exists (S0), we directly virtualize it. Otherwise (S1), we choose a DCQP and fetch the target node’s DCT metadata (2) accordingly. Finally, we virtualize the selected QP so that the client can send RDMA requests with them (3).

To increase the likelihood of hitting RCQPs, KRCORE analyzes the host’s networking patterns and creates RCQPs in the background (e.g., to S1).

Architecture. Figure 6 presents the KRCORE library architecture. On each node, KRCORE is a loadable Linux

Fig. 6. An overview of KRCORE architecture.

```

KRCORE's extended verb's control path API
int qbind(ibv_qp *qp, ibv_gid gid, int port); ## like POSIX bind
int qconnect(ibv_qp *qp, ibv_gid gid, int port); ## like POSIX connect

KRCORE's extended verb's data path API
int qpop_msgs(ibv_qp *qp, int num_entries, ## like POSIX(accept) +
              ibv_qp **src_qp, ibv_wc *wc); ## verbs(ibv_poll_cq)

Example code: Client
1 ibv_qp_init_attr attr;
2 attr.qp_type = KRCORE_VQP;
3 qp = ibv_create_qp(..., &attr);
4 qconnect(qp, gid, port);
5 ibv_send_wr wr;
6 ibv_send_wr *bad_wr_ptr;
  ## send a message
7 ibv_post_send(qp, &wr, &bad_wr);

Example code: Server
1 ibv_qp_init_attr attr;
2 attr.qp_type = KRCORE_VQP;
3 qp = ibv_create_qp(..., &attr);
4 qbind(qp, gid, port);
5 ibv_qp *new_conn = NULL;
6 ibv_wc wc;
  ## receive a message
7 qpop_msg(qp, 1, &new_conn, &wc);

```

Fig. 7. The KRCORE extended API atop of verbs and a simplified use case. Lines in and are extended code for the client and server, respectively. Applications can also use the verb's data path call (e.g., `ibv_post_send`) to issue RDMA requests with KRCORE.

kernel module hosting per-application (e.g., VQP) and per-node (e.g., Hybrid QP Pool) data structures (§4.2). KRCORE also deploys meta servers (MS) on a few nodes to facilitate DCT metadata lookup. These servers are backed by DrTM-KV [58]—a state-of-the-art RDMA-enabled KVS—to accelerate the metadata lookup. The metadata is broadcasted by each machine during its boot time.

4 Detailed Design

4.1 Programming interface of KRCORE

To simplify application development and porting, it is important to keep backward compatibility between KRCORE and verbs, the de facto standard for using RDMA. In principle, KRCORE can provide the same interface with verbs similar to existing work (i.e., Freeflow [30]). However, verbs is not designed for elastic computing and may bring inflexibility or under-utilization of KRCORE. Therefore, we propose an extended API based on verbs inspired by Demikernel [64], as shown in Figure 7. Specifically, KRCORE introduces a new type of QP (VQP) with the following new primitives:

qconnect and qbind. The verbs API has no method for ‘connect’ commonly found in networking libraries. Therefore, developers have to implement and optimize RDMA connection setups themselves. We provide a `qconnect` API to abstract the fast connection provided by KRCORE. Specifically, after calling `qconnect` on a VQP to a remote host (identified by the RDMA address (gid) and a port), the VQP can issue one-sided and two-sided requests to it. Note that remote end must bind to the address using `qbind` beforehand so that the sender can issue two-sided requests, similar to POSIX `bind`.

qpops_msgs. RCQPs are one-to-one connected—meaning the server must know how many clients may connect. This is unhandy for elastic applications because clients can dynamically connect to a server. Therefore, KRCORE VQP is many-to-one: after binding to an address, a VQP can dynamically accept new connections when receiving messages: `qpops_msgs` will return a list of (`src_qp`, `message`) pairs, where the `src_qp` is a VQP connected to the corresponding sender of the `message`.

Besides the extended API, KRCORE also supports common verbs data path API, e.g., `ibv_post_send`, `ibv_post_recv` and `ibv_poll_cq` (see §2.2). Figure 7 shows a simplified code example of sending a message from a client to a server with VQP. At the client, it can use `KRCORE_VQP` as a marker to create a VQP. After successfully connecting the VQP with `qconnect`, the client can call `ibv_post_send` to send the message.

Note that the VQP has the semantic as RCQP—meaning that they have reliability guarantees and support all RDMA operations (with various low-level optimizations).

4.2 Data structures

Hybrid QP pool. Each VQP (§4.1) is backed by a kernel-space virtual QP that has an identifier, a reference to a physical QP and virtualized counterparts of RDMA queues (see §2.2). The physical QP is selected from a hybrid QP pool with both DCQPs and RCQPs. The DCQPs are statically initialized upon boot time and RCQPs are created on-the-fly.

In principle, the pool only needs one DCQP to handle all the RDMA requests of the host. However, only using one DCQP introduces extra latency when sending concurrent requests to different servers. Specifically, if two requests targeting different hosts go over the same DCQP, the second must wait for an additional reconnection before RNIC can process it. This can be mitigated by increasing the DCQP pool size since reconstructions can run concurrently. Yet, the best choice of the pool size depends on the hardware setting (§5.2). On our platform, we choose 8 DCQPs in the pool.

To further prevent lock contention [26], we divide the pool on a per-CPU basis: Each VQP only virtualizes QPs from its local CPU's pool. This strategy is optimized for cases when each QP is exclusively used by one thread, a common pattern in RDMA applications [47, 55, 26, 17, 33]. In case

of thread migrations, KRCORE also re-virtualizes QPs in the background with a transparent QP transfer protocol (§4.6).

Meta Server. For steady and low-latency DCT metadata query, we replicate all the nodes’ metadata at a few global meta servers backed by DrTM-KV [58], a state-of-the-art RDMA-enabled KVS. Note that replicating all the DCT meta at one server is practical because they are extremely small (e.g., 17KB for a 1,000-server cluster).

The meta server stores a mapping between the RDMA address (key) and its corresponding DCT number and key (value). These key-value pairs can be queried via DrTM-KV with a few one-sided RDMA READs. Since sending one-sided requests also requires RDMA connections, each node pre-connects to nearby meta servers (e.g., one in the same rack) with RCQPs during boot time and thus, it can find the DCT metadata of a given server in several microseconds even under high load.

Optimization: DCCache. Observing that the DCT metadata is extremely small (12B), each node further caches them locally to save network round-trips querying the meta server. The metadata is suitable for caching because they are only invalidated when the corresponding host is down.

ValidMR and MRStore. To safely virtualize a physical QP to multiple VQPs, KRCORE additionally checks the validity of remote memory accesses to prevent QP state corruption (§4.4). These checks were originally done by the RNIC using the information stored in the NIC cache. Thus, we should also record them in KRCORE. We additionally bookkeep the registered memory regions (MR)s in ValidMR, which is also implemented with DrTM-KV. After the bookkeeping, KRCORE can query the local/remote ValidMRs to check the local/remote memory regions’ validity.

Like DCCache, we also cache the checked remote MR locally (in MRStore) to avoid extra round-trips. However, caching remote MRs may introduce consistency problems: unlike long-lived DCT metadata, MRs are managed by the applications and can be de-registered on-the-fly. To this end, KRCORE adopts a lease-based lightweight invalidation scheme: the cached MRs are periodically (e.g., 1 second) flushed. Upon de-registration, KRCORE waits for this period before freeing the MR.

4.3 Control path operations

KRCORE reuses initialized QPs upon VQP connection and creation, whose simplified pseudocode executed in the KRCORE kernel is shown in Algorithm 1.

`vqp_create` initializes the basic data structures of VQP—mainly allocating the software send and completion queues in the kernel. The physical QP assignment is delayed to the VQP connection (line 5) because we are unaware of the remote target during creation.

`vqp_connect` connects a VQP to a remote end by assigning a pre-initialized kernel-space QP (either RCQP or

Algorithm 1: VQP creation and connection

```

1: Function vqp_create (Q):
2:   Q.id ← allocate a free identifier
3:   Q.comp_queue ← allocate a software queue
4:   Q.recv_queue ← allocate a software queue
5:   Q.qp ← NULL ← Updated by qconnect
6: Function vqp_connect (Q, addr):
7:   if Q.qp == NULL then
8:     if addr in HybridQPPool.RC then
9:       Q.qp ← select in HybridQPPool.RC[addr]
10:    else
11:      Q.qp ← select in HybridQPPool.DC
12:      if addr not in DCCache then
13:        meta ← query nearby connected MetaServer
14:        add meta to DCCache
15:      Q.dct_meta ← meta

```

DCQP) to it. Given the remote *addr*, it first checks whether an RCQP is available in the HybridQPPool (line 8). If so, we choose an available QP and assign it to *Q.qp* (line 9). Otherwise, we select a DCQP (line 11). Note that all DCQPs in the pool are available because KRCORE can virtualize one physical QP to multiple VQPs (§4.4).

When assigning a DCQP to VQP, we need to fetch the remote end’s DCT metadata (line 12–15) if the metadata is not cached in the *DCCache*. We issue one-sided RDMA READs to the *MetaServer* to query it (line 13).

Background RCQP creations. To increase the likelihood of hitting an RCQP in the pool, KRCORE maintains background routines to sample frequently communicated nodes, create RCQPs for frequently communicated ones in the *HybridQPPool* and reclaim rarely used RCQPs. Currently, we choose a simple LRU strategy for the reclamation.

Other control path operations. Besides VQP creation and connection, other control path operations (e.g., memory registration, MR) have a straightforward implementation: we forward them to the corresponding verbs API and record the results in KRCORE. If necessary, we will also return the virtual handler of the recorded results to the user. Due to space limitations, we omit a detailed description.

4.4 Data path operations

As we have mentioned in §3.1, a key challenge in virtualizing a physical QP to multiple VQPs is preventing shared QP state corruption. Specifically, we must consider:

1. **Detecting malformed request.** An incorrect operation code or an invalid memory reference would transit a QP into error states. Since an error states QP cannot handle any RDMA requests, we must filter out malformed requests before posting them to the physical QP.
2. **Preventing NIC queue overflow.** The physical QP has a limited queue capacity. If the user overflows a QP, the QP will also enter an error state. Preventing queue overflow is challenging under sharing because it can overflow even if all the shared users correctly avoid the queue overflows.

Algorithm 2: kernel handler of `post_send` and `poll_cq`

```
1: Function post_send_virtualized(Q, wr_list):  
   < wr_list: the RDMA requests list  
   < Assumption: the size of wr_list is smaller  
   than Q.qp.sq.max_depth and Q.qp.cq.max_depth  
2: while Q.qp.sq.max_depth - Q.qp.uncomp_cnt <  
   wr_list.length do  
3:   | poll_inner(Q)  
4:   unsignaled_cnt ← 0  
5:   for req in wr_list do  
6:     | if req has invalid MR or invalid Op then  
7:       | return Error  
8:     | if req is signaled then  
9:       | Q.comp_queue.add(NotReady, req.wr_id)  
10:      | req.wr_id ← encode the pointer of Q and  
      | (unsignaled_cnt + 1)  
      | unsignaled_cnt ← 0  
11:     | else  
12:       | unsignaled_cnt += 1  
13:       | Q.qp.uncomp_cnt += 1  
14:   if last_req in wr_list is not signaled then  
15:     | mark last_req as signaled  
16:     | last_req.wr_id ← encode NULL and  
17:     | (unsignaled_cnt + 1)  
18:   return post_send(Q.qp, wr_list)  
19: Function poll_inner(Q):  
20:   wc ← poll_cq(Q.qp.cq)  
21:   if wc is ready then  
22:     | VQ, comp_cnt ← decode wc.wr_id  
23:     | Q.qp.uncomp_cnt -= comp_cnt  
24:     | if VQ is not NULL then  
25:       | VQ.comp_queue.head()[0] = Ready  
26: Function poll_cq_virtualized(Q):  
27:   poll_inner(Q)  
28:   if Q.comp_queue.has_head() and  
   Q.comp_queue.head()[0] is ready then  
29:     | user_wr_id ← Q.comp_queue.pop()[1]  
30:     | return READY, user_wr_id  
31:   return NULL, 0
```

The queue can be cleared via explicit signaling and polling. Nevertheless, we should poll as little as possible because they have overheads [24].

3. **Dispatching completion events.** The polled results of a physical QP can be from different VQPs. Therefore, we must correctly dispatch them to the targets, i.e., software queues of VQPs.

To this end, KRCORE will (1) check the request integrity before posting it to a shared QP; (2) inject necessary polls to the physical QP and (3) encode the VQP information in the request's `wr_id`—that will be returned upon request completion—to help the dispatch. Specifically, KRCORE executes `post_send_virtualized` and `poll_cq_virtualized` after the user calls `ibv_post_send` and `ibv_poll_cq`, respectively. Algorithm 2 shows their simplified pseudocode. For simplicity, we assume the request list (`wr_list`) depth is smaller than the QP capacity, which can be achieved by segmenting the request list before posting it.

post_send_virtualized. It first clears the physical QP's send and completion queues to prevent overflows

(line 2–3) via polling the physical completion queue (line 20). Polling is tricky when considering unsignaled requests—the requests that don't generate completion events. Their entries are freed until a later signaled request is polled. Thus, we must track how many requests a signaled one is responsible to clear (line 4 and line 13), and encode the number in `wr_id` (line 10). Therefore, after polling a completion we can determine the left spaces of queues (line 23). Further, if the last request is unsignaled, we signal it (line 15–17).

For each request, we also check whether it is malformed (line 6) and record the dispatch information for the signaled ones (line 9–10). Finally, we can safely post these requests to the physical QP (line 18).

For two-sided primitive, KRCORE must additionally notify the receiver the sender information. Otherwise, the receiver cannot create proper connections in `qpop_msgs`. Hence, we piggyback the sender's address in the message header (omitted in the algorithm).

poll_cq_virtualized. It first calls `poll_inner` to poll the physical QP events and dispatch the events to the proper VQPs according to the information recorded in the `wr_id` (lines 22–25). After the dispatch, it can check whether the virtualized QP has a completion event. KRCORE examines the head of the virtualized `comp_queue` and returns the head's `wr_id` to the application if the head exists.

Due to space reasons, we briefly describe other operations:

ibv_post_recv. This function registers the buffers to the VQP by recording them in the virtualized `recv_queue`.

qpop_msgs. It polls the physical QP's `recv_queue` and dispatches the received messages, similar to `poll_inner`. To hold in-coming messages, we pre-post message buffers to physical QP before virtualizing it to the applications. The challenge of pre-post is that the KRCORE doesn't know the exact payloads of the incoming messages. For now, we assume the pre-posted buffers can always hold the incoming message. §4.5 will describe how we cope with out-of-bound messages in detail. After receiving a message, we will check its destination VQP and copy it the user-registered buffer (from `ibv_post_recv`).

Besides receiving messages, `qpop_msgs` also creates a VQP connected to the sender (§4.1). The creation and connection follow the control path operations discussed in §4.3. To prevent the DCT metadata query, we further piggyback the metadata in the message header. Thus, `qpop_msgs` doesn't involve additional networking requests.

4.5 Zero-copy protocol for two-sided operations

The basic `qpop_msgs` (§4.4) has two issues. First, it incurs extra memory copies. Though the copy overhead is negligible for small messages (e.g., less than 1KB), it is non-trivial for the large ones (e.g., see results in Figure 9 (b)). Second, it cannot receive messages with payloads larger than the pre-posted buffers.

To this end, we adopt a zero-copy protocol to overcome the above issues. Intuitively, for large or out-of-bound messages, the receiver will use one-sided RDMA READ to read them to the user-registered buffers, inspired by existing RDMA-enabled RPC frameworks [48, 17]. Specifically, if the payload is larger than the kernel’s registered buffer, the sender will first send a small message containing the destination VQP ID, the source message address and its size. The receiver can then use one-sided RDMA READ to read the message directly to the user-registered buffer in a zero-copy way. The cost of sending an additional message is trivial for large messages because the network transfer will dominate the time.

4.6 Physical QP transfer protocol

KRCORE supports seamlessly changing the physical QP virtualized by a VQP to another. The challenge of doing so is how to preserve the RCQP’s FIFO property [7] of the VQP during transfer, i.e., after a request completes, all its previous requests are finished.

To ensure FIFO, upon the transfer starts, we first post a fake signaled RDMA request to the source QP and wait for its completion before the change. Meanwhile, we also notify the remote peers to transfer their physical QP. Otherwise, the VQP can no longer receive the remote end’s message. For correctness, we must wait for the remote acknowledgments before changing the physical QP at the sender.

5 Evaluation

We aim to answer the following questions during evaluations:

1. How fast is the KRCORE control plane (§5.1)?
2. What are the costs to the data plane (§5.2)?
3. How RDMA-aware applications that require elasticity can benefit from KRCORE (§5.3)?

Implementation. We implement KRCORE from scratch as a loadable Linux kernel (4.15) module, which has more than 10,000 LoC Rust code. It exports system calls via *ioctl* without modifying the kernel. To simplify user-kernel interactions, we further implement a 100 LoC C shim library atop *ioctl* to provide the interfaces described in §4.1. Finally, we port DCT to the kernel-space RDMA driver by adding around 250 LoC C code to the *mlx-ofed-4.9* driver: DCT is currently only implemented in the user-space RDMA drivers.

Testbed setup. We conduct experiments on a local rack-scale RDMA-capable cluster with ten nodes. Each node has two 12-core Intel Xeon E5-2650 v4 processors, 128GB DRAM and one ConnectX-4 MCX455A 100Gbps InfiniBand RNIC. All nodes are connected to a Mellanox SB7890 100Gbps InfiniBand Switch. Without explicit mention, we deploy one meta server for KRCORE.

Comparing targets. We compare KRCORE with user-space *verbs* (*verbs*) and LITE⁵. Original LITE has an unoptimized control plane: it uses a centralized cluster manager to

⁵<https://github.com/WukLab/LITE>

Fig. 8. The *qconnect* performance of KRCORE when using DCQP with DCT metadata uncached. (a) Connecting to a single server, and (b) establishing connections in a full-mesh fashion.

establish connections between servers and can only connect tens of RCQPs per second. Therefore, we further optimize it by enabling a decentralized QP connection scheme via RDMA’s unreliable datagram (UD). Our optimized version can achieve an optimal kernel-space RDMA control plane performance—it is now only bottlenecked by the hardware limits. §5.1 will describe this in more detail. Note that our optimization leaves the LITE data plane unchanged.

5.1 Control path performance

The evaluations for the control path focus on creating and connecting RDMA connections. The costs of the other operations in KRCORE (and *verbs*) are typically much smaller. For example, registering 4MB memory only takes 1.4μs in KRCORE. Therefore, we omit their results.

We use two synthetic workloads (single and full-mesh connection establishment) to evaluate the control path performance. The connection pool and DCCache of KRCORE are cleared before the evaluations. Otherwise, KRCORE only has system call overheads and is extremely small (0.9μs).

Single-connection establishment performance. We first evaluated the latency and throughput of establishing a single RDMA-capable connection to one server w.r.t. the number of clients. Figure 8 (a) reports the throughput-latency graph when increasing the number of clients from 1 to 240. From the figure we can see that KRCORE can have several orders of magnitude better performance than *verbs* and LITE. At one client, KRCORE can establish a connection in 5.4μs, while *verbs* and LITE take 15.7ms and 2ms, respectively. The performance gain of KRCORE comes from replacing the costly RDMA control path operations (analyzed in §2.3.1 and §2.3.2 in detail) with fast RDMA data path operations, i.e., two one-sided RDMA READs to the meta server. For LITE, it saves the driver loading cost but still needs to create and configure QP on its control path. At 240 clients, KRCORE can handle 22 million (M) connections per second, while *verbs* and LITE can only establish 712 RCQPs per second. They are both bottlenecked by the server creating hardware resources, while KRCORE always reuses existing ones to prevent these overheads.

Full-mesh connection establishment performance. Besides establishing a single connection, creating full-mesh connections at a set of workers is common in elastic applica-

Fig. 9. (a) Performance comparisons of different DCT meta query methods, and (b) the effects of zero-copy protocol (KRCORE+opt) of KRCORE two-sided operations.

tions, e.g., burst-parallel serverless workloads [51]. Specifically, each worker should connect to the others and vice versa. Figure 8 (b) presents the full-mesh performance by varying the number of involved workers. In general, KRCORE can reduce 99% of the full-mesh creation time regardless of the worker number, thanks to the orders of magnitude faster single-connection establishment performance (see Figure 8 (a)). For example, KRCORE connected 240 workers in 81 μ s, while verbs and LITE used 2.7 secs and 2.3 secs, respectively. These results suggest that KRCORE can handle complex control path operations well.

Benefit of the meta server. A key design choice of KRCORE is to use an RDMA-based meta server to store DCT meta. Figure 9 (a) illustrates the benefit of this design using the single-connection establishment workload of Figure 8 (a). The baseline (RPC) uses a kernel-space FaSST [26] RPC for the querying. FaSST is the state-of-the-art RDMA-based RPC that builds on RDMA’s unreliable datagram. It also has no control plane overhead in the kernel because UD is connectionless. To save CPU resources, we only deploy one kernel thread to handle the queries. We can see that a meta server design achieves an 11.8X better throughput and up to 13X query latency compared with RPC. The RPC design is bottlenecked by the server CPU for handling DCT queries, while the RDMA-based meta server bypasses the CPU with one-sided RDMA.

5.2 Data path performance

KRCORE trades data path performance for a faster control plane. We first use a set of microbenchmarks to evaluate these overheads using two communication patterns: **sync** and **async**. In the sync mode, each client issues RDMA requests to one server in a run-to-completion way, aiming to achieve low latency [17, 47]. For async, each client posts requests in batches to achieve the peak throughput [57, 24, 25]. Without explicit mention, the workloads are inbound, i.e., multiple clients sending RDMA requests to one server. We reported the aggregated throughput of clients and their average latency.

One-sided operations. Figure 10 presents the one-sided data path performance of KRCORE when it virtualizes from DCQP (KRCORE(DC)) and RCQP (KRCORE(RC)), and compare them to verbs⁶. During the experiment, each client

⁶LITE’s data path API is different so we compare to it separately.

Fig. 10. The one-sided RDMA performance.

Fig. 11. The two-sided RDMA performance of KRCORE.

issued 8B random requests to the server, and we varied the number of clients from 1 to 240.

(1) Sync. For one-sided RDMA READ in Figure 10 (a), the latency of KRCORE (DC) and (RC) is 27%–46% and is 25%–41% higher than verbs. The additional latency of KRCORE under sync mode is dominated by the system call cost. On our hardware, we measure a $\sim 1\mu$ s overhead communicating with the kernel. For reference, when using one client, the latency of KRCORE (RC) is 3.15μ s, and the verbs is 2.15μ s. Another observation is that adopting DCQP has little latency overhead in the sync mode as DC reconnection is extremely fast. For example, the latency of KRCORE (DC) under one client is 3.24μ s. The results of one-sided RDMA WRITE in Figure 10 (c) are similar to the READ.

(2) Async. For one-sided RDMA READ in Figure 10 (b), KRCORE (RC) can achieve a similar peak throughput as verbs (138M reqs/sec) when using 240 clients. With the same configuration, KRCORE (DC) is 14% slower (118 M reqs/sec). KRCORE (RC) and verbs are both bottlenecked by the server RNIC, while KRCORE (DC) is slower due to extra DCT processing at the RNIC. For one-sided RDMA WRITE in Figure 10 (d), the results are similar: KRCORE (RC) and verbs achieve a peak throughput of 145M reqs/sec while KRCORE (DC) is 8.9% lower (132M reqs/sec).

Two-sided operations. Figure 11 presents the two-sided throughput and latency of KRCORE w.r.t. to the number of clients (1 to 240). Each client sends an 8B request to the server in an echo fashion: after receiving a request, the server

Fig. 12. (a) A factor analysis of the data path cost introduced by KRCORE using one-sided RDMA READ. (b) The performance of KRCORE in data transfer benchmark of serverless computing.

will send the request back, and the client will issue another request after getting the acknowledgment. The server utilizes all cores (24 threads) to handle these requests.

(1) Sync. In this mode, the performance comparisons are similar to one-sided RDMA: compared with verbs, KRCORE (RC) and (DC) have 4–21% and 14–31% higher latency, respectively. The KRCORE overheads added to two-sided RDMA are also dominated by the user-kernel interactions. For example, at one client, one KRCORE (RC) echo takes $9.6\mu\text{s}$ while verbs takes $7.9\mu\text{s}$. Compared to one-sided RDMA, the absolute latency gap is larger. KRCORE two-sided has an additional system call overhead: the server needs to enter the kernel to receive a message.

(2) Async. Unlike one-sided RDMA, KRCORE cannot achieve the same peak inbound throughput (when using 240 clients) as verbs for two-sided RDMA: it is 20% slower than verbs: which can only achieve 33.7M reqs/sec regardless of RC or DC. In comparison, verbs can achieve 42.3M reqs/sec. The extra bottleneck comes from CPU processing costs at the server due to user-kernel interactions. As a result, KRCORE cannot saturate the RNIC’s high performance. This also explains why KRCORE has a similar performance when using RC and DC.

Effects of zero-copy optimization. We next examine the costs of memory copy—that KRCORE uses to dispatch messages between virtual QPs—to the two-sided operations. We further demonstrate how we mitigate it with a zero-copy protocol (§4.5). Figure 9 (b) shows the two-sided echo latency when using one client to communicate with the server w.r.t. the payload size. We can see that the memory copy cost is negligible for small transfers ($\leq 16\text{KB}$) but is significant for large messages. Specifically, when transferring $> 16\text{KB}$ messages, the latency of KRCORE is 1.45–3.1X higher than verbs. To this end, the zero-copy optimization (KRCORE+opt) reduces the overheads to 0.08–0.23X when transferring $\geq 16\text{KB}$ messages.

Factor analysis. Figure 12(a) conducts a factor analysis to show the detailed data path costs of KRCORE in a sync one-sided RDMA READ request. The main observations are: (1) The biggest cost to data path operations is additional RDMA requests to check the MR validity when the remote MR information is not cached locally (+MR miss, takes

Fig. 13. The slowdown of KRCORE compared to verbs on one-sided RDMA READ (a) and WRITE (b), respectively.

Fig. 14. (a) The impacts of DCQP pool size. (b) The CDF of latency of sending RDMA requests to different servers.

$4.5\mu\text{s}$). Note the checks are rare because KRCORE always caches the checked MR after a miss.

(2) For normal requests without MR checks, system call dominates the overheads (+System call), resulting in $1\mu\text{s}$ latency increase ($3.15\mu\text{s}$ vs. $2.14\mu\text{s}$). Other costs—including using DCQP (+DCQP) and KRCORE check to prevent QP state corruptions (+Checks, see §4.4) are trivial (less than $0.5\mu\text{s}$).

Impacts of payload size to one-sided RDMA. The overhead of KRCORE becomes smaller for one-sided RDMA with a larger payload, since transferring data through the network dominates the time. Figure 13 reports the slowdown compared to verbs on different request payloads. We measure the latency of sync one-sided RDMA with one client. For one-sided RDMA READ, the overhead is negligible for larger than 256KB reads ($< 7\%$). For WRITE, the overhead is negligible for larger than 8KB payloads.

Impacts of DCQP pool size. A larger DCQP pool is typically better for concurrently sending requests to different machines (§4.2). Figure 14 (a) reports the latency when sending a batch of 64 one-sided RDMA READs to different targets at one client with different pool sizes. The targets are randomly selected in 10 machines. We can see that when the pool only has one DCQP, KRCORE (DC) has a 1.32X higher latency (99 vs. $75\mu\text{s}$) than KRCORE (RC), since requests to the same QP are processed sequentially with reconnections. Increasing the pool size can significantly improve the latency. Interestingly, when the pool size is larger than 2, DC outperforms RC by 28–78%. RC needs 64 different connections to send these requests, and it has to do 63 additional polls than DC.

Tail latency. Figure 14 (b) reports the tail latency when using 50 clients sending sync one-sided RDMA READ to 5 servers. Under such a fan-out scenario, KRCORE (DC) has a higher tail latency than the others due to extra round-trips caused by DC reconnections. The 99.9% latency of verbs,

Fig. 15. (a) A comparison of memory usage on connections: KRCORE caches all DCT metadata, while LITE caches all RCQPs. (b) A comparison of data path performance when KRCORE uses DCQP.

KRCORE (RC) and KRCORE (DC) are $2.8\mu\text{s}$, $3.8\mu\text{s}$ and $6\mu\text{s}$, respectively.

Comparison to LITE. Finally, we show that KRCORE can achieve a similar (or better) data path performance than LITE with smaller memory usage.

(1) Memory. Figure 15 (a) shows the memory used for caching RDMA connections. In general, KRCORE consumes orders of magnitude smaller memory when supporting the same number of connections. For example, to maintain 5,000 connections, LITE consumes 780MB of memory, even without counting the memory of message queues (1.5GB if counted). In comparison, KRCORE only consumes 6.3MB of memory because it just maintains a (small) constant number of DCQP (48), and each DCT metadata only consumes 12B.

(2) Performance. Figure 15 (b) further compares the throughput when issuing 64B random one-sided RDMA READ from one node to others. We configure both systems to deploy a pool of 32 connections, preventing LITE from encountering RCQP scalability issues [26]. KRCORE uses DCQP for its connections. For sync, we can see that KRCORE is up to 20% slower than LITE due to performance issues of DCQP. On the other hand, KRCORE achieves a 3X higher peak async throughput (15.6M/sec vs. 5.2M/sec) in the async mode. LITE has a limited peak performance because it fails to run with more than 6 threads. LITE doesn't prevent QP queue overflows (see issue #3 in §2.3.2), so it will trigger QP errors for more than 6 threads. KRCORE handles overflows well (§4.4) and can thus, scale to more threads.

5.3 Application performance

5.3.1 Scaling RACE Hashing

Overview and setup. RACE hashing [67] is a production RDMA-enabled disaggregated key-value store. We chose it as our case study because it requires elastically—a demand not commonly found in existing RDMA-based key-value stores. At a high level, RACE separates the storage nodes and computing nodes by RDMA, where the computing nodes execute key-value store requests by issuing one-sided RDMA requests to the storage nodes. RACE further allocates computing nodes on-demand to cope with various workloads in a resource-efficient way, where the newly started nodes need dynamically establish RDMA connections to memory nodes. To improve performance, it embraces a set of low-level RDMA-

Fig. 16. Under load spikes, KRCORE can quickly bootstrap computing nodes for RACE Hashing [67].

aware optimizations—e.g., doorbell batching [25] that are tailed to RDMA's low-level verbs interface.

Since RACE is not open-sourced, we implement a simplified version atop of verbs, LITE and KRCORE, respectively. We have calibrated that the performance is close to their reported ones. For example, RACE reports a peak 24M req/sec Get throughput on ConnectX-5 under YCSB-C [11]. Our (verbs) version can achieve 27M req/sec with more machines (8 vs. 5) on a similar RNIC (ConnectX-4).

Performance under load spikes. Our evaluating workload contains a load spike commonly found in real-world applications [8, 28, 2]. Under spikes, RACE allocates more computing processes to increase performance. During process startups, KRCORE can reduce its bootstrap time thanks to its fast control plane.

Figure 16 shows the timelines of RACE atop of verbs, LITE and KRCORE under load spikes, respectively. The spikes happen at time 0, and RACE forks 180 new processors to handle it. When using KRCORE, RACE can finish the startup in 244ms, 83% and 76% faster than verbs (1.4 seconds) and LITE (1 second), respectively. KRCORE is bottlenecked by OS creating worker processors. On the other hand, LITE and verbs are bottlenecked by RDMA's slow control path (§2.3). A fast boot further reduces the tail latency: during time 0-3, KRCORE has a 4.9X lower 99% latency than verbs.

Benefit of virtualizing a low-level RDMA API. KRCORE virtualizes a low-level RDMA (e.g., `ibv_post_send`), and thus, it can transparently apply existing RDMA-aware optimizations (see Issue #3 in §2.3.2). This leads to better performance of KRCORE on RACE compared to LITE: as shown in Figure 16, KRCORE has a 1.73X higher peak throughput (26M reqs/sec vs. 15M reqs/sec) than LITE after time 3.

Benefit of virtualizing hybrid QPs. As shown in Figure 16, using RCQP (e.g., after time 3) brought 1.4X (26M vs. 18M req/sec) throughput improvements to KRCORE, achieving a similar performance as verbs (26M reqs/sec). This is because RACE issues RDMA requests asynchronously, and KRCORE's RC async peak throughput is similar to verbs (see Figure 10 (b)). Further, we can see the overhead of switching from DCQP to RCQP is negligible (at time 2.2). However, there is a lag for detecting the switch because KRCORE needs time to collect the necessary information to decide which RC-

QPs to create.

5.3.2 Accelerating data transfer in serverless computing

Finally, we show that KRCORE can improve the communication performance between functions in serverless computing. We use an RDMA-version of data transfer testcase in ServerlessBench [62] (TestCase5), a state-of-the-art Serverless benchmark suite. This testcase measures the data transfer time between two serverless functions. The experiment runs on Fn [43], a popular open-source serverless platform.

Figure 12 (b) reports the time to pass a message w.r.t. the payload size when using verbs and KRCORE, respectively. The receiver function runs in a separate machine using a Docker container after the sender finishes execution. We use warm start to techniques [40] to reduce the control plane costs of starting containers. From the figure we can see KRCORE reduces the data transfer latency of verbs by 99% when transferring 1KB to 9KB bytes. The performance improvements are mainly due to the reduced RDMA control path of KRCORE, which we have extensively analyzed in §5.1.

6 Discussion

Trade-offs of a kernel-space solution. KRCORE chooses kernel-space RDMA for a microsecond-scale control plane (5,900X faster than verbs). Though it retains most benefits of RDMA (e.g., zero-copy), we sacrifice kernel-bypassing benefit and thus, result in a slower data path (up to 75% slowdown). We argue that such cost is acceptable to many elastic applications. First, the application usually issues a few networking requests. For example, the functions in ServerlessBench [62] and SeBS [12] only issue one request to read/write remote data on average. Second, the control path overhead (ms-scale) is commonly orders of magnitude higher than the cumulative data path overhead (μ s-scale), see Figure 3. Finally, existing work (i.e., LITE [53]) also showed that kernel-space RDMA is efficient for many datacenter applications.

Other RNICs. Our analysis focuses on Mellanox ConnectX-4 Infiniband RNIC. Nevertheless, we argue the cost is unlikely to reduce due to hardware upgrades or different RDMA implementations (e.g., RoCE) since the cost is dominated by configuring the NIC resources. For example, we also evaluate the control path performance on ConnectX-6, where the user-space driver still takes 17ms for creating and connecting QP, similar to the ConnectX-4 we evaluated (15.7ms, see Figure 3).

KRCORE in virtualized environments. We currently focus on accelerating RDMA control plane with host networking mode. Using RDMA in virtual machines or virtualized RDMA network [30, 20] is also popular in the cloud. We believe the principles and methodologies of KRCORE are also applicable in these environments. For example, Freeflow [30] is an RDMA virtualization framework designed for containerized clouds. It leverages par-virtualization that intercepts virtualized RDMA requests to a software router. We can inte-

grate our hybrid connection pool to the router to support a fast control plane atop of it. We plan to investigate applying KRCORE in virtualized environments in the future.

7 Related Work

RDMA libraries. Many user-space RDMA libraries exist [32, 4, 3, 36, 64], e.g., MPI, UCX [4], rsocket [3]. They can hardly provide a fast control plane because they are all based on verbs. LITE [53] is the only kernel-space RDMA library and is the closest to our work. We have extensively analyzed the issues when deploying LITE in elastic computing (§2.3.2) and how KRCORE addresses them (§3—§4).

DCT-aware and hybrid-transport systems. Several works used DCT to improve the performance and scalability of RDMA-enabled systems [49, 41]. Subramoni et al. [49] showed that DCT could provide comparable performance to RC while reducing memory consumption for MPI applications. Meanwhile, several works leveraged a hybrid-transport design to overcome the shortcoming of a single transport [31, 23]. For instance, Jose et al. [23] utilized UD to reduce the memory consumption of RC in Memcached.

RDMA-enabled applications. KRCORE continues the line of research on accelerating systems with RDMA, from key-value stores [38, 55, 67, 24, 13, 39], far-memory data structures [45, 6, 44], RPC frameworks [48, 26, 9, 27], replication systems [5, 42, 54, 29], distributed transactions [58, 46, 14, 10, 57, 65, 56], graphs [47, 59, 61, 18] and distributed file systems [66, 33, 60], just to name a few. Most of these systems do not target elastic computing, but we believe there are opportunities for applying them in such a setting. In such scenarios, they can benefit from KRCORE.

8 Conclusion

This paper presents KRCORE, a μ s-scale RDMA control plane for RDMA-enabled applications that require elasticity. By retrofitting RDMA dynamic connected transport with kernel-space QP virtualization, we show that it is possible to eliminate most RDMA control path costs on commodity RNICs. Meanwhile, the data path costs introduced by KRCORE are acceptable for many elastic applications. Our experimental results confirm the efficacy of KRCORE.

9 Acknowledgment

We sincerely thank the anonymous shepherd and reviewers for their insightful suggestions. We also thank Dingji Li for discussing how to apply KRCORE to virtual machines, Xiating Xie for improving the figures and Sijie Shen, Zhiyuan Dong, Rongxin Chen and Yuhan Yang for their valuable feedback. A Artifact Appendix

Abstract. The artifact provides the source code and scripts to reproduce the experimental results from the USENIX ATC 2022 paper—"KRCORE: A Microsecond-scale RDMA Control Plane for Elastic Computing". KRCORE is a kernel-space RDMA solution that provides fast RDMA connection setups to user-space applications.

Scope. The artifact can be used to reproduce the evaluations in §5. It can also benefit the development of kernel-space RDMA-enabled applications.

Contents. The artifact contains the source code, the instructions for building and installation, and instructions for running the experiments in §5. All the above instructions can be found according to the steps in the `README.md` at the root directory of the artifact.

Hosting. The artifact is hosted on <https://github.com/SJTU-IPADS/krcore-artifacts> under the `main` branch with commit version `7ba3bf6`.

Zero-Change Object Transmission for Distributed Big Data Analytics

Abstract

Distributed big-data analytics heavily rely on high-level languages like Java and Scala for their reliability and versatility. However, those high-level languages also create obstacles for data exchange. To transfer data across managed runtimes like Java Virtual Machines (JVMs), objects should be transformed into byte arrays by the sender (*serialization*) and transformed back into objects by the receiver (*deserialization*). The object serialization and deserialization (OSD) phase introduces considerable performance overhead. Prior efforts mainly focus on optimizing some phases in OSD, so object transformation is still inevitable. Furthermore, they require extra programming efforts to integrate with existing applications, and their transformation also leads to duplicated object transmission. This work proposes Zero-Change Object Transmission (ZCOT), where objects are directly copied among JVMs without any transformations. ZCOT can be used in existing applications with minimal effort, and its object-based transmission can be used for deduplication. The evaluation on state-of-the-art data analytics frameworks indicates that ZCOT can greatly boost the performance of data exchange and thus improve the application performance by up to 23.6%.

1 Introduction

High-level languages like Java and Scala are welcomed in areas like big-data analytics thanks to their reliable and versatile managed runtime environment. However, the abstraction provided by the managed runtime also introduces performance overhead, especially for data exchange. Since managed runtimes like Java Virtual Machines (JVMs) store data in an opaque object-based format, they have to transform objects into interpretable binary streams before exchanging. The transformation contains two phases: a *serialization* phase transforming objects into a byte array, and a *deserialization* phase transforming the byte array back into objects. The object serialization/deserialization (OSD) mechanism introduces considerable transformation overhead and has become a

significant performance bottleneck in distributed object transmission, especially for applications demanding large-scale data exchange through network [3, 6, 13, 15, 44].

Prior work has recognized the performance problem in OSD and proposed different approaches, both in software [26, 38, 39] and hardware [16, 32, 40, 46], to mitigate its effect. However, those approaches mainly focus on optimizing specific phases in OSD, and the data transformation is still inevitable. Furthermore, although they can boost the performance of OSD, many of them require extra programming efforts to annotate serialization points or change the original inter-JVM communication model. Last but not least, they treat the transferred data as a monolithic byte array instead of individual objects, which makes it difficult to identify duplicated transmission and misses optimization opportunities.

Instead of optimizing OSD, this work aims at directly eliminating the whole OSD process. To this end, this work proposes Zero-Change Object Transmission (ZCOT), which provides an ideal data exchange mechanism where objects are transferred among JVMs through **direct object copying**. When a JVM receives objects from others, it can directly process them without any modifications (*Zero-Change*). ZCOT removes the demands for object transformation and thus improves the performance of data exchange.

However, it is non-trivial to achieve zero-change communication given each JVM manages objects in a process-specific and opaque format. To this end, ZCOT first introduces a globally shared abstraction named *exchange space*, a part of the Java heap space accessible for multiple JVMs in a distributed environment. ZCOT further adopts its distributed class-data sharing (DCDS) mechanism, which provides a unified object format to make objects in the exchange space interpretable for all JVMs. To remain compatible with traditional OSD-based applications, ZCOT proposes a two-level transmission mechanism to bridge the gap between object-based copying and traditional byte-based transmission.

As ZCOT introduces a globally shared exchange space, it is responsible to manage objects shared among multiple JVMs. By introducing a metadata server, ZCOT memorizes

the stored location for objects and helps build data transmission channels between JVMs. Since objects in big-data analytics are usually exchanged as a whole dataset, ZCOT embraces *group-based object management*, which organizes objects in groups and greatly reduces the traffic between the metadata server and JVMs. Furthermore, ZCOT also integrates with the garbage collections (GC) triggered in individual JVMs and reduces the GC pause time.

ZCOT sends objects instead of byte arrays during transmission, which makes it object-conscious and easier to identify duplicated objects. This work thus proposes a data deduplication mechanism to further optimize the data transmission. The deduplication module in ZCOT leverages the exchange space abstraction to memorize which objects have been sent and avoids unnecessary object transmission in the future. Nevertheless, deduplication may introduce references (or dependencies) among different datasets. To this end, ZCOT extends its distributed memory management module to consider inter-group dependencies.

This work implements ZCOT in the HotSpot JVM of OpenJDK 11, the long-time-support version for OpenJDK. ZCOT is well-integrated with existing features in OpenJDK (like APPCDS [30]) to remain friendly to Java developers. We evaluate ZCOT against state-of-the-art OSD libraries and optimizations with both the micro-benchmark and macro-benchmark. The micro-benchmark contains both basic and complicated data structures for data transmission, while the macro-benchmark contains two big-data analytics frameworks (Spark and Flink). The result for micro-benchmark shows that ZCOT outperforms other OSD libraries, especially for complicated data structures, and reaches up to $4.35 \times$ speedup compared with Naos [39], a state-of-the-art optimization on OSD. As for macrobenchmark, ZCOT outperforms the default OSD libraries in both Spark and Flink and thus boosts the application time by up to 23.6% and 22.2%, respectively.

To summarize, the contribution of ZCOT includes:

- A distributed shared abstraction named *exchange space* to enable zero-change object transmission among JVMs while remaining compatible with traditional OSD-based applications.
- A memory management mechanism on the globally shared space integrated with GC in individual JVMs.
- A data deduplication module to identify and eliminate unnecessary object transmission for further performance improvement.
- Experiments on communication-intensive workload to show the performance improvement of ZCOT over existing OSD libraries.

Figure 1: The workflow of OSD

2 OSD Background

2.1 OSD

Language runtimes provide a high-level abstraction for platform-independent code execution. As for user objects, runtimes store them with an opaque format, which maintains object data together with corresponding metadata (type information, synchronization, memory management, etc.). Taking Java as an example, JVMs maintain a *header* for each object to store its metadata.

However, when data exchange among JVMs is required, objects must go beyond the runtime scope. For example, objects might be persisted into disks and reused by other JVMs later; they can also be sent and received through network. To support those scenarios, objects have to be interpretable even when leaving JVMs. Therefore, JVMs embrace the object serialization/deserialization (OSD) mechanism, which transforms Java objects into a generalized data format (serialization) and transforms back when reusing in JVMs (deserialization). The Java system library (JSL) already provides a built-in OSD library for applications. Figure 1 shows the workflow of JSL’s OSD. As for the serialization part, objects are transformed into a byte array that follows a data format agreed among JVMs. The byte array will be written into disks or sent through network. When another JVM receives the byte array, it transforms the byte array back into objects through deserialization.

The OSD mechanism has two major advantages. First, the library provides a general-purpose data format so that Java objects can be transformed among JVMs with different versions and configurations. Second, the serialized data is compressed and induces smaller footprints in both disks and network.

2.2 Limitations and opportunities

The major disadvantage for OSD is its performance penalty. The performance problem of OSD in big-data analytics is three-fold.

Transformation overhead. OSD introduces extra phases for object persistence and transmission. To serialize an object, OSD should traverse all its reachable objects and store their type information. As for deserialization, OSD should scan serialized data and reconstruct objects.

Memory footprint. OSD generates a considerable number of temporary objects during data transformation. As shown

Figure 2: Duplicated data transmission in the page-rank application

in Figure 1, byte arrays are generated during serialization and become useless after sending out. Those temporary objects can increase the memory pressure and cause more frequent GCs.

Duplicated transmission. Big-data analytics leverage OSDs in many rounds of communication and duplicated objects may be repetitively transformed and exchanged in each round. Figure 2 shows a concrete example in Spark [44], which calculates the popularity for each URL (simplified as letters) with the page-rank algorithm [31]. Since the algorithm executes for multiple iterations, the data transmission is also conducted in many rounds. In the first round, the URL-based network topology is sent through network, which consists of many string pairs to indicate the point-to relationships among URLs. In the later rounds, the rank value for each URL is iteratively propagated, which is organized as key-value pairs. Note that the strings in the key-value pairs are URLs that have been sent in the first round. Unfortunately, since all objects have been transformed and merged into byte arrays, JVMs cannot tell that some objects have been received before. They have to receive all objects as a monolithic byte array, which leads to unnecessary network transmission and OSD phases. In the Spark page-rank application, over 60% of transferred objects are duplicated.

Furthermore, the advantages of OSD also fade with advances in hardware technologies. For example, the bandwidth of off-the-shelf network devices can reach 100Gb/s or larger, which makes network transmission time less important, so OSD may become a more significant bottleneck. On the other hand, the general data format is not always required. Therefore, many optimizations have been proposed to reduce the performance overhead of OSD, both in software [26,38,39] and hardware [16,32,40,46]. Since hardware-based approaches require building customized hardware accelerators to improve OSD, this work mainly focuses on software-based approaches with off-the-shelf hardware.

2.3 State-of-the-art optimizations

The basic idea behind OSD is to achieve an *agreement* on object representation among JVMs. Therefore, optimizations on OSD should consider how to create the agreement so that objects can cross JVMs' boundaries. Besides, they also need to consider issues like compatibility with existing applications.

Kryo. Kryo [38] is a fast OSD library for Java. Compared to JSL's OSD, Kryo refines the binary data format to achieve a smaller serialized data size and better performance. Applications like Spark have leveraged Kryo as its default serializer. Nevertheless, Kryo does not eliminate any phases in OSD; objects still need to be transformed back and forth.

Skyway. Skyway [26] proposes to directly send object graphs instead of serialized bytes. With Skyway, the serialization phase is nearly removed as objects are no longer transformed to a binary format. Although Skyway has simplified phases in OSD, modifications on objects are still required. First, it needs to transform the type information in the headers to a globally-agreed ID so that it can be identified by all JVMs. Second, it needs to fix references after copying, as objects have been moved to different addresses. Moreover, Skyway also requires programmers to mark the point where the serialization phase starts manually.

Naos. Naos [39] is a network-specific data transmission mechanism. Similar to Skyway, Naos also employs a global service to reach agreements for types, but it relies on RDMA technology to achieve rapid zero-copy object transmission. However, Naos still requires modifications on both object headers and references. Besides, it only supports network-based transmission, and existing applications need significant modifications to leverage Naos.

2.4 Summary

Prior optimizations have proposed different solutions to reduce the overhead of OSD. However, they cannot eliminate the whole OSD process. Table 1 compares the built-in OSD in JSL with other optimizations. Although recent work like Naos eliminates the serialization phase, a deserialization phase is still required to fix the type information and the references. Besides, none of them has considered the duplicated data transmission problem.

This work proposes ZCOT (short for Zero-Change Object Transmission), which aims to eliminate the whole OSD process during data exchange. In ZCOT, object transmission is conducted in the most straightforward way: the sender JVM copies objects and the receiver can directly use them without any modifications. ZCOT also considers the duplicated transmission problem and provides a deduplication module. Finally, ZCOT is not bound to specific network technologies (like RDMA) and provides easy-to-integrate interfaces for existing applications.

Data transmission mechanisms	Serialization	Deserialization	Ease of Integration	Data deduplication
JSL	Slow	Slow	Yes	No
Kryo	Medium	Medium	Yes	No
Skyway	Fast (removed)	Medium	Medium	No
Naos	Fast (removed)	Medium	No	No
ZCOT (this work)	Fast (removed)	Fast (removed)	Yes	Yes

Table 1: Comparisons on existing OSD optimizations against our work ZCOT

3 Design of ZCOT

3.1 Overview

The core idea of ZCOT is to build a distributed-shared-memory (DSM)-like abstraction for JVMs running on different machines. Figure 3 illustrates the architecture of ZCOT. In a ZCOT-enabled system, the heap for each JVM consists of two parts: its private space (the original Java heap) and a globally shared *exchange space*. Objects are originally managed in the private space. When they require to be sent through network or persisted into disks, they will be copied to the exchange space. The exchange space is an abstraction available for all JVMs; each JVM can directly access objects therein. Therefore, object transmission can be achieved with direct copying to the exchange space, and the whole OSD process can be eliminated.

Figure 3: The architecture of ZCOT

The idea for building a DSM-like abstraction is well-known and has been studied for decades [2, 7, 9, 14, 20, 21, 25, 33–35, 41, 42, 45]. Although our exchange space shares similar wisdom with DSM, it is only used for data exchange and does not need to tackle complicated issues like coherence. It also assumes objects in the exchange space are immutable, which usually holds for big-data analytics like Spark and Flink. If a write operation occurs on objects in the exchange space, ZCOT creates a copy for it on the JVM’s private heap. Nevertheless, combining the DSM concept with data transmission in high-level languages is still not trivial. To enable efficient and easy-to-use object transmission, ZCOT has to resolve the following challenges.

- How to build a shared exchange space so that all JVMs can access it freely? (Section 3.2)
- How to leverage the exchange space abstraction to support OSD-based applications? (Section 3.3)
- How to manage objects in the exchange space in the presence of garbage collections in individual JVMs?

(Section 4)

- How to resolve the duplicated transmission problem? (Section 5)

3.2 Distributed class-data sharing

ZCOT relies on its distributed class-data sharing (DCDS) mechanism to build a globally accessible shared space. DCDS guarantees that class-related metadata will be mapped into the same virtual memory address for all JVMs. This helps JVMs to achieve an agreement on the class metadata, so no type-related modifications (e.g., identifiers) are required.

Figure 4: The workflow of distributed class-data sharing

Figure 4 elaborates the workflow of DCDS. First, the cluster manager should prepare a shared class archive for all JVMs. The class archive should contain all classes whose corresponding object instances would be shared during inter-JVM communication. ZCOT relies on the tools provided by OpenJDK to generate such class archives [30]. Afterward, the archive will be used during JVM startup, and classes in the archive will be mapped to a given virtual address. The virtual address range is also memorized and marked as a part of the exchange space (*class space* in Figure 4). This step assures that JVMs share the same view on the classes. As shown in Figure 4, an object in the exchange space stores a reference to its class-related metadata. Since the reference points to the class space, the object’s class information is interpretable for all JVMs. Although DCDS requires the data types of applications should be known in advance, mainstream big-data analytics frameworks usually guarantee this by sending a fat jar file for execution.

Figure 5 shows how ZCOT transfers objects through network with its DCDS support. First, the sender JVM applies for an available memory chunk in the exchange space for object copying. This is achieved by communicating with an external

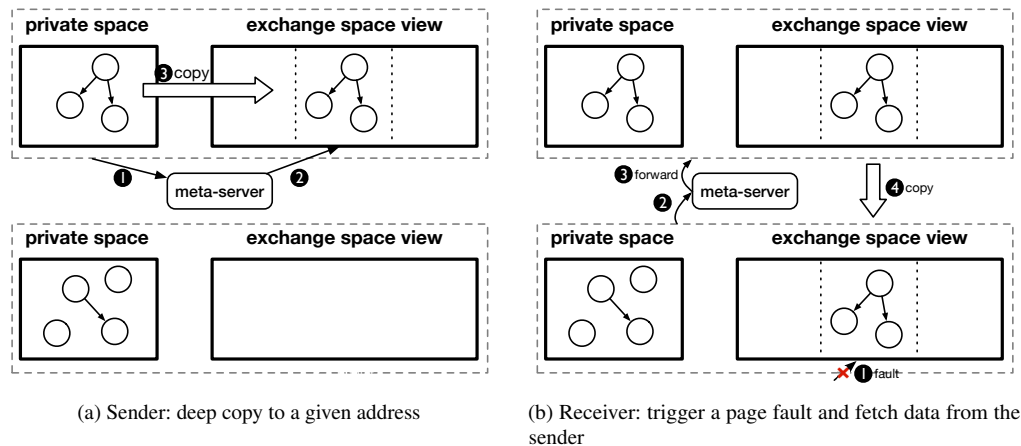

Figure 5: The workflow of ZCOT

metadata server (details in Section 4). Second, the sender JVM copies objects to the chunk’s memory address. This step is similar to a deep copy in a normal Java application. To detect cycles and avoid repeated copying on the same object, we add a marker word in each object header to store its new address if it has been copied.

The copied objects are kept on the sender machine and lazily retrieved by receivers. When a receiver JVM tries to access this part of data (Figure 5b), it encounters a page fault since the data is unavailable on its machine. We have registered the page fault handler in ZCOT-enabled JVMs so that they can request the metadata server for faulted pages. The metadata server has tracked the ownership of memory addresses in the exchange space, so it forwards the request to the data owner. Afterward, the sender builds a connection with the receiver and puts the requested objects to the desired address. Now the receiver can directly access those objects for further processing, with neither metadata updating nor reference fixing (namely *zero-change*).

3.3 Supporting OSD-based scenarios

Thanks to the exchange space abstraction, a JVM can directly access received objects without any modifications. However, this mechanism is not compatible with traditional OSD-based applications, which usually adopt byte arrays for communication. To this end, ZCOT should provide user-friendly interfaces to integrate easily with applications.

Programming interfaces. JSL provides stream-based classes for OSD implementation. The `ObjectOutputStream` class provides the `writeObject` method to serialize an object into a stream (usually files or network). Similarly, the `ObjectInputStream` class provides the `readObject` method to deserialize data into objects. Therefore, prior OSD optimizations like Skyway implement new serializers/deserializers by inheriting those two classes for

ease of integration. ZCOT adopts a similar strategy and Figure 6 shows its basic classes: `ZCObjectOutputStream` and `ZCObjectInputStream`, which are subclasses of `ObjectOutputStream` and `ObjectInputStream`, respectively. Compared with `ObjectOutputStream`, `ZCObjectOutputStream` slightly modifies the interface for `writeObject` to support different OSD-based scenarios (discussed later). To use ZCOT-based communications, applications only need to replace the original stream classes with ours. In contrast, prior work requires developers to modify the original communication model or annotate the serialization points [26, 39].

OSD-compatibility. To remain compatible with OSD interfaces (`writeObject` and `readObject`), ZCOT should also transfer data with byte arrays. To this end, ZCOT adopts a two-level transmission mechanism. As illustrated in Figure 7, ZCOT transfers data via both *frontend* and *backend*. The frontend transmission is compatible with OSD interfaces, but it only sends metadata, including the object’s start address and the data length. When `ZCObjectInputStream` receives the metadata through `readObject`, it directly accesses the corresponding address and fetches objects through backend transmission if a page fault is triggered (as mentioned in Figure 5b). ZCOT will launch dedicated VM threads in both sender and receiver JVMs to transfer the requested objects. This two-level design fills the gap between the byte-based OSD interfaces and the object-based transmission in ZCOT.

Supporting different OSD scenarios. In OSD libraries, objects are serialized and written into a stream (e.g., the `out` variable defined on Line 3 in Figure 6) when invoking `writeObject`, which are usually redirected into files or network. To support both scenarios, ZCOT adds a parameter `volatile` in the constructor of `ZCObjectOutputStream` (Line 6). When `volatile` is set to `false`, the copied objects will be written into a file, and the memory pages can be soon reclaimed

```

1 // Output class
2 class ZCObjectOutputStream extends ObjectOutputStream {
3     private OutputStream out; // Private output stream
4
5     // Constructor
6     public ZCObjectOutputStream(OutputStream out,
7         boolean volatile /* Mode */)
8         throws IOException {...}
9
10    // Compatible with the serialization interface
11    public void writeObject(Object obj)
12        throws IOException {...}
13    ...
14 }
15 // Input class
16 class ZCObjectInputStream extends ObjectInputStream {
17     private InputStream in; // Private input stream
18
19     // Constructor
20     public ZCObjectInputStream(InputStream in)
21         throws IOException {...}
22
23     // Compatible with the deserialization interface
24     public Object readObject()
25         throws IOException {...}
26     ...
27 }

```

Figure 6: Basic classes in ZCOT

through GC (details in Section 4). Nevertheless, those objects still reserve a corresponding virtual address in the exchange space. When the object data is read by other JVMs, the metadata server asks the sender to pass the file so the receiver can map it to the corresponding memory address. The case is simpler when *volatile* is *true*, which indicates a network-based transmission. In this scenario, objects are only kept in memory and can be reclaimed only if they have been read by others.

Figure 7: The two-level data transmission mechanism in ZCOT

Assumptions. Note that ZCOT is mainly designed to improve the data exchange phase for big data analytics, so it makes several assumptions about the transferred data. First, all classes related to communication should be known in advance so that they can be packed into the class archive. Second, the transferred objects are read-mostly, otherwise copy-on-write

operations would be triggered for modification operations. Lastly, objects are managed in large groups and share similar life cycles, so they can be efficiently managed in the exchange space. Since representative big-data analytics systems like Spark conform to the above assumptions, ZCOT works well for them.

4 Memory Management

Since the global exchange space is built atop a DSM-like abstraction, ZCOT should manage objects distributed to different machines. Furthermore, the managed runtimes complicate the scenario as they introduce their own memory management strategy: garbage collections (GC). This section will introduce how ZCOT manages the distributed exchange space while remaining harmonized with GC in JVMs.

4.1 Group-based management

Unlike traditional DSM-based systems, ZCOT introduces *group*, a semantic-aware notion for distributed memory management. As analyzed in Section 2, big-data analytics frameworks treat serialized objects as a whole dataset (monolithic byte array) and retrieve them together. Therefore, ZCOT puts all objects copied in the same `writeObject` invocation to a group so that they are managed together. When a receiver encounters a page fault, ZCOT will send all related data pages belonging to the same group to the receiver and avoid future faults. This mechanism, namely *group-based prefetching*, leverages the semantics in the OSD scenario to mitigate the page-based management overhead in traditional DSM.

4.2 Metadata server

The metadata server is the core module for ZCOT’s memory management. JVMs communicate with the metadata server through remote procedure calls (RPCs) to acquire or release memory resources in the exchange space. Figure 8 illustrates the core data structures in the metadata server. The metadata server is agnostic to groups; groups are only managed by individual JVMs. It partitions the shared exchange space into equal-sized memory chunks (256MB by default) for memory allocation and deallocation. It also maintains an *allocation bitmap* to mark if a chunk has been allocated. Each chunk is assigned with an integer ID, which is calculated by its relative offset compared with the exchange space’s start address. To track the stored locations of chunks, the metadata server maintains a *copy set* for each chunk, which is stored in a *chunk mapping table*. The copy set contains JVMs storing a copy of the corresponding chunk (in memory or disk), which are also represented with integer IDs. The mapping between a JVM’s ID and information (e.g., IP address) is stored in a separated *member table*.

Since each JVM needs to communicate with the metadata server, its reliability becomes considerable. To tolerate failures on the metadata server, we can introduce replicas for it, and the overhead would be acceptable given the low frequency of communications between the metadata server and worker JVMs (several times in a data-processing stage lasting for seconds).

Figure 8: Important data structures in the metadata server.

4.3 RPC interfaces

The metadata server provides four important RPC interfaces listed below.

```
int register(std::string ip, int port);

Chunk* acquire();

Chunk* get_remote(Address addr);

int release(Chunk* chunk);
```

register. `register` is only invoked when a JVM is launched. ZCOT has provided a JVM option `-XX:+UseZCOT`, and a JVM enabling this option automatically spawns an RPC thread and sends a `register` RPC to the metadata server with its IP address and listening port. After receiving the RPC, the metadata server saves the IP and port number to the member table, generates an integer as the JVM's ID, and returns with the ID. For subsequent RPCs, JVMs should always attach the returned ID to help the metadata server maintain the stored locations of objects (omitted in the interfaces above).

acquire. When a JVM runs out of allocated memory from the exchange space, it should send `acquire` RPCs for more memory resources. After receiving an `acquire` request, the metadata server scans its bitmap to allocate an available chunk. Afterward, the metadata server memorizes the relationship between the allocated chunk and the JVM's ID and returns the chunk. To reduce the overhead of bitmap scanning, ZCOT memorizes the address of the last successfully allocated chunk and starts scanning there. If the scanned address reaches the end of the exchange space, ZCOT will continue scanning from the beginning. To handle simultaneous `acquire` requests, ZCOT introduces a bitmap lock to ensure the bitmap is exclusively accessed.

get_remote. The `get_remote` interface is used by JVMs encountering a page fault when accessing a virtual address. Since a page fault indicates the requested objects are not stored locally, the JVM sends `get_remote` to fetch the corresponding chunk. After receiving `get_remote`, the metadata server gets the corresponding chunk containing the address and finds which JVMs store the chunk by scanning the chunk mapping table. As illustrated in Section 3.2, the metadata server forwards the request to the corresponding JVM for actual data transmission. Since the size of a chunk is relatively large, sending chunks may introduce considerable performance overhead. To reduce the transferred data size, the sender JVM only sends used pages in the chunk, which are represented as the length of data in the frontend transmission (Figure 7). Due to ZCOT's group-based prefetching mechanism, the sender may directly send multiple chunks in the same group to the receiver. In this case, the receiver is responsible for sending an auxiliary RPC to update the copy set in the metadata server.

release. The `release` interface is relatively simple. When a JVM finds that objects in a chunk are no longer used, it sends `release` to give up this chunk. After receiving `release`, the metadata server removes the JVM's ID from the corresponding copy set in the chunk mapping table. If no JVM stores this chunk, the metadata server will reclaim it by marking the corresponding bit as *free* in the bitmap.

4.4 Garbage collection

JVMs have already implemented their garbage collection (GC) algorithms to automatically reclaim unused memory. When GC is triggered, JVMs track all live objects and reclaim memory consumed by dead ones. Since objects in the exchange space are reachable from individual JVMs, they will also be affected by GC. To this end, ZCOT has integrated its memory management strategy with G1, the default GC algorithm in OpenJDK, to ensure the correctness of distributed memory management and reduce GC overhead.

G1 basics. G1GC (short for Garbage-first Garbage Collection [8]) is the default garbage collector after OpenJDK 9 [29]. G1 divides the Java heap into equal-sized *regions* for ease of management. It also maintains per-region metadata named *remember sets* to memorize all references pointing to objects in the same region. The remember set is updated by instrumenting all write operations in Java code (also known as *write barriers*). The G1 algorithm is mostly stop-the-world, which means that application threads should be paused until GC ends. During GC¹, each selected region is processed simultaneously: a dedicated GC thread scans the remember set of a region, finds all reachable objects, and copies them to an empty region (named *survivor region*).

Integrated with G1. ZCOT extends the region-based design of G1 to support the exchange space. It proposes *ZCRe-*

¹For simplicity, we only discuss the young GC and mixed GC in G1

gion, a new kind of region allocated from the metadata server. Compared with regions in G1, the size of ZCRegion is not fixed. Each ZCRegion corresponds to a group in the exchange space, and all objects therein are expected to have the same life cycle. Since objects in ZCRegions have different behaviors compared with those in other regions, G1 should treat them specially. First, we modify the behavior of write barriers to consider ZCRegions. When a reference points to objects in a ZCRegion, we do not memorize this reference but only mark the ZCRegion as used. This is because objects in a ZCRegion are only collected when no references point to any of them. Similarly, GC threads do not need to scan ZCRegions during GC because all objects are treated as alive if there exists any reference pointing to the region. When GC ends, the JVM will scan all ZCRegions and find those containing no incoming references. For those ZCRegions, the JVM invokes the `release` RPC to reclaim corresponding chunks. If objects in a group are written into disks, the corresponding ZCRegion can also be reclaimed by GC, but the JVM does not invoke `release` since the virtual address is still reserved by the group.

In summary, our design successfully integrates the memory management of the exchange space with G1GC. When GC ends, the memory resource in the exchange space is automatically reclaimed by following the reachability-based algorithm. Furthermore, by specially handling regions in the exchange space, we avoid unnecessary metadata tracking and object scanning. In some cases, this design can even reduce GC pause time (as shown in Section 6.3).

5 Transmission Deduplication

Since ZCOT sends objects instead of byte arrays during transmission, it would be much easier to track transmitted objects and conduct deduplication. This section introduces the data deduplication module in ZCOT based on its object-centric transmission mechanism.

5.1 Overview

Figure 9 shows the effect of ZCOT's data deduplication module in the aforementioned page-rank example (compared against Figure 2). When sending the URL-based network topology in the first round, the sender has copied all URL string pairs (together with two string objects) into their corresponding addresses. In the next few rounds, the application sends key-value pairs to update rank values for each URL. Since all key-value pairs are sent as objects, it is much simpler for ZCOT to find that all URL objects have been sent. Therefore, the sender can directly update the references in those key-value pairs with the addresses in the exchange space and thus remove duplicated transmission on URL objects.

ZCOT runtime should be further extended to achieve data deduplication. First, ZCOT should track copied objects to rapidly find duplicated transmission. Second, ZCOT should

manage dependencies among object groups for safe memory reclamation.

5.2 Duplication detection

A straw-man design for duplication detection would be scanning all objects in the exchange space. However, this design would induce considerable overhead given the large number of objects. ZCOT instead follows a simple detection criterion: if an object is in the exchange space, an attempt to copy it is a duplicated one.

We still use page-rank as an example to explain ZCOT's duplication detection. Suppose a JVM receives the network topology in round 1 (consider Figure 9); it reads URL objects from the exchange space and uses them in the following rounds. Therefore, when it propagates updated rank values to other JVMs, it still uses the URL objects received from others. When copying the URL-rank pairs in the next few rounds, ZCOT checks each object's address and thus avoids copying those URL objects already in the exchange space.

5.3 Dependency management

Although data deduplication in ZCOT can reduce the network overhead by avoiding repeated copying on the same object, it also complicates memory management by introducing inter-group references. As mentioned in Section 4.1, each invocation to `writeObject` creates a new group for object management, and each group is separately used by calling `readObject`. After deduplicating objects from different groups, objects in a group can hold references to those in another group, which should be correctly handled especially when a group is being garbage collected. To this end, ZCOT has managed those references as *dependencies* among groups.

Due to the large number of inter-group references, ZCOT does not maintain reference-level dependencies. When a group holds a reference to any objects in other groups, ZCOT marks the group as dependent on others. The dependency tracking is still achieved by extending the write barriers. To memorize all dependencies, ZCOT extends the chunk mapping table in the metadata server to contain a *dependency set* for each chunk, which stores all other chunks it relies on. When a JVM finds that its group relies on another group after deduplication, it sends a new RPC `add_dependency` to the metadata server. Since the metadata server is not aware of groups, the RPC should specify all chunk IDs owned by the group it relies on. Those chunk IDs will be added to the corresponding dependency set by the metadata server.

Figure 10 uses an example to illustrate how ZCOT leverages dependencies during object copying. After encountering a page fault on chunk 4, the receiver JVM sends a `get_remote` RPC to the metadata server. By fetching the dependency set in the chunk mapping table, the metadata server finds all chunks that chunk 4 depends on. Afterward,

Figure 9: ZCOT avoids duplicated object transmission in page-rank

Figure 10: ZCOT avoids sending duplicated data with dependency tracking

ZCOT checks the copy set for each chunk to find if the receiver JVM already has a copy. If the receiver does not have a copy, ZCOT adds the corresponding chunk ID in a message, which will be forwarded to the sender JVM later for real data transmission. In our example, since the receiver JVM already has copied chunk 0 and 1, it only needs to receive chunk 4 (requested) and chunk 3 (dependent). This example indicates that ZCOT can avoid duplicated data submission with slight modifications on the metadata server.

5.4 Garbage collection

Adding dependencies also complicates GC for individual JVMs. Since a group (represented as ZCRegions) can be referenced by others stored in remote JVMs, local GC cannot determine if a group can be safely reclaimed. For example, suppose JVM 0 stores a group (chunk 0) that contains a reference to another group (chunk 1) stored on JVM 1. Although JVM 1 no longer contains references to chunk 1, the chunk should not be collected because JVM 0 may access it through references in chunk 0. To this end, we extend G1GC to consider remote inter-group references.

In our refined GC algorithm, once a JVM detects a ZCRegion has incoming references from other ZCRegions (through write barriers), it marks the region as *pinned* and thus cannot be reclaimed. It also sends the dependency relationship to the metadata server through RPCs. When GC ends, the JVM

skips all pinned ZCRegions and only collects those with no incoming references. A pinned ZCRegion can be reclaimed when the metadata server finds that all chunks relying on it have been released. In this case, the metadata server will send a `canRelease` message to all JVMs in the corresponding copy set, and those JVMs will mark the ZCRegion as *unpinned* to safely reclaim it in later GC cycles.

5.5 Internalization

Big-data analytics usually generate a large number of objects with simple types, such as Integer, String, Double, etc. OpenJDK has provided an *internalization* mechanism to merge those objects with the same content together. For example, Integer objects whose values are between -128 and 127 would be merged into one if their values are equal. ZCOT also embraces this mechanism for deduplication, but in its distributed exchange space. It extends DCDS so that all JVMs allocate a small region at the same virtual address during start-up to contain globally-shared Integer objects. Thanks to this optimization, the number of transferred Integers can be greatly reduced.

6 Evaluation

6.1 Experimental setup

ZCOT is implemented atop the HotSpot JVM in OpenJDK 11.0.8-GA, with 8,327 lines of C code and 654 lines of Java code. We leverage the following workloads to evaluate ZCOT.

Microbenchmark. The microbenchmark contains four different data types used in prior work [26, 39]: 2-dimension points, key-value pairs, hashmaps, and media objects. To simulate big-data scenarios, we transfer them in large arrays whose length is 65536. Since some baselines crashed for large arrays of media objects, we reduced the length to 16384 for this data structure.

Spark. Spark (v3.0.0) is a data analytics engine that requires massive data transmission among JVMs.

Flink. Apache Flink [6] (v1.14) is a distributed data processing engine for both batch and streaming workloads.

As for baselines, we compare ZCOT with two commonly-used OSD libraries (JSL and Kryo) and two state-of-the-art OSD optimizations (Naos and Skyway²).

Our test environment includes a cluster with four nodes connected by 100 Gbit/s Mellanox ConnectX-5 NICs. Each node contains dual Xeon E5-2650 CPUs and 128GB DRAM.

6.2 Microbenchmark

To directly compare ZCOT with state-of-the-art OSD optimizations, we leverage the *microperf* tester in the Naos’ open-source repository for evaluation. The tester involves a sender and a receiver deployed on two separate machines and reports the communication time with different type of data objects. The heap size for all workloads is 16GB.

Figure 11 shows the results for ZCOT and other baselines, which are the average of 1000 times of repetitive execution. ZCOT achieves the best performance of all except for 2-dimensional points. The average speedup is 2.28×, 1.94×, 2.19×, 3.95× compared with Naos, Skyway, Kryo, and JSL, respectively. The result also suggests that ZCOT performs better for complicated data structures. The media class from the Java serialization benchmark set (JSBS) [37] is the most complicated one, so the improvement is the largest especially against Naos (4.35×). This is because the computation overhead increases when the data structure becomes more complex. For simple data structures like points, ZCOT’s reduction on data transformation is offset by larger network overhead, so it performs slightly worse than Naos and Skyway.

Figure 11: The evaluation results for microbenchmark

6.3 Spark

Ease of integration. To adopt ZCOT in Spark, we need to implement a new data serializer `ZCSerializer` to replace the default `KryoSerializer`. Although the name seems to

²Both implemented by Naos’ authors

Figure 12: The performance of Spark applications

involve OSD phases, it is only for compatibility considerations and still remains zero-change during transmission. `ZCSerializer` contains 70 lines of code, and most of them are inherited from the JSL serializer. Furthermore, we replace the original stream classes from JSL with ours. If a Spark user wants to enable ZCOT, she only needs to (1) configure the `spark.serializer` to `ZCSerializer` and (2) add `-XX:+UseZCOT` to the launch option of all JVMs, which is quite simple.

Evaluation results. We leverage five applications in the example directory of Spark for evaluation. Their descriptions and evaluated datasets are shown in Table 2. We configure one node as the metadata server and Spark master while the other three servers as Spark workers. The Java heap size for each node is set to 80GB.

Figure 12 shows the results for all applications. The results indicate that ZCOT can improve the performance by 13.9% and 24.1% on average compared with Kryo and JSL, respectively. Although Kryo has optimized the OSD performance over JSL, our evaluation shows that the data transmission can be further improved.

Application	Dataset
PageRank (PR)	LiveJournal [4]
Word Count (WC)	LiveJournal
KMeans (KM)	USCensus1990 [10]
Transitive Closure (TC)	Blogs [1, 17]
Logistic Regression (LR)	SUSY [5]

Table 2: Evaluated applications and datasets for Spark

We have further broken the results into four different phases: write (serialization), read (deserialization), compu-

tation, and garbage collection (GC). Since the four phases are not overlapped in Spark (the GC phase only contains stop-the-world time), the accumulated time is equal to the overall execution time. Figure 12 indicates that the performance mainly comes from the improvement in OSD-related parts. Since OSD occupies a considerable portion in page-rank execution, ZCOT can reach its best improvement (23.6% and 38.1% w.r.t. Kryo and JSL). Averaged across all applications, ZCOT can reach $4.19\times$ speedup in the write part and $2.95\times$ in the read part over the default Kryo serializer ($4.52\times$ and $3.81\times$ speedup for write and read part in JSL). As for GC, ZCOT shows comparable pause time with others. In PR, LR, and TC, the GC time is even shorter than JSL and Kryo. Although ZCOT needs to manage the copied groups (ZCRegions), its coarse-grained collection strategy avoids scanning objects inside ZCRegions. Moreover, ZCOT avoids generating monolithic byte arrays by eliminating the serialization phase, which can mitigate the memory pressure and introduce less frequent GC.

Note that the computation time in ZCOT is somewhat larger than that in JSL and Kryo. This can be explained by two reasons. First, since ZCOT does not compress the object contents during transmission to achieve zero-change, the transferred data size is larger than JSL and Kryo, which leads to larger network overhead (included in the computation part). Second, the data deduplication module makes objects in the same dataset scattered into different virtual address ranges, which may lead to more random memory accesses and cache misses. Nevertheless, the overall performance improvement is satisfying.

Results for deduplication. We have also studied the effect of our data deduplication module. As shown in Table 3, ZCOT can reduce the transferred data size for all four applications, ranging from 8.1% to 53.8%. Even for the non-iterative application (WC), ZCOT is also helpful thanks to its internalization optimization technique. Meanwhile, LR and KM receive smaller savings because they generate many different Double objects in each iteration, which cannot be reused and deduplicated. The result indicates that duplicated transmission is common in data analytics and ZCOT’s optimizations are helpful. Note that the number of transferred bytes after deduplication is still much larger than that in Kryo and JSL, since both of them converts objects in a compact format before transmission. Therefore, it is still preferred to use ZCOT with larger network bandwidth.

	PR	WC	TC	KM	LR
dedup	15.25	4.13	5.03	5.37	5.55
no-dedup	31.64	5.50	10.88	5.86	6.04

Table 3: Average transferred bytes (GB) for Spark executors

Various settings and overhead analysis. We evaluate the performance of ZCOT with various settings on the heap size and the chunk size by using PR as an example. The results in

Figure 13 show that ZCOT is not sensitive to different settings and reaches similar performance. We have also studied the overhead of write barriers by running Spark applications atop ZCOT’s JVMs (with Kryo serializers) and comparing the performance against vanilla JVMs. The average overhead among all applications is 2.73%, which is much smaller compared with the improvement brought by ZCOT. We also find the average communication overhead with the metadata server is only several milliseconds for each data-processing iteration, which usually lasts for seconds.

Figure 13: Results for PR under various settings

6.4 Flink

Ease of integration. We have also integrated ZCOT to Flink, another big-data analytics framework. Although Flink adopts its built-in serializer and deserializer for OSD, the integration is not complicated since we only need to replace them with ZCOT’s OSD-compatible interfaces and streams.

Evaluation results. We leverage four representative SQL queries in the TPC-H benchmark for evaluation (Q1, Q3, Q6, and Q10) and rely on its built-in generator to create input data (10GB). The configuration is similar to Spark: we launch three workers on different machines for evaluation, but the Java heap for each node is 20GB. Since the read and write phases are overlapped in Flink, we do not break the execution time into parts. The results in Figure 14 show that ZCOT outperforms the built-in serializer in Flink for three out of four queries and leads to 2.3%-22.2% improvement in query execution time. ZCOT does not improve Q6 since it does not involve a reduce operator and the amount of transferred data is limited. It performs the best for Q10 (22.2%) since it reaches $4.40\times$ improvement for the write part and $1.44\times$ for the read part. The speedup is smaller compared with Spark since Flink’s built-in serializers are manually optimized for specific data structures (like tuples). Nevertheless, ZCOT still shows better performance than the vanilla version of Flink, which suggests the importance of zero-change transmission mechanism.

Figure 14: The performance of Flink applications

7 Related work

7.1 OSD optimizations

OSD has become a considerable performance bottleneck especially for large-scale communication-intensive applications. To optimize the time-consuming phases in OSD, prior work such as Kryo [38], Skyway [26], and Naos [39] has refined the transmission data format or leveraged the advances in network hardware technologies. ZCOT instead aims at eliminating the whole OSD process. Apart from software-based techniques, another line of work adopts hardware-based approaches to reduce OSD overhead. Optimus Prime [32] builds a data transformation accelerator (DTA) to improve the OSD throughput for microservices. Cereal [16] co-designs the data transmission format with hardware accelerators to improve the performance and energy efficiency of Spark applications. Morpheus [40] moves the deserialization phase into smart SSDs, while Hgum [46] leverages FPGAs to handle OSD tasks. ZCOT is based on off-the-shelf hardware and thus orthogonal to those hardware-based optimizations.

7.2 Distributed language runtimes

The idea for building a distributed language runtime (e.g., distributed JVMs) has been explored for decades. Java/DSM [43] builds a distributed JVM atop DSM for heterogeneous computing. JESSICA [21, 47] provides a single global thread space and transparently migrates Java threads for load balance. Comet [14] builds a DSM-abstraction for JVMs running on both mobile devices and the cloud and relies on its memory model to achieve effective code offloading. Semeru [41] proposes a universal Java heap abstraction so that a Java application can freely access all memory resources in a memory-disaggregated architecture. Those systems leverage a shared heap to synchronize data among different endpoints, but they do not consider the performance overhead of inter-JVM communication for large applications. XMem [42] enables efficient type-safe object sharing among multiple JVMs on the same physical machine, but it does not consider distributed environments. ZCOT also proposes a distributed runtime design,

but it mainly focuses on boosting data transmission among multiple JVMs.

7.3 Runtime optimizations for Java

High-level languages like Java are intensively used in large-scale, distributed applications, which stimulates research interests in runtime optimizations for performance improvement. ITask [11] makes data processing tasks interruptible when facing large memory pressure, which leads to better performance and fewer out-of-memory errors. Yak [27] divides the application execution into epochs and triggers GC when an epoch ends. Broom [12] embraces a region-based design and puts objects with the same lifecycle into the same region for fast reclamation. ScissorGC [18, 19] proposes shadow regions to improve the scalability of full GC phase. Taurus [22, 23] coordinates GC from different JVMs to reach better performance or smaller tail latency. Facade [28] and Deca [36] store massive data objects in off-heap memory to reduce GC pressure, while Gerenuk [24] enables speculative execution on serialized data to reduce both memory footprint and GC overhead. ZCOT focuses on eliminating the OSD process and duplicated object transmission, and it also collects objects by coordinating with the metadata server.

8 Conclusion

This work introduces ZCOT, which aims to eliminate the object serialization/deserialization phase in data exchange among language runtimes (like JVMs). ZCOT provides an exchange space where objects are interpretable for all JVMs, which removes the need for any data transformation during object transmission. It also uncovers the duplicated object transmission problem and provides a corresponding deduplication mechanism. The evaluation shows that ZCOT can significantly improve the performance of object transmission.

A Artifact Appendix

Abstract

ZCOT, or Zero-Change Object Transmission, is proposed to optimize data exchange among multiple Java virtual machines (JVMs) in a distributed environment. Instead of sending and

receiving data with the costly object serialization/deserialization (OSD) phase, ZCOT allows JVMs to directly communicate with Java objects, which significantly improves the data exchange time, especially for applications like big data analytics.

Scope

This artifact (including binaries, source code, documents, and scripts) is used to conduct the main experiments in ZCOT, which consists of the following two parts:

- **Micro-benchmark performance.** The result should show that ZCOT outperforms recent OSD optimizations (Skyway [26] and Naos [39]) and state-of-the-art OSD libraries (Kryo [38] and JSL) for most data structures used in Naos' microbenchmark.
- **Spark performance.** The result should show that ZCOT outperforms Kryo and JSL-based Spark applications in both data exchange and task execution.

Note that we only report numbers evaluated on our machines, so the results might be different with various hardware configurations.

Contents

We pack all related files into a zipped one, which contains the following contents.

- **README.** A file containing instructions for artifact evaluation.
- **ZCOT-jdk.** The source code of a modified OpenJDK to support ZCOT.
- **Meta-server.** The source code of the metadata server used in ZCOT.
- **Micro.** Scripts and jars used for the micro-benchmark.
- **Spark.** Since the code size of Spark is quite large, we provide an executable binary for Spark, which is slightly modified to evaluate ZCOT.
- **Naos-jdk.** A slightly modified version of Naos' OpenJDK to compare with ZCOT.

Hosting

Currently our code is not ready for open-source. Nevertheless, you can contact us via mingyuwu@sjtu.edu.cn to obtain the artifact.

Requirements

Hardware requirements. We evaluate ZCOT on four nodes connected by 100 Gbit/s Mellanox ConnectX-5 NICs. The NIC bandwidth has a significant impact on ZCOT's performance.

Software requirements. The operating system used in our machines is Ubuntu 16.04.2, but higher versions are also acceptable. Note that huge pages should be enabled to run ZCOT. Dependencies for installing OpenJDK have been listed in the README file.

Abstract

Distributed systems are hard to design and implement correctly. Recent work has tried to use formal verification techniques to provide rigorous correctness guarantees. These works present a hard choice, though. One must either opt for the power of refinement-based approaches like IronFleet and Verdi, at the cost of large amounts of manual effort; or choose the more automated approach of I4, IC3PO, SWISS and DistAI which give up the ability to prove refinement and the power and scalability that come with it.

We propose an alternative approach, Sift, that combines the power of refinement with the ability to automate proofs. Sift is a two-tier methodology that uses a new technique, *refinement-guided automation*, to leverage automation in a refinement proof and a divide-and-conquer technique to split a system into more refinement layers when necessary. This combination advances the frontier of what systems can be proven correct using a high degree of automation. Contrary to what was possible before, our evaluation shows that our novel approach allows us to prove the correctness of a number of systems with little manual effort, and to extend our proofs to include not just the protocols, but also an executable distributed implementation of these systems.

1 Introduction

Recently, formal verification has emerged as a potential alternative to the traditional approach of testing. The promise of formal verification—to eliminate all bugs by construction—is particularly attractive for distributed systems, which are notoriously hard to design and implement correctly.

Despite recent efforts, however, formal verification of distributed systems is still not ready for real-world applications. The most powerful techniques, such as IronFleet [34] and Verdi [63], rely on *refinement* proofs [1, 25, 42] to reason about complex systems and verify real implementations. Alas, the power of those techniques comes at a high cost: performing these refinement proofs manually requires large amounts of manual effort.

In an attempt to reduce the manual verification effort, the Ivy tool [56] proposes to express distributed protocols using decidable—and thus simpler to verify—reasoning [57]. The Ivy tool achieves remarkable automation, but still requires significant human effort to complete the proof. More recent approaches, like I4 [50, 51], IC3PO [27], SWISS [33] and DistAI [66], leverage model checking and SMT solvers to automate the most challenging part of proving the correctness of distributed protocols: finding an *inductive invariant*. Alas, this automation comes at the expense of expressiveness and applicability, because tools like I4 and DistAI were designed to prove properties of *monolithic* protocols which consist of a single layer. As such, they cannot prove refinement.

Refinement [1, 25, 42], however, is an essential concept in proving the correctness of real, complex systems. It allows us to prove the correctness of a system by showing that it is equivalent to a simpler, more abstract version of that system. The power of refinement comes in many forms:

Concise specification As Lamport has argued [45] and as IronFleet demonstrated, specifications should be written as simple, abstract state machines. Consider the specification of a Paxos-based State Machine Replication in IronFleet, where the goal is to prove that the entire service is linearizable. Expressing linearizability as a set of properties on the requests and responses is daunting and will likely yield a complex specification. Using refinement, the task is simple: just show that the entire service is equivalent to a single machine executing requests one at a time. Similarly, the sharded key-value store in IronFleet was simply proven equivalent to an abstract, logically centralized key-value store; i.e., a map.

Scaling to complex systems As IronFleet and Verdi demonstrated, the key to dealing with the complexity of a real system is to take a modular approach: split the proof into multiple layers and show that each layer refines the one above it. This is especially true when verifying actual implementations, as these tend to be much more complex than abstract protocols. In the absence of refinement, we are left with the task of reasoning about a single, monolithic system, whose complexity now becomes a limiting factor for both

manual and automated approaches.

Dealing with undecidability Even when one only cares about proving the correctness of the protocol, and not of the implementation, being unable to split a monolithic system into multiple layers can be a showstopper for automation. As Padon et al. demonstrated [55], some protocols may be undecidable by construction and thus not amenable to the automation of I4 and IC3PO. In these cases, one can use refinement to split the protocol into two layers, each of which is separately decidable [62].

We aim to get the best of what are currently two distinct worlds: the *power of refinement* (i.e. IronFleet-style proofs) but with only *a fraction of the manual effort* (i.e. using the automation of monolithic provers like I4, IC3PO, SWISS and DistAI). This combination allows us to not only achieve simple, concise specifications, but also to scale our proofs to more complicated distributed protocols, and even to distributed implementations.

To achieve this goal, we introduce Sift, a two-tier methodology that combines automated verification with a small amount of manual effort to push the boundary on the kinds of systems that can benefit from proof automation. Just like IronFleet before it, Sift is a *methodology*, not a tool. Its contribution is a way of structuring refinement proofs in order to leverage the automation of existing tools. Similar to how IronFleet guided developers to manually construct proofs based on the existing tools (TLA+ and Dafny), so does Sift show developers how to construct proofs that leverage the automation of more recent tools, like IC3PO and Ivy.

The first tier of Sift introduces a new technique, called *refinement-guided automation*, which leverages the automation of monolithic provers in the context of a refinement proof. At the high level, this technique enables the automation of refinement proofs between two layers by *encapsulating* the state of the upper, more abstract, layer into the state of the lower, more concrete layer. This encapsulation allows us to transform a two-layer refinement proof into a single-layer, monolithic proof that provers like I4, IC3PO, SWISS and DistAI can perform.

Leveraging automation to prove refinement is not always enough, though. Monolithic provers have their limits and thus some refinement proofs are just too complex to prove automatically. When that happens, we provide developers with an escape hatch. The second tier of the Sift methodology describes a divide-and-conquer technique for introducing intermediate layers, thus splitting a complex proof into chunks that are small enough for the prover to handle.

The Sift methodology applies refinement-guided automation within each refinement step and uses our divide-and-conquer technique to split a refinement step into smaller, more manageable steps. As a result, Sift allows us to apply, for the first time, automation to refinement-based proofs and scale to much harder problems than was previously possible. We use Sift to automate the verification of four distributed imple-

mentations, whose proof required minimal manual effort (less than five minutes, in most cases).

We further use our divide-and-conquer technique to prove the correctness of an implementation of Raft [54] and an implementation of MultiPaxos [43, 44] — a feat that was only possible before by providing a fully manual proof of correctness. Using Sift, we were able to automate most of the proof for both Raft and MultiPaxos. The manual effort required to complete the proof with Sift is not only significantly less than that of previous approaches, it is also much less reliant on having expertise in formal verification.

Overall, this paper makes the following contributions:

- We introduce *refinement-guided automation*, a technique that leverages the automation of monolithic-oriented tools to perform more complex, refinement-based proofs.
- We present a divide-and-conquer technique for splitting a complex refinement proof into smaller pieces, such that each piece is amenable to automated verification.
- We introduce Sift, a methodology that incorporates refinement-guided automation and our divide-and-conquer technique. We evaluate Sift on six distributed implementations and find that it allows us to prove their correctness in a mostly automated manner which drastically reduces the manual effort required compared to previous refinement-based approaches.

The rest of the paper is structured as follows. Section 2 discusses the tradeoff between automation and refinement. Section 3 recaps some background material, while Section 4 gives an overview of Sift. Section 5 introduces refinement-guided automation and Section 6 shows how to introduce intermediate refinement layers when needed. Section 7 evaluates the effectiveness of using Sift to automate the verification of a number of distributed implementations. Section 8 presents the limitations of Sift and discusses future work. Section 9 discusses related work and Section 10 concludes.

2 The Price of Automation

As discussed earlier, there are currently two approaches for verifying the correctness of distributed systems. The first is the powerful but manual approach of IronFleet and Verdi [34, 35, 63], where the developer uses refinement to show that a complex implementation is equivalent—through a series of layers or transformations—to an abstract specification.

The second approach is that of I4 [50], IC3PO [27], SWISS [33] and DistAI [66] which leverage the power of model-checking and SMT solving [5] to automatically prove the correctness of abstract system descriptions at the protocol level. These approaches aim to prove that a given safety property holds for the protocol at hand, by automatically identifying an *inductive invariant* that implies this safety property.

While such automation is undoubtedly a desirable property, it comes at a heavy price. In particular, I4, IC3PO, SWISS and DistAI can only perform *monolithic* proofs: they can prove

that a protocol—defined as a single layer—satisfies a given safety property. As we described in Section 1, this not only limits the type of specifications we can use, but also severely limits the scalability of the approach.

Most importantly, the scalability limitation is not an artifact of the implementation of *monolithic provers*—like I4, IC3PO, SWISS and DistAI—but rather inherent in their design. By asking the underlying solver to find an inductive invariant that supports the desired safety property, they essentially adopt an *all-or-nothing* approach: either the solver is powerful enough to find an inductive invariant or it is not. If we consider more and more complex systems, we soon reach a point where the solver is simply not powerful enough to find an inductive invariant.

In fact, a similar dichotomy presents itself when the protocol description has elements outside the *decidable* fragment of logic [47,55]. In several of these cases, the solver struggles considerably, even when it is trivial for a human to split the problem into decidable sub-problems. Without the ability to split this monolithic proof into multiple pieces, there is no middle ground. For example, I4 simply fails when the problem lies outside the decidable fragment, even though it is still possible to use refinement to split the protocol into two layers, each of which is separately decidable [62].

In this paper, we show that there exists a middle ground between the fully manual approaches that support refinement, like IronFleet and Verdi; and the automated-but-monolithic approaches, like I4, IC3PO, SWISS and DistAI. This middle ground, enabled by our novel Sift methodology, allows for refinement-based reasoning—and thus allows us to prove the correctness of complex distributed implementations—while making heavy use of automation to drastically reduce the amount of manual effort required compared to IronFleet and Verdi.

3 Background

3.1 Multi-Layer Refinement

Sift is heavily based on the notion of refinement. We will therefore first recap the notion of refinement and how it can be used to prove the correctness of complex systems.

A system P *refines* another system Q if the observable outputs produced by any execution of Q can also be produced by some execution of P . In the case of distributed systems, the only outputs that are visible to external observers are the messages produced by these systems.

In the simplest application of refinement, the developer writes two layers: a specification and an implementation. The specification is written as a simple, logically centralized state machine. In the case of a sharded key-value store, for example, the specification is a simple map, where the only possible actions are to put something to the map, or to get something from the map [34,35]. The developer then shows that the

implementation refines the specification, thus proving the correctness of the implementation.

In more complex systems, directly proving refinement from the implementation to the specification can be difficult [34,35,63]. In that case, the developer must insert one or more increasingly complex layers between the implementation and specification, thus creating a multi-layer structure, where each layer must be proven to refine the one above it. We explain how to design and insert intermediate layers in Section 6.

3.2 Automated Reasoning and Monolithic Provers

Traditional verification languages [4,46] rely on the developer to write a full proof, including a large number of manual annotations. As a result, approaches like IronFleet [34,35] and Verdi [63] incur a high proof-to-code ratio. To reduce this manual effort, Ivy [56] uses decidable logic to guarantee completeness. With Ivy, the developer only needs to find an *inductive invariant*—an invariant which is closed (inductive) under the system transitions—and the prover can automatically identify if this inductive invariant is correct. Ivy significantly simplifies the effort of proving the correctness of distributed systems, but finding such inductive invariants is still a non-trivial task that relies on human intuition and an intimate understanding of the system at hand.

To push the automation a step further, I4 [50] leverages the regularity of distributed protocols, so that the inductive invariant can be automatically inferred from a small, finite instance. Unfortunately, such a strategy only applies to monolithic protocols, not refinement proofs. Thus, I4 doesn't scale well when the system has a large state space and complex transitions. More recent tools [27,33,66] have followed the direction of using finite instances to guide the verification of distributed protocols. All these tools, however, apply only to monolithic proofs and cannot support refinement. We call such tools *monolithic provers*.

3.3 IC3PO: Our Monolithic Prover of Choice

The design of Sift does not rely on the internals of the monolithic prover that it uses. The refinement-guided automation technique of Sift can leverage any tool designed for automating monolithic, single-layer proofs. In fact, we previously tried I4 as the monolithic prover in Sift, but later found that IC3PO performs better. Our experience so far shows that IC3PO also outperforms SWISS and DistAI. As new and more powerful monolithic provers become available, Sift can adopt them to perform even larger refinement steps to further reduce manual effort. The next paragraph gives a short overview of IC3PO.

IC3PO [27,28] is a recently-developed prover that uses the synergistic relationship between symmetry and quantification to prove the safety of distributed protocols fully automatically,

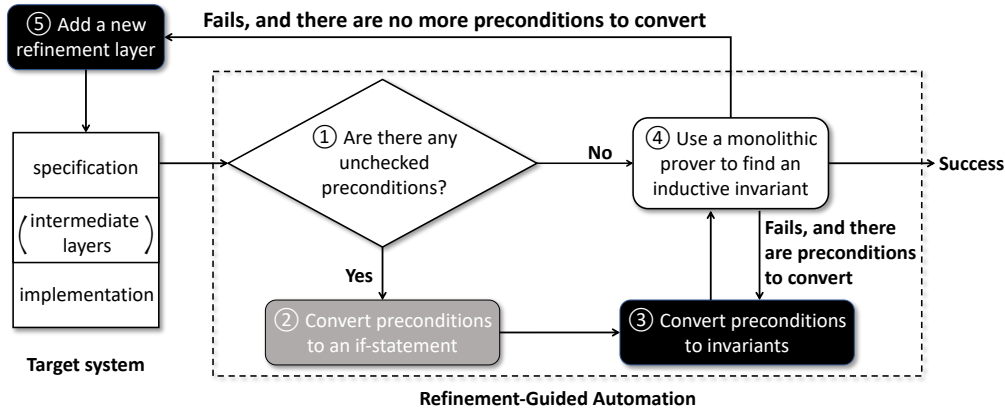

Figure 1: Summary of the Sift methodology. White boxes are fully automated, gray boxes indicate a trivial syntax change, and black boxes denote manual effort.

by inferring compact inductive invariants with both *universal* and *existential* quantifiers. At its core, IC3PO exploits the inherent regularity present in distributed protocols to significantly scale up IC3/PDR-style verification [10, 23] over finite instances of the protocol. Starting with an initial instance size, IC3PO systematically computes quantified inductive invariants over protocol instances of increasing sizes, until protocol behaviors *saturate*, concluding with an inductive proof that works for all instances of the protocol.

4 Overview of Sift

This paper introduces Sift, a methodology that allows reasoning about complex systems while still using a large degree of automation in proofs. Sift accomplishes this by employing a small amount of manual effort, when needed, to split the system into a number of layers, where each layer can be shown to refine the layer above it.

Figure 1 shows an overview of the Sift methodology. Initially, the developer starts with an implementation of the system, along with a specification, both written in the Ivy language [56]. If one were to use the Ivy prover, they would have to provide a manual proof of refinement between the specification and implementation. Sift, instead, introduces our *encapsulation* technique to merge the two layers into a single proof that our monolithic prover can attempt to solve.

Indeed, the first step of the Sift methodology is to attempt to prove refinement directly between the implementation and specification layers. If this proof is too much for the prover to handle, the developer adds an additional layer of refinement and tries again. Each additional layer of refinement splits the proof into smaller pieces that are more amenable to automation; but, of course, this comes at the cost of some manual effort, as the developer must manually introduce the new layer.

In the next two sections, we describe the Sift methodology in more detail. Section 5 describes how we can use the

Algorithm 1 Specification of the Sharded Hash Table (SHT)

```

1  function requests(R : request) : bool
2  function replies(R : reply) : bool
3  function map(K : key) : value
4  initialization {
5     $\forall R. requests(R) \leftarrow false$ 
6     $\forall R. replies(R) \leftarrow false$ 
7     $\forall K. map(K) \leftarrow 0$ 
8  }
9  action commit(req : request, rep : reply) = {
10   require rep.type = req.type
11   require rep.src = req.src
12   require rep.key = req.key
13   require req.type = read  $\Rightarrow$  rep.data = map(req.key)
14   if  $\neg requests(req)$  {  $\triangleright$  require  $\neg requests(req)$ 
15     if req.type = write {
16       map(req.key)  $\leftarrow$  req.data
17     };
18     requests(req)  $\leftarrow$  true;
19     replies(rep)  $\leftarrow$  true;
20   }
21 }
```

automation of a monolithic prover to perform a refinement proof between two layers (steps ①–④ in Figure 1). Section 6 presents the methodology for adding intermediate layers to the refinement structure (step ⑤).

Case Study: Sharded Hash Table Throughout this paper, we use the example of a Sharded Hash Table application (SHT) [34] to illustrate the Sift methodology. SHT implements a distributed key-value store, and consists of two layers, a specification layer and an implementation layer. As shown in Algorithm 1, the specification layer describes a key-value store as a simple *map* from keys to values. It maintains two local sets (modeled as boolean-valued functions, lines 1 and 2) to keep track of which messages (requests and replies) have

Figure 2: Encapsulation: to enable automatic refinement proofs, the state of the upper layer (A, B, C) is encapsulated inside the state of the lower layer (1, 2, 3, 4) refining it.

been sent. Initially, all keys are mapped to 0, and no messages have been sent. Requests can either be read requests or write requests. The only transition allowed by this specification is to *commit* a request *req* and its reply *rep*: i.e., perform the update (if this is a write request) and mark the corresponding messages as sent by setting *requests(req)* and *replies(rep)* to *true*. The specification layer consists of 32 lines of Ivy code.

In the implementation layer, every node contains a local hash table containing some subset of the total keys in the system and a delegation map. The node uses the delegation map to maintain its knowledge of where keys are stored on remote nodes. Each node can service a request using *get* and *set* actions for the keys that are locally stored, or use the delegation map to look up and forward requests to the appropriate node in the system if the requested key is not local. Nodes at the implementation layer can dynamically exchange sets of keys they are responsible for, by exchanging *delegate* messages (each carrying a key-value pair) among themselves. The implementation layer consists of 127 lines of Ivy code.

We aim to show that the implementation layer *refines* the specification, i.e., that any observable output produced by any execution of the implementation layer can also be produced by some execution of the specification. A key property is that for every key owned by a node at the implementation layer, the data matches the value stored in the specification. Additionally, every key is either owned by exactly one node in the system, or part of an in-flight *delegate* message.

5 Refinement-Guided Automation

We first explain the key high-level idea behind automating refinement proofs (step ④ in Fig. 1, Section 5.1). We then present what modifications Sift makes to the layers of a target system description to ensure that the correspondences between the layers are correctly represented before a proof is attempted (steps ①–③ in Fig. 1, Section 5.2).

Algorithm 2 Example of encapsulation in SHT

```

1  action set(req : request) = {
2    require req.type = write
3    owner ← delegation.get_owner(req.key)
4    if owner = me {
5      hash(req.k) ← req.v
6      rep ← create_reply(req)
7      call spec.commit(req, rep)
8      call network.send_reply(rep)
9    } else {
10   call network.forward_request(req, owner)
11   }
12 }
```

5.1 From Monolithic Proofs to Refinement

A key feature of Sift is that it uses the automation of monolithic provers to perform more complex, refinement-based proofs. As we explained in Section 2, monolithic (i.e. single-layer) proofs do not scale to complex systems, either due to complexity or undecidability. Yet, monolithic proofs are the only type of proof supported by these provers. The first innovation of Sift is that it converts a refinement proof between two layers into a monolithic proof which can be given as input to any monolithic prover.

We perform this transformation using our *encapsulation* technique, depicted in Figure 2. The idea of encapsulation is simple: if we want to show that a lower layer *L* refines an upper layer *U*, then we augment the state of *L* with the state of *U*. Additionally, whenever the state machine *L* makes a transition, the *encapsulated U* state also makes an upper-layer transition. In practice, this is expressed as a function call in Ivy, where the lower layer invokes a transition on its encapsulated state. For example, in the SHT application, the lower layer includes an encapsulated *spec* object (see Algorithm 1) and a lower-layer transition calls *spec.commit()* if it refines the *commit* transition of the upper layer.

Encapsulating the upper-layer state into the lower layer effectively creates a single, *augmented lower layer* that can be used to reason about the relation between the upper and lower layer. Most importantly, we can now leverage traditional single-layer provers to show whether a certain property—the refinement property—holds for this augmented lower layer.

Case study: refinement proof for the SHT Algorithm 2 shows a simple example of encapsulation at the implementation layer of SHT. To perform this encapsulation, the implementation layer imports (in Ivy) the specification layer. In this example of handling a *set* request, the program checks if this node (*me*) is the owner of the key in the request (line 4). If it is the owner, the implementation layer internally makes a call (line 7) to *spec.commit* (shown in Algorithm 1). This transition corresponds to the transition from state 1 to state 2 in Figure 2: the implementation layer transitions from state 1

to state 2, while each of these states encapsulates the corresponding upper layer state, indicating a transition from state A to state B at the upper layer.

If this node is not the owner, it simply redirects the request to the owner. Such an implementation layer transition does not entail a specification layer transition and so the code does not call *spec.commit* or any specification-level function. This is usually called a “stuttering” step of the specification layer—essentially a *no-op*—and corresponds to the transition from state 2 to state 3 in Figure 2.

To prove that the implementation refines the specification, we ask our monolithic prover to prove a simple property:

$$\forall R: reply, N: node. net.replied(R, N) \implies spec.replies(R)$$

This property says that any reply *R* sent to any node *N* at the network (implementation level) can only be present if the same reply *R* is present at the specification level. Since replies are the only observable outputs of the system, it ensures that every output of the implementation is also an output of the specification, thus ensuring that the implementation is indeed a refinement of the specification. Note that the reply message at the implementation layer is part of the network and thus modeled as *net.replied*(*M*, *N*).

5.2 Enforcing pre- and postconditions across layers

When calling functions from a lower layer to an upper layer, an upper-layer transition’s precondition must be met. The preconditions of the callee (in the upper layer) become postconditions (assertions) for the caller (in the lower layer) to check. For example, on line 13 of SHT’s specification (Algorithm 1), before committing a request, the precondition concerning the request, *req*, and the corresponding reply, *rep*, must be met:

$$req.type = read \implies rep.data = map(req.key)$$

This precondition ensures that every time a read request is committed, the data contained in the response must correspond to the data in the abstract map. Since it is the caller’s responsibility to guarantee that this precondition is met before committing the request, this precondition is effectively an assertion that needs to be checked by the monolithic prover. Unfortunately, the current state-of-the-art monolithic provers do not support checking these kinds of assertions, and can only find an inductive invariant for a safety property.

If we attempt to ignore this assertion check and let the monolithic prover prove the refinement property as is, the result could be unsound—i.e., the proof may go through even if the implementation is buggy. For example, let us consider again the refinement property for SHT:

$$\forall R: reply, D: node. net.replied(R, D) \implies spec.replies(R)$$

Without precondition checks, a buggy implementation can send a bogus reply message and call *commit* at the encapsulated specification layer. This would make the refinement property trivially inductive—since the *commit* call adds the message to the *replies*—without guaranteeing that contents of that message are correct.

To avoid this problem, Sift needs to consider the assertions in function calls to maintain soundness in automated refinement proofs. In the rest of this section, we explain how we transform the assertions to either conditionals (if/else) or invariants that the monolithic prover can reason about.

5.2.1 Converting Assertions to Conditionals

A straightforward approach to model assertions in function calls is to convert the callee to an *always-enabled action* using a conditional if/else block [35]. The developer can manually rewrite an assertion *P* as follows: if *P* holds, take the transition; otherwise, do nothing. In this context, the entire if/else block is always-enabled, in that it has no preconditions and can always be taken.

For example, the original SHT specification had a precondition $\neg requests(req)$ in the specification of the *commit* action, which we convert to an if-statement (Algorithm 1, line 14). This precondition ensures that the specification can never execute the same request twice.

The benefit of this approach is that it does not rely on any understanding of the system, which makes it very easy to implement. It has, however, two downsides. First, adding an if/else block in place of a precondition makes the proof a little harder for monolithic provers, since it is harder to find an inductive invariant for a weaker problem. Second, if the if-statement refers to ghost state—i.e., proof-related state that is not compiled to an executable—such as the sets corresponding to network messages, these if-statements are not compiled directly to executable code. Therefore, if there are any assertions that refer to ghost states at the implementation layer, we cannot rely on the approach of converting assertions to conditionals. In these cases, we need to convert them to invariants, as we describe below.

5.2.2 Converting Assertions to Invariants

A second, more involved approach to the problem is to convert these assertions into invariants. Doing so requires human intuition but reduces the difficulty for the monolithic prover. For every assertion that needs to be checked, there must be an invariant to support its proof. The key idea is simple: a programmer can trace backward through a function call from the upper layer (the callee) to the lower layer (the caller) to find the enabling precondition. For the SHT precondition example above, we observe that only the node who owns the key can commit the reply. Leveraging this observation, we can construct an invariant that if node *N* thinks it is the owner

of key K , the local value for key K at node N , which forms the reply, must match the value in the spec:

$$\forall N : \text{node}, K : \text{key}. \text{server}(N).\text{delmap}(K, N) \implies \text{server}(N).\text{hash}(K) = \text{spec.map}(K)$$

where $\text{server}(N).\text{delmap}(K, N)$ indicates that from the perspective of server N , the owner of key K is N (delmap stands for the delegation map). By maintaining this invariant, Sift can ensure the associated assertion will never be violated during the execution of the system. Note that the invariant is not necessarily inductive, but Sift leverages the automation of the monolithic prover to complete the proof.

Case study: converting assertions for the SHT The manual effort involved in the SHT proof requires converting seven assertions into two if-statements and five invariants. The assertion $\neg \text{requests}(r1)$ is converted from an assertion to an if-statement, as described in Section 5.2.1. On the other hand, the first three assertions (lines 10 to 12 in Algorithm 1) are already enforced by the implementation layer and do not need to be converted. We could further use the methodology described above in Section 5.2.2 to convert the fourth assertion (line 13) to an invariant, but it turns out that monolithic provers are powerful enough to complete the proof even if we simply convert it to a if-statement.

6 Introducing Intermediate Layers

We have discussed how to use automation to prove refinement between two layers. However, sometimes, the automation provided by the monolithic prover is not powerful enough to prove the desired refinement. This can happen either due to the complexity of the proof, or the presence of undecidable reasoning. When faced with such complex proofs, monolithic provers will either time out or run out of memory.

To perform such complex proofs, the solution is to introduce an intermediate layer (step ⑤ in Figure 1), thereby splitting the proof into two simpler refinement proofs: one refinement proof from the original lower layer to the intermediate layer, and another refinement proof from the intermediate layer to the original upper layer. By repeatedly using this proof-splitting technique until every refinement proof is automated, we effectively execute a *divide-and-conquer strategy* that allows us to tackle complicated refinements.

This idea is similar to IronFleet’s methodology of introducing an intermediate protocol layer to simplify the proof. In IronFleet, however, the developer needed to both *write* an intermediate layer and *manually prove* it correct. By contrast, Sift uses the automation of monolithic provers to dispense with most of the latter manual effort of writing the proof, and only requires the user to write intermediate layers—a much smaller effort than coming up with manual proofs.

Thankfully for developers, introducing an additional layer is done incrementally. The new layer is essentially a variation of the layer above or below it: either a more detailed version of the layer above it or a more abstract version of the layer below it. This helps keep the manual effort needed to introduce such layers small.

In the rest of this section, we discuss the strategies that we have developed and used to introduce intermediate layers, and walk through the process on a MultiPaxos example.

6.1 Intermediate Layers for Complexity

In most cases, the biggest challenge for a monolithic prover to automatically prove a refinement is its complexity. If the system is too complex, the prover either times out or runs out of memory. When this happens, we can split the refinement proof into two simpler refinement proofs by introducing an intermediate layer. We list here a number of ways in which such a split can simplify the proof burden. This list is extracted from our experience adding intermediate layers to facilitate refinement, and is not meant to be a complete enumeration of all possible layer-splitting strategies.

Abstract Away Messages Not Needed for Safety. Some of the messages used in the implementation may only be needed for liveness or performance, but not for safety. When trying to prove safety, those messages can be abstracted away in an intermediate layer: they are removed from the intermediate layer but kept in the implementation layer—itsself proven to be a refinement of the intermediate layer.

For example, in MultiPaxos the current leader needs to periodically broadcast a heartbeat message to indicate that it is still alive. This message is not needed for safety and can therefore be removed in an intermediate layer—though it is preserved in the implementation layer. The resulting intermediate layer is now simpler and thus easier to prove equivalent to the specification.

Merge Multiple Transitions into One Abstract Transition. Sometimes, the intermediate layer can take an abstract transition which is broken into multiple transitions in the low-level implementation.

For example, in MultiPaxos the learner can only receive one vote (two_b message) from an acceptor at a time. But what the learner really needs is a quorum of messages to learn a value. In this case we can merge multiple transitions of receiving each message separately into one abstract transition of receiving a quorum, and remove local variables for temporary results. This significantly simplifies the intermediate layer, with fewer state variables and simpler transitions.

Simplify Local State and Requirements for Transitions. Implementation layers have to take into account implementation constraints: for example, a node can only read its local

state when taking a transition; and it cannot access messages sitting in the network. But intermediate layers are essentially proof constructs and thus do not need to respect such implementation constraints.

For example, in MultiPaxos, a node needs to maintain an explicit local history of previous *two_b* votes to construct its *one_b* promise to a new leader, since a promise message depends on previous votes. In an intermediate layer however, a node can directly access all sent messages in the network, thus eliminating the need for this local history. Moreover, in an implementation a node can only read its local history, thus requiring a proof that the local history is consistent with sent messages. In the intermediate layer, since the node has access to all sent messages, it can directly check that the *one_b* promise is consistent with the vote messages, thus eliminating the need for this proof.

6.2 Intermediate Layers for Decidability

When the verifier returns an explicit decidability error, it means our refinement is not in the EPR decidable logic [47] and may take forever to check. Such an issue is typically resolved by introducing an intermediate layer and a ghost state (also known as a derived relation [55]) to hide the existential quantifier creating the undecidability [55, 62]. We apply a similar technique in Sift.

For example, in MultiPaxos an acceptor needs to send its last votes for different slots in a *one_b* message to a new leader to decide what value to propose. When a proposer becomes a leader, it needs to have a quorum of *one_b* messages, resulting in the following $\forall Round \exists Votes$ alternation:

$$\begin{aligned} \forall N : Node, R : Round. \text{quorum_of}(R).contains(N) \\ \implies \exists V : votes. \text{one_b}(N, R, V) \end{aligned}$$

The alternation of the \forall and \exists quantifiers, along with the inductive invariant, means that this proposition is outside the decidable logic of EPR. We leverage results from a followup work on Ivy [62], and introduce an intermediate layer to abstract away the payload (previous votes), thereby breaking the quantifier alternation. In this case, we only need an intermediate-layer state *joined_round*(*N*, *R*) to represent $\exists V. \text{one_b}(N, R, V)$.

7 Evaluation

We evaluate Sift by using it to formally verify the correctness of six implementations of distributed systems: a *leader election* protocol (Section 7.1), a *distributed lock* protocol (Section 7.2), a *two-phase commit* protocol (Section 7.3), a *sharded hash table* (SHT, Section 7.4), and two consensus protocols: *Raft* (Section 7.5) and *MultiPaxos* (Section 7.6). We use Ivy to implement these systems, and extract the executable

code to C++ using Ivy’s built-in translator. For the more complex systems (*SHT*, *Raft* and *MultiPaxos*), we also perform a performance evaluation (Section 7.7) to demonstrate our automated approach does not impact the performance of implementations.

For all systems in our evaluation, we consider crash failures and an asynchronous network, which can arbitrarily delay, drop, or duplicate messages. Both of these can be easily implemented in Ivy. Note that since Sift (like all its predecessors that also target automation) does not support liveness proofs, it does not need to explicitly reason about crash failures—a crash results in a machine no longer taking any steps and thus has no effect on safety properties.

We find that we are able to prove these complex systems with little manual effort within a reasonable memory and time budget, using IC3PO [27] as our monolithic prover. Our verification results are in Table 1. The complexity of different systems is illustrated by the number of different types that are needed to express state transitions for a given system. For example, for the leader election protocol, there are just two types: *node* and *id*. In contrast, MultiPaxos contains 14 different types, e.g., *round*, *inst*, *value*, *time*, *node*, etc.

We now give details about the proofs of the aforementioned systems, followed with a performance evaluation (Section 7.7) of three of the more complex resulting implementations (i.e., SHT, Raft and Paxos). We ran our performance experiments on a cluster where nodes have a 16-core Intel Xeon E5-2667 v4 @3.20 GHz processor and are connected with a 10 GB Ethernet connection running Ubuntu 16.04. All our implementation and artifact can be found in GitHub [49]

7.1 Leader Election

The *leader election* protocol aims to elect a unique leader from a ring with an unbounded number of nodes with unique integer IDs [13, 50, 56]. The specification layer dictates a single action the system can take: elect a node as the leader, under the condition that no other node is already the leader. This layer contains 13 lines of Ivy code.

In the implementation layer, the nodes are totally ordered in a ring so that every node has a next node. A node *n* has two valid actions: (a) periodically send its ID *idn*(*n*) to the next node in the ring; or (b) forward an ID *i* received from its predecessor if *i* > *idn*(*n*). Once *n* receives its *idn*(*n*), it knows that no other node in the system has a larger ID, and can now safely become the leader. The implementation layer consists of 28 lines of Ivy code.

To prove refinement between the implementation and the specification layers, we ensure that when a message stating that a leader is elected is sent in the implementation, the destination of the message should correspond to the leader node in the specification.

We perform a manual, albeit trivial, syntactic change to the specification layer to convert one precondition into an

System	Proof Effort	Refinement	# of types	Solution to Preconditions	# of Clauses in Invariant	Time (sec)	Memory (MB)
Leader Election	< 5 min	spec to impl	2	1 if-statement	6	196	1744
Distributed Lock	< 5 min	spec to impl	2	1 if-statement	8	111	425
Two-Phase Commit	< 5 min	spec to impl	4	3 if-statements	12	613	815
SHT	< 30 min	spec to impl	7	5 invariants, 2 if-statements	13	1021	856
Raft	1 person-month	spec to layer 0	6	manual			
		layer 0 to layer 1	6	15 invariants	22	787	4178
		layer 1 to impl	10	15 invariants, 1 if-statement	17	1239	2981
MultiPaxos	Previously proved	spec to layer 0	9	manual			
	3 person-weeks	layer 0 to layer 1	9	7 invariants, 2 if-statements	12	49	249
		layer 1 to layer 2	11	8 invariants, 8 if-statements	21	258	719
		layer 2 to layer 3	11	19 invariants	28	841	1935
		layer 3 to impl	14	19 invariants	25	196	398

Table 1: Summary of our six distributed systems; “spec” stands for specification, “impl” stands for implementation, and “layer i ” represents intermediate layers. The number of different types that are needed to express the state transition illustrates the complexity of different system.

if-statement, which takes less than 5 minutes. We then simply use Sift’s encapsulation technique to convert the refinement between the implementation and specification layers into a monolithic proof that is proven automatically by IC3PO.

7.2 Distributed Lock

The *distributed lock* protocol [34, 50, 56] models an unbounded number of nodes that transfer the ownership of a single lock. In this system, the ownership of a lock is associated with an ever-increasing epoch: only one node can own the lock at each epoch. This makes for a concise specification layer—12 lines of Ivy code—that only contains a lock history to indicate which node holds the lock at every epoch.

In the implementation layer, there are two possible transitions for a node: (a) transfer the lock if it holds the lock; or (b) accept the lock and jump to a higher epoch by sending a *locked* message to indicate ownership. This implementation has 35 lines of Ivy code.

The refinement property in this system is that all *locked* messages should have a corresponding node in the specification layer’s lock history.

The only manual effort involved in this proof is converting one precondition to an if-statement in the specification layer, which takes less than 5 minutes. After this transformation, we can use the encapsulation technique from Sift to convert the refinement between the implementation and specification layers into a monolithic proof, and prove the *locked* message is equivalent to the lock history.

7.3 Two-Phase Commit

The *two-phase commit* protocol [31] is used by a group of nodes, known as resource managers (RMs), to coordinate the decision on whether to abort or commit a transaction. The RMs vote to either commit or abort the proposed transaction and a transaction manager (TM) node is in charge of coordinating the decision-making procedure.

The specification layer of this system uses the Transaction Commit protocol by Lamport [30, Sec. 2] translated from TLA+ [45] to Ivy. The safety property does not allow a node to commit if another node aborts. The specification contains 54 lines of Ivy code.

The implementation of this system is an Ivy translation inspired by the TLA+ specification of Two-Phase Commit [30, Sec. 3]. This layer introduces a special TM node, which coordinates all RMs. An RM can send a *Prepared* message to the TM when transiting into the *prepared* state, or unilaterally decide to abort. Upon receiving a *Prepared* message from every RM, the TM can decide to commit, broadcasting a *Commit* message to every RM node. The receipt of a *Commit* message from the TM allows an RM to decide to commit the transaction. This implementation of two-phase commit has 110 lines of code.

The refinement property between the implementation and specification ensures that all RMs commit or abort at the same time between the implementation and the specification.

After a trivial syntactic change converting preconditions to three if-statements in the specification layer, this refinement property is proven automatically.

7.4 Sharded Hash Table (SHT)

The Sharded Hash Table protocol was previously introduced as a running example in Section 4. Its specification is a simple key-value map processing read and write requests. We can automatically prove the refinement from the implementation to the specification, after converting preconditions to five invariants and two if-statements to guide IC3PO, as detailed in Section 5.2. Compared to IronKV (IronFleet’s implementation of SHT), we simplify the delegate messages by transferring one key at a time. Transferring intervals of keys would require a loop iterating over keys and a loop invariant [59, 65], which cannot be found automatically by IC3PO.

The network interface for SHT is more complex than that of other systems. In particular, SHT’s network interface requires that messages are not delivered twice, so that requests can only be committed once and only one node at a time can own a key. As this is not part of refinement, we leverage an existing proof [53] for these requirements.

7.5 Raft

Raft [54] implements a shared log among nodes, which can be used to implement a fault-tolerant distributed service. The log is maintained as a set of (index, value) pairs.

Raft is a *term*-based protocol. In each term, a node can be elected as the leader, append values to the log, and replicate its log to other nodes by sending an *append* message. For safety, each node maintains its own log and only votes for a leader whose log is not earlier than its own. When the leader receives reply messages for its *append* message from a majority of nodes, the leader can consider all previous log entries committed. This strategy ensures that all future leaders contain the committed log.

At the specification layer, Raft can commit a prefix to an index in the leader’s log and ensure that only one value is committed at each index. The refinement property from the implementation to the specification ensures that they have the same log.

7.5.1 Intermediate Layers and Proof Effort

Our Raft implementation is similar to the previous Ivy implementation of Raft [62] with 212 lines of code. Due to undecidability, we could not refine the implementation to the specification directly. Instead, we build a first intermediate layer—layer 0—to separate the quantifier alternation (as outlined in Section 6.2). We tried to prove the refinement from specification to layer 0 automatically, but the inductive invariant contains complex quantifier alternations, which IC3PO was unable to handle. As a result, we manually prove the refinement from specification to layer 0. The refinement from spec to layer 0 took two person-weeks (including understanding the protocol). Layer 0 contains 143 lines of code.

From layer 0, the implementation is still too complex to refine directly using IC3PO. We introduce another intermediate layer, layer 1, to help IC3PO automatically prove the refinement. To write layer 1, we follow the strategies presented in Section 6, specifically by merging actions into one abstract action. In the abstract action a node can receive a quorum of messages at once, rather than receiving each of them individually in separate transitions. Layer 1 changes 57 lines from layer 0. We spent another two person-weeks to identify this intermediate layer and debug our implementation.

Overall, we were able to complete the proof of Raft in one person month, which compares favorably to the three person months needed by the original proof [62] written in Ivy. This reduction was the result of using a much higher degree of automation, by splitting the proof into layers and leveraging the power of IC3PO to prove each refinement between consecutive layers.

7.6 MultiPaxos

MultiPaxos [43, 44] is a common consensus protocol that is widely used in industry (e.g., Chubby [11], Megastore [2], and Spanner [19]). However, MultiPaxos is notoriously complex and difficult to verify.

At the specification level, *MultiPaxos* maintains an array of values; some that have been decided (i.e., agreed upon and finalized) and some that are empty. The only possible transition in the specification is to add a new decided value to this array. Similar to Raft, our refinement ensures that the implementation maintains the same values as the array in the specification.

The implementation of MultiPaxos is very similar to that of Raft but uses different strategies to ensure safety. In Raft, the leader can only be a node with the most up-to-date logs, while MultiPaxos relies on the messages from other nodes to generate an up-to-date log for the new leader.

7.6.1 Intermediate Layers and Proof Effort

Our design of the MultiPaxos protocol is inspired by previous work on expressing Paxos and MultiPaxos in the EPR decidable logic [55, 62]. Our evaluation uses the MultiPaxos implementation from [62], removing certain re-transmissions that are unnecessary for safety to simplify the refinement.

Since proving refinement directly between the implementation layer and the specification layer would introduce undecidability (see Section 6.2), we initially introduce a single intermediate layer, layer 0, to circumvent this undecidability. Moreover, as the refinement from the specification to layer 0 contains complex quantifier alternations that are too hard for IC3PO to prove automatically, we borrow the existing manual proof from Ivy. Layer 0 contains 88 lines of Ivy code.

After addressing undecidability concerns through layer 0, we found that a direct refinement from the implementation to

Figure 3: SHT performance

layer 0 remains infeasible for IC3PO. Using our divide-and-conquer technique, we added three additional intermediate layers to simplify this refinement. Following the strategies outlined in Section 6.1, we first added a layer 1 that abstracts away liveness messages and merges transitions to receive a quorum of messages. We augmented this by introducing a layer 2 that uses a local variable to track the current round, receives one *two_b* message, and keeps track of when a valid quorum can be formed. We then introduced a final intermediate layer that more closely resembles the implementation by using an array to track previous voted values for acceptors, and restricting a node to only receive one message during a transition.

With the addition of the four intermediate layers, Sift splits the complex refinement proof into manageable pieces, where each refinement between layers is amenable to automated verification. Producing the three intermediate layers (layers 1, 2, and 3) and converting the necessary preconditions to invariants is still a non-trivial task which takes about two person-weeks. About one third of the time is spent waiting for IC3PO to run out of time or memory, which indicates that another layer is needed (step ⑤ in Figure 1). While non-negligible, this manual effort is significantly less than the original attempt in Ivy, which was two person-months to refine layer 0 to the implementation [62].

7.7 Performance Evaluation

7.7.1 SHT Performance

We compare the throughput and latency of our verified Sift implementation of SHT with IronKV [34], as shown in Figure 3. IronKV is the closest verified implementation of a SHT that we could compare against. The SHT cluster was preloaded with 1,000 keys delegated evenly across the three nodes and serviced requests from an increasing number of clients in a closed loop. In one experiment, client processes send an even 50/50 mix of randomized GET and SET requests. We further increase the percentage of GET requests to 90%. IronKV scales about 25% better than our version of SHT. The disparity in performance between these two systems can be attributed to both unoptimized generated C++ from Ivy and design choices made in IronKV, which added extra manual proof complexity for the sake of performance purposes, such

Figure 4: Raft and MultiPaxos performance

as an efficient delegation map data structure that each node maintains and consists of 833 lines of Dafny code.

7.7.2 Raft and MultiPaxos Performance

We evaluated the performance of the verified Sift implementations of Raft and MultiPaxos by varying the load of each system with an increasing number of clients submitting requests in a closed loop, as shown in Figure 4. For both systems, the experimental setup consists of three replicas on separate machines, with a fourth machine containing the client processes.

We tried to compare the performance of these systems with IronRSL, IronFleet’s verified Paxos-based replicated state machine library, but the performance results of IronRSL were not reproducible for a direct comparison. By re-running the original implementation from the IronFleet paper [34], we found the performance for IronRSL to be lower than originally reported [34, Sec. 7]¹. The performance of our implementation of MultiPaxos, which does not support batching, is comparable to the results reported for IronRSL in non-batch mode [34, Fig. 13].

We do compare both Raft and MultiPaxos with the Ivy-based manually-verified implementations [62]. The performance of Raft is almost identical to the version of Raft, but we find that our MultiPaxos system exceeds the performance of MultiPaxos from that work. These results show that the automation and reduced proof effort gained by using Sift does not impact the performance of either system.

8 Limitations and Future Directions

Our experience with Sift suggests that it advances what is possible in the realm of automated verification of complex systems. For all of its successes, however, there are still more steps to be taken in this direction.

- **Automating simple transformations.** While Sift greatly increases the automation of complex refinement proofs, parts of the methodology still require manual effort that could potentially be automated, such as converting assertions to if-

¹Even after close discussions with two of the IronFleet authors, this discrepancy was not resolved. They attributed this to possible code changes between what was originally evaluated and the currently available code.

statements and transforming to invariants through automatic computation of weakest preconditions [22].

- **Loop invariants.** Certain complex systems, such as SHT, may require loop invariants to prove optimizations that are added to enhance the performance of executable code. Loop invariants are similar to regular inductive invariants, in that both are inductive under some transitions. As described in Sections 7.4 and 7.6.1, any loop invariant in Sift must currently be written manually. In the future, we hope to add support for automatic derivation of loop invariants in Sift, by building further on the existing literature [59, 65].

- **Leveraging multiple monolithic provers.** As shown in recent works [27, 33, 66], different monolithic provers show complementary strengths in different scenarios. Since the design of Sift is independent of the choice of monolithic prover, we plan to employ a portfolio of monolithic provers in parallel to derive refinement proofs with even higher scalability.

9 Related Work

We now provide a summary on previous efforts relevant to applying formal methods to verify distributed systems.

Automated Verification. With the advancements in automated reasoning [6, 20, 36] and abstraction techniques [3, 16, 29], automatically verifying correctness through model checking [17, 58] has significantly improved in different domains, both for hardware [9, 10, 23, 26, 61] and software [3, 7, 8, 37, 41]. However, model checking still does not scale well to large complex systems, due to state-space explosion [18, 21].

More recently, several approaches [24, 27, 33, 38, 40, 50, 66] have extended induction-based model checking [10, 23] to automatically infer inductive invariants for infinite-state distributed protocols. I4 [50] leverages the regularity of distributed protocols, combining finite model checking with unbounded reasoning in distributed protocols. IC3PO [27], described in detail in Section 3.3, incorporates invariant generalization with model checking for better scalability. SWISS [33] derives an inductive invariant by performing an exhaustive search over candidate invariants in an optimized invariant search space. DistAI [66] uses a data-driven approach and is guaranteed to find a universally-quantified inductive invariant in finite time.

All the aforementioned techniques [24, 27, 33, 38, 40, 50, 66], however, target monolithic, single-layer verification, primarily at the protocol level, and cannot scale to detailed system implementations. In contrast, our approach combines these monolithic provers with the well-founded concepts of refinement [1, 25, 42] to scale verification all the way to complex executable implementations.

Systems Verification. Much effort has gone to verifying real systems, including OS kernels [15, 32, 39, 52], file, and storage systems [12, 14, 67]. These works provide strong guarantees of correctness, but at the cost of extensive manual effort; Sift,

by contrast, requires little manual proof effort while verifying systems of considerable complexity, such as MultiPaxos.

Within the realm of distributed systems, there have been attempts at manually verifying implementations of protocols [60, 64]. Ivy [56] requires the developer to iteratively refine an invariant until an inductive invariant is identified. IronFleet [34] and Verdi [63] have been used to verify practical implementations of distributed systems. In stark contrast to our work, all three approaches rely on considerable amounts of manual effort (in the order of person months) to complete a proof of correctness. Additionally, while IronFleet always uses three layers of refinement (i.e., specification, protocol, and implementation), most of the distributed systems we verify are refined directly from an implementation to a specification, with intermediate layers only added when needed to reduce the proof complexity for our monolithic provers.

More recently, Lorch et al. [48] presented Armada, a tool designed to verify concurrent programs. While Armada has some superficial similarities to Sift—namely the use of refinement and automation—it is in fact drastically different. It operates in an environment almost diametrically opposed to that of Sift: single-machine, multi-threaded code where communication happens via shared memory, as opposed to Sift’s sequential execution on a distributed system where communication happens via message passing. Additionally, while Armada makes heavy use of automation to generate proofs, it still requires its users to write significant parts of the proof—hundreds of lines of code—manually.

10 Conclusion

This paper introduces Sift, a novel two-tier methodology that combines the power of refinement with the ability to automate proofs. Sift decomposes the proofs of complex distributed implementations into a number of refinement steps, each of which is amenable to automation. We use Sift to prove the correctness of six distributed implementations—including the notorious MultiPaxos—none of which had an automated proof before. Our evaluation shows that this combination of refinement and automation lets us verify complex distributed implementations with little manual effort.

Abstract

Transformer verification draws increasing attention in machine learning research and industry. It formally verifies the robustness of transformers against adversarial attacks such as exchanging words in a sentence with synonyms. However, the performance of transformer verification is still not satisfactory due to bound-centric computation which is significantly different from standard neural networks. In this paper, we propose **Faith**¹, an efficient framework for transformer verification on GPUs. We first propose a semantic-aware computation graph transformation to identify semantic information such as bound computation in transformer verification. We exploit such semantic information to enable efficient kernel fusion at the computation graph level. Second, we propose a verification-specialized kernel crafter to efficiently map transformer verification to modern GPUs. This crafter exploits a set of GPU hardware supports to accelerate verification-specialized operations which are usually memory-intensive. Third, we propose an expert-guided autotuning to incorporate expert knowledge on GPU backends to facilitate large search space exploration. Extensive evaluations show that Faith achieves $2.1\times$ to $3.4\times$ ($2.6\times$ on average) speedup over state-of-the-art frameworks.

1 Introduction

Transformers [8, 21, 25, 32, 33, 38, 45] is an important category of neural networks (NNs) in machine learning research and industry. Transformers are first designed for natural language processing (NLP) and have achieved state-of-the-art accuracy across many NLP tasks such as neural machine translation [1, 26, 31] and sentiment analysis [7, 37, 48]. Due to its success, transformers have been widely used in many industrial products such as Facebook for hate speech detection [10] and Alexa for question answering [14]. Recently, transformers also show extraordinary accuracy for many computer vision tasks [9, 19, 44, 47, 55] and become the new trending model.

¹The project is open-sourced at <https://github.com/BoyuanFeng/Faith>

Figure 1: Illustration of transformer verification. Here, all perturbed inputs share the same prediction “positive” since the lower bound probability for “positive” (0.4) is higher than the upper bound probability for “negative” (0.39).

However, similar to prior NNs, transformers are also vulnerable to adversarial attacks that add imperceptible perturbations to input data for maliciously changing transformer predictions [2, 3, 16, 17, 22]. One specific example of adversarial attack is to exchange words (*e.g.*, cold) in a sentence with carefully selected synonyms (*e.g.*, frigid). This vulnerability may result in security concerns for real-world applications. For example, an intentionally crafted hate speech may spread widely on social network.

Transformer verification has been proposed to formally verify the robustness of a transformer against adversarial attacks [4, 18, 35, 42]. Given an input data x and a transformer $F(x)$, transformer verification identifies a maximal bound ϵ , such that all inputs x' that are “close” to the input data (*i.e.*, $|x' - x| \leq \epsilon$) cannot “mislead” the transformer (*i.e.*, $F(x) = F(x')$). A larger ϵ indicates better robustness. Early verification approaches [18] enumerate all possible inputs x' that satisfy $|x' - x| \leq \epsilon$ and conduct inference on each input to check predictions. These approaches show prohibitive latency due to the large number of inputs x' . Recent transformer verification [35, 42] avoids such enumeration by providing a single pair of lower and upper bounds for transformer predictions over all these inputs, as illustrated in Fig. 1. We can verify the robustness of a transformer if the lower bound of the correct prediction is higher than the upper bound of other predictions. The key computing pattern is a *bound-centric computation*, which computes a pair of inequality bounds for individual neurons. It first represents the input perturbations with inequality bounds over input neurons (*e.g.*, $x - \epsilon \leq x' \leq x + \epsilon$) and then propagates these bounds across layers to generate

Figure 2: Overview of Faith Framework

the bounds for transformer predictions.

While transformer verification can formally verify the robustness of transformers, it also introduces high latency and limits its applications. In particular, transformer verification usually leads to second-level latency [35] in contrast to millisecond-level latency of standard transformers. We identify three challenges behind efficient transformer verification.

Lack of performance optimization over transformer verification computing patterns. Existing transformer verifications usually utilize the existing deep learning (DL) frameworks, such as PyTorch [30], which are designed for standard NNs. However, transformer verification shows significantly different computing patterns from standard NNs due to the nature of bound-centric computation. For example, when computing the upper bound of an output neuron, transformer verification needs to use the upper bound of the input neuron if the weight is positive; and the lower bound of the input neuron if negative. Straightforwardly deploying transformer verification to the existing DL frameworks usually leads to poor performance.

Lack of framework support for verifying diverse NN layers. Transformer verification shows large diversity in the bound computation for different types of NN layers such as projection layer with only perturbed features and self-attention layer with both perturbed weights and features. Even for the same type of NN layers, diverse upper bounds and lower bounds may be designed which requires different implementations. For example, Crown [52] utilizes two ReLU bound designs for generating more precise bounds for verification, where these bounds are selected dynamically according to the range of input neurons. This diversity makes it challenging to hand optimize GPU kernels in transformer verification.

Lack of verification-specialized adaptability towards modern GPUs. Transformer verification involves abundant memory-intensive operations such as reduction and broadcast. These memory-intensive operations can usually be significantly accelerated with rich architecture supports (*e.g.*, warp-level synchronized reduction) in modern GPUs. However, existing DL frameworks usually only focus on computation-intensive operations (*e.g.*, convolution) and ignore abundant optimization opportunities for memory-intensive operations. This leads to significant overhead in transformer verification with a large number of memory-intensive operations.

In this paper, we build **Faith**, the first framework for efficient transformer verification on GPUs. We show an overview

of the Faith framework in Fig. 2. First, we propose *semantic-aware computation graph transformation* to fully exploit fusion opportunities in transformer verification at the computation graph level. Our key insight is that transformer verification shows significantly different computing patterns (*e.g.*, two kernels for computing lower and upper bounds involve similar input data) from standard NNs. These computing patterns usually exhibit abundant data reuse opportunities. By exploiting such semantic information, Faith can fully harvest performance potential in transformer verification and achieve significant speedup over existing DL frameworks.

Second, we propose a *verification-specialized kernel crafter* to optimize transformer verification towards modern GPUs. Transformer verification contains abundant memory-intensive operations, such as elementwise computation, reduction, and broadcast. These operations may have complex dependencies and lead to performance bottlenecks. To this end, Faith automatically exploits a set of GPU architecture supports to improve the parallelism of such operations. Moreover, Faith introduces a set of optimizations to effectively mitigate memory access and improve performance by exploiting GPU memory hierarchies.

Third, we propose *expert-guided autotuning* to efficiently search optimized implementations in the large search space. Existing DL frameworks [6, 54] usually conduct autotuning in a hardware-agnostic approach where an ML-based cost model is deployed to implicitly learn hardware impact over performance from scratch. Instead, we propose a rule-based expert knowledge metafile to explicitly provide a small set of hardware characterizations and an expert-guided cost model to incorporate the expert knowledge. Faith exploits these two components to achieve efficient schedule exploration in the large design space of transformer verification.

In summary, this paper makes the following contributions:

- We build Faith, the first efficient framework to optimize the performance of transformer verification on GPUs.
- We propose a set of verification tailored system optimizations. In particular, we design a *semantic-aware computation graph transformation* to identify and exploit novel fusion opportunities for transformer verification, a *verifier-specialized kernel crafter* to effectively map transformer verification kernels to GPU backends, and an *expert-guided autotuning* to incorporate a set of expert knowledge on modern GPU architecture to guide large design space exploration.
- Extensive experiments show that Faith achieves up to $3.4\times$ speedup ($2.6\times$ on average) over state-of-the-art frameworks.

2 Related Work and Motivation

In this section, we first introduce the background of transformer verification (§2.1). Then, we discuss related work on DL frameworks (§2.2). Finally, we present opportunities

Figure 3: Illustration of transformer verification. (a) model prediction and verification bound; (b) an example of verifying a model with a fully connected layer and a ReLU layer; (c) computation graph of projection layer in transformer verification; (d)-(e) two types of bounds for ReLU layer; (f)-(g) two types of bounds for the *Tanh* layer.

and challenges for efficient transformer verification on GPUs ([§2.3](#)).

2.1 Transformer Verification

Standard Transformers. Transformer [8, 25, 38, 45] takes a sentence as input and predicts a label for this sentence (e.g., hate speech or benign speech). Given a sentence with *Length* tokens, we usually first map each token to a pretrained embedding [28] of dimension *Dim_in* and represent the feature of a sentence as a tensor of shape $Length \times Dim_in$. For a batch of sentences, we have input feature X as a tensor of shape $Batch_size \times Length \times Dim_in$, where *Batch_size* is the number of sentences in a batch. Since the number of tokens varies across sentences, *Length* is set to the maximal number of tokens over all sentences in a batch.

A transformer has three types of operators. The first type is the *elementwise operator* that applies computation on individual feature scalars. For example, on each scalar x in the input feature, we have $ReLU(x) = \max(0, x)$ and $Tanh(x) = \frac{e^{2x} - 1}{e^{2x} + 1}$. The second type is the *matrix multiplication operator* that takes an input tensor X , a weight matrix W , and generates an output tensor $Y = XW$. We note that these two types are similar to operators in prior neural networks. The third type is the *dot product operator*, which is the key idea behind the transformer model. Informally speaking, it takes two input tensors Q and K of the same shape $Batch_size \times Length \times Dim_in$. Then, it computes an output tensor $Y = Q^T K$ of shape $Batch_size \times Length \times Length$ to measure the pairwise similarity between individual words in a sentence. This similarity can significantly improve the learning capacity of the model and the prediction accuracy.

Adversarial Attack on Transformers. Adversarial attack [2, 3, 15, 16, 17, 22] identifies small perturbations to input data X that can change the transformer prediction. Formally, consider a transformer $f(\cdot)$, an input sentence X , and a tolerable input perturbation bound ϵ , where the transformer cor-

rectly classifies X as a label i (e.g., hate speech). In other words, the sentence has label i and $y_i > y_j$ for any $j \neq i$ where y_j is the predicted probability. Adversarial attack identifies a slightly perturbed sentence $X' = X + \eta$ such that $\eta \in B(0, \epsilon)$ and there exists a label j (e.g., benign speech) such that $y_i < y_j$. This perturbed sentence X' is an *adversarial example*.

Transformer Verification. Transformer verification [4, 18, 35, 42] computes a maximum bound ϵ and mathematically proves that there does not exist an adversarial example X' within the ϵ -ball of X (i.e., $(X' - X) \in B(0, \epsilon)$). Verifying transformers is challenging since transformers are essentially non-convex functions. The key idea of transformer verification is to utilize linear bounds as an approximation to NN predictions. We illustrate transformer verification at the model prediction layer in [Fig. 3\(a\)](#). Given these linear bounds, transformer verification can simply check if the predictions inside the bounds satisfy certain linear requirements, such as $y_i > y_j + c$, where c is a positive number. As illustrated in [Fig. 3\(a\)](#), this bound-based approach is sound since the linear bound covers the non-convex area of NN predictions.

We show an example of bound-centric computation of transformer verification in [Fig. 3\(b\)](#). Consider a fully connected layer $Y[j] = \sum_{i=1}^n W[j, i] \cdot X[i]$ where $Y[j]$, $W[j, i]$, and $X[i]$ are scalars. Here, we skip the index for batch size and length for notation simplicity. A formal summary of notations can be found in [Table 1](#). For each neuron $X[i]$, there is a lower and an upper bound

$$X[i] \geq X_{lb}[i] + X_{lw}[i] * \vec{\epsilon}, \quad X[i] \leq X_{ub}[i] + X_{uw}[i] * \vec{\epsilon}$$

where $X_{lb}[i]$ and $X_{ub}[i]$ are scalars, $X_{lw}[i]$, $X_{uw}[i]$, and $\vec{\epsilon}$ are vectors. For the input neurons, we have $X_{lb}[i] = X_{ub}[i] = X[i]$, $X_{lw}[i]$ and $X_{uw}[i]$ are one-hot vectors with 1 at the index i and 0 at other indices. Given this linear bound, we can compute *concretized* bounds for each neuron as

$$X_l[i] = X_{lb}[i] - \epsilon * \|X_{lw}[i]\|, \quad X_u[i] = X_{ub}[i] + \epsilon * \|X_{uw}[i]\| \quad (1)$$

where $\|\cdot\|$ computes the norm with reduction operations.

Table 1: Notations in transformer verification.

W	Transformer weights. Shape: $Dim_in \times Dim_out$
X	Input feature tensor. Shape: $Batch_size \times Length \times Dim_in$
X_{lb}, X_{ub}	The tensor of lower and upper bound bias of input features. Shape: $Batch_size \times Length \times Dim_in$
X_{lw}, X_{uw}	The tensor of lower and upper bound weights of input features. Shape: $Batch_size \times Length \times Dim_in \times Dim_out$
X_l, X_u	The tensor of concretized lower and upper bounds of input features. Shape: $Batch_size \times Length \times Dim_in$

When computing the bounds for output neuron $Y[j]$, we note that bound computation depends on the sign of weights $W[j, i]$. In particular, we have upper bounds $Y_{ub}[j]$ as

$$\begin{aligned}
 Y[j] &\leq Y_{ub}[j] + Y_{uw}[j] * \bar{\epsilon} \\
 &= \left(\sum_{W[j,i] \geq 0} W[j,i] \cdot X_{ub}[i] + \sum_{W[j,i] < 0} W[j,i] \cdot X_{lb}[i] \right) \\
 &\quad + \left(\sum_{W[j,i] \geq 0} W[j,i] \cdot X_{uw}[i] + \sum_{W[j,i] < 0} W[j,i] \cdot X_{lw}[i] \right) * \bar{\epsilon}
 \end{aligned} \tag{2}$$

The lower bounds can be computed in a similar way. This bound computation (Eq. 2) is significantly different from standard NN computation since it explicitly considers the sign of weights. Previous transformer verification directly exploits the standard DL frameworks to build a computation graph (Fig. 3(c)) for computing bounds, which leads to inefficient memory access and computation overhead. We will discuss the opportunities and challenges of efficient transformer verification in §2.3.

For the same NN layer, diverse bound computation designs may still be developed to provide tighter bounds on NN predictions. We illustrate two types of bounds for the ReLU layer in §2(d)-(e) and two types of bounds for the Tanh layer in §2(f)-(g). A tighter bound (*i.e.*, less space between linear bounds and ReLU function) is preferred to provide a better linear bound approximation to NN prediction. For example, consider the concretized lower bound $X_l[i]$ and upper bound $X_u[i]$ for an input neuron $X[i]$, when we have $abs(X_l[i]) > abs(X_u[i])$, linear bound in Fig. 3(d) is preferred over the linear bound in Fig. 3(e) since the former one provides a tighter approximation. This diversity in bound design adds more complexity to developing frameworks for transformer verification.

2.2 Deep Learning Frameworks on GPUs

GPUs have been widely exploited to accelerate deep learning workload [13, 39, 40, 46, 49]. Efficiently mapping deep learning workloads to the GPU computing and memory hierarchy is usually the key to improve performance [11, 23, 41, 50, 51]. GPU computing hierarchy contains threads, warps, and blocks [29]. Each block has multiple warps and each warp has exactly 32 threads that compute with single-instruction-multiple-data (SIMD). GPU memory can be generally treated as a hierarchy of registers, shared memory, and global memory. Accessing registers is much faster than accessing shared memory, which is faster than accessing global memory. Each thread can only

Figure 4: Latency breakdown of transformer verification on sentences with length 8 and 20. Here, we show the latency of verifying individual operators such as dot product and Tanh.

access its own registers and threads in a block cannot access shared memory from other blocks.

Many DL frameworks [6, 30, 54] have been developed recently to efficiently support NN workload on GPUs. Early works such as PyTorch [30] take user-specified computation graphs for neural networks and maps towards hand-tuned kernels on backend platforms (*e.g.*, GPUs). However, this approach usually builds upon kernels developed for standard NNs and cannot efficiently support transformer verification computation. Recent works, such as TVM [6] and Anso [54], can automatically generate such backend kernels based on a set of heuristic rules on fusion and operator optimizations. However, these heuristic rules are developed specifically for standard NNs. Naively incorporating these rules into transformer verification may lead to unsatisfactory performance due to the significant difference in computation patterns. For example, Fig. 3(c) shows the computation graph for utilizing the kernels of standard NNs on transformer verification. This approach leads to heavy sparsity and redundant memory access. In particular, only half of the elements in W_{pos} and W_{neg} are non-zero values, leading to 50% sparsity. To this end, we build Faith, the first framework for efficient transformer verification on GPUs.

2.3 Opportunities and Challenges

In this section, we introduce optimization opportunities and challenges in enabling efficient transformer verification.

We show the latency of verifying individual transformer operators in Fig. 4. We profile this latency breakdown based on the state-of-the-art transformer verification implemented with PyTorch [30]. We have three major observations. First, dot product accounts for around 45% latency. Dot product takes two input tensors Q and K where both inputs may be perturbed during adversarial attack, which is significantly different from matrix multiplication that only one input (*i.e.*, feature X) may be perturbed. This adds complexity to the verification of dot product operators [35] and longer latency. Second, elementwise operators such as Tanh and ReLU account for a large portion of latency in transformer verification. This is significantly different from standard NNs where elementwise operators can usually be fused with remaining operators and show low latency. Third, we observe that ma-

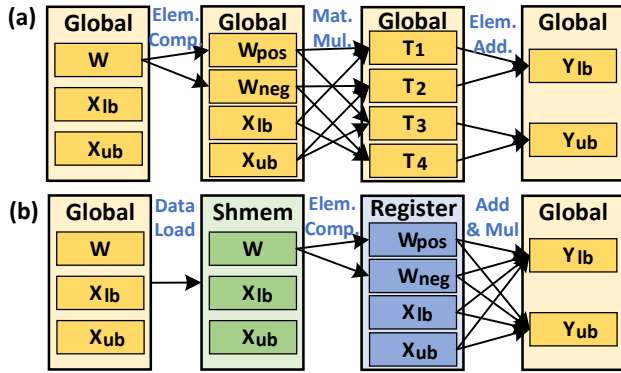

Figure 5: Illustration of Semantic-aware Kernel Fusion. We show the memory access pattern before and after applying semantic-aware kernel fusion in (a) and (b), respectively.

trix multiplication and softmax accounts for certain latency.

Opportunities: There are two major opportunities to accelerate transformer verification. The first opportunity is to exploit the semantics of transformer verification to minimize redundant memory access and computation. Our investigation shows that transformer verification has rich semantic information (e.g., 50% sparsity in W_{pos} and W_{neg}), which can be exploited to accelerate transformer verification. The second opportunity is to exploit the modern GPU architectures to efficiently support diverse computing patterns in transformer verification. One example is to accelerate abundant reduction computation in Eq. 1.

Challenges: Although these ideas sound promising, the efforts to realize the benefits are non-trivial due to several challenges. First, transformer verification shows significantly different computing patterns from standard NNs. Straightforwardly borrowing optimizations for standard NNs such as kernel fusion can hardly bring similar benefits. Second, while exploiting GPU architecture supports may bring benefits, we still need specialized designs as a synergy between architecture and specialized computing patterns. Moreover, exploiting advanced GPU architecture supports will add more complexity to the search space of optimized kernels which motivates novel autotuning optimizations.

3 Semantic-aware Computation Graph Transformation

In this section, we propose *semantic-aware computation graph transformation* for efficient transformer verification. We first propose **semantic-aware kernel fusion** to fuse kernels within a transformer layer. It contains two novel types of fusions – *weight-pairing based fusion* and *double bound based fusion*. Then, we propose **bound-aware cross-layer fusion** to efficiently fuse kernels across transformer layers.

3.1 Semantic-aware Kernel Fusion

The semantic-aware kernel fusion fuses operators in a single transformer layer to minimize memory access. Different from standard transformers, a single layer in transformer verification usually involves multiple kernels to compute the bounds adaptively to the sign of weights, as discussed in §2.1. Existing transformer verification [35, 42] usually uses a set of GPU kernels developed for standard transformers to serve the need for transformer verification. We illustrate the memory access pattern of this baseline approach in Fig. 5(a). These kernels need to independently read data from the global memory of GPUs and lead to heavy memory overhead. Moreover, these kernels fail to exploit semantic information in transformer verification and show heavy redundancy during memory access. For example, baseline approaches usually first split the weight matrix W into two weight matrices W_{pos} and W_{neg} according to weight signs and then use each matrix for computing lower and upper bounds. Here, these two split matrices W_{pos} and W_{neg} have the same shape of $M \times N$ as the weight matrix W . However, reading these matrices independently requires loading $2MN$ scalars, which leads to redundant memory access.

We propose semantic-aware kernel fusion to minimize such memory overhead by exploiting transformer verification semantics and GPU memory hierarchies (i.e., global memory, shared memory, and registers). We illustrate our semantic-aware kernel fusion in Fig. 5(b). Our key insight is to first load data collaboratively from global memory and only distinguish data semantics (e.g., W_{pos} and W_{neg}) at the register level to mitigate redundant memory access. In particular, we identify *weight-pairing based fusion* and *double bound based fusion* as the two most important semantics in transformer verification.

Weight-pairing based fusion. We first propose weight-pairing-based fusion to mitigate redundant memory access when reading W_{pos} and W_{neg} . Our key observation is that the zero values in W_{pos} are exactly the position of non-zero values in W_{neg} . Formally, we have $W_{pos} + W_{neg} = W$. To this end, instead of using an operator to split weight matrix W into W_{pos} and W_{neg} , we first load the matrix W from global memory to shared memory without distinguishing the sign of individual scalars. Then, we split the weight matrix W into W_{pos} and W_{neg} when loading data from shared memory to registers, as illustrated in Fig. 5(b). In our design, we only need to load MN scalars from global memory, which leads to significantly reduced memory access compared with loading $2MN$ scalars in baseline approaches.

Double bound based fusion. Our second optimization is a double-bound-based fusion. One important semantics in transformer verification is to multiply the same weight matrix with lower and upper input bounds (e.g., X_{lb} and X_{ub}) to compute the output bounds (e.g., Y_{lb} and Y_{ub} in Fig. 5(b)). Meanwhile, when computing the bound for output neurons, we usually need to read both lower and upper bounds for

computation. For example, when computing the upper bound of output neurons, we need to read upper bound when weight is positive and read lower bound when weight is negative. Suppose the input bounds X_{lb} and X_{ub} have shape $N \times K$, we need to load $4NK$ scalars during transformer verification.

Instead, we propose to fuse the computation of lower and upper bounds such that the lower and upper bounds only need to be loaded once to save memory access. In particular, we first use threads across GPU blocks to collaboratively load tiles of input matrices from global memory to shared memory, which can be accessed by different GPU threads. Here, we use shared memory to enable data sharing across GPU threads since different threads may multiply the same input bound scalar with different weight scalars (e.g., multiplying the first row in X_{lb} and X_{ub} with various columns in W). Then, each thread loads independent data from shared memory to registers and directly accumulates output bounds Y_{lb} and Y_{ub} in registers. We note that this design further improves performance by eliminating the redundant global memory access during generating Y_{lb} and Y_{ub} .

3.2 Bound-aware Cross-layer Kernel Fusion

Bound-aware cross-layer kernel fusion fuses the verification of kernels across multiple transformer layers to further minimize memory access. Existing frameworks for accelerating standard NNs usually rely on a set of rules to fuse kernels. One popular example is to fuse convolution kernel with the following elementwise kernels (e.g., ReLU kernel for elementwise comparison with 0). However, these rules usually cannot be applied to fuse kernels for transformer verification. For example, verifying the ReLU kernel requires first a concretization operation with a global reduction to compute the concretized bounds for a neuron and then applies different computation according to the concretized bounds (see §2.1).

To this end, we propose a set of rules for cross-layer kernel fusion in transformer verification. In particular, we recognize three types of operators. The first type is *input-reduction-compute* that conducts reduction or concretization operation on the input data before computation. One example is verifying nonlinear activation functions such as *ReLU* and *Tanh* that requires concretized bounds to apply different computation. Another example is the *softmax* operator that computes a global summation for normalization. The second type is *strict-elementwise* that contains only elementwise computation and does not require concretization or global summation. The third type is *dense-computation* such as matrix-matrix multiplication kernels. In our cross-layer kernel fusion design, we can always fuse a *dense* operator with its following *strict-elementwise* operator. However, we cannot fuse *dense* operator with *input-reduction-compute* due to the concretization or reduction operation. In addition, we can fuse *input-reduction-compute* with its following *strict-elementwise* operator. Finally, we can fuse multiple *strict-elementwise* operators (e.g.,

elementwise addition and multiplication).

4 Verification-specialized Kernel Crafter

In this section, we propose a verification-specialized kernel crafter to efficiently map transformer verification towards modern GPUs. We exploit intrinsic properties (e.g., abundant reduction operations) of transformer verification which are significantly different from standard transformer operators. One major challenge in building the kernel crafter is the large diversity in verification designs across operators (see Fig. 3(d)-(g)). To tackle this challenge, we first propose a *verification pattern categorization* to abstract such diversity and provide a small set of computing patterns over verification of diverse operators. Then, we propose three optimizations to efficiently support these computing patterns of transformer verification.

4.1 Verification Pattern Categorization

While there are diverse bound designs across different operators, we characterize transformer verification into four typical computing patterns. Based on this characterization, Faith can abstract the diversity in bound designs into a combination of computing patterns and exploit optimizations towards individual computing patterns for improving performance. Similar to standard NNs, one important computing pattern is *generalized matrix multiplication (GEMM)* when verifying projection layers and fully connected layers. Matrix multiplication is the major bottleneck in standard NNs and has been well-optimized by existing DL frameworks. Besides GEMM, transformer verification introduces three other time-consuming computing patterns, which are highlighted as follows:

The first computing pattern is *generalized vector reduction*. One typical source of generalized vector reduction is concretization that computes the norm and generates the concretized lower and upper bounds for individual neurons (see Eq. 1). Formally, consider a matrix $X = [\vec{x}_1, \vec{x}_2, \dots, \vec{x}_m] \in \mathbb{R}^{m \times n}$ where $\vec{x}_i = [x_{i,1}, x_{i,2}, \dots, x_{i,n}]$ are vectors of length n . The generalized vector reduction computes an output $Y = [y_1, y_2, \dots, y_n] \in \mathbb{R}^n$ that satisfies

$$y_i = \text{reduction}(\vec{x}_i) = \sum_{j=1}^n f(x_{i,j}), \quad i \in \{1, 2, \dots, m\} \quad (3)$$

Here, $f(x)$ is an elementwise function that takes a scalar input and generates a scalar output. One example for $f(x)$ is x^2 when computing the L_2 norm for input vectors.

The second computing pattern is *generalized elementwise multiplication* which appears frequently when verifying elementwise operators such as ReLU and Tanh. Formally, consider a concretized lower bound $l \in \mathbb{R}^{m \times n}$ and an upper bound $u \in \mathbb{R}^{m \times n}$ where $l_{i,j}$ and $u_{i,j}$ are concretized lower and upper bounds for the neuron at position (i, j) . Let $X \in \mathbb{R}^{m \times n}$ be the input values. The generalized elementwise multiplication

computes an output $Y \in \mathbb{R}^{m \times n}$ that satisfies

$$y_{i,j} = f(l_{i,j}, u_{i,j}) * x_{i,j}, \quad i \in \{1, 2, \dots, m\}, j \in \{1, 2, \dots, n\} \quad (4)$$

Here, transformer verification introduces a function $f(\cdot, \cdot)$ that takes the lower and upper bounds for an input neuron and computes a scaling parameter which is multiplied with the input value of this neuron. One example is the tangent line between the concretized lower and upper bounds when verifying Tanh layer, which accounts for more than 20% latency as we profiled in Fig. 4. Another example is $f(l_{i,j}, u_{i,j}) = 1$ when verifying ReLU layer and $l_{i,j}$ is non-negative. While $f(\cdot, \cdot)$ shows large diversity across operators, we stress that the same computing pattern is shared across these operators such that a uniform framework can be applied to improve performance.

The third computing pattern is *generalized scalar-vector multiplication*. This computing pattern exists widely when verifying dot products in the self-attention layer of transformers. This computing pattern accounts for more than 40% latency in transformer verification, as discussed in Fig. 4. Formally, consider a vector $S = [s_1, s_2, \dots, s_m] \in \mathbb{R}^m$ and a matrix $X = [\vec{x}_1, \vec{x}_2, \dots, \vec{x}_m] \in \mathbb{R}^{m \times n}$, where s_i are scalars and $\vec{x}_i = [x_{i,1}, x_{i,2}, \dots, x_{i,n}]$ are vectors of length n . The generalized scalar-vector multiplication computes an output $Y = [\vec{y}_1, \vec{y}_2, \dots, \vec{y}_n] \in \mathbb{R}^{n \times n}$ that satisfies

$$\vec{y}_i = f(s_i) * \vec{x}_i = [f(s_i) * x_{i,1}, f(s_i) * x_{i,2}, \dots, f(s_i) * x_{i,n}], \quad i \in \{1, 2, \dots, m\} \quad (5)$$

Here, $f(\cdot)$ is a function that takes a scalar input and generates a scalar output.

Generability to diverse NN operators. Faith can effectively support verifying diverse NN operators such as SiLU and Leaky ReLU. Our key insight is that verifying diverse NN operators usually share the same generalized computing pattern while the concrete computation formula might be different. For example, $SiLU(x) = \frac{x}{1+e^{-x}}$ is an activation function that has significantly different concrete computation formula from $ReLU(x) = \max(0, x)$. However, both verifying SiLU and ReLU can be treated as the generalized elementwise multiplication (Eq. 4) and the same optimizations can be applied to improve performance.

In the following sections, we first demonstrate a *workload-adaptive reduction* to improve the performance of generalized vector reduction (Eq. 3). We then propose a *sharing-oriented workload scheduling* to improve the performance of generalized elementwise multiplication (Eq. 4). Finally, we demonstrate *broadcast-aware super threading* to efficiently support the generalized scalar-vector multiplication (Eq. 5).

4.2 Workload-adaptive Reduction

Transformer verification contains abundant reduction operations where a sequence of scalars are summed up into one scalar. One common reduction operation is the concretization operation that computes the concretized lower and upper

Figure 6: Illustration of Workload-adaptive Reduction. (a) Sequential Mode; (b) Parallel Mode. Here, x_i and T_i are the i -th data and thread, respectively.

bounds for individual neurons, as discussed in §2. Another common reduction operation is the softmax operation that is applied in each self-attention layer for measuring the relationship between individual words. These reduction operations pose challenges between parallelism and data locality. One baseline approach is to use a single thread to read and accumulate a sequence of scalars as illustrated in Fig. 6(a). However, this approach usually leads to low parallelism and fails to exploit abundant threads in GPUs. For example, we need 32 iterations to accumulate 32 scalars. Another baseline approach is to first split this sequence of scalars into multiple chunks and allocate one thread to each chunk for accumulation. Then, each thread writes the accumulated results for each chunk to global memory and uses an additional thread to finally accumulate the sum of each chunk. While this approach improves parallelism, it requires expensive global memory access and high overhead.

Workload-adaptive Reduction with length $n = 32$. We propose a *workload-adaptive reduction* to fully exploit GPU memory hierarchies and the inter-register communication functionalities. We illustrate our design in Fig. 6(b). Our design achieves high parallelism by enabling multiple threads for reduction simultaneously. Meanwhile, we avoid the expensive data communication through global memory and exploit only efficient registers. In particular, we use 32 threads (*i.e.*, a warp) to read these 32 scalars simultaneously from global memory. Considering these 32 scalars are consecutive in global memory, we can efficiently load them with 32 threads through coalesced memory access. Then, we exploit the specialized instruction `_shfl_down_sync` to directly communicate data in registers across individual threads. As illustrated in the parallel mode of Fig. 6(b), our design involves only five iterations of cross-thread data communication to generate the final accumulated result, rather than the 32 iterations in the sequential mode of Fig. 6(a).

Workload-adaptive Reduction with Arbitrary Length n . For an arbitrary length n , one naive approach is to repeatedly use 32 threads to reduce 32 scalars and then use 1 thread to accumulate the final results. However, this approach may lead to unnecessary communication across threads. Suppose we are accumulating a vector of length $n = 32k$, we need 5 iterations for reducing every 32 scalars, leading to $5k$ iterations in total for accumulating the vector. Instead, we propose

Figure 7: Illustration of sharing-oriented workload scheduling

a *hybrid mode* to minimize the number of iterations while still achieving high parallelism. In particular, we first split the input sequence into chunks where each chunk contains 32 scalars. Then, we use 32 threads to read one chunk simultaneously from global memory and accumulate individual chunks iteratively. For example, the 1-st thread accumulates the 1-st scalar in each chunk. Here, the accumulation is conducted in registers and does not require communication across threads. Finally, we apply a single 5-iteration reduction across 32 threads. In total, our design has only $k + 5$ iterations which are significantly less than $6k$ iterations in the naive approach.

4.3 Sharing-oriented Workload Scheduling

We propose *sharing-oriented workload scheduling* to efficiently verify elementwise operators. Different from standard transformers, verifying elementwise operators, especially non-linear ones (e.g., ReLU and Tanh), accounts for a large portion of latency in transformer verification as we discussed in Fig. 4. Verifying these operators usually first requires computing a concretized lower bound X_l and upper bound X_u for each input neuron and then computes the bounds for the output neuron. Different signs of concretized input bounds usually lead to different computations for output bounds, which could easily lead to warp divergence and unsatisfactory performance. Moreover, when computing the output bound weights (i.e., Y_{lw} and Y_{uw}) for a neuron, we need to repeatedly use the same input bounds which leads to extra memory overhead.

To efficiently verify elementwise operators, we propose *sharing oriented workload scheduling* to minimize memory access and improve performance. Our key observation is that the same set of input bound weights X_{lw} and X_{uw} are used to compute the concretized input bounds X_l and X_u , while these input weights are also used for computing the output bound weights Y_{lw} and Y_{uw} . Instead of repeatedly loading X_{lw} and X_{uw} , we can exploit the GPU memory hierarchies to cache X_{lw} and X_{uw} and minimize the global memory access to improve the overall performance.

As illustrated in Fig. 7, we use a set of $T (= 32)$ threads to first (Step 1) load input bound weights X_{lw} and X_{uw} from global memory to shared memory. Here, T is a hyper-

parameter to balance the parallelism and compute intensity, which will be selected in §5. Then (Step 2), these T threads load input bound weights from shared memory and collaboratively compute the concretized lower and upper bounds X_l and X_u , following our design in §4.2. These concretized lower and upper bounds are stored in shared memory which can be accessed by individual threads. Finally (Step 3), each thread independently loads individual X_{lw} and X_{uw} scalars from shared memory and rescales according to the concretized bounds X_l and X_u . Here, all threads in a warp are computing the output bound weights for the same neuron and the concretized input bounds are the same across threads in a warp. Thus, all threads in a warp can apply the same rescaling computation and avoid warp divergence. We also note that input bound weights are only loaded once from global memory which mitigates redundant global memory access.

4.4 Broadcast-aware Super Threading

We propose *broadcast-aware super threading* to efficiently support generalized scalar-vector multiplication, as discussed in Eq. 5. One naive approach is to use one thread to read a scalar s_i and a vector \vec{x}_i and computes the generalized scalar vector multiplication $f(s_i)\vec{x}_i$. However, this approach fails to exploit the parallelism opportunities in generalized scalar vector multiplication. Another approach is to split the vector \vec{x}_i into multiple chunks and use one thread for each chunk. However, this approach requires threads to repeatedly read the same scalar s_i from global memory and shows redundant memory access.

Instead, we propose a broadcast-aware super threading to achieve high parallelism while minimizing memory access. We consider two types of super threading for generalized scalar vector multiplication. The first type is a group of 32 threads (i.e., a warp for one vector). When using 32 threads to compute the multiplication between a scalar s_i and a vector \vec{x}_i , these 32 threads can read the scalar s_i once, broadcast across threads with modern GPU memory, and compute $f(s_i)$ simultaneously. Based on this broadcast, we can mitigate the redundant memory access that each thread repeatedly read the same scalar s_i . The second type is a group of $32t$ threads (i.e., t warps for one vector). In this case, we use one warp to read the scalar s_i and use shared memory to broadcast s_i across warps.

5 Expert-guided Autotuning Optimization

Considering the large design space of optimization towards GPUs, one natural question arises: *Can we effectively incorporate hardware knowledge to find optimal operator implementation?*

Existing works such as TVM [6] and Ansor [54] usually autotune operator implementations in a hardware-agnostic way. In particular, these works extract implementation-specific parameters such as tiling size and use a cost model to implicitly

learn the relationship between these parameters and performance. However, there are two drawbacks in this hardware-agnostic approach. First, there is a complex interaction between implementation and the hardware properties, which could be hard to be implicitly learned by the cost model. For example, existing works [12, 20, 24, 43] on hand-tuning large matrix-matrix multiplication operators usually maximize the number of registers in use to improve cache performance. However, this optimization is also limited by the number of registers for each GPU thread since exceeding such limitation may lead to register spilling [27] and a significant performance drop. A careful reasoning on the interaction between the implementation-specific parameters (e.g., the number of registers for caching data) and the hardware properties (e.g., the number of registers per thread) is usually necessary to maximize the performance. To tackle this challenge, we propose an *expert-guided autotuning optimization* to automatically reason both implementation-specific parameters and hardware properties. In particular, we have the following designs.

Rule-based Expert Knowledge Metafile. We propose a *rule-based expert knowledge metafile* to capture hardware properties. This metafile only needs to be set once for each type of GPUs and requires limited manual efforts. In particular, we consider two types of rules. The first type is *hard rules* which represents hardware limitation such as the maximal shared memory size and the maximal number of registers per thread. Violating these rules may lead to significant performance drop such as register spilling. The second type is *soft rules* which represents intrinsic trade-offs related to the hardware properties such as the number of streaming multiprocessors (SM) and the number of threads per SM. One typical design choice is the number of threads per block which will be mapped to threads on the same SM. Allocating more threads per block usually leads to better parallelism for the sub-task assigned to a block. However, allocating more threads per block may also hinder executing multiple blocks on the same GPU SM hardware and lead to worse overall parallelism.

Expert-guided Cost Model. We propose an *expert-guided cost model* to automatically tackle the complex interaction between implementation-specific parameters and hardware properties. Given a set of candidate operator implementations, we have two phases to select the optimal implementation. The first phase is to estimate the shared memory and register usage for each candidate. We rule out candidates that consume more shared memory and registers than hardware capacity, as specified in the expert knowledge metafile.

The second phase is to train a cost model for the remaining candidates and use the cost model to select the best candidate. We use XGBoost [5] as the cost model. It takes as input the implementation-specific parameters (e.g., tiling size) for candidates and the hardware properties (e.g., shared memory size). We use the cost model to predict the latency of candidates and select top-k candidates with low latency. Finally, we profile the latency of these top-k candidates on GPUs and use

Dataset	#Train	#Val	#Test	Length		
				min	mean	max
SST	67,349	872	1,821	4	25	62
YELP	560,000	0	38,000	5	98	128

Table 2: Dataset statistics

the profiled latency to further finetune our cost model. We repeat this procedure for a pre-defined iterations (=5 by default) and select the implementation with the lowest latency.

When training the cost model, we construct the training dataset as follows. We randomly select a small number of candidates and use their implementation-specific parameters and the hardware properties as feature X . Then, we profile the latency of each candidate implementation on GPUs as the label Y . We collect these (X, Y) as the training dataset to train the cost model.

6 Evaluation

In this section, we comprehensively evaluate Faith over various datasets and GPU backends. We first present our experiment setup in §6.1. Then, we show the overall speedup on end-to-end transformer verification in §6.2. Finally, we provide more optimization analysis on individual transformer layers in §6.3.

6.1 Experiment Setup

Baselines. We compare Faith with the state-of-the-art transformer verification [35] based on PyTorch. We further compare with TVM [6] and Anso [54], as stronger baselines. TVM and Anso are two state-of-the-art deep learning compilers for standard neural networks. We feed the pytorch model into TVM and Anso through relay frontend [34] which will automatically optimize transformer verification performance. While TVM and Anso take minutes to compile an operator implementation, we do not incorporate this compilation latency and record only inference latency for a fair comparison.

Datasets. We evaluate two popular datasets, Yelp [53] and SST [36], following the setting in state-of-the-art transformer verification [35]. These two datasets are widely used in the natural language processing for analyzing sentiment in languages. We summarize the statistics of these two datasets in Table 2. SST dataset contains 67,349 training sentences, 872 validation sentences, and 1,821 testing sentences. In SST dataset, there are 4 to 62 tokens in each sentence and the average number of tokens in a sentence is 25. YELP dataset contains 560,000 sentences as training data and 38,000 sentences as testing data. In YELP dataset, there are 5 to 128 tokens in each sentence and the average number of tokens in a sentence is 98.

Transformer Networks. We evaluate Faith on transformer networks with 1 to 6 layers to demonstrate the performance on large models. Following popular transformer settings, each transformer layer has 4 attention heads and an embedding size

Figure 8: Overall speedup on SST dataset.

Figure 9: Overall speedup on Yelp dataset.

of 128. Furthermore, we study the Faith performance under diverse embedding sizes in §6.3.

Experiment Configuration. We evaluate with an NVIDIA A100 GPU and an NVIDIA V100 GPU to show Faith performance on various GPU backends. The host server with A100 GPUs is an AMD EPYC 7742 64-Core Processor and runs Ubuntu 20.04 with CUDA 11.3. The host server with V100 GPUs has 32 cores of Intel(R) Xeon(R) CPU E5-2620 v4 @ 2.10GHz and runs Ubuntu 16.04 with CUDA 10.1.

6.2 Overall Performance

We show the overall speedup on SST dataset and Yelp dataset in Fig. 8 and Fig. 9, respectively. We show the performance improvement over transformers with diverse numbers of layers from 1 to 6, which covers popular settings in the natural language processing domain. While the length of input sentences may have an impact on the performance improvement, we show the averaged speedup over all testing sentences in this section and study the impact of sentence length in §6.3. We compare Faith with the PyTorch baseline following existing transformer verification open-source implementations [35]. We further compare Faith with two state-of-the-art deep learning frameworks (*i.e.*, TVM and AnsoR) to provide a comprehensive comparison, as we discussed in §6.1.

We show the overall speedup on SST dataset and A100 GPU in Fig. 8(a). Compared with PyTorch, we observe $2.3\times$ to $3.2\times$ speedup ($2.5\times$ on average). We contribute this performance improvement to our semantic-aware computation graph transformation (§3) and verification-specialized kernel crafter (§4). We further observe $17.2\times$ and $15.9\times$ speedup over TVM and AnsoR, respectively. The main reason is that

TVM and AnsoR focus on optimizing standard neural networks and fail to efficiently support verification-specific computing patterns, as discussed in §2.2. While Faith and these three baselines show different performance, we stress that the same verification bounds are generated, and the only difference resides in system optimizations. Comparing across different numbers of transformer layers from 1 to 6, the performance improvement remains similar around $2.5\times$. This result shows that Faith can efficiently support transformer verification with diverse numbers of transformer layers. We show the overall speedup on SST dataset and V100 GPU in Fig. 8(b). We have similar observation about the results on A100 GPU which shows that Faith can effectively adapt to diverse GPU backends, thanks to expert-guided autotuning optimization (§5).

We show overall speedup on Yelp dataset and A100 GPU in Fig. 9(a). Sentences in YELP dataset has 5 to 128 tokens (98 on average), which is longer than sentences in SST dataset with 4 to 62 tokens (25 on average). This provides an opportunity to show Faith performance on long sentences. Overall, we observe $2.1\times$ to $2.3\times$ speedup ($2.2\times$ on average) when comparing with the PyTorch baseline. We also observe $26.7\times$ and $28.3\times$ speedup on average over TVM and AnsoR, respectively. This speedup is similar to the performance improvement on SST dataset and shows the good generality of Faith over diverse input data. We also have similar observations on Yelp dataset and V100 GPU in Fig. 9(b).

6.3 Optimization Analysis

In this section, we show speedup from individual Faith optimizations. We first show speedup on *verification of matrix*

Figure 10: Speedup on verification of matrix multiplication over the diverse lengths. Embedding Size: 128.

Figure 11: Speedup on verification of matrix multiplication over the diverse embedding sizes. Length: 16.

Figure 12: Speedup on verification of ReLU over the diverse lengths. Embedding Size: 128.

Figure 13: Speedup on verification of Tanh and dot product over the diverse lengths. Embedding Size: 128.

multiplication over the diverse lengths and diverse embedding sizes. Verification of matrix multiplication plays an important role in verifying projection layers and fully connected layers in transformers. Then, we show the benefits on verification of ReLU, verification of TVM, and verification of Tanh, which in total accounts for around 70% latency in transformer verification. Since we observe similar performance on A100 GPU and V100 GPU, we focus on A100 GPU and omit results on V100 GPU in this section due to page limits.

Performance benefits on verification of matrix multiplication. We show speedup on verification of matrix multiplication over the diverse lengths in Fig. 10. We study the speedup over diverse lengths from 2 to 128, following the setting in the popular natural language processing datasets as summarized in Table 2. Overall, we observe $5.1\times$ speedup on average over the PyTorch baseline. This result shows significant performance benefits from utilizing Faith on accelerating transformer verification. Comparing across lengths, we observe a higher speedup of $5.54\times$ over the PyTorch baseline on shorter sentences with 2 to 32 words. The reason is that our autotuning optimization (§5) automatically adjusts the number of threads and memory layout to improve the parallelism. We achieve a smaller speedup of $3.85\times$ on longer sentences with 64 and 128 words. For these longer sentences, we have achieved high occupancy on GPUs and the speedup is limited by the hardware capability.

Surprisingly, we observe that TVM and Anso achieve $0.33\times$ and $0.73\times$ speedup, which is significantly slower than PyTorch baselines on verification of matrix multiplication. The main reason is that TVM and Anso focus on accelerating standard NNs and cannot efficiently support computing

patterns in the verification of matrix multiplication (Fig. 3(c)). Instead, Faith exploits a semantic-aware kernel fusion (§3.1) to efficiently support such computing patterns in verification.

We show speedup on verification of matrix multiplication over the diverse embedding sizes in Fig. 11. We study embedding size from 64 to 640 following popular transformer settings. We note that transformer in natural language processing usually adopts a relatively small embedding size (e.g., 64 to 256), which is different from convolutional neural networks in computer vision that adopts a large embedding size (e.g., 1024). Overall, Faith achieves $4.2\times$ speedup on average over the PyTorch baseline. This result shows that Faith can improve performance over diverse embedding sizes. We also observe that Faith achieves larger speedup for smaller embedding sizes, which is similar to the case when verifying matrix multiplication over diverse lengths.

Performance benefits on verification of ReLU. We show speedup on verification of ReLU over diverse lengths in Fig. 12. As we discussed earlier in §4.1, verification of ReLU represents an important computing pattern of verifying elementwise operators. Due to similar behaviors between diverse lengths and embedding sizes, we focus on verification over diverse lengths and keep embedding size as 128, which is a popular setting in transformers. Overall, Faith achieves $141\times$ speedup over PyTorch baseline. This large speedup shows it promising to accelerate verification of elementwise operators. Besides, Faith achieves $13.4\times$ and $13.5\times$ speedup over TVM and Anso. The reason is that our *workload-adaptive reduction* (§4.2) can significantly improve parallelism during reduction and *sharing-oriented workload sharing* can minimize memory access with GPU memory hierarchy.

#Layers	1	2	3	4	5	6
PyTorch	9.1	18	25	28	31	37
Faith	4	7.2	7.8	10.9	12.6	15.4

Table 3: Latency on SST dataset and A100. Unit: Second.

Performance benefits on verifying Tanh and dot product layers. We show the speedup from Faith over the PyTorch baseline on verification of Tanh and verification of dot product in Fig. 13. We skip the results of TVM and Ansor since these two frameworks do not support computing patterns in verification of Tanh and verification of dot product. Here, we show results of verification of Tanh since it is a popular elementwise operator in transformer verification. We also show results of verification of dot product since it accounts for around 45% latency in transformer verification. Overall, we observe that Faith achieves $138\times$ speedup on average for verification of Tanh. This result is similar to the performance improvement for verification of ReLU, since both Tanh and ReLU are elementwise operators and share benefits from the same set of optimizations. We also observe that Faith achieves $26.5\times$ speedup on average for verification of dot product. This result shows the performance benefits from semantic-aware kernel fusion (§3.1) and broadcast-aware super threading (§4.4) that mitigate redundant memory access.

Raw latency on transformer verification. We show the raw latency for transformer verification on the SST dataset and NVIDIA A100 GPU in Table 3. Faith requires only a few seconds to verify the NN prediction on a long sentence (with on average 25 tokens). More specifically, when verifying transformers with 1 to 6 layers, Faith only requires 4 to 15.4 seconds to verifying a sentence. This results brings transformer verification to the level of being practical for use.

7 Discussion

Why Faith performs better than prior approaches. Existing frameworks, such as PyTorch, TVM, and Ansor, only support limited computation patterns for standard NNs. They cannot directly support bound-centric computation patterns in transformer verification. While several frameworks like TVM allow autotuning for diverse operators, there is no magic. They still rely on hand-written GPU kernels (e.g., matrix multiplication) as the parametric templates (e.g., with tiling size as a parameter) and can only tune these tiling sizes. When applying to bound-centric computation patterns, they will break an operator for transformer verification into several hand-written GPU kernels for standard NNs. This leads to significantly higher memory access when aggregating computation results across GPU kernels into one transformer verification output.

Instead, Faith provides direct support for bound-centric computation patterns. Instead of breaking into several GPU kernels for standard NNs, we consider the bound-centric computation patterns as a whole and design a set of optimizations to reduce the memory and computation cost. For example,

we found the lower and upper bounds are usually multiplied with the same weight matrix and can be loaded once to reduce memory overhead.

Practicality of transformer verification with Faith. Faith brings transformer verification to be practical by consuming only around 10 seconds to verify a long sentence (e.g., 25 tokens). We remark that transformer verification is one of the hottest topics in deep learning. Hundreds of related papers have been published in top deep learning conferences. The performance is essential to bring transformer verification into practical applications. However, existing efforts mainly reside in the algorithmic domain. In this paper, we build the first framework for efficient transformer verification on GPUs. Our work will open a new system research direction on developing high-performance systems for deep learning verification.

8 Conclusion

Verifying the robustness of transformers draws increasing attention from both the academic and industry fields over the recent years. Unfortunately, an efficient system design for transformer verification is still yet to come. Existing transformer verification still exploits standard neural network frameworks which are unoptimized towards transformer verification workload. The main reason is that efficient systems for transformer verification require both expertise from the machine learning community on mathematical verification designs and the system community on efficient memory and parallelism designs.

In this paper, we propose a Faith framework for efficient transformer verification. Specifically, we first design a set of semantic-aware computation graph transformations to fully exploit fusion opportunities in transformer verification at the computation graph level. Then, we propose a verifier-specialized kernel crafter to efficiently map fused verification kernels towards modern GPUs with minimized memory overhead and improved parallelism. Finally, we propose an expert-guided autotuning to dynamically optimize kernels according to the transformer verification workload and GPU backend characteristics. Comprehensive experimental evaluation shows that Faith significantly improves the performance of transformer verification over state-of-the-art frameworks.

Looking ahead, we believe our work in transformer verification would highlight a new direction on developing high-performance systems for deep learning verification. This will encourage system experts with diverse backgrounds to build the next-generation deep learning systems and facilitate the wide application of secure deep learning.

Abstract

The DNN inferences are often batched for better utilizing the hardware in existing DNN serving systems. However, DNN serving exhibits diversity in many aspects, such as input, operator, and load. The unawareness of these diversities results in inefficient processing. Our investigation shows that the inefficiency roots in the feature of the existing batching mechanism: one entry and one exit. Therefore, we propose **DVABatch**, a runtime batching system that enables the multi-entry multi-exit batching scheme. We first abstract three meta operations, new, stretch, and split, for adjusting the ongoing batch of queries to achieve the multi-entry multi-exit scheme. The meta operations could be used to form different scheduling logics for different diversities. To deliver the meta operations to an ongoing batch, we slice the DNN models into multiple stages. Each stage corresponds to one executor, which is managed by a state transition diagram. Compared with state-of-the-art solutions, our experimental results show that DVABatch reduces 46.4% average latency and achieves up to $2.12\times$ throughput improvement.

1 Introduction

Deep neural networks (DNNs) [27, 37, 57] are widely used in intelligent services [1, 5, 6, 12]. Since user queries have stringent QoS in terms of end-to-end latency, dedicated accelerators like GPUs [10, 11] and NPUs [21] are used to speed up the DNN inferences. However, a single DNN query often cannot fully utilize these accelerators [17, 18, 43, 46, 65] (e.g., An Nvidia Titan RTX GPU has 72 SMs [10]). Therefore, emerging DNN serving systems (e.g., Clipper, Triton, TF-Serving) [9, 23–26, 51, 62, 63] batch queries for better taking advantage of the accelerators' parallelism. Queries that arrive in a given batch time window are organized into a batch, and an *executor* (process) is used by the DNN serving system to process the entire batch at a time. Such a batching policy uses the same batch size (*bs*) across a single inference process.

On GPUs, due to the single program multiple-data (SPMD) design, all the queries in a batch return at the same time. This

Figure 1: Serving diversities in real-world services.

batching pattern is referred to be the *single-entry single-exit batching pattern*. It works great for best-effort applications, and the services when the queries arrive in uniform intervals [22]. However, DNN serving scenarios show various diversities, and the single-entry single-exit batching pattern results in the long response latency of inference queries on GPUs. For instance, we find at least three types of diversities when serving DNN models, as shown in Figure 1.

Input Diversity. The inputs of user queries show high diversity (e.g., in natural language processing services). Short queries are all padded to the size of the longest query for batching. The benefit of batching may be negated by the wasted computation of the padded part.

Operator Diversity. While all the operators of a DNN model share the same batch size, they have different preferred batch sizes. An operator's preferred batch size is the smallest batch size that fully utilizes the current GPU. The hardware is not fully utilized if an operator's preferred batch size is larger than the used batch size. Otherwise, the processing time is increased unnecessarily.

Load Diversity. The service queries do not arrive in a uniform interval. In this case, the number of queries collected in a single batch time window varies. When the load bursts, a previous non-full batch results in the long latency of subsequent queries. In other words, hardware resources are wasted while the queries are waiting in the next batch time window.

The diversities result in inefficient processing of user queries (discussed in more detail in Section 3). The ineffi-

Figure 2: The work manner switch of stage executors.

ciency stems from the batching pattern of single-entry single-exit. To address the inefficiency, we, therefore, propose a *multi-entry multi-exit batching scheme* for DNN serving on GPUs. For instance, with the multi-entry multi-exit batching scheme, a short query can exit early without waiting for the entire batch to exit (input diversity), a batch can be split into smaller batches to execute an operator with a preferred smaller batch size (operator diversity), and the queries that arrive later can join an ongoing but non-full batch (load diversity).

It is nontrivial to implement the multi-entry multi-exit batching scheme for GPUs. *It necessitates the ability of the serving system to dynamically alter the batch size of an ongoing query batch.* Specifically, such a system should enable the joining of incoming queries into the ongoing batch and the splitting of an ongoing batch into smaller batches (The queries in the smaller batches could exit independently). *Moreover, it introduces extra complexity for designing executors in the DNN serving system.* With the multi-entry multi-exit scheme, the inference of batched queries is broken down into multiple stages, and each stage’s execution requires one executor. Multiple executors have to coordinate with each other to ensure the validity of the query inference.

To this end, we propose **DVABatch** to enable the multi-entry multi-exit batching scheme effectively. DVABatch provides three meta operations, *new*, *stretch*, and *split*, to adjust the ongoing batch (Section 5). The *new* operation creates a new batch, just like the traditional batching strategy. The *stretch* operation adds new queries to the ongoing batch. The *split* operation breaks a running batch into multiple batches, which could be scheduled separately. Query batching can be done in a variety of ways using the three meta operations.

To deliver the meta operations to the stage executors, a *batch queue* that stores the batch information is added between adjacent stage executors, and a global *batch table* is utilized to record the to-be-performed meta operations at each stage (Section 5). When an executor completes its computation for a batch of queries, it verifies the to-be-performed meta operations for the next stage in the *batch table*. If a *split* or *stretch* operation is required, the executor applies the corresponding meta operation on the current batch and pushes new batches of queries into the batch queue of the next stage.

While multiple active executors run independently like a software pipeline, DVABatch should manage them properly. Otherwise, the naive parallel execution of the executors invalidates the execution due to data hazard and results in unnecessary long latency. For instance, the executor should

run batches with different input sizes in parallel for the input diversity, and run the sub batches after the *split* meta operation sequentially for the operator diversity. DVABatch introduces a state transition diagram based solution to support the executors’ complicated runtime scheduling (Section 6). Each executor has four states: *active*, *checking*, *working*, and *inactive*. Through the state transition diagram, the work manners depicted in Figure 2 are both supported.

The main contributions of this paper are as follows.

- We propose a multi-entry multi-exit batching scheme for efficient DNN service processing on GPUs.
- We provide a general scheduling mechanism that leverages meta operations, and state transition diagram to create policies for different serving diversities.
- We implement DVABatch with Triton, a state-of-the-art DNN serving system. Our experimental results on Nvidia Titan RTX show that DVABatch reduces 46.4% average latency and achieves up to $2.12\times$ throughput improvement for the involved serving diversities.

2 Related Work

Many systems have been proposed for efficient DNN inference [9, 25, 35]. Clipper [23], TF-Serving [51], Triton [9] adopted the traditional batch strategy that uses batch time window and the maximum allowed batch size. They treated the DNN model as an indivisible whole. They left the scheduling of inner operators to their supported backends. These works do not perceive the serving diversity and utilize the DNN operator scheduling for efficient processing.

There are some prior research on improving operator scheduling. TensorFlow Fold [47], DyNet [49], and BatchMaker [31] focused on the runtime scheduling of operators for RNN. They are model-specific solutions, removing padding for RNNs. The RNN cells of the same type share the same parameter weights and are executed recursively [38]. These works relied on this property to remove the padding. The design is restricted to resolving the input diversity for RNN. It cannot be applied to other models with input diversity, e.g., attention-based models, and BatchMaker-like batch mechanism can be achieved through DVABatch’s meta operations. Besides, LazyBatch [22] cared about the load fluctuation and proposed batching queries lazily. LazyBatch performed per-operator scheduling that incurs high scheduling overhead. It could not handle other diversities. In this work, we focus on resolving the problems caused by serving diversities in a holistic way.

There are also some prior works about ragged tensor for the input diversity [4, 29]. They generated the customized implementation of operators to remove the padding. However, operators like GEMM and convolution cannot be optimized through these works, which dominate the computation in DNN. These works are orthogonal to DVABatch and can be combined together to enable even lower latency.

3 Background and Motivation

This section shows the long query latency problem due to the single-entry single-exit batching, and motivates the design of DVABatch. Figure 3 shows the three involved diversities. For simplicity of illustration, we assume that each operator completes in 1 time unit (T), and the batch size is 4. In this case, once 4 queries are received or the batch time window ends, the received queries are batched and issued to run.

3.1 Input diversity

Input diversity widely exists in DNN services. E.g., natural language processing services often process sentences of different lengths. Figure 4 shows the sequence length distribution in 10 workloads of the General Language Understanding Evaluation (GLUE) dataset [59]. As observed, most sentences have 5-20 words, but some have more than 100 words.

For these models, the input of short queries is padded to the same size as the input of the longest query so that they can be batched to run [28]. Case-I in Figure 3 shows the batching with input diversity. As shown in the upper part of Case-I, the hardware resources are wasted for the computation of extra paddings (the queries in a batch return simultaneously).

The lower part of Case-I shows a better batching strategy: the batch is divided into two smaller batches, one for short queries ①, ②, and ③, and one for the long query ④. In this way, queries ①, ②, and ③ return earlier, and the average latency is reduced by 37.5% (from $4T$ to $2.5T$). Note that the two

batches may run in parallel before the short batch completes if 4 operators are required to fully utilize the GPU.

3.2 Operator diversity

For a DNN service, the operators often require different batch sizes to fully utilize the GPU. Figure 5 shows the latencies of two General Matrix Multiplication (GEMM) operators converted from two convolution operators of Resnet50 [37], with the shapes of $[bs * 3136, 576] \times [576, 64]$ and $[bs * 49, 576] \times [576, 512]$. GEMM operators dominate DNNs (occupying 86% of the computation time) [44].

As shown, the preferred batch sizes of *GEMM-A* and *GEMM-B* are 1 and 8, respectively. For *GEMM-A*, batching only increases its latency without improving the processing throughput. For *GEMM-B*, using a batch size smaller than 8 is not able to fully utilize a GPU (the processing time does not increase until the batch size is larger than 8).

Case-II in Figure 3 shows the batching with operator diversity. In Case-II, operator *A* prefers batch size 4, operator *B*, *C*, and *D* prefer batch size 1. The lower part of Case-II shows a better batching strategy: we can run operator *A* with batch size 4, split the batch into four smaller batches with batch size 1 at operator *B*, and run the small batches sequentially. In this way, query ①, ②, and ③ return earlier. The average latency can be reduced by 28.1% (from $4T$ to $2.875T$).

Many DNN models suffer from operator diversity. Figure 6 shows the processing time of the operators in Unet [56], a widely used image segmentation network with different batch

Figure 6: Operator duration of Unet on Titan RTX with variable batch sizes.

sizes on an Nvidia Titan RTX GPU. In the figure, the x-axis represents each operator’s id in the executive order. As observed, most operators in the former part (OPG_A) benefit from large batch sizes (e.g., larger than 32), but the operators in the latter part (OPG_B) only benefit from small batch sizes (smaller than 8). Using a batch size larger than 8 for Unet, the operators in OPG_B have longer latency without throughput improvement. On the contrary, using a batch size smaller than 32, the operators in OPG_A do not fully utilize the GPU.

3.3 Load diversity

User queries do not arrive in a uniform interval, as end users may randomly submit their queries. The number of received queries in a single batch time window varies [30,34,36,41,55].

Case-III in Figure 3 presents the batching with the load diversity. The batch time window is $4T$, the operators prefer batch size 4. With the current batching policy (the upper part of Case-III), query ① starts to run alone after it waits for $4T$, and the GPU is not fully utilized. During the processing of query ①, three queries ②, ③, and ④ arrive, but they have to wait to be executed in the next batch.

The lower part of Case-III shows a better way to run the four queries: the first batch (query ①) waits for the second batch after the first operator A completes. Then, the two insufficient batches are merged into a new batch that fully utilizes the hardware. In this way, the average latency can be reduced by 34.4% (from $8T$ to $5.25T$).

3.4 Diversities among DNN services

The three types of diversities may exist in the same DNN services. Current batching policies with simple modifications cannot effectively handle them. In this case, designing a static batching policy is not able to fulfill the ever-changing diversities. A low-level batching mechanism that supports configuring the batching policy accordingly is required. Analyzing the three better batching cases in Figure 3, they share three requirements for the batching mechanism.

First of all, the mechanism should be able to interrupt an ongoing batch so that we can adjust the inappropriate batching decision. Second, the mechanism should be able to split a large batch into small batches. In this way, the small batches may run in a parallel manner (Case-I) or sequentially (Case-

Figure 7: Design of DVABatch.

II). Third, the mechanism should be able to merge multiple insufficient batches. In this way, we can build a large batch to better utilize the hardware resource (Case-III).

A multi-entry multi-exit batching scheme fulfills all three requirements, and has the potential to achieve better batching, together with appropriate batching policies.

4 Design of DVABatch

We therefore design and propose DVABatch to resolve the long latency problem due to the serving diversities.

4.1 Overview

Figure 7 illustrates DVABatch’s methodology. DVABatch enables the multi-entry multi-exit batching scheme for the upper-level DNN serving systems (e.g., Triton, TF-Serving).

In general, in order to support the multi-entry and multi-exit batching, DVABatch slices a DNN model into multiple fine-grained stages, and each stage has multiple adjacent operators. The queries are able to join a batch at the beginning of a stage, and exit from a batch at the end of a stage. Based on the stages, DVABatch designs and implements batching policies that manage the batching operation of each stage, based on the real-time diversities. DVABatch supports three meta-operations *new*, *stretch*, *split* for adjusting the batching. The *new* operation creates a new batch, *stretch* adds new queries to the ongoing batch, and *split* breaks a running batch into multiple smaller batches. Various batching policies can be implemented based on the meta-operations.

As shown in Figure 7, DVABatch comprises a *batch table*, *stage executors*, *batch queues*, and *DVAScheduler*.

- The *batch table* records the running status of the ongoing batches. It supports three meta operations for adjusting the batches at each stage.
- A *stage executor* is a process that is responsible for the corresponding stage’s execution. DVABatch utilizes a state transition diagram for executor management.
- There is a *batch queue* between the two adjacent stages, for transmitting the batch information. A stage executor pulls

Figure 8: Implementing the meta operations with batch table and batch queues between stages.

out batches from its previous *batch queue* for execution, and pushes batches into the *batch queue* of the next stage.

- *DVAScheduler* provides diversity-aware scheduling using various batching policies implemented with the three meta operations. The policies can be customized according to the serving diversity.

4.2 The Serving Workflow with DVABatch

Figure 7 also shows DVABatch’s serving workflow for the involved diversities. The steps for using DVABatch to serve a DNN service are as follows:

- ① DVABatch checks the input data pattern of the service, and profiles it to obtain the diversity patterns. Based on the profiling, the DNN model is sliced into stages automatically. A diversity-aware policy is generated for the DNN model.
- ② Each stage executor loads the corresponding stage of the model, and *DVAScheduler* uses the scheduling logic in the policy to schedule the accepted queries.
- ③ If a specific condition defined in the *DVAScheduler* is satisfied, the batch table is instructed to adjust the ongoing batch by *new*, *stretch*, *split* operations accordingly.

For a new DNN service, DVABatch handles input diversity before operator diversity. This is because handling input diversity directly reduces computation while handling operator diversity better schedules computation.

5 Enabling Multi-entry Multi-exit Scheme

In this section, we propose the abstraction of meta operations and how we achieve the multi-entry multi-exit scheme.

5.1 Defining the Meta Operations

As stated before, to achieve low latency query scheduling, the batched queries should be able to join and exit the batching system in several forms: **Multi-entry**. When a new batch of queries arrives, it can interrupt an ongoing batch, catch up with the progress of the interrupted one, then be merged into a single larger batch. In addition, the new incoming batch also can join the processing by co-running with the ongoing batches in different stage executors without pausing the ongoing one. **Multi-exit**. If some queries inside a batch need to

exit early, we need to split the batch into several batches and allow them to exit execution independently.

DVABatch abstracts three meta scheduling operations inside the *DVAScheduler*: *new*, *stretch*, and *split*, for supporting the multi-entry multi-exit scheme. With *new*, the new incoming queries are organized into a new batch. The batch created by *new* operation could co-run with the previous batches; With *stretch*, an ongoing batch is stretched with new incoming queries. At a specific stage, these queries are merged into the ongoing batch for processing; With *split*, a large ongoing batch is split into several smaller batches to be processed separately. The three meta operations can be used to form complicated scheduling logic when necessary.

5.2 Implementing the Meta Operations

It is challenging to support the meta operations, as a batch runs in multiple stages. The meta operations should be performed based on the stages’ execution status. In general, DVABatch tracks the stage status of the batches, and notifies the meta operations to the corresponding stage executors.

5.2.1 Batch Table and Batch Queues

DVABatch uses a *batch table* to track the processing status of all the batches on a GPU. The batch table is updated by the *DVAScheduler* through the meta operations.

As shown in Figure 8, a row in the batch table records the status of an ongoing batch. In a row, *id* is the batch’s identifier, *bs* is its current batch size, *time* is the timestamp the batch is created, *status_map* is a map that records the number of completed queries in each stage of the batch. For instance, the first row of *status_map* in Figure 8(a) means stage 1 has completed 2 queries in its batch. We need *status_map* because the latter queries of a *stretched* batch should catch up with the ongoing queries. With *status_map*, the executors could get the right number of queries to execute after *stretch* operation.

After the current stage executor completes its execution, it notifies the subsequent stage executor to run. DVABatch maintains *batch queues* between adjacent stage executors to trigger such execution. In a row of a batch queue, *id* is the batch’s identifier, *start* is the id of the to-be-processed query, and *num* is the number of to-be-processed queries in the batch.

The stage executor pulls a batch from its batch queue, and processes the queries accordingly. For instance, $executor_1$ in Figure 8(a) will run query 0 to query 1 ($start = 0, num = 2$) in the current batch. Once the execution completes, the stage executor updates the row of the processed batch in batch table, and pushes an item into the next batch queue.

5.2.2 Handling Meta Operations

Based on batch table and batch queues, Figure 8 shows an example that three meta operations are performed on the same batch, $batch_0$. In the example, we first *new* the batch $batch_0$ with 2 queries (Figure 8(a)); Then, we *stretch* the batch $batch_0$ with another 2 new queries while it is already processed by $executor_2$ (Figure 8(b)); Last, we *split* the batch $batch_0$ into 2 smaller batches at the third stage (Figure 8(c)).

Handling new. Once $batch_0$ is received, ① a *new* operation is instructed, and a new item is added to the batch table. Meanwhile, an item is pushed to the first stage executor’s batch queue ($BatchQueue_1$). ② the executor of the first stage (hereinafter, we refer to the executor of $stage_i$ as $executor_i$) is notified to obtain the item and perform the execution. Once $executor_1$ completes, it ③ updates $status_{map}$ in the batch table, and ④ pushes an item into $BatchQueue_2$.

Handling stretch. ① As 2 new queries are added into $batch_0$ with the *stretch* operation at stage 2, bs of $batch_0$ in the batch table is changed from 2 to 4. Because $batch_0$ is *stretched* to 4 queries while being processed by $executor_2$, the executor does not push an item into $BatchQueue_3$, but only updates $status_{map}$. ② A new item (a batch with $id = 0, start = 2, num = 2$) is pushed into $BatchQueue_1$, so that the newly added queries can catch up with the progress of the current batch. ③ Once the new queries catch up, $executor_2$ updates $status_{map}$ and ④ pushes a merged batch into $BatchQueue_3$ (a batch with $start = 0$ and $num = 4$). The *stretch* operation is only performed on the latest batch stored in the batch table.

Handling split. When $batch_0$ goes to stage 3, ① $executor_3$ pulls $batch_0$ from the batch queue and runs it with $bs = 4$. After that, $executor_3$ is instructed with a *split* operation. ② The original batch is split into two batches in the batch table. ③ Lastly, the generated batches are all pushed into $BatchQueue_4$ one by one. The *split* operation can happen when a new batch of queries comes or during the execution of an ongoing batch.

The meta operations co-exist without conflict. Although *split* happens at any stage, a potential *split* operation can be known when generating the batch by *new* and *stretch*. We disable further *stretch* for the batch that we perceive *split* operation. The batches generated by *split* inherit this property.

6 Managing Stage Executors

In this section, we present the way the stage executors are organized to process the batches.

Figure 9: (a) Stage executor processes batches with multiple buffers; (b) Traditional state transition diagram of $executor_i$.

6.1 Processing with Multiple Buffers

With multiple stages, the executors of adjacent stages have “producer-consumer” relationships. In this case, there are data hazards on the buffers between stages.

Figure 9(a) shows the way the stages are connected. Multiple buffers are used because multiple batches may be active concurrently. An executor needs to obtain an input-output buffer pair before it can process a batch. The output buffer of $executor_i$ is also the input buffer of $executor_{i+1}$. If $executor_i$ is using a buffer pair bp , there is a Write-After-Read hazard on bp ’s input buffer, as $executor_{i-1}$ may write to the very buffer before $executor_i$ reads the data. Similarly, there is a Read-After-Write hazard on bp ’s output buffer.

For ensuring the execution correctness, a buffer can be in the *available*, *invalid*, *inreading*, or *inwriting* state. A buffer is *invalid* when it cannot be used as an input buffer currently. It is *inreading/inwriting* when it is used as an input/output buffer for a batch’s execution. It is *available* when it is not used by any executor. Figure 9(a) shows an example that $executor_i$ is using the first buffer pair bp_1 , and $executor_{i+1}$ is using the output buffer of the second buffer pair bp_2 as its input.

- The input buffer of bp_1 is in *inreading* state and the output buffer of bp_1 is in *inwriting* state.
- The input buffer of bp_2 is in *invalid* state because the output buffer of bp_2 is currently used by $executor_{i+1}$ for execution. $executor_i$ cannot use it to run a new batch.
- The third buffer pair are both in *available* states.

A stage executor can run a batch only when it successfully obtains a legitimate buffer pair. A buffer pair is legitimate, when both the input and output buffer are *available*, or the input buffer is *available* but the output buffer is *invalid*. This is because an *invalid* buffer can be used as the output buffer of an executor, but cannot be used as the input buffer of the later stages.

6.2 State Transition of the Executors

Based on the buffer states, there are some traditional ways to create a naive state transition rule for the stage executors to run as a pipeline. For instance, a stage executor can be in three states: *active*, *working*, *inactive*, and the states change

Figure 10: (a) Inconsistency of buffer pairs; (b) Fail to run in serial manner with single buffer pair.

according to the diagram in Figure 9(b).

However, these traditional state transition rules assume all the stage executors use the buffer pairs in some fixed order (e.g., ID order). **While the traditional rules work well for the single-entry single-exit pipeline, they will encounter the validity problem for the multi-entry multi-exit pipeline.**

Specifically, the requirement of meta operations *stretch* and *split* invalids the above traditional transition rules. *stretch* merges the outputs from different buffer pairs into a single one, and *split* may split the output into multiple buffer pairs. That means some stage executors may use more buffer pairs than others, and the access order of these buffer pairs is scrambled. As shown in Figure 10(a), while $executor_i$ is using bp_3 for execution, $executor_i$ is active with bp_2 . Such inconsistency invalidates the traditional state transition rule.

On the other hand, stage executors need to run multiple batches in parallel for load diversity and input diversity, and run batches sequentially for operator diversity (Section 3). The traditional transition rule supports parallel manner well but fails to satisfy the requirement of serial manner. As shown in Figure 10(b), the stage executors always run in parallel even if only one buffer pair is used. Because $executor_i$ legitimizes bp_1 for $executor_{i-1}$ after it completes the execution, $executor_{i-1}$ is active with bp_1 , when $executor_{i+1}$ is in working state with bp_1 . In this case, $executor_{i-1}$ is able to run in parallel with $executor_{i+1}$.

We therefore design the transition diagram in Figure 11. Suppose $executor_i$ is in the active state with a legitimate buffer pair currently. **Once $executor_i$ pulls out a batch with buffer pair bp_j , it checks the states of bp_j instead of starting execution directly.** If bp_j is legitimate, $executor_i$ enters working state and starts the execution. Meanwhile, the input buffer and output buffer of bp_j enter in-reading and in-writing states respectively. **If bp_j is not legitimate, $executor_i$ enters checking state, waiting for bp_j to become legitimate.** When $executor_i$ completes a batch with bp_j , the input buffer of bp_j enters invalid state, and the output buffer of bp_j restores to its previous state. If $executor_i$ gets another legitimate buffer pair, it enters active state. Otherwise, it enters inactive state. The last stage executor always re-enters active state directly.

Note that, after $executor_i$ re-enters active state with any legitimate buffer pair, $executor_i$ updates the j -th input buffer of $executor_{i-1}$ to available state. It denotes that

Figure 11: State transition diagram of $executor_i$ in DVABatch.

$executor_{i-1}$ can use bp_j now.

In short, we first add a *checking* state for the stage executor to guarantee using the right buffer pair. We also move the buffer pair legitimation for $executor_{i-1}$ after $executor_i$ enters active state. In this case, while DVABatch only configures one available buffer pair, all stage executors stay in inactive state until the current batch is executed by the last stage executor. Therefore, the serial work manner is supported.

6.3 Implementing the Transition Diagram

We implement the transition diagram of stage executors through CUDA synchronization APIs for the correctness guarantee. Each stage executor is bound to a CUDA *stream* for parallel execution, and each buffer pair is equipped with a CUDA *event* to enforce its legitimation. Upon finishing launching the CUDA functions with a buffer pair, the stage executor performs a *record* operation with the buffer pair's *event* on its *stream*. After that, if the corresponding buffer pair is legitimate, the other stage executor requires synchronization with the *event* on its own *stream* before using the buffer pair to avoid data hazards on GPUs. In order to deliver the best performance, the stage executor calls *cudaStreamWaitEvent* instead of explicit synchronizations on the host side.

7 Scheduling Policies of Serving Diversities

In this section, we present the way to deal with the serving diversities using DVABatch. First of all, we identify the existing diversities in a DNN model and divide the model into several stages. Then, at runtime, DVABatch is able to schedule the batches of the model appropriately.

7.1 Identifying Diversities and Slicing Models

For a DNN service, We identify the existing diversities and slice the model offline, by checking the input patterns and profiling the model with several different batch sizes (e.g., 1, 2, 4, 8, 16, 32, 64) using the tools provided by Nvidia [7, 8].

All the models are considered to have load diversities, as the load pattern is often determined by the end-users. The model that accepts inputs with different shapes (dynamic dimension

```

1 //stage executors run within a while loop
2 void Run():
3     Batch& inBatch = BatchQueue.Get();
4     CheckBuffer(inBatch); //Check buffer pair
5     Execute(inBatch);
6     Schedule(inBatch, outBatches);
7     for (auto& batch : outBatches):
8         nextBatchQueue.Push(batch)
9         getBuffer(); //get legitimate buffer pair
10        updatePrExecutor(); //update preceding executor
11 //call Schedule to perform meta operations
12 void Schedule(Batch& inBatch, vector<Batch>&
13 outBatches):
14     BatchTable.update(inBatch);
15     if userDefined1:
16         outBatches = BatchTable.New(inBatch);
17     else if userDefined2:
18         outBatches = BatchTable.Stretch(inBatch);
19     else if userDefined3:
20         outBatches = BatchTable.Split(inBatch);
21     else:
22         outBatches.Copy(inBatch);

```

Figure 12: Creating scheduling policies with meta operations.

except for batch size) has input diversity. During the profiling, we obtain the preferred batch size of each operator, as shown in Figure 5. When the operators have different preferred batch sizes, the model has operator diversity.

Once the diversities are identified, DVABatch slices the DNN models into stages. If a model is sliced into N_{st} stages, the operators are time-evenly assigned to the stages in the topological order for simplicity. It is non-trivial to theoretically identify the optimal N_{st} . If N_{st} is too small, the opportunity for batch scheduling is limited. Otherwise, if N_{st} is too large, the fine-grained stages incur heavy scheduling overhead. Moreover, unlike Pipedream [48], the model slicing in DVABatch can also be tight with diversities. E.g., DVABatch considers the operators’ preferred batch size and slices a model at specific operators for operator diversity. We currently determine the optimal N_{st} through profiling. It can be done in 10 minutes (8 tries) for emerging benchmarks on each type of GPU. It is worth noting that the model slicing does not conflict with the compilation techniques like kernel fusion [64]. We slice the model after it is already optimized by the DNN compilers.

7.2 Defining Policies with Meta Operations

Figure 12 shows the interface provided by DVABatch to define batch scheduling policies with the meta operations. Each stage executor runs in a while loop (Line 2-11) to execute the batches (Line 3, 6, 8 stated in Section 5, Line 4, 5, 9, 11 stated in Section 6). The stage executor calls `Schedule()` to schedule the batches at Line 5. Inside `Schedule()`, the stage executor updates the batch table, and performs meta operations if user-defined conditions are satisfied accordingly.

Figure 13: Scheduling according to the preferred batch size.

The policy is implemented outside user models, and does not require modification to the model. We then show the policies defined to handle the three diversities.

Policy I for input diversity. The input diversity requires running multiple small batches in parallel. While accepting a batch of queries from the upper-level serving systems, DVAScheduler clusters the queries according to their input sizes. The queries with similar input sizes are batched and padded to the same size for processing. DVABatch processes these batches in parallel for better utilizing the hardware parallelism. As the batches run in parallel, the scheduler prefers a smaller batch time window instead of generating the batches as large as possible. Practically, we set the batch time window to be the duration of the first stage with the largest allowed batch size bs_{max} . The number of active queries in the software pipeline does not exceed bs_{max} .

Policy II for operator diversity. Figure 13 shows the way DVABatch schedules the next stage when a stage completes. Assume the current batch size (denoted by bs) is 64 for $stage_1$ in the figure. The DVAScheduler compares the processing time of all the remaining stages with different batch sizes. Let T_{remain_i} represent the time needed when batch size is i . In Figure 13, if $T_{remain_64} \geq 2 \times T_{remain_32}$, the large batch is split into two batches with $bs = 32$. The two smaller batches run in the serial manner, as the hardware is already fully utilized with $bs = 32$. The duration of each stage with the different batch sizes is already profiled offline.

Policy III for load diversity. At load diversity, a latter batch should be able to join a previous batch, if it does not result in the QoS violation of the previous batch. In this case, DVABatch uses `stretch` operation to enlarge the batch at runtime. We set a time threshold T_{comp_wait} to eliminate the possible QoS violation. If a batch is already processed for T_{comp_wait} , no `stretch` operation is allowed on this batch.

Load diversity is widespread. For input diversity, as the new batches are allowed to enter the software pipeline independently, it already resolves the load diversity. For operator diversity, Policy III and Policy II work together due to the co-existence of `stretch` and `split`, as stated in Section 5.2.2.

8 Evaluation of DVABatch

In this section, we evaluate the performance of DVABatch in reducing the latencies of DNN services.

Figure 14: Average latencies of six DNN services at low, medium, high load with ZeroBatch, DelayBatch, and DVABatch.

Table 1: Evaluation specifications.

Hardware	CPU: Intel Xeon E5-2620, GPU: Nvidia Titan RTX
OS & Driver	Ubuntu: 18.04.6 (kernel 4.15.0); GPU Driver: 470.57
Software	CUDA: 11.4; TensorRT: 8.03; Triton 21.10
Benchmarks	Unet [56]; LinkNet [16]; BertBase; BertLarge [27]; VGG19 [57]; ResNet152 [37]
Dataset	GLUE [59]

8.1 Experiment Setup

We implement the prototype of DVABatch with 5k lines of C++ codes as a runtime backend for Triton [9], a DNN serving system from Nvidia. As the latency of a DNN model/operator varies with DNN frameworks [14, 19, 20, 39, 52] or compilers, we use TensorRT [13] to provide SOTA operator performance. DVABatch relies on Triton to batch the accepted queries. However, Triton sends the batched queries to DVABatch in an asynchronous fashion, and DVABatch enables the multi-entry multi-exit scheme for it. We also modify the model loading logic to load multiple stages (each stage is a sub-model) for a single DNN service.

Table 1 lists the setups of the experiments. We perform all the experiments on a machine that equips an Nvidia Turing Titan RTX (Titan RTX) GPU. We use six representative image processing and natural language processing DNN models as the benchmarks. All models experience load diversity. Besides, *BertBase* and *BertLarge* show input diversity, *LinkNet* and *Unet* show operator diversity.

We compare DVABatch with two batching policies: the default scheduling policy with batch time window $T_{window} = 0$ (ZeroBatch for short), and one with an optimized T_{window} (DelayBatch for short). The optimized T_{window} of DelayBatch is tuned for supporting the max peak throughput [2]. In all experiments, the maximum allowed batch size bs_{max} is 64 and the QoS target is 200ms to support a high load. Current production DNN serving systems (e.g., Triton [9], Clipper [23], TFServing [51]) all use the above batch time window and batch-size-based batching mechanism [22].

The load used for evaluation is generated using the method in MLperf [55], and the arrival time pattern satisfies the Poisson distribution [55]. We obtain the performance of the benchmarks at low, medium, and high loads. For a benchmark, we use 1/4, 3/5, 9/10 of its peak throughput as low load, medium

load, high load. The three load levels are obtained by feeding each benchmark with a stepping load [3] in Section 8.3. For BertBase and BertLarge, we use the workloads in GLUE [59] to simulate the sequence length distributions of real-world services. By default, the RTE workload of GLUE is used for evaluating BertBase and BertLarge. Other workloads are evaluated in Section 8.4.

8.2 Reducing Average Latency

Figure 14 shows the average latencies of all benchmarks with ZeroBatch, DelayBatch, and DVABatch at low, medium, high loads. DVABatch reduces the average latency of the benchmarks by 16.1%/39.0%/57.7% compared with ZeroBatch, 35.4%/47.3%/48.5% compared with DelayBatch on average at low, medium, and high loads, respectively. DVABatch reduces the average latency in all cases with the multi-entry multi-exit batching scheme. Meanwhile, DelayBatch shows lower average latency at high load compared with ZeroBatch, and ZeroBatch achieves lower latencies at low load. It is because DelayBatch has an optimized batch time window for peak throughput, and ZeroBatch does not introduce latency due to the batch time window at low load.

BertBase and BertLarge show both input diversity and load diversity. The latency reduction of DVABatch is comparatively high at all loads compared with the two baselines. This is because DVABatch perceives the input diversity, and splits the large batches into small batches to reduce the extra computation due to padding in all cases. DVABatch processes the small batches in the form of a software pipeline to accelerate the computation, which further reduces the latency.

LinkNet and Unet show both operator diversity and load diversity. At low load, DVABatch and ZeroBatch reduce latency due to the smaller batch window, compared with DelayBatch. At high load, DVABatch performs much better than ZeroBatch and DelayBatch. When the load is high, the batch received from the upper-level serving system has more queries. There is a higher opportunity that DVABatch can split a large batch into batches with the preferred batch size. Operators do not use a batch size larger than their preferred batch sizes. Some queries can exit the batching early with shorter latency.

VGG19 and ResNet152 only show load diversity. At low load, DVABatch achieves equivalent latency performance compared with ZeroBatch, and reduces the average latency

Figure 15: Latencies and peak throughput of DelayBatch and DVABatch fed with stepping load.

Figure 16: 99%-ile latencies of six DNN services at three loads with ZeroBatch, DelayBatch, and DVABatch.

compared with DelayBatch. This is reasonable because DVABatch and the baselines are all processing the queries with $bs = 1$ in this case. At high load, DVABatch and DelayBatch both perform better than ZeroBatch. The latency reduction benefits from the reasonable batching parameters. With DVABatch, early arrived queries are executed in advance, and latter queries are also considered to be merged with the former batch. Then, their response latencies are all reduced.

Comparison with Limited Solutions. While we do not compare DVABatch with BatchMaker [31] and LazyBatch [22] directly in this section, DVABatch outperforms them for the evaluated benchmarks. BatchMaker cannot handle input diversity for BertBase and BertLarge, as it is RNN-specific for input diversity and Bert-like models are not based on RNN cells. In this case, BatchMaker performs the same as the two baselines presented in Figure 14. LazyBatch only handles load diversity and performs per-operator scheduling. DVABatch degenerates to LazyBatch while evaluating VGG19 and ResNet152, if we slice the model into the granularity of operators and only enable *stretch* operation. However, experiments in Section 8.7 indicates this incurs severe performance degradation. Meanwhile, per-operator model slicing for LazyBatch cannot be implemented with TensorRT, as it is against the compilation techniques like kernel fusion. Compared with them, DVABatch achieves better performance for all evaluated benchmarks by promising a multi-entry multi-exit batch scheme with minimal runtime scheduling overhead.

Comparison of Tail Latency. Other than the average latency, Figure 16 shows the 99% latencies of all benchmarks. DVABatch reduces the 99%-ile latencies by 16.9%/27.4%/53.7% compared with ZeroBatch, and 45.2%/45.1%/29.2% compared with DelayBatch. In terms of tail latency, DelayBatch has better performance at high

load, ZeroBatch performs better than DelayBatch at low load. The multi-entry multi-exit design allows DVABatch to maintain consistent low tail latency at varying loads.

8.3 Robustness at Stepping Load

In this experiment, we evaluate the robustness of DVABatch in handling dynamic loads. Similar to prior work [3, 40], we use stepping load to obtain the peak load supported by DVABatch. We only compare DVABatch with DelayBatch in the following section, as ZeroBatch always shows poor performance at high load.

The stepping load is generated as follows. At first, the load is low (66 queries per second), and we gradually increase the load for every 2000 queries. After 30,000 queries, the load is increased to 4000 queries per second (QPS). We use the corresponding highest load under the constrain, that the latency is shorter than the QoS target $200ms$, as the peak throughput.

Figure 15 shows the latencies of the benchmarks at stepping loads. In each subfigure, the x -axis represents the query ID in the issuing order. The left y -axis represents the latency of each query, and the right y -axis represents the load.

As observed, all the benchmarks have lower latency with DVABatch than with DelayBatch in all cases. For BertBase and BertLarge, DVABatch improves the peak throughput, because it eliminates the computation wasted for the padded inputs. On average, DVABatch increases 46.81% peak throughput for BertBase, $1.37\times$ peak throughput for BertLarge. For operator diversity and load diversity, DVABatch has not impact on the computation. In that case, the peak throughput of DVABatch is limited by the hardware capacity. DVABatch maintains the same peak throughput as DelayBatch.

8.4 Impact of Input Distributions

The effectiveness of DVABatch for input diversities is affected by how different the inputs are. In this experiment, we show the performance of DVABatch when different workloads in GLUE [59] are used as the inputs of Bert and BertLarge. We use the same stepping load in Section 8.3.

Figure 17 shows the supported peak loads of BertBase and BertLarge with different workloads in GLUE. As observed,

Figure 17: Peak load supported by DVABatch for BertBase/BertLarge with different workloads.

Figure 18: Comparison of *split* operation for LinkNet/Unet.

DVABatch improves the peak throughput by 46.8% for BertBase, $1.37\times$ for BertLarge compared with DelayBatch on average. DVABatch brings different throughput improvements for different datasets. The more imbalanced the sequence distribution is, the higher the workload’s input diversity is.

In general, DVABatch works better for workloads with higher input diversity, as DVABatch can eliminate more unnecessary padding. For instance, while the input diversity of SST-2 is higher than that of MRPC, the performance gap between DelayBatch and DVABatch for SST-2 workload is much larger than that for MRPC. The more imbalanced the sequence distribution is, the higher throughput improvement DVABatch achieves.

8.5 Effectiveness of *split* operation

In this experiment, we evaluate the effectiveness of *split* for load diversity. Figure 18 shows the average latencies of LinkNet and Unet with DVABatch, DVABatch-*split*, and DelayBatch. DVABatch-*split* is a variant of DVABatch that only *split* is enabled in DVABatch.

As shown, DVABatch-*split* reduces the latencies most at high load for LinkNet and Unet. Compared with DelayBatch, DVABatch-*split* reduces average latency by 15.0% at high load. This is because DVABatch-*split* rarely has the choice to split a batch at low and medium loads.

We can also find that DVABatch-*split* brings different improvements for the two DNN services. The difference originates from the operator diversity and load diversity. We look into the processing details and find that DVABatch-*split* generates larger batches for LinkNet than Unet. Half of the batches generated for LinkNet are with $bs > 50$ and Unet are with $bs > 30$. In this case, DVABatch-*split* has more chances to identify the preferred batch size for LinkNet than Unet.

Figure 19: The average latencies of DVABatch with different number of buffer pairs under peak load.

Figure 20: The average latencies and peak throughput of the benchmarks when sliced into different numbers of stages.

8.6 Impacts of the Number of Buffer Pairs

This experiment evaluates the impact of the number of buffer pairs used in DVABatch. Figure 19 presents the average latencies of DVABatch with different numbers of buffer pairs at the peak load. As shown, the average latencies are always the lowest with two buffer pairs for all benchmarks.

Therefore, two buffer pairs are already enough to preserve the execution validity and enable the work manner switch. More buffer pairs degrade the performance. Each buffer pair uses a set of CUDA [50] synchronization data structures to guarantee scheduling correctness. When two buffer pairs are used, DVABatch only needs to switch between them. However, managing many buffer pairs requires extra FIFO queues to transmit these data structures. Too many buffer pairs incur a high scheduling overhead.

8.7 Impacts of the Stage Numbers

In this experiment, we investigate the number of stages on the performance of DVABatch. We use BertBase, LinkNet, and ResNet152 as the representative benchmarks with the three types of diversities, respectively, due to the limited space.

Figure 20 shows the throughputs and average latencies of the benchmarks with different stage numbers. In the figure, the left y-axis represents the peak throughput and the right y-axis represents the corresponding average latencies.

As observed, the best stage number is 2 for BertBase, 4 for LinkNet and ResNet152 in terms of latency and throughput, respectively. For BertBase, the accepted batch is *split* into two batches in most cases. DVABatch avoids generating too many small batches to reduce scheduling overhead. Therefore, 2 stages are enough for BertBase. LinkNet and ResNet152 require more stages to enable *stretch* and *split*. If the number of stages is too large (e.g., 20), managing queues between stages incur a high overhead for all benchmarks.

Figure 21: Close-loop latencies of ZeroBatch and DVABatch.

8.8 Scheduling Overhead

As mentioned in Section 7.1, the profiling for model slicing needs to be done for a single time on each type of target GPU, and completed in 10 minutes. To measure the runtime overhead introduced by DVABatch, we run the six benchmarks in a close loop, and compare the end-to-end latencies of the queries with ZeroBatch. In this experiment, we set the batch time window of DVABatch to 0. Figure 21 shows the experimental results.

As observed, the average latency overhead is 0.29ms, and DVABatch achieves almost the same latency compared with ZeroBatch. DVABatch has a low overhead because it does not interrupt the execution of stage executors at the extremely low load, and the two executors overlap the overhead of CPU-GPU synchronization for each stage. As depicted in Figure 12, *Line5* is usually an asynchronous operation on GPU and the scheduling operation in *Line4* is overlapped by the execution. Moreover, the model slicing in DVABatch does not invalidate the optimization of DNN compilers.

DVABatch needs extra global memory (buffer pairs) to avoid read-write hazards while maintaining the software pipeline, which takes 200 MB of space on average.

9 Discussion

9.1 Implication for Future DNN Inference

Omnipresent Diversity. Readers can find that all the mentioned diversities are caused by dynamic attributes (dynamic input, operator, load). Existing DNNs may have a dynamic architecture in depth, width, and routing [32,33,45,53,58,60]. As more dynamic attributes emerge, diversity spreads across new DNNs.

Intra-model Scheduling. DVABatch performs fine-grained scheduling within the DNN models. As DNNs grow larger and show more diversity, the execution of DNNs cannot be treated as a single function call. Large models [15,54] like Bert are being deployed on multiple machines. MoE [42] models activate different paths for different inputs. Intra-model scheduling is a trend for future DNN inference.

9.2 Flexibility

DVABatch is flexible to other diversities. For instance., in the services with early-exiting and layer-skip[42,53,55] models,

the inference returns at early stages or skips some stages when the intermediate results satisfy a predefined threshold. Users can modify the user-defined condition in DVABatch to check the intermediate results during batch inference. If some queries meet the predefined threshold, users then utilize the *split* operation for them to exit the ongoing batch without executing the rest layers. Then, the layer skip mechanism is implemented by the holistic design of multi-entry and multi-exit in DVABatch.

9.3 Limitations

DVABatch targets on efficient batch processing of models with diversities. It performs the same as the traditional batch policy for the models without any diversity. The CV models commonly crop the images to the same size before processing. Then input diversity does not exist in these models. Because the same blocks share the favored batch size, models with repetitive blocks like ResNet-50 and Bert do not show operator diversity. Load diversity also vanishes when the queries arrive with a uniform load. In these cases, DVABatch has no opportunity to achieve a better batch scheme. But as stated in Section 9.1, more and more model are showing diversities due to dynamic attributes. As long as a more efficient batch scheme is available for the diversities, DVABatch takes effect through its holistic design, even on platforms like CPUs [61].

10 Conclusion

In this work, we utilize the multi-entry multi-exit scheme to resolve the long latency problem due to serving diversity in existing DNN serving systems. We dig out the root inefficiency of the existing batching policy when facing serving diversities. Therefore, we propose DVABatch runtime batching system. Firstly, DVABatch divides the DNN models into stages and abstracts three meta operations to support the multi-entry multi-exit scheme. Secondly, DVABatch introduces a state transition diagram to manage the execution of stages. And then, DVABatch conducts diversity-aware batch scheduling with the meta operations for the incoming batch of queries. Overall, DVABatch achieves 46.4% average latency reduction and up to $2.12\times$ throughput improvement for involved diversities, compared with state-of-art solutions.

Abstract

As machine learning (ML) techniques are applied to a widening range of applications, high throughput ML inference serving has become critical for online services. Such ML inference servers with multiple GPUs pose new challenges in the scheduler design. First, they must provide a bounded latency for each request to support a consistent service-level objective (SLO). Second, they must be able to serve multiple heterogeneous ML models in a system, as cloud-based consolidation improves system utilization. To address the two requirements of ML inference servers, this paper proposes a new inference scheduling framework for multi-model ML inference servers. The paper shows that with SLO constraints, GPUs with growing parallelism are not fully utilized for ML inference tasks. To maximize the resource efficiency of GPUs, a key mechanism proposed in this paper is to exploit hardware support for spatial partitioning of GPU resources. With spatio-temporal sharing, a new abstraction layer of GPU resources is created with configurable GPU resources. The scheduler assigns requests to virtual GPUs, called *gpulets*, with the most effective amount of resources. The scheduler explores the three-dimensional search space with different batch sizes, temporal sharing, and spatial sharing efficiently. To minimize the cost for cloud-based inference servers, the framework auto-scales the required number of GPUs for a given workload. To consider the potential interference overheads when two ML tasks are running concurrently by spatially sharing a GPU, the scheduling decision is made with an interference prediction model. Our prototype implementation proves that the proposed spatio-temporal scheduling enhances throughput by 61.7% on average compared to the prior temporal scheduler, while satisfying SLOs.

1 Introduction

The wide adoption of machine learning (ML) techniques poses a new challenge in server system designs. Traditional server systems have been optimized for CPU-based computa-

tion for many decades. However, the regular and ample parallelism in widely-used deep learning algorithms can exploit abundant parallel execution units in GPUs. Powerful GPUs have been facilitating the training computation of deep learning models, and the inference computation is also moving to the GPU-based servers due to the increasing computational requirements of evolving deep learning models with deeper layers [11, 38, 45].

However, the GPU-based inference servers must address different challenges from the batch-oriented processing in ML training servers. First, inference queries must be served within a bounded time to satisfy service-level objectives (SLOs). Therefore, not only the overall throughput is important, but bounded response latencies for processing inference queries are also critical to maintain consistent service quality [15, 38, 45]. Second, to improve the utilization of server resources, many heterogeneous models are served by consolidated cloud-based systems. As even a single service can include multiple heterogeneous ML models [38], multiple models with different purposes coexist in a system. The heterogeneity of ML models raises scheduling challenges to map concurrent requests of heterogeneous models to multiple GPUs. Incoming queries for different ML models with their own computational requirements, must be properly routed to the GPUs to meet the SLO, while improving the overall throughput. In addition, the number of required GPU nodes must be dynamically adjusted to reduce the cost of serving inferences for cloud-based systems.

While the demands for GPU-based ML inferences have been growing, the computational capability of GPUs with many parallel execution units has been improving precipitously. Such ample parallel execution units combined with increasing GPU memory capacity allow multiple ML models to be served by a single GPU. In a prior study [38], more than one model can be mapped to a GPU, as long as the GPU can provide the execution throughput to satisfy the required SLO. However, unlike CPUs which allow fine-grained time sharing with efficient preemption, GPUs perform only coarse-grained kernel-granularity context switches. Such coarse-grained time

sharing incurs inefficient utilization of enormous computational capability of GPUs, as a single batch of an ML inference may not fill the entire GPU execution units.

However, the recent advancement of GPU architecture opens a new opportunity to better utilize the abundant execution resources of GPUs. Recent GPUs support an efficient spatial partitioning of GPUs resources (called MPS mechanism in NVIDIA GPUs [12]). The partitioning mechanism supports the computational resources of a GPU to be divided to run different contexts simultaneously. Such a unique spatial partitioning mechanism can augment the limited coarse-grained time sharing mechanism, as the GPU resource can be spatially partitioned to serve multiple ML tasks concurrently. This unique spatial and coarse-grained temporal resource allocation in GPUs calls for a novel abstraction to represent partitioned GPUs and a new scheduling framework targeting high throughput ML servers under SLO constraints.

To address the emerging challenges of ML scheduling in partitionable GPUs, this paper proposes a new abstraction for GPUs called *gpulet*, which can create multiple virtual GPUs out of a single physical GPU with spatial and temporal partitioning. The new abstraction can avoid the inefficiency of coarse-grained time sharing by creating and assigning the most efficient GPU share for a given ML model. Such a new abstraction of GPU resources allows latencies of ML execution to be predictable even when multiple models are concurrently running in a GPU, while achieving improved GPU utilization.

Based on the *gpulet* concept, we propose an ML inference framework prototyped with the PyTorch interface. It can serve concurrent heterogeneous ML models in multi-GPU environments with auto-scaling support. Figure 1 illustrates the extended search space of our scheduling mechanism. Our framework aims to find a global optimum by considering both temporal and spatial scheduling for enhanced performance. The search space for scheduling becomes three-dimensional with spatial and temporal shares of GPU resources in addition to batch size adjustment, unlike the prior work with two-dimensional searches [17, 38]. In the experimental results for SLO-preserved throughput presented by Figure 13, time scheduling and spatial scheduling yield on average 1,023 and 1,076 requests-per-second (RPS), respectively. The spatio-temporal scheduling significantly improves the SLO-preserved throughput to 1,584 RPS.

For each ML model, its computational characteristics are measured and registered to the framework. Based on the profiled information of each ML model, the scheduler routes requests to where the throughput would be maximized while satisfying the SLO constraints. One necessary mechanism for spatial and temporal partitioning of GPU shares is to identify the potential performance overheads when two models are concurrently running on a GPU. Our scheduling framework incorporates the interference estimation mechanism to consider the effect of concurrent execution.

Figure 1: Multi-dimensional search space for providing globally optimal performance.

We evaluated the proposed ML inference framework on server systems with four and eight GPUs. The evaluation with four GPUs shows that the proposed scheduling technique with *gpulets* can improve the throughput with SLO constraints for seven ML inference scenarios by 61.7%, compared to the one without partitioning GPU resources.

This study explores a new resource provisioning space of GPUs for machine learning inference serving. The contributions of this paper are as follows:

- It proposes a new GPU abstraction named *gpulet*, to support virtual GPUs with partitions of resources out of physical GPUs. It allows heterogeneous ML models to be mapped to multiple *gpulets* in the most cost-effective way.
- It proposes a scheduling framework for *gpulets*, which searches the most cost-effective schedule by multi-dimensional search considering batch sizes, temporal sharing, and spatial sharing. It adjusts the number of required GPUs for a given set of heterogeneous models, supporting auto-scaling.
- For accurate performance prediction, the scheduling framework considers the effect of interference among *gpulets* for concurrent ML inference execution on partitions of a single GPU.

The rest of the paper is organized as follows. Section 2 describes the background of ML computation on GPUs and prior scheduling techniques. Section 3 presents the motivational analysis of heterogeneous ML tasks on multiple GPUs. Section 4 proposes our design to efficiently utilize GPU resources for heterogeneous ML tasks, and Section 5 presents experimental results. Section 6 presents related work, and Section 7 concludes the paper.

2 Background

2.1 Batch-Aware ML Inference Serving

As high throughput ML inference serving has become widely required for online services, an increasing number of service vendors are adopting GPUs [9, 13, 15, 24, 25, 32, 38, 41, 42, 45, 46] or even hardware accelerators such as TPUs [3,

7, 18, 19]. While GPU-based systems offer low latency for ML inference, obtaining high utilization is a challenging task, unlike ML training. The key difference between training and inference in terms of GPU utilization is the suitability for *batching*. For training, since the input data is ready, the system can batch a large number of input data, which allows GPUs to effectively leverage the massive parallelism. On the contrary, the ML inference server underutilizes GPUs as it is an on-demand system where inference tasks can be assigned to the compute engines once the requests arrive.

One scheduling option is to wait until the desired number of inference requests to be accumulated and then to initiate the execution for the large batch. However, the applications cannot indefinitely wait to collect a batch, due to the service-level objective (SLO) requirements. Prior work [15, 36, 38, 45] have adopted *adaptive batching*, where a batch size is decided adaptively with estimated times to build and execute a batch of the selected size. By using the profiled latencies and observed incoming rates, the effective time for a batch is estimated, and adaptive batching chooses the maximum batch size that does not violate the SLO.

2.2 Temporal Scheduling for ML on GPUs

Temporal scheduling allows sharing of a GPU where each inference takes up the entire GPU resource one at a time with time sharing. With multiple models with different execution characteristics and SLO requirements, guaranteeing SLO is challenging for the temporal scheduling of the heterogeneous models. The ML inference scheduling problem on GPU-based multi-tenant serving systems resembles the traditional bin packing problem. The capacity constraints of bins are the available resource on the GPUs, and an item weight is the necessary GPU resource to handle a given inference request.

An inspiring prior work, Nexus [38], has tackled this problem and proposed a novel variant of bin packing algorithm, namely *squishy bin packing* (SBP). The term, *squishy*, is originated from the property that the required resource for processing a task (i.e., item) and its latency vary as the batch size changes. The SBP algorithm takes a set of models as input, each of which comes with a given request rate. It assigns the inferences tasks across GPUs with a selected batch size, and may map multiple models to a single GPU with time sharing, if one task does not fully utilize a GPU.

Figure 2 illustrates an example of how the SBP algorithm is applied. In this scenario, the server handles two models, A and B, by building and executing the per-model batches simultaneously. The SLO violation occurs when the summation of batch building time and batch execution time exceeds the SLOs. Therefore, the SBP algorithm heuristically finds a maximum possible duration for batch building, called *duty cycle*, and the corresponding batch sizes in such a way that all the consolidated models would not violate the SLOs. The SBP algorithm repeats the duty cycles in a pipelined fashion

Figure 2: Round-based execution of SBP for two models consolidated on a GPU. *Duty cycle* is the interval for a round.

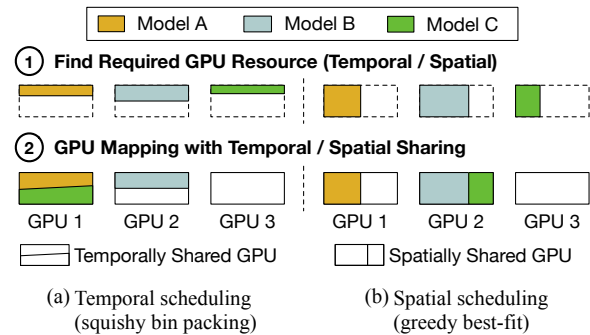

Figure 3: Temporal scheduling (SBP) vs. spatial scheduling (greedy best-fit partitioning).

until there is a significant change in the request rates, which would require rescheduling.

Baseline temporal scheduling algorithm: We use SBP as our baseline temporal sharing algorithm. Figure 3 (a) presents temporal sharing with batch adjustment by the SBP algorithm. The algorithm finds individual duty cycles and batch sizes for ML models with given request rates, and maps them to a minimum number of GPUs with temporal sharing. To map ML models to GPUs, it compares all eligible pairwise combinations. If a pair is eligible for temporal sharing, the pair will share one GPU and the batch size is further adjusted to ensure the SLO when both tasks are interleaved. The process continues until no more pairs can be temporally shared.

2.3 Spatial Sharing on GPU

Spatial sharing is a resource partitioning technique that splits a GPU resource into multiple pieces, as recent server-scale GPUs offer hardware-supported spatial sharing features to users. While temporal scheduling may potentially cause a GPU underutilization problem when the batch size is not sufficiently large to leverage all resources on a GPU, spatial sharing improves GPU utilization allowing high throughput without SLO violation.

With these resource partitioning features, the users can split the given resource of a GPU into a set of GPU *partitions*, each of which is assigned to a fraction of GPU resource¹. Note

¹In this paper, we only use the computation resource partitioning technique since we have at our disposal 2080 Ti GPUs, the microarchitecture of

that GPU *partitioning* is available on both NVIDIA MPS and Multi-Instance GPU (MIG), which has been featured since Ampere architecture GPUs. MIG provides physical partitioning with multi-GPU abstraction, while MPS provides logical execution resource partitioning by percentage. With physical partitioning, MIG allows partitions of memory capacity, memory bandwidth, and caches to be dedicated to each instance, in addition to execution cores.

A prior work, GSLICE [17], leverages GPU partitioning to increase throughput and utilization of GPUs. GSLICE employs a self-tuning algorithm for adjusting the amount of GPU resources per partition based on performance feedback. After adjusting the amount of resources, the batch size is heuristically decided by the SLO for the given task. However, the solution provided in GSLICE uses only spatial sharing and is limited to a single GPU.

Baseline spatial scheduling algorithm: As a baseline spatial sharing algorithm for our multi GPU framework, we use the *greedy best-fit* algorithm. Greedy best-fit algorithm chooses the minimum required partition size for each model to handle a given request rate with SLO constraint. It allocates the partitions of multiple ML models to GPUs through best-fit searching. Figure 3 (b) presents the spatial scheduling used by the greedy best-fit algorithm. Unlike the SBP or greedy-best fit algorithm, our scheduling scheme aims to simultaneously employ both temporal and spatial scheduling to maximize utilization and minimize the number of required GPUs.

3 Motivation

3.1 Optimal Batch Size and Partition

To understand the performance implications of batching and GPU partitioning, we perform an experimental study, using four ML models: GoogLeNet, ResNet50, SSD-MobileNet-V1, and VGG-16. The detailed descriptions for the ML models and GPU server specifications are provided in Section 5.1.

Figure 4 shows the batch inference latency results as the batch size increases from 1 to 32. For each batch size, we sweep through the increasing fractions of GPU resources, ranging from 20% to 100% to observe how the batch size and computing resource utilization are correlated. When the batch size is large, the latency significantly drops as more resource is added. The large slope of the curves implies that the inference execution for the particular batch size can use the additional resource effectively to reduce the latency. On the contrary, with a small batch, the latency is not largely affected by the amount of GPU resources, which implies that the GPU resource becomes underutilized when larger fractions are assigned. Hence, both batch size and amount of GPU resource must be considered as a joint factor when making cost-effective scheduling decisions.

which is Turing, an older generation than Ampere that offers the memory bandwidth isolation feature.

Figure 4: Batch inference latency as the fraction of computing resource assigned to the model inference changes from 20% to 100%, for the four ML models. Each curve represents a different batch size, and bn is a batch size of n .

Figure 5: Number of schedulable scenarios when the SBP algorithm performs the scheduling *without* (left) and *with* (right) a fixed 1:1 GPU partitioning scheme.

3.2 Schedulability and GPU Partitioning

For a given set of SLO latencies for ML models, if incoming request rates are beyond the level that an inference server can cope with, the SLO will not be met as requests cannot be served on time. We define *schedulability* as the capability of a scheduling algorithm for serving the given request rates while not violating the SLO. A scheduler can improve schedulability by having better GPU utilization and in turn, having higher throughput with SLO satisfaction. To investigate the potential of GPU partitioning on the schedulability improvement, we evaluate a large number of possible multi-model inference serving scenarios. A *schedulable* scenario is the one in which the scheduler can successfully make a decision for the given rate while preserving SLO.

For the evaluation, we use nine models, and each corresponding SLO latency is listed in Table 3. For each scenario, models have one of the following request rates: 0, 100, and 200 requests per second (req/s). Since the zero req/s is in-

Figure 6: Comparison of SLO preserved throughput for temporal (SBP), spatial (greedy best-fit), and static ideal scheduling, normalized to spatial scheduling.

cluded in the set of possible request rates, we assume that a subset of the nine models may not be served at all. Excluding the scenario where all the models have zero request rate, we obtained total 19,682 ($= 3^9 - 1$) scenarios for the experiment.

Figure 5 reports the number of schedulable scenarios when we use the two different scheduling algorithms: 1) the default SBP algorithm without GPU partitioning support, and 2) the SBP algorithm with GPU partitioning. In this motivational result, a GPU is split into two partitions with the same resource in each partition, although our scheduler later will use a wider range of partitioning of GPUs. With the fixed 1:1 GPU partitioning, schedulable scenarios increased significantly from 5,772 with SBP to 19,682 by SBP with two partitions. Even though the GPU is partitioned with a fixed 1:1 ratio, the results show that GPU partitioning is capable of putting wasted GPU compute power to use, enabling higher resource utilization.

3.3 Performance of Effective Partitioning

To demonstrate how a cost-effective partitioning scheme affects performance, we compare SLO preserved throughput of three scheduling schemes: temporal (SBP), spatial (greedy best-fit), and ideal scheduling. The SLO preserved throughput is the maximum throughput sustainable by a system while supporting SLOs for all models running in the system. Figure 6 presents the normalized SLO preserved throughput with the three scheduling schemes. We use two GPUs for this experiment, and a pair of ML models are scheduled. The models are selected from Table 3. The pair used for the experiment are (1) *ssd/be*, (2) *res/vgg*, (3) *goo/mob*, and (4) *nas/den*.

The first scheme, temporal scheduling, does not partition GPUs, but schedules tasks in a time-sharing manner with the SBP algorithm. The second schemes partitions GPUs by our baseline spatial scheduling algorithm (greedy best-fit) introduced in Section 2.3. The last scheme, static ideal exhaustively searches all possible GPU partitioning ratios among (2:8), (4:6), and (5:5) for two GPUs. For each pair of tasks, it uses a GPU partitioning option which yields the highest performance. For these selected sets of ML models, the spatial scheduling (greedy best-fit) outperforms the temporal scheduling (SBP) by 51% on average, proving the performance benefits of spatial sharing. The static ideal scheduling shows 23%

Figure 7: Cumulative distribution of latency overhead when pairs of inference executions are consolidated on a GPU.

improvements on average, compared to greedy best-fit. This experiment shows only limited example scenarios, but the results imply that partitioning can potentially improve the GPU utilization for certain scenarios, and better scheduling can further improve spatial scheduling.

3.4 Interference in Consolidated Executions

Cost-effective GPU partitioning allows enhancing the schedulability of SBP significantly. However, one important downside is the *performance interference* caused by multiple inference executions concurrently running on a GPU. One common cause of such performance interference is the bandwidth sharing for the external memory, but other contentions on on-chip resources may engender performance degradation too. To identify the interference effects, we perform an additional preliminary experimental study using a set of scenarios with ML models running together on a GPU. The model pairs were chosen among five models from Table 3: GoogLeNet, LeNet, ResNet50, SSD-Mobilenet, and VGG-16 (i.e., $C(5, 2) = 10$). Each pair runs with five different batch sizes (i.e., 2, 4, 8, 16, 32) creating 250 unique pairs in total. We also partition a GPU into two partitions using five different ratios: (2:8), (4:6), (5:5), (6:4), and (8:2). Then, we map the ML model pairs to the different partition pairs to observe the interference effects in various settings.

Figure 7 presents the cumulative distribution function (CDF) of latency overheads due to the consolidated inference executions, in comparison with the case where the models are run independently. As noted in the figure, for 90% of the scenarios, the interference-induced overhead is modest (lower than 18%). However, the CDF reports the long tail, suggesting that the interference effect could be severe in certain circumstances. In such cases, the interference may cause incorrect scheduling decisions, and the interfered task would experience latencies that are largely off from the expected range. Motivated by the insight, we devise an interference model and leverage it to make the scheduling decisions more robust, which reduces SLO violation rates.

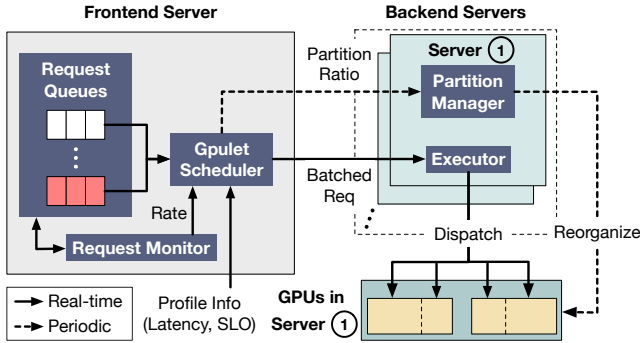

Figure 8: Overview of the scheduling framework with gplets.

4 Design

4.1 Overview

The goal of this study is to devise a scheduling framework for multi-model ML inference serving, which aims to assign incoming inference requests to the minimal number of GPUs while maximizing their utilization. The scheduling of ML inference workloads with SLO requirements must consider three aspects: batching, temporal scheduling, and spatial scheduling. Unlike the prior approaches which consider a subset of the three dimensions [17, 38], we propose a scheduler that fully explores all three dimensions to find the most effective point for scheduling.

In this study, using the spatial sharing capability of GPUs, we introduce an abstraction of GPU partition, called *gpulets*. Multiple gpulets can utilize a GPU by both temporal and spatial sharing. For each trained ML model, a minimal performance profile is collected offline. Based on the profiles of models, the scheduler distributes tasks to gpulets across multiple physical GPUs. Our scheduling framework minimizes the number of required physical GPUs while satisfying the current request rates with the SLO requirements. Also, our framework auto-scales the number of GPU servers by adapting to the changes in request rates.

Figure 8 presents the overall architecture of our proposed scheduler. The scheduler is composed of a frontend server responsible for making scheduling decisions, and multiple backend servers for executing the decisions. The scheduler on the frontend decides and sends batched requests to the backend servers, and the executor in each backend server dispatches requests to GPUs. The scheduling decision is made by utilizing profiled information of each model (e.g., SLO and inference latency for a pair of batch size and partition size) and incoming request rates. The request monitor tracks the number of newly arrived requests per second for each model. Based on the tracked request rates, the gpulet scheduler decides whether a new organization of partitions is required if the change of request rates is significant enough to update scheduling decisions. If a reorganization is necessary, the new partition ratios are sent to the backend server responsible for

the GPU which needs reorganizing. The partition manager in the backend server prepares the partitions on the GPUs so that they can serve requests with the new partition ratios. The scheduling period is empirically determined based on the GPU partitioning latency to make the overhead of partitioning hidden by the scheduling window.

4.2 Search Space Challenge

The challenge of the three-dimensional scheduling space (batching, temporal, and spatial sharing) for gpulets is that the scheduling decision is affected by several variables dependent on each other. The best size of GPU partition depends on the computational requirement of the model and batch size. Also, the batch size is dependent on the amount of allocated resource and how it is temporally shared with other models to ensure SLO. Therefore, the most cost-effective configuration would sit on the sweet spot in the search space built upon the three dimensions, which creates a huge search space.

To represent the search space, let P be the number of possible GPU partitioning options on a GPU, N be the number of GPUs to schedule, and M be the number of models to serve. Therefore, there are total P^N possible options to partition N GPUs. The M models can be placed on a partition, possibly having all the M models on a single partition. Since we need to check if the consolidation of multiple models violates the SLO, we must evaluate at most M^2 model placements per partition to assess schedulability. As we have NP partitions on the system, the possible mappings of M models to the GPUs is NPM^2 . The complexity of search space is as follows:

$$\text{Total Search Space} = O(P^N NPM^2)$$

As the search space is prohibitively large, it is impractical to exhaustively search and pick a solution. To address the problem, we take a greedy approach, which effectively reduces the search space by allocating partitions to gpulets on GPU incrementally.

4.3 Elastic Partitioning Algorithm

This section discusses our scheduling algorithm called *elastic partitioning* which finds an efficient set of gpulets for given ML inference tasks.

Elastic partitioning: Algorithm 1 describes the overall procedure of scheduling ML models to gpulets. Table 1 lists the variables used in the algorithm. The algorithm receives the following inputs for each model: (1) $L(b, p)$: profiled execution latency of batch size b on partition size p , (2) $intf$: interference function, (3) SLO : per-model SLO in latency, and (4) $gpulet.size$: size of partition allocated for *gpulet*. For every scheduling period, the server checks the request rates of each model. If rescheduling is required, the scheduler performs elastic partitioning with provided inputs (*line 1*).

Name	Description
$L(b,p)$	Latency function of batch size b and partition size p
$intf$	Interference overhead function
SLO_i	SLO (in latency) of model i
$gplet.size$	Actual partition size of gplet

Table 1: Definitions of variables for Algorithm 1.

Algorithm 1: Gplet Scheduling Algorithm

```

ELASTICPARTITIONING( $L(b,p)$ ,  $intf$ ,  $SLO$ ):
1 for each period do // If rescheduling is required
2   Sort every model by  $rate_m \times SLO_m$  in ascending order
3   for each model  $m$  do
4     while ISREMAINRATE() and ISREMAINGPULET()
5       do
6          $rate \leftarrow$  Remaining rate of model  $m$ 
7          $p_{eff} \leftarrow$  MAXEFFICIENTPARTITION()
8          $p_{req} \leftarrow$  MINREQUIREDPARTITION( $rate$ )
9          $p_{ideal} \leftarrow$  MIN( $p_{eff}$ ,  $p_{req}$ )
10         $gplet \leftarrow$  FINDBESTFIT( $p_{ideal}$ ,  $SLO_m$ ,  $intf$ )
11        Apply  $gplet$  to system
12      end
13    end
14  end
15  FINDBESTFIT( $p_{ideal}$ ,  $SLO_m$ ,  $intf$ ):
16  Sort every remaining gplets by size in ascending order
17  for  $gplet$  in GETREMAINGPULETS() do
18    if  $gplet.size \geq p_{ideal}$  then
19      if  $gplet$  is unpartitioned then
20        Split and allocate  $gplet$  to  $p_{ideal}$  size partition
21      end
22       $b \leftarrow \operatorname{argmax}_{k \in \mathbb{N}} (L(k, gplet.size) + intf \leq SLO)$ 
23      if  $b$  exists then
24        TEMPORALSCHEDULING( $gplet$ )
25        return  $gplet$ 
26      end
27    end
28  end

```

Each model is sorted in ascending order by $rate \times SLO$, which corresponds to the amount of work needed for the model (line 2). We allocate starting from the model with the least amount of work to the model which requires the most amount of work as a heuristic optimization for allocating resources. For each model m , the scheduler allocates one or more gplets until the incoming rate can be satisfied or no more gplet is left in the system (line 3-4).

Determining the most effective gplet size: Based on the observation from Section 3.1, the scheduler maximizes the system-wide throughput by allocating the most cost-effective size for gplet.

p_{eff} is the partition size that yields the highest performance per resource, which is the knee point in Figure 4. It is determined during profiling. p_{req} is the partition size satisfying SLO with the batch size that can handle the input rate. When request rates are low, p_{req} can be smaller than p_{eff} .

Figure 9: Max efficient partition (p_{eff}) and min required partition (p_{req}).

The scheduler chooses p_{eff} as the best partition size unless p_{req} is smaller than p_{eff} . If p_{req} is smaller than p_{eff} , p_{req} is chosen for the partition size, not to overprovision the GPU resource. Note that for a given model, a matching batch size is fixed for the p_{eff} of the model. Figure 9 presents two cases of p_{eff} and p_{req} . In the algorithm, MAXEFFICIENTPARTITION calculates a sweet spot of profiled gplet size and uses the gplet size at the knee as p_{eff} (line 6). MINREQUIREDPARTITION examines the minimum size of gplet, p_{req} , which is necessary to support the SLO on under the given request rate (line 7). The scheduler picks the minimum of p_{eff} and p_{req} as the ideal partition size p_{ideal} to ensure cost-effective gplet size (line 8).

Incremental allocation with best-fit: After finding p_{ideal} , FINDBESTFIT performs a best-fit search. First, the scheduler sorts the remaining gplets by partition size in ascending order (line 14). The algorithm searches through remaining gplets until a $gplet.size$ is greater or equal to p_{ideal} (line 16). Since the gplets are sorted in ascending order, the sweeping naturally guarantees the best-fit. If the partition of gplet can be split, which means the chosen gplet has a size of 100%, the gplet is split into two gplets, each with a size of p_{ideal} and $100 - p_{ideal}$ (line 17-19). The maximum batch size b is decided and checked whether it can meet the SLO when there is additional interference-induced overhead (line 20). If a valid batch size exists, then the gplet is chosen (line 21).

Temporal scheduling for gplets: After a $gplet$ is chosen, elastic partitioning attempts temporal scheduling between the returned $gplet$ and previously allocated gplets in the system (line 22). Temporal scheduling for gplets follows the same rules which is introduced in Section 2.2: 1) adjust the duty cycle and batch size accordingly, and 2) check whether the SLO can be guaranteed for all models. We introduce an additional rule to consider $gplet.size$ when calculating the batch size and duty cycle. For every pair of gplets, the aforementioned rules are applied to see if temporal sharing is available. If a pair of gplets has a different size, the larger size will be chosen to check if the SLO can be successfully guaranteed or not. If successful, two gplets are merged to a single gplet, thus reducing the total number of required gplets. The scheduler updates the remaining and allocated

Figure 10: Cumulative distribution of relative error rate. Proposed analytical model can predict up-to 95% of cases with less than 13.98 % error rate.

gpulets with the result of `FINDBESTFIT` (line 10).

Reduced Search Space: Because the cost of iterating through every possible strategy is not required, the search space introduced in Section 4.2 is reduced as follows.

$$\text{Reduced Search Space} = O(NPM^2)$$

Instead of searching every case of P possible partitioning, for every N GPU in the system, each GPU is partitioned incrementally and the cost of checking temporal scheduling for M models still remains. Our search algorithm practically approximates the ideal one and removes P^N from the full search complexity. As a cost of the approximation, it may not always produce a theoretical optimal result. However, our evaluation shows that the algorithm performs closely to the ideal one as presented in Figure 16 (Section 5).

4.4 Modeling Interference

A key challenge in interference handling is to predict latency increases when multiple inferences are executed in different gpulets of the same GPU. As shown in Figure 7, the interference effects are modest for the majority of consolidated executions, yet the overhead could be significant in a few cases.

To confine the interference effect, we provide a simple yet effective interference-prediction model based on two key runtime behaviors of GPU executions. The interference effects of spatial partitioning are commonly caused by the bandwidth consumption in internal data paths including the L2 cache and the external memory bandwidth. To find application behaviors correlated to the interference effects, we profile the GPU with concurrent ML tasks with an NVIDIA tool (Nsight-compute). Among various execution statistics, *L2 utilization* and *DRAM bandwidth utilization* are the most relevant factors correlated to the interference.

Based on the observation, we build a linear regression model with the two parameters (L2 utilization and DRAM bandwidth utilization) as follows:

$$\text{interference_factor} = c_1 \times L2_{m_1} + c_2 \times L2_{m_2} + c_3 \times \text{mem}_{m_1} + c_4 \times \text{mem}_{m_2} + c_5$$

$L2_{m_1}$ and $L2_{m_2}$ are L2 utilization of model m_1 and m_2 , when they are running alone with a given percentage of GPU re-

Algorithm 2: GPU Scaling Algorithm

```

SCALING(GPU_LIMIT):

3    $result \leftarrow$  ELASTICPARTITIONING with  $N$  GPUs
4   while  $result$  is fail and  $N < GPU\_LIMIT$  do
5      $N \leftarrow N + 1$ 
6      $result \leftarrow$  ELASTICPARTITIONING with  $N$  GPUs
7   end
8   if  $result$  is fail then
9     Report an unschedulable event
10  end
11 end

```

source. mem_{m_1} and mem_{m_2} are memory bandwidth consumptions of model m_1 and m_2 . Parameters (c_1 , c_2 , c_3 , c_4 , and c_5) are identified by running the linear regression.

We have profiled total 1,250 pairs (total 2,500 data) of inference interference and recorded how much interference each inference task has received. Among 2,500 data, we have randomly selected 1,750 data of execution as training data and 750 data for validation. Figure 10 presents the cumulative distribution of the prediction error with our interference model. The proposed model can predict up to 90% of cases within 10.26% error rate and up to 95% if 13.98 % of error is allowed.

Linear regression is chosen for its relatively high accuracy and low model construction complexity, so it satisfies our purpose in scheduling. Several prior studies have also used such linear models for predicting interference overheads [5, 43, 47].

4.5 Scaling GPUs for Request Rate Changes

During a scheduling period, the monitor tracks the request rates of all ML tasks. If the rates change, it triggers the rescheduling procedure. The rescheduling procedure checks whether the changed rates can be sustained by the current number of GPUs. If not, it tries to increase the number of GPUs to support the SLOs for the new rates. Algorithm 2 presents the rescheduling procedure. It first attempts to use the same number of GPUs of the previous scheduling period (line 2-3). If the *result* fails due to the insufficient number of GPUs, the elastic partitioning is repeated with one additional GPU. However, when the number of required GPUs exceeds the given limit, it reports that an unschedulable event occurs.

4.6 Implementation

SW prototype: The SW prototype of our scheduler was developed in C++ and the approximate lines of code is 20.7K. We have chosen PyTorch for implementing ML inference due to its wide adoption in ML communities, in addition to the readiness to use C++ interfaces.

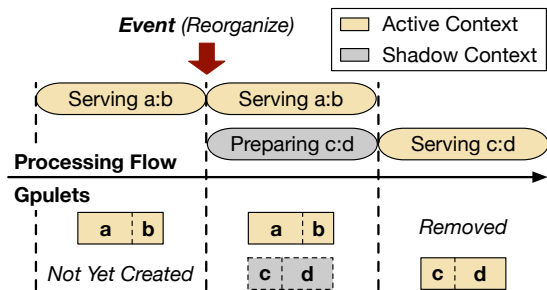

Figure 11: Illustration of dynamic partition reorganization.

Dynamic partition reorganization: NVIDIA provides the MPS control daemon, which allows users to control the proportion of computing resource reserved for processes spawned by the user. The amount of reserved resources is fixed when a process is created. Therefore, To change the proportion of reserved resource, a new process must be created with a new designated amount. This limitation affects our rescheduling procedure with a high cost of adjusting gpulets.

Our scheduling prototype controls gpulet partition size, by spawning a new proxy process to allocate a different amount of partition to gpulet. Preparing a new partition includes spawning a new process, loading kernels used by PyTorch, loading required models, and warming up. As illustrated in Figure 11, to hide the overhead of preparing new partitions when reorganizing is necessary, we overlap the procedure of preparing new partitions with serving the current partitions. The scheduling period for reorganization is 20 seconds which is a conservative estimate of time required for preparing a new partition.

5 Evaluation

5.1 Methodology

Inference serving system specifications: Table 2 provides a detailed description of the evaluated inference system and the used GPU specification. We use two identical multi-GPU inference servers, each of which is equipped with two NVIDIA RTX 2080 Ti GPUs supporting post-Volta MPS capabilities. The table also provides the versions of the operating system, CUDA, NVIDIA drivers, and machine learning framework.

Each GPU server operates as a backend server responsible for executing inference queries on two GPUs. One server additionally generates inference requests while the other server assumes the role of a frontend server to manage backend servers and make scheduling decisions. Both servers are network-connected, imitating inference serving system architecture, with 10 Gbps bandwidth.

Baseline scheduling algorithms: For our baseline, we have ported the Squishy bin-packing (SBP) algorithm (from Nexus [38]) and greedy best-fit introduced in Section 2. We evaluate two versions of our proposed algorithm, gpulet +int

System Overview	
CPU	20-core, Xeon E5-2630 v4
GPU	2 × RTX 2080 Ti
Memory Capacity	192 GB DRAM

Table 3: List of ML models used in the evaluation.

considers interference overhead while gpulet does not.

We do not provide a direct comparison to Nexus [38] due to the following reasons: 1) Nexus deploys optimizations that are orthogonal to our work, and 2) several benchmarks that Nexus used in evaluation were not interoperable with our prototype server, as the models are not supported by PyTorch. However, we deploy the same type of video processing models that Nexus used to evaluate the system and show how spatially partitioning GPUs can further enhance performance.

ML models: Figure 12 delineates the detailed dataflow graph of the applications that contain ML models as well as the input/output data. The *game* application analyzes the digits and images from the streamed video games by using seven models in parallel. The *traffic* application is a traffic surveillance analysis with two phases, which are object detection and image recognition. The SLO latency is set as 108 ms and 202 ms for game and traffic, respectively. Each SLO latency is calculated by doubling the longest model inference latency.

Deeper look into particular request scenarios: We choose five model-level scenarios to take a deeper look into the multi-model inference serving. These five scenarios are characterized by the member of models and each respective memory footprint. Table 4 shows the details of each scenario.

Request arrival rate: We sample inter-arrival time for each model from a Poisson random distribution, based on previous literature [48] claiming real-world request arrival rates resemble a Poisson distribution.

Evaluation of request scenarios and applications: For a given scenario or application, we evaluate the scheduling decisions by deploying scheduling results on our prototype

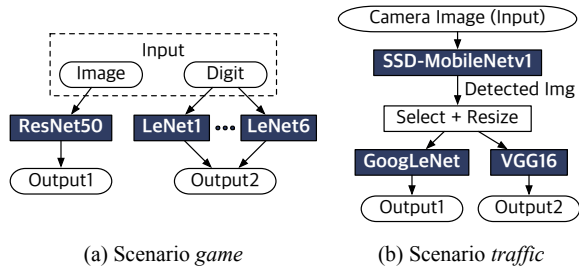

Figure 12: Two multi-model applications: *game* and *traffic*.

Name	Group Composition by Memory Footprint		
	<1GB	1GB - 2GB	>2GB

servers and measuring the throughput under SLOs and SLO violation rates. To consider the unpredictable performance variations, we iterate the experiment three times for each scenario and application, and pick the median result.

5.2 Experimental Results

SLO preserved max throughput: We first evaluate the throughput implications of our schedulers. The *SLO preserved max throughput* is defined to be the maximum achievable throughput while 99% of requests are processed within the SLO latency. We measure the SLO preserved max throughput of the schedulers by gradually increasing the request rate until SLO violation rate exceeds 1% of total requests.

Figure 13 reports the SLO preserved max throughput for the two multi-model applications and five scenarios for four different scheduling algorithms. Our proposed *gpulet +int* scheduler offers higher throughput than both algorithms SBP and greedy best-fit by an average of 61.7% and 81.2%, respectively. Additionally, considering interference yields 7.5% better throughput on average. Although the benefit may seem marginal, we argue that such caution is necessary since a scheduler must be able to guarantee SLO at all times.

The low performance of greedy best-fit is caused by the lack of effective temporal sharing. In Figure 4, models show diminishing returns (over increasing GPU partitions) beyond a knee point. Note that different batch sizes can have different knee points. The greedy best-fit chooses the maximal batch size which satisfies SLOs and sets the partition for the batch size. The spatio-temporal scheduling can select the batch size and partition to better utilize GPU by considering smaller

Figure 13: SLO preserved max throughput of the two multi-model applications (*game* and *traffic*) and five scenarios.

batches with temporal sharing across models. The limitation of greedy best-fit is clearly shown in *game*. Its flow has many small parallel tasks (LeNets), which cannot fill even a small GPU partition efficiently. Note that batch sizes cannot be increased arbitrarily as request rates and SLO limits it.

The reported throughput improvement is achievable merely through the MPS features already available in the most server-class GPUs and scheduling optimization in software, using the same GPU machine. Thus, by utilizing otherwise wasted GPU resources, the proposed scheduling scheme would be able to virtually offer cost savings for the ML inference service providers. For instance, *gpulet +int* achieves 1,650 req/s throughput for *game* while SBP does 690 req/s, utilizing the identical physical system, which can be translated into 58.2% effective cost saving ($= \{1 - \frac{690}{1650}\} \times 100$).

The effect of interference model: This analysis shows how the interference model can avoid SLO violations by correctly incorporating the interference effect into the scheduling decision. In this result, we measured SLO violation rates by gradually increasing request rates until both *gpulet* and *gpulet +int* consider the current rate not schedulable. Figure 14 presents the SLO violation rates when the system is receiving the maximum request rate before both of them reach the not schedulable decision. In the figure, if the violation rate is higher than 1%, the case is highlighted with a red round. The scheduler *gpulet*, which does not consider interference, shows violation rates higher than 1% even for the rates that it considered to be schedulable for *scen2*, *scen3*, and *scen5*. However, *gpulet +int* successfully filters out such rate by either classifying as *not schedulable (N)* as shown in *scen2* and *scen3* or successfully scheduling tasks without violating the SLO such as *scen5*.

Evaluation of scalability: To evaluate whether our prototype scheduler can successfully scale *gpulets* to accommodate fluctuating rates, we measure the performance of our scheduler while submitting inference requests with varying rates for all models in *scen3*. We have chosen *scen3* because of its evenly distributed model size to reproduce a realistic workload.

To evaluate scalability beyond our testbed, we launched multiple servers by running each server with docker container. By running one container per GPU with four more identical GPUs, we conducted our experiment on total eight servers. Additionally, the request generator and frontend server were specially tailored to send dimensional data, instead of actual

Figure 14: SLO violation rates of two multi-model applications and five scenarios. Request rates are increased until both gpulet and gpulet+int concluded the rate to be *Not Schedulable*.

Figure 15: (a) Throughput(req/s), (b) number of GPUs, (c) sum of partition size (%) of gpulet, (d) SLO violation (%) of each model for 3,200 seconds.

data for inference request, for overcoming network bottleneck between physical servers. The backend servers behave identically other than generating random data with dimensions provided from frontend server. Figure 15 reports how our scheduling framework performed for a 3,200 second window. The top graph shows a stacked graph of the accumulated throughput of each model. The second and third graph reports how many GPUs were scheduled and the sum of partition sizes of gpulets, respectively. The last graph depicts the percentage of SLO violation (including dropped requests) for 20 second period. Between 0 and 1,200 seconds, the rate gradually increases and decreases to its initial rate. As the rate rises, our proposed scheduler successfully allocates more GPUs to preserve SLO. When the rate decreases, the sum of utilized partitions also decreases by reorganizing partitions. The following wave, starting from 1,400 seconds, rises to a

Figure 16: Comparison of the numbers of schedulable scenarios between the ideal scheduler and gpulet +int scheduler.

Figure 17: Comparison of the normalized maximum schedulable rates with real-world multi-model benchmarks and five scenarios.

higher peak than the previous wave of requests. Nonetheless, our scheduler successfully adjusts gpulets and preserve SLO, guaranteeing SLO violation rate lower than 1%.

Comparison to the ideal scheduler: We evaluate the scheduling capability of elastic partitioning by comparing the scheduling results produced from an ideal scheduler. To produce various model-level inference request scenarios, we use the same methodology described in Section 3.2, which populates a set of 19,682 possible scenarios. The ideal scheduler makes scheduling decisions by exhaustively trying all 4^4 partition combinations, where 4 GPUs can be partitioned into either (2:8), (4:6), (5:5), or (10:0). The search continues until all cases are searched or a case produces a viable scheduling result for a given request scenario. For a fair comparison, the ideal scheduler uses the same set of partitions as gpulet+int. Figure 16 compares the number of scenarios classified as schedulable by each scheduler. gpulet+int can schedule 520 fewer cases compared to ideal, which is 2.6% of the total 19,682 cases.

Figure 17 reports the maximum schedulable rate of each multi-model scenario. All rates are normalized to the maximum rate which ideal can provide. gpulet+int can achieve an average 92.6% of the maximum rate which the ideal scheduler can provide.

6 Related Work

6.1 Prior ML Systems Studies

Machine learning service platforms: A wide variety of computer systems and researches have been proposed to improve the quality of machine learning services [1, 2, 9, 13, 15,

Table 5: Comparison with prior work.

17, 21, 22, 24, 26, 32, 35, 36, 37, 38, 39, 40, 41, 45]. INFaaS is a platform for serving inference that guarantees SLO and minimizes the cost by choosing an adequate variation of a model [36]. INFaaS adopts a reactive approach when dealing with interference caused by co-locating model variants on the same hardware resource. Clockwork focuses on providing an accurately predictable system by leveraging the fact that the latency of inference is relatively consistent [21]. Clockwork preferred predictability over utilization gains from co-locating models and thus does not consider spatial sharing.

Although this paper did not cover training, past research inspired this study with schedulers for optimizing GPU resource [16, 24, 33, 42, 46]. Another related research direction focus on how to ease the burden of deployment and optimization for machine learning across various platforms [6, 27, 28, 31, 32]. Prior studies related to cluster scheduling have also influenced this paper [20, 30, 43].

Interference estimation: Precise estimation of interference has been a key issue for high-performance computing. Bubble-up [29] and bubble-flux [44] models an application’s sensitivity to cache and fits a sensitivity curve to predict performance. Han *et al.* extend using sensitivity cure to distributed computing where interference can propagate among processes [23]. Prophet models concurrent task execution behavior for non-preemptive accelerators [4].

Multi-tenancy in Accelerator: GPU vendors have included HW/SW support for providing multi-tenancy to users such as NVIDIA Multi Process Service (MPS) [12], Multi Instance GPU (MIG) [14], and AMD MxGPU [10]. Academic researches also proposed multi-tenancy support in accelerators. Pratheek *et al.* devised page-walking stealing for multi-tenancy support in GPU [34]. Choi *et al.* proposes fine-grain batching scheme [8]. PREMA proposed time-multiplexing solution with preemption [7]. Planaria supports multi-tenancy by partitioning processing elements [19].

6.2 Comparison to Prior Work

Table 5 provides a summarized comparison of our work to related ML inference frameworks. All the prior studies are capable of dynamically tuning batch size by either leveraging profiled latencies or incoming request rates during runtime. As more ML workloads are consolidated in cloud-based GPU servers, scheduling of multiple heterogeneous ML models in a system and scaling GPU servers under fluctuating request rates become more important. However, some prior studies

do not consider such multi-model supports or GPU scaling.

Regarding scheduling dimensions such as temporal and spatial sharing, a majority of the prior work employ temporal sharing by leveraging profiled information of latency. Only GSLICE considered spatial sharing but it does not consider multi-GPU scheduling and temporal sharing. On the other hand, our study addresses all challenges, scheduling dimensions, and predicting potential interference among partitions in the same GPU.

7 Conclusion

This study investigated an SLO-aware ML inference server design. It identified that common ML model executions cannot fully utilize GPU compute resources when their batch sizes are limited to meet the response time-bound set by their SLOs. By leveraging spatial partitioning features, our framework significantly improved throughput of multi-GPU configurations while supporting SLOs. Based on the new spatio-temporal scheduling technique, this study showed that a new abstraction of GPU resources (*gpulet*) can improve ML inference serving under SLOs. The source code is available at <https://github.com/casys-kaist/glet>.

A Artifact Appendix

A.1 Abstract

To maximize the resource efficiency of inference servers, we proposed a key mechanism to exploit hardware support for spatial partitioning of GPU resources. With the partitioning mechanism, a new abstraction layer of GPU resources is created with configurable GPU resources. The scheduler assigns requests to virtual GPUs, called gpulets, with the most effective amount of resources. The prototype framework auto-scales the required number of GPUs for a given workloads, minimizing the cost for cloud-based inference servers. The prototype framework also deploys a remedy for potential interference effects when two ML tasks are running concurrently in a GPU.

A.2 Hosting

The artifact is hosted on the following platforms:

- **Zenodo:** We have published the artifact on Zenodo: <https://doi.org/10.5281/zenodo.6544909>
- **GitHub:** Although the artifact provided in Zenodo contains all necessary and functional code, it is still in its early stage of development and needs improvement in terms of UI and code readability. Further improvement of code will be provided in the following GitHub repository: <https://github.com/casys-kaist/glet>.

A.3 Scope

The artifact is capable of:

- Serving machine learning inference on multiple multi-GPU servers.
- Adding new models defined and saved by TorchScript (provided as .pt files).
- Scheduling multiple models and guarantee SLO.
- Providing stand-alone ML inference executor for profiling performance and GPU resource usage.

The artifact does *not* provide the following:

- Utilize CPU for ML inference.
- Schedule heterogeneous GPUs.
- Guarantee availability (e.g. heartbeat, failure recovery).
- Add new models or deleting old models to serve while the frontend server is running.

A.4 Contents

A.4.1 SW Components

- **Frontend Server:** Receives requests from M clients and schedule requests to N backends.

- **Backend Server:** Receives batched requests from frontend server and conveys request to 0 servers running on the same machine.
- **Proxy:** Receives inputs from backend server and executes ML inference on a gpulet
- **Standalone Inference:** Executes inference on a GPU. Useful for debugging and profiling GPU resource utilization.
- **Standalone Scheduler:** Provides scheduling decision for given set of models and input rate of each model as stand-alone SW. Useful for inspecting scheduling decisions.

Please refer to *binaries.md* for further information of how to run and setup each components.

A.4.2 Models

The artifact includes 0 CNN models of VGG16 and ResNet50. Both models are stored as .pt file. All models are also available on Torchvision.

A.4.3 Dataset

A subset of ImageNet data and camera surveillance footage are each compressed as imagenet_data.tar and camera_data.tar respectively.

A.4.4 Docker Images

The following prerequisites must be installed in order to use the Docker images for this artifact:

- **Docker Ver.** ≥ 20
- **Nvidia-docker** (for utilizing GPUs)

Two Docker images are made public for experimenting with the provided artifact. One is the server Docker image available on sbchoi:glet-server and the other is the base Docker image used for building the backend Docker image available on sbchoi:glet-base.

We highly recommend using Docker images for experimenting since it contains all required code and scripts. For further instructions, please refer to the README file on <https://github.com/casys-kaist/glet>.

A.5 Requirements

A.5.1 Hardware

The artifact was evaluated on multi-GPU servers. Each GPU server had the following hardware specifications:

- **GPU:** NVIDIA RTX 2080ti (11GB global memory)
- **CPU:** Intel Xeon E5-2630 v4
- **Network:** Servers connected with 10 GHz Ethernet

A.5.2 OS and Kernel

The artifact was evaluated on Ubuntu 18.04 with a Linux kernel version 4.15.

A.5.3 Software

The artifact was built with the following drivers and libraries:

- LibTorch(PyTorch library for C++) = 1.10
- CUDA \geq 10.2
- cuDNN \geq 7.6
- Boost library \geq 1.6
- OpenCV \geq 4.0
- CMake \geq 3.19

A.6 Experiment Setup

Experiments can be run by using the scripts provided in the artifact. We have also provided example files required for configuring experiments. Below are a few steps to configure multiple GPU servers using Docker images we have provided:

1. Run MPS daemon
2. Create and run an overlay network for Dockers
3. Setup and execute backend servers
4. Setup and execute frontend server, connecting all backend servers for serving inference.
5. Run clients
6. Analyze the content of `glet/scripts/log.txt` for how each request has been handled.

Please refer to the *README* file and *binaries.md* in <https://github.com/casys-kaist/glet> for detailed instructions of how to configure

PilotFish: Harvesting Free Cycles of Cloud Gaming with Deep Learning Training

Abstract

Cloud gaming services have become important workloads in cloud datacenter. However, our investigation shows that a cloud gaming service cannot saturate the modern cloud GPUs. One way to improve the GPU utilization is to co-locate multiple workloads within one GPU, which is challenging for cloud gaming due to its highly fluctuated and unpredictable GPU usage pattern. In this paper, we present PilotFish, a high-performance system that harvests the free GPU cycles of cloud gaming with deep learning (DL) training, while incurring almost zero interference to cloud gaming. We co-locate DL training jobs with cloud gaming, because they have stable and predictable workloads and have no strict latency requirement. In more detail, PilotFish captures the idle periods of the game's GPU usage with its low-overhead instrumentation to graphic libraries in sub-millisecond granularity. To avoid the potential interference to cloud gaming, PilotFish schedules training computation kernels only when they can finish before the idle GPU periods, and preempts straggler kernels running longer than expected. Our evaluation on popular cloud games and DL models shows PilotFish can harvest up to 85.1% of the idle GPU time from cloud gaming with no interference.

1 Introduction

Cloud gaming is gaining popularity in recent years. As shown in Figure 1, players of cloud gaming only use a thin client that interacts with games running on cloud servers and receives the stream of rendered frames via Internet [38]. Cloud gaming greatly reduces the hardware requirement of high-quality video games. Mobile clients with no or weak GPU can still enjoy the good visual effect of powerful GPUs. Cloud gaming has become an important workload in major cloud service providers, e.g., Microsoft's Xbox Remote Play [11], Google's Stadia [7], Nvidia's Geforce Now [15], Sony's PlayStation Now (running on Azure) [18], Amazon's AppStream [1].

*This work is done while Wei Zhang is an intern in Microsoft Research.

Figure 1: In cloud gaming games, players send control messages (keyboard and mouse) to cloud servers. Game scenes are rendered as frames in cloud servers and streamed to edge devices via internet.

Due to the limitations of the network, encoding and decoding capability, and resolution of mobile devices, major cloud gaming service only provides limited streaming quality that is far lower than the increasing capability of modern GPUs. For example, Microsoft's Xbox Remote Play and PlayStation Now only support up to 1080p at 60FPS. However, the latest GPUs for gaming (e.g., Nvidia's 3090Ti) can support 4K (2160p) resolution at up to 144FPS. Running cloud gaming of limited streaming quality on powerful GPUs would inevitably waste the GPU cycles. Our evaluation of popular games shows most of them have a utilization lower than 50% with cloud gaming GPUs. It is important to improve the utilization to reduce the operation cost of cloud gaming services.

To improve GPU utilization for cloud gaming, a natural solution is to co-locate multiple workloads in one GPU (e.g., multiple games [29, 36] or other GPU workloads [23–25, 50, 51]). Such approaches face great challenges, due to the high randomness of the gaming workload. A game's utilization of different resources (including GPU, CPU, PCI-e and disk I/O) varies greatly across video frames. Such variation is difficult to predict due to the random interaction between players and changing game scenes. Moreover, different games could exhibit very diverse resource usage patterns, further increasing the degree of unpredictability. Co-locating multiple games in a GPU would inevitably lead to interfer-

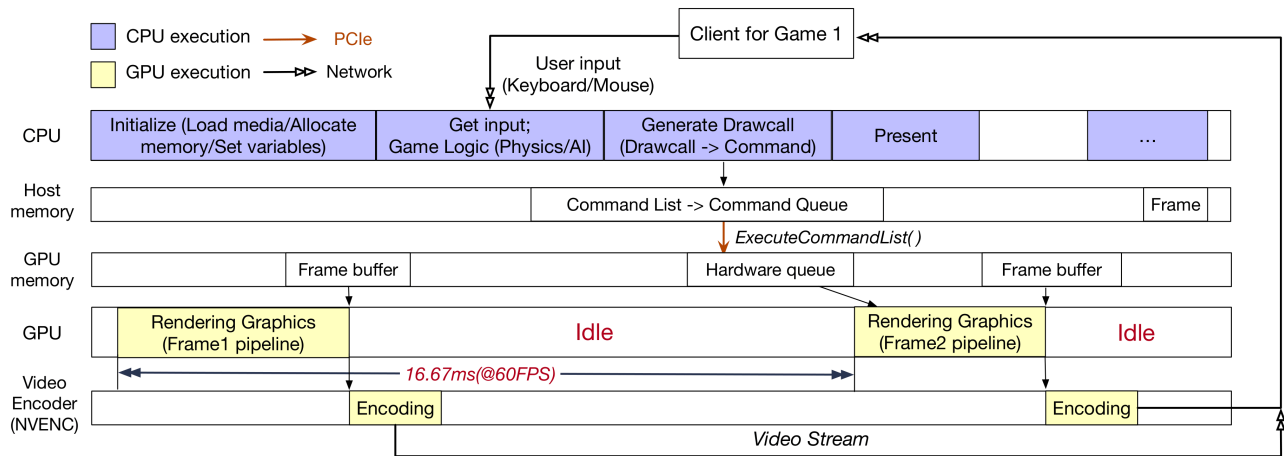

Figure 2: The procedures of cloud gaming. On receiving user input, the game logic decides the content of the scene to be rendered, which is comprised of a list of draw calls using graphic libraries. The draw calls are pushed into a command queue for the frame and submitted to the hardware for rendering the frame. The rendered frames are encoded by dedicated chips (e.g., NVENC [13] of Nvidia’s GPUs) and sent to the cloud gaming client.

ence when long rendering times from different games collide. To safely harvest the GPU free cycles from cloud gaming, it is necessary to choose a more predictable and stable workload for co-location, where we find Deep Learning (DL) training, a pervasive workload in cloud data centers, is a good fit.

In this paper, we present PilotFish, a high-performance system that harvests the free GPU cycles of cloud gaming with deep learning training, without impacting gaming experiences. Instead of predicting the varying gaming workload, PilotFish exploits idle GPU periods in a reactive manner. PilotFish exposes a real-time resource monitoring interface by instrumenting graphic libraries (e.g., DirectX or Vulkan) for quickly reporting (within 10 μ s) the start and completion of the rendering of a game frame. This way, PilotFish can precisely capture idle GPU periods of games. This design allows PilotFish to support all games running on common graphic libraries without modifying or re-compiling game code.

PilotFish further leverages the *predictability* of deep learning training in the scheduling. It is well-known that deep learning training consists of iterative training steps. The compute kernels in each training step have a highly predictable execution time and can be obtained through offline profiling [40,46]. With the known duration of a specific DL training kernel (usually on the order of sub-millisecond), PilotFish is able to safely schedule a deep learning training job to leverage the idle time of gaming workload, without violating the QoS of cloud gaming. The interference on other types of hardware resources is also avoided via state-of-the-art techniques, e.g., Baymax [25] for PCI-e. Furthermore, to prevent from training anomaly, where a DL training kernel does not complete in the estimated time, PilotFish can proactively terminate the training (<1ms) with limited loss of training progress.

We have implemented a prototype of PilotFish to sup-

port games on DirectX 12 [3] and DL training using Nvidia CUDA 11 [14]. We evaluate PilotFish using popular games for cloud gaming and widely-used DL models for training. Evaluation result proves PilotFish can strictly guarantee the QoS of cloud gaming when co-located with DL training. PilotFish can harvest up to 85.1% of the idle GPU time without interference, compared to straw-man baselines that degrade the 99%-ile FPS by over 30% to achieve the same harvest ratio.

The key contributions of the paper are as follows:

- We identify the low GPU utilization problem of cloud gaming and the challenges of co-location due to the randomness of games.
- We characterize the cloud gaming workload and point out that DL training is a right workload to be co-located with cloud gaming to improve GPU utilization.
- We propose mechanisms for quickly capturing idle GPU periods of gaming and fine-grained scheduling of co-located DL training workload, which guarantee no interference.

2 Motivation

In this section, we study the common cloud gaming pipeline shown in Figure 2. We investigate why there is low utilization issue in cloud gaming services and the challenges of harvesting free GPU cycles from games. Then we motivate why DL training is a good fit for co-location.

Table 1: The GPU and CPU utilization of cloud gaming.

Game	Average GPU Util.	Peak GPU Util.	VRAM (GB)	CPU Util.	FPS
Dota 2	38.2%	45%	1.61	21.9%	59.9
League of Legends	26.9%	41%	1.16	22.0%	59.8
PUBG	40.6%	95%	4.05	28.9%	60.1
CS:GO	45.0%	57%	2.6	69.7%	201
Civilization 5	32.3%	42%	1.11	15%	59.8
The Division 2	89.5%	98%	3.12	46.11%	58.66
Assassin's Creed Odyssey	69.2%	78%	2.39	66.3%	59.68
Ashes of the Singularity	89.8%	98%	3.42	79.23%	57.31

Figure 3: The average FPS and GPU utilization of independent execution of popular games and their co-located execution on Nvidia RTX 2060. (HIT: HITMAN3, RDR2: Red Dead Redemption 2 and AOS: Ashes of the Singularity)

2.1 GPU Under-utilization of Cloud Gaming

Existing cloud gaming platforms allocate each player to a dedicated server for running the requested game to ensure players' satisfactory experiences. For cloud gaming service providers, major concerns are focused on network latency and operational cost. The network latency is considerably reduced today and becomes viable for cloud gaming. However, the low resource utilization still leads to significant operation cost. We use the Nvidia RTX 2060 GPU, of which the computing ability is 6.4 teraflops, as the experimental platform, which has comparable performance to the Xbox One X's GPU (6.01 teraflops) used by Microsoft's cloud gaming service. We investigate the performance of eight of the most popular games. Table 1 summarizes the resource utilization of these games on NVIDIA RTX 2060 with cloud gaming rendering quality, mostly 1080p and 60 Frames Per Second (FPS). Five of the eight games have a GPU utilization of lower than 50%, showing the potential opportunities for improvement.

Modern GPUs are becoming more and more powerful. However, the QoS of cloud gaming is much lower than the capability of modern GPUs. According to Steam's survey [19], over 83.67% of PC gamers use resolution $\leq 1920 \times 1080$. Most smartphones only have a screen $\leq 1080p$ resolution. Also, the higher resolution requires better network quality and hardware capability (for decoding). Currently, Xbox remote play

Figure 4: The fluctuation of frame time over time of three popular games.

Figure 5: The fluctuation of CPU, storage and network utilization over time of Hitman 3.

only supports streaming quality of at most 1080p and 60 FPS.

We anticipate the low GPU utilization issue will become more severe on the latest generation of GPUs used by gaming clouds. For example, Google Stadia uses an AMD GPU with 10.7 teraflops [7], Microsoft's Xbox Series X chip has 12 teraflops [11], Nvidia's RTX 3090 has 35.58 teraflops.

2.2 Challenges

A natural idea to improve the GPU utilization of cloud gaming is to co-locate multiple games into the same GPU. However, we observe co-locating multiple games could severely interfere with each other, even when the GPU is still underutilized.

Figure 3 demonstrates the FPS of three popular cloud games and their GPU utilization in two situations: independently execution and co-located execution. When the games run alone, they can achieve around 50% of GPU utilization on 60 FPS. However, when two games are co-located, the FPS drops greatly (e.g., RDR2's FPS drops to 20 from 60) but the GPU utilization is only improved by up to 24%.

The main cause of the degraded co-location performance comes from the randomness of games. As shown in Figure 4, a game's frametime (the time to render a frame) could vary significantly over time due to the different complexity of the scene. Different games would further exhibit a very diverse pattern of GPU consumption. Moreover, in addition to GPUs, the resource usage of other resource types (CPU, storage, etc.) also fluctuates over time as illustrated in Figure 5. When contention appears on these resources, the submission of draw calls would be blocked, which also leads to lower GPU utilization. This explains why the co-located games only have

limited improvement on GPU utilization in Figure 3.

The highly random gaming behaviours make it impossible to co-locate the other random and interactive workloads like game without impacting the gaming experience. Previous works [36, 43] using static profiling to co-locate multiple games in a best-effort manner could still suffer from the interference due to random rendering content. We seek to find a more stable and predictable workload as the candidate for co-location, where we find DL training is a good fit.

2.3 Co-location with DL Training

DL training is a pervasive workload in cloud data centers. The major cloud gaming service providers (e.g., Microsoft, Google, Amazon) also have a huge demand for training DL models with GPUs [33]. The key reason we consider DL training for co-location with cloud gaming is its predictability and fine-granularity. Figure 6 shows the execution time of statistical top 20 frequent kernels from six popular DL training models. The figure shows that the duration of all training kernels is relatively stable, it usually varies within a few percent. Thus, by leveraging the predictability and iterative pattern of DL kernels, the system can know their duration *beforehand*. Also, the execution time of DL kernels is typically less than 1ms, thus it is very suitable to be scheduled to exploit the GPU idle time.

Figure 6: The execution time of top 20 frequent kernels from six popular models. (each bar is a kernel).

Despite the opportunity, the direct co-location of gaming and DL training without leveraging the characteristics of DL training could still incur a severe drop in FPS due to complex interference behaviors. For example, if the DL training kernels are submitted when a frame is still under rendering, both workloads would contend for GPU time and postpone the completion of game rendering.

Figure 7: FPS of games when co-located with DL training.

Figure 7 shows the normalized 99%-ile FPS when five popular games are co-located with DL training tasks on a Nvidia 2060 GPU. The DL training tasks includes Resnet50 [30], VGG [44] and Mobilenet [31]. In the figure, the x-axis indicates the combination of games and DL training tasks, and the y-axis shows the 99%-ile FPS normalized to its FPS target. All games are affected by naively co-locating with DL training models. During co-location, we observe that the FPS of game is affected by the *duration of frame rendering*, the *DL training kernel scheduling* and the *contention on shared resources*. Therefore, it requires very careful management of the co-located DL training jobs to avoid interfering the cloud gaming, which is the main goal of PilotFish.

3 PilotFish Overview

We consider the scenario that DL training has a lower priority than the interactive cloud gaming service. Therefore, it is required that DL training should not generate interference to cloud gaming. PilotFish co-designs the cloud gaming services and deep learning training frameworks so that they can collaboratively work together. Figure 8 demonstrates the overall design of PilotFish.

Instead of predicting the random gaming behaviours, *PilotFish monitors the frame-level execution and resource-usage information in real time with very low overheads*. Existing frame monitoring tools [8, 9, 17] for gaming are usually based on event-tracing technology [4], which is for general-purpose application by design and infeasible for PilotFish’s requirement due to its high latency. To capture the idle GPU periods, PilotFish instruments the graphic libraries to quickly and precisely detect when the rendering of a frame finishes and when the next frame will be submitted (according to the FPS requirement).

Within the idle period of a game, *PilotFish schedules the computation kernels safely without interfering with the games*. The computation kernels for DL training should only be executed between the end of the previous frame and the start of the next frame. This relies on the kernel duration predictor to provide the execution time of the computation kernels, by leveraging their predictability as we discussed in Figure 6. A computation kernel can be submitted only when it can finish

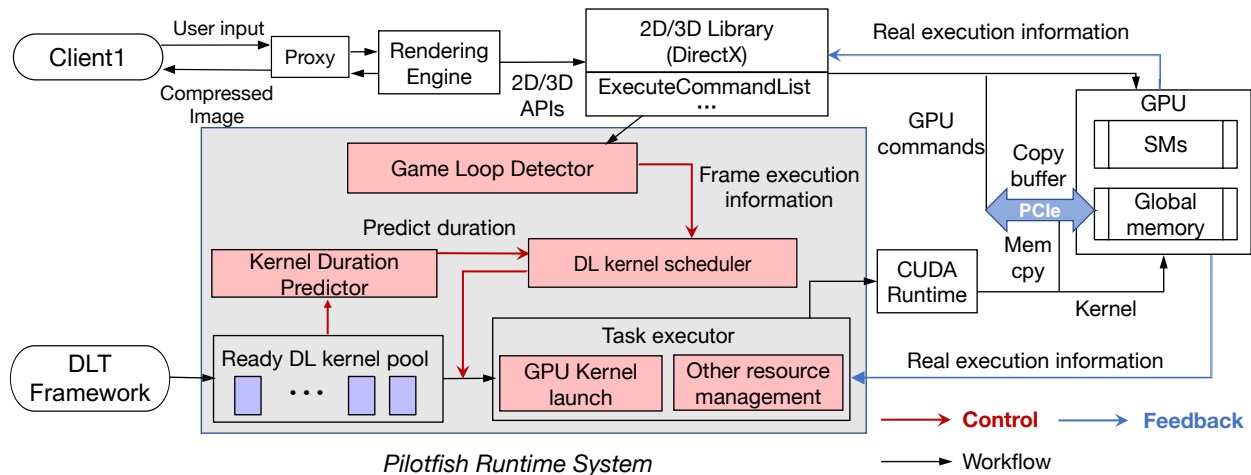

Figure 8: The Overall design of PilotFish. The Game Loop Detector quickly obtains the idle GPU periods via instrumenting the graphic libraries. The DL kernel scheduler dynamically and safely schedules the kernels with the predicted kernel duration. The task executor guarantees the DL kernel execution will not interfere with cloud gaming on GPU and other types of resources.

before the rendering of the next frame starts so that it will not contend with the game rendering on GPU. Since PilotFish only schedules DL kernels without changing its computation, it has no impact on the computation result of DL training.

During the execution of DL training’s computation kernels, PilotFish keeps monitoring their progress in its task executor. Once potential interference could appear due to straggler kernels, *PilotFish should immediately preempt the job to guarantee cloud gaming is not affected*. To minimize the loss of training progress due to preemption, we introduce a low-overhead checkpointing mechanism to only kill the computation kernels without losing the trained weight in memory.

We explain in § 4 how PilotFish instruments the graphic libraries to obtain the idle GPU periods. In § 5, we elaborate on how the computation kernels of DL training are scheduled. Then, we demonstrate the task executor in § 6 that manages the task execution on GPUs and other types of resources to provide the strict guarantee of no interference to games.

4 Game Loop Instrumentation

To capture the random idle GPU cycles from games, we need to monitor the frame execution information, i.e., the start and end rendering time of each frame, in real time. Nowadays, there are many popular frame monitoring software for rendering workloads including PresentMon [17], IntelGPA [9], GpuView [8], and FrameView [5]. They all use event-tracing technology [4], which records events with high latency (usually >1 second). However, cloud gaming usually requires 60 frames per second, i.e., 16.67 ms per frame, which cannot accept such a large tracing latency.

In PilotFish, we exploit the fact that most games are developed on common graphic libraries (e.g., DirectX [3],

Table 2: The Game Loop Detector Performance.

	Avg. Overhead / 60 frame	Avg. Err.
ACOdyssey	0.1058 ms	0.363%
Genshin Impact	0.070668 ms	0.526%

Vulkan [20]), which translate the graphical operations into GPU commands. When the game finishes generating the draw calls, the GPU commands will be submitted to the GPU via a specific API (e.g., ExecuteCommandList in DirectX). PilotFish instruments the command submission API of graphic libraries to detect the start time of frame rendering. The instrumentation latency is very low, usually within 1 microsecond per frame. Moreover, to obtain when the rendering completion time of the submitted frame, PilotFish inserts an additional GPU command for notification of rendering completion at the end of the submission queue. Since the QoS of cloud gaming determines the maximum frame rate, e.g., an FPS of 60 means there is at most one frame per 16.67ms. When PilotFish is notified with the rendering completion, we can calculate when the next frame would appear, thus the time period before the next frame is guaranteed to be idle. Table 2 shows the average overhead and error for FPS perception through the game loop detector. The overhead is negligible where the average overhead per 60 frames is around 0.1ms. We also validate FPS measured from PilotFish by comparing with PresentMon [17] as the ground-truth. The average measurement error of FPS is 0.526%. Instrumenting the graphic libraries that most games built on allows PilotFish to generally support a wide range of existing games and future games without specific modification for every game.

Algorithm 1: DL training scheduler

```
1 while true do
2   if isFrameRendering() then
3     WaitForFrameComplete();
4     freeTimeslice = FrameTimeQoS -
       LastFrameRenderingTime;
5   else
6     kernel = GetKernelFramePool();
7     kernelTime = PredictDuration(kernel);
8     if freeTimeslice > kernelTime then
9       LaunchKernel(kernel);
10      freeTimeslice =
        freeTimeslice - kernelTime;
```

5 DL Training Scheduler

With the captured GPU idle periods, PilotFish will schedule the computation kernels from DL training to harvest the free GPU cycles. As shown in Figure 9, PilotFish only allows the DL kernels to execute within the idle GPU periods to avoid GPU contention. Algorithm 1 describes the scheduling strategy of PilotFish: (1) when the game is using GPU to perform rendering, it will wait for the notification of the rendering completion; (2) when the game finishes rendering a frame, the scheduler sends the DL kernels that can finish before the deadline when FPS QoS is affected (e.g., when the QoS is 60 frames per second, the start time between two frames should be no more than 16.67 ms).

PilotFish’s DL training scheduler relies on the prediction of computation kernels to decide whether the submitted kernel can finish before the next frame starts (Line 7 in Algorithm 1). PilotFish leverages the predictability and iterative pattern of DL training. The kernels for the same model will be repeatedly submitted in every iteration with different input data. As we have shown in Figure 6, the kernel duration has a very low variance, which can be easily obtained via offline profiling. In PilotFish, the DL training jobs to co-locate with games will be profiled on idle GPUs for tens of iterations (usually a few minutes), and record their kernel execution time.

Note that, the GPU context for DL training is first created in the job initialization, thus its overhead does not affect the scheduling of DL kernels. Also, the launching of computation kernels has an overhead of 10 us, which is usually less or equal to a kernel’s execution time. To hide the kernel launching overhead, like most training frameworks, PilotFish submits the computation kernels asynchronously (as shown in Figure 9). Therefore, PilotFish only suffers from at most one kernel launching overhead at the first DL kernel in each frame, which is negligible.

Figure 9: Fine-grained scheduling of DL kernel.

6 Task Executor

After the DL kernel is scheduled, the task executor monitors the kernel execution to avoid straggler kernels that run longer than expected and do not finish before the next rendering frame. In case the potential interference could appear, the task executor will terminate the process quickly to reclaim the GPU for game rendering while minimizing the loss of training progress. In addition to GPUs, the task executor also manages the other resource types including CPUs, PCIe bus and Disk I/O to avoid non-GPU interference.

6.1 GPU Kernel Execution

During the execution of computation kernels, PilotFish’s task executor keeps monitoring the running kernels on their execution time. Although, not often, some straggler kernels may run longer than the predicted time, which may postpone the rendering if they do not finish before the next frame appears. Note that the straggler kernels will not lead to QoS violation if the rendering time of the next frame is short and can still be finished within the deadline. Also, a slight drop in FPS (1 ~ 2 FPS) may not affect the gaming experience for non-sensitive players. Therefore, PilotFish provides two types of guarantees:

1) Hard guarantee: once a straggler kernel appears that it can not finish before the next frame rendering begins, the task executor suspends the running DL kernel on the GPU immediately.

2) Soft guarantee: PilotFish does not terminate the straggler kernels unless FPS drop exceeds a certain threshold.

Using soft guarantee is more friendly to DL training models that contain kernels of long execution time, e.g., the longest kernel of LSTM runs for 2.4 ms. Our evaluation in § 7.4 shows using the soft guarantee can harvest over 30% more GPU cycles than the hard guarantee when we co-locate LSTM with RDR2.

6.2 Low-overhead Pause and Resume

Figure 10 shows the design of PilotFish’s DL training pause and resume. In order to terminate the straggler kernel quickly, PilotFish leverages the multi-priority streams of modern GPUs to send asserting signal to DL training kernels at the highest priority. The preemption can be done very fast within 0.7 ms. However, asserting the kernel would wipe out all the

memory state that results in loss of the training progress. Although DL training may periodically save checkpoints, it is done in a less frequent manner (usually every a few epochs that takes hours).

Figure 10: PilotFish’s low-overhead pause and resume.

Note that, we only want to terminate the computation to avoid the interference to games thus it is not necessary to clear the memory. To maintain the model weight while DL training job suspension, PilotFish builds a shared memory pool in an isolated process, that stores a backup version of the model weight. When resuming a DL training job from suspension, the pointer of shared memory is directly shipped to the memory manager of the training frame. If the GPU supports inter-process communication (IPC), the shared memory pool is placed on GPU thus no memory copy is needed. Otherwise, The shared memory pool is placed on the host memory thus requires resume the model weights by copying them from host to GPU. Our evaluation shows resuming the model from the host memory for ResNet-34, VGG-16, MobileNet and LSTM takes 64, 69, 63 and 30 ms respectively. But PyTorch’s requires over 7 seconds via its default checkpointing mechanism.

6.3 Mitigating Other Resource Contention

In addition to contention on GPU, both cloud gaming and the DL training involve other resource types thus also need careful management for interference avoidance.

CPU contention. For the DL training tasks, the CPU is used for data pre-processing, e.g., image decoding, re-shaping, data augmentation. Games use CPU for processing game logic and simulate physical effects. CPU contention may appear when the CPU-heavy DL training and games are co-located, resulting in a decrease in FPS and an increase of game loading time. PilotFish solves the resource contention on CPU by setting the priority of threads: game threads use a high priority and DL training threads use a low priority. Figure 11 shows the FPS of RDR2 to be co-located with a job that only pre-processes the data of DL training. By increasing the stress of the co-located job, the FPS and loading time of the game is affected severely if they have the same CPU thread priority. The Windows OS’s scheduler can fully mitigate the interference on CPU after we set the thread priority of the co-located job to low.

PCIe contention. Using PCIe bus, games transfer vertex data and primitive data from pageable memory to GPU dur-

Figure 11: The FPS and loading time of RDR2 when co-located with CPU threads for DL training.

Figure 12: The inference to RDR2 on PCIe bus and Disk I/O.

ing execution, and the rendered frames are passed back from GPU [21]. The DL training uses PCIe to transfer data and model parameters. We have tested two popular games’ performance benchmarks (Shadow of the Tomb Raider and The Division 2). The average memcopy time per frame is 0.1748ms and the frames with copy time greater than 0.5ms account for 3.9% of all frames. When games use pageable memory and transfer data through PCIe bus alone, the achieved data transfer rate is 11,045MB/s. Because the theoretical peak bandwidth of 16x PCIe 3.0 bus used in our platform is 15,800MB/s and the effective bandwidth is 12,160MB/s, the bus can only support at most $\lfloor \frac{12160}{11045} \rfloor = 1$ memcopy task to transfer data in their full speeds in the same direction. Therefore, it is necessary to guarantee no interference on PCIe to avoid the game’s data transfer. In PilotFish, we rely on the bandwidth reservation technique proposed in Baymax [25] to reserve the enough PCIe bandwidth for cloud gaming. The DL training can only transfer data when the game is not using PCIe.

Figure 12a shows the FPS of game RDR2 when co-located with a stress test progress of memory copy. This stress test copies data from the host memory to the global memory of GPU, and then back to the host memory every 60 ms. We control the proportion of the memcopy time to the total time by controlling the size of the copied data. With increased memory copy stress, the FPS drops greatly without reserving the PCIe bandwidth for the game. The reservation guarantees the game is not affected by PCIe contention.

Disk I/O contention. From disk, games loads rendering

resources (e.g., texture) and DL training loads training data. Contention on disk I/O may lead to longer loading time for games. Figure 12b illustrates the FPS and loading time of a game co-located with a disk stress benchmark performing sequential read/write and 4K read/write [2]. Without any isolation, the FPS does not change but the loading time is increased by 21%. Moreover, we observe some objects are not rendered in the displayed frame, which is unacceptable to players. We apply the widely used I/O isolation techniques, including namespace [12] and I/O priority [10]. We find both techniques can guarantee the game performance by isolating the I/O operations.

GPU memory and caches. To avoid swapping data among GPU memory and host memory, PilotFish only co-locates a game and a DL training job when the sum of their peak GPU memory demand can fit into the GPU memory. Since DL kernels are only executed in the idle GPU cycles, their data movement between GPU memory and GPU caches has no overlap with gaming. GPU commands from game and DL training are serialized without preemption thus there is no context switching overhead. DL training may flush the GPU cache of rendering data of the previous frame. But we do not observe impact on rendering time to the next frame.

Network and video stream encoding. In PilotFish, we assume the distributed training uses a separate network from the cloud gaming service due to security and performance concern, thus there is no interference in network. Also, as we have explained in Figure 2, video stream encoding is done in a separate hardware encoder, thus is not interfered by DL training.

7 Evaluation of PilotFish

We have implemented a prototype of PilotFish on DirectX 12, CUDA 11.1, Windows 10, and PyTorch 1.8 with 2400 lines of code. As far as we know, PilotFish is the first system that co-locate cloud gaming with DL training. Therefore, we compare PilotFish with several straw-man solutions to evaluate its effectiveness. Overall, PilotFish can harvest up to 85% of idle GPU cycles from cloud gaming without generating interference.

7.1 Experimental Setup

We evaluate PilotFish with Steam Remote Play & Steam Link (cloud gaming platform) using the Nvidia RTX 2060 GPU. Table 3 summarizes the software and hardware experimental configurations. Note that PilotFish does not rely on any special hardware features of RTX 2060, and is easy to be set up on other GPUs. As listed in Table 4, we use five popular DirectX 12 games and four DL training applications to perform the experiment.

Throughout our experiments, the FPS target of games is 60 FPS (16.67 ms/frame). The QoS of the game is defined

Table 3: Hardware and software specifications.

	Specification

HITMAN3 (HIT3)	Ultra quality on 2560*1440; FPS: 60
DL Training	ResNet-34 (RS) [30]; VGG-16 [44]; MobileNet (MN) [31]; LSTM [45]; Dataset: ImageNet-1k, Wikitext-2

as the 99%-ile latency normalized to 60 FPS. We calculate the GPU utilization as the portion of time when the GPU is busy, which is the same as the definition of nvidia-smi [16]. We define the metric, harvest ratio, as the portion of GPU idle time that is harvested for DL training, which is calculated as

$$\text{Harvest Ratio} = \frac{\text{GPUUtil}_{\text{co}} - \text{GPUUtil}_{\text{Game}}}{100\% - \text{GPUUtil}_{\text{Game}}}, \quad (1)$$

where $\text{GPUUtil}_{\text{Game}}$ is the GPU utilization of running game independently, and $\text{GPUUtil}_{\text{co}}$ is the GPU utilization when game and DL training are co-located. For PilotFish, the time of model checkpointing is not considered as harvested.

Comparison Baselines. To compare the performance of PilotFish, we propose three straw-man solutions:

1. **GameMode** [6] is a feature introduced by Windows to prioritize CPU threads of games. It does not control GPU execution.
2. **Constant-Speed** controls the DL kernel submission speed with a constant rate.
3. **Adaptive-Speed** controls the DL kernel submission speed dynamically according to the FPS profiled from the event-tracing tool PresentMon [17]. If $\text{FPS} < 60$, the DL kernel submission speed is halved, otherwise, it is multiplied by 1.2.

7.2 GPU Utilization Improvement and FPS Guarantee

We first demonstrate the effectiveness of PilotFish by comparing PilotFish with the three baselines on all combinations of cloud games and DL models listed in Table 4. By default, the Constant-Speed baseline is set to 50% of the ideal speed (i.e., training the model on the same GPU without co-location).

Figure 13: The 99%-ile FPS, harvest ratio and training wall time of different co-location combinations of games and DL models.

Figure 13 presents the 99%-ile FPS of the cloud games normalized to the FPS target (60 FPS), and the harvest ratio of idle GPU time. Note that, due to bursty complex frames, the cloud game may not always maintain at 60 FPS either even without co-location. Figure 13a shows that PilotFish achieves almost the same 99%-ile FPS compared to that without co-location. The three baselines all experienced severe FPS drops. GameMode drops the most, by up to 78.6% (e.g. SOTTR+RS). Constant-Speed(50%) and FPS-Based drop from 16.3% to 69.2% and from 20.7% to 66.3%, respectively. In the game of SOTTR and HIT, all baselines suffer from severe interference. Since SOTTR switches scenes multiple times during the benchmark, its rendering time of frames fluctuates more severely than the other four games. The three baselines cannot quickly adapt to the fluctuation thus perform poorly.

Figure 13b shows the harvest ratio in the different combinations. As shown in the figure, PilotFish w/ hard guarantee harvests 78.56% of idle times on average in all five games co-located with three DL training tasks (MobileNet, Resnet-34 and VGG-16) without interfering with the cloud games. When cloud games are co-located with LSTM, the harvest ratio drops to 39.03%. Because LSTM contains some large kernels that run for ~ 2.4 ms, they may not be scheduled if the idle GPU time is short with PilotFish’s hard guarantee. Since the rendering time of game F1 is lower than other games, its harvest ratio on LSTM is relatively higher than others, which is 48.43%. With the huge penalty of FPS drop, GameMode

achieves the highest harvest ratio (83% on average) since it does not control the speed of DL training. The harvest ratios of the Constant-Speed (50%) and Adaptive-Speed range from 26% to 50% and 11% to 74%. These two baselines not only harvest less idle GPU time than PilotFish but also degrades the FPS significantly. They prove the necessity of PilotFish’s mechanisms to fast and safely schedule DL kernels.

Figure 13c shows the training wall time of the co-located DL models normalized to training them on dedicated GPU. The training wall time is almost inversely proportional to the harvest ratio. Because GameMode occupies more GPU cycles from games in addition to the idle cycles, it has the least slowdown at the price of severely affected game FPS. Because of higher harvesting efficiency, PilotFish’s training wall time is better than Constant-Speed and Adaptive-Speed for most models without affecting the FPS of games.

7.3 Dissecting Execution

To demonstrate how cloud game runs when co-located with DL training, in Figure 14, we show the instantaneous FPS (the inverse of frame time) fluctuation of RDR2 over time when co-located with ResNet-34. We select a game segment (50 seconds) during the stable running of the game. We find PilotFish can always be stable near the original FPS without co-location. The baselines experience serious FPS fluctuations, especially GameMode and Constant-Speed since they are not

Figure 14: The instantaneous FPS of RDR2 over time when co-located with ResNet-34. The FPS is normalized to the average FPS without co-location.

Figure 15: The rendering quality of PilotFish (left), No co-location (middle), and GameMode (right). The rendering quality in GameMode is much worse than the others due to interference.

adaptive at all. The fluctuated and degraded FPS leads to very poor experience for players. When FPS drops, some games with adaptive rendering mechanism will actively reduce the rendering quality to maintain a smooth playing experience. Figure 15 compares the rendering quality of PilotFish, no co-location, and GameMode. PilotFish has the same rendering quality with running the game without co-location. But the game co-located with DL training in GameMode reduces the rendering quality under the bridge due to interference.

7.4 Sources of Improvement

Dynamic Scheduling. Figure 16 shows normalized 99%-ile FPS and the harvest ratio of the pair (RDR2+RS) under the different kernel submission speed in Constant-Speed policy. The kernel submission speed ranges from 3% to 100% (normalized to the ideal speed without co-location). The right-most column shows the results of PilotFish for comparison. As expected, we find that the 99%-ile FPS decreases and the harvest ratio increases as the submission speed grows from 3% to 100%. We specifically listed the 99%-ile FPS at the kernel submission speed 3% and 4%. We find the FPS target can be satisfied only when the kernel submission speed is very low. When the submission speed is higher than 4%, 99%-ile FPS begins to drop. Without degrading the 99%-ile FPS, PilotFish can achieve the same harvest ratio of Constant-Speed at 80% submission speed.

Figure 17 shows the harvest ratio of HIT under different rendering qualities when co-located with MobileNet and LSTM.

Figure 16: The impact of kernel submission speed in Constant-Speed v.s. PilotFish.

Figure 17: (HIT+MN/LSTM) the 99%-ile FPS and harvest ratio of PilotFish with different graphic quality.

Since MobileNet is mainly comprised of small kernels, it is easier to fit into short idle GPU periods. But the LSTM model contains some long kernels (~ 2.4 ms), which requires longer idle GPU periods. Therefore, reducing the rendering quality allows LSTM to harvest more GPU cycles from the game than MobileNet.

The two experiments in Figure 16 and Figure 17 imply the dynamic scheduling of DL kernels is necessary to handle the high randomness of game frames and diverse characteristic of different combinations of game and DL model.

Effective training pause and resume. To verify the need for the training pause mechanism introduced in Section 6.1, we disable this mechanism to compare its impact with PilotFish's policies of hard guarantee and soft guarantee. Figure 18 shows the 99%-ile FPS (normalized to 60 FPS) and the harvest ratio with different pause policies. When using the policy of hard guarantee, PilotFish achieves the same FPS of that without co-location. When the pause condition is relaxed by 5% (3 FPS), the FPS using the policy of soft guarantee is degraded within the threshold while the harvest ratio is increased. When disabling the pause mechanism, the FPS further decreases at the cost of no FPS guarantee. The impact of the pause policies is different for models: ResNet-34 is less impacted than LSTM since the computation kernels of ResNet-34 is much shorter than LSTM. In the worst case, if a DL training task submits a long-running kernel, the game rendering could be infinitely postponed. Therefore, we suggest using the policy of soft guarantee when the cluster opera-

Figure 18: The 99%-ile FPS and harvest ratio of PilotFish with different training pause policies.

Figure 19: (RDR2+RS) the lost progress of DL training.

tor wants to trade a limited interference with a higher GPU utilization.

Figure 19 shows the lost progress of DL training due to training pause with the hard guarantee. Compared with the epoch-level checkpoint in PyTorch whose lost progress is 69.62% on average, PilotFish reduces the lost progress by 4.6 times to 15.04% with the weight backup in the shared memory pool. LSTM loses more training progress than other models since it triggers more training pause due to its longer computation kernel.

8 Scale to Data Center

To evaluate the potential benefit of PilotFish to cloud gaming service running in a large cluster of GPUs, we use a simple heuristic cluster-level scheduler to decide which games and DL training jobs are suitable for co-location on the same GPU, as shown in Figure 20. The heuristic cluster scheduler collects the average resource usage of DL jobs and games through offline profiling. It greedily matches the DL training job with the game with the DL training job so that the remaining resource is minimized. For the DL model using synchronous data parallel training, the scheduler prefers to deploy each of its workers to the servers with a similar utilization so that each worker can run at a similar speed, which can reduce the synchronization overhead.

We compare this heuristic policy with a random scheduling policy that co-locates games and DL training models randomly. We simulate a cloud gaming cluster composed of one thousands Nvidia RTX2060 GPUs. We select ten popular games as the workload of cloud gaming, including Dota 2,

Figure 20: Cluster-level Scheduler.

Figure 21: The variation of active players on Steam. Figure 22: The GPU utilization in the simulated cluster.

League of Legends, PUBG, CS:GO, Civilization 5, Assassin's Creed Odyssey, The Division 2, Ashes of the Singularity, RDR2, and Genshin Impact. The games are launched with the same probability. The number of running games follows the active player variation reported by Steam (shown in Figure 21), which has a strong diurnal pattern. We regard the peak point in Figure 21 as the situation when all the 1000 GPUs are used by cloud games. For the DL Training workloads, we select 750 instances evenly from the five models: ResNet-34, ResNet-50 [30], VGG-16 [44], MobileNet [31], and DenseNet [32]. Each model has 100 non-distributed training instances and 50 distributed training instances.

Figure 22 shows the GPU utilization of no co-location, random scheduler and the greedy heuristic scheduler. When there is no co-location, the cloud gaming cluster only has a GPU utilization of $\sim 40\%$. The random policy can improve the utilization to 68.89% due to PilotFish's efficient execution. Since the greedy policy is aware of the resource usage pattern of cloud games and DL training, it can further improve the cluster utilization to 81.12%. It implies the games and DL training jobs should be carefully scheduled at the cluster-level to maximize the benefit of co-location, which is an interesting future direction.

9 Related Work

General CPU co-location. There has been a large amount of prior work focusing on improving application QoS and

hardware utilization for CPU co-location. They can be broadly categorized as (1) profiling-based methods [26, 27, 41, 48, 52] and (2) partitioning-based methods [39, 53]. The profiling-based methods, such as Bubble-Up [41], Bubble-Flux [48], SMiTe [52], uses offline profiling of user-facing services and batch applications to predict their performance degradation to avoid contention on shared cache and memory bandwidth. They periodically adjust the allocation of shared resources according to the QoS feedback of user-facing services.

However, these techniques would fail on cloud gaming because they neglect the complex interaction of interference on different shared resources on GPUs.

General GPU co-location. Several techniques were proposed in the prior work to improve the utilization of GPUs with co-location. TimeGraph [34] and GPUSync [28] use priority-based scheduling to guarantee the performance of real-time kernels. High-priority kernels are executed first if multiple kernels are launched to the same GPU. GPU-EvR [35] launches different applications to different streaming multiprocessors (SMs) on one GPU. However, they are not applicable to our problem because they all rely on the simulator to synthesize the execution trace of co-located applications. Laius [50] and Baymax [25] predict the kernel duration and reorder the kernel based on the QoS headroom of user-facing queries. But it is difficult to predict the rendering frame time of game with a low overhead. AntMan [47] only co-locates multiple DL training jobs, which cannot handle the unpredictable game rendering. Nvidia Volta MPS (Multi-Process Service) [42] enables multiple applications to share a GPU concurrently with static partition, however, cannot handle the dynamic load of cloud gaming. Moreover, MPS-based solutions rely on the special hardware feature that only supports CUDA applications but not games, and is not applicable to non-Nvidia GPUs.

Co-location of cloud gaming. Specifically for cloud gaming, several works have been proposed to improve resource utilization by co-locating multiple games [37, 43, 49]. vGASA [49] adaptively schedules rendering tasks from multiple games to meet the SLA in a best-effort manner. However, when a hard SLA guarantee is required, vGASA has to reserve the resource for the worst cases so that all running games can meet the SLA at the most complex scenes. As we have shown in Section 2.2, cloud gaming has a high variance in GPU usage. Conservatively guaranteeing the worst case would waste resources with a significant over-provisioning.

GAugur [36] and dJay [29] dynamically tune the game settings for the co-located games during gameplay to adapt to changes of game scenes for improving performance. However, as we have shown in Figure 4, the frame time and GPU load in the gaming could fluctuate drastically even within a short period of time. Frequently changing the game setting is noticeable to players and could greatly degrade the gaming experience. This is unacceptable to commercial cloud gaming services. Instead, the computation of DL training is highly

predictable. PilotFish can accurately predict the execution of DL kernels and schedule them only when it is safe. This is the main reason why we claim DL training is the right workload to be co-located with cloud gaming.

10 Conclusion

Cloud gaming service suffers from low GPU utilization issue due to the limitation of network and edge devices. Since cloud gaming utilizes GPUs in a very random manner, existing co-location solutions for GPU cannot meet the QoS requirement of cloud gaming. PilotFish addresses this issue by co-design cloud gaming service and deep learning training framework. PilotFish can harvest free GPU cycles using DL training with no interference to cloud gaming. PilotFish achieves this hard guarantee by (1) quickly capturing the idle GPU periods from cloud gaming via low-overhead instrumentation to graphic libraries (e.g., DirectX); (2) leveraging the predictability of DL computation to safely schedule DL kernels; and (3) providing a low-overhead mechanism to pause DL computation when they could potentially interfere with games. Our evaluation shows that PilotFish can harvest a significant portion of idle GPU time of cloud gaming up to 85.1% without affecting the gaming experience. PilotFish reveals a principled design to co-locate unpredictable workloads with predictable low-priority workloads. In addition to co-locating cloud gaming with DL training, it is interesting to generalize PilotFish's solution on other predictable workloads, e.g., scientific computing [22, 50].

Privbox: Faster System Calls Through Sandboxed Privileged Execution

Dmitry Kuznetsov
Tel Aviv University

Adam Morrison
Tel Aviv University

Abstract

System calls are the main method for applications to request services from the operating system, but their invocation incurs considerable overhead, which has been aggravated by mitigation mechanisms for transient execution attacks. Proposed approaches for reducing system call overhead all break the semantic equivalence between system calls and regular function calls (e.g., by making system calls asynchronous), and so their adoption requires rearchitecting applications.

This paper proposes *Privbox*, a new approach for lightweight system calls that maintains the familiar synchronous, function-like system call model. Privbox allows an application to execute system call-intensive code in a *semi-privileged, sandboxed* execution mode, called a “privbox”. Semi-privileged execution is architecturally similar to the kernel’s privileged execution, which enables faster invocation of system calls, but the code is sandboxed to ensure that it cannot use its elevated privileges to compromise the system. We further propose *semi-privileged access prevention* (SPAP), a simple hardware architectural feature that alleviates much of Privbox’s instrumentation overhead.

We implement Privbox based on Linux and LLVM. Our evaluation on x86 (Intel Skylake) hardware shows that Privbox (1) speeds up system call invocation by 2.2×; (2) can increase throughput of I/O-threaded applications by up to 1.7×; and (3) can increase the throughput of real-world workloads such as Redis by up to 7.6% and 11%, without and with SPAP, respectively.

1 Introduction

System calls are the de-facto method for processes to request services from the operating system (OS), but they are orders of magnitude slower than a regular function call. Much of the overhead stems from switching the processor’s execution mode between unprivileged user-mode and privileged kernel execution on system call entry and exit [1]. User-to-kernel mode switches are further slowed down by the protection mechanisms [2, 3] recently added to mitigate transient execution vulnerabilities such as Meltdown [4] and Spectre [5].

Reducing system call overhead has attracted significant research attention over the years (e.g., [6, 1, 7, 8, 9, 10]), and the increased overhead imposed by the mitigations of transient execution vulnerabilities [10] underscores the importance of addressing the problem. Current approaches, however, *break*

the semantic equivalence between system calls and regular function calls. For instance, FlexSC [1] and *io_uring* [8] make system calls asynchronous; the *io_uring* model and similar models [6, 11, 12] also limit how system calls can be composed. Consequently, benefitting from these system call designs requires rearchitecting applications to use the new system call models.

In this work, we propose *Privbox*: a new approach for lightweight system calls that maintains the familiar user-space programming model of synchronous, function-like system calls. In our design, an application can demarcate system call-intensive code and have it execute in a *privbox*, in which system call invocation is cheap—e.g., 2.2× faster than a regular system call on an Intel Skylake CPU. An application can thus enjoy low-overhead system calls with an unchanged synchronous system call model and only minor source code modifications to demarcate privboxed code regions.

Privboxed code runs in a “semi-privileged” mode. Semi-privileged execution consists of the processor running in privileged mode with the kernel address space mapped, which reduces user/kernel system call transition time, similarly to kernel-mode Linux (KML) [7]. But unlike KML, semi-privileged privboxed code runs *sandboxed*, so that it has the same access as the regular, unprivileged code of its process—thus it cannot violate OS security.

Our sandbox design is inspired by the software fault isolation approach of NaCl [13, 14], which uses compile-time instrumentation to generate verifiably safe code. We adapt NaCl’s instrumentation approach to the circumstances and environment of semi-privileged privboxed execution. In our design, source code demarcated for privboxed execution is instrumented at compile-time to prevent it from reading/writing arbitrary kernel memory or jumping to arbitrary kernel code. The kernel verifies the correctness of the instrumentation before allowing the code to begin its privboxed execution. The privboxed code then runs natively, without any runtime environment, but under a custom page table configuration that blocks it from executing uninstrumented user-mode code.

Unfortunately, the sandbox’s instrumentation slows down execution of the privboxed code, which reduces the benefit from faster system calls. We identify instrumentation of memory operations (load and store instructions) as the main culprit. Motivated by this finding, we propose *SPAP* (semi-privileged access prevention), a simple hardware architectural modification that enables omitting load/store instrumentation

from privboxed code. With SPAP, privileged mode hardware execution blocks an instruction from reading/writing a kernel address if that instruction resides in a user-mode address (as privboxed instructions do). SPAP's check can be implemented analogously to how x86-64 implements its supervisor mode access prevention (SMAP) [15] feature, which blocks privileged mode execution from accessing user-mode addresses.

We implement Privbox for x86-64 by adding support for semi-privileged execution to Linux and the musl standard C library [16], as well as extending LLVM to support generation of instrumented (sandboxed) code. We evaluate Privbox in two contexts:

1. Applications that use patterns such as I/O threads and reactors [17]. These patterns are system call intensive with little user-space logic, and are therefore less impacted by instrumentation overhead. We find that such applications can gain over $1.7\times$ speedup, even without SPAP.
2. Applications that combine I/O and user-space logic. Specifically, we modify Redis [18], memcached [19], and SQLite [20] to use Privbox. For simplicity, we compile the entire application with instrumentation, which gives us a lower bound on Privbox's benefit. Using Privbox in these applications requires little effort (20–30 lines of code) and yields an improvement of up to 7.6% on today's hardware without SPAP and up to 11% in a configuration that approximates performance under SPAP.

Contributions We make the following contributions:

- **Privbox design (§ 3).** We design Privbox, a new systems programming mechanism for lightweight system. Privbox maintains the familiar user-space system call model and its adoption requires no application source code changes.
- **Implementation (§ 4).** We implement support for Privbox for x86-64 in Linux, the musl C library, and LLVM.
- **SPAP (§ 5).** We propose semi-privileged access prevention, a simple hardware modification that enables omitting load/store instrumentation from privboxed code.
- **Evaluation (§ 7).** We show that Privbox improves (1) system call overhead by $2.2\times$; (2) I/O thread execution time by over $1.7\times$; and (3) real-world workload throughput by as much as 7.6% without SPAP and 11% with SPAP.
- **Availability.** The Privbox implementation and benchmarks are available at <https://github.com/privbox>.

2 Background & motivation

Monolithic kernels like Linux rely on hardware *privilege modes* to enforce process isolation and to mediate I/O access to peripheral devices. The kernel offers a set of *system calls* for processes to request services requiring OS mediation, such as input/output (I/O) to devices, inter-process communication, and virtual address space modification. System calls

are semantically equivalent to function calls, but are orders of magnitude slower. This problem has spurred research on reducing their overhead. These proposals, however, break the semantic equivalence between system and function calls, so adopting them requires rearchitecting applications to use a new system call model. Our goal is thus to address the problem without changing the system call programming model.

Privilege modes The basic hardware mechanism used to implement the OS isolation model is the distinction between unprivileged and privileged processor execution modes. The kernel runs in *privileged* mode, which allows full access to the entire instruction set, including *privileged instructions* for, e.g., installing a page table or enabling/disabling interrupts. Applications run in *unprivileged* mode, which only allows execution of non-privileged instructions that cannot circumvent OS isolation. Implementation of the execution privilege modes differs between hardware architectures. In this paper, we focus on the x86-64 architecture. It defines four hardware privilege levels, also called *rings*, numbered 0 to 3 in decreasing order of privilege. Most OSes execute user applications in ring 3 and the kernel in ring 0. The CPU has a *code segment* (CS) register that (indirectly) defines the CPU's current ring, also called *current privilege level* (CPL).

System calls A *system call* is a mechanism for a controlled and safe transfer of execution from untrusted unprivileged code to privileged kernel code. On x86-64, system calls are implemented by the `syscall` instruction. This instruction elevates the CPU's privilege mode and transfers control to a pre-determined kernel memory address, called the system call entry point. The entry point code determines the kernel function to service the desired call by inspecting certain CPU registers (determined by a software, OS-specific convention), executes it, and finally executes a "return to user" instruction which lowers the CPU's privilege mode and transfers control back to the unprivileged code.

System call overhead A system call is semantically equivalent to a function call from an application's perspective. But it is orders of magnitude slower, as its invocation/return is a multi-step procedure in both hardware and software, in which hardware elevates/lowers its privilege level and saves/restores certain CPU state, and kernel code saves/restores remaining CPU state and determines and executes the system call code.

System call overhead is exacerbated by mitigations of hardware microarchitecture vulnerabilities, such as Meltdown [4] and Spectre [5]. These vulnerabilities involve malicious user code abusing microarchitectural state shared by the CPU's privilege modes to read memory that is not architecturally accessible to the attacking user code. Mitigation accordingly involves modifying the relevant CPU state on system call entry, which adds overhead. For instance, on affected hardware, Linux's system call entry code flushes the CPU indirect branch predictor's state [3] to block Spectre v2 attacks. In addition, Linux's page table isolation (PTI) [2] Meltdown mit-

igation switches page tables during system call entry, which is a costly operation that also implies a TLB flush on x86-64. Indeed, our evaluation (§ 7.1) finds that while a standard system call invocation entry/exit time is $28\times$ slower than a function call/return, PTI makes it $52\times$ slower. And while Linux’s software mitigations are not used on recent processors that mitigate the vulnerabilities in hardware, the hardware mitigation itself slows down the system call instruction [10].

Reducing system call overhead There are several proposals to reduce the overhead of system call entry/exit. They generally achieve this by compromising on the semantic equivalence between system and function calls.

Flexible system calls (FlexSC) [1] makes system calls asynchronous instead of synchronous. It offloads system call execution to a kernel “syscall thread” associated with the process, with which the process communicates over a shared-memory interface, thereby eliminating CPU cycles spent on system call entry/exit. However, FlexSC requires *rearchitecting applications to use an asynchronous programming style*.¹ It also increases CPU usage due to the added threads and polling of the shared-memory communication structures.

System call overhead can be reduced by batching. The *multi-call* approach invokes several system calls with one kernel entry/exit. Linux includes several multi-calls, such as `preadv`, which performs a sequence of seek-followed-by-read operations. Cassyopia [6] explores compiler optimizations to batch several system calls together. But since a multi-call specifies the participating calls up front, it *does not support arbitrary composition of system calls and user-space logic offered by the standard system call model*.

Recent Linux versions offer an `io_uring` [8] mechanism. `io_uring` allows submitting I/O requests through a memory interface, like FlexSC, but it does not support arbitrary system calls. Like multi-calls, multiple requests can be submitted to a submission queue, but the submitted operations can be of different kinds and interact with different file descriptors. Overall, `io_uring` can be viewed as a combination of FlexSC and batching specialized for I/O, and thus suffers from the same limitations as those approaches.

Kernel bypasses avoid system call overhead by doing away with system calls for device access. For instance, DPDK [9] and SPDK [21] allow applications to interact directly with networking and storage devices, respectively. But since the kernel no longer mediates device access, its standard interfaces such as sockets or files cannot be used, and user-space has to implement all the abstractions it requires.

Ward [10] targets overhead related to Spectre and Meltdown mitigations. It constructs process page tables which do contain mappings of kernel memory, but only memory that is safe to expose to that process. At best, Ward reduces system

¹FlexSC offers a threading library that makes its asynchronous system calls transparent to applications, but this library is relevant only for applications with many user-mode threads.

call overhead to that of the pre-Spectre/Meltdown baseline, which is still significantly slower than a function call.

BPF for Storage [22] is a recent approach for reducing I/O path overhead by leveraging Linux’s eBPF subsystem [23], which is an in-kernel virtual machine that can execute user-loaded bytecode programs. The idea in BPF for Storage is to use eBPF programs to bypass kernel layers and avoid system calls, e.g., by searching an on-disk B+tree inside the kernel instead of via multiple system calls. However, *eBPF is a severely limiting programming model*, as the bytecode must pass static verification [24] before it can be executed in the kernel, and verification considerations limit eBPF programs to be small and to have provably bounded memory and execution time.

3 Design

Privbox is a new execution model for system call intensive code. Privbox provides standard synchronous, function-like system calls but with significantly lower invocation cost. Using Privbox thus requires no rearchitecting of application source code, as opposed to, e.g., the asynchronous system calls provided by FlexSC or `io_uring` (see § 2). We describe Privbox in the context of Linux on x86-64 hardware, but its design can be extended to other monolithic operating systems and/or hardware architectures.

Privbox provides an interface for executing code sections (e.g., ELF objects) in a *semi-privileged* execution mode (§ 3.1); we refer to such code as being *privboxed*. In semi-privileged execution, the processor is in privileged mode and kernel memory is mapped, which enables fast system call execution (§ 3.2), but for security, the code runs sandboxed, so that it has the same access as the process that loads it (§ 3.3). This sandbox is enforced by compile-time instrumentation (verified by the kernel) and by virtual memory restrictions.

Privbox and eBPF (§ 2) share some similarity in that both offer safe execution of user-supplied code in privileged processor mode, but the designs have a fundamental difference. eBPF runs code *in kernel context*, invoked to handle certain events, and so eBPF programs must be verified to terminate and be provided with interfaces for kernel operations. In contrast, privboxed code is *conceptually process code, just with faster system calls*. It can access the process’ address space, be scheduled and context switched, and can only interact with the kernel via the system call interface—in particular, it invokes the kernel and not vice versa. Privbox is thus a general-purpose design, whereas eBPF requires customization for each new use case (e.g., [22]).

While we focus on the general use case, in which privboxed code must be isolated from other processes in the system, some scenarios can use Privbox without sandboxing. One such example is a workload running by itself on a dedicated virtual machine. This use case can employ Privbox without sandboxing, as the privboxed code cannot compromise any-

```

main:
  fd = open("priv.so")
  call priv_code_load(fd)
  call priv_code_invoke("privfunc1")

privfunc1:
  loop:
    fast_syscall ...
  call priv_code_return()

```

Listing 1: Example usage of privcall mechanism.

thing other than itself.

3.1 Execution & usage model

Privbox introduces an operating system interface with the following system calls:

- *Load privboxed code.* This method can accept a pointer to a buffer with machine instructions or a file descriptor of an ELF object file. Internally, it verifies the code’s safety (§ 3.3) and relocates it to a dedicated, immutable memory region from which it will be executed.
- *Invoke privboxed code.* This method accepts a pointer or symbol from the loaded ELF file, and begins executing it in semi-privileged mode. I.e., from the calling application’s perspective, this method returns only when the privboxed code returns, as explained next.
- *Return from privboxed code.* This method can only be called by privboxed code. It exits semi-privileged execution and transfers control to the code that invoked it, while making a return value available.

Listing 1 shows an example program utilizing the above interface to invoke a function from the ELF object `priv.so`.

Usage model While an entire application can be privboxed, Privbox’s sandboxing instrumentation imposes overhead, so only code sections with a large fraction of cycles spent on system call entry/exit will benefit from privboxing. Privbox adoption thus consists of (1) the developer identifying system call intensive code sections for privboxing; (2) isolating such code sections into separate build units, which are built with the required instrumentation (e.g. into ELF objects); and (3) modifying application source code to load and invoke these objects as privboxed code at run time. Crucially, a privboxed code section itself requires no modification: it is simply another object file linked or loaded into the application.

We envision steps (2)–(3) being performed by tools, after developers demarcate privboxed code sections in the source code. In this paper, however, we perform them manually. For manual Privbox adoption, the “low hanging fruits” consist of applications whose software architecture already separates system call intensive code from computation code into distinct modules that communicate via some mechanism (e.g., SEDA [25]). Figure 1 depicts such an architecture. Because these architectures already isolate I/O (or other system call-heavy) code from other parts of the code, it is straightforward to surgically apply instrumentation only to that code. This approach minimizes Privbox’s instrumentation overhead, as compute heavy parts remain unaffected, while the I/O parts waste less cycles on system call entry/exit.

Figure 1: Software architecture that separates threads performing I/O (or system calls) from threads that perform other kinds of logic.

3.2 Semi-privileged execution

Privboxed code runs with the processor in privileged mode and kernel memory mapped, which enables it to perform a system call with a function call, without the `syscall` instruction, as detailed below. Except for having the ability for fast system calls, the OS treats privboxed code as user-space (process) code and its access is similarly restricted, hence the term *semi-privileged execution*. When privboxed code is invoked, the kernel transfers control to it with a new (ring 0) code segment (CS). Other than having a different CS value, the privboxed code runs similarly to unprivileged code—with interrupts enabled and the same priority, capabilities, and permissions. The kernel can preempt its execution at any moment and re-schedule it, as it would any other process.

Privboxed code runs with a custom page table, which modifies the standard virtual address space layout in several ways. Figure 2 shows the baseline layout of user and kernel memory in Linux. Privbox adds a special *privboxed code region* to the user part of the address space. This region is located in the lower part of the process address space and is unwritable by the process. After the kernel successfully verifies privboxed code, it relocates the code to the privboxed code region, from which it is later executed.

Normally, kernel mode execution has both kernel and user addresses mapped and accessible, and user mode execution only has user addresses accessible.² Privbox’s custom page table maps the same memory regions as the process’ page table, but using different access modes: user memory (excluding the privboxed code region) is marked not executable (see § 3.3) and kernel memory is marked accessible and executable, unlike user mode execution. (Despite kernel memory being

Figure 2: Example of memory map on x86-64 with 48-bit virtual address space. Lower address spaces are reserved for user program memory, higher address space are reserved for kernel memory. Access to memory at non-canonical addresses generates a trap.

²Without PTI, kernel addresses are still mapped, but their page table entries have a “supervisor” bit set, which allows access to the pages only when $CPL < 3$ (i.e., privileged mode). With PTI, kernel addresses are not mapped at all.

mapped accessible, privboxed code cannot directly access it due to the sandboxing instrumentation (§ 3.3.) Privbox’s custom page table is implemented by switching the top-level page table node to one in which the page entries (PTEs) mapping the user-space and kernel address ranges have the appropriate permissions, i.e., Privbox does not create nor maintain a copy of the process’ entire page table.

The execution environment of privboxed code enables a fast implementation of system calls. Privboxed code does not invoke a system call using the `syscall` instruction; it invokes a system call using a standard function call. Privbox provides a new kernel function that serves as a *gate* for system call invocation. This function has similar semantics to system call entry code: it sets up kernel execution environment (switching to kernel stack, storing registers) and routes requests to system call functions based on the system call number provided by calling code. Crucially, calls to this special function are not blocked by the sandbox instrumentation, so privboxed code can branch to it to perform a system call.

Modern x86-64 processors support supervisor mode access/execution prevention (SMAP [15]/SMEP), which disallow privileged execution from accessing/executing pages that are marked as user-space pages in the page table. Because privboxed code runs in “supervisor mode” but needs to execute and access user memory, SMAP/SMEP is disabled during privboxed execution. When privboxed code enters the kernel (e.g., a system call or interrupt), SMAP is re-enabled (this costs ≈ 26 cycles) but SMEP remains disabled (because toggling it costs thousands of cycles). § 6 discusses the security implications of this limitation.

A process that starts semi-privileged execution stays in that mode until it either invokes the “return from privboxed code” system call or an OS event that would result in non-sandboxed code execution occurs, such as invocation of an `exec` system call to load a new binary into the process address space. In such cases, the OS terminates the process’ semi-privileged execution, moving it to standard user-mode execution.

3.3 Sandboxing semi-privileged execution

Privbox must guarantee that a semi-privileged execution (of privboxed code) cannot perform any operation or memory access that the regular unprivileged execution of its process cannot perform. Importantly, this guarantee must also hold for transient execution of privboxed code (e.g., due to indirect branch misprediction) [4, 5]. This section describes our design for enforcing this safety property, which combines run-time virtual memory restrictions and compile-time instrumentation whose safety is verified by the kernel. § 6 analyzes the security of our design.

3.3.1 Sandboxing techniques

Three types of machine instructions can violate our desired safety property: (1) memory loads and stores, which have

Execution mode: \Rightarrow	User mode (CPL=3)	Privbox mode (CPL=0)	Kernel mode (CPL=0)
Accessed memory \Downarrow			
Kernel memory	N^\dagger/N^\ddagger	N^\ddagger/N^\ddagger	Y/Y
Privbox code	Y/Y	Y/Y	Y^*/Y^*
User memory	Y/Y	N^\dagger/Y	Y^*/Y^*

\dagger Restricted through page table access controls.

\ddagger Restricted through instrumentation.

* Subject to SMAP/SMEP.

Table 1: Access to memory regions under different execution modes. Left symbol: instruction fetching, right symbol: data load/store.

potential to access kernel memory; (2) control flow instructions, which can be used to branch into non-instrumented code; and (3) privileged instructions, usually reserved to operating system code. In the following, we describe how Privbox mitigates each of these risks.

Memory access and control-flow Privbox uses a combination of compile-time instrumentation and virtual memory (page table) protection to protect memory accesses. Table 1 summarizes which types of memory (rows) each type of execution mode (column) is allowed to access (for code execution/data), and how these restrictions are enforced.

We prevent privboxed code from executing user-space code outside of the (verified) privboxed code region, taking advantage of the “NX bit” feature of x86-64. On x86-64, each page table entry (PTE) has a No-Execute (NX) bit. When the NX bit is set, fetching instructions (code execution) is not permitted from the page(s) mapped by the PTE. Thus, the custom page table installed for Privbox’s semi-privileged execution maps user-space addresses outside the privboxed code region as non-executable.

We use compile-time instrumentation to ensure all other types of memory accesses are safe. Indirect load/store instructions (where the operand is known only at run time) are instrumented by introducing instructions that “sanitize” the memory operand, ensuring it does not point to kernel memory. For Linux on x86-64, we use the fact that clearing the most significant bit of a virtual address is guaranteed to create either a user address or an illegal non-canonical address, whose access will generate an exception (Figure 2).

Indirect control-flow instructions, such as calls, jumps, and returns are similarly instrumented, to ensure that privboxed code does not branch to arbitrary kernel addresses, because the kernel’s address space is mapped as executable. Our control-flow instrumentation also ensures that control-flow instructions can only branch to addresses which are verified when the code is loaded. Therefore, at run time, privboxed code can execute only instructions that were checked by the verifier.

Overall, our instrumentation approach guarantees that instruction memory operands are never kernel addresses, even for transient instructions, and thus blocks both non-transient and transient execution attacks (see § 6).

Privileged instructions We rely on Privbox’s verifier to check that loaded code does not contain privileged instruc-

tions. Rejecting code with privileged instructions does not limit Privbox’s applicability, as compilers do not emit such instructions unless specifically instructed.

3.3.2 Verification

The kernel verifies that privboxed code is correctly instrumented before allowing it to execute. Verification faces a challenge due to x86-64’s variable-length instructions, which mean that decoding the same code at different offsets can yield completely different instruction sequences. It is therefore possible that a seemingly benign instruction sequence would include malicious code at certain offsets [13].

To address this problem, our design relies on code being packed into *chunks*, which enables sound disassembly and verification of any possible execution of the loaded code. We define a code *chunk* as an aligned and fixed-length byte sequence containing machine instructions that always executes from its first to last instruction (i.e., a small fixed-size basic block). For example, 32-byte code chunks are expected to be 32-byte aligned in memory and be exactly 32 bytes long. The compiler breaks long basic blocks into chunks, using no-op instructions to pad the created chunks to their desired fixed length. The compiler adds “sanitizing” instructions which align targets of control-flow instructions (including returns) to guarantee that they branch to the beginning of a chunk, i.e., to a chunk-aligned address. (See § 4.2.2 for details.)

The verifier deems the loaded code safe by verifying each code chunk individually. For each chunk, the verifier verifies that if the chunk contains a control-flow instruction, it is the last one, and that it is sanitized as described above. This ensures verified code can only branch to verified code, keeping execution inside the sandbox. In addition, the verifier checks that memory operations are preceded, within the same chunk, by the instructions sanitizing their address operands and that the chunk does not contain privileged instructions.

3.3.3 Discussion: Privbox vs. NaCl

Our sandbox design is inspired by Native Client (NaCl) [13, 14]. NaCl enables safe execution of native code downloaded from a web site inside a web browser at near native speed. The browser verifies loaded programs and makes sure the loaded code does not write to, or jump, outside of a sandboxed region. The sandboxed code is loaded into a memory region that is gapped by unmapped memory regions on both ends. To ensure sandboxed code does not write or execute memory outside of the sandbox, NaCl relies on “offset-from-known-base” operations. A *base pointer register* (immutable by sandboxed code) points at this memory region. A memory access is allowed only with an offset from base pointer register, which results in accesses always being either: (1) inside the allowed memory region; or (2) in the unmapped memory areas.

Privbox’s instrumentation shares some similarities with

NaCl: (1) execution is limited to code running inside the sandbox; (2) memory stores have to be instrumented (because kernel memory is accessible); and (3) instructions have to be aligned in specific manner. In contrast to NaCl, however, Privbox (1) has no need for a base pointer register—we use absolute addresses, appropriately sanitized; (2) instruments memory loads as well, because kernel memory is readable; and (3) must avoid privileged instructions.

4 Implementation

This section describes our prototype implementation of the Privbox design in Linux. § 4.1 describes OS and library modifications and § 4.2 describes the sandboxing compiler. We do not implement the verifier part of the design (§ 3.3.2), as it is not required for evaluating performance under Privbox.

4.1 OS & library support

The following describe various parts of our implementation and their size in lines of code (LOC).

Semi-privileged execution (750 LOC) To implement semi-privileged execution, we apply the techniques of kernel-mode Linux (KML [7]) to Linux v5.8 on x86-64. KML is an existing kernel patch to support execution of an entire application in kernel mode. It is based on Linux v4.0 (circa 2015), and does not isolate its in-kernel processes from each other or the kernel from them.

Linux v5.8 on x86-64 uses “legacy stack switching,” where the stack is switched by the hardware only on a CPL change (i.e., an interrupt while user code is executing). However, Privbox’s semi-privileged execution has $CPL = 0$ but with a user stack. This means that an interrupt received during semi-privileged execution would cause the interrupt handler to run with the user’s stack, which is problematic because: (1) the user stack is accessible to user code, which might hijack execution by modifying the stack frame (from another thread); (2) writing to the stack might fault (e.g., if the stack pointer points to an unmapped page), but the page fault would not change the stack either, crashing the system; and (3) the user’s stack includes a red zone [26] that must not be written to. We therefore adjust our Linux version to use x86-64’s *interrupt stack table* (IST) for all interrupts and exceptions. With IST, each exception/interrupt/trap can be configured to switch to a specific stack.

Call gate (80 LOC) Privbox exposes a system call gate (§ 3.2), which is a kernel function that serves as the system call entry point for privboxed code. The gate follows Linux’s `syscall` conventions for passing the system call number and parameters. It is similar to the standard system call entry code but avoids performing unnecessary steps, such as modification of page tables and toggling of interrupts. In particular, Linux’s entry code (with PTI) assumes it is called from user-space and thus unconditionally switches the page

table from the user-space to the kernel page table. This is unnecessary for privboxed code, which already has kernel memory mapped in its custom page table.

Limitations For implementation simplicity, we inhibit receipt of signals during semi-privileged execution. This is not a design limitation, and there are several designs for supporting signals: (1) ensuring that the signal handler code points to verified and safe code; or (2) aborting privileged execution (i.e., having it return to the code that launched it with an `EINTR` indication). Importantly, privboxed code can still receive signals in our prototype using the `signalfd` [27] mechanism.

Library support (260 LOC) Applications usually invoke system calls through a C library function, which then invokes the `syscall` instruction. We thus create a modified standard C library, based on the `musl` C library [16], in which the library’s system call wrappers use `syscall` or Privbox’s system call gate based on the execution’s CPL. The entire library is compiled with Privbox’s instrumentation, so that privboxed code objects can be linked with it.

In this paper, we modify an application to use Privbox by changing its build environment to link privboxed code with the above C library. The reason is that current compilers and linkers do not support linking an entire application with both the system’s C library and our modified, instrumented C library, as both export the same symbols and the tools cannot resolve which library version the application code refers to. This problem can be solved by adding compiler annotations for demarcating privboxed code; we leave this to future work.

4.2 Code instrumentation

We implement Privbox’s sandboxing instrumentation by introducing a machine function pass and several other changes to the x86-64 backend of the LLVM toolchain [28], which consist of 1200 LOC. Our modified LLVM emits machine code in which unsafe instructions are replaced with equivalent but safe instruction sequences (§ 3.3).

Instrumented code is partitioned into fixed-size chunks (§ 3.3.2). Our implementation uses 32-byte chunks. The reason is that an x86-64 instruction can be up to 15 bytes long, so a 32-byte chunk can fit at least an instruction of the privboxed code plus the added instrumentation instructions that make it safe. (This is the worst case; most chunks contain more than one instruction.)

When instrumenting an instruction, it is placed in its own chunk, preceded with the instrumentation instructions, which is achieved by emitting an alignment directive in the code (`.align`). This ensures any instrumentation sequence starts at beginning of a new chunk.

4.2.1 Load/store instrumentation

Loads/stores are non-branching instructions that access memory. Their address operand is either static, verifiable at load

time, or dynamic, derived from values of registers. Dynamic values cannot be verified at load time, so instrumentation is required to ensure kernel memory is not accessed. Our instrumentation “sanitizes” operands by clearing their most significant bit (MSB), which ensures it does not point to kernel memory (§ 3.3).

On x86-64, memory operands are based on four elements: scale, index, base and displacement. Scale and displacement are scalars while index and base are registers. The effective address of a memory operand is calculated by: $Displacement + Base + Scale * Index$. Either the base or index registers can be omitted and are calculated as zero in such case. Scale can be 1, 2, 4 or 8. Displacement can be either 1, 2, 4 or 8 bytes long.

The memory operand of an instruction I is sanitized by the prefixing I with the following instruction sequence: (1) computing I ’s effective address with a load-effective-address instruction (`lea`); (2) clearing its MSB with a bit-test-and-reset instruction (`btr`); and (3) replacing I ’s original memory operand with one dereferencing the sanitized value. Listing 2 shows this sequence. The `btr` instruction has a side-effect of updating the x86-64 `EFLAGS` register. Our compiler code therefore checks if the `EFLAGS` register has meaningful state at the point of instrumentation, and if so, emits `SAVE_EFLAGS` and `RESTORE_EFLAGS` around the instrumentation sequence. These are abstract operations implemented by LLVM and translated to instructions such as `sahf/lahf` (save/load flags).

A shorter instrumentation sequence is used for memory operands that specify (1) only one of base or index registers; and (2) 1/2/4-byte displacement. In this case, the effective address is sanitized with a single `btr` instruction (and `EFLAGS` save/restore, if needed). Appendix A.1 provides the details.

Similarly to NaCl, we avoid instrumentation of stack loads/stores by maintaining and verifying invariants on manipulations of the stack pointer, which guarantee that stack accesses always target user memory. Appendix A.2 elaborates on handling of stack accesses. This approach greatly reduces the emitted instrumentation, as stack accesses are very common.

4.2.2 Control-flow instrumentation

Control-flow instructions are instructions that can modify the instruction pointer (beyond advancing it to next instruction). As with load/store instructions, we are concerned only with instructions whose operand is unknown at load time. Control-flow instructions can compromise safety of semi-privileged execution by branching to (1) arbitrary kernel code or (2) privboxed code at the middle of a chunk. The latter is dangerous because the verifier verifies code starting at chunk boundaries.

Similarly to load/store instrumentation, kernel addresses are avoided by clearing the MSB of branch targets. Chunk-unaligned addresses are avoided by clearing the low 5 bits of the target. While this allows branching to any chunk-aligned

```

.align CHUNK_SIZE
SAVE_EFLAGS
%Reg1 = lea disp(%Idx, scale, %Base)
%Reg2 = btr $63, %Reg1
RESTORE_EFLAGS
OP operand1, (%Reg2)

```

Listing 2: Instrumentation of load/store instruction with memory operand.

```

.align CHUNK_SIZE
pop %rcx
add $(CHUNK_SIZE - 1), %rcx
and $~(CHUNK_SIZE - 1), %rcx
btr $63, %rcx
jmp *%rcx

```

Listing 4: Instrumentation of return instruction.

address in user memory, only the privileged code section is mapped executable in the privboxed code’s page table (§ 3.3).

Return instrumentation A return is equivalent to popping an address from stack and jumping to it. To ensure a valid destination, we replace each return instruction with an equivalent but safe sequence that pops the address into a register, clears its MSB, aligns it to the next 32 bytes, and jumps to the obtained value. Listing 4 details this instrumentation sequence. Linux’s calling convention specifies that the RCX register is not preserved on calls, so we explicitly use it to store the return address. The `add` (addition) and `and` (logical AND) instructions are used to align-up the value in RCX to 32 bytes (start of next code chunk). The `btr` (bit-test-and-reset) clears the MSB.

This instrumentation ensures branching is possible only to code chunk aligned, non-kernel addresses. While in theory it is possible to hijack execution by overwriting the return address (e.g., by buffer overflow), the effects of such hijacking are very limited. Any address popped from the stack is guaranteed to be sanitized before use, so an attacker can only redirect execution to valid and verified code inside the Privbox code region or to non-executable memory (either user addresses or non-canonical). The former one does not pose a threat as privboxed code is verified as safe, and the latter causes a fault, effectively stopping the execution.

Call/jump instrumentation Call/jump instructions with an indirect destination (i.e., non embedded as an instruction-relative offset) can have their destination stored in one of two ways: (1) in a register operand and (2) in a memory operand.

Register operands are sanitized similarly to a return (sans stack pop), as shown in Listing 5. Since a return aligns addresses before branching, an alignment directive is required right after a call to push the next instruction to a chunk boundary. The EFLAGS register has to be preserved only in case of jumps, as the calling convention states that it is not preserved across calls.

```

.align CHUNK_SIZE
%Reg1 = lea *disp(%Idx, scale, %Base)
%Reg2 = btr $63, %Reg1
%Reg3 = mov *%Reg2
%Reg4 = btr $63, %Reg3
%Reg5 = and $~(CHUNK_SIZE - 1), %Reg4
call *%Reg5
.align CHUNK_SIZE

```

Listing 3: Instrumentation of memory-operand call.

```

.align CHUNK_SIZE
%Reg1 = btr $63, %Reg
%Reg2 = and $~(CHUNK_SIZE - 1), %Reg1
call *%Reg2
.align CHUNK_SIZE

```

Listing 5: Instrumentation of register-operand call.

A call/jump with a memory operand is equivalent to a memory-to-register load followed by a register operand call. Sanitization is this performed analogously: (1) the memory operand is sanitized with load/store instrumentation; (2) a `mov` instruction is used to load the address into a register; and (3) the loaded address is sanitized as a register operand call. Listing 3 shows the generated instruction sequence.

Jumps are similar to calls, except that they have to preserve the EFLAGS register and aligning the succeeding instruction is unnecessary, as jumps do not return. Appendix A.3 provides the details.

4.2.3 Code alignment

The instrumentation described in the previous sections deals with unsafe instructions, co-locating instrumentation sequences within same code chunks, and aligning return sites of calls. The compiler also makes sure that all branch destinations (functions, basic blocks) are aligned to the chunk boundary, because indirect branches target addressed with 5 lowest bits cleared. It additionally inserts no-op instructions before any instruction that would otherwise cross code chunk boundary, so that it moves to a chunk-aligned address. Combined, these rules partition the emitted code instructions into fixed-size chunks.

5 SPAP: Hardware support for reducing instrumentation overhead

Our analysis of Privbox’s performance (§ 7.3) shows that load/store instrumentation is responsible for a considerable part of instrumentation overhead. To address this problem, we propose *semi-privileged access prevention* (SPAP), a simple hardware architectural modification that enables omitting load/store instrumentation from privboxed code.

SPAP SPAP is a hardware feature that guarantees semi-privileged (privboxed) code cannot (1) read/write kernel memory nor (2) indirect branch to kernel memory. Of course, the CPU has no notion of “kernel memory” or “semi-privileged execution”—we define *kernel memory* as any virtual address mapped by a PTE with the ‘supervisor’ bit set, and *semi-privileged execution* as instructions executing in privileged mode (CPL = 0) but that are located in non-kernel memory (i.e., a clear ‘supervisor’ bit in the code page’s PTEs).

Assuming SPAP, it is possible to forgo all load/store instrumentation and limit control-flow instrumentation (§ 4.2) only to masking of jump targets to guarantee their chunk alignment. Listing 6 shows the simplified instrumentation call instruction enabled by SPAP (compared to Listing 3). The code chunk size

```

.align 16
%Reg1 = mov *disp(%Idx, scale, %Base)
%Reg2 = and $0xf, %Reg1
call *%Reg2
.align 16

```

Listing 6: Control-flow only instrumentation of memory-operand call.

is reduced to 16 bytes, which is enough to fit both the instrumented instructions and the required prefixes.

SPAP implementation We argue that SPAP can be implemented analogously to how current x86-64 processors implement SMAP/SMEP, which block *privileged mode execution* from accessing *user addresses*.³ Restricting privboxed code data accesses and branching can happen at the same pipeline stages that enforce SMAP and SMEP, respectively. Listing 7 describes how the hardware can restrict privboxed code’s data access: other than the CPL and PTE of the accessed page, which are already required by SMAP, SPAP only depends on the current instruction’s PTE, which is available in the instruction TLB. Similarly, Listing 8 shows how SPAP hardware restricts privboxed branching. The information required is same as what is needed for the SMEP mechanism, plus the information of whether the current instruction is an indirect branch.

Expected overhead We claim that SPAP’s additional access checks should have little to no effect on the latency of memory instructions. We base this claim on the overhead observed from enabling SMAP/SMEP, shown below, and the similarity of SPAP to them.

We evaluate SMAP overhead (on the platform described in § 7). We measure average load latency when accessing differently sized working sets from kernel space, with and without SMAP. Our test traverses each cache line in the working set buffer in random order (to prevent prefetching), with each load depending on the result of the previous one (to prevent the CPU’s out-of-order execution from overlapping load execution). Preemption is disabled during the test, to ensure it has exclusive use of the CPU. We measure average cycles per load (i.e., total number of cycles divided by number of loads performed). Each test is run 31 times and we report the average of the last 30 runs.

Figure 3 shows results for working set sizes targeting the capacity of the CPU’s TLB and L1/L2/L3 caches. We find that SMAP does not impact performance in a significant way, as (1) some tests still execute faster with SMAP enabled; and (2) the variance is greater than the difference between the configurations.

```

if (
  CPL < 3 and
  AccessedPage.S_bit is Set and
  CurrInstPage.S_bit is Cleared
):
  trap()

```

Listing 7: Hardware enforcement that semi-privileged execution loads/stores do not access kernel memory.

  CurrInst is Indirect Branch and
  CPL < 3 and
  FetchPage.S_bit is Set and
  CurrInstPage.S_bit is Cleared
):
  trap()

```

Listing 8: Hardware enforcement that semi-privileged execution does not indirect branch to kernel code.

³The idea is to prevent exploits of kernel memory safety bugs that attempt to, e.g., jump to user-space code [15].

Figure 3: SMAP overhead on load instructions. Results are normalized to execution with SMAP disabled.

6 Security

We analyze Privbox’s security against architectural and microarchitectural (transient execution) attacks. Recall that in privboxed code, every chunk (a 32-byte range at a 32-byte aligned address) contains a correctly instrumented, non-privileged instruction sequence of exactly 32 bytes, perhaps ending with no-ops (see § 3.3.2). This is verified by the kernel.

Semi-privileged execution has the following invariants:

- Inv1** The target of *any* load/store instruction is not a kernel address. (Enforced by the instrumentation; § 4.2.1.)
- Inv2** The target of *any* control-flow instruction (including returns) is a 32-byte aligned non-kernel address. (Enforced by the instrumentation; § 4.2.2.)
- Inv3** The privboxed code section is read-only and user-space addresses outside of it are non-executable during semi-privileged execution. (Enforced by the virtual memory permissions; §§ 3.2–3.3.)

For normal (non-transient) instruction execution, Inv2 and Inv3 imply that semi-privileged execution can run only (instrumented) code located in the privboxed region. By Inv1, such code cannot access kernel memory, and the verifier guarantees it does not contain privileged instructions. Therefore, if regular unprivileged execution cannot perform some operation or memory access, neither can semi-privileged execution.

It remains to analyze transient execution attacks. Generally, such an attack uses architecturally-incorrect flows (whose instructions execute but do not subsequently commit) to leak memory contents via a microarchitectural side-channel [29]. Privbox’s goal is thus to protect kernel memory.

The core observation is that transient execution of a *complete instrumented* chunk is safe, because it still sanitizes the operands of any memory operation in the chunk. We therefore only need to consider if transient execution can branch mid-chunk or outside of the privboxed region, either of which can happen due to indirect branch or return target misprediction. Crucially, we consider *any* “supervisor mode” transient execution—both semi-privileged and standard kernel execution—to cover attacks of privboxed code on the kernel. To this end, we analyze how the branch predictor can be “trained,” i.e., which targets it observes and may mispredict execution to later:

We assume any training by user-space execution cannot affect “supervisor mode” execution, due to existing mitigations

such as Intel’s enhanced indirect branch restricted speculation (eIBRS) [30] or Arm’s CSV2 [31]. If this assumption does not hold, then the kernel is vulnerable regardless of Privbox.

We assume kernel execution can only train valid kernel branch/return targets (and therefore the kernel cannot transiently branch to privboxed code), because if an attacker can cause the kernel to train arbitrary addresses, they can attack the kernel regardless of Privbox. This still means that semi-privileged execution may (transiently) branch to a valid kernel function, possibly creating a speculative type confusion vulnerability [32]. Privbox’s instrumentation can mitigate this problem (with run-time overhead) using *retpolines* [33] for indirect branches.

Finally, by *Inv2*, semi-privileged execution can only train non-kernel, chunk-aligned addresses. It might thus train user-mode addresses outside of the privboxed region. We assume that instructions from non-executable memory are not executed in transient execution,⁴ so by *Inv3*, semi-privileged execution cannot be exploited by such training. However, training by semi-privileged can cause subsequent kernel execution to (transiently) branch to user-space instructions and execute them, as Privbox disabled SMEP. On current hardware, training by semi-privileged execution can be prevented from affecting the kernel’s execution using a mechanism such as Intel’s indirect branch predictor barrier (IBPB) [36] in the Privbox system call gate, but this will slow down system calls in privboxed code. (Our Privbox prototype does not implement this mitigation.) Future hardware could support SPAP-like extensions to eIBRS to make predictions of branches executed from supervisor pages uncontrollable by branches executed from user-level pages.

We assume SPAP can be implemented so that its restrictions apply to both normal and transient execution, as SMAP/SMEP have this guarantee [34, 35].

Limitation: Disabled SMEP Privbox’s security drawbacks stem from disabling SMEP for semi-privileged execution without re-enabling it for kernel execution, as Privbox does for SMAP. As a result, semi-privileged execution can (1) exploit pre-existing kernel vulnerabilities that were mitigated by SMEP and (2) mount transient execution attacks against the kernel, as explained above. The SMEP limitation can be addressed by hardware reducing the cost of toggling SMEP. This should be possible, given that hardware has optimized SMAP toggling, an action the kernel frequently performs.

7 Evaluation

We evaluate the impact of Privbox on system call latency (§ 7.1), on system call-intensive I/O threads (§ 7.2), and the impact of privboxing complete real-world applications (§ 7.3).

⁴This holds on x86-64, where documentation states that SMEP and virtual memory execute restrictions apply to transient execution [34, 35].

Figure 4: Cycles taken to execute a roundtrip to kernel using different entry methods. Regular call added for reference.

Platform We use a Dell PowerEdge R740 server with a 28-core Intel Xeon Gold 6132 (Skylake) CPU and 192 GiB of DRAM. Hyper-Threading is disabled. Due to current cloud computing trends, virtualized platforms represent the environments where evaluated workloads usually run. We therefore use a Linux v5.8 guest in a KVM virtual machine hosted on a Ubuntu 18.04 host. Reported measurements are averages of 10 executions after a single warmup run; error bars indicate standard deviation.

7.1 System call latency

We measure the end-to-end latency of invoking a non-existing system call, which covers user-to-kernel transition, entry code execution, and kernel-to-user return (with a “bad call” error). Our benchmark invokes the system call 100 M times and reports average invocation latency, measured with the CPU’s cycle counter.

We compare the latency of a regular system call invocation with and without PTI to the latency of invoking the system call from within privboxed code. Figure 4 shows that a system call invocation alone takes about 950 and 510 cycles with and without PTI, respectively. Invocation from privboxed code takes on average 425 cycles, 2.2× and 1.2× faster, respectively, than the baseline with and without PTI.

The reason that a privboxed system call invocation is slower than a regular function call is that while Privbox eliminates hardware user/kernel transition costs, it must still manage software-related user/kernel transition steps. For instance, Privbox’s system call gate (§ 3.2) switches the stack and saves/restores register state.

7.2 I/O-thread workloads

Here, we characterize the impact of Privbox on an I/O thread-based application architecture (see § 3.1 and Figure 1). We benchmark a generic server program that receives requests, processes them, and returns response. The server is composed of I/O and compute threads, which are responsible, respectively, for socket operations and the “business logic” of computing responses to incoming requests.

Our benchmark has two tunable parameters: (1) *Compute time*, the time compute thread spends on each request, which allows controlling how compute-heavy the workload is; and (2) *I/O size*, the number of bytes each for each socket I/O operation. We use fixed-sized messages, so the I/O size determines the number of system calls per message, i.e., how system call-intensive the workload is.

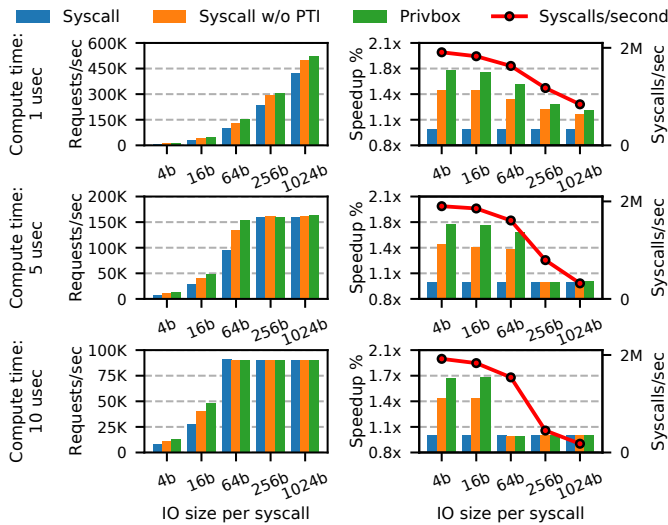

Figure 5: Privbox impact on an I/O-thread based server. Left: absolute throughput (requests/second), right: throughput normalized to default Linux (with PTI). Rows describe different compute times.

We compare between Privbox and standard execution with PTI (default Linux configuration) and without it. When using Privbox, only the I/O thread code is privboxed (and therefore compiled with instrumentation). Figure 5 shows the server’s throughput (requests/second) as we vary the compute time (across rows) and I/O size (X axis in each row). For large I/O sizes (above 256 bytes) and compute time (above 5 μ s), system call invocation frequency decreases and so all kernel entry methods yield similar throughput, as most CPU time is spent on compute or inside system calls (waiting for I/O). However, for fast compute and/or high rate of system calls (small I/O size), Privbox results in up to $1.72\times$ speedup compared to regular execution with system calls.

7.3 Real-world workloads

This section analyzes the impact of Privbox on several popular real-world applications: Redis [18], memcached [19], and SQLite [20]. We modify each application to use Privbox, which requires changing/adding about 20–30 lines of code to make the application’s main loop execute privboxed. All binaries are compiled with `-O2` optimizations and linked with our instrumented `musl-1.2.0` C library. Importantly, we compile the entire application with Privbox’s instrumentation, not only the part that runs privboxed. The reason is that our Privbox prototype does not support compiling an application with both instrumented and uninstrumented versions of the C library (see § 4.1). The upshot is that our results here are *lower bounds* of Privbox’s benefit, as we instrument code that a full Privbox implementation would not.

To analyze instrumentation overhead, we measure each application with three instrumentation levels: (1) No instrumentation (*noinstr*), which shows the benefit from fast system call invocation; (2) full instrumentation (*fullinstr*, § 4.2), which shows Privbox’s benefit (faster system calls, but with instru-

Figure 6: Redis server under load of redis-benchmark running 2 threads, 50 connections, 1 M requests. Top: throughput (requests/seconds). Bottom: throughput relative to ‘noinstr-nopriv’.

mentation overhead) on current hardware; and (3) control-flow only instrumentation (*brinstr*, § 5), which omits load/store instrumentation, thereby emulating Privbox’s benefit on hardware with SPAP support.

To analyze the benefit from Privbox’s fast system calls, we measure each instrumentation level with and without executing the privboxed code sections in privileged mode (tagged *priv* and *nopriv*, respectively). The speedup of *priv* over *nopriv* quantifies how Privbox’s fast system calls offset instrumentation overhead.

Redis Redis [18] is a popular key-value store, often used as cache, document store, or for publish/subscribe messaging. We use Redis’ recommended default setup of a single instance running a single thread, without persistency. We modify Redis’ main loop to execute privboxed. The privboxed loop returns to user-space once per 10 K iterations to service signals (due to limitations of our prototype, see § 4.1).

We evaluate Redis using two benchmarks: (1) *redis-benchmark*, with which we simulate running various Redis commands by 50 concurrent clients that send 1 M requests, and (2) *memtier_benchmark* [37], a stress tester for NoSQL databases, which we run with a 10:1 read/write ratio of 32-byte objects.

Figure 6 shows redis-benchmark throughput of various Redis commands. Reducing system call overhead offers significant benefit: ‘priv’ executions have on average 13% higher throughput than their ‘nopriv’ variants. While Privbox’s instrumentation overhead offsets some of this benefit, overall, a Privboxed Redis (‘fullinstr-priv’) obtains up to 7.6% higher throughput than its baseline (‘noinstr-nopriv’). Had the CPU supported SPAP (enabling less instrumentation: ‘brinstr-priv’), the throughput would improve to up 10% higher than the baseline. Results from *memtier_benchmark* (Figure 7) show similar trends, with ‘fullinstr-priv’ and ‘brinstr-priv’ obtaining 6% and 10% higher throughput than the ‘noinstr-nopriv’ baseline.

Figure 7: Redis server under load of memtier_benchmark, running 4 threads, 50 clients/thread, 10 K requests/client, no pipelining, 32 byte objects, 10:1 read/write ratio. Left: throughput (requests/seconds). Right: throughput relative to ‘noinstr-nopriv’.

Figure 8: Memcached under load of memtier_benchmark, running 4 threads, 50 clients/thread, 10 K requests/client, no pipelining, 32 byte objects, 10:1 read/write ratio. Left: throughput (requests/seconds). Right: throughput relative to ‘noinstr-nopriv’.

Memcached memcached [19] is a distributed object caching system offering a key-value store interface. Similarly to Redis, we modify the main loop to execute privboxed, and break out to user-space once per 10 K iterations.

We evaluate memcached by measuring the throughput obtained by memtier_benchmark, again with a 10:1 read/write ratio and keys/values of 16/32 bytes, respectively. Figure 8 shows the results, which mirror those of Redis. Specifically, ‘priv’ executions have on average 19% higher throughput than their ‘nopriv’ variants, which is sufficiently high for Privbox to outperform the baseline: ‘fullinstr-priv’ and ‘brinstr-priv’ obtain 4.5% and 6.9% higher throughput than the baseline.

SQLite SQLite [20] is a relational database engine. We evaluate it using sqlite-bench [38], a tool that measures throughput of various access patterns: writing/reading of sequential/random values in asynchronous/synchronous/batched modes. We use a RAM filesystem (tmpfs) to store the database files.

Figure 9 shows throughput obtained for each access sequence. Many sequences stand to benefit from Privbox’s fast system calls (evidenced by an average 8% speed up of ‘priv’ over ‘nopriv’ variants), but these benefits are negated by instrumentation overhead. However, some patterns (“readrandom” and “fillseqsync”) do not benefit from fast system calls.

Figure 10 explains the above results. It shows the ratio between number of system calls invoked to time spent in user code (i.e., CPU time minus system call execution time). We find a strong correlation between speedup from fast system calls and the system call/user time ratio. For example, “readrandom” suffers greatly from instrumentation because SQLite performs read queries using loads/stores (which are instrumented) without invoking system calls. The “fillseq-

Figure 9: SQLite throughput. Top: throughput (operations/second). Bottom: throughput relative to ‘noinstr-nopriv’.

Figure 10: SQLite ratio of system calls to time spent in user-space code (log scale). Correlation can be seen with the bottom half of Figure 9: tests with a high system call to user time ratio show better speedup from ‘priv’ execution.

batch” sequence, which behaves the same with and without fast system calls (‘priv’), batches I/O operations and thus performs fewer system calls. Finally, the “fillseqsync” sequence, which behaves the same for all instrumentation levels and execution modes, uses slow synchronous writes and so spends most of its time waiting, as opposed to running user code or entering/exiting the kernel.

8 Conclusion & future work

We propose Privbox, a design for speeding up system calls by sandboxed semi-privileged execution, without changing the underlying system call programming model. We believe Privbox can also be useful to improve isolation and fault tolerance within the kernel, e.g., by privboxing modules and device drivers to limit the memory and kernel APIs they access.

Our Privbox prototype uses simple compile-time instrumentation which incurs non-negligible overhead, offsetting some of the benefit from Privbox’s fast system call invocation. There are several directions for reducing instrumentation overhead, which we leave to future work: Hardware features such as Intel’s control-flow enforcement technology (CET [39]) can be useful for reducing control-flow instrumentation. Finally, a more sophisticated verifier can avoid redundant instrumentation (e.g., sanitizing a previously-sanitized register).

A Instrumentation details

A.1 Special case load/store instrumentation

Listings 9 and 10 detail instrumentation for non stack-relative operations which have only one of the index/base registers specified, and displacement is either 1, 2 or 4 bytes long. In these scenarios, we can ensure any provided address value will become either a user or a non-canonical address by clearing bit 60 of the specified (base or index) register. This is sufficient because neither multiplication (in case of index register) nor addition of a 4-byte long displacement value will result in a canonical kernel address with 1s in all 16 most significant bits.

jmp *%Reg5
```

Listing 12: Instrumentation of memory-operand jump

A.2 Stack accesses

Stack-based operations can be considered safe as long as we ensure that at any point in time, the stack pointer points to valid user memory. The safety of stack-relative operations is ensured by maintaining the following invariant:

- When entering semi-privileged execution, the stack pointer must be set to a known valid value.
- When the stack pointer is set to a specific value, i.e. copied from another register, the copied value must be sanitized in a similar manner to an operand of a load/store instruction (i.e., clear its MSB).
- Each operation modifying/incrementing/decrementing the stack pointer must change the value by no more than a page, and must access the memory pointed by the new stack pointer value unconditionally afterwards (e.g., in same basic block). This permits operations like `push` and `pop`, as well as operations such as `add` and `sub`, as long as the memory is accessed through the stack pointer shortly after.

Incrementing/decrementing stack pointer without dereferencing can expose the code to an attack where the same sequence of instructions is used to modify stack pointer in small increments to an arbitrary value, until it points to kernel memory. Enforcing a stack access after the stack pointer changes makes sure that the stack pointer does not travel over inaccessible memory, such as the gap between kernel and user memory and the zero page in user memory, thereby preventing the stack pointer from overflowing/underflowing into kernel memory.

The above restrictions ensure that stack pointer always points to user memory, so loads/stores relative to the stack pointer register can be considered safe, as long as verifier successfully verifies that the above invariants hold.

A.3 Jump instructions

Listings 11 and 12 describe instrumentation of register and memory operand jumps, as mentioned in § 4.2.2.

B Artifact Description

Abstract

Our artifacts include all of the Privbox prototype code, as well as the scripts and benchmarks used to produce the results presented in this paper.

Scope

The artifacts can be used to:

- Set up a development and runtime environment for our prototype (§ 4).
- Run the experiments described in § 7, specifically, to reproduce results we present in Figures 3–9.

Refer to the artifact’s README (<https://github.com/privbox/devenv/blob/privbox/README.md>) for complete instructions.

Contents

- **devenv** [40] - a repository containing a README and scripts to set up a development and evaluation environment for the Privbox prototype.
- The Privbox prototype, which consists of:
 - **Linux** [41] and **musl C library** [42] - Operating system and C library with Privbox support.
 - **LLVM** [43] - LLVM toolchain capable of creating binaries instrumented for Privbox.
- **Benchmarks** [44, 45, 46, 47] - programs we used to evaluate Privbox.

Hosting

Our artifacts are available on Github (<https://github.com/privbox/>), as well as archived on Zenodo [40, 48, 41, 43, 45, 42, 47, 44, 46].

Requirements

Evaluation of our artifact requires an Intel x86-64 machine running Linux (we have used Ubuntu 18.04). Additionally, we rely on Docker and QEMU/KVM.

- **CPU type:** Our evaluation uses an Intel Skylake CPU. While any modern Intel-architecture CPU is suitable, evaluation results might differ due to microarchitectural changes.

- **Virtualization:** Our prototype runs as a KVM-based virtual machine. In our evaluation, we use a bare-metal server as a platform. It is possible to use a virtual machine, as long as it supports nested virtualization. However, nested virtualization incurs additional overhead that might affect evaluation results.

BBQ: A Block-based Bounded Queue for Exchanging Data and Profiling

Abstract

Concurrent bounded queues have been widely used for exchanging data and profiling in operating systems, databases, and multithreaded applications. The performance of state-of-the-art queues is limited by the interference between multiple enqueues (enq-enq), multiple dequeues (deq-deq), or enqueues and dequeues (enq-deq), negatively affecting their latency and scalability. Although some existing designs employ optimizations to reduce deq-deq and enq-enq interference, they often neglect the enq-deq case. In fact, such partial optimizations may inadvertently increase interference elsewhere and result in performance degradation.

We present Block-based Bounded Queue (BBQ), a novel ringbuffer design that splits the entire buffer into multiple blocks. This eliminates enq-deq interference on concurrency control variables when producers and consumers operate on different blocks. Furthermore, the block-based design is amenable to existing optimizations, *e.g.*, using the more scalable *fetch-and-add* instruction. Our evaluation shows that BBQ outperforms several industrial ringbuffers. For example, in single-producer/single-consumer micro-benchmarks, BBQ yields 11.3x to 42.4x higher throughput than the ringbuffers from Linux kernel, DPDK, Boost, and Folly libraries. In real-world scenarios, BBQ achieves up to 1.5x, 50.5x, and 11.1x performance improvements in benchmarks of DPDK, Linux `io_uring`, and Disruptor, respectively. We verified and optimized BBQ on weak memory models with a model-checking-based framework.

1 Introduction

Concurrent bounded queues are pervasive in operating systems, databases, and multithreaded applications. They transport data, distribute work, and are used to profile and decouple components. Their performance is crucial for achieving highly scalable and low-latency operation of numerous systems.

The main factor determining performance of a queue is the interference between concurrent operations, *i.e.*, between

enqueues, between dequeues, or between enqueues and dequeues. We refer to these as *enq-enq*, *deq-deq*, and *enq-deq* interference, respectively. Interferences manifest in the form of 1) cache-line bouncing when control variables are frequently updated by one thread and read by another, *e.g.*, to check if the queue has data, and 2) serialization of contended updates to control variables, *e.g.*, when multiple threads try to create or read the same entry. Existing queue designs often employ optimizations to reduce enq-enq and deq-deq interference, *e.g.*, updating control variables with “always-successful” atomic instructions such as *fetch-and-add* (FAA) [14, 40, 41, 47] because, in principle, they can be serialized in hardware and thus perform better under high contention than software solutions with *compare-and-swap* (CAS) [38, 43]. However, existing designs tend to neglect the enq-deq interference even though it substantially impacts performance, in particular in the common single producer or single consumer scenarios, *e.g.*, ringbuffers for asynchronous I/O in Linux `io_uring` [13].

In fact, some queue optimizations from the literature [38, 40] inadvertently increase the enq-deq interference or introduce undesirable side-effects that degrade performance in uncontended cases. For example, dequeue operations using FAA must either block in a pessimistic way [14], or risk overtaking slow concurrent enqueue operations; to avoid data corruption, such enqueue operations must be invalidated and repeated later [40]. Besides harming performance, such strategies cannot be applied for online profiling where enqueues writing a log should not be delayed by dequeues that read the log. Similarly, some techniques that avoid concurrent enqueue operations from waiting for each other also require dequeue operations to invalidate parts of the queue [38]. Strategies to improve performance of these techniques by reducing the number of invalidations, *e.g.*, busy-looping before invalidating [38, 40], drastically increase the latency of dequeue calls on empty queues, making them unsuitable for certain workloads, *e.g.*, multiplexing across multiple message queues.

We present Block-based Bounded Queue (BBQ), a novel ringbuffer design that dramatically reduces the enq-deq interference by splitting the entire buffer into multiple blocks and splitting the control variables into the block-level and queue-level variables. In the common case, enqueue and de-

*Ming Fu (ming.fu@huawei.com) is the corresponding author.

queue only access block-level control variables of their current blocks. When enqueue and dequeue work on different blocks, the disjoint control variables avoid any interference between these operations. That is particularly important in reducing the cache-line bouncing of head and tail pointers when determining whether the queue is full or empty. Furthermore, we use hardware-serialized `FAA` operations to update block-level control variables for allocating entries inside blocks, while queue-level control variables on the other hand are updated with slower, software-serialized `CAS` operations; since this is only necessary in the rare event that operations need to move to the next block, the performance impact of these operations is negligible. Our block-based approach allows us to perform these optimizations without incurring undesirable side-effects. Finally, to ensure that BBQ correctly works on weak memory models (WMMs) — including those from Arm [2] and RISC-V [28] architectures — we have verified and optimized the barriers and fences of BBQ with the `VSYNC` framework [42].

In contrast to previous work, our block-based approach is applicable to a large spectrum of scenarios. BBQ supports single or multiple producers/consumers, fixed- or variable-sized entries, and retry-new and drop-old modes. Retry-new is the typical producer-consumer mode for message passing and work distribution scenarios; drop-old is a lossy/overwrite mode for profiling/tracing [5, 24] and debugging [44] scenarios, in which producers may overwrite unconsumed data if the buffer is full.

In our experimental evaluation, BBQ outperforms several industrial queues and ringbuffers. In single-producer/single-consumer micro-benchmarks, BBQ yields 11.3x to 42.4x higher throughput than Linux circular buffer [22], DPDK ring buffer [9], Boost lock-free queue [4], and Meta’s Folly queue [14]. In real-world scenarios, BBQ achieves up to 1.5x, 50.5x, and 11.1x performance improvements in benchmarks of DPDK, Linux `io_uring` [13], and LMAX Disruptor [23], respectively. In our profiling benchmarks, BBQ enabled with the lossy/overwrite mode achieves up to 4.7x higher throughput than Google’s Guava `EvictingQueue` [15] and Apache Commons `CircularFifoQueue` [1], and can sustain up to 143.2x lower enqueue latency than the other two queues.

The remainder of this work is organized as follows. In Sec. 2, we gradually introduce the challenges of reducing the interference between enqueue and dequeue operations, discussing how existing queues tackle these challenges, and the limitations of their solutions. In Sec. 3, we present our block-based approach and the high-level design of BBQ. In Sec. 4, we describe BBQ implementation including the support for retry-new and drop-old modes and variable-sized entries. In Sec. 5, we report our results in verifying BBQ on WMMs and relaxing its memory barriers. In Sec. 6, we experimentally compare the performance of BBQ and several industry-grade concurrent queues. In Sec. 7, we conclude our work.

Figure 1: A simple MPMC bounded queue. `CAS`, `LOAD`, and `STORE` are atomic operations with sequentially consistent semantics on WMMs. `C.head` and `C.tail` refer to consumers; `P.head` and `P.tail` refer to producers.

2 Background and Related Work

We now introduce scalability challenges of bounded queue designs and discuss related work and their limitations. Figure 1 illustrates the discussion in this section depicting a simple lockless bounded queue with multiple-producer multiple-consumer (MPMC) support, which is the algorithm behind the widely-used DPDK ringbuffer [9].

Producers first check whether the queue is full (Line 5) and then try to *allocate* the next entry via `CAS` (Line 7). Upon success, the producer copies the data into the entry and *commits* it (Line 11). Similarly, consumers first try to *reserve* an entry (Line 20). Upon success, the consumer copies the data back and confirms that the data has been *consumed* (Line 24).

(P1) Consumer contention on C.head. A straightforward form of deq-deq interference is caused by multiple consumers concurrently calling dequeue and contending on updates to `C.head`. Several works (on bounded and unbounded queues) tackle this contention using `FAA` to update the head [38, 40, 43] because `FAA` is more scalable than `CAS` on common architectures. However, since `FAA` cannot conditionally update the memory location, it may break, for example, the invariant of `C.head` never exceeding `P.tail`. To address that, Meta’s Folly queue [14] implements the partial, not total dequeue method, which spins until dequeue succeeds [33]. With such interface, dequeue calls return only if there is an entry to consume, otherwise blocking the thread indefinitely.

Another solution is to “fix the state” when `C.head` exceeds `P.head` by invalidating entries between them, as done by LCRQ [38]. Unfortunately, that causes consumers to hamper the progress of producers. SCQ [40] solves the producer starvation by limiting the number of consecutive invalidations with a threshold, as we describe below. Nevertheless, the remaining invalidations still degrade the enqueue performance, and the SCQ implementation [39] employs a trick

to reduce the probability of invalidating entries: Consumers check several times in a loop whether the entry has been committed before actually invalidating it. Unfortunately, this *delayed invalidation* trick increases the latency of dequeue when the queue is empty by several orders of magnitude — we experimentally demonstrate this empty-deq in Sec. 6.2.3.

(P2) Producer contention on P.head. A straightforward form of enq-enq interference is caused by multiple producers concurrently calling enqueue and contending on updates to P.head. Here, Folly queue again resorts to FAA and turns enqueue into a partial method, which waits until free entries are available, potentially blocking the thread forever.

Nikolaev proposes a novel idea to implement a total queue while using FAA [40]: SCQD combines two SCQ index queues (fq and aq) with a data array. Upon enqueue on SCQD, the thread gets an index from fq, copies the data in the corresponding entry of the data array, and then puts the index into aq. Dequeueing works the other way around. The index queues are total on dequeue but partial on enqueue, *i.e.*, dequeue returns EMPTY if the queue is empty, whereas enqueue loops until it succeeds. Nevertheless, the combined SCQD is still total since index queues are never full, *i.e.*, the number of indexes is fixed and matches the maximum size of the index queues. Besides the constant overhead introduced by index queues, the high latency caused by the empty-deq issue in each SCQ index queue translates into high latency in SCQD for both empty-deq and full-enq cases (see Sec. 6.2).

(P3) Delayed P.tail and C.tail updates. Another typical enq-enq or deq-deq interference arises from the *in-order* policy to commit (resp. consume) entries — the default policy in DPDK ringbuffer. The head/tail mechanism, which resembles a ticket lock, brings issues analogous to Lock-Holder- and Lock-Waiter-Preemption [45]. For example, the preemption of a thread that is about to update P.tail (resp. C.tail) causes other enqueue calls (resp. dequeue calls) to uselessly spin (Lines 10 and 23) for arbitrary time periods.

Several queues implement, instead, *out-of-order* policies, allowing producers (resp. consumers) to commit (resp. consume) entries independently. In LCRQ, once consumers increment C.head such that it reaches P.tail, they start invalidating entries until C.head reaches P.head. That prevents producers from committing entries at indexes preceding C.tail, ensuring linearizability [34]. This approach starves producers and even livelocks the queue. For example, a consumer in an ongoing dequeue invalidates an entry when $C.head = P.tail < P.head$; the producer in the ongoing enqueue increments P.head to retry; the consumer realizes C.head still did not reach P.head and retries consuming, potentially invalidating the new entry if not yet committed; and so on.

SCQ uses a threshold T to restrict the number of consecutive entries invalidated, and, thus, avoid livelocks. When a consumer invalidates an entry, it atomically decrements T . A successful enqueue resets T to its initial constant $3n - 1$, where n is twice the queue capacity. This constant is care-

fully derived to guarantee linearizability is never violated [40]. However, it introduces additional contention among producers and consumers updating the threshold variable, which has to be again mitigated by delayed invalidation.

DPDK [9] ringbuffer implements a more practical out-of-order policy called RTS mode [27], which trades linearizability to avoid invalidations. Consumers never move C.tail forward if C.tail would reach P.tail, returning EMPTY despite of any committed entry between P.tail and P.head; thus, violating linearizability. Producers employ the reciprocal strategy.

To enable out-of-order commits, RTS records whether all entries between P.tail and P.head are committed. The *prohibited window* between P.tail and P.head has dynamic length because P.tail is moved forward only once the last producer writing between P.tail and P.head commits. If producers would keep allocating entries, they would keep incrementing P.head and extending the prohibited window up to the total capacity of the queue. To prevent consumers from starving, RTS sets up a threshold to limit the maximum distance between P.tail and P.head. If that distance is reached, enqueue blocks until all producers between P.tail and P.head have committed. RTS enables out-of-order consumes with the reciprocal approach.

(P4) Causes of enq-deq interference. There are two sources of interference between enqueues and dequeues: algorithmic and cache-related. While focusing on enq-enq or deq-deq cases, previous techniques introduce algorithmic interferences between enqueue and dequeue, *e.g.*, requiring producers and consumers to retry operations, increasing latency, potentially causing thread starvation, or even livelock.

Let us again consider the simple algorithm of Fig. 1. Even though cache misses caused by writing or reading the data cannot be eliminated, cache misses on the control variables are relevant. Every time a producer calls enqueue, it allocates an entry and increments P.tail. Every time a consumer calls dequeue, it potentially suffers a cache miss by reading P.tail. If the producer is far ahead the consumer, the cache misses at P.tail seem unjustifiable. Similarly, the producer suffers cache misses on C.tail even when there is plenty space in the queue between producers and consumers. In contrast to enq-enq and deq-deq, enq-deq interference is relevant even to the single-consumer/single-producer scenario, an important scenario for the industry. In Sec. 6, we experimentally show a correlation between a strong decrease of L1 cache misses and the performance improvements of BBQ (Sec. 3 and 4).

3 Design of BBQ

3.1 The Block-based Approach

BBQ splits the ringbuffer into blocks, as shown in Fig. 2. Each block contains one or more entries, usually multiple, depending on the configuration. The queue control variables are also split into queue-level and block-level variables. Control variables C.head and P.head now point to blocks instead

Figure 2: Block-based bounded queue (BBQ).

of entries; P.tail and C.tail are unnecessary for the algorithm. The block-level control variables include four cursors called allocated, committed, reserved, and consumed, which track the corresponding actions within each block.

The block-based approach greatly reduces the enq-deq interference. After a block is fully committed, its producer cursors (allocated/committed) remain unmodified until the block is fully consumed, causing no additional cache misses for consumers. Moreover, producers can always determine whether a block is fully allocated without accessing consumer cursors (reserved/consumed).

Multiple producers in the same block still contend on allocated and committed. Fortunately, the block-based approach enables the enqueue operation to use FAA, avoids costly invalidations, and still allows for a total method. Producers start using a block only once it has been fully consumed. Therefore, inside the block, FAA never allocates an entry that is not consumed yet, allowing enqueue to be total. FAA may make allocated out of the bound of the block, but state fixing is not required. Since each block has its own control variables, an out-of-bound cursor in one block does not affect the following block.

Although our dequeue operation employs CAS to avoid consumers from invalidating entries currently used by producers, BBQ still achieves similar or better performance than other designs with FAA-based dequeues. To further improve performance for machines with Armv8.1 [2] processors supporting Large System Extensions [3] (LSE), BBQ uses the atomic maximum instruction MAX instead of CAS in dequeue.

Finally, the block-based approach enables a practical out-of-order policy similar to RTS mode of DPDK. In this case, instead of updating control variables with double-width CAS, BBQ employs more scalable FAA and MAX instructions.

3.2 BBQ from a Bird's-eye View

In this section, we describe the high-level algorithm of BBQ, as shown in Fig. 3.

Producers. To enqueue data, a producer first retrieves the current value of P.head and the corresponding block identifier (Line 4). Next, it tries allocating an entry in the block (Line 5). If successful, the producer writes the data into entry ety and commits it (Line 7). The allocation fails if the block has already been fully allocated (Line 9). In this case, the

```

1  status := OK(T) | FULL | EMPTY | BUSY
2  status BBQ<T>::enqueue(T data){
3  loop:
4      (ph, blk) = get_phead_and_block();
5      switch (allocate_entry(blk)){
6          case allocated(ety):
7              commit_entry(ety, data);
8              return OK();
9          case BLOCK_DONE:
10             switch (advance_phead(ph)){
11                 case NO_ENTRY: return FULL;
12                 case NOT_AVAILABLE: return BUSY;
13                 case SUCCESS: goto loop;
14             }
15         }
16     }
17 status BBQ<T>::dequeue(){
18 loop:
19     (ch, blk) = get_thead_and_block();
20     switch (reserve_entry(blk)){
21         case reserved(ety):
22             data = consume_entry(ety);
23             if (data != NULL) return OK(data);
24             else goto loop;
25         case NO_ENTRY: return EMPTY;
26         case NOT_AVAILABLE: return BUSY;
27         case BLOCK_DONE(vsn):
28             if (advance_thead(ch, vsn)) goto loop;
29             else return EMPTY;
30     }
31 }

```

Figure 3: High-level design of BBQ.

producer tries to advance P.head to the next block (Line 10). If successful, the producer jumps back to the loop label and retries the allocation (Line 13). In retry-new mode, advancing P.head fails if the next block is not yet fully consumed, *i.e.*, the whole queue is considered full. BBQ distinguishes the failure reason: BUSY when some dequeue operation is ongoing and FULL otherwise. Returning BUSY allows for custom back-off implementations at the caller side, *e.g.*, parking threads after a number of retries. In drop-old mode, advancing P.head does not fail except for a seldom case discussed in Sec. 4.3, for which BUSY is returned.

Consumers. The dequeue operation is somewhat analogous to enqueue. The consumer starts by retrieving the current value of C.head and the corresponding block identifier. Next, it attempts to reserve an entry to consume (Line 20), advancing reserved. If the reservation succeeds, the consumer reads the data (Line 22) and advances consumed. In drop-old mode, the consumer may have to retry consuming if the producers have overwritten the block (Line 24). Reserving an entry can fail in several ways. When the next entry in blk is allocated but not yet committed, dequeue returns BUSY (Line 26). When blk is not fully allocated and all committed entries were already consumed, dequeue returns EMPTY (Line 25). Finally, when blk is fully committed and fully consumed, the consumer tries advancing C.head (Line 28). Upon success, it retries reserving an entry, jumping to loop. Otherwise, dequeue returns EMPTY.

Progress guarantees. Similarly to DPDK ringbuffer, BBQ is a deadlock-free queue, its progress depend on a fair scheduler. In contrast to DPDK, BBQ is less affected by CPU oversubscription (see Figure 9g, Section 6). To see why this is the case, consider the situation where DPDK producers form a waiting chain: the last to allocate an entry can only commit once the previous has committed its entry, and so on. This waiting chain hampers the performance because the scheduler is unlikely to unpark the preempted producers in the chain's order. In BBQ, there is no such waiting chain, *i.e.*, producers commit independently. Consumers may wait for producers only in seldom cases. For example, a consumer waits for a preempted producer on the same block if the producer has allocated but not yet committed an entry. Nevertheless, any order in which the fair scheduler unparks preempted producers allows the consumer to make progress.

3.3 Two-Level Control Variables

Essentially, BBQ splits the control variables into two levels, namely the queue-level and block-level variables (see Fig. 2). Queue-level control variables point to blocks (C.head and P.head), whereas block-level control variables to entries (allocated, committed, reserved, and consumed).

Versions. As in other queues such as DPDK ringbuffer, control variables have to be versioned to identify multiple reuses of the same memory locations and, in this way, avoid ABA problems¹. Therefore, queue-level control variables have two fields, an *index* pointing to a block and a *version* identifying how many rounds the whole queue has been reused. Similarly, block-level control variables have an *offset* field pointing to an entry within the block and a *version* field identifying how many times the block has been reused.

Phantom heads. Before producers can allocate entries in a block *B*, one producer has to reset *B*'s allocated cursor as well as advance P.head to point to *B*. Without making both updates atomic, whichever update executes first may trigger an ABA problem as well. To allow both being updated atomically, we introduce the concept of *phantom head*, which is based on the following observation. The index and version values of P.head can be inferred from the versions of all allocated cursors in the queue (as described in Sec. 4.2.2). Similarly, the phantom C.head can be inferred from the versions of all reserved cursors. Since the phantom P.head (resp. phantom C.head) is implicitly updated whenever any allocated cursor (resp. reserved cursor) is updated, we use them instead of queue-level head variables.

¹Often algorithms try to guarantee operation atomicity by reading from a control variable before and after the operation. If the same value *A* is read both times, the programmer assumes absence of concurrent updates and hence that the operation was atomic. This assumption breaks if other threads can temporarily change the value to $B \neq A$ and then back to *A*; algorithms in which this situation can occur are said to suffer from the ABA problem [32].

Cached heads. In principle, phantom heads allow us to eliminate the C.head and P.head variables altogether. Unfortunately, phantom heads are costly: To infer them, one needs to compare the cursors of every block. Instead of eliminating C.head and P.head, we consider them to be *cached heads*, *i.e.*, potentially stale values of the phantom heads. Cached heads only exist for performance reasons; their staleness does not affect correctness.

4 Implementation of BBQ

Figure 4 shows the low-level detail of BBQ, including data-fields, enqueue and dequeue operations for retry-new mode and drop-old mode. The drop-old mode will be introduced in Sec. 4.3.

4.1 Structure

Heads and cursors. BBQ has two queue-level Head variables and four block-level Cursor variables in each block. Head and Cursor types are 64-bit integers, which can be atomically updated. We reserve two bit-segments in Head to represent the version and index and two bit-segments in Cursor to represent the version and offset. Given a total number of blocks (BLOCK_NUM) and the capacity of a block (BLOCK_SIZE), the segments have the following bit-lengths:

$$\begin{aligned} |\text{Index}| &= \log_2(\text{BLOCK_NUM}) \text{ bits} \\ |\text{Offset}| &> \log_2(\text{BLOCK_SIZE}) \text{ bits} \\ |\text{Version}| &= 64 - \max(|\text{Index}|, |\text{Offset}|) \text{ bits} \end{aligned}$$

The bit-length of Offset is larger than $\log_2(\text{BLOCK_SIZE})$ to allow for FAA-overflow detection. The Index and Offset are the least significant bits of Head and Cursor, respectively; Version bits immediately follow them; and reminder bits, if existent, are set to 0 and ignored. That allows us to easily manipulate these fields with FAA and MAX instructions.

For convenience, we access the bit-segments from Head and Cursor variables as if they were regular fields named idx, off, and vsn, *e.g.*, allocated.idx. Moreover, we construct variables (*e.g.*, Head) with the short-hand notation Head{.vsn=version, .idx=index}, initializing unspecified fields with 0. We may omit the type when clear from the context.

Initially, idx and off in the first block are zero and for remaining blocks off is set to BLOCK_SIZE. The initial value of vsn will be introduced in Sec. 4.2.2.

Other types. Block has shared cursors, annotated with shared<>, and an array of entries of type T (Line 38). EntryDesc is an entry descriptor; it points to a block and contains offset to location the actual entry and a version data-consistency checks used in drop-old mode (Line 41). Finally, BBQ contains the shared heads and an array of Block<T>.

```

1 <Head, Block> BBQ<T>::get_phead_and_block(){
2   ph = LOAD(phead);
3   return (ph, blocks[ph.idx]);
4 }
5 state BBQ<T>::allocate_entry(Block blk){
6   if (LOAD(blk.allocated).off >= BLOCK_SIZE)
7     return BLOCK_DONE;
8   old = FAA(blk.allocated, 1).off;
9   if (old >= BLOCK_SIZE)
10    return BLOCK_DONE;
11  return ALLOCATED(EntryDesc{.block=blk, .offset=old});
12 }
13 void BBQ<T>::commit_entry(EntryDesc e, T data){
14   e.block.entries[e.offset] = data;
15   ADD(e.block.committed, 1);
16 }
17 state BBQ<T>::advance_phead(Head ph) {
18   nblk = blocks[(ph.idx + 1) % BLOCK_NUM];
19   cons = LOAD(nblk.consumed);
20   if (cons.vsn < ph.vsn ||
21       (cons.vsn == ph.vsn && cons.off != BLOCK_SIZE)) {
22     reserved = LOAD(nblk.reserved);
23     if (reserved.off == cons.off) return NO_ENTRY;
24     else return NOT_AVAILABLE;
25   }
26   cmtd = LOAD(nblk.committed);
27   if (cmtd.vsn == ph.vsn && cmtd.off != BLOCK_SIZE)
28     return NOT_AVAILABLE;
29   MAX(nblk.committed, Cursor{.vsn=ph.vsn + 1});
30   MAX(nblk.allocated, Cursor{.vsn=ph.vsn + 1});
31   MAX(phead, ph + 1);
32   return SUCCESS;
33 }
34 class BBQ<T> {
35   shared<Head> phead, chead;
36   Block<T>[] blocks;
37 }
38 class Block<T> {
39   shared<Cursor> allocated, committed;
40   shared<Cursor> reserved, consumed;
41   T[] entries;
42 }
43 class EntryDesc {
44   Block block; Offset offset; Version version; }

```

```

45 <Head, Block> BBQ<T>::get_thead_and_block(){
46   ch = LOAD(thead);
47   return (ch, blocks[ch.idx]);
48 }
49 state BBQ<T>::reserve_entry(Block blk){
50   again:
51   reserved = LOAD(blk.reserved);
52   if (reserved.off < BLOCK_SIZE) {
53     committed = LOAD(blk.committed);
54     if (reserved.off == committed.off)
55       return NO_ENTRY;
56     if (committed.off != BLOCK_SIZE){
57       allocated = LOAD(blk.allocated);
58       if (allocated.off != committed.off)
59         return NOT_AVAILABLE;
60     }
61     if (MAX(blk.reserved, reserved + 1) == reserved)
62       return RESERVED((EntryDesc){.block=blk,
63                                     .offset=reserved.off, .version=reserved.vsn});
64     else goto again;
65   }
66   return BLOCK_DONE(reserved.vsn);
67 }
68 T BBQ<T>::consume_entry(EntryDesc e){
69   data = e.block.entries[e.offset];
70   ADD(e.block.consumed, 1);
71   allocated = LOAD(e.block.allocated);
72   if (allocated.vsn != e.version) return NULL;
73   return data;
74 }
75 bool BBQ<T>::advance_thead(Head ch, Version vsn){
76   nblk = blocks[(ch.idx + 1) % BLOCK_NUM];
77   committed = LOAD(nblk.committed);
78   if (committed.vsn != ch.vsn + 1)
79     return false;
80   MAX(nblk.consumed, Cursor{.vsn=ch.vsn + 1});
81   MAX(nblk.reserved, Cursor{.vsn=ch.vsn + 1});
82   if (committed.vsn < vsn + (ch.idx == 0))
83     return false;
84   MAX(nblk.reserved, Cursor{.vsn=committed.vsn});
85   MAX(thead, ch + 1);
86   return true;
87 }

```

retry-new mode | drop-old mode

Figure 4: Low-level details of BBQ.

4.2 Operations

Enqueue and dequeue operations are divided into different cases: First, when the allocation in the enqueue or the reservation in the dequeue do not fail. Second, when enqueue or dequeue have to advance respective heads to the next block.

4.2.1 Successful allocation/reservation

The producer uses `FAA` to allocate an entry (Line 8) and returns its location as `EntryDesc` if there is enough space in the current block (Line 11). A pre-check (Line 6) avoids endless increasing of `allocated` when the queue is full, which could cause `FAA` overflows and impact performance negatively. For the consumer, the entry is reserved through `MAX`² (Line 61),

²Unlike `FAA`, `MAX` provides conditional update semantics. Moreover, for some cases, `MAX` has similar semantics to `CAS` but better performance observed

which atomically sets a variable if the given value is greater than the variable's value and returns the old value. Consumers never pass producers (Line 54) and can read when out-of-order commit are not ongoing in the same block, which means all allocated entries are committed (Line 58).

4.2.2 Advancing to the next block

Monotonic version updates. Head and cursor versions are initially zero. Both enqueue and dequeue calls start by reading the current cached head (`phead` and `thead`, respectively) into a local variable (`ph` and `ch` in Fig. 3). After failing to allocate or reserve an entry, these calls try to advance the respective phantom heads by calling `advance_phead` or `advance_thead`.

from experimental results. We use `CAS` and while loop to achieve the same functionality for architectures that do not support `MAX` such as x86 [16].

These functions *try* to reset the cursors of the next block with the previously read version of the cached head plus one (Lines 29, 30, 80, and 81 in Fig. 4). Subsequently, the functions *try* update the cached head itself (Lines 31 and 85).

The reset of cursors and the update of cached head may not always succeed. Consider the following example. Two producers try to allocate entries at block B_0 and fail. Both have read `phead` with value `{.vsn=0, .idx=0}`. Now both call `advance_phead` concurrently and are at Line 30. Producer P_1 stalls while producer P_2 succeeds updating the allocated cursor of block B_1 . P_2 also allocates one or more entries such that now B_1 's `allocated` has the value `{.vsn=1, .off=16}`. If now P_1 would be able to succeed resetting `allocated`, then the allocations of P_2 would be lost. Nevertheless, to avoid such ABA situations, the reset of cursors and update of cached head do not have to be performed with an expensive CAS. The recent MAX atomic instruction from Armv8.1-LSE can provide the required monotonicity.

Invariants. Producers have to ensure they advance `phead` only if the next block that has no unconsumed data. Consumers have to ensure they advance `chead` only if the next block has committed data.

We guarantee these invariants by ensuring that the version difference between phantom `phead` and phantom `chead` never exceeds 1. When producers advance `phead` and reset the `allocated` and `committed` cursors of the next block with version `ph.vsn+1` (Line 30), the `consumed` cursor must have version `ph.vsn` (Line 21). Similarly, when consumers advance `chead` and reset the `reserved` and `consumed` cursors of the next block with version `ch.vsn+1` (Line 80), the `committed` cursor must have version `ch.vsn+1` (Line 79).

Order matters. Often the order in which shared variables are accessed is crucial for correctness. For example, reading `reserved`, `committed`, and `allocated` variables (Lines 51, 53, and 57) in a different order can cause the consumer to read garbage. Moreover, updating cached heads (Lines 31 and 85) must happen after updating block-level variables (Lines 29, 30, 80, and 81), otherwise blocks may be fully skipped.

To guarantee shared variables are accessed in the program order of Fig. 4 on architectures with weak memory models, C/C++ implementations of BBQ can employ atomic LOAD, STORE, MAX, FAA, and CAS instructions with sequentially consistent memory barriers (see C11/C++11 atomics [6]). In Sec. 5, we report a correct relaxation of these barriers.

4.3 Drop-old Mode

Unlike the retry-new mode, where producers cannot insert data when the queue is full, in drop-old mode, producers continue to write even if the data is not yet consumed. Consequently, producers no longer depend on the consumers to make progress. The FIFO property still holds, except that some data might be lost. In other words, entries are consumed

in the order in which they were allocated, but some committed entries may not be consumed.

Speculative reads. Drop-old mode is widely used in profiling scenarios, where enqueue calls writing a log should not be delayed by dequeue calls that read the log. To reduce the chances of dequeue calls interfering with enqueue calls, consumers read data in a speculative fashion. The consumer first reads the data and then checks whether it has been overwritten. If so, it discards the data and tries reserving another entry.

From retry-new to drop-old mode. A few differences exist between retry-new and drop-old mode. First, producers avoid advancing to blocks that are still not fully committed in the previous round, returning BUSY (Lines 27 and 28).

Second, consumers guarantee FIFO order by checking if the version of the next block is greater than or equal to the current one (Line 82). If that is the case, `reserved` is reset with the version of `committed` (Line 84), indicating the block is ready to be read. The first block is a special case because, in contrast to other blocks, its version is always off-by-one. Therefore, we add 1 to the comparison if `ch.idx == 0`.

Third, the data-consistency check is based on the fact that a block is not overwritten as long as `allocated` and `reserved` versions are equal. Therefore, before reading data, we record the `reserved` version (Line 63), and after copying the data from the entry, we check if corresponding `allocated` version still matches the `reserved` (Line 72).

4.4 Variable-sized Entries

BBQ can support variable-sized entries with minor algorithmic changes. Each entry has an additional metadata `size` to support different entry sizes in one queue. Block-local cursors and `BLOCK_SIZE` indicate the space of entries instead of their number. MAX at Line 61 is no longer sufficient; CAS must be used instead.

Dummy entry. Unlike the fixed-size version of BBQ, where entries can exactly fill up a block, here, the remaining space of a block might not be enough to contain the new entry. In such cases, we mark the space with a dummy entry and return `BLOCK_DONE` to trigger a retry in the next block. Since enqueue uses FAA, the producers that cause `allocated` go over the boundary marks the dummy entry by setting its `size` to zero and commits it. Consumers that read an entry with `size` zero ignore the dummy entry and retry in the next block. Upon reading the dummy entry, the consumer also sets `consumed` to be equal to `BLOCK_SIZE`.

4.5 Other Implementation Details

We have implemented BBQ in C and Java. We have also implemented a wrapper with the Java Native Interface (JNI) [20] to call the C version from Java.

Finally, we have optimized BBQ for SPSC scenarios as follows: (1) `phead` and `chead` are no longer shared variables and

can be accessed with non-atomic loads/stores. (2) `allocated` and `committed` (resp. `reserved` and `consumers`) are merged into one variable and updated with `STORE`.

5 Verification and Optimization of BBQ

Concurrent data structures are complicated beasts and are easy to get wrong [30]. To increase confidence in our C implementation and find intricate bugs, we generate a series of small hand-crafted tests that can trigger corner cases in the algorithm and then use `VSYNC` [42], an extension to the GenMC model checker [36]. The tool generates all executions of the algorithm on those tests, including executions that can only happen on WMMs, exercising the following critical corner cases: (1) queue full or empty, (2) FIFO, (3) wrap-around, and (4) termination of bounded loops with bounded effect [37, 42].

Bugs. We found three concurrency bugs in an earlier version of the drop-old mode of BBQ.

1. A test revealed a bug in which enqueue operations incorrectly returned `BUSY`. The block was detected as `NOT_AVAILABLE` because, in that version, the condition at Line 27 was `committed.off == BLOCK_SIZE && committed.vsn == ph.vsn`. Therefore, even if other producers reset the next block and have the space to allocate, the block would still be `NOT_AVAILABLE`. That violated linearizability.
2. We have found a termination bug in which the checking in Line 82 was written as `blk.committed.vsn >= nblk.committed.vsn`, missing the special case of the version number in the first block, which may let consumers advancing the block forever if the queue is empty and all blocks happen to have the same version number.
3. The wrap-around test revealed a bug due to a missing fence, where readers could return incorrect data when a fast writer overwrote the entry they were currently reading.

We found these bugs through the verification with model checking. They were not found during stress testing, nor by running the small test cases directly on hardware. However, we could retrospectively construct test cases that reproduce these bugs on real hardware. Concurrent algorithms, especially those using complicated synchronization such as drop-old mode, are hard to get right using traditional methods.

Barrier optimization. We used `VSYNC` to run the memory barrier optimization for WMMs. The results consistent with the order analyze of reading/updating shared variables in Sec. 4.2.2. For the fixed entry size version, 14 atomic instructions with full memory barriers are optimized to 3 release barriers, 3 acquire barriers, and 8 relaxed barriers, respectively.

6 Evaluation

6.1 Environment Setup

Hardware. All of our experiments are performed on three x86 machines with 88, 96, and 12 hyperthreads, respectively (denoted as x86-88T, x86-96T, and x86-12T), and an ARM machine with 96 cores (arm-96T). x86-88T and x86-96T are connected through two 10Gbps links.

Software. On these servers, we installed Ubuntu 20.04.3 LTS, with Linux kernel 5.4.0. We use Linux `perf` [26] to get results of L1 cache misses, the version of it is the same with the Linux kernel. Java-based experiments use JDK v11 [19].

6.2 Microbenchmarks

Workloads. We have the following 3 workloads for microbenchmarks implemented in C/C++ and Java:

- **simple:** Each producer or consumer has its own thread, where they keep executing enqueue or dequeue operations in a loop. Data is validated after each dequeue.
- **complex:** Based on the simple workload. Producers and consumers allocate space for data, preform enqueue and dequeue then manually free (C/C++ version) or let JVM garbage collection it [46] (Java version). Additionally, each operation also performs a deterministic random busy-loop of at most one hundred `nop` instructions.
- **profiling:** Based on the simple workload. The throughput of producers and consumers is fixed at 10kop/s and 1kop/s, respectively.

Thread affinity. For MPSC or SPMC scenarios, we assign a single producer or consumer at the first core/hyperthread and then distribute the other threads sequentially to cores/hyperthreads. For MPMC, we assign producers and consumers interleaved one by one; if their number differs, the surplus is assigned at the end.

Experiments. We perform the following experiments, each measuring a different metric:

- **throughput:** Total number of consumed entries per second.
- **data-latency:** Average time each data stays in the queue.
- **op-latency:** Average latency of each enqueue or dequeue operation.
- **cache-miss:** Average number of L1 cache misses per consumed entry, measured with Linux `perf`.
- **fairness:** Throughput of each producer and consumer (only for MPSC and SPMC).
- **full/empty:** Latency of enqueue when the queue becomes full and latency of dequeue when the queue becomes empty (only used with simple workload).
- **oversubscription:** Throughput with more producers and consumers than than cores/hyperthreads.

Each experiment runs 3 times. If not specified otherwise, solid lines represent average results; shaded area represents

Figure 5: BBQ throughput and latency varying number of blocks and entries (x86-88T).

standard deviation; and vertical dashed lines indicate when threads cross NUMA nodes, are assigned to hyperthreads in the same core, or are oversubscribed.

Configuration. The data size is always 8 bytes, a size all queues can support. For the data-latency experiment, the number of entries is around 128. For the other experiments, the buffer size is 32k bytes unless specified otherwise.

6.2.1 BBQ Parameters and Design Choices

We start by evaluating parameters and design choices of BBQ.

Configuring the number of blocks. Figure 5 shows throughput and data-latency experiments for BBQ with four producers and one consumer. The color scale shows the existing trade-off between number of entries and number of blocks; users have to be aware of that when choosing the buffer size and number of blocks. We use the following heuristic function to determine the number of blocks in all rest experiments: $number\ of\ blocks\ (log) = \max(1, \lfloor number\ of\ entries\ (log) / 4 \rfloor)$.

Performance impact of FAA. Figure 6 shows the results of an MPSC throughput experiment on our Arm machine. BBQ is configured to use FAA instruction from Armv8.1 LSE, standard FAA and CAS implemented with load-exclusive and store-exclusive instructions. Except for the 1 thread case, LSE-based FAA shows the best scalability, outperforming the other two by at least 5 times.

Support for variable-sized entries. Figure 6 also shows the throughput of the BBQ with fixed- and variable-sized entries. The size of each data is the same, yet the varied entry version has to store additional size information for every entry. Nevertheless, the throughput difference between both is negligible.

Consumer-producer interference in drop-old mode. Finally, Figure 6 shows the throughput of BBQ with drop-old mode in two configurations: MPSC and MPNC (multiple-producer/no-consumer). The throughput of the producers (nr-prod) with no consumers is less than 8% higher than with consumer (sr-prod). Moreover, the consumers manage to consume at least 99.97% of the entries except for the 1 thread case (sr-cons). These results illustrate that consumers with the speculative-read method incur a rather minor interference on producers — please refer to Sec. 6.2.3 for a baseline with existing implementations.

Figure 6: BBQ throughput with CAS and FAA; with support for variable-sized entries; and with drop-old mode (arm-96T).

6.2.2 State-of-the-art Comparison: Retry-new Mode

We now compare BBQ against 5 state-of-the-art bounded queues: dpdkrb, DPDK ringbuffer v21.08 [9]; scqd, a lock-free bounded queue [40]; linuxrb, the ringbuffer in the Linux kernel v5.16 [22]; boostq, the bounded queue in C++ Boost libraries v1.71 [4]; and follyq, the bounded queue (with total method) [25] in Meta’s open-source Folly library v2021.11.8. For dpdkrb and follyq, we use their SPSC versions to run corresponding SPSC experiments.

Effectiveness of the Block-based Approach. To isolate the effect of the blocks, we first focus on SPSC experiments because BBQ do not profit from FAA in such scenarios. Figure 7 shows that BBQ greatly outperforms all other bounded queues in all experiments. For the simple workload, BBQ yields 11.3x to 42.4x higher throughput than other libraries. The throughput of BBQ is $1.41 \cdot 10^8$ op/s, while the second-best one follyq is $1.24 \cdot 10^7$ op/s. For the complex workload, which has a random busy-loop to limit the maximum throughput, BBQ still outperforms follyq by 2x. BBQ’s better performance is mainly due to the massive decrease in L1 cache misses with the block-based approach (notice the y-axis log scale).

Throughput in MPSC and SPMC scenarios. Figures 9a and 9b show BBQ performing on par or better than other queues in the simple and complex workloads. For MPSC scenarios, BBQ performs up to 10.13x and 3.65x faster than the second-best queue, respectively. For SPMC scenarios, BBQ performs up to 1.88x and 2.39x faster than the second-best queue, respectively.

The throughput difference between MPSC and SPMC results can be attributed in part to the different L1 cache misses measurements (see Fig. 9c). BBQ consumers employ CAS operations in every dequeue, and these can fail and have to be retried, each time suffering another cache miss.

Data latency. We measure the average time data stays in the queue in the complex workload, as shown in Fig. 9d. For MPSC case, BBQ performs consistently better than other bounded queues; up to 17.22x lower latency than the second-best queue. For the SPMC case, scqd performs best, up to 7.45x lower latency than BBQ. That is an artifact of the delayed invalidation trick (see Sec. 2): Once the queue is empty (C.head = P.tail), consumers invalidate the entries pointed by C.head after a delay. Since consumers first increment C.head and then wait, multiple consumers will be pending on differ-

Figure 7: SPSC comparison of BBQ against state-of-the-art on x86-88T.

Figure 9: MPSC and SPMC comparison of BBQ against state-of-the-art on x86-88T (and x86-12T for oversubscription).

ent entries. As soon as the producer commits a new entry, one consumer aborts its delay and immediately returns the data.

Full and empty queues. Figure 9e shows the latency for failed enqueue on a full queue (top figure), and failed dequeue on an empty queue (bottom figure). In such scenarios, the delay invalidation of scqd incurs a high cost: the latency of failed operations in scqd is around 1000x higher than in most other queues. For linuxrb, the latency increases with the number of producers/consumers due to its coarse-grained locking.

Fairness between producers or consumers. Figure 9f shows the relation between maximum and minimum throughput of producers (top figure) and consumers (bottom figure). linuxrb provides exceptional fairness because it relies on a fair spinlock³. Other queues show unfair throughput after crossing the first NUMA node (at 22 producers/consumers) except for scqd, which becomes unfair when hyperthreads of the same cores start being used (at 44 producers/consumers).

Oversubscription effects. Figure 9g shows the results of our oversubscription experiment on x86-12T with up to 5x more threads than hyperthreads. Both dpdkrb and linuxrb are highly affected by oversubscription; the former due to their in-order policy (see Sec. 2), the latter due to its coarse-grained locking. Under oversubscription (*i.e.*, with more than 12 threads), BBQ outperforms the second-best queue by a small margin: 2.22x in MPSC and 1.23x in SPMC scenarios.

³In our userspace port of linuxrb, we employ a ticket lock.

6.2.3 State-of-the-art Comparison: Drop-old Mode

We now compare BBQ with other two bounded queues that support overwriting old values, namely EvictingQueue from Google Core Libraries Guava [15], and CircularFifoQueue from Apache Commons [1]. The experiments are conducted on the arm-96T machine.

Producer performance. Figure 10a shows the enqueue throughput with *no consumers* for the complex workload. On the one hand, BBQ-JNI yields 3.2x higher enqueue throughput than EvictingQueue and CircularFifoQueue. On the other hand, BBQ yields an enqueue throughput rather similar to them. Intuitively, BBQ-JNI has a better performance since employs real *FAA* instructions, whereas, in the Java version of BBQ, the JVM translates *FAA* into *CAS* [35].

Figure 10c shows the enqueue latency, again with *no consumers*, for the profiling workload. Remember that producers issue 10k enqueue calls per second in the profile workload. With BBQ and BBQ-JNI, the enqueue latency slowly increases: 147.9ns and 176.4ns with 1 thread, respectively, to 965.6ns and 914.3ns with 94 threads, respectively. Up to 44 producers, EvictingQueue and CircularFifoQueue perform similar to BBQ variants. With more than 44 producers, however, their enqueue latency quickly increases up to 70 μ s (72x higher than BBQ). From Fig. 10a, we know that their maximum enqueue throughput is about 450kops. Hence, these queues already reached throughput limit with 44 producers, and any additional producers can only increase the latency. We believe the spike at 95 threads (BBQ with 5.1 μ s and BBQ-JNI with 2.0 μ s)

Figure 10: Cross comparison results for drop old mode on arm-96T.

may caused by garbage collection, but further investigation is necessary.

Enq-deq interference. We now introduce a single consumer to understand the interference of dequeue on the enqueue operations. Ideally, the enqueue operations should incur a small overhead (latency) to the profiled program; and this overhead should be minimally affected by concurrent dequeue calls. Moreover, if enqueue calls interfere with dequeue calls too frequently, more data may be dropped, *i.e.*, overwritten before being consumed.

Figure 10b shows the enqueue and dequeue throughput (marked with • and ×, respectively) for the complex workload. Comparing Figs. 10a and 10b, we observe that the enqueue throughput of BBQ is similar in both figures and of BBQ-JNI is similar up to 47 threads, but after that it drops to about $1.89 \cdot 10^6$ op/s. The enqueue throughput of EvictingQueue and CircularFifoQueue is initially lower when a consumer is concurrently calling dequeue. The reason for this lower enqueue throughput can be explained by observing the difference between enqueue and dequeue in Fig. 10b.

First, note that with more than a few producers, the enqueue and dequeue throughput of each queue do not match, *i.e.*, the consumer is not fast enough to read out all the data before the producers start overwriting the oldest entries. Also note that the more the enqueue throughput of EvictingQueue and CircularFifoQueue recovers (by increasing producers), the lower is the dequeue throughput. Once their throughput is back to the level of Fig. 10a with 15 threads, their dequeue throughput is no more than $4.92 \cdot 10^5$ op/s. In contrast, BBQ and BBQ-JNI sustain a much higher dequeue throughput up to 46 threads ($2.89 \cdot 10^6$ op/s and $5.07 \cdot 10^6$ op/s, respectively).

Figure 10d shows the enqueue latency for the profiling workload. BBQ and BBQ-JNI provide enqueue latencies varying from 730.6ns and 519.9ns with 2 producers, respectively, up to 1082ns and 9503ns with 95 producers — we ignore the noisy region with 81 producers. Comparing the results of Figure 10c and Figure 10d reveal that the enqueue latency of EvictingQueue and CircularFifoQueue, for example with 8 producers increase by 124.97 times when adding a single consumer with a relatively low dequeue frequency.

The latency increases as well as the throughput decreases of BBQ-JNI after 47 producers could be related to the JNI overhead of calling C code from Java.

Figure 11: Throughput comparison between BBQ or DPDK ring buffer.

6.3 Macrobenchmarks

We now explore three benchmarks that represent the real-world usage queues.

6.3.1 DPDK’s End-to-end Benchmark

We replace the ring buffer in DPDK’s event library [12] and network driver [11] with BBQ, and run the multiprocess benchmark [8] from the DPDK Test Suite [10] (DTS). The benchmarks consists of one server process receiving and distributing packets, and two client processes performing level-2 packet forwarding [7]. These processes run on the device under test (DUT), our x86-88T machine. The tester and traffic generator TRex [29] run on our x86-96T machine. The packet size is 64 bytes (along with the UDP header) as well as the entry size of the queue. The versions of DPDK, DTS, and TRex are 21.08, 21.02, and 2.92, respectively. We report the end-to-end throughput (in million packets per second) measured by the traffic generator.

Figure 11 shows our experimental results. BBQ provides 1.5x higher throughput with different buffer sizes in the driver. We observed no further improvements with larger buffer sizes, indicating that the ring buffer may not be a bottleneck any more. We also replaced the so-called software queue in the multiprocess benchmark, and observed no improvement.

6.3.2 Linux io_uring

Linux io_uring [13] is a new asynchronous I/O [31] API for kernel-user space communication. It consists of two ring buffers, one for request submissions (SQ) and another for completion confirmations (CQ). It supports batched submission and batched confirmations with configurable batch sizes [18].

Figure 12: Latency per request comparison of BBQ and Linux `io_uring` on x86-88T.

We port `io_uring` from Linux kernel (v5.14-rc6) [17] to userspace, omitting I/O related functionality and replacing its ring buffers with BBQ. To avoid unstable results, we disable the option of overflowing entries into an additional linked list. We set the CQ size to twice the SQ size as recommended [21]. Our benchmark runs three threads: The first submits request batches (via SQ); the second (representing the kernel) consumes them and immediately produces confirmations (via CQ); and the third consumes the confirmation batches. We configure submission and confirmation batches with size 1 or with a random value from 1 to 32. Each experiment runs 10 times, measuring the time to submit 1M requests.

Figure 12 shows a significant improvement of the latency per request when using BBQ. For example, with batch size of 1 and SQ size of 32 and 1024, BBQ yields 6.7x and 6.9x lower latency than the original ring buffer, respectively. For random batch size and the same SQ sizes, BBQ yields even lower latencies: 20.9x and 50.5x, respectively.

6.3.3 LMAX Disruptor Benchmarks

Disruptor [23] is concurrency mechanism used for high-performance financial exchange. Its core component is a ring buffer. We compare its throughput with the Java and JNI versions of BBQ with three official Disruptor benchmarks: `OneToOneThroughputTest`, `ThreeToOneThroughputTest`, and `OneToThreeThroughputTest`. We modify these benchmarks to support not just three, but more producers or consumers. Apart from this modification, all other parameters (e.g., number of iterations, sleep time between operations, number of repetitions) are unchanged.

Disruptor can randomly change the batch size based on the workload. To make the comparison as fair as possible, we first run the benchmark with Disruptor to get the average batch size used, and then run BBQ with that batch size. Figure 13 shows the throughput of Disruptor, BBQ, and the baseline Java queue (`java.util.concurrent.BlockingQueue`) for several scenarios. The number on each bar refers to the (average) batch size, and the label $pPcC$ indicates the number of producers (p) and consumers (c).

In the 1P1C scenario, Disruptor yields almost 3x higher throughput than the Java queue (3 Mop/s versus 1.3 Mop/s). BBQ and BBQ-JNI, however, yield an order of magnitude

Figure 13: Throughput comparison of BBQ and BBQ-JNI against LMAX Disruptor on x86-88T.

higher throughput (14.1 Mop/s and 12.1 Mop/s, respectively). The higher performance of BBQ over BBQ-JNI is due to the JNI call overheads. With 8 producers, the difference between Disruptor and BBQ is lower (2.2 Mop/s and 3.7 Mop/s, respectively). BBQ-JNI yields 3x Disruptor's throughput (6.7 Mop/s) due to its use of `FAA`. With 32 producers, BBQ and BBQ-JNI again outperform Disruptor by an order of magnitude (3.0 Mop/s, 3.3 Mop/s, and 0.6 Mop/s, respectively).

With a single producer and multiple consumers, BBQ-JNI has no opportunity to gain performance by using `FAA`. Due to that, its performance pays the penalty of the JNI call overheads. Nevertheless, BBQ still outperforms Disruptor in most configurations. For example, BBQ yields 1.23x higher throughput than Disruptor with 2 consumers (1P2C); and 1.68x higher throughput with 8 consumers. With 32 consumers, Disruptor yields 1.42x higher throughput than BBQ.

7 Conclusion

We presented BBQ, a novel ringbuffer design that dramatically reduces the enq-deq interference by splitting the entire ringbuffer into multiple blocks. BBQ is applicable to a large spectrum of scenarios, from exchanging data to profiling, with single or multiple producers/consumers, sending fixed- or variable-sized entries, among others. Our experimental results show that BBQ outperforms several industrial ringbuffers (e.g., DPDK, LMAX Disruptor, Linux `io_uring`, Meta's Folly queue) in the great majority of workloads.

To support modern architectures such as Armv8.1, we verified and optimized BBQ with a model checker for weak memory models. Even though far from sound, verification with model checkers has proven a valuable, low-cost method of catching bugs.

Currently, our `io_uring` benchmark evaluates whether BBQ is promising for such scenarios without involving kernel details. In the future, we plan to port BBQ to kernel space to replace Linux `io_uring`.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their insightful comments. We specially thank Bohdan Trach for the helpful discussions and for proofreading this manuscript.

Sibylla: To Retry or Not To Retry on Deep Learning Job Failure

Taeyoon Kim, Suyeon Jeong, Jongseop Lee, Soobee Lee, and Myeongjae Jeon
UNIST

Abstract

GPUs are highly contended resources in shared clusters for deep learning (DL) training. However, our analysis with a real-world trace reveals that a non-negligible number of jobs running on the cluster undergo failures and are blindly retried by the job scheduler. Unfortunately, these job failures often repeat and waste GPU resources, limiting effective GPU utilization across the cluster. In this paper, we introduce Sibylla which informs whether an observed failure of DL training will repeat or not upon retry on the failure. Sibylla employs a machine learning model based on RNNs that trains on stdout and stderr logs of failed jobs and can continuously update the model on new log messages without hand-constructing labels for the new training samples. With Sibylla, the job scheduler is learning-enhanced, performing a retry for a failed job only when it is highly likely to succeed with the retry. We evaluate the effectiveness of Sibylla under a variety of scenarios using trace-driven simulations. Sibylla improves cluster utilization and reduces job completion time (JCT) by up to 15%.

1 Introduction

Deep learning (DL) has made tremendous advances in a wide range of tasks, including object detection [18], translation [32], and speech recognition [21]. To support the rapid development of DL models, enterprises typically set up a large cluster of hardware accelerators, preferably GPUs, and build a management stack to facilitate the fine-grained sharing of large-scale hardware resources. DL training often requires the use of multiple GPUs and that tasks on the allocated GPUs be scheduled simultaneously [16]. This requirement of gang-scheduling poses high communication and locality constraints on cluster management, which are less contemplated in traditional data analytics setups. In the last decade, a number of new DL cluster designs have been proposed, aiming to optimize job scheduling [5, 20, 24, 26, 34, 35], network communication [10, 16], and back-end storage systems [41], and have substantially improved cluster utilization.

In comparison, little effort has been made to address wasteful re-execution, resulting from framework support for reliable DL training. When users issue training jobs to the cluster, they wish to have their training jobs completed successfully with a high probability. The high success rate is primarily related to how effectively DL frameworks can handle job failures rooted in errors at runtime. These errors are known to occur across the stack, including infrastructure, AI engine, and user program [16, 38].

To continue training upon failure, the cluster manager can take periodic checkpoints for model weights and retry execution from the most recent checkpoint taken prior to the failure [16]. If the failure is transient and *non-deterministic* (e.g., MPI runtime failure), the job will continue training upon resuming from the checkpoint, as transient issues are not supposed to repeat [16]. However, this approach does not help recover from *deterministic* failures (e.g., syntax or configuration errors), as the same faulty condition will recur while re-running the failed job. DL training that experiences these two types of failures implies that retrying job executions on deterministic failures would waste GPU cycles. Our characterization study shows that the resource inefficiency caused by the unnecessary retries is non-negligible (§ 2).

Our approach. We introduce a case for *learning-enhanced* job scheduling that substantially reduces unnecessary job retries. Our system, Sibylla, *predicts* whether a failed job deserves a retry or not. Since failures can occur anywhere across the stack, the prerequisite for failure prediction with high accuracy is to collect a training dataset that faithfully reflects failure-related information. We use standard error streams of training jobs directed into log files (i.e., stdout and stderr) – every software stack makes use of these error streams to record execution path/status- and error-related information. Sibylla employs a recurrent neural network (RNN)-based DL model to train the log files and build a failure classifier. Sibylla further automates the process by adopting auto-labeling that allows new training samples to be incorporated without hand-constructing their labels. With this technique, Sibylla can automatically update the model upon aggregating new log

messages from recently completed jobs without access to human experts for labeling data (§ 3).

One major contribution of Sibylla is that it avoids using a static way for failure classification, which would be impractical in the long run. For example, as log formats are unstructured and diverse, grepping log files for specific keywords that are endemic to deterministic/non-deterministic failures, as done in [16], requires someone to keep identifying new error-related expressions, which is too manual and time-consuming. We even tried a clustering model as a non-DL approach to automatically group failures and classify their types based on similar words, but the accuracy is much lower than our DL-based approach (§ 4).

Results. We evaluate Sibylla through simulations [10] using traces derived from a Microsoft production cluster [2]. We account for the effectiveness in both the best case and the worst case, where avoiding retries on deterministic failures guided by our predictor is associated with the longest-running jobs and the shortest-running jobs, respectively. Sibylla reduces the average job completion time (JCT) by 6.5–15.4% for the best case and 3.6–10.5% for the worst case.

2 Job Failures in Deep Learning Cluster

DL platform overview. A shared cluster for deep learning training typically consists of a number of multi-GPU machines that constitute a pool of hundreds to thousands of GPUs. The GPU machines are connected to a high-speed network (e.g., 100-Gbps InfiniBand) to speed up distributed training that requires multiple GPUs. The cluster scheduler has an objective to decide the jobs to run next (e.g., minimizing JCT) and a strategy for placing the jobs on available GPUs (e.g., preferably onto the same machine). Docker container is used to isolate CPU, GPU, and memory resources between concurrent jobs. For distributed training, we are based off data parallelism that performs model synchronization via either parameter servers or collective communication libraries (e.g., MPI [7], NCCL [25]). A back-end distributed storage system is dedicated to storing stdout and stderr logs generated during training across the entire cluster. Target DL applications are run on popular engines like TensorFlow [3] and PyTorch [27].

Deterministic vs non-deterministic. Failures come from the job scheduler, the storage system, and other components that constitute the DL platform. We categorize failure occurrences into either deterministic (DT) or non-deterministic (NDT) to determine retry on failure. Table 1 shows how existing DL job failures [16, 38] can be classified into these two categories according to failure reasons.

Deterministic failures (or *DT failures*) are caused by inherent code syntax errors, API misuse, misconfigured settings, etc. For example, a job may try to load non-existent data, data in an inconsistent format, or data in corruption. Alternatively, a job may use a library version that the platform does not

Type	Category	Failure Reason Examples
DT	Deep Learning Specific	Framework API Misuse, Tensor Mismatch
	Environment Error	Path/Library Not Found, Permission Denied
	Code Error	Key/Attribute Not Found, Illegal Arguments
	Data Error	Corrupted Data, Unsupported Encoding
NDT	CPU OOM	CPU Out of Memory
	GPU OOM	GPU Out of Memory
	Runtime Error	MPI Daemon Failure, Network Conn. Failure
	Node Error	Unexpected Worker Node Exited

Table 1: Failure classification and failure reason examples.

support or has dependency issues. Jobs experiencing these failures will end up in unsuccessful training as the failures repeat.

On the contrary, *non-deterministic failures* (or *NDT failures*) are accidental and usually related to temporal network connection loss or transient issues of the job’s assigned node. For example, workers of a distributed training job may not communicate with each other due to network outages or MPI daemon errors on the host machine. Or, a job may use host memory more than allowed and want to be scheduled on a larger machine. Retry from failure helps overcome this type of failure.

Failure handling today. Due to the intricate process of failure classification, job schedulers today are utterly ignorant of the type of failure that occurred and takes simple heuristics for failure handling. Failed jobs in Microsoft Philly [16] are retried a fixed number of times to overcome NDT failures and successfully complete more jobs after retries. To facilitate this, in Philly each job is configured to create a model checkpoint after finishing a certain number of epochs. On the other hand, NoRetry¹ in a large enterprise terminates every job that experiences a failure to avoid worthless re-execution of jobs in DT failure.

However, these approaches face significant challenges that limit their merits: (1) Philly cannot prevent GPU cycles wasted by DT failures; (2) NoRetry cannot achieve as good training productivity as Philly because it terminates all NDT failure jobs that deserve retries for successful training. In addition, the retry mechanism in NoRetry greatly obfuscates our understanding of the reasons behind failures between DT and NDT, affecting user experience.

A DT failure repeats regardless of how the scheduler places the job on GPUs, whereas an NDT failure may not repeat after a new scheduling attempt. Therefore, we also call them repetitive failure versus non-repetitive failure. Although some jobs terminate quickly during DT failures, there are DT failures that take a fairly long time for the failures to be manifested (e.g., incorrect data inputs).

Opportunities. In this paper, we propose a failure classifier using machine learning to separate deterministic and non-deterministic failures at runtime. To reveal opportunities for using it for predictive retry, we conduct workload character-

¹Anonymized upon request by the company.

Figure 1: Job retry rates and the fraction of GPU hours spent during retries for DT and NDT over different job sizes.

ization using an openly available Philly trace [2]. The trace contains information about each training job, including each attempt of job scheduling, GPUs allocated for the attempt, the start and end time of job execution during the attempt, and the job’s final completion status. As a scheduling attempt occurs in both the initial job issue and subsequent retries on failures, using the trace we can estimate job retry rates (i.e., # jobs experiencing retry ÷ # all jobs) and the fraction of GPU hours spent during retries out of all GPU hours. Figure 1 shows the results for two failure types, DT and NDT, over different job sizes based on the GPU request distribution.

First, in Figure 1(a), we observe that jobs are frequently exposed to DT failures and thus waste a significant portion of GPU hours due to useless retries. Specifically, jobs that use more GPUs retry execution more often while GPU hours consumed during retries account for 12.3–19.9% across job sizes. This is the amount of GPU hours wasted by Philly, yet can be saved by an optimal predictive retry. Moreover, as previously stated, DT failures could exhibit high run times to failure (RTF). In particular, for failed executions, the median RTF is 614 and 2,458 seconds for DT and NDT, respectively, with the 80th-percentile increasing to 6,037 seconds for DT and 34,133 seconds for NDT.

NoRetry does not waste these GPU cycles at all since no retry occurs. However, Figure 1(b) implies that the training success rate in NoRetry will go down by around 4.5% since all NDT failure jobs are doomed to be aborted. To circumvent NDT failure, users will need to resubmit those jobs to the cluster and restart training from the initial state. Such restarting indicates that the GPU hours spent in the previous job executions before the failures become wasteful.

Based on the observations, we believe cluster utilization and reliability of DL platforms can be enhanced by performing job retry only when predicted as non-repetitive, guided by a failure classifier. The idea of adapting job retry based on failure type is not new but instead has been presented merely as a design implication [16, 28, 38]. To the best of our knowledge, our work is the first to evaluate its feasibility.

3 Sibylla Design

Sibylla is an RNN-based prediction system that has the following design goals.

- **High accuracy.** Sibylla should achieve high prediction accuracy for both types of failures. Otherwise, mispredictions can lead to low cluster efficiency or low training success rates.
- **Ease of use.** It is cumbersome to build a new training dataset every time new failure samples are generated. Once a prediction model is built, Sibylla provides an option to label new failure samples and re-train the model automatically.
- **Ease of integration.** Sibylla operates in a stand-alone agent or runs on the application side (e.g., Application Master in Apache YARN) to interact with the scheduler. The scheduler only needs to send a prediction input to Sibylla and get notified with the output (DT or NDT). Sibylla does not interfere with the scheduler’s main tasks, such as job placement.

Samples for training. We use stdout and stderr log messages to train Sibylla. These logs record the execution information of the software stack and have been widely used in anomaly detection and distributed system or software troubleshooting scenarios [13, 19, 29, 36]. Similarly, every software stack in the DL cluster records execution- and error-related information in standard error streams. So, stdout and stderr logs are our choice of training data in Sibylla. However, using messages in the log poses a critical challenge: log messages are unstructured and contain many redundant and uninteresting lines of text to exclude.

Training workflow. Figure 2 illustrates the workflow of Sibylla. It first performs data preprocessing to extract useful log sequences and convert them into semantic vectors. Then, our RNN-based models are trained with these vectorized inputs. Sibylla includes an additional auto-labeling stage based on a reliable ensemble method to learn new incoming data.

Step 1) Data preprocessing. Because the log file size is typically non-uniform, it is necessary to transform each original log to be uniformly sized. A log often indicate failure symptoms at the line with relevant keywords (such as failure, error, etc). With this insight, Sibylla takes up to 5 lines after the line where such a keyword is present. Sibylla also includes some lines preceding the keyword as they may indicate a log sub-sequence that leads to failure. We empirically tested a variety of line lengths and landed on 20 lines because this is overall the minimum number of lines producing the highest prediction accuracies. On not observing the failure keyword,

Figure 2: Overall architecture of Sibylla.

Sibylla takes the last 20 lines from the log file as an input for further preprocessing.

Since the log is in an unstructured plain-text form, we need *parsing* and *vectorization* stages to extract semantic information, as shown in Figure 3. At the parsing stage, each log is categorized into a structured *template* that primarily removes words unrelated to the semantics, such as non-character words and stop words. The structured template is thus informative enough to represent the original text. Sibylla applies the state-of-the-art parsing tool called Drain [12], which has been widely exploited in prior log-based analysis studies for its superior effectiveness [11, 22, 37, 39]. A structured text template is transformed into a *semantic vector* and fed into the training model. This vectorization process first digitizes each word into a vector. It then accumulates all word vectors of each line in the template into a single semantic vector entry by weighing each word based on TF-IDF (term frequency-inverse document frequency) score. Sibylla uses the FastText algorithm [17] to extract a semantic information across the log.

Step 2) Model training. The semantic vector sequences serve as an input to model training. There are two representative RNN models involved in training Sibylla: bi-directional long short-term memory (LSTM) and attention-based gated recurrent unit (GRU).

Training a log-based detection model can be supervised, unsupervised, or semi-supervised. Supervised learning ensures that the model achieves high performance, but this approach necessitates all data to be labeled ahead of time. However, cluster job executions generate a significant amount of log data, making it infeasible to have domain experts label all DT and NDT failure samples for supervised learning. Instead, unsupervised learning can proceed with fully unlabeled data but usually sacrifices model performance. Sibylla adopts semi-supervised learning. It starts model training with partially labeled data and keeps updating the model with unlabeled data by auto-labeling them in an online fashion.

Automatic sample labeling. For auto-labeling to be effective, the classifier is required to make a robust decision. In other words, the classifier should make good decisions even for

Figure 3: Data preprocessing steps in Sibylla.

unseen data that may confuse the classifier. Sibylla automates the labeling process by allowing the classifier to leverage the prediction results of multiple RNN models with different architectures. It takes advantage of an ensemble method that performs voting on the prediction results to decide the failure type, mitigating the effect of a single wrong prediction. Specifically, Sibylla trains K RNN models independently ($K = 2$ in our default setup) and makes a classification decision by aggregating information from individual models regarding the predicted failure type. The final decision is made through a majority voting mechanism, where each model has an equal weight of reflecting its decision on DT versus NDT.

Integrating into cluster managers. There are two tasks to be done by cluster managers to use Sibylla. First, when a failure of a DL job occurs with a stdout/stderr log containing an error, the cluster manager transmits it to Sibylla and receives the notification of the expected failure type. Second, the cluster manager delivers a batch of log files with labels to build an initial model or files without labels to improve the model on observing new failures. Note that our main focus in this paper is on presenting the design principle of predictive retry. Nonetheless, we believe Sibylla can be imported into commodity GPU cluster managers without significant hurdles.

4 Evaluation

We present Sibylla’s accuracy (§ 4.1) and JCT improvements using a GPU cluster simulator with Philly trace (§ 4.2).

Dataset. Since no dataset for failed DL jobs is publicly released, we construct one that contains most of the known failures. We obtained 97 failure log files from the company operating NoRetry and collected additional 159 failure messages through a manual search on Stack Overflow [1], including 20 out of 21 failure categories (w/o GPU ECC error) presented in [16]. We then apply data augmentation to enlarge a training dataset while retaining key properties of the data. For our scenario, two popular text augmentation methods, WordNet [23] and Word2Vec [9], are used to replace words in an original log file with cognitive synonyms and create a new augmented

Figure 4: Precision and recall for NDT over training rounds.

file. As a result, we have 4468 log files as a dataset.

Although NDT failures are fewer in number than DT failures in reality, our dataset is augmented such that samples are balanced between DT and NDT and across failure categories [38]. This sample balancing is mainly to make the decision boundary of the model not biased [4, 6, 30, 31, 33]. Further, DL applications appearing in the data are diverse, e.g., image classification, language model, and audio recognition, and run on popular engines like TensorFlow and PyTorch.

Accuracy metrics. For DT/NDT, classifier accuracy is measured using *precision* (fraction of predictions that are truly deterministic/non-deterministic failures) and *recall* (fraction of true deterministic/non-deterministic failures predicted correctly by the classifier). Thus, for both precision and recall, higher is better.

4.1 Classifier Performance

Accuracy		Clustering	RNN Model		Sibylla	Oracle
			LSTM	GRU		
NDT	Precision	89.72	94.78	96.92	97.36	98.66
	Recall	85.71	97.32	98.21	98.66	98.66
DT	Precision	86.67	97.32	98.24	98.68	98.70
	Recall	90.43	94.78	96.96	97.39	98.70

Table 2: Final accuracy among competing classifier designs.

Experiment process. We assess the effectiveness of Sibylla over training on multiple insertions of new log data. For this evaluation, we split the dataset into ten partitions $\{p_1, p_2, \dots, p_{10}\}$ and go through eight rounds of training $\{R_1, R_2, \dots, R_8\}$. Each round has training, validation, and test data, where training and validation data are used for model training, while test data is used to report prediction accuracy (i.e., precision and recall). As the round moves on, Sibylla auto-labels the previous test data and uses it as new validation data. To illustrate, in the first round (R_1), we use p_1 , p_2 , and p_3 as training, validation, and test data, respectively. With proceeding to R_2 , the next unused partition (p_4) becomes new test data, while training and validation data are reorganized into $p_1 + p_2$ and p_3 , respectively. Here, p_3 is auto-labeled by Sibylla. Continuing this process will report accuracy incrementally over eight rounds of training.

Results. We compare Sibylla using the proposed ensemble classifier with other classifier designs based on a single NN model (LSTM and GRU) and a non-NN model (Clustering). Currently, our ensemble model is created by combining two models, LSTM and GRU. Since these classifiers serve as auto-labeling, as a baseline we include an oracle method in which all data used for model training are labeled 100% correctly. Table 2 shows the prediction accuracy of all competing classifiers observed in the final round of the incremental training (i.e., R_8) for both DT and NDT. The results show that as compared to the clustering method, NN-based classifiers achieve overall higher accuracy for predicting both DT and NDT. Among NN-based classifiers, Sibylla obtains the highest accuracy while approaching the closest to the oracle’s performance.

In Figure 4, we show how the prediction accuracy for NDT changes during the incremental training – DT has similar trends. Our ensemble approach provides prediction with consistently higher precision over training rounds, with Clustering significantly worse than others as expected. For recall, there is no substantial difference among NN-based methods. As higher precision and recall are always desirable, we prefer an ensemble approach over approaches using a single model for classification and auto-labeling.

4.2 Simulation Results

Setup. Next, we evaluate our predictive retry while replaying the Philly trace on the GPU cluster simulator designed for prior work [10]. We use three job scheduling policies, smallest-job-first w.r.t. GPU requirement (SJF), 2D-LAS (DLAS), and 2D-Gittins index (GITTINS) [10], to schedule jobs in the trace. The cluster comprises 200 nodes, each having 8 GPUs, 256 GB of host memory, and 64 CPU cores.

As the trace mainly contains information about each job’s retry and final status without its log messages, we choose to apply our classifier created from our dataset (with the prediction accuracy in Table 2) considering the worst (**Worst**), average (**Average**), and best case (**Best**). For Worst and Best, we apply misprediction to the longest-running and shortest-running jobs, respectively – so, the penalty of misprediction is the highest versus the lowest. For Average, we select the jobs experiencing misprediction randomly. We have two baselines

Figure 5: JCT reductions for using different schedulers.

to compare with Sibylla: **Oracle**, which makes 100% correct predictions, and **Full-Retry**, which retries jobs without prediction as done in Philly. For a fair comparison, we take into account the average JCT (including the queuing time) of successfully completed jobs only.

As Figure 5 shows, all adaptive retry strategies can reduce the average JCT compared to the conventional method, Full-Retry. Best improves the JCT by 15.4% for SJF, 6.5% for DLAS, and 6.5% for GITTINS, and even Worst reduces the JCT by 3.6–10.5%. Moreover, strategies based on Sibylla (i.e., Best, Average, and Worst) are, on average, only 1.3% worse than Oracle, which delivers the most JCT reduction. With high accuracies, Sibylla has a negligible impact on the job success rate resulting from mispredicting NDT as DT. Our recall for predicting NDT is 98.66%, lowering the job success rate by only 0.06% from 75.04%.

5 Related Work

Machine learning-based anomaly detection. Prior work studies using machine learning on textual log data obtained from various systems such as HDFS (Hadoop Distributed File System) and BGL (BlueGene/L) [14] to detect abnormal and anomalous system behaviors. DeepLog [8] adopts an LSTM model [15] for anomaly detection and diagnosis. It first trains the model on normal log messages to learn their sequences and uses the model to recognize abnormal sequences from online log data for anomaly detection. LogAnomaly [22] concatenates log sequences as a template to extract more precise log semantics and applies the anomaly detection method similar to DeepLog. LogRobust [39] leverages existing learned word collections such as Word2Vec [9] to analyze various unstructured logs and measures abnormal logs using Attention-based Bidirectional LSTM [40]. PLELog [37] proposes semi-supervised learning based on probabilistic label estimation to make the sample labeling process more practical.

These strategies aim to detect abnormalities in large-scale system logs through deep learning. Despite similarities, our work is differentiated in that it focuses on predicting repetitive DL job failures and assessing how such capability helps improve job completion times in shared GPU clusters.

DL job failure analysis. Our work is motivated by numer-

ous works that reveal the cluster inefficiency caused by DL job failures [16, 38]. These works analyze logs for program failures of industrial jobs from Microsoft Philly, whose public scheduler log is used for our study. They investigate the categories and root causes of job failures, suggesting that current practices of failure handling in DL platforms can be enhanced. Although they are the first to stress the necessity of an adaptive retry mechanism driven by the failure type, no prior work has faithfully evaluated its feasibility.

6 Concluding Remarks

To deal with DL job failures, it is critical to precisely predict whether the current failure will repeat or not upon re-execution. Our RNN-based predictor, Sibylla, correctly informs this repetition potential, enabling the cluster scheduler to incorporate it to perform an adaptive retry on failure. With Sibylla, today’s DL platforms not only reduce resource waste by avoiding retries for repetitive failures but also retain job productivity by continuing job executions for transient failures. We confirm this efficacy with trace-driven simulations.

Future works. Misprediction for deterministic failure may repeat when a job produces similar messages over retries. To avoid this repetitive misprediction, we could revise the classifier to incorporate the feedback about predictive re-execution from the cluster scheduler.

Another interesting future work is extending our method for new failure types that have not occurred. An assumption we made in the design of Sibylla is that a new type of failure with unseen semantics does not appear. However, failure message formats from online logs could be diverse as developers’ message logging practice is personalized and unstructured. We have done a brief study on how destructive unknown failure types are by measuring accuracy when a new failure type appears in the middle (7th round) of training from Figure 4. It turns out that the classification accuracy of Sibylla for deterministic failure can drop to 40%, especially for precision. Thus, we may need to incorporate human experts for labeling new data in low prediction confidence rather than relying on auto-labeling. Nonetheless, we think the chance of observing new types of failures is somewhat low.

Speculative Recovery: Cheap, Highly Available Fault Tolerance with Disaggregated Storage

Nanqinqin Li, Anja Kalaba, Michael J. Freedman, Wyatt Lloyd, and Amit Levy
Princeton University

Abstract

The ubiquity of disaggregated storage in cloud computing has led to a nascent technique for fault tolerance: instead of utilizing application-level replication, newly-launched backup instances recover application state from disaggregated storage (REDS) after a primary's failure. Attractively, REDS provides fault tolerance at a much lower cost than traditional replication schemes, wherein at least two instances are running. Failover in REDS is slow, however, because it sequentially first detects primary failure and only then starts recovery on a backup.

We propose *speculative recovery* to accelerate failover and thus increase the availability of applications using REDS. Instead of proceeding with failover sequentially, speculative recovery safely and efficiently parallelizes detecting primary failure and running recovery on a backup, by employing our new `super` and `collapse` primitives for disaggregated storage. Our implementation and evaluation of speculative recovery demonstrate that it considerably reduces failover time.

1 Introduction

Replicated, network-attached storage devices have all but replaced local disks in cloud settings. Such *disaggregated disks* provide a host of useful features, including scalable storage capacity and performance, convenient data backup, and disk fault-resilience [16, 33, 49].

Their ubiquity has led developers to begin leveraging *disk* fault-tolerance to achieve *application* fault-tolerance [12, 15, 50]. When an application running on one instance, the primary, uses a disaggregated disk, its state survives its failure. This enables an emerging fault-tolerance technique we term *recovery from disaggregated storage* (REDS) where a backup instance recovers application state from the disaggregated disk and continues serving the application. In general, single-node applications can use REDS unmodified as long as they are crash-consistent—i.e. they persist state updates to disk before *externalizing* them to clients and are able to recover state from disk after a crash [27, 39, 58]. This includes most relational databases, local key-value stores, and file systems.

REDS is an alternative to the traditional *application-level replication*, where the application running on the primary con-

tinuously replicates its state to at least one backup [20, 22, 24, 42, 44, 56, 62, 66]. Application-level replication provides *high availability* since it ensures that a backup can service requests immediately should the primary fail. However, application-level replication is also expensive as each backup runs an entire instance of the application, requiring as much CPU, memory, storage, network resources, etc., as the primary.

In contrast, REDS only requires running a single instance of the application at a time but sacrifices availability since failover can be slow. In particular, REDS requires that the disaggregated disk be detached from a potentially faulty instance *before* initiating recovery on a new one. As a result, REDS risks long recovery periods on the new instance when the original may have come back online faster, e.g., when a transient networking issue resolves itself, or waiting too long to determine the original instance has indeed failed.

In this paper, we introduce *speculative recovery*, an application fault-tolerance technique that leverages disaggregated disks to achieve resource efficiency similar to REDS with significantly higher availability. Speculative recovery begins as soon as the primary *appears* unavailable, e.g., when it stops responding to health checks. It immediately begins recovery on a new backup instance by creating an independent clone of the disk and attaching it to the backup, while the primary instance is not interfered with to allow it an opportunity to come back in parallel. Whichever instance, the primary or the backup, becomes available first serves the application while the other is deallocated. This reduces unavailability to the minimum of either the primary becoming available again or the backup's speculative recovery completing.

There are two major challenges in realizing speculative recovery on existing disaggregated storage systems. The first is ensuring application correctness, i.e., linearizability [37], when both the primary and the backup are using a clone of the same application disk. This requires that updates to the disk from one instance do not interfere with the other, and that the external world only ever sees the effects of updates from one instance. The second challenge is ensuring good disk performance for the backup instance to recover the application. Many existing disaggregated storage systems have designs for disk clones that provide poor performance.

To address these challenges, speculative recovery introduces new primitives, `super` and `collapse`, for disaggregated disks. `super` allows a disk to be in a *superposition* temporarily where two independent versions of the disk are allowed to diverge until a `collapse` when one is observed, and it appears as though the other never existed. In essence, `super` provides disk clones with isolation and good performance, and `collapse` guarantees correctness by ensuring only one, primary or backup, of the clones can be observed.

`super` uses copy-on-write to achieve effective isolation, and the ephemeral nature of superposition enables a new design we term *collocated-clone* that minimizes the negative performance impact of copy-on-write. With *collocated-clone*, a disk clone directly refers to its parent's allocation table to locate data blocks, eliminating the overhead of re-populating the clone's own allocation table, which is a major bottleneck in some existing disaggregated storage systems. *Collocated-clone* also adopts a minimal data path by keeping all data blocks of a clone on the same storage shards as the corresponding blocks of its parent. We believe that such collocation does not skew the data distribution of a storage cluster given that only one clone continues after `collapse`.

`collapse` uses a *dirty bit* to ensure only one clone of the disk is ever externally observable. The dirty bit reflects whether there have been any updates to the disk from the primary after `super` is invoked. If so, `collapse` determines that the primary may have been observed and then aborts speculative recovery by deallocating the disk clone and the backup. Otherwise, `collapse` ensures no future writes from the primary will be accepted and then informs the backup that it can start externalizing state updates.

We implement `super` and `collapse` based on Ceph [68], an open-source distributed storage system, and use them to implement speculative recovery from disaggregated storage (SpecREDS). Our evaluation compares SpecREDS to REDS for three stateful applications: MySQL, PostgreSQL, and MariaDB. We find that our *collocated-clone* design achieves near-normal disk performance that supports application recovery up to an order of magnitude faster compared to Ceph's native clone design. Such improvement enables SpecREDS to achieve significantly faster failover in some scenarios.

In summary, the main contributions of this paper include:

- Speculative recovery, which increases the availability of applications that achieve cheap fault tolerance using REDS.
- The `super` and `collapse` primitives and their designs including *collocated-clone* for disk cloning with near-normal performance and the dirty bit for guaranteeing correctness.

2 Highly Available Applications

Stateful data center applications strive to provide high availability in the face of individual machine failures. This is often

exacerbated on the cloud because developers may have no way to recover data from a virtual machine's or a container's disk after a failure. Practitioners today adopt both traditional fault-tolerance techniques at the application-level as well as cloud-native techniques that rely on disaggregated storage.

2.1 Application-level Replication

A standard approach to highly available fault tolerance for stateful applications is to replicate the application across multiple compute instances (physical machines, VMs, containers, etc.). Commonly, applications use primary-backup replication where a primary instance handles all client requests and forwards the execution logs to backup instances. If the primary fails, backups are ready to be promoted with minimal overhead since their local state is already up-to-date.

However, application-level replication has two major drawbacks. First, it can be costly. Because backups require redundant compute resources—CPU, memory, etc.—adding a backup costs as much as hosting the original application. Second, support for application-level replication is often implemented separately for each application [53, 56]. While many stateful applications support replication, including MySQL, PostgreSQL, and MongoDB, many do not, including SQLite, LevelDB, and RocksDB.

2.2 Recovery From Disaggregated Storage

Two recent trends have enabled alternative fault-tolerance strategies. First, cloud platforms have adopted disaggregated storage [28, 41, 45, 52] to provide virtual block devices to enable more efficient resource management and provide more reliable services [16, 33, 49]. Data stored on these disaggregated disks is striped and replicated across a storage area network to provide highly available and highly durable block devices that can outlast failures of the compute instances they are attached to. Second, provisioning compute instances (VMs or containers) has become fast—new compute instances can be spawned in seconds rather than in minutes [2, 5, 13, 47].

As a result, practitioners have adopted an alternative fault-tolerance mechanism, REDS, leveraging disaggregated disks and fast provisioning [12, 15, 50]. In REDS (Figure 1), instead of maintaining live backup replicas of the application, a backup instance is only spawned after the primary instance is presumed down. The disaggregated disk is then moved from the failing primary to the new backup and the application is restarted on the backup. Since the application data stored on disk persist through machine failures, the backup can recover the application to a consistent pre-failure point.

REDS provides fault tolerance to stateful applications at virtually no additional cost, since only a single instance is provisioned most of the time, with at most a short overlap of a primary and backup instance during failures. Moreover,

Figure 1: **REDS vs speculative recovery.** REDS sequentially times out the unresponsiveness and restarts the application on a new instance by moving over the application disk, whereas speculative recovery parallelizes the two instances.

unlike application-level replication, it does not require explicit support from the application and can thus support any crash-consistent [27, 39, 58] application—i.e., any application that persists state changes before externalizing them and can recover to a consistent state from disk following a crash failure. This includes most relational databases, local key-value stores, and file systems.

2.2.1 Lower Application Availability

Compared to application-level replication, REDS suffers from lower availability due to the relatively long process of restarting the application after failure has occurred.

As shown in Figure 1, the failover process in REDS includes two steps: (1) determining whether the primary instance has failed and (2) recovering the application on a backup instance. Step 1, the timeout phase, is typically achieved using a timeout of unresponsiveness for the primary to avoid spurious downtime during Step 2. Step 2 recovers the application by spawning a new instance as the backup, moving over the application disk, and restarting the application.

These steps *must* happen sequentially since both require exclusive access to the disk. For the timeout phase, the primary needs the disk attached in case it becomes responsive again. For the recovery phase, the backup needs the disk to restart the application. As a result, downtime following a failure is dictated by the sum of the timeout and the recovery phase.

Clearly, short recovery and short timeouts would improve availability. Much of recovery—spawning a new virtual machine or container and attaching a disaggregated disk to these instances—is relatively fast and becoming faster in modern data center infrastructure. For example, an AWS EC2 virtual machine can be allocated and spawned in a few seconds with optimized operating system distributions [57], while

containers as well as other cloud virtualization techniques can allocate runtime environments an order of magnitude faster [13, 47]. Similarly, disaggregated disks, such as a Ceph block device, can be attached to a new virtual machine or container in a few hundred milliseconds.

Application recovery time, on the other hand, is less predictable—the same application might require a few seconds or several minutes to recover depending on, e.g., the state of the application’s write-ahead-log. As a result, very short timeouts risk triggering such long recoveries unnecessarily when the primary’s unresponsiveness is ephemeral (e.g. the monitor is faulty, a packet is lost, etc.). For instance, if a temporary network problem leads to 6 seconds of unavailability for the primary, using a short 5 second timeout to trigger a 1 minute recovery leads to 65 seconds of unavailability. In contrast, a longer timeout would have only 6 seconds of unavailability in this scenario. In practice, “primary-is-failed” timeouts are often quite long—for example, Kubernetes uses a default 5 minute timeout to detect node failure [43].

3 Introducing Speculative Recovery

REDS can result in poor availability because the primary must be marked irreversibly failed before recovery can be attempted on a backup. Timeout lengths are chosen conservatively to avoid long recoveries if the failure is temporary, and recovery cannot begin until *after* this timeout is expired. In the worst case, this results in downtime during a long timeout followed by more downtime until a long recovery completes.

This is fundamental to REDS because there is no way to predict the future. When downtime is detected, we do not yet know if the primary has actually failed, if the failure can self-heal quickly, or if a failed health-check was actually due to temporary network issues or a faulty monitor, etc. We also cannot know how long it would take for a backup to be ready to process requests from clients—depending on the disk state when the primary failed, it could be seconds or minutes.

But suppose an *oracle* did know, at the moment of apparent failure, how long recovery would take on a backup as well as how long the primary’s apparent failure would last. Such an oracle could achieve considerably better availability by avoiding timeouts completely while avoiding a slow recovery when the primary’s failure is temporary. In particular, the oracle’s optimal decision would be to choose the shorter of waiting for the primary to self-heal or immediately beginning recovery on a backup without waiting.

We propose a new failover design, *speculative recovery*, that makes similarly optimal choices *in practice*, without knowing the future. Speculative recovery pursues both paths (Figure 1) in parallel and either aborts recovery if the primary becomes available first, or irreversibly marks the primary failed if recovery completes first.

To accomplish this, speculative recovery creates and attaches an independent clone of the primary’s disk to a new

backup instance immediately when primary downtime is detected. The backup begins recovery from the cloned disk, potentially in parallel with the primary’s continued operation if it is not actually failed. This results in a “superposition” where the parent and child disks are permitted to temporarily diverge, as long as neither is observed externally. Once one of them is observed (i.e., if the primary becomes available or when clients are redirected to a fully recovered backup), the superposition collapses and the unobserved disk is destroyed. Specifically, this superposition state collapses in two cases:

- **Observing the primary.** If any *writes* to the parent disk are observed, the primary is assumed to be available and the superposition is collapsed by aborting recovery on the backup and deallocating the child disk.
- **Observing the backup.** If recovery on the backup completes successfully and no writes have been issued to the parent disk, the superposition is collapsed by deallocating the parent disk, destroying the primary, and promoting the backup to be the new primary by pointing all clients to it.

Thus, speculative recovery on the backup can complete though the primary *may* still be operational, while guaranteeing external correctness. As long as the application is crash-consistent, observing clients cannot distinguish between speculative recovery and REDS, except that failover may appear much faster. If a client receives an acknowledgement from the primary for a request that modifies application state, crash consistency mandates that the primary must have written to the disk, which would halt failover to the backup, in turn ensuring the backup is never observable.

Conversely, if a client is directed to communicate with the backup, the primary cannot have acknowledged any state-modifying operations or is no longer servicing client requests, and thus the backup’s state is consistent with all previous reads from the primary.

To realize these important properties, speculative recovery introduces two new disaggregated storage primitives: `super` and `collapse`. `super` produces a temporal, performant disk clone using copy-on-write (COW) semantics, resulting in a superposition in which the parent disk (attached to the primary) and the child disk (attached to the backup) diverge from the same state. `collapse` destroys the parent disk if and only if it has not changed since `super`, otherwise it destroys the, yet unobserved, child disk.

It is critical that disk clones spawned by `super` are fast to create and performant, so as not to slow down recovery on the backup significantly. `super` uses a new form of COW disk, *collocated-clone*, that improves COW writes over existing designs by up to an order of magnitude and performs almost as well as a regular, non-COW disk. Similarly, `collapse` must operate atomically—it must determine whether any writes have been made to the parent disk *and* block future writes if

not, atomically—but should also not unduly delay failover. `collapse` uses a single, global *dirty bit* for the entire parent disk to track whether writes have occurred in the superposition, allowing `collapse` to use a simple protocol with only a single round trip to one storage shard. In both cases, these designs are enabled by the temporal nature of the superposition.

4 Design

This section details our design for speculative recovery. It describes the system components, the design of `super`, the design of `collapse`, why and when speculative recovery is correct, and finally discusses some performance concerns.

4.1 Components and Overview

A speculative recovery system consists of three components: (1) an instance pool to host applications; (2) disaggregated storage that provides highly durable and highly available virtual disks to applications with the `super` and `collapse` primitives; (3) a failure monitor that monitors the health of the running application instances and coordinates speculative recovery for failed instances.

When the failure monitor presumes the primary instance is unhealthy, e.g., if the monitor fails to connect to the application, it initiates speculative recovery. It invokes `super` on the primary’s disaggregated disk which creates a lightweight clone using COW semantics (§4.2). In addition, `super` causes the parent disk to begin tracking writes to support the `collapse` protocol (§4.3). Next, the monitor spins up a new backup instance from the same application boot image as the primary, except with the cloned child disk attached in place of the parent. When the backup finishes restarting the application, the monitor calls `collapse`, which either atomically promotes the backup if there have been no writes to the parent disk or deallocates it if there have been writes.

4.2 `super`: Creating a Disk Superposition

As the backup instance boots and starts up the application, it may write to the child disk. For example, `fsck` might fix corruption in the file system and the application may replay and commit or rollback uncommitted transactions from its write-ahead log (WAL). Meanwhile, the primary is still allowed to function should it become available before recovery on the backup is complete. As a result, the parent and child disks are likely to diverge. However, this divergence retains application correctness because the backup is not observable to clients until after it is determined that the primary has not acknowledged any state-modifying requests.

This design is relatively simple to realize using existing primitives in disaggregated disks. In particular, many disaggregated disks provide copy-on-write clones that are quick to create. In principle, this should allow speculative recovery

Figure 2: **Concurrent writes on EBS.** Writes are issued simultaneously in batches of 1 write to 32 concurrent writes.

to explore both paths simultaneously—waiting out the unresponsiveness on the primary and recovering the application on the backup—and achieve the same outcome as an oracle. In addition, COW clones provide the child disk with the same level of durability guarantee as the parent since dirtied data blocks are copied as new blocks and thus can be applied the same replication schema (e.g., three-way replication).

Unfortunately, existing designs for COW disk clones perform very poorly for recovery workloads. We conducted black-box experiments on EBS to measure the I/O performance of EBS clones. EBS supports clones by first creating a snapshot from a volume and then creating a new volume from that snapshot. Figure 2 shows the write performance of EBS clones with varying levels of parallelism. Normally, concurrent writes on a regular EBS volume can exploit disk parallelism well (the green line): the average latency when 32 writes are in-flight is only 2.6x the latency of a single write. However, for a cloned EBS volume (the red line), this relation becomes 7x, indicating significant performance bottlenecks for a cloned volume under highly parallel writes.

To understand the underlying reasons, we instrumented the open-source Ceph codebase where a similar behavior exists: on a cloned disk, the average latency with 32 writes in-flight is 7.1x the latency of a single write (more results and details are described in §6.2). We discovered two fundamental problems with the Ceph clone implementation, and we speculate that these may be general to many other clone designs.

First, because disaggregated disks typically treat a clone’s dirtied blocks like any other new disk block, most COW designs copy dirtied blocks to different storage shards than the ones hosting the original blocks. This results in considerable overhead compared to modifying blocks in place. Second, each dirtied block requires allocating a new location in the storage area network, which is typically a blocking operation. As a result, concurrent writes that touch mostly newly dirtied blocks are performed in *sequence* rather than in parallel.

In short, copying dirty blocks to new locations over the network increases single write latency significantly, while serialized allocation eliminates most of the parallelism benefit for concurrent writes. These overheads are reasonable for typical uses of COW-cloned disks, where COW writes, and particularly concurrent writes, are infrequent [25]. How-

ever, a recovery workload is often write-intensive. As a result, these overheads can dramatically increase the time to recover applications—in some cases from seconds on a regular disaggregated disk to several minutes on a COW clone.

4.2.1 Collocated-Clone

super addresses both performance issues, copying overhead and serialization of COW writes, using a mechanism we term *collocated-clone*. Rather than treating copied dirty blocks the same as newly allocated blocks, *collocated-clone* reuses the parent’s allocation table to collocate child blocks with their corresponding parent blocks. This accomplishes two things. First, copying a dirtied block *never* traverses the network, as child blocks are always on the same shard as the parent blocks. Second, COW writes never require a blocking allocation operation as the parent’s allocation table already contains enough information to derive the child block’s location—specifically, it is always on the same shard as the parent’s and its name can be derived from the parent block’s name.

As a result, COW writes in *collocated-clone* require only marginally more work than normal writes. The dirtied block must be copied, but only locally—incurring local disk overhead, but not network overhead. Moreover, these writes *never* require a new block allocation, so concurrent writes are always just as parallelizable as on a regular, non-COW disk.

Collocated-clone is not suitable for many uses of COW-clones because it risks amplifying any skew in the original disk’s allocation. However, in speculative recovery, clones are temporary: after a short period of coexistence, it is either the child being deallocated or the child succeeding the parent and carrying on. Shards only need to have sufficient extra storage to store dirtied blocks temporarily.

In addition, *collocated-clone* only provides limited isolation between the parent and child. Because *collocated-clone* does not require the parent to do COW, the parent can directly update its data blocks in case it self-recovers. Thus, if the parent updates a data block the child has not copied, the child can see those updates, breaking the isolation. Again, this is permissible in the special semantics of *superposition* since if the parent is ever updated, the child will never be externalized.

4.3 collapse: Collapsing a Superposition

By allowing the parent and child disks to diverge in their *superposition*, speculative recovery introduces potential application inconsistency that must be hidden from clients. To prevent such inconsistencies, *collapse* uses a single disk-global dirty bit to indicate whether there have been writes applied to the parent disk since the creation of the child. It must also have a means of atomically promoting the backup instance to be the new primary, even with in-flight operations from the old primary.

Tracking primary writes. When `super` is invoked on a disk, its disk-global `dirty` and `allow-write` bits are initially set to false and true, respectively, on a fault-tolerant tracking shard in the storage cluster (this may simply be one of the data shards). When a shard of the parent disk receives a write request, before servicing the write, it requests permission to perform the write from the tracking shard. If the `allow-write` bit is true, the tracking shard sets the `dirty` bit and allows the shard to proceed with the write. Otherwise it responds that the shard should reject the write.

Atomic promotion. `collapse` operations are performed on the tracking shard. This shard atomically checks the `dirty` bit and, if it is still false, sets the `allow-write` bit to false, preventing any future write attempts to the parent disk. It then returns an acknowledgment that the parent disk is disabled and being deallocated. Otherwise, if the `dirty` bit is true, it responds that the parent disk has been observed, that the backup should be taken down, and begins asynchronously deallocating the child disk, aborting failover.

Tracking disk modification using a disk-global `dirty` bit allows `collapse` to complete quickly, as the only atomic operation is limited to a single node in the disaggregated storage cluster, avoiding expensive multi-node protocols such as two-phase commit. Such a tracking mechanism may be unnecessary and inappropriate for long-lived COW-clones that may have subsequent children and grandchildren. However, due to the ephemeral nature of the superposition, and because it is at most one clone of a disk at any given time, this design allows `collapse` to be supported efficiently.

After promotion of the backup is complete, the primary might still be able to service client reads from its in-memory cache, even though its disk has been deallocated by `collapse`. This would externalize potentially stale values. To prevent this, a stronger method is needed to sever the old primary from the clients. The specific mechanisms to achieve this may be cloud-platform dependent, but one option is to use an “elastic IP” [18] to remap the old primary’s IP address to the newly promoted primary, automatically rerouting clients. Other mechanisms such as using a firewall to block the primary’s access to the network would also work.

4.4 Correctness and the Failure Model

Speculative recovery ensures correctness, i.e., linearizability [37], by ensuring two properties. First, only one instance of an application is accessible to clients at any point in time. Second, if the backup is promoted and becomes accessible, its state begins from the previous primary’s last acknowledged changes and thus it looks like a continuation of the old primary. The first property is achieved trivially using atomic promotion. The second property is achieved using `super` and `collapse` in sequence for a crash-consistent application: a backup is only promoted by `collapse` if there have been no

writes since `super`, and thus the disk it recovers from must include the previous primary’s last acknowledged changes as required by crash consistency.

Our design of `collapse` uses writes to the primary’s disk as a signal of liveness to abort failover. This will correctly detect crash failures where the primary stops completely. However, it will not detect more nuanced kinds of failures such as partial failures or fail-slow failures. For example, even if the primary is disconnected from the clients, it may still write to disk for internal operations such as log rotation and garbage collection. This means that writes to the primary’s disk may not always reflect client-visible application state changes, and `collapse` would abort failover in these cases. In addition, fail-slow failures, where applications are slow but not inaccessible, can occur [26, 34, 40, 60]. In these failure situations, speculative recovery can be falsely and repeatedly aborted, causing an increased failover latency. In all these cases, speculative recovery should fall back to REDS by using a timeout to force failover when recovery is aborted repeatedly.

5 Implementation

We implemented a prototype speculative recovery system, SpecREDS, and deployed it on AWS EC2. The instance pool is implemented as a docker container pool on top of EC2 compute instances, where application images can be directly pulled from the docker registry. The failure monitor is implemented as a simple daemon process that pings the application instances with read-only queries to determine connectivity and health. As an independent component, the monitor also needs to be fault-tolerant. Many orchestration architectures provide fault-tolerant monitors such as those in EC2 Auto Scaling groups, Kubernetes, etc.

Our implementation of the disaggregated storage layer is based on Ceph [68], an open-source distributed storage system. On top of its backend object store called RADOS, Ceph provides highly durable and highly available block storage called `rbd` (Rados Block Device) that can remotely attach a `rbd` disk as a Linux block device through its kernel driver. SpecREDS focuses on the block interface due to its prevalent adoption on cloud and its simpler interface. We believe that the concept of speculative recovery can be applied to other cloud storage interfaces like network file systems [17] and object stores [19]. The implementation is based on Ceph release v16.2.4. The artifact of SpecREDS is publicly available. Please refer to the appendix for the artifact description.

Background on Ceph `rbd`. We give a short background on `rbd` necessary to understand our implementation. `rbd` also provides disk clone functionality: a disk snapshot is first taken, then a disk clone can be created from that snapshot. While clone creation is fast, `rbd`’s native clone implementation has the performance problems of copying over the network and serialized concurrent COW writes, as discussed in §4.2.

Figure 3: **Parent and child write path after `super`.** The parent and child disks are assigned ID P and C , respectively. Only the first parent write to shard Y performs steps 3 and 4.

`rbd` implements the functionality of an “allocation table” with two separate utilities. First, each `rbd` disk has an object map, a bit map indicating the *existence* of the disk’s data objects. A COW write needs to update the child’s object map by marking the corresponding bit “dirty”, which is a blocking operation due to locking, causing the effect of serialized concurrent COW writes. Second, the location of a data object is *calculated* deterministically by an algorithm based on the object name and the cluster layout [69]. Since objects have unique names, a child object will likely be placed on a different shard than its parent. For clarity, this section assumes that a `rbd` disk has an “allocation table” that combines the two utilities, as shown in Figure 3.

In addition, a `rbd` clone disk depends on its parent snapshot, and such dependency prevents the parent from deletion unless the cloned child is deleted first. As a result, for repeated failovers, the latest child will carry a chain of parent dependencies. These parents keep taking up space even though they are not needed anymore, as well as the child keeps suffering from COW penalties even after the failover is complete.

Collocation by reusing parent’s “allocation table.” To accomplish this, `super` directly assigns the parent disk to the child, including all data objects and the object map. This achieves two things. First, a COW write *never* needs to update the object map since by reusing parent’s object map, the corresponding bit is already updated by the parent. Second, the child uses the same object names as the parent to locate objects, allowing for collocation of parent and child objects.

To differentiate, the parent and the child are assigned a unique ID. When accessing the disk, they identify themselves to the storage cluster using that ID. This means that creating the child disk is fast because it only involves the assignment of a unique ID. The names of the objects are tagged with the unique ID to identify the object ownership (parent or child).

To determine how to serve a child I/O, the data shard first checks the existence of the child object and the corresponding parent object by directly querying the backend object store. COW is performed for a child write if the child object does not exist but the parent object does. Figure 3 demonstrates this process (dashed red arrows). By reusing the allocation table, child access will be directed to the same shard holding the corresponding parent objects (steps 1 and 2) and thus allowing for collocation (step 3).

Object size. Another factor affecting COW performance is the object size since objects are the minimal unit of copying. But if a COW write contains some whole objects, copying is unnecessary for these objects. With large objects, data copying imposes huge overhead; with small objects, writes are more likely to contain whole objects to reduce copying overhead, but the overhead of allocating more smaller objects could overwhelm and thus degrade the overall performance. Our benchmark shows that `rbd`’s default 4 MB object size is not ideal for many database applications whose default page size is only 4 KB to 64 KB. The the sweet spot for these applications is around 64 KB.

Dirty bit tracking and atomic promotion. `collapse` elects the data shard that stores the parent disk’s metadata (which is a single object) as the tracking shard. When `super` is invoked on the parent disk, its unique ID is registered to the tracking shard and then broadcasted to all data shards. The data shards then add the ID to a tracking list. When receiving a write with ID in the tracking list, the data shard must ask the tracking shard for permission to proceed (blue solid arrow, step 3 in figure 3). If permission is granted, the data shard can then submit this write and remove the ID from the tracking list; otherwise, this write must be rejected.

The tracking shard, by default, grants permission to any data shard requesting (step 4 in figure 3), sets the dirty bit associated with the ID, and notifies the other data shards to remove the ID from their tracking lists. The tracking shard also persists the dirty bit by writing it to the disk’s metadata, allowing it to be replicated along with the metadata. In case the current tracking shard fails, another shard holding a replica of the metadata is elected the new tracking shard.

When initiating an atomic promotion, based on the dirty bit status of the parent disk, the tracking shard performs either of the two actions *atomically*: (1) if the dirty bit is set, the tracking shard returns an error to indicate that promotion is rejected and the child disk should be deallocated; (2) otherwise, the tracking shard starts rejecting all requests-for-permission to the parent disk and acknowledges that promotion can proceed.

Dirty bit tracking adds one additional RTT to at most the number of writes equivalent to the number of data shards in the cluster. Our evaluation shows that this has negligible performance impact (§6.2).

Deallocation with garbage collection. `collapse` deallocates the child disk by asynchronously garbage-collecting all objects associated with the child’s unique ID. Similarly, the parent disk is deallocated by asynchronously garbage-collecting parent objects that have a corresponding child object and reassigning those who do not to the child’s ownership. After this process is complete, the child no longer depends on the parent and no longer needs to do COW. Asynchronous garbage collection minimizes the performance impact to the storage cluster’s normal operation.

6 Evaluation

This evaluation answers the following questions:

- How does the performance of colocated-clone disks compare to that of normal disks and general-clone disks? (§6.2)
- What is the recovery latency for various applications and failure scenarios when using a colocated-clone disk compared to using a normal disk and a general-clone disk? (§6.3)
- How does the failover latency of SpecREDS compare to REDS? (§6.4)
- What are the overheads of SpecREDS over REDS in terms of application performance after recovery, resource overhead, and overhead due to false positives? (§6.5)

We find that our implementation of a colocated-clone disk provides disk-level performance *close* to that of a normal disk and is much faster than a general-clone disk (§6.2). This performance translates to recovery latency when using a colocated-clone disk being close to using a normal disk (§6.3). This similar recovery latency leads to speculative recovery always providing failover latency comparable to REDS and often providing much lower failover latency across a wide variety of failover scenarios (§6.4).

6.1 Experimental Setup

We conducted our evaluation on EC2. The SpecREDS storage layer has four storage shards by EC2 instance type `i3en` with access to 7500 GB NVMe local SSDs and 25 Gbps network bandwidth. As shown in Table 1, our storage layer delivers performance comparable to popular cloud storage services.

For the primary and backup instances, we use the `m5n` instance type with 16 vCPUs, 64 GB RAM, and 25 Gbps network bandwidth, and for the application clients, we use an instance with 32 vCPUs, 128 GB RAM, and 25 Gbps network bandwidth. All instances are in the same availability zone as each other and the storage layer. We also set up a simple docker orchestrator environment on the primary and backup instances where applications are running in docker containers. The client instance runs `oltpbench` [31] with 100 virtual clients sending requests to the active instance. The primary is initially the active instance, while the failover process with our orchestrator makes the backup the active instance as it completes. The failure monitor, which pings the instances every second, runs as a separate daemon process on the client machine. We believe that this setup mimics existing systems like EC2 Auto Scaling groups and GCP Kubernetes Engine.

We pick three representative database applications: MySQL with InnoDB, PostgreSQL, and MariaDB with RocksDB. These applications meet the requirements of REDS and are widely used. The `oltpbench` client loads these application by running the TPC-C workload [65].

	KIOPS	Tput (MB/s)	Latency (ms)
EBS gp3	16/16	1000/1000	0.5/0.7
GCP SSD PD	15/15	245/245	0.6/0.7
Our storage layer	75/26	1000/630	0.38/2.0

Table 1: **Raw disk performance.** Comparing the raw disk performance of EBS General Purpose SSD (gp3), GCP SSD Persistent Disk, and our storage layer. Numbers in each cell are for read/write.

6.2 Disk-level Performance

To build up to an end-to-end availability comparison, we start by showing a disk-level performance comparison between a regular, non-COW `rbd` disk, a colocated-clone disk implemented with `super`, and a general-clone disk implemented with native `rbd` cloning (`rbd-clone`). We use an object size of 64 KB for all disks. The experiments examine single write performance, concurrent write performance, performance for real recovery workloads, and the impact of the dirty bit on the parent disk performance. Our results indicate that the main source of improvement comes from the elimination of object map update operations, which could increase the latency of a single write by 6.1x under highly parallel I/Os.

Single COW write latency. As the first set of experiments, we isolate the latency impact of the COW designs when there is no concurrency with an experiment that issues *single writes*, where only a single write is in flight at a time. Figure 4a compares the mean latency (averaged over 20,000 writes) of COW writes with `super` and `rbd-clone` to normal writes with `rbd` for varying write sizes. A closed-loop client issues writes to random offsets.

For writes smaller than the object size, write latency on `super` is 14% higher than `rbd` while `rbd-clone` is 220% higher. `super` provides this similar performance because it avoids an object map update operation and does the copy locally instead of having to transmit data over the network. When the write size equals the object size (64 KB), no COW is necessary. This isolates the latency effect of object map update operations. For `rbd-clone`, this results in 2 ms of added latency (the update operation is basically another write), while `super` has identical performance to normal writes because it does not need to update the object map.

Concurrent COW writes. Next, we evaluate the latency of COW write under varying levels of concurrency. Figure 4b shows the mean latency of 4 KB COW writes as we vary concurrency from 1 write in flight at a time up to 32 writes in flight. A closed-loop client simultaneously issues n writes to random offsets, waits for all of their responses, and then repeats this process.

The latency of `rbd-clone` increases sharply with concurrency: the mean latency with 32 writes in flight is 6.1x higher than the mean latency with 1 write in flight. We found that this high latency is due to parallel object map update opera-

Figure 4: **COW performance comparison.** (a) Latency for varying size COW writes with no concurrency; (b) Latency for 4 KB COW writes under increasing levels of concurrency; (c)/(d) Read/write CDFs from replaying a trace of recovery operations.

tions being serialized by the client’s disk driver. In contrast, `super` provides similar performance to `rd` under concurrency because it avoids updates to the object map: both have comparable mean latency that ranges from 2 ms with a concurrency of 1 to 4 ms with a concurrency of 32.

Performance on real recovery workloads. To quantify how these improvements of `super` translate to performance in real application recovery workloads, Figures 4c and 4d show read and write CDFs collected from replaying a recovery workload trace with `fiio` [32]. The trace captures the recovery work for a Postgres database with 20 GB TPCC data and 1 GB of WAL at the time of an injected kernel panic failure.

For read, all three disks have similar read latency up to p99.9. `super` and `rd-clone` have higher read latency beyond p99.9 due to the overhead of COW that may occupy a majority of disk throughput under high load and cause heavy I/O contention. For write, the write latency of `rd-clone` is much higher than `rd`. In contrast, the write latency of `super` is comparable to `rd` up to p99.9.

Dirty bit tracking overhead. As discussed in §5, the dirty bit tracking mechanism of SpecREDS may impact the performance of the parent disk because some parent writes require an additional round trip to set the dirty bit. This could become a problem if the primary instance self-heals and continues serving the application. We performed an experiment that invokes `super` every second while measuring raw IOPS on the parent disk. Even under such an extreme condition, the parent disk achieves the same IOPS numbers. Thus, the only overhead of dirty bit tracking is increased latency for the few writes that set the dirty bit when the primary is still alive.

Summary. We believe that these disk-level improvements of `super`, as shown in Figure 4, can achieve recovery latency very close to a regular `rd` disk in real failure scenarios, enabling end-to-end application availability improvement for SpecREDS, as presented in the next two subsections.

6.3 Application Recovery Latency

We ran a series of experiments to understand how disk-level performance of the three disk types (`rd`, `super`, and `rd-clone`) affects recovery latency as we vary failure type and failure timing. SpecREDS operates on a disk clone (`super` by default or `rd-clone`) with COW penalties, which increases application recovery latency compared to REDS using a regular `rd` disk without COW. It is critical for such latency increase to be relatively minor to show practical improvement in end-to-end application availability (§6.4)

For these experiments, the application initially runs in a container on the primary instance, handling requests from the clients. Then, a failure is injected to the primary. To isolate recovery latency, the failure monitor detects loss of connectivity with no timeout and immediately initiates failover, and the application restarts on the backup instance. The recovery latency is measured at the client side as the length of time between when the TPC-C throughput drops to zero and when it resumes. Failures are injected either by synchronously stopping the docker container and unmounting the disk (clean failures) or by causing a kernel panic (unclean failures).

We found the type of failure has a major effect on recovery latency. Stopping the primary container tries to gracefully shut down the application (this is the case for MariaDB but not for MySQL and Postgres), and unmounting the disk flushes file system cache such that the file system is not corrupted. Therefore, the disk is in a cleaner state and can recover faster. Kernel panic, on the other hand, immediately crashes the instance without giving a chance to clean up, leaving the disk in an unclean state that takes longer for the backup to recover. In addition, we found the size of WAL at time of failure also significantly impacts recovery latency.

Our full range of experiments have recovery latencies that vary from 1–70 s when run on `rd`. We capture block-level traces of those recovery workloads with `blktrace` and then replay them with `fiio` on `rd`, `super`, and `rd-clone`. Replaying traces ensures the workload is identical for all three disks.

Figure 5: **Application recovery latency from various disk states.** Recovery latency is shown for our three applications running on `rd`, `super`, and `rd-clone`. Failures are injected using docker stop (S) or a kernel panic (P). Labels are failure types followed by WAL size in GB.

To make results legible while demonstrating the effect of varying WAL sizes and failure types, we select three scenarios to show for each application. The recovery latency for each disk with these scenarios is shown in Figure 5. In all cases, we see that `super` improves performance over `rd-clone`. This is especially pronounced for Postgres whose recovery workload is generally more write-intensive, exacerbating the write performance bottlenecks in `rd-clone` shown in §6.2. Further, recovery on `super` is only slightly slower than recovery on `rd` by 13% on average.

6.4 End-to-end Failover Latency

To quantify the effect of speculative recovery for complete end-to-end failover scenarios, we simulated various failover scenarios and compare the latency across REDS (using `rd`), SpecREDS (using `super` by default), SpecREDS (using `rd-clone`), and the oracle model (using `rd`). The oracle model shows the lower bound on failover latency: it runs recovery on a `rd` disk immediately after a primary issues its last write (or simply waits for primary to come back online, whichever is shorter). Thus, the oracle shows failover latency without either REDS’s timeout or SpecREDS’s slower disk performance. On the other hand, REDS initiates recovery after a full timeout, while SpecREDS initiates much sooner after only *one second* of an unresponsive ping.

The simulations explored three variables: the primary-is-failed timeout, the recovery latency for the backup, and if/when the primary self-heals. Results are divided into broad categories depending on the timeout length (short, medium, or long), recovery length (short or long), and whether the primary self-heals after the timeout but before backup recovery completes (true or false positive recovery for REDS). Results with a long timeout (e.g., the Kubernetes default timeout of five minutes) are similar to a medium timeout but have even higher failover latency for REDS, so we only show results for a medium timeout. Results with false positive recovery for

Figure 6: **End-to-end failover latency.** Representative failover scenarios, picked by varying the lengths of timeout and recovery. Bar group IV shows a false positive (FP) failover for REDS

REDS all similarly inflate only the latency of REDS, so we only show one of these results. This leads to five categories.

Figure 6 shows a representative result from each of these five categories. The medium timeout is one minute and the short timeout is five seconds. The recovery latencies are picked from the results in §6.3. The long recovery is from Postgres with an unclear failure and a 5 GB WAL (around 70 seconds of recovery latency on `rd`). The short recovery is from Postgres with a clean failure and a 0.4 GB WAL (around 8 seconds on `rd`).

The two leftmost bar groups show scenarios with medium timeouts and demonstrate one major part of SpecREDS’s availability improvement over REDS. Because SpecREDS starts recovery early without waiting for a full timeout, it completes failover much sooner and thus significantly reduces application unavailability.

The three rightmost bars in Figure 6 demonstrate short timeout failure scenarios. Bar groups III and V shows similar performance for REDS and SpecREDS with a long (III) or short (V) recovery. In these cases, SpecREDS start recovery slightly sooner than REDS. But, its recovery takes slightly longer because its `super` disk is slightly slower than the `rd` disk used by REDS. With a long recovery (III), this makes REDS’s unavailability marginally shorter than SpecREDS. With a short recovery (V), this makes SpecREDS’s unavailability marginally shorter than REDS. Finally, bar group IV shows a false positive failover where the primary is available again (we used 15 seconds for illustration) shortly after the timeout. SpecREDS decreases unavailability considerably in this scenario by allowing the primary to continue instead of committing to recovery on the backup with no turning back.

Overall, there are three takeaways. First, the failover latency of SpecREDS (`rd-clone`) is consistently the highest, indicating that the improved performance of the `super` disk is the key to achieving the availability improvement of SpecREDS. Second, SpecREDS achieves significantly lower failover latency when REDS uses a medium timeout (bar groups I and

Figure 7: **Throughput after recovery.** Time 0 is right after recovery completes and clients resume.

II) because this timeout dominates REDS’s unavailability; SpecREDS also achieves lower failover latency for false positives when REDS uses a short timeout (IV), while achieving similar failover latency in other cases (III and V). Third, SpecREDS is always close to the oracle lower bound, suggesting it achieves most of the possible availability improvement for a REDS-based fault tolerance scheme.

6.5 Other SpecREDS Overheads

To understand the other overheads of SpecREDS, we evaluated application performance immediately after recovery is complete, analyzed production health monitor logs to estimate the resource overhead of SpecREDS, and discussed the performance overhead on the storage layer’s normal operation due to false positives.

Application performance after recovery. After the backup instance completes recovery and gets promoted, collapse asynchronously transfers parent objects to the child. During this time, COW is still used for writes that go to objects whose ownership has not yet been transferred. Figure 7 compares application performance following recovery (Postgres, unclean failure with 1 GB WAL) on REDS, SpecREDS, and SpecREDS (`rbd-clone`). SpecREDS using `rbd-clone` has low throughput due to the continued impact of COW because the parent-child dependency still exists, as discussed in §5. In contrast, we see that SpecREDS has a throughput curve very similar to REDS. Thus, we conclude that SpecREDS adds negligible overhead to application performance after recovery.

Resource overhead of SpecREDS. Due to running two instances concurrently during speculative recovery and the possibility of aborted recovery, SpecREDS incurs additional resource overhead compared to REDS. The key to understanding SpecREDS’s resource overhead is to see how often it would be incurred. We analyzed a complete collection of health monitor logs from more than 80 production caching servers for the past five years. On average, a server is reported

inaccessible once every 2.8 days. Of these reported events, 90% are transient: the server becomes accessible again within 10 seconds. Even with such a high false positive rate, the frequency of possible server inaccessible event is quite small. The resource overhead of SpecREDS would be, on average, an unnecessary backup instance allocation for up to 10 seconds once every 3.1 days: a 0.004% overhead.

Performance overhead due to false positives. False positives that trigger speculative failover that is aborted impose performance overhead on the storage layer due to garbage collection (GC). This may be troublesome since short-lived failures are common in today’s data center networks [21, 48, 54, 60], which could introduce frequent GC that could harm the storage layer’s normal operation. Our log analysis described above, however, found that a server is reported inaccessible once every 2.8 days on average, meaning that SpecREDS incurs GC overhead only once every few days. Moreover, GC incurs minor performance overhead, since GC is asynchronous and thus does not block regular disk I/O operations, as shown in Figure 7.

7 Related Work

This section reviews related work on application-level replication, state machine replication, virtual machine replication, slow recovery in databases, shared storage clustering, disk snapshotting, and other related uses of speculation within systems. The most closely related work is the industry’s adoption of REDS, which is introduced in §2.2 and discussed extensively throughout the paper.

Application-level replication. This is a widely implemented technique for providing high-availability fault tolerance. SQL databases, including MySQL, PostgreSQL, Microsoft SQL Server, as well as NoSQL databases such as MongoDB, replicate client transactions synchronously and persistently to backups before responding to clients [7–10]. This can provide excellent performance with failover latency shorter than SpecREDS. However, it requires an extensive implementation for each individual application since the replication logic and implementation are application-specific. Many useful persistence applications do not provide high-availability at the application layer, including SQLite, LevelDB, and RocksDB [1, 3, 4, 6, 11]. In contrast, Both REDS and SpecREDS support these applications without any modification or explicit support, since they work at the block-device layer.

Application-level replication requires multiple application instances at all times to provide fault tolerance: at least the primary instance and one backup. In contrast, REDS and SpecREDS only run a single instance almost at all times, which makes it far cheaper.

Application-level replication may also have lower performance in normal operation since it runs expensive replication protocols for client requests. We believe that this argument

needs meticulous measurements to validate because REDS and SpecREDS do not eliminate the need for a replication protocol but instead runs it at the storage level. In addition, the replicas in application-level replication can provide read-only throughput. Though disaggregated storage can also offer better disk-level read throughput from data replicas, single application instance often cannot fully utilize it due to bottlenecks at CPU and network bandwidth [41]

State machine replication (SMR). This technique provides high availability for applications that use its interface, which is typically a log of requests executed in order [62]. SMR is typically implemented either using a consensus algorithm like Paxos [44] or a primary-backup approach [24]. SMR can often provide shorter recovery times than SpecREDS. But, like application-level replication, it requires multiple instances and thus is more costly than SpecREDS.

Virtual machine (VM) replication. This technique provides application-agnostic high-availability fault tolerance [23, 29, 53, 63]. This technique replicates an entire VM and thus can make any application or a collection of applications fault tolerant. However, VM replication is heavy-weight because it replicates the entire virtual machine (e.g., all changes to memory must be replicated before they are externalized to provide linearizability). Also, it requires at least two instances at all times to provide fault tolerance. Speculative recovery supports the smaller set of applications that are crash consistent, but is much lighter weight and provides high availability at a much lower cost

Database slow recovery. This is a technique that precedes the cloud by decades where logs are periodically shipped to a backup that stores, but does not apply, them until a failover is needed. This similarly requires fewer backup resources in the normal case but results in slower recovery. REDS and SpecREDS build on this technique to provide a similar tradeoff more generally for any crash-consistent application and in a cloud-native way by using disaggregated storage to provide the backup its own copy of the disk instead of requiring any computation from a backup.

Shared storage clustering. This technique allows a storage volume to be attached to and accessible from multiple application instances at the same time, enabling faster failover in a clustered application setup without dismounting and remounting the volume to another instance [51]. The cloud-native version of this technique is “multi-attach” [14]. These techniques require a standby backup instance, which is not the case for REDS and SpecREDS.

Snapshots and checkpoints. Other forms of storage copy such as snapshots and checkpoints are widely used for data backup and rollback-based disaster recovery [38, 46, 67]. Many cloud platforms also support automatically taking snapshots of application disks on a user-specified schedule. How-

ever, this method does not provide linearizability amid failures because updates following the latest snapshot will be lost.

Speculation. This is a widely used technique to accelerate the performance of systems. Here we discuss a few of these systems that inspired us. Zyzzyva [42] is a Byzantine fault tolerance SMR protocol where the replicas speculatively execute client requests without agreeing on a single total ordering, and it is then the client’s responsibility to observe and help resolve any inconsistencies. Speculative recovery adopts a similar idea that inconsistency can be allowed temporarily and resolved later.

Speculative Paxos [59] is a SMR protocol where replicas speculatively execute client requests based on the message delivery order provided by the underlying network layer. In cases where this order is violated, a reconciliation protocol is in place to rollback inconsistent operations. Such inconsistencies are detected before externalizing. Speculative recovery is similar in that inconsistencies cannot be externalized. This is also inspired by a similar idea in “rethink the sync” [55] where external clients are the real observer of the system.

Speculation is also widely adopted for tolerating tail latency in data-parallel computing such as Hadoop and Spark [64, 70]. When a computing job is taking an unexpectedly long time, the same job will be sent to another worker, and the system uses the results from whichever finishes first. Hedged requests are a similar technique that is used for applications that access many backend systems [30] as well as other domains such as RAID storage arrays [35, 36]. Speculative recovery is similar to these techniques in that there are two racing paths and latency is determined by the first path to finish.

8 Conclusions

We presented speculative recovery, a cheap, highly available fault-tolerance scheme based on disaggregated storage for crash-consistent applications. At the core of speculative recovery are the two new primitives, `super` and `collapse`, for disaggregated storage. `super` provides performant disk clones with the novel colocated-clone design, and `collapse` ensures application correctness, i.e., linearizability, in a failover process with a disk-global dirty bit. Speculative recovery achieves the same level of resource efficiency as REDS with significantly higher availability in most failover scenarios.

A Artifact Appendix

Abstract

The artifact provides a framework for evaluating SpecREDS as shown in the evaluation section of the paper. The artifact includes the source code of SpecREDS's disaggregated storage layer (based on Ceph), configuration files and pre-captured application recovery traces, and handy scripts for instrumenting the experiments. Readers can easily use this artifact to reproduce figures shown in the paper.

Scope

There are two main claims from the paper that the artifact seeks to validate: **(1)** the disk-level I/O performance of `super`, our novel design and implementation of light-weight, fast disk clones, is *close* to that of a regular, non-COW disk, while significantly outperforming Ceph's existing clone implementation `rbd-clone`; **(2)** SpecREDS using `super` can bring practical end-to-end application availability improvement over REDS in various failover scenarios.

Specifically, the paper uses Figures 4 and 5 to prove the point of the first claim and Figures 6 and 7 to prove the second claim. The artifact contains experiments to reproduce these four figures, and readers should be able to compare them with the original figures in the paper to validate the claims.

Contents

The artifact contains the following items

- The source code of SpecREDS's disaggregated storage
- A simple tool for measuring disk-level performance
- Pre-configured configs, disk images, and traces
- Scripts for instrumenting all experiments
- Detailed readmes

Hosting

The artifact is hosted on our public GitHub repository at <https://github.com/princeton-sns/specreds>. The tag for the OSDI/ATC artifact evaluation is `atc22ae`. To get started, please follow the detailed instructions in the repo.

Requirements

The artifact does not require special hardware or software, but we highly recommend running the artifact on CloudLab with a `c220g2` or `c220g5` machine where the artifact is tested to be reproducible. If not available, we recommend using a machine with at least 16 CPU cores, 64 GB memory, 400 GB of free space on an SSD, and Ubuntu 20.04. We also provide a `qcow2` image for booting up a QEMU VM.

Direct Access, High-Performance Memory Disaggregation with DIRECTCXL

Donghyun Gouk, Sangwon Lee, Miryeong Kwon, Myoungsoo Jung
Computer Architecture and Memory Systems Laboratory,
Korea Advanced Institute of Science and Technology (KAIST)
<http://camelab.org>

Abstract

New cache coherent interconnects such as CXL have recently attracted great attention thanks to their excellent hardware heterogeneity management and resource disaggregation capabilities. Even though there is yet no real product or platform integrating CXL into memory disaggregation, it is expected to make memory resources practically and efficiently disaggregated much better than ever before.

In this paper, we propose directly accessible memory disaggregation, DIRECTCXL that straight connects a host processor complex and remote memory resources over CXL's memory protocol (CXL.mem). To this end, we explore a practical design for CXL-based memory disaggregation and make it real. As there is no operating system that supports CXL, we also offer CXL software runtime that allows users to utilize the underlying disaggregated memory resources via sheer load/store instructions. Since DIRECTCXL does not require any data copies between the host memory and remote memory, it can expose the true performance of remote-side disaggregated memory resources to the users.

1 Introduction

Memory disaggregation has attracted great attention thanks to its high memory utilization, transparent elasticity, and resource management efficiency [1–3]. Many studies have explored various software and hardware approaches to realize memory disaggregation and put significant efforts into making it practical in large-scale systems [4–16].

We can broadly classify the existing memory disaggregation runtimes into two different approaches based on how they manage data between a host and memory server(s): i) page-based and ii) object-based. The page-based approach [4–10] utilizes virtual memory techniques to use disaggregated memory without a code change. It swaps page cache data residing on the host's local DRAMs from/to the remote memory systems over a network in cases of a page fault. On the other hand, the object-based approach handles disaggregated memory from a remote using their own database such as a key-value store instead of leveraging the virtual memory systems [11–16]. This approach can address the challenges imposed by address translation (e.g., page faults, context switching, and write amplification), but it requires significant source-level modifications and interface changes.

While there are many variants, all the existing approaches need to move data from the remote memory to the host memory over remote direct memory access (RDMA) [4, 5, 11–13, 15, 16] (or similar fine-grain network interfaces [7, 9, 10, 17]). In addition, they even require managing locally cached data in either the host or memory nodes. Unfortunately, the data movement and its accompanying operations (e.g., page cache management) introduce redundant memory copies and software fabric intervention, which makes the latency of disaggregated memory longer than that of local DRAM accesses by multiple orders of magnitude. In this work, we advocate *compute express link* (CXL [18]), which is a new concept of open industry standard interconnects offering high-performance connectivity among multiple host processors, hardware accelerators, and I/O devices [19]. CXL is originally designed to achieve the excellency of heterogeneity management across different processor complexes, but both industry and academia anticipate its cache coherence ability can help improve memory utilization and alleviate memory over-provisioning with low latency [20–22]. Even though CXL exhibits a great potential to realize memory disaggregation with low monetary cost and high performance, it has not been yet made for production, and there is no platform to integrate memory into a memory pooling network.

We demonstrate DIRECTCXL, direct accessible disaggregated memory that connects host processor complex and remote memory resources over CXL's memory protocol (CXL.mem). To this end, we explore a practical design for CXL-based memory disaggregation and make it real. Specifically, we first show how to disaggregate memory over CXL and integrate the disaggregated memory into processor-side system memory. This includes implementing CXL controller that employs multiple DRAM modules on a remote side. We then prototype a set of network infrastructure components such as a CXL switch in order to make the disaggregated memory connected to the host in a scalable manner. As there is no operating system that support CXL, we also offer CXL software runtime that allows users to utilize the underlying disaggregated memory resources through sheer load/store instructions. DIRECTCXL does not require any data copies between the host memory and remote memory, and therefore, it can expose the true performance of remote-side disaggregated memory resources to the users.

In this work, we prototype DIRECTCXL using many cus-

tomized memory add-in-cards, 16nm FPGA-based processor nodes, a switch, and a PCIe backplane. On the other hand, DIRECTCXL software runtime is implemented based on Linux 5.13. To the best of our knowledge, this is the first work that brings CXL 2.0 into a real system and analyzes the performance characteristics of CXL-enabled disaggregated memory design. The results of our real system evaluation show that the disaggregated memory resources of DIRECTCXL can exhibit DRAM-like performance when the workload can enjoy the host processor’s cache. When the load/store instructions go through the CXL network and are served from the disaggregated memory, DIRECTCXL’s latency is shorter than the best latency of RDMA by $6.2\times$, on average. For real-world applications, DIRECTCXL exhibits $3\times$ better performance than RDMA-based memory disaggregation, on average.

2 Memory Disaggregation and Related Work

2.1 Remote Direct Memory Access

The basic idea of memory disaggregation is to connect a host with one or more memory nodes, such that it does not restrict a given job execution because of limited local memory space. For the backend network control, most disaggregation work employ remote direct memory access (RDMA) [4, 5, 11–13, 15, 16] or similar customized DMA protocols [7, 9, 10]. Figure 1 shows how RDMA-style data transfers (one-sided RDMA) work. For both the host and memory node sides, RDMA needs hardware support such as RDMA NIC (RNIC [23]), which is designed toward removing the intervention of the network software stack as much as possible. To move data between them, processes on each side first require defining one or more memory regions (MRs) and letting the MR(s) to the underlying RNIC. During this time, the RNIC driver checks all physical addresses associated with the MR’s pages and registers them to RNIC’s memory translation table (MTT). Since those two RNICs also exchange their MR’s virtual address at the initialization, the host can simply send the memory node’s destination virtual address with data for a write. The remote node then translates the address by referring to its MTT and copies the incoming data to the target location of MR. Reads over RDMA can also be performed in a similar manner. Note that, in addition to the memory copy operations (for DMA), each side’s application needs to prepare or retrieve the data into/from MRs for the data transfers, introducing additional data copies within their local DRAM [24].

2.2 Swap: Page-based Memory Pool

Page-based memory disaggregation [4–10] achieves memory elasticity by relying on virtual memory systems. Specifically, this approach intercepts paging requests when there is a page fault, and then it swaps the data to a remote memory node instead of the underlying storage. To this end, a disaggregation driver underneath the host’s kernel swap daemon (*kswapd*) converts the incoming block address to the memory node’s

Figure 1: Data movement over RDMA.

virtual address. It then copies the target page to RNIC’s MR and issues the corresponding RDMA request to the memory node. Since all operations for memory disaggregation is managed under *kswapd*, it is easy-to-adopt and transparent to all user applications. However, page-based systems suffer from performance degradation due to the overhead of page fault handling, I/O amplifications, and context switching when there are excessive requests for the remote memory [16].

Note that there are several studies that migrate locally cached data in a finer granular manner [4–7] or reduce the page fault overhead by offloading memory management (including page cache coherence) to the network [8] or memory nodes [9, 10]. However, all these approaches use RDMA (or a similar network protocol), which is essential to cache the data and pay the cost of memory operations for network handling.

2.3 KVS: Object-based Memory Pool

In contrast, object-based memory disaggregation systems [11–16] directly intervene in RDMA data transfers using their own database such as key-value store (KVS). Object-based systems create two MRs for both host and memory node sides, each dealing with buffer data and submission/completion queues (SQ/CQ). Generally, they employ a KV hash-table whose entries point to corresponding (remote) memory objects. Whenever there is a request of Put (or Get) from an application, the systems place the corresponding value into the host’s buffer MR and submit it by writing the remote side of SQ MR over RDMA. Since the memory node keeps polling SQ MR, it can recognize the request. The memory node then reads the host’s buffer MR, copies the value to its buffer MR over RDMA, and completes the request by writing the host’s CQ MR. As it does not lean on virtual memory systems, object-based systems can address the overhead imposed by page swap. However, the performance of object-based systems varies based on the semantics of applications compared to page-based systems; *kswapd* fully utilizes local page caches, but KVS does not for remote accesses. In addition, this approach is unfortunately limited because it requires significant source-level modifications for legacy applications.

3 Direct Accessible Memory Aggregation

While caching pages and network-based data exchange are essential in the current technologies, they can unfortunately significantly deteriorate the performance of memory disaggregation. DIRECTCXL instead directly connects remote memory resources to the host’s computing complex and allows users to access them through sheer load/store instructions.

Figure 2: DIRECTCXL's connection method.

Figure 3: DIRECTCXL's network and switch.

Figure 4: DIRECTCXL software runtime.

3.1 Connecting Host and Memory over CXL

CXL devices and controllers. In practice, existing memory disaggregation techniques still require computing resources at the remote memory node side. This is because all DRAM modules and their interfaces are designed as passive peripherals, which require the control computing resources. CXL.mem in contrast allows the host computing resources directly access the underlying memory through PCIe buses (*FlexBus*); it works similar to local DRAM, connected to their system buses. Thus, we design and implement CXL devices as pure passive modules, each being able to have many DRAM DIMMs with its own hardware controllers. Our CXL device employs multiple DRAM controllers, connecting DRAM DIMMs over the conventional DDR interfaces. Its CXL controller then exposes the internal DRAM modules to FlexBus through many PCIe lanes. In the current architecture, the device's CXL controller parses incoming PCIe-based CXL packets, called *CXL flits*, converts their information (address and length) to DRAM requests, and serves them from the underlying DRAMs using the DRAM controllers.

Integrating devices into system memory. Figure 2 shows how CXL devices' internal DRAMs are mapped (exposed) to a host's memory space over CXL. The host CPU's system bus contains one or more CXL root ports (*RP*s), which connect one or more CXL devices as endpoint (*EP*) devices. Our host-side kernel driver first enumerates CXL devices by querying the size of their base address register (*BAR*) and their internal memory, called host-managed device memory (*HDM*), through PCIe transactions. Based on the retrieved sizes, the kernel driver maps *BAR* and *HDM* in the host's reserved system memory space and lets the underlying CXL devices know where their *BAR* and *HDM* (base addresses) are mapped in the host's system memory. When the host CPU accesses an *HDM* system memory through load/store instruction, the request is delivered to the corresponding *RP*, and the *RP* converts the requests to a CXL flit. Since *HDM* is mapped to a different location of the system memory, the memory address space of *HDM* is different from that of *EP*'s internal DRAMs. Thus, the CXL controller translates the incoming addresses by simply deducting *HDM*'s base address from them and issues the translated request to the underlying DRAM controllers. The results are returned to the host via a CXL switch and FlexBus. Note that, since *HDM* accesses have no software intervention or memory data copies, DIRECTCXL can expose the CXL device's memory resources to the host with low access latency.

Designing CXL network switch. Figure 3a illustrates how DIRECTCXL can disaggregate memory resources from a host using one or more and CXL devices, and Figure 3b shows our CXL switch organization therein. The host's CXL *RP* is connected to *upstream port* (*USP*) of either a CXL switch or the CXL device directly. The CXL switch's *downstream port* (*DSP*) also connects either another CXL switch's *USP* or the CXL device. Note that our CXL switch employs multiple *USPs* and *DSPs*. By setting an internal routing table, our CXL switch's *fabric manager* (*FM*) reconfigures the switch's crossbar to connect each *USP* to a different *DSP*, which creates a virtual hierarchy from a root (host) to a terminal (CXL device). Since a CXL device can employ one or more controllers and many DRAMs, it can also define multiple logical devices, each exposing its own *HDM* to a host. Thus, different hosts can be connected to a CXL switch and a CXL device. Note that each CXL virtual hierarchy only offers the path from one to another to ensure that no host is sharing an *HDM*.

3.2 Software Runtime for DirectCXL

In contrast to RDMA, once a virtual hierarchy is established between a host and CXL device(s), applications running on the host can directly access the CXL device by referring to *HDM*'s memory space. However, it requires software runtime/driver to manage the underlying CXL devices and expose their *HDM* in the application's memory space. We thus support DIRECTCXL runtime that simply splits the address space of *HDM* into multiple segments, called *cxl-namespace*. DIRECTCXL runtime then allows the applications to access each CXL-namespace as memory-mapped files (*mmap*).

Figure 4 shows the software stack of our runtime and how the application can use the disaggregated memory through *cxl-namespaces*. When a CXL device is detected (at a PCIe enumeration time), DIRECTCXL driver creates an entry device (e.g., `/dev/directcxl`) to allow users to manage a *cxl-namespace* via *ioctl*. If users ask a *cxl-namespace* to `/dev/directcxl`, the driver checks a (physically) contiguous address space on an *HDM* by referring to its *HDM* segment table whose entry includes a segment's offset, size, and reference count (recording how many *cxl-namespaces* that indicate this segment). Since multiple processes can access this table, its header also keeps necessary information such as spinlock, read/write locks, and a summary of table entries (e.g., valid entry numbers). Once DIRECTCXL driver allocates a segment based on the user request, it creates a device for *mmap* (e.g., `/dev/cxl-ns0`) and updates the segment table. The user

Figure 5: CXL-enabled cluster.

application can then map the `cxl-namespace` to its process virtual memory space using `mmap` with `vm_area_struct`.

Note that `DIRECTCXL` software runtime is designed for direct access of CXL devices, which is a similar concept to the memory-mapped file management of persistent memory development toolkit (PMDK [25]). However, it is much simpler and more flexible for namespace management than PMDK. For example, PMDK’s namespace is very much the same idea as NVMe namespace, managed by file systems or DAX with a fixed size [26]. In contrast, our `cxl-namespace` is more similar to the conventional memory segment, which is directly exposed to the application without a file system employment.

3.3 Prototype Implementation

Figure 5a illustrates our design of a CXL network topology to disaggregate memory resources, and the corresponding implementation in a real system is shown in Figure 5b. There are n numbers of compute hosts connected to m number of CXL devices through a CXL switch; in our prototype, n and m are four, but those numbers can scale by having more CXL switches. Specifically, each CXL device prototype is built on our customized add-in-card (AIC) CXL memory blade that employs 16nm FPGA and 8 different DDR4 DRAM modules (64GB). In the FPGA, we fabricate a CXL controller and eight DRAM controllers, each managing the CXL endpoint and internal DRAM channels. As yet there is no processor architecture supporting CXL, we also build our own in-house host processor using RISC-V ISAs, which employs four out-of-order cores whose last-level cache (LLC) implements CXL RP. Each CXL-enabled host processor is implemented in a high-performance datacenter accelerator card, taking a role of a host, which can individually run Linux 5.13 and `DIRECTCXL` software runtime. We expose four CXL devices (32 DRAM modules) to the four hosts through our PCIe backplane. We extended the backplane with one more accelerator card that implements `DIRECTCXL`’s CXL switch. This switch implements FM that can create multiple virtual hierarchies, each connecting a host and a CXL device in a flexible manner.

To the best of our knowledge, there are no commercialized CXL 2.0 IPs for the processor side’s CXL engines and CXL switch. Thus, we built all `DIRECTCXL` IPs from the ground. The host-side processors require advanced configuration and power interface (ACPI [27]) for CXL 2.0 enumeration (e.g., RP location and RP’s reserved address space). Since RISC-V does not support ACPI yet, we enable the CXL enumeration by adding such information into the device tree [28]. Specifically, we update an MMIO register designated as a property of

the tree’s node to let the processor know where CXL RP exists. On the other hand, we add a new field (`cxl-reserved-area`) in the node to indicate where an HDM can be mapped. Our in-house softcore processors work at 100MHz while CXL and PCIe IPs (RP, EP, and Switch) operate at 250MHz.

4 Evaluation

Testbed prototypes for memory disaggregation. In addition to the CXL environment that we implemented in Section 3.3 (`DirectCXL`), we set up the same configuration with it for our RDMA-enabled hardware system (RDMA). For RDMA, we use Mellanox ConnectX-3 VPI InfiniBand RNIC (56Gbps, [29]) instead of our CXL switch as RDMA network interface card (RNIC). In addition, we port Mellanox OpenFabric Enterprise Distribution (OFED) v4.9 [30] as an RDMA driver to enable RNIC in our evaluation testbed. Lastly, we port FastSwap [1] and HERD [12] into RISC-V Linux 5.13.19 computing environment atop RDMA, each realizing page-based disaggregation (Swap) and object-based disaggregation (KVS).

For better comparison, we also configure the host processors to use only their local DRAM (Local) by disabling all the CXL memory nodes. Note that we used the same testbed hardware mentioned above for both CXL experiments and non-CXL experiments but differently configured the testbed for each reference. For example, our testbed’s FPGA chips for the host (in-house) processors and CXL devices use all the same architecture/technology and product line-up.

Benchmark and workloads. Since there is no microbenchmark that we can compare different memory pooling technologies (RDMA vs. `DirectCXL`), we also build an in-house memory benchmark for in-depth analysis of those two technologies (Section 4.1). For RDMA, this benchmark allocates a large size of the memory pool at the remote side in advance. This benchmark allows a host processor to send random memory requests to a remote node with varying lengths; the remote node serves the requests using the pre-allocated memory pool. For `DirectCXL` and Local, the benchmark maps `cxl-namespace` or `anonymous mmap` to user spaces, respectively. The benchmark then generates a group of RISC-V memory instructions, which can cover a given address length in a random pattern and directly issues them without software intervention. For the real workloads, we use Facebook’s deep learning recommendation model (DLRM [31]), an in-memory database used for the HERD evaluation (MemDB [12]), and four graph analysis workloads (MIS [32], BFS [33], CC [34], and BC [35]) coming from Ligra [36]. All their tables and data structures are stored in the remote node, while each host’s local memory handles the execution code and static data. Table 1 summarizes the per-node memory usage and total data sizes for each workload that we tested.

4.1 In-depth Analysis of RDMA and CXL

In this subsection, we compare the performance of RDMA and CXL technologies when the host and memory nodes are

Figure 6: RDMA vs. CXL.

Figure 7: Sensitivity tests.

Figure 8: Memory hierarchy performance.

configured through a 1:1 connection. Figure 6 shows latency breakdown of RDMA and DirectCXL when reading 64 bytes of data. One can observe from the figure that RDMA requires two DMA operations, which doubles the PCIe transfer and memory access latency. In addition, the communication overhead of InfiniBand (Network) takes 78.7% (2129 cycles) of the total latency (2705 cycles). In contrast, DirectCXL only takes 328 cycles for memory load request, which is $8.3\times$ faster than RDMA. There are two reasons behind this performance difference. First, DirectCXL straight connects the compute nodes and memory nodes using PCIe while RDMA requires protocol/interface changes between InfiniBand and PCIe. Second, DirectCXL can translate memory load/store request from LLC into the CXL flits whereas RDMA must use DMA to read/write data from/to memory.

Sensitivity tests. Figure 7a decomposes RDMA latency into essential hardware (Memory and Network), software (Library), and data transfer latencies (Copy). In this evaluation, we instrument two user-level InfiniBand libraries, `libibverbs` and `libmlx4` to measure the software side latency. Library is the primary performance bottleneck in RDMA when the size of payloads is smaller than 1KB (4158 cycles, on average). As the payloads increase, Copy gets longer and reaches 28.9% of total execution time. This is because users must copy all their data into RNIC’s MR, which takes extra overhead in RDMA. On the other hand, Memory and Network shows a performance trend similar to RDMA analyzed in Figure 6. Note that the actual times of Network (Figure 7a) do not decrease as the payload increases; while Memory increases to handle large size of data, RNIC can simultaneously transmit the data to the underlying network. These overlapped cycles are counted by Memory in our analysis. As shown in Figure 7b, the breakdown analysis for DirectCXL shows a completely different story; there is neither software nor data copy overhead. As the payloads increase, the dominant component of DirectCXL’s latency is LLC (CPU Cache). This is because LLC can handle 16 concurrent misses through miss status holding registers (MSHR) in our custom CPU. Thus, many memory requests (64B) composing a large payload data can be stalled at CPU, which takes 67% of the total latency to handle 4KB payloads. PCIe shown in Figure 7a does not decrease as the payloads increase because of a similar reason of RDMA’s Network. However, it

	Per-node usage		Total usage	Data stored in remote memory
	Local	Remote		
DLRM [31]	Less than 100MB	17GB	68GB	Embedding tables.
MemDB [12]	100MB	4GB	16GB	Key-value pairs and tree structure.
Ligra [36]		7GB	28GB	Deserialized graph structure.

Table 1: Memory usage characteristic of each workload.

is not as much as what Network did as only 16 concurrent misses can be overlapped. Note that PCIe shown in Figures 6 and 7b includes the latency of CXL IPs (RP, EP, and Switch), which is different from the pure cycles of PCIe physical bus. The pure cycles of PCIe physical bus (FlexBus) account for 28% of DirectCXL latency. The detailed latency decomposition will be analyzed in Section 4.2.

Memory hierarchy performance. Figure 8 shows latency cycles of different components in the system’s memory hierarchy. While Local and DirectCXL exhibits CPU cache by lowering the memory access latency to 4 cycles, RDMA has negligible impacts on CPU cache as their network overhead is much higher than that of Local. The best-case performance of RDMA was 2027 cycles, which is $6.2\times$ and $510.5\times$ slower than that of DirectCXL and L1 cache, respectively. DirectCXL requires 328 cycles whereas Local requires only 60 cycles in the case of L2 misses. Note that the performance bottleneck of DirectCXL is PCIe including CXL IPs (77.8% of the total latency). This can be accelerated by increasing the working frequency, which will be discussed shortly.

4.2 Latency Distribution and Scaling Study

Latency distribution. In addition to the latency trend (average) we reported above, we also analyze complete latency behaviors of Local, RDMA, and DirectCXL. Figure 9 shows the latency CDF of memory accesses (64B) for the different pooling methods. RDMA shows the performance curve, which ranges from 1790 cycles to 4006 cycles. The reason why there is a difference between the minimum and maximum latency of RDMA is RNIC’s MTT memory buffer and CPU caches for data transfers. While RDMA cannot take the benefits from direct load/store instruction with CPU caches, its data transfers themselves utilize CPU caches. Nevertheless, RDMA cannot avoid the network accesses for remote memory accesses, making its latency worse than Local by $36.8\times$, on average. In contrast, the latency behaviors of DirectCXL are similar to Local. Even though the latency of DirectCXL (reported in Figures 6 and 7b) is the average value, its best performance is the same as Local (4~24 cycles). This is because, as we showed in the previous section, DirectCXL can take the benefits of CPU caches directly. The tail latency is $2.8\times$ worse than Local, but its latency curve is similar to that of Local. This is because both DirectCXL and Local use the same DRAM (and there is no network access overhead).

Speed scaling estimation. The cycle numbers that we reported here are measured at each host’s CPU using register-level instrumentation. We believe it is sufficient and better

Figure 9: Memory-level latency CDF (64B).

Measurement clock domain →	DIRECTCXL	PCIe 5.0 x8 (Estimated)	
	CPU (100MHz)	CPU (1.2GHz)	Time delay
L1/L2 cache	30	30	25 ns
CXL IPs (2.0)*	165	287	239 ns
PCIe FlexBus	91	69	57 ns
DRAM controller	42	126	105 ns
Total	328	512	426 ns

*Including RP, EP, and Switch

Unit: cycles

than a cross-time-domain analysis to decompose the system latency. Nevertheless, we estimate a time delay in cases where the target system accelerates the frequency of its processor complex and CXL IPs (RP, EP, and Switch) by 1.2GHz and 1GHz, respectively. Table 2 decomposes `DirectCXL`'s latency of a 64B memory load and compares it with the estimated time delay. The cycle counts of L1/L2 cache misses are not different as they work in all the same clock domain of CPU. While other components (FlexBus, CXL IPs, and DRAM controller) speed up by $4\times$ ($250\text{MHz} \rightarrow 1\text{GHz}$), the number of cycles increases since CPU gets faster by $12\times$. Note that, as the version of PCIe is changed and the number of lanes for PCIe increases by double, FlexBus's cycles decrease. The table includes the time delays corresponding to the estimated system from the CPU's viewpoint. While the time delay of FlexBus is pretty good ($\sim 60\text{ns}$), the corresponding CXL IPs have room to improve further with a higher working frequency.

4.3 Performance of Real Workloads

Figure 10a shows the execution latency of `Swap`, `KVS`, and `DirectCXL` when running `DLRM`, `MemDB`, and four workloads from `Ligra`. For better understanding, all the results in this subsection are normalized to those of `Swap`. For `Ligra`, we only compare `DirectCXL` with `Swap` because `Ligra`'s graph processing engines (handling in-/out-edges and vertices) is not compatible with a key-value structure. `KVS` can reduce the latency of `Swap` as it addresses the overhead imposed by page-based I/O granularity to access the remote memory. However, it has two major issues behind `KVS`. First, it requires significant modification of the application's source codes, which is often unable to service (e.g., `MIS`, `BFS`, `CC`, `BC`). Second, `KVS` requires heavy computation such as hashing at the memory node, which increases monetary costs. In contrast, `DirectCXL` without having a source modification and remote-side resource exhibits $3\times$ and $2.2\times$ better performance than `Swap` and even `KVS`, respectively.

To better understand this performance improvement of `DirectCXL`, we also decompose the execution times into `RDMA`, network library intervention (`Software`), and application execution itself (`Workload`) latencies, and the results are shown in Figure 10b. This figure demonstrates where `Swap` degrades the overall performance from its execution; 51.8% of the execution time is consumed by kernel swap daemon (`kswapd`) and `FastSwap` driver, on average. This is because `Swap` just expands memory with the local and remote based on `LRU`, which makes its page exchange frequent. The

(a) Execution Time.

(b) Execution breakdown.

Figure 10: Real workload performance.

reason why `KVS` shows performance better than `Swap` in the cases of `DLRM` and `MemDB` is mainly related to workload characteristics and its service optimization. For `DLRM`, `KVS` loads the exact size of embeddings rather than a page, which reduces `Swap`'s data transfer overhead as high as $6.9\times$. While `KVS` shows the low overhead in our evaluation, `RDMA` and `Software` can linearly increase as the number of inferences increases; in our case, we only used 13.5MB (0.0008%) of embeddings for single inference. For `MemDB`, as `KVS` stores all key-value pairs into local DRAM, it only accesses remote-side DRAM to inquiry values. However, it spends 55.3% and 24.9% of the execution time for `RDMA` and `Software` to handle the remote DRAMs, respectively. In contrast, `DirectCXL` removes such hardware and software overhead, which exhibits much better performance than `Swap` and `KVS`. Note that `MemDB` contains 2M key-value pairs whose value size is 2KB, and its host queries 8M `Get` requests by randomly generating their keys. This workload characteristic roughly makes `DirectCXL`'s memory accesses be faced with a cache miss for every four queries. Note that `Workload` of `DirectCXL` is longer than that of `KVS`, because `DirectCXL` places all hash table and tree for key-value pairs whereas `KVS` has it in local DRAM. Lastly, all the four graph workloads show similar trends; `Swap` is always slower than `DirectCXL`. They require multiple graph traverses, which frequently generate random memory access patterns. As `Swap` requires exchanging 4KB pages to read 8B pointers for graph traversing, it shows $2.2\times$ worse performance than `DirectCXL`.

5 Conclusion

In this paper, we propose `DIRECTCXL` that connects host processor complex and remote memory resources over CXL's memory protocol (`CXL.mem`). The results of our real system evaluation show that the disaggregated memory resources of `DIRECTCXL` can exhibit DRAM-like performance when the workload can enjoy the host-processor's cache. For real-world applications, it exhibits $3\times$ better performance than `RDMA`-based memory disaggregation, on average.

6 Future Work and Acknowledgement

The authors are extending the kernel for efficient CXL memory management and consider having an SoC silicon as future work of `DirectCXL`. This work is protected by one or more patents. The authors would like to thank the anonymous reviewers for their comments, and Myoungsoo Jung is the corresponding author (mj@camelab.org).

Not that Simple: Email Delivery in the 21st Century

Abstract

Over the past two decades, the number of RFCs related to email and its security has exploded from below 100 to nearly 500. This embedded the Simple Mail Transfer Protocol (SMTP) into a tree of interdependent and delivery-relevant standards. In this paper, we investigate how far real-world deployments keep up with this increasing complexity of delivery- and security options. To gain an in-depth picture of email delivery apart from the giants in the ecosystem (Gmail, Outlook, etc.), we engage people to send emails to eleven differently configured target domains. Our measurements allow us to evaluate core aspects of email delivery, including security features, DNS configuration, and IP version support on the sending side across different types of providers.

We find that novel technologies are often insufficiently supported, even by large providers. For example, while 65.4% of email providers can resolve hosts via IPv6, only 44.3% can also deliver emails via IPv6. Concerning security features, we observe that less than half (41.5%) of all providers rely on DNSSEC validating resolvers, and encryption is mostly opportunistic, with 89.7% of providers accepting invalid certificates. TLSA, as a DNS-based certificate verification method, is only used by 31.7% of the providers in our study. Finally, we turned our eye to the impact modern standards have on unsolicited bulk email (SPAM). We found that greylisting is effective, reducing the SPAM volume by roughly half while not impacting regular delivery. However, and interestingly, SPAM delivery currently seems to focus on plaintext IPv4 connections, making IPv6-only, TLS-enforcing inbound email servers a more effective anti-SPAM measure—even though it also means rejecting a major portion of legitimate emails.

1 Introduction

Electronic mail (email) relies on the Simple Mail Transfer Protocol (SMTP) for delivery. This protocol was first specified in 1982 in RFC 821 and is now close to celebrating its

*Christian Doppler Laboratory for Security and Quality Improvement in the Production System Lifecycle, Security & Privacy Group, Faculty of Computer Science

Figure 1: Overview of the explosion of email-related standards (“SMTP Camel”), compared to DNS-related standards.

40th birthday [39]. SMTP had two design goals, namely to allow *reliable* and *efficient* delivery of emails. As with many protocols of the time, security and authenticity were not priorities [16]. In fact, anyone could relay emails through an SMTP server, which was the default configuration for many email servers – like Sendmail – until the late 1990s [3].

However, the practical reality of the Internet led to increased security and authenticity requirements [16]. Since the mid-1990s, hundreds of protocols and extensions have been introduced to cover these gaps, as illustrated in Figure 1. In order to authenticate email, attempts mostly rely on the *Domain Name System* (DNS), which, in turn, suffers from authenticity issues. To address those issues, the *DNS Security Extensions* (DNSSEC) were introduced in 1999, which enabled signing DNS entries [1]. Besides authenticity, the original email protocol faced other security-related challenges, most notably confidentiality, as emails were exchanged in plaintext. In addition to end-to-end encryption approaches like Pretty Good Privacy (PGP) [7], this led to an extension of SMTP for Transport Layer Security (TLS) [18]. Finally, like all protocols on the Internet, SMTP was also affected by the introduction of IPv6.

All these factors have turned the *simple* from SMTP to *complex*. To outline this increase in complexity, we created the *SMTP Camel* in Figure 1 (after the famous DNS Camel of

Bert Hubert, who illustrated the complexity of DNS with “*How many features can we add to this protocol before it breaks?*” [23]). Figure 1 visualizes RFCs related to email – and, for reference, DNS. We compiled this list by performing a title/keyword search on all RFCs on September 28, 2021.¹ In total, we found 481 email-related RFCs compared to 298 DNS-related ones. Among these, more than half of the RFCs belong to the standards track, representing mature standards. We see no development in draft standards as they were declared as deprecated in 2010 [21]. In June 2021, we reached a total of 225 proposed standards. Proposed standards only advance to Internet standards once they have “*widespread deployment of multiple implementations from different code bases*” [21]. Currently, only eleven email-related RFCs have met this requirement, and also the handling of this guideline by the Internet Engineering Task Force (IETF) varies. This indicates that the development of new standards has outpaced their implementation. Furthermore, since the latest email measurement study in 2020 [31], seven new email-related RFCs have been published.

In this paper, we investigate how the increasing number of additional standards has influenced email delivery in the wider ecosystem. Related work already demonstrated that adoption rates of email-related standards are low and implementations often rely on insecure defaults [8, 14, 17, 22, 26, 31, 37, 45]. However, previous work predominantly focused on large operators, such as Google (Gmail) or Microsoft (Outlook), and did not investigate fundamental aspects of email standards, like supported IP versions and the DNS infrastructure of sending systems. We take a step back and investigate the most fundamental aspects of email in transit across a wide sample going beyond major email providers.

To accomplish this, we introduced eleven target address configurations to verify how email providers implement email-related standards and protocols, i.e., we set up systems that – depending on the remote server’s configuration and implementation – either do or do not receive measurement emails. Our measurement technique allows us to measure IP support, STARTTLS configuration, DNSSEC validation, and how different SMTP applications react to greylisting, an anti-SPAM technique by which incoming emails are initially rejected. Our focus is on protocols that influence email delivery once an email has been submitted. To increase the providers’ coverage, we crowdsourced the sending of emails to participants recruited through mailing lists and social media.

As a result, we collect emails from three different sources, spanning (1) small participants in the email ecosystem, (2) large providers, and (3) unsolicited bulk email, aka SPAM. We are the first to discuss the impact of new and established standards on email delivery, as – in contrast to most related measurements – we rely on actively collecting emails, allowing us a more in-depth view of email server configurations.

¹https://www.rfc-editor.org/search/rfc_search_detail.php

In summary, we make the following contributions:

- We introduce a new ranking method using passive data to find the top 15 email providers. Our results highly overlap with Liu et al. [32], while causing significantly less measurement overhead (see Section 3).
- We illustrate challenges in the interoperability between large centralized operators and smaller operators, including how the ability to deliver emails as the main objective limits the adoption of new network and security protocols. We describe how our datasets cover different actors in the email ecosystem in Section 4.
- We are the first to measure and connect the impact of protocol extensions in protocols email relies on – DNS(SEC) and IPv6 – to email delivery and the contrast between smaller and larger providers (see Section 5).
- We illustrate protocol support and compliance in the heavy-tail of the email ecosystem, i.e., in a large set of smaller email operators, and contrast this to earlier work and patterns found in large providers (see Section 6).
- Based on our results, we derive recommendations for email system operators on how they can utilize modern protocol compliance to – currently – reduce SPAM delivery (see Section 7).

Artifacts: Our measurement can be executed using any valid domain and a set of machines connected to the Internet. Along with our paper, we publish a setup-documentation and the scripts we used to receive and analyze emails sent to our systems at <https://github.com/ichdasich/email-measurement-toolchain>. For privacy reasons, we cannot publish our email dataset. This also applies to the SPAM dataset, as even SPAM may contain PII, for example in the recipient addresses.

2 Background: Protocols and Standards

In this paper, we focus on standards influencing email delivery between email servers, i.e., the Mail Transfer Agent (MTA). Email submission, e.g., the communication between Mail User Agent (MUA) and Mail Submission Agent (MSA), is not part of our study. We focus on IP- and DNS-related mechanisms that impact delivery. Interpretations of higher-level delivery security features, like the Sender Policy Framework (SPF) [27], DomainKeys Identified Mail (DKIM) [9], Authenticated Received Chain (ARC) [4], and Domain-based Message Authentication, Reporting, and Conformance (DMARC) [30] are out of scope for our study, as they only influence the receiver’s decision on whether to accept incoming emails or not. We also did not include MTA Strict Transport Security (MTA-STS) in our study as this RFC was too recent

when we set up our infrastructure [33], but Section 3 describes how our work can be extended to include it in the future.

IPv4 [38] and IPv6 [10]. Since addresses in the 2^{32} bit address space of the Internet Protocol Version 4 (IPv4) are running out [41], Internet Protocol Version 6 (IPv6) with a 2^{128} bit address space was introduced in the late 1990s. Two concurrent IP versions introduce a great challenge in terms of interoperability on the network layer, especially as the adoption of IPv6 is still slow [25]. IP version support impacts email delivery *indirectly* via DNS support, i.e., the authoritative and recursive servers support the same IP version, and *directly*, i.e., in terms of whether the involved email servers both support the same IP version. Servers can support IPv4, IPv6, or both—also referred to as “dual-stack.”

DNSSEC [5]. The DNS-Security Extensions (DNSSEC) provide authenticity to DNS responses by signing DNS entries via a keychain along the path of the DNS tree. A DNSSEC validating recursor responds with `SERVFAIL` in case of a validation error. As a consequence, the target domain cannot be resolved, and email delivery fails. Hence, in case of misconfigurations – common in system operations [11] – or attacks, the DNSSEC validation behavior of DNS resolvers at email-sending servers becomes important for email delivery. Similarly, DNSSEC is a prerequisite for DANE (see below).

STARTTLS [19]. The SMTP Service Extension for Secure SMTP over TLS (STARTTLS) enables TLS for email delivery. The connection is established on the same port as SMTP. The original SMTP handshake remains in cleartext. Sending- and receiving servers can (1) not support TLS, (2) support TLS and cleartext, (3) enforce TLS. TLS can be configured either in an (a) opportunistic or (b) strict manner. While opportunistic TLS configurations allow for encrypted connections not validating the remote certificate, strict configurations cause email delivery to fail in case of (1) invalid certificates, (2) not supporting mandatory ciphers, or (3) a connection to a non-TLS-supporting server. In turn, this can then impact email delivery, depending on whether a connection can be established or not.

DANE [20]. The DNS-Based Authentication of Named Entities (DANE) prevents MTA-to-MTA transport encryption from downgrade attacks, even in the absence of certificates signed by a certificate authority (CA); this is done through recording valid CA or end-entity certificates for a domain name via the TLSA DNS record. Trusting/guaranteeing the authenticity of TLSA records (i.e., preventing MITM and DNS cache poisoning scenarios) requires the use of DNSSEC, as described above. Several email server implementations, including Sendmail and Microsoft Exchange, do not yet support requesting TLSA records, in contrast to for example, Postfix and Exim [31].² DANE can be implemented similar to

²Microsoft announced support after our measurement period in Feb, 2022 (see <https://techcommunity.microsoft.com/t5/exchange-team-blog/releasing-outbound-smtp-dane-with-dnssec/ba-p/3100920>)

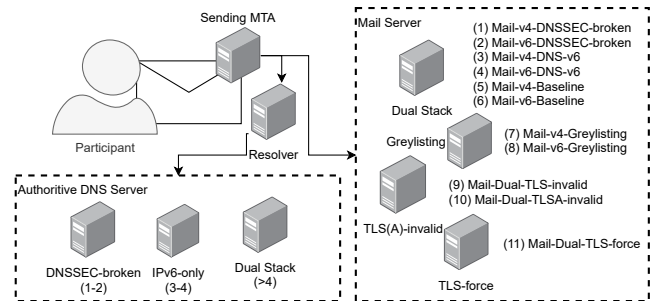

Figure 2: Overview of our measurement setup: 3 DNS servers serve 4 email servers with 11 differently configured target addresses.

TLS in an opportunistic or mandatory manner. Email delivery fails for both opportunistic and mandatory configurations if a signed TLSA record is available but certificate validation fails or for mandatory configurations if no TLSA record can be found.

Anti-SPAM (Greylisting [29]). Greylisting is one of the most simplistic approaches to reduce SPAM emails. It works by initially responding with SMTP code `4xx temporary failure`. While reputable servers usually re-attempt email delivery after several minutes, many SPAM senders do not keep enough state for this. For email delivery, greylisting introduces delays, and email delivery fails if an implementation does not attempt redelivery.

3 Methodology

Measurement Platform. Our measurement setup consists of four email servers running Postfix 3.6 [40] on OpenBSD 6.7 [36] in OpenBSD virtual machines (VMM). As we conduct non-performance bound network measurements, the exact type and model of the used hardware are not relevant to our measurement platform. Furthermore, we rely on three PowerDNS authoritative nameservers in version 4.3.1 to measure the impact of different DNS server setups. We configured a non-default TTL of 300 seconds for all entries in our DNS zones to minimize the impact of caching, i.e., a DNS resolver used by multiple study participants. This also affects our weekly spam domain rotations, pointing them at different measurement target addresses. However, we consider a maximum overlap of five minutes in comparison to a one-week measurement period negligible. IPv6 connectivity to our systems was provided via a Hurricane Electric IPv6 tunnel, while IPv4 connectivity was provided via dedicated IP space from the RIPE region. On these systems, we set up eleven email addresses, as shown in Figure 2. For each of these addresses, we applied different configuration states, which either enable or prevent remote servers from sending emails to them, depending on their own configuration state. This allows us to measure the remote servers’ email delivery capabilities and protocol use by measuring whether they are able to deliver

Figure 3: List of email addresses for the 11 target configurations.

emails to these email addresses. We then asked participants to send *one* email with all measurement addresses in the `To:` field. If we do not receive a message at a specific target address but see in our baseline that the target is included in the `To:` header, we know that the respective feature is not supported. The target addresses can be easily extended to cover new protocols, e.g., MTA-STS [33] was introduced as a barrier against downgrade or interception attacks for domains that are unable to deploy DNSSEC. MTA-STS can be measured by adding two new target addresses in the future. One could implement the TLS-RPT standard to measure TLS reporting frequency, and the other could measure if providers still deliver emails in case of an enforced MTA-STS policy with non-matching MX records.

3.1 Target Address Configurations

We configured the following eleven different email addresses at the unique destination domains listed in Figure 3. Below, we describe the purpose of each of these addresses, i.e., which configuration parameters we tested with them:

IP Support. In order to test basic delivery behavior, we created for both IPv4 (`measurement@v4-mail.`, *Mail-v4-Baseline*) and IPv6 (`measurement@v6-mail.`, *Mail-v6-Baseline*) one address which is configured with no restrictions on delivery. Similarly, we created distinct IPv4- and IPv6 addresses for the DNS and greylisting measurements described below. Note that during our study, we noticed that our choice not to support STARTTLS on this system did indeed introduce an unexpected parameter in the case of senders that enforce STARTTLS use. In turn, this allowed us to detect six providers that enforce STARTTLS for outgoing emails.

DNS Recursion IPv6 Support. To test whether the recursive resolvers of an email sending host support IPv6, we created a subdomain that can only be resolved via IPv6, i.e., the zone had only AAAA glue records, and the hosts in the zone’s NS records also only have AAAA records. Under that domain, we then again created two addresses for IPv4 and IPv6 delivery (`measurement@v4-mail.v6only.`, *Mail-v4-DNS-v6* and `measurement@v6-mail.v6only.`, *Mail-v6-DNS-v6*).

DNSSEC Validation. To test if the remote site validates DNSSEC, we set up a subdomain with a non-matching DS RRset in the parent, i.e., we provide a public key in the parent zone that does not match the key with which records are signed in our zone. Hence, a DNS recursive resolver validating DNSSEC is unable to validate DNSSEC for our domain and should therefore refuse to resolve it. Thus, an email server using a validating resolver cannot deliver emails to that domain. Under that domain, we again created two addresses for IPv4- and IPv6 delivery (`measurement@v4-mail.dnssec-broken.`, *Mail-v4-DNSSEC-broken* and `measurement@v6-mail.dnssec-broken.`, *Mail-v6-DNSSEC-broken*).

TLS Configuration. In order to test the TLS and TLSA behavior of sending hosts, we configured three email addresses that required the use of TLS to deliver emails:

- `measurement@mail-tls-force.`
Mail-Dual-TLS-force on a correctly configured TLS enabled server.
- `measurement@mail-tls-invalid.`
Mail-Dual-TLS-invalid on a server that provides a certificate with a non-matching CN/DNS0 entry.
- `measurement@mail-tlsa-invalid.`
Mail-Dual-TLSA-invalid on a server that has a TLSA record configured, which does not match the supplied certificate.

This setup allows us to verify if systems (1) support STARTTLS, (2) perform opportunistic encryption, and (3) verify TLSA records. Due to a misconfiguration, these systems initially did not support TLS1.3. Hence, remote systems that only support TLS1.3 would be unable to deliver their emails. We were able to isolate the affected cases (76 emails from 29 providers) and reconstructed the actual state from the stored SMTP sessions, as the abort conditions differ between ‘not supporting TLS,’ ‘rejecting the certificate/TLSA record,’ and ‘not having a matching cipher.’

Anti-SPAM (Greylisting). To identify RFC-compliant SMTP implementations, and as an additional control, we set up Postgrey that performs greylisting as an anti-SPAM measure (`measurement@v4-mail-greylisting.`, *Mail-v4-Greylisting* and `measurement@v6-mail-greylisting.`, *Mail-v6-Greylisting*). By configuring these addresses, we can test the impact of greylisting on average SPAM received and check whether legitimate email servers support multiple delivery attempts.

3.2 Email Collection and Recruitment

In order to provide different views on email delivery, we target three types of actors in the email ecosystem: (1) Regular providers by actively engaging users to send emails to our measurement system. (2) A set of top-ranked email providers

Table 1: Recruitment channels for study participants.

Type	Name	Description

Personal	-	Colleagues and personal networks, especially in the APNIC and LACNIC regions

by registering user accounts and sending emails. (3) Spammers by registering expired domains and collecting unsolicited emails targeting these domains.

Regular Providers. To collect emails, we actively engaged Internet users to participate in our study. We recruited participants via a social media campaign on Twitter, LinkedIn, and Reddit, via mailing lists focusing on email and network operators, blog articles promoted by Internet governance bodies, and our personal networks (see Table 1). Our recruitment message asked users to visit our website, which provided instructions on how the reader can participate in our study, what the purpose of our study is, and what data access and deletion rights they have. One critical aspect was to ensure that we would be able to distinguish whether an email to one of our measurement hosts was sent and not delivered or not sent at all. Thus, we instructed participants to add all measurement addresses to the `To:` field of a single email. In case a participant's provider performed pre-filtering, e.g., did not accept delivery to domains they cannot resolve, we removed affected emails from the dataset.

Large Providers. In order to rank email providers, we rely on the passively collected Farsight SIE DNS dataset [43]. This enables us to count email servers to which a lot of domains point their MX records, i.e., email servers used for a lot of domains. We assume that the number of domains using a provider's email servers correlates to the provider's size. For our ranking, we use DNSDB MX data extracted for November 2020, which includes data of 73,705,268 different MX lookups. We do not rank providers based on the amount of MX lookups, as low TTLs or different DNS resolver setups might bias the number of lookups. For each MX, we extract the public suffix, i.e., 'example.com' for 'mail.example.com' and 'example.co.uk' for 'mail.example.co.uk' using the Public Suffix List [35]. This results in 23,378,583 different public suffixes. We rank public suffixes of MX records by counting

Table 2: Categories of domains from ExpiredDomains.

Category	Description
1990s	Domains with the first screenshot available on Archive.org between 1990 and 2000 (= "birth year")
alexa	Domains selected based on Alexa traffic rank
backlinks	Domains based on number of Majestic external backlinks
dmoz	Domains found in the latest snapshot of dmoz.org (~2017)
majestic	Domains with low Majestic million global rank
wiki	Domains with high numbers of Wikipedia links

the number of different domains pointing their MX records towards them. We then register accounts at the top 15 providers according to this ranking to send emails to our target domains, as done in prior work [17, 22, 31, 32, 45]. This enables us to compare email delivery from regular providers with an exclusive set of large providers, but also to compare the results of our measurement pipeline to the results of prior work.

Spammers. To collect SPAM emails, we registered expired domains that are still likely to receive SPAM. To do so, we relied on `expirreddomains.net` for a list of domains [42]. To increase the likeliness that respective domains still receive SPAM, we chose them from different categories, based on their age ("birth year," i.e., the first entry in `Archive.org`), their popularity according to rankings from Alexa and Majestic, and the number of links from Wikipedia and the (now defunct) DMOZ content directory. Table 2 lists these categories; Table 3 lists the domains in each category, as well as the volume of SPAM we received during our measurements.

Once registered, we pointed MX records of respective domains at our target domains. To identify if domains still receive SPAM, we executed a three-week baseline measurement. During this period, all 50 re-registered domains pointed their MX records to the MX of *Mail-v4-Baseline*, i.e., our most basic configuration. We classified the domains' value for our measurement based on the amount of SPAM received as *high* (multiple times a week), *low* (once a week), and *none* (none received). To verify that received messages are SPAM, we consulted four active DNS blocklists: `bl.spamcop.net`, `ip.s.backscatterer.org`, `pbl.spamhaus.org` and `sbl.spamhaus.org`. We continuously verified the liveness of these blocklists by requesting IP 127.0.0.2 as a test record.

In total, we found 26% of domains receive SPAM on a regular basis, thus falling into category *high*. In the next step, we pointed high-value SPAM domains towards a set of our target addresses in a weekly rotation until each domain had been pointed at each target at least once. This allowed us to monitor the change in SPAM volume based on the corresponding test conditions. For these measurements, we relied on a reduced set of target addresses. As we only received individual emails and did not simultaneously measure all conditions for each sender, we did not differentiate IPv6 behavior for different target addresses. We only verified general IPv6 support (*Mail-v6-Baseline*), IPv4 sending for IPv6 only DNS (*Mail-*

v4-DNS-v6), DNSSEC behavior (*Mail-v4-DNSSEC-broken*), as well as our three TLS configurations.

3.3 Ethical Considerations

As our measurements focus on the technical aspects of the involved email setups, this study was not within the scope of our local human subject research ethics council. Nevertheless, we informed participants about the purpose of our data collection, which information we collected, and that they could withdraw from the study at any time. We received one request to be removed from the dataset and complied with this request immediately. In addition, we followed network measurement best practices as outlined in the Menlo report [6, 12].

Figure 4: Validation of regular study participants tend to be/use small email providers. We match regular providers to the passive DNS ranking.

This means that we took the necessary technical precautions to protect the only Personally Identifiable Information (PII) we collect, i.e., the sending email addresses. We removed these addresses from our dataset as soon as possible before we started the aggregation of our collected data. Also, since the provider name might reveal PII, we do not publish or share provider names of smaller providers. For our measurements of large providers, we registered accounts ourselves and published their names for better comparison to related work, in accordance with common practice for email-related measurements [17, 22, 31, 32, 45].

4 Datasets

By following our approach, we collected three datasets covering (a) regular providers by volunteers sending emails to our measurement infrastructure, (b) large providers by registering accounts and sending emails ourselves, and (c) spammers by collecting unsolicited emails sent to re-registered domains.

(a) Regular Providers. Between July 4, 2020 and October 29, 2021 we received a total of 5,847 emails. After filtering emails that do not cover all eleven target addresses in the To: field, a total of 4,660 emails sent by 622 study participants remained for further analysis. There is a clear dominance of emails from European countries, see Table 5, a consequence of recruiting via our personal channels (e.g., on Twitter).

Multiple participants used the same infrastructure to send emails; beyond, emails of the same user might be sent by multiple servers in the same domain (e.g. `server1.domain.any` and `server2.domain.any`). Thus, we grouped the data set using the email servers’ first-level domain (EHLO name) at the granularity of providers. This yields a total of 436 providers.

(b) Large Providers. Analysis of the Farsight SIE DNS dataset revealed the top 15 providers as presented in Table 4. We noticed a large gap in served domains even within the top 15 providers, ranging from 14.1% (Google) to 0.68% (1&1) of first-level domains (FLDs) in our passive DNS dataset. The top 15 providers jointly serve 33.8% of all FLDs with MX hosts. To gain an overview of provider sizes in our regular dataset, we matched regular providers with domains in the

Table 4: Top 15 providers based on passive DNS data. Providers greyed out have no online email service, e.g., *Above.com* is a domain broker.

Table 5: Number of countries/emails/AS per region. Our social media promotion led to an increased number of emails from European countries. We skipped large providers as geographical data has no impact on our provider ranking.

Region	Africa	Asia	Europe	N. America	Oceania	S. America
Regular						
Countries	5	12	30	2	1	3
Emails	48	168	3,368	1,045	1	30
ASes	5	19	202	60	1	3
SPAM						
Countries	22	32	36	15	2	11
Emails	95	2,056	1,963	2,437	17	204
ASes	50	254	234	170	9	119

passive DNS dataset. Figure 4 shows the amount of FLDs pointing at each of the study participants’ domains for email. 80% of regular providers have less than 150 domains relying on them for email service. Comparing our top 15 providers with previous work, we find the largest overlap, namely eleven providers, with Liu et al. [32], who used a five-step approach including MX records, Banner/EHLO messages, and TLS certificates to detect large email providers. Previous work relying on manual ranking results in less overlaps, namely six [14], three [17], two [31, 45], and one [22] (see Table 4), and suggests that human perception of providers is different from their actual dominance in the email ecosystem.

(c) Spammers. We executed SPAM measurements in three phases. First, we conducted a baseline measurement from March 30, 2021 to April 6, 2021. Next, we pointed SPAM domains to our other target addresses in a weekly rotation. Finally, we did another baseline measurement to ensure that the baselines remained stable over our observation time. We received a total of 6,772 unsolicited emails. Thereof, 4,442 (65.7%) were classified as SPAM by one of our four DNS blocklists, suggesting that emails towards the re-registered domains are indeed SPAM. We included all received emails in our further analysis. In comparison to our regular provider dataset, SPAM emails are not dominated by a single region (see Table 5). In comparison to regular and large providers, we can only measure the SPAM volume and its reduction in dependence of the different configurations.

5 Results

For each of the three datasets, namely (a) *regular providers*, (b) *large providers*, and (c) *spammers*, Figure 5 shows the ratio of delivered to undelivered emails per target address. We provide the individual results for the top 15 providers, including a line indicating the optimal configuration, in Table 4. The optimal configuration includes IPv4- and IPv6 support for both email servers and DNS resolvers. Regarding TLS, providers should implement opportunistic STARTTLS, i.e., still use transport encryption when facing self-signed or expired certificates.

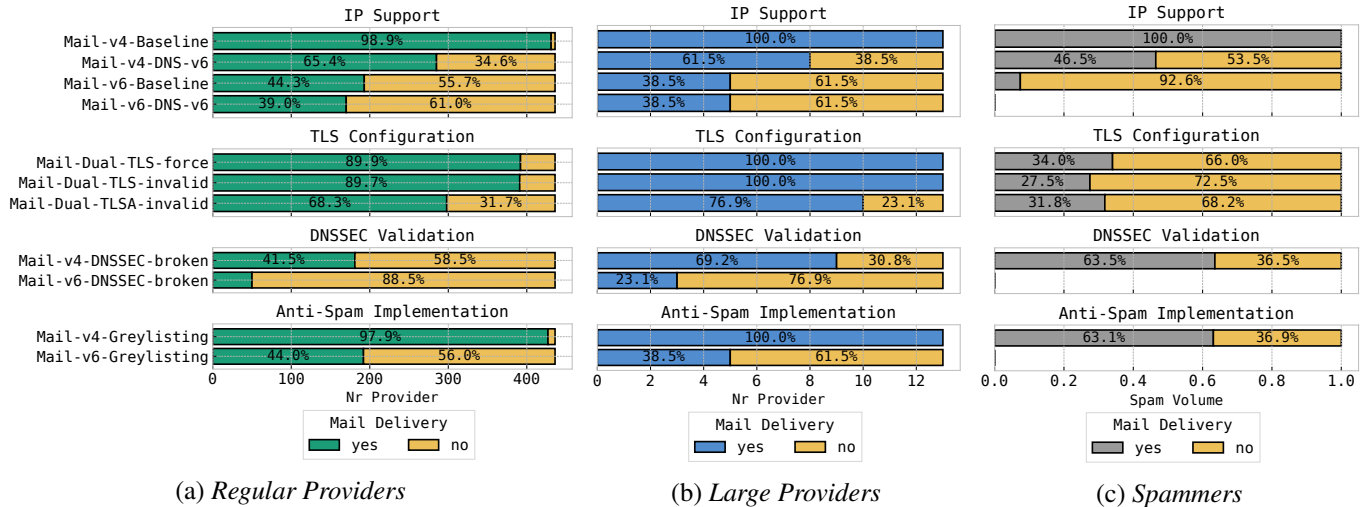

Figure 5: Impact of different target address configurations on email delivery. For our investigation of spammers we skipped the IPv6 target addresses other than the baseline (this affects greylisting, DNSv6, DNSSEC).

However, they should validate TLSA records and reject email delivery in case of an invalid record. As a foundation for DANE and other DNS-based security standards, a provider should rely on a DNSSEC supporting and -validating resolver. Looking at the top 15 providers, we find major discrepancies for even the largest providers. We discuss our measurement results on IP support, TLS configuration, DNSSEC validation, and anti-SPAM implementation in the following sections.

5.1 IP Support

Email Servers. The *Mail-v4-Baseline* is configured without any restrictions on email delivery. For regular providers, however, this baseline is reduced by 5/436 (1.2%) as five providers enforced TLS causing undeliverability (see also Section 3.1). For large providers, the baseline is met by all providers. For spammers, the baseline is necessary to estimate the number of SPAM emails that are typically sent to the investigated domains. For all three populations, the delivery to *Mail-v6-Baseline* is reduced compared to the IPv4 baseline, implying limited deployment of IPv6 at email servers. Differences among regular and large providers remain small – the first received IPv6-only mails in 193/436 (44.3%) of the cases, the latter in 5/13 (38.5%) –, however, SPAM towards the IPv6 target is drastically reduced and accounts for 7.4% of the IPv4 baseline.

DNS Resolvers. Both targets, *Mail-v4-DNS-v6* and *Mail-v6-DNS-v6*, rely on an IPv6-only authoritative nameserver and allow to infer whether resolvers are capable of IPv6. The number of successfully delivered emails to *Mail-v4-DNS-v6* is consistently higher than for IPv6-only email servers (*Mail-v6-Baseline*) – 285/436 (65.4%) vs. 193/436 (44.3%) (regular providers), 8/13 (61.5%) vs. 5/13 (38.5%) (large providers),

Table 6: DNS and email server IP support levels (IPv4 only, IPv6 only or dual stack) of regular providers; reads f.e. 22 (5.0%) have dual stack email servers, but IPv4-only DNS resolver.

DNS	Email			
	IPV4	IPV6	Dual	
IPV4	125	28.7%	1	0.2%
IPV6	0	0.0%	0	0.0%
Dual	116	26.6%	0	0.0%
			22	5.0%
			1	0.2%
			171	39.2%

and 46.5% vs. 7.4% (spammers) – and lead to the conclusion that IPv6 support is more prevalent among DNS resolvers than among email servers. The difference is particularly remarkable for SPAM, and suggests that spammers rely on external DNS resolvers. In comparison to *Mail-v6-Baseline*, delivery towards *Mail-v6-DNS-v6* is, if at all, only slightly reduced – 193/436 (44.3%) vs. 170/436 (39%) (regular providers), and 5/13 (38.5%) vs. 5/13 (38.5%) (large providers) –, i.e., IPv6 support at the email server typically implies IPv6 support at the respective DNS resolver. For the regular providers, Table 6 shows interdependencies concerning IP support: Most dominant are dual stack implementations 171/436 (39.2%) resp. IPv4-only configurations for email and DNS 125/436 (28.7%), as well as IPv4-only email servers with dual stack DNS resolvers 116/436 (26.6%).

Key Findings. In summary, we find that less than half of all regular email providers support IPv6 for their email deployments. Interestingly, IPv6 support for DNS is more frequent, even for providers that do not support IPv6 for their email servers. We conjecture that this is connected to – especially in smaller setups – using public resolvers like the commonly known Cloudflare (1.1.1.1) or Google (8.8.8.8) instances. Interestingly, we also find that 23/436 (5.3%) of the observed

providers *do* use IPv6 for their email setup while *not* using it for their DNS resolvers. Even though finding this case is not unsurprising – PowerDNS, for example, does not perform IPv6 resolution by default—it still means that these operators are not able to deliver emails to IPv6-only zones, even though their email servers support IPv6.

5.2 TLS Configuration

TLS Enforcement. If our target *Mail-Dual-TLS-force* enforces the use of TLS, 392/436 (89.9%) of the regular and all large providers behave accordingly. These numbers indicate a high prevalence of TLS capability among email servers. Concerning SPAM, TLS enforcement has a considerable effect and reduces the number of emails to 34.0%.

TLS Validation. In the presence of invalid certificates, as provided by *Mail-Dual-TLS-invalid*, a similar picture emerges for regular and large providers. As common practice suggests [13] providers regularly fall back on opportunistic STARTTLS. Just one of the regular providers is more strictly configured and rejects email delivery in the case of a certificate with a non-matching CD/DNS0 entry. TLSA mismatch as caused by *Mail-Dual-TLSA-invalid* should technically prevent opportunistic encryption from being used. However, we find that only 138/436 (31.7%) of regular providers and 3/13 (23.1%) of large providers honor the TLSA record and refuse delivery. When we turn our eye to SPAM delivery, we find that enforcing TLS has a significant impact on the number of received emails. On our two TLS-enforcing targets, only 27.5% (*Mail-Dual-TLS-Force*) and 31.8% (*Mail-Dual-TLSA-Invalid*) of the baseline values of emails are received.

Key Findings. The broad majority of providers support TLS. However, emails from 10.1% of regular providers in our dataset would be lost in case of enforcing it. Providers fulfilling TLS enforcement typically also fall back on opportunistic encryption in case of invalid certificates. TLSA – a method to move beyond opportunistic encryption, even in the absence of CA-signed certificates – is sadly ignored by the majority of providers. At the same time, TLS enforcement does not only increase security, but it also reduces SPAM by more than 65%. While spammers could implement TLS quickly, it still would force them to adopt more costly TLS handshakes.

5.3 DNSSEC Validation

Targets *Mail-v4-DNSSEC-broken* and *Mail-v6-DNSSEC-broken* allow to infer the prevalence of resolvers validating DNS records. For regular providers, 181/436 (41.5%) delivered emails to our first target. The remaining 255/436 (58.5%) of all providers conducted a thorough validation for DNSSEC. Among the large providers, DNSSEC validation appears less prevalent: Only 4/13 (30.8%) (IPv4) and 2/5 (40.0%) (IPv6) of providers validate DNSSEC. We suspect that operators

refrain from deploying DNSSEC to avoid customers missing emails or being unable to send emails due to misconfigurations. Furthermore, we observed a significant SPAM reduction for domains with broken DNSSEC. We conjecture that this is due to common open resolvers that validate DNSSEC being regularly used by spammers. This suspicion was confirmed when we revisited our DNS servers' logs to identify the most commonly used DNS resolvers. Query logs are, however, not fully available as log rotations removed some logs due to high response numbers. Still this enabled us to identify the most commonly used DNS resolvers. We were able to match resolvers for 2839/4660 (61%) regular emails and for 3399/6772 (50.2%) of emails sent by spammers. We found 1,443 unique resolver IPs for regular providers and 1,774 for spammers. Relying on MaxMind's public GeoLite AS database, we looked up AS information for each IP. This resulted in 259 unique ASes used for DNS resolution for regular providers and 269 for spammers. Comparing the DNS servers used by regular and large providers with those used by spammers revealed an overlap of 138 IPs and 62 ASes.

Key Findings. DNSSEC validation is performed in 255/436 (58.5%) (IPv4) and 143/193 (74.0%) (IPv6) and regular providers. The numbers for large providers are lower, i.e., 4/13 (30.8%) (IPv4) and 2/5 (40.0%) (IPv6). In comparison, previous work [8] found DNSSEC to be less common; however, those measurements focused on zones using DNSSEC. The numbers for DNSSEC validation among spammers are – surprisingly – comparable to those of large providers. However, this connects to spammers regularly using public resolvers that already validate DNSSEC.

5.4 Anti-SPAM (Greylisting)

The greylisting targets *Mail-v4-Greylisting* and *Mail-v6-Greylisting* provoked an error in delivery the first time and accepted the email in a second – delayed – attempt. Legitimate providers reattempt to deliver emails in case of a failure, and our measurements indeed show that this is the case. Only 4/436 (0.9%) (IPv4) and 1/193 (0.5%) (IPv6) of the regular providers refrain from retransmission, and no large provider does so. However, greylisting reduces the number of received SPAM emails by 36.9%. Interestingly, this makes greylisting a less effective anti-SPAM measure than enforcing TLS.

Key Findings. Greylisting reduces the SPAM volume by 36.9% and does not introduce delivery problems for legitimate email. However, greylisting has less impact than TLS enforcement, which reduces SPAM by over 65%.

6 Related Work

In the past years, email has been receiving significant attention from the research community. In this section, we systematize eleven email-related measurement studies from 2014 onward.

Table 7: Measured adoption rates by related work. Percentages are collected for domains with MX records. SPF, DKIM and DMARC are included for comparison only as they merely influence the receiver’s decision to accept incoming emails.

Citation	Year	Active Meas.	Domains	Sample Size	SPF	DKIM	DMARC	DNSSEC	DANE	TLS (inc.)
Adkins et al. [2]	2014		Facebook	/	-	-	-	-	-	76%
Foster et al. [17]	2015		Alexa	1M	42.3%	-	1%	3.4%	-	-

*: We can only verify the percentage of DNSSEC resolvers and TLSA validating email servers.
 •: Studies with active measurements
 x: Mix of Alexa top 1M, Tranco, Majestics

We find that these studies use different sample sets and measurement methodologies. Sample sets range from top 1M domain lists to email collections with sample sizes from a million domains to a few thousand. However, using different methodologies, they all ultimately report comparable adoption rates of security-related email protocols, including SPF, DKIM, and DMARC. Hence, we compare their adoption rates and findings to our results in Table 7 to validate our methodology and provide a comprehensive picture of current providers’ email delivery capabilities. Related work on email delivery so far primarily focused on large providers and did not consider the transport perspective – especially IPv6 and DNS – highlighting the gap our work fills.

Adoption Rates. Looking at the reported adoption rates from related work, we do find an upward trend in adoption, especially for security-related standards. We can also observe the difference in adoption rates per region. For example, .nl sees a 53% adoption rate of DNSSEC, which is significantly higher than the, e.g., 7.67% adoption rate for DNSSEC for Tranco Top 10K domains reported by Yajima et al. [34]. We attribute this high adoption rate to the Registrar Scorecard, a campaign incentivizing the deployment of standards by the Dutch domain name registrar SIDN, responsible for the .nl top-level domain [44]. In contrast to the number of DNSSEC-enabled zones, we find the number of validating resolvers to be considerably higher. We find a 57.35% of participants in our study rely on DNSSEC-validating resolvers, mostly due to common public resolvers, for example, the popular 8.8.8.8 resolver offered by Google.

Large Providers. Related work uses several methods for identifying and ranking large email providers (see Table 8): Durumeric et al. [14], Hu et al. [22], and Tang et al. [45] used manual rankings by relying on their own expertise. However, this might induce bias towards the researcher’s experience and location. Foster et al. [17], and Lee et al. [31] relied on email address domains from the leak of Adobe user records

Table 8: Overview of large provider sets used in related work.

Year	Rel. W.	Overlap	Size	Method
2015	Durumeric et al. [14]	6	19	Manually
2015	Foster et al. [17]	3	22	Adobe leak
2018	Hu et al. [22]	1	35	Manually
2020	Lee et al. [31]	2	29	Adobe leak
2021	Tatang et al. [45]	2	25	Manually
2021	Liu et al. [32]	11	15	Custom
2021	Our work		15	passive DNS

in 2013 [28] to rank email providers. However, this approach is limited to a one-time data dump and in completeness as it cannot detect different domains pointing their MX records at the same provider. Liu et al. [32] proposed a more comprehensive approach to detect and rank email providers in 2021. One of their major components is certificate information gathered through Internet-wide SMTP handshakes. In contrast, we introduce a new ranking method based on already existing passive DNS data from DNSDB (see Section 3). Based on this ranking we list the top 15 providers in Table 4. Our method thereby overlaps highly with the results of Liu et al., while introducing significantly less measurement overhead and revealing additional providers.

Sender-side Evaluation. We only found two related measurement studies relevant to the sender-side aspects of email delivery [8, 31]. Chung et al. [8] performed a study focusing on DNSSEC adoption independent of email delivery setups in 2017. They set up ten differently misconfigured target domains (missing, incorrect, expired RRSIGS; missing DNSKEYS; incorrect DS; etc.), collecting data from 4,427 DNSSEC capable resolvers (DO bit set) from the Luminati proxy service. They found that 3,635 (81.1%) failed to validate DNSSEC responses. Only 543 (12.2%) resolvers did handle all ten different scenarios correctly. As we did not focus on DNSSEC validation specifically, but only wanted to test if validation was attempted, we relied on a single DNSSEC

setup for our measurement. Similar to us, Lee et al. [31] used 14 target domains to measure DNSSEC, STARTTLS, and DANE validation in 2020. However, they only measured the top 29 providers ranked by email addresses in the Adobe leak. The measurement setup is similar to ours, but contrary to Lee et al., we actively engaged participants to send emails to our target domains. Hence, we were able to cover a wider range of providers. Our set of large providers also differs from Lee et al. as we used a more comprehensive ranking method, similar to that of Liu et al. [32]. Other studies evaluate email-related protocols from the receiver’s perspective [2, 14, 17, 26], i.e., evaluating emails once they are successfully delivered. For example, studying DNS TXT records between 2015 and 2018, van der Toorn et al. [46] observed a rise in the adoption of email security standards, such as SPF and DKIM, and attributed this to stricter policies from large email providers. However, this line of work generally finds similar problems on the receiver side as we observed on the sender side, e.g., the high complexity of standards, generally low adoption, and therefore, low validation rates. Durumeric [14] found that SPF network ranges are usually configured overly broad, e.g., nearly 30% of domains allow IPv4 address ranges of more than a /16 to originate emails. Furthermore, SPF inclusions are not used carefully, and a multitude of domains trust the same handful of cloud providers. Hu et al. [22] found that 34 of 35 (97%) of popular email providers deliver forged emails to inboxes even if validation of either one or multiples of SPF/DKIM/DMARC failed. Tatang et al. [45] compiled a list of DKIM selectors and found that domains do not only commonly share the same selector, but also the same key.

Standard Complexity. In 2021, Yajima et al. [34] first discussed how standards’ complexity influences their adoption rate. They measured DNS-based security mechanisms and found that setup difficulty influences the adoption rate. Their rating of setup difficulty awards points for the following configuration aspects: DNS record (1pt); DNS server configuration (2pt); email server configuration (2pt); web server configuration (2pt); required third party (3pt). DNSSEC and DANE score the highest with 6 points. While DANE is a relatively new standard introduced in 2012, DNSSEC was introduced in 1999 and still faces a relatively low adoption and validation rate. Potential causes include a (perceived) high risk of service disruptions due to misconfigurations – even in 2021, we still regularly see outages of top-level domains due to misconfigured DNSSEC [24] – and complexity in maintaining DNSSEC. Further investigating the complexity of DNSSEC key material handling, Chung et al. [8] found that a majority of domains roll keys too infrequently, use weak keys, or do not perform rollovers correctly.

7 Discussion

Successful system operation includes design, implementation, and maintenance. In a world of ubiquitous networking, sys-

tems like the email ecosystem cannot be redesigned from scratch, but have to be carefully adapted. This means that successful further development has to consider the impact of improvements on the existing ecosystem. Hence, our measurement provides a perspective on the current state of email.

Our measurements pinpoint an apparent gap between the email ecosystem as standardized by the IETF and its actual deployment. Recently introduced standards such as TLSA (validation) have not made it into practice. Thus, our results suggest that the development of new email standards has to be accompanied by strategies fostering their actual deployment.

7.1 Heavy-tail Email

A pattern that emerges in our measurements as well as in the work of, e.g., Liu et al. [32] is the heavy-tail nature of email: As Table 4 shows, a small portion of operators provide email services to the majority of users and domains on the Internet. Our investigation of related work also shows that studies often focus only on this top part of email providers. However, when we want to understand the email ecosystem, the major challenge is identifying and measuring the diverse tail of email providers and small self-hosted email instances. This becomes particularly challenging if – like in our measurements – user participation is necessary, and might lead to a situation where smaller providers are less investigated with potentially negative impact on their security, resilience, etc.

In a more techno-philosophical dimension, this development also raises concerns in the context of centralization. For example, in 2021 Fiebig et al. measured the migration of universities to large cloud providers, including their email infrastructures [15]. Centralization might accelerate the adoption of standards (e.g., if the relevant players are directly involved in standardization), but this can also potentially enforce the deployment of burdensome standards by small operators, effectively creating a walled garden. Beyond, failure of a single large provider, either due to an accidental error or a deliberate attack, affects a large share of users/domains, emphasizing the importance of decentralization and diversity for the resilience of the overall email ecosystem.

What we certainly highlight – if we want to keep a distributed Internet – is that future development efforts should not only focus on improving standards themselves, but also make it easier to follow these standards and enable operators to run their email infrastructure in full standard compliance. We encourage RFCs drafted by the IETF to be accompanied by *technical and organizational measures facilitating implementation*, reducing the gap between standardization and deployment.

7.2 Delivery vs. Adoption

Looking at the large provider dataset in our study, we find that currently especially large providers prioritize email delivery over security, e.g., DNSSEC validation is enabled for

Google's public DNS service, but not for the resolvers Gmail relies on. This is understandable from an operational standpoint but suggests that security is still considered subordinate to functional goals. We conjecture that Google prioritizes the deliverability of emails over strict enforcement of DNSSEC. The status-quo appears to represent an upside-down world: Precisely for large providers, the deployment of a new security feature appears manageable; yet, they refrain from doing so in a strict manner. At the same time, small operators implement the respective features at a disproportionate operational overhead.

This divergence of the email ecosystem ultimately creates challenges, as new security features often do address actual problems. Hence, the operations community must discuss how this divide can be addressed in the future. The Registrar Scorecard has already proven that financial incentives are successful [44]. Thus, we suggest including the design of such systems already during standardization. The Internet Governance Forum also recommends financial incentives by translation of standards into business cases [47]. However, this poses various challenges, among others the collaboration of multiple stakeholders, funding, and the operation of respective evaluation systems, which have to be solved by future work.

7.3 Standard Deployment and SPAM

In our study, we find that TLS enforcement and IPv6-only delivery have a significant impact on the amount of SPAM systems receive. While IPv6-only delivery naturally has a significant negative impact on legitimate emails being delivered, this impact is smaller when enforcing TLS. According to our measurements, emails from about 10% of regular providers would be affected. However, it is hard to determine an adoption threshold for which enforcement of standards is justified. On the one hand, TLS is an old and well-understood standard, fully supported by large providers which represent the driving force in standard deployment; also the implementation effort is low compared to other standards like DNSSEC or DANE. On the other hand, it is unclear why 10.1% of these providers have not implemented (START)TLS. If this is the case because delivery is still possible without, enforcement of TLS should take place; if the reasons are rooted in structural aspects (e.g., lacking support for certain types of systems or adequately educated staff), we suggest to target these root causes first, again requiring additional technical and organizational measures accompanying RFCs.

8 Conclusion

We investigated email delivery, especially in terms of protocol use (IPv4 vs. IPv6, recursive DNS servers' configuration, TLS sending support) and thereby complement existing related work, which mostly investigated the receiving side of the email ecosystem. Together with a review of related work on

email delivery, this allows us to paint a comprehensive picture of the complexity of email delivery in 2021.

We find that 'new' protocols and extensions relevant to email delivery, like IPv6 and DNSSEC, lack adoption. The overall ecosystem is slow in this regard, especially since large email providers prioritize email delivery and – while trying to offer as many options as possible to receive emails – take a conservative stance when trying to deliver emails to others. This highlights the importance of including the heavy-tail of smaller providers in email-related measurements. Our results show that standard deployment is lower than it could be. At the same time, we know that financial incentives work well to increase deployment rates. Hence, we suggest that such incentive systems should accompany Internet standards. However, continuous funding appears to be difficult; thus, future work should also address the impact of non-financial incentives.

Abstract

Fast Internet-wide scanning is essential for network situational awareness and asset evaluation. However, the vast IPv6 address space makes brute-force scanning infeasible. Although state-of-the-art techniques have made effective attempts, these methods do not work in seedless regions, while the detection efficiency is low in regions with seeds. Moreover, the constructed hitlists with low coverage cannot truly represent the active IPv6 address landscape of the Internet.

This paper introduces *AddrMiner*, a systematic and comprehensive global active IPv6 address probing system. We divide the IPv6 address space regions into three kinds according to the number of seed addresses to discover active IPv6 addresses from scratch, from few to many. For the regions with no seeds, we present *AddrMiner-N*, leveraging an organization association strategy to mine active addresses. It fills the gap of address probing in seedless regions and finds active addresses covering 86.4K IPv6 prefixes announced by BGP, accounting for 81.6% of the probed announced prefixes. For the regions with few seeds, we propose *AddrMiner-F*, utilizing a similarity matching strategy to probe active addresses further. The hit rate of active address probing is improved by 70%-150% compared to existing algorithms. Moreover, for the regions with sufficient seeds, we present *AddrMiner-S* to generate target addresses based on reinforcement learning dynamically. It nearly doubles the hit rate compared to the state-of-the-art algorithms. Finally, we deploy *AddrMiner* and discover 2.1 billion active IPv6 addresses, including 1.7 billion de-aliased active addresses and 0.4 billion aliased addresses, through continuous probing for 13 months. We would like to further open the door of IPv6 measurement studies by publicly releasing *AddrMiner* and sharing our data.

1 Introduction

Internet-wide active address probing is a prerequisite for Internet-scale network surveys. Existing network research and applications rely heavily on Internet-wide active address scanning. For example, the probed active addresses can be used

to examine trends and adoption rates of different technologies [11, 30], measure network topology for reflecting interconnections of nodes [4, 52], probe Internet services for wide-ranging assessments [9, 25] and resource census [23], and test network security by measuring the attack surface [16, 34].

Under IPv4, it is feasible to achieve Internet-wide active address probing by brute-force scanning the entire IPv4 address space at the minute level with high-speed scanning tools such as ZMap [9]. With the rapid development of the Internet as a globally crucial infrastructure, IPv4 no longer meets its development needs, and IPv6 has been promoted and deployed at an accelerated pace worldwide. For example, more than 36.6% of users accessed Google via IPv6 in 2021, compared to fewer than 0.7% in 2012 [21]. However, under IPv6, there are significant challenges to Internet-wide active address discovery. The main reason is that the vast address space of IPv6 makes it more difficult, if not infeasible, to obtain globally active addresses. For example, it would take at least millions of years to scan the entire IPv6 address space using 10 Gigabit links and high-speed scanning tools such as ZMap [9].

To address this issue, researchers usually collect known active IPv6 addresses (i.e., seeds), learn the characteristics of seeds, and generate the target addresses that may have a higher probability of being active for scanning. Although previous research efforts have examined how to detect active IPv6 addresses, the issue of how to perform comprehensive global active IPv6 address discovery remains, mainly in the following aspects:

(1) *Limited usage*. In regions where seeds are missing, existing methods cannot perform effective active IPv6 address probing or even work [7, 15, 18, 24, 33, 36, 47, 51]. This is because they need to learn the characteristics of the seeds to generate target addresses that are more likely to be active. There is still a gap in active IPv6 address probing in regions lacking seeds.

(2) *Limited detection efficiency*. State-of-the-art algorithms [7, 24, 47] have improved the efficiency of active IPv6 address probing. However, these methods are too dependent on seeds. The seed address sampling bias reduces the efficiency of

active address probing because it makes the characteristics of the actual active address inconsistent with those of the seeds.

(3) *Limited coverage*. Previous studies, while building a list of active addresses, called IPv6 hitlist, have tended to be limited to a few IPv6 prefixes announced by BGP [15, 18, 42, 47]. For example, active IPv6 addresses in the latest hitlist [18] cover only 25.5K announced prefixes, which is only $\sim 21.3\%$ of all announced prefixes. They are not truly representative of the active IPv6 address landscape of the Internet. Active detection methods by analyzing seeds are often also limited by the coverage of the seeds [15, 18, 24, 33, 36, 42, 47, 51].

In general, there still lacks a systematic methodology for comprehensive global active IPv6 address probing. To solve the above problems, we design and implement an active address probing system, *AddrMiner* (§4). At its core, *AddrMiner* divides active address probing into three sub-tasks: active IPv6 address probing for 1) address space regions with no seeds, 2) address space regions with few seeds, and 3) address space regions with sufficient seeds, respectively.

First, we present *AddrMiner-N* for the address space regions without seeds (§5). The core idea is based on the observation that address patterns (i.e., structure) tend to have similarities across network configurations. It obtains common patterns by mining the structural features of active addresses collected in other regions, and then migrate to regions without seeds to generate targets for scanning. *AddrMiner-N* leverages graph data structures to describe the similarity of address structure features under different networks (§5.2). Then, it uses graph community discovery algorithms to mine common address structure features for building a common pattern library (§5.3). We observe that the address configuration patterns are more similar within the same network organization than within different organizations. *AddrMiner-N* selects the most similar patterns from the library based on organization association strategy to generate targets (§5.4).

Second, we propose *AddrMiner-F*, an active address probing algorithm for the case where the address space regions contain few seeds (§6). Existing methods cannot effectively learn seed characteristics for active address probing in this scenario due to the lack of seeds. The core idea of *AddrMiner-F* is also to generate targets for probing by selecting the most relevant patterns from the common pattern library and migrating to regions with only a few seeds. Similar to *AddrMiner-N*, *AddrMiner-F* first uses the same method to build a common pattern library (can reuse the one built by *AddrMiner-N*). Then, it improves the efficiency of address detection by extracting relevant patterns from the common pattern library to generate scanning targets using only a few seeds. This is because a few seeds can also provide some information for guiding pattern selection.

Third, we present *AddrMiner-S*, which learns the density characteristic of seeds and corrects density bias to find the real high-density regions of active addresses for address detection,

for the case where the address space regions contain sufficient seeds (§7). The key idea of *AddrMiner-S* is motivated by the higher density regions of active addresses, the higher the hit rate of active addresses. It uses reinforcement learning to update the density distribution of the seeds based on the rewards found for the active addresses and moves toward the actual address distribution to correct the density bias caused by the sampling of seeds.

AddrMiner naturally works in all announced prefix spaces and enables comprehensive active IPv6 address probing in different scenarios by corresponding algorithms to gradually discover active IPv6 addresses from scratch, from few to many.

Contributions. We make the following contributions:

- We present an active IPv6 address probing method, *AddrMiner-N*. It fills the gap of address probing in the seedless address space regions and discovers active IPv6 addresses covering 86.4K prefixes announced by BGP, accounting for 81.6% of all announced prefixes.
- We propose an active IPv6 address probing method, *AddrMiner-F*, which can further discover active IPv6 addresses in address space regions with few seeds. It can find 70%-150% more active addresses than *AddrMiner-N* and the state-of-the-art algorithms.
- We present an efficient active IPv6 address probing method, *AddrMiner-S*, which can efficiently perform active IPv6 address probing in address space regions with sufficient seeds. Compared with state-of-the-art algorithms, the results show *AddrMiner-S* improves the hit rate of active addresses from 28.9% to 56.3%.
- We originally design and implement a global active IPv6 address probing system and discover 2.1 billion active IPv6 addresses, including 1.7 billion de-aliased active addresses and 0.4 billion aliased addresses, through continuous running *AddrMiner* for 13 months. The developed code and continuously probed active addresses are made publicly available at:

<https://github.com/AddrMiner/AddrMiner>

2 Background

In this section, we briefly introduce the background of IPv6 addresses and discuss the characteristics of IPv6 addresses.

IPv6 addresses are 128 bits long. IPv6 unicast addresses consist of a global routing prefix, a local subnet identifier, and an interface identifier (IID). We represent IPv6 addresses in a human-readable text format using eight groups of four hexadecimal characters, each group having 16 bits in total, separated by a colon (“:”). We refer to each hexadecimal character (corresponding to the four bits

of the address) as a nybble. An example IPv6 address is 2001:0db8:0000:0000:0008:8000:200c:417a. To simplify the IPv6 representation, the leading zeros of each group are usually excluded, and the longest all-zero group sequence is replaced with a double colon (“::”). Thus, the simplified representation of the IPv6 address in this example is 2001:db8::8:8000:200c:417a.

IPv6 addresses have the following characteristics. (1) Vastness of IPv6 address space: IPv6 address space is 2^{128} , 2^{96} times of IPv4 address space. This makes active IPv6 addresses very scarce and more hidden, making it a challenging task to find active IPv6 addresses. (2) Diversity of IIDs: IID can be assigned in various ways, such as static configuration [20], stateless address autoconfiguration [37], and DHCPv6 [40]. IPv6 addresses with random IIDs are more difficult to detect.

3 Related Work and Motivation

This section reviews related work and clarifies the motivation of our work on discovering active addresses in the vast IPv6 address space. The existing work can be divided into the following three categories:

Public Resources Extraction. This method obtains active IPv6 addresses through public resource lookup or resolution [6, 13, 18, 50]. DNS is a common and effective channel. Strowes et al. [50] obtained 965K globally routable IPv6 addresses by exhaustively enumerating the reverse DNS domains in the IPv4 address space and performing AAAA queries on the results. Fiebig et al. [13, 14] walked the rDNS tree and collected 5.8M IPv6 addresses. Borgolte et al. [6] also obtained 2.2M IPv6 addresses through DNSSEC-signed reverse zones. Besides, Gasser et al. [18] collected 58.5M IPv6 addresses from public data sources, including Domain Lists [1, 2, 17, 41, 44, 49], FDNS [46], AXFR [35], Bitnodes [54], and RIPE Atlas [38].

Although we can get IPv6 addresses through public resources, in the latest hitlist [18], these addresses only cover 25.5K announced prefixes, which is only $\sim 21.3\%$ of all announced prefixes. Therefore, it is challenging to obtain globally active IPv6 addresses from public sources alone.

Passive Collection. This approach entails passively collecting traffic or log files at vantage points and extracting active IPv6 addresses from them [15, 19, 42, 47]. For the first time, Plonka et al. [42] used IPv6 addresses collected from the activity logs of all customers accessing a global CDN as a dataset and analyzed the characteristics of active IPv6 addresses. Subsequently, Foremski et al. [15] proposed a technique for obtaining potentially active IPv6 addresses from the initial seed dataset. A similar attempt was made by [19, 47] using a large Internet Exchange Point as a vantage point to collect active IPv6 addresses.

However, the above studies have the following shortcomings. First, the vantage point used is not publicly available and is difficult for others to access. Second, to obtain global active

Figure 1: High-level overview of *AddrMiner*

IPv6 addresses, many vantage points need to be deployed worldwide, with high probing overhead. *AddrMiner* removes the vantage point limitation and decreases the threshold for address probing. Any node configured with IPv6 network can use *AddrMiner* to probe active addresses.

Active Address Probing. A viable approach is to discover more active IPv6 addresses by collecting seeds, mining the structural patterns and characteristics of the seeds to generate target addresses, and probing the target addresses [7, 15, 18, 24, 33, 36, 47, 51]. Ullrich et al. [51] proposed a pattern-based recursive algorithm that greedily includes more seeds for scanning each iteration through a variable address range. Entropy/IP [15, 18] learns the internal structural characteristics of seeds to generate target addresses and then scans them to discover active IPv6 addresses. 6Tree [33] and 6Hit [24] combine the hierarchical characteristic of seeds to construct hierarchical space trees, and dynamically guides the direction of address generation based on the probing results. 6Gen [36] and DET [47, 48] use the density characteristic of seeds to detect active IPv6 addresses in high-density regions of seeds. 6GAN [7] aims to discourage aliased address generation via generative adversarial nets with reinforcement learning.

Although all the above methods improve active IPv6 address probing efficiency, the sampling bias of seeds makes the characteristics of actual active addresses inconsistent with those of seeds, resulting in the inability to efficiently generate target addresses for scanning. Although 6Hit attempts to use reinforcement learning to reduce the dependence on seeds, it simply uses the hierarchical characteristic and uses a space repartition mechanism, which leads to random changes in the probe space to reduce the address probing efficiency.

4 Overview of *AddrMiner*

This section describes an active IPv6 address probing system, *AddrMiner*, capable of performing systematic and comprehensive probing of active IPv6 addresses to achieve the accumulation of detected globally active addresses from scratch.

Figure 1 illustrates a high-level overview of *AddrMiner*. It collects seeds to make an IPv6 hitlist from public sources and divides them into different announced prefix spaces. Then, it classifies these announced prefix spaces into different scenar-

ios based on the number of seeds each prefix space contains. The policy engine uses different policies for active address probing according to different scenarios. 1) For announced prefixes with no seeds, *AddrMiner-N* uses the organization association strategy to select candidate patterns to probe for active IPv6 addresses (§5). 2) For announced prefixes with few seeds, *AddrMiner-F* uses the similarity matching strategy to select candidate patterns to discover active addresses further (§6). 3) For announced prefixes with sufficient seeds, *AddrMiner-S* uses reinforcement learning techniques to learn seed address characteristics while circumventing the shortcomings of similar existing schemes to perform active address probing more effectively (§7). The classification of the scenarios for prefix spaces with seeds is discussed in detail in Appendix C. The detected active addresses discovered from the policy engine are tested for aliased prefixes. After eliminating the aliased prefixes, the de-aliased active addresses are the globally active IPv6 addresses and are added to the IPv6 hitlist.

AddrMiner enables comprehensive probing of global active IPv6 address, and provides more and balanced data to support further measurement and security analysis of IPv6 networks.

5 AddrMiner-N

This section presents *AddrMiner-N*, which can guide active address detection under an announced prefix without seeds using patterns of active addresses under other prefixes owned by the same organization to which the prefix without seeds belongs.

5.1 Overview of AddrMiner-N

Since there are no seeds in the address space region, we cannot use seeds to guide active address probes. An effective way to generate targets under such regions is to use specific IPv6 address patterns, i.e., mining the structural characteristics of active addresses collected in other regions and then migrating to regions without seeds to generate targets for scanning. This idea is feasible due to the observation that address patterns tend to have similarities across network configurations [20]. Our analysis of the tens of millions of IPv6 addresses on the Gasser’s hitlist [18] confirms this observation. For example, gateway addresses often have a suffix of ::1 or ::2. Therefore, the crux of the problem is to obtain a common pattern library containing address patterns commonly used in address space regions that have seeds. Our solution, *AddrMiner-N*, is to use undirected graphs to represent the similarity between patterns (§5.2), and then use graph community discovery methods to find communities with high pattern similarity. Each community represents a common address pattern, and these communities construct a common pattern library (§5.3). Finally, it uses the organization association strategy to migrate these

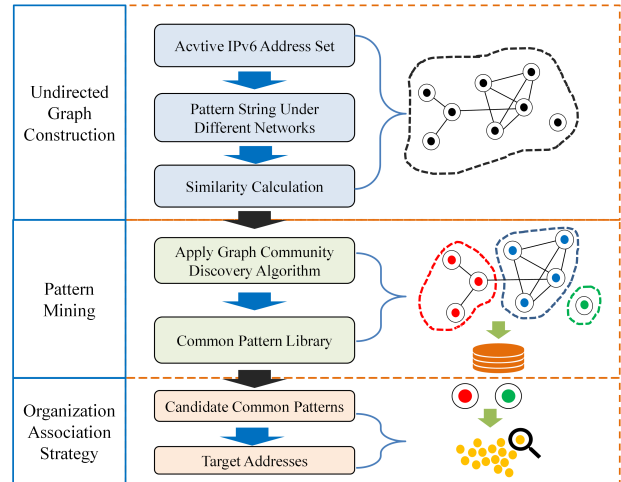

Figure 2: Workflow of *AddrMiner-N*

common address patterns to any announced prefix for address generation (§5.4).

5.2 Undirected Graph Construction

AddrMiner-N constructs an undirected graph to describe the differences between address patterns. The nodes represent the address patterns, and the weights of the edges represent the similarity between different patterns.

Pattern Representation. The address patterns constructed by existing strategies [20, 22, 29, 32, 47] often do not correspond to an accurate probing space. If the space is too large, such as Embedded-IPv4, it will waste a lot of probing resources and reduce the probing efficiency; if the space is too small, such as low-byte, it will limit the probing range and fail to find a large number of active addresses. To solve such a problem, we use **Balanced Spatial Pattern Representation (BSPR)** [31] to extract address patterns. BSPR can accept any IPv6 address set as input and generate flexible patterns representing the structural characteristics of that address set, which can be used to generate targets.

First, the BSPR uses four representations to describe the range of values for any nybble of an IPv6 address, including Single, List, Interval, and Wildcard:

Single: The nybble takes a fixed value, which means that the addresses in the address set do not change in the value taken at that nybble position.

List: The value taken for this nybble is variable, and the range is the set of values taken for the IPv6 addresses in the address set at the nybble position.

Interval: The nybble value is variable. The range is a closed interval consisting of the minimum and maximum values of the IPv6 address set at the nybble position, possibly including values that do not appear at the nybble position.

Wildcard: The nybble value is variable and ranges over

Table 1: The relationship between the four representations and three statistics used by BSPR

ID	Range	Entropy	Values	Representation	Example	Number of values
0	0	0.00	1	Single	a	1
1	$\geq t_r$	$\geq t_e$	$\geq t_c$	Wildcard	*	16
2	$\geq t_r$	$\geq t_e$	$< t_c$	List	[1cf]	3
3	$\geq t_r$	$< t_e$	$\geq t_c$	Interval	[1-e]	14
4	$\geq t_r$	$< t_e$	$< t_c$	List	[2be]	3
5	$< t_r$	$\geq t_e$	$\geq t_c$	Interval	[6-b]	6
6	$\geq t_r$	$\geq t_e$	$< t_c$	List	[679]	3
7	$< t_r$	$< t_e$	$< t_c$	List	[67]	2

all hexadecimal values and may include values that do not appear at the nybble position, as indicated by the wildcard *.

To choose a suitable representation, BSPR introduces three statistics for each nybble of IPv6 address in the input address set: range, Shannon entropy, and value count. The range is equal to the maximum value of the value taken by the nybble minus the minimum value; the Shannon entropy can be calculated according to Formula (5-1); the value count is equal to the number of values that have appeared at the position of the nybble.

$$E(x_i) = - \sum_{v=0x0}^{0xf} p(x_i = v) \log_{16} p(x_i = v) \quad (5-1)$$

The base of Formula (5-1) is 16 because the value count of the nybble is 16, which makes the result of the Shannon entropy calculation fall into the interval [0,1], where x_i represents the i th nybble. The value range of i is [1,32], meaning the 32 nybbles of an IPv6 address. $p(x_i = v)$ can be obtained by dividing the number of IPv6 addresses that take the value v at the i th nybble position in the address set by the total number of addresses.

Table 1 shows how BSPR decides the nybble representation based on these three statistics. Whether these three statistics are large or small is determined by three thresholds t_r , t_e and t_c for range, entropy, and value count respectively.

Second, BSPR needs to solve how to determine the value of the three hyperparameter thresholds. If the thresholds are set too small, the modeled address space increases rapidly. At one extreme, all three hyperparameters are set to 0, and the address generation patterns are all in Wildcard. If the thresholds are set too large, the modeled address space is too small. At the other extreme, all three hyperparameters are taken to their maximum values. The patterns of address generation are all in List, and the value of each nybble represented by List depends entirely on the value of the seed address set, which will aggravate the sample bias.

Suppose the counts of List, Interval, and Wildcard in a pattern are l , r , and w , respectively. L_j , R_j represent the count of values taken at the j th List or Interval, respectively. The value range of Wildcard is the 16 values of a single hexadecimal number. Therefore, the size of the space range (SR) of any

Figure 3: Calculation of the similarity of two patterns

pattern string is thus calculated as follows:

$$SR = 16^w \cdot \prod_{j=1}^l L_j \cdot \prod_{j=1}^r R_j \quad (5-2)$$

Since l , r , and w are affected by the three hyperparameters, t_r , t_e and t_c , SR is a ternary function with respect to these three parameters. The domains of t_r and t_c are the integer of [0,15] and [1,16], respectively. The domain of t_e is the real number of [0,1], which can be discretized, for example, with an interval of 0.05. Let the range of the ternary function SR be the set Y . Since its domain of definition is a finite set, and the range of Y is also a finite set. Let the number of elements of Y be N . The most balanced space range BSR chosen by BSPR should be the average of the Y range. Here, we use the geometric mean because it is less influenced by extreme values than the arithmetic mean.

$$BSR = \sqrt[N]{\prod_{SR_j \in Y} SR_j} \quad (5-3)$$

Third, BSPR can choose the set of hyperparameters when the value of SR is closest to that of BSR as the values of t_r , t_e and t_c , as shown in Formula (5-4). Finally, a pattern is generated based on Table 1.

$$\arg \min_{t_r, t_e, t_c} |SR - BSR| \quad (5-4)$$

Similarity Calculation. The core of constructing undirected edges is to determine between which nodes undirected edges need to be created and the weights of these undirected edges. Since patterns are represented by strings, the common methods of calculating the similarity between strings can also be used. *AddrMiner-N* introduces Jaccard similarity [28] and Hamming distance-based similarity [53] to calculate the similarity between patterns (specific definitions are given in Appendix A).

Figure 3 shows an example of calculating the similarity between two pattern strings. Two main aspects are considered in the calculation: the similarity of the corresponding nybble representation and the similarity of the values taken by the

Figure 4: Merging process of different patterns

representation. For the similarity of the corresponding nybble representation, the main focus is to compare whether the two pattern strings have the same fixed value taken at the same nybble position, i.e., whether they belong to the Single representation or not. Non-Single representations include List, Interval, and Wildcard. We convert all Single representation nybbles to a zero value, and Non-Single representations are represented as one, as shown in Sequence 1 and Sequence 2 in Figure 3. In this way, the similarity of the corresponding nybble representation is obtained by calculating the Hamming distance between Sequence 1 and Sequence 2. Regarding the similarity of the values taken by the representation, Jaccard similarity is used to calculate the similarity of the two sets of values of the representation at the same nybble position. Thus, the similarity of the two pattern strings can be obtained by weighting the Jaccard similarity of the corresponding nybble with the Hamming distance-based similarity of each nybble representation as the weight. The calculation is shown in Formula (5-5), where a_i and b_i denote the values of Sequence 1 and Sequence 2 at the i th position, and A_i and B_i indicate the sets of values of pattern strings p_1 and p_2 at the i th nybble representation, respectively.

$$score = \sum_{i=1}^{32} r_i(a_i, b_i) \cdot J(A_i, B_i), \quad (5-5)$$

where r_i indicates Hamming distance-based similarity at the i th nybble and J indicates Jaccard similarity.

Finally, a threshold value h_{min} needs to be determined. If the similarity between two pattern strings exceeds h_{min} , an undirected edge is created. The similarity is used as the weight of that edge. Otherwise, no undirected edge is created. The length of announced prefixes generally does not exceed 56 (14 nybbles). Some prefixes are highly similar, e.g., 2a02:26f0:128:100:/56 and 2a02:26f0:128:500:/56, which causes the merge pattern to contain unannounced prefixes, e.g., 2a02:26f0:128:*00:/56, but addresses in the unannounced space are inactive. Therefore, when constructing the undirected graph, we set h_{min} to 14.0 to avoid generating non-announced spaces as much as possible.

5.3 Pattern Mining

After constructing the undirected graph (§5.2), we apply the community discovery algorithm to cluster similar nodes in

Figure 5: Organization association strategy

undirected graphs and build a common pattern library by mining common patterns from communities.

The graph community discovery algorithm will produce many communities. These nodes have high similarity in the same community but low similarity in different communities. After obtaining the community, we merge the patterns of the nodes contained in the community to extract the common pattern about the community. To make the pattern contain more seeds, we adopt the union method to obtain the pattern. Suppose that C represents a community, which contains k nodes. That is, $C = \{p_1, p_2, \dots, p_k\}$. Then the common pattern of the community is: $p_C = \bigcup_{i=1}^k p_i$. At the nybble positions corresponding to the different patterns, we take a union of the values corresponding to the nybble. Figure 4 shows the merging process of different patterns.

5.4 Organization Association Strategy

To probe active addresses under announced prefixes with no seeds, *AddrMiner-N* adopts an organization association strategy, the core of which is to extract the most relevant patterns of the specified announced prefix from the pattern library and then use them to generate target addresses for scanning. The reason for adopting this strategy is that address configuration patterns are more similar within the same network organization than within different organizations. In the constructed common pattern library, for example, the announced prefixes of organization "Wireless Broadband Service Provider Malaysia" contain the following common patterns: the sixth group of nybbles is represented by Wildcard, and the other nybbles are represented by Single, where the last nybble is 1, and the other nybbles are 0. Specifically, the prefix 2405:7c00:a004::/48 contains the pattern 24057c00a00400000000****00000001 and the prefix 2405:7c00:a000::/48 contains the pattern 24057c00a00000000000****00000001. *AddrMiner-N* makes full use of the organization information of announced prefixes to filter relevant patterns from the pattern library. The evaluation results in §8.1 show that this strategy can enhance significantly improve the probing efficiency.

Figure 5 shows the method of filtering the pattern library using organization labels. We first construct organization labels for the announced prefixes to which the patterns in the

pattern library belong. We obtain the organization label by querying the whois information in Hurricane Electric [10]. To avoid the influence of generic words on the organization association strategy, we remove generic words, such as corporation, international, etc. For example, the organization label of the prefix 2a01:111:2003::/48 is "Microsoft Corporation", we add an English word "Microsoft" to the organization label of the prefix. Similarly, we obtain the organization labels of the announced target prefixes in the same way. To calculate the degree of similarity between the organization labels, we next convert these labels directly into vectors by using the most popular fastText [5, 26, 27] pre-training model in word embedding. Then, we use Euclidean distance to calculate the similarity between the organization label of the target prefix and the organization labels of each pattern in the pattern library. The calculation is shown in Formula (5-6) and yields a list of k_{org} most similar patterns:

$$similarity = \sum_{i \in T, j \in W} d(v_i, v_j), \quad (5-6)$$

where T is the set of words for the organization label of the target prefix, W is the set of words for the organization label of a common pattern in the pattern library. This approach can identify the same network organization, e.g., identifying "Akamai Technologies, inc" and "Akamai International B.V." as belonging to the organization "Akamai" and thus selecting more relevant patterns. Note that when the similarity is small, i.e., the prefixes belong to different organizations, such as "Akamai" and "Fastly", the candidate patterns are randomly selected from the common pattern library.

After obtaining the candidate patterns, we use them to generate target addresses under the target prefix. More specifically, iterate over each candidate pattern to generate a specified number of targets, and then replace the prefixes of the generated target addresses with target prefix. Finally, we probe whether these addresses are active or not.

6 AddrMiner-F

Target regions with few seeds come from both (1) prefix space regions containing few seeds selected from the public IPv6 hitlist, and (2) transformed by detecting few active addresses after running *AddrMiner-N* in regions without seeds. We experimentally find that the active address hit rate of the state-of-the-art algorithm [47] decreases with the number of seeds, especially when the number of seeds is less than 10, the hit rate is already less than 1% (See more details in Appendix C). However, the number of announced prefixes with only few seeds is large. As shown in §8.1, we find more than 30K announced prefixes with less than 10 seeds. To solve this problem, we propose *AddrMiner-F*, which can use few seeds to extract the most relevant patterns from the common pattern library to generate targets for scanning and achieve effective detection of active addresses in announced prefixes

Figure 6: Similarity matching strategy

with few seeds. We call this strategy of matching address patterns using few seeds the similarity matching strategy. *AddrMiner-F* also consists of three steps: undirected graph construction, pattern mining, and similarity matching strategy. Among them, the first two steps have been introduced in §5.2 and §5.3, respectively. The similarity matching strategy is described in detail below.

In this case, we have a small number of IPv6 seeds under the target prefix. Therefore, the similarity matching strategy mainly combines these seeds to filter out a more relevant candidate pattern list from the pattern library. Figure 6 shows the process of similarity matching strategy. We first use BSPR to obtain the patterns of few seeds under the target prefix (i.e., the target pattern). Then we traverse the pattern library and use Formula (5-5) to calculate the similarity between the target pattern and each pattern in the pattern library separately and find the k_{heap} most similar candidate patterns. After getting the candidate patterns, we use the address generation method in §5.4 to generate the target addresses and probe whether they are active or not.

7 AddrMiner-S

Target regions with sufficient seeds come from three scenarios: (1) prefix space regions containing sufficient seeds selected from the public IPv6 hitlist, (2) transformed by detecting sufficient active addresses after running *AddrMiner-N* in regions without seeds, and (3) transformed by detecting sufficient active addresses after running *AddrMiner-F* in regions with few seeds. If the address space regions have enough seeds, the state-of-the-art address generation algorithms based on seeds are effective attempts. They learn the characteristics of seeds to generate target addresses for scanning. However, due to the seeds' sampling bias, the characteristics of the seeds do not coincide with the characteristics of the actual active addresses under the address space regions. The sampling bias reduces the probing efficiency and wastes resources. Although 6Hit attempts to use reinforcement learning to eliminate sampling bias, it simply uses the hierarchical characteristic of seeds and its space repartition mechanism randomly generates target addresses to reduce the efficiency of active address detection. In our work, we propose *AddrMiner-S*, which learns seeds' density characteristic and uses reinforcement learning to correct the discrepancies in the density distribution caused

by the sampling of seeds. In space expansion, *AddrMiner-S* guide the target address generation in a larger address space by merging subspace density characteristic. The model about *AddrMiner-S* is built in Appendix B.

7.1 Target Address Generation Based on Reinforcement Learning

We know the higher the density of active addresses, the higher the hit rate of active addresses (The theoretical proof is in Appendix B). Although the active address density of each region in the real IPv6 network is unknown, we estimate the active address density of each region through Thompson sampling. After discovering seeds' high-density regions, we use the reinforcement learning method to select candidate regions for generating target addresses in the seed address's high-density regions, update the active address density distribution through feedback rewards of each iteration's scanning results, and dynamically adjust the target address generation's direction. As the number of iterations increases, the evaluation of the probability of each action's reward will become more accurate. Eventually, high-density regions of active addresses in the real network will be discovered, and address generation will be performed in the high-density regions.

Space Partition: We first discover the high-density regions $X = \{x_1, x_2, \dots, x_k\}$ of seeds. To quickly cluster the density space distribution of seeds, we use the density space tree [47] to find high-density regions of the seeds in linear time. The root node represents the entire active address space, and the leaf node represents a high-density region of seeds. In each node region x_i , there are two attributes α_i and β_i . Where α_i represents the number of active addresses probed in region x_i , and β_i represents the number of inactive addresses discovered in region x_i . Initially, we take out all the leaf nodes from the density space tree as the high-density regions set X .

After discovering regions with a high density of seeds, we dynamically probe active IPv6 addresses based on reinforcement learning. The iterative process of reinforcement learning consists of three main steps: 1) Generate target addresses to probe (action), 2) Update the reward of probed regions with the number of active addresses and inactive addresses (action's reward) to update the density distribution, and 3) Merge the nodes of the space tree to meet the needs of exploring a larger address space.

Target Generation: To adapt to the large-scale probing of addresses and speed up address probing, we select multiple target regions in each iteration, and the budget (the probing number of target addresses) consumed is b . Since the node region with a larger reward is more likely to discover active addresses, in each iteration, we select the top P searchable regions based on the reward for target address generation in the candidate regions X . We use prior events (action's reward) to evaluate the distribution of active address density. However, the larger space, the higher the risk of searching in the node

region (more difficult to find active addresses). For example, in extreme cases, the hit rate of active addresses is extremely low in the entire IPv6 address space. To reduce the risk of low address probing efficiency due to excessive space, we use the region address variable space (variable dimensions) to adjust the probability of generating active addresses in each region. The number of target addresses generated in each region is calculated as follows:

$$p(x_i) = \frac{e^{R_i}}{\log(V_i) * \sum_{i=1}^n \frac{e^{R_i}}{\log(V_i)}} \quad (7-1)$$

$$N(x_i) = b * p(x_i) \quad (7-2)$$

Where R_i indicates the expected reward in region i , $p(x_i)$ indicates the probability of generating target addresses in region x_i , $N(x_i)$ indicates the number of target addresses generated in region x_i , V_i represents the number of variable dimensions in active addresses in region x_i , and n represents the probing regions of the top P percent of the candidate regions X , b represents the budget consumed per iteration.

Reward Update: We update node regions' reward to increase the chance of generating target addresses in high-density regions for next-round probing. After each round of probing, we need to update the probed node region's reward value based on the probing result. Initially, we take out all the leaf nodes from the density space tree as the high-density regions set X and each leaf node's reward in x_i is initialized as follows:

$$R_i^1 = \text{Beta}(\alpha_i^1, \beta_i^1) \quad (7-3)$$

where R_i represents the expected reward in leaf node region x_i . Initially, α_i^1 is the number of seeds distributed in the leaf node region x_i plus 1, and $\beta_i^1=1$.

After each iteration, the expected reward of the probed region x_i is updated as follows:

$$R_i^{t+1} = \text{Beta}(\alpha_i^t + \alpha^*, \beta_i^t + \beta^*) \quad (7-4)$$

where α^* represents the number of new active addresses from scanning result in node region x_i , and β^* represents the number of new inactive addresses from scanning result in node region x_i . We assume b^* represent the target address generated in the node region x_i in each iteration. α^* , β^* and b^* satisfy the following relationship: $b^* = \alpha^* + \beta^*$.

Node Merging: The search space in the node is defined as the seed address's variable dimensions, but this will cause the search space to be incomplete. We adopt the method of merging upward after the child node's space search is completed, thus ensuring that space not included in the child node can be searched in the parent node.

When a leaf node region needs to be merged, we need to merge all the leaf nodes of the subtree (T) rooted at this leaf node's parent node to ensure that addresses continue to be generated in the high-density region. We can get all

the leaf nodes recursively, but the time consumption is too high. Because the leaf nodes of T are all included in the density regions X to be searched, we can store all the node's child nodes during the tree-building process and only need to intersect with X to get all the leaf nodes when merging. The merging strategy of the node's parameters is as follows:

1) Probed addresses merge: The active addresses (α_f) and inactive addresses (β_f) found in the parent node (f) region is equal to the union of the set of active addresses found in all child nodes ($C = \{x_1, \dots, x_j\}$). The specific relationship is expressed as follows: $\alpha_f = \bigcup_{i=1}^j \alpha_i$ and $\beta_f = \bigcup_{i=1}^j \beta_i$.

2) Reward merge: The parent node's reward value still satisfies beta distribution, and the reward = $Beta(\alpha_f, \beta_f)$ is calculated based on the active and inactive addresses obtained by strategy 1).

3) Space merge: The target address generation space of the parent node is equal to the variable space of the parent node minus the variable space of the child nodes. The specific relationship is expressed as follows:

$$f.var_space = f.var_space - \bigcup_{i=1}^j x_i.var_space.$$

8 Evaluation

This section highlights the evaluation of the effectiveness of active address probing for *AddrMiner*. *AddrMiner* is an active measurement method to discover active addresses. Therefore in our experimental evaluation, we compare *AddrMiner* with active address probing methods, not with passive collection methods (e.g., vantage point mirroring traffic) or public resource extraction methods (e.g., rDNS, Domain Lists, FDNS, AXFR). In all following experiments, we perform aliased prefix detection and aliased address removal.

Data: We automated the process of obtaining Gasser's publicly de-aliased active addresses from December 2020 to June 2021, and obtained 46.2M active IPv6 addresses, covering 49.2K announced prefixes. In addition, we obtained 105,973 announced prefixes from the Pysn project [3]. As shown in Table 2, we classify announced prefix spaces into no seed address spaces, few seed address spaces, and sufficient seed address spaces according to the number of seeds each announced prefix space contains. We have explored the number of seeds on the probing efficiency in Appendix C and selected target regions with the number of seed addresses less than ten as few seed scenarios.

Active Detection: When judging whether the target address is active, we send an ICMPv6 request packet using the ZMap to each address. If we receive a response from an address, we determine that it is active at the time of detection.

Default Parameters: We empirically set the important parameters. In undirected graph construction, h_{min} is set = 14.0. In pattern mining, the Louvain algorithm is used for graph community discovery. Pattern strings with space range SR greater than 10^7 are filtered. In *AddrMiner-S*, we set P to

Table 2: Scenarios classification in the data set

Scenarios Classification	The number of announced prefixes
No seeds	56,730
Few seeds (≤ 10)	31,771
Sufficient seeds	17,472

Figure 7: Hit rate of active addresses in the no seed scenario.

0.05, i.e., the top 0.05 percent of the highest reward nodes are selected for probing. We set k_{org} and k_{heap} to 10.0. The maximum number of seeds contained in each leaf node is 4, i.e., $\delta = 4$. We set the granularity of the IPv6 address representation to 4, i.e., $\gamma = 4$.

8.1 Efficiency of *AddrMiner-N*

Suppose b_{count} represents the number of announced prefixes to be probed, p_{count} indicates the number of candidate patterns for each announced prefix, and g denotes the number of addresses generated in each pattern. Thus, the number of addresses generated in each announced prefix is $p_{count} \times g$, and the number of target addresses generated in all announced prefixes is $M = b_{count} \times p_{count} \times g$. We generate different numbers of target addresses for each announced prefix without seeds, i.e., $b_{count} = 56,730$, $p_{count} = 10$, and $g = 1, 10, 100, 1000$.

Figure 7 shows the active address probing results of *AddrMiner-N* and other existing methods in the seedless address scenario. The vertical axis represents the average hit rate of probed prefix spaces without seeds (b_{count}). We found that state-of-the-art target address generation algorithms, including Entropy/IP [15], 6Gen [36], 6Tree [33], 6Hit [24], and DET [47], do not work in seedless regions since they need to learn seeds' characteristics. Compared with random scanning, which has extremely hit rate of only about 0.6%, *AddrMiner-N* has a higher hit rate of up to 3.6% for active address probing.

Furthermore, we perform a more comprehensive probing through the announced prefix space. We use 105,973 announced prefixes as probing regions, employ 500 patterns under each announced prefix, and generate 100 target addresses under each pattern, i.e., $b_{count} = 105,973$, $p_{count} = 500$, and

Table 3: The probing results of the two probing methods

Probing Method	#Active Adrs	#BPFs	Coverage
<i>AddrMiner-N</i>	158,959,500	86,423	81.6%
Random Scanning	708,697	1,421	1.3%

BPFs: prefixes announced by BGP.

Figure 8: Hit rate of active addresses in the few seed scenario.

$g = 100$. Thus, we generated about 5.2 billion target addresses for probing. Table 3 shows the number of active addresses discovered by the two probing methods and the number of announced prefixes covered by the active addresses. *AddrMiner-N* discovered approximately 159.0M active addresses, covering 86.4K announced prefixes, accounting for 81.6% of all announced prefixes. It indicates that *AddrMiner-N* can perform active address probing over a broader address space and is more suitable for global active IPv6 address probing.

8.2 Efficiency of *AddrMiner-F*

In few seed scenario, we evaluate *AddrMiner-F* by comparing active address hit rate with *AddrMiner-N* and the state-of-the-art target address generation algorithms. We generated different numbers of target addresses among 31,771 announced prefixes containing few seeds, i.e., $b_{count} = 31,771$, $p_{count} = 10$, and $g = 1, 10, 100, 1000$. Figure 8 shows the hit rate of active address probing. When target addresses are small, DET, 6Hit, and 6Tree randomly generate target addresses in low nybble space. As the target addresses increase, the larger the target address will cause the hit rate to decrease. Therefore, in the scenario with few seeds, the state-of-the-art target address generation algorithms are inferior. The hit rate of active addresses is very low when the target space represented by the pattern is too large or too small. We probed all mined common patterns and found that the hit rate was highest when the pattern contained 2 variable nybbles ([32-256] targets). This is because we choose the pattern space closest to the probing number (G) to generate targets randomly. This explains why the hit rate of *AddrMiner-N* increases and then decreases

Table 4: Ratio of common patterns in the pattern library

Patterns	Example of patterns in pattern library	Ratio/%
Low-byte	20010db8000000000000000000000000[1-a]	25.886
Embedded-IPv4	20010db80122034400000000874b2b[3-f][4-f]	7.420
Embedded-port	20010db800000000000000000000[01]***	0.100
ISATAP	fe80000000000000002005efec0000***	0.002
EUI-64	fe80000000000000002aa00ffe3f[2-f][a-c]1c	3.100
Other	240085001000000000de00e300**00**	63.490

in Figure 7 and Figure 8. As the number of target addresses increases, the expansion of the probe space reduces the effectiveness of similarity matching, which affects the efficiency of *AddrMiner-F* probing. However, *AddrMiner-F* is more effective overall than the other methods. When *AddrMiner-F* generates 10-10,000 target addresses for each announced prefix containing few seeds, the active address probing efficiency is improved by 70%-150% compared to existing methods. *AddrMiner-F* enables a more efficient transition from few active address scenario to sufficient address scenario.

8.3 Common Pattern Library Analysis

The common pattern library generated by *AddrMiner* is a set of pattern strings. We analyze this pattern library and provide some further guidance for active IPv6 address probing.

RFC documents [20, 32] presents several common patterns in the IID of IPv6 address, e.g., may be a low-byte IID with a run of zeroes followed only by a low number, an embedded-IPv4 IID inserting one IPv4 address, an embedded-port IID including the service port in the lowest-order byte of the IID, an ISATAP IID with "0200:5EFE" flag and IPv4 address, an EUI-64 IID with an embedded MAC address. Table 4 shows the common address patterns, examples of pattern strings, and the ratio in the pattern library. We find that EUI-64 IID and ISATAP take fixed values at some locations where the address is fixed, so the pattern strings use the Single policy, which is a non-dynamically changing nybble, at these fixed locations. Low-byte address patterns will have more consecutive nybbles in the middle that takes on a value of zero and only change at the end in multiple consecutive nybble positions, such as 20010db800000000000000000000[1-a] for 2001:db8::1 or 2001:db8::4 for these types of IPv6 address structures. The high percentage of the low-byte address pattern in the pattern library means that a brute-force scanning can be attempted for such structures, i.e., fixing the value of the middle nybbles to 0 and traversing only the last consecutive nybbles. It explains the high hit rate of incremental scanning when the number of targets is small. In addition, *AddrMiner* can find many additional address patterns, such as the other types in Table 4, which also account for 63.49% of the total. Although such address patterns do not correspond to address patterns known from RFC documents, their stronger regularity can reduce the difficulty in brute-force scanning of such addresses and improve the efficiency of address probing.

In short, *AddrMiner* can dig out address patterns that not only contain the address patterns of RFC documents, but can also discover more valuable address patterns. We do not consider the assignment of given address space to one of the classes to be static. Furthermore, *AddrMiner* adds newly discovered addresses to the IPv6 hitlist, and updates the common patterns promptly for dynamic IPv6 address spaces.

8.4 Efficiency of *AddrMiner-S*

We evaluate the efficiency of *AddrMiner-S* in probing active addresses by comparing the active address hit rate of *AddrMiner-S* and the state-of-the-art algorithms.

Here, we randomly select announced prefixes that contain more than 1K seeds. We run the above algorithms for each announced prefix to generate target addresses with a budget of 10 times the seeds. Figure 9(a) illustrates the address probing efficiency of *AddrMiner-S* in announced prefixes with sufficient seeds. We observe that the active address hit rate of *AddrMiner-S* outperforms other state-of-the-art algorithms in every announced prefix. In particular, the active address hit rate of *AddrMiner-S* reaches 35.2% in prefix 2001:1291::/32.

To further validate the efficiency of *AddrMiner-S*, we randomly select 1M active addresses as seeds from Gasser’s public hitlist. We use *AddrMiner-S* and state-of-the-art algorithms (Note that 6GAN is not suitable for large-scale global active address detection since the time complexity is too high based on deep learning framework) to generate target addresses with budgets ranging from 10M to 50M. We set the budget b consumed for each iteration to 10K. Figure 9(b) shows the probing results after removing the aliased addresses. We find that *AddrMiner-S* outperforms the other algorithms. When the budget is 50M, the hit rates of the algorithms from highest to lowest are *AddrMiner-S* (56.3%), DET (28.9%), 6Tree (12.9%), 6Gen (14.6%), and Entropy/IP (3.1%), 6Hit (2.6%), and the hit rate of *AddrMiner-S* is almost twice as much. In particular, 6Hit has a high hit rate when the budget is small. Still, space expansion leads to a rapid decrease in hit rate as the budget increases because the target addresses are generated randomly due to the spatial repartition mechanism of 6Hit. *AddrMiner-S* maintains the state learned from sub-space during space expansion to avoid a rapid decrease in hit rate and effectively improve detection.

In the ideal sampling case, the density distribution of seeds is consistent with the density distribution of active addresses in the actual network. The reward (R_i) of each iteration reflects the active address density distribution of the real network. The density distribution of seeds updated by rewards in the next iteration (R_i^{t+1}) is more convergent to the distribution of active addresses in the actual network compared to the previous iteration (R_i^t). Therefore, the similarity between the current seed address density distribution and the actual network’s active address density distribution can be obtained by calculating the difference in reward ranking after each

iteration using Hamming distance. As shown in Figure 9(c), the density distribution of seeds increasingly converges to the density distribution of active addresses in the actual network as the number of iterations increases. In addition, *AddrMiner-S* strikes a balance between exploration and exploitation (the specific analysis is given in Appendix D).

9 IPv6 Hitlist

AddrMiner probes each IPv6 prefix announced by BGP, requiring approximately one month to probe all announced prefixes. As the number of all announced prefixes exceeds 100K, this results in a long probing time. Therefore, to deal with the dynamic changes in the IPv6 space, we repeat the probing of IPv6 prefixes announced by BGP every month. The probe period should be set as short as possible to get a more accurate view of active IPv6 addresses, depending on the probe resources. We have developed *AddrMiner* for continuously probing active IPv6 addresses worldwide for 13 months and discovered 2.1B active addresses (covering 86.4K announced prefixes), including 1.7 billion de-aliased active addresses (IPv6 hitlist) and 0.4 billion aliased addresses. Meanwhile, we found 1.1M aliased prefixes, which are described and analyzed in Appendix E. The IPv6 hitlist is analyzed as follows:

Time Characteristics. Active IPv6 addresses have time characteristics. IPv6 addresses, especially client addresses, have a short lifetime. Therefore, when a probe response is received, we can only determine that the IPv6 address is active at the response time. We analyze the stability of addresses to determine addresses’ lifetime, mainly by separating server addresses, router addresses, persistent or stable client addresses, and temporarily active client addresses.

We define nd -stable to represent the stability of the address. For example, 1d-stable is active for at least one day during the continuous detection period, and nd -stable address means active for at least n days. The active address of nd -stable is also the address of $(n-1)d$ -stable. We send an ICMPv6 request to each address we collect every day and record these addresses’ lifetime according to the response information from January 8, 2021. As shown in Table 5, we found that the long-term active addresses(100d-stable addresses) are more than 46%. Compared with temporarily active client addresses, long-term active addresses are more meaningful for detection.

IID Analysis. We analyze the IID types of active address assignments to understand the global IPv6 address configuration landscape. Utilizing the `addr6` tool [12], we have divided the IID portion of IPv6 addresses into different types.

In Table 5, we analyze the IID allocation types of different stable addresses. The 1.7 billion 1-stable de-aliased addresses mean IPv6 hitlist we collected. We found that pattern-bytes (some discernible patterns) IID addresses accounted for as high as 40.8%, closely related to our detection strategy because we mainly detect active addresses by constructing common pattern library (similarly, low-byte IID and embedded-

Figure 9: Comparisons between the *AddrMiner-S* and the state-of-the-art algorithms with sufficient seeds.

Table 5: IID Analysis of Discovered n-stable Addresses

-	#IPs	EUI-64	Embedded-IPv4	Pattern-bytes	Randomized	Low-byte
1d-stable(Hitlist)	1.7B	71.4M (4.2%)	251.6M (14.8%)	676.6M (39.8%)	411.4M (24.2%)	277.1M (16.3%)
7d-stable	1.1B (65.8%)	57.8M (3.4%)	212.5M (12.5%)	506.6M (29.8%)	113.9M (6.7%)	227.8M (13.4%)
30d-stable	919.4M (54.1%)	760.8K (0.0%)	204.0M (12.0%)	498.1M (29.3%)	13.6M (0.8%)	202.3M (11.9%)
60d-stable	860.2M (50.6%)	701.6K (0.0%)	190.4M (11.2%)	464.1M (27.3%)	13.5M (0.8%)	188.7M (11.1%)
100d-stable	783.7M (46.1%)	680.4K (0.0%)	173.4M (10.2%)	425.0M (25.0%)	10.3M (0.6%)	173.3M (10.2%)

IPv4 IID addresses). In addition, the IPv6 hitlist contains 24.2% of randomized IID addresses, which are randomly generated in high-density regions. The EUI-64 IID addresses are only 4.2%. This is because Gasser’s hitlist contains a small proportion of EUI-64 IID addresses. At the same time, the detected address space is small, and there is no address generation in the EUI-64 flag. In vertical analysis, we found that randomized IID and EUI-64 IID addresses are more unstable during continuous detection. The proportion of temporarily active client addresses is high, and the lifetime is less than seven days. Embedded-IPv4 IID, low-byte IID, and pattern-bytes IID addresses have high stability and a long lifetime. These are more likely to contain long-term active and stable client addresses, server addresses, router addresses, etc.

We further analyze the organization and location distribution of active addresses in the IPv6 hitlist in Appendix F.

10 Ethical Considerations

To perform global IPv6 address probing, we follow ethical conventions for network measurement, including recommendations provided by Partridge et al. [39] and Dittrich et al. [8]. We first evaluate whether active address measurements induce harm to the probed hosts and networks. We send only one probe packet to each IP address, which minimally affects the host and the network where the IP is located. To avoid duplicate probes, *AddrMiner* removes IPv6 addresses that have already been probed from the generated target addresses. Next, we evaluate whether the probing behavior will cause harm to the local network. We will use distributed probes with a probing rate limit of 10 Mbps per probe to avoid causing problems to the network where the probing point is located during active address probing.

11 Conclusion and Future Work

This work proposes a systematic methodology, *AddrMiner*, which comprehensively probes the global active IPv6 addresses. We follow ethical conventions for network measurement. *AddrMiner* divides the global active IPv6 address probing into three scenarios and accumulates active addresses from none to many. We used *AddrMiner* to probe the global active IPv6 addresses and found 2.1 billion active addresses within 13 months. *AddrMiner* removes the limitation of using a vantage point for active IPv6 address probing. Our work will effectively support more researchers to conduct in-depth IPv6 network measurement and security research. We share code and data at: <https://github.com/AddrMiner/AddrMiner>.

In future work, we will continue to probe active IPv6 addresses. In addition, the blocking strategies and middle boxes can affect the detection of active addresses [25], we will further study their impact on active address detection.

12 Acknowledgments

We would like to thank our shepherd, Adrian Perrig, and the anonymous reviewers for their insightful comments. We also thank Chenglong Li, Enhuan Dong, Yichao Wu, Jinjin Wei, Jinlei Lin, Long Pan, Hao Gao, Yirui Luo, and Leyao Nie for their feedback and suggestions. A Similarity Definition

In this section, we give the definition of Jaccard similarity and Hamming distance-based similarity.

- **Jaccard similarity:** Jaccard similarity can be used to calculate the similarity between any two sets. The calculation is shown in Formula (1), where U_1 and U_2 are both sets. In particular, if U_1 and U_2 are both empty sets, then $J(U_1, U_2)$ is 0.

$$J(U_1, U_2) = \frac{|U_1 \cap U_2|}{|U_1 \cup U_2|} \quad (1)$$

- **Hamming distance-based similarity:** For two sequences of the same length z_1 and z_2 , their similarity based on Hamming distance is calculated as follows:

$$S_{HD} = \sum_{i=1}^n r(z_1[i], z_2[i])$$

$$r(a, b) = \begin{cases} 1, & \text{if } a = b \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

B Model Building of AddrMiner-S

We use a multi-armed bandit model [45] based on Thompson sampling [43] to dynamically update the density distribution in the active address space to correct the inconsistency in the density distribution between the seeds and the actual active addresses.

We divide the IPv6 address space into different density regions $X = \{x_1, x_2, \dots, x_k\}$, and each address region is an arm of the multi-armed bandits. There are k actions $A = \{a_1, a_2, \dots, a_k\}$, and a_i refers to scanning the target address in x_i and probing whether it is an active address, where $i \in [1, k]$. $\Theta = \{\theta_1, \theta_2, \dots, \theta_k\}$ represents the mean reward. The distribution of each arm reward is the Bernoulli score with Θ as the parameter:

$$P(r|a_i, \theta_i) = \begin{cases} \theta_i, & \text{if } r = 1 \\ 1 - \theta_i, & \text{otherwise} \end{cases} \quad (3)$$

When a_i is played, the action produces a reward of one with probability θ_i , and a reward of zero with probability $1 - \theta_i$. The θ_i can be interpreted as an action’s success probability or mean reward. Let the agent begin with an independent prior belief over each θ_i . Take these priors to be beta-distributed with parameters $A = \{\alpha_1, \dots, \alpha_k\}$ and $B = \{\beta_1, \dots, \beta_k\}$. In particular, for each action a_i , the prior probability density function of θ_i is:

$$P(\theta_i) = \frac{\Gamma(\alpha_i + \beta_i)}{\Gamma(\alpha_i)\Gamma(\beta_i)} \theta_i^{\alpha_i-1} (1 - \theta_i)^{\beta_i-1} \quad (4)$$

where Γ denotes the gamma function. As observations are gathered, and the distribution is updated according to Bayes’s rule. It is particularly convenient to work with Beta distributions because of their conjugacy properties. In particular, each action’s posterior distribution is also beta distribution with parameters that can be updated according to a simple rule:

$$(\alpha_i, \beta_i) \leftarrow \begin{cases} (\alpha_i, \beta_i), & \text{if } a_i \neq i \\ (\alpha_i, \beta_i) + (r_i, 1 - r_i), & \text{otherwise} \end{cases} \quad (5)$$

In other words, we choose region x_i to scan a target address. If we find the target address is active (reward = 1), we will add one to the corresponding α_i (β_i remains unchanged); otherwise (reward = 0), will add one to the corresponding β_i (α_i unchanged). α_i represents the active address probed in region x_i , $\alpha_i + \beta_i$ represents the address budget consumed in region x_i , so the hit rate of active addresses in region x_i is $\frac{\alpha_i}{\alpha_i + \beta_i}$. As in Formula (6), the x_i ’s active address density is proportional to the hit-rate of active address.

$$x_i.\text{density} = \frac{x_i.\text{active addresses}}{x_i.\text{size}} \propto \frac{\alpha_i}{\alpha_i + \beta_i} \quad (6)$$

In active IPv6 address probing, the key issue is to achieve a high active address hit rate within a given budget. Assuming

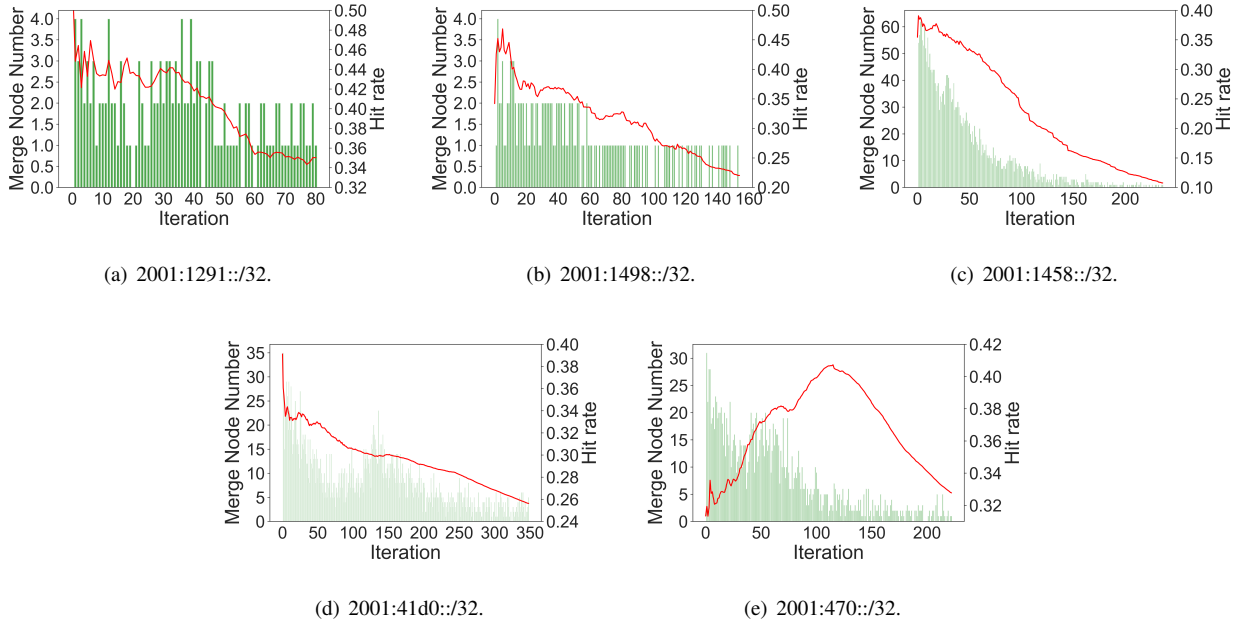

Figure 10: Comparisons of the probing efficiency between the *AddrMiner-S* and other address generation algorithms for different budgets in announced prefixes with sufficient seeds.

that our probing budget is B and the objective function of address probing is f , the active address probing is a combinatorial optimization problem of (X, B, f) , they need to satisfy the following relationship:

$$\sum_{i=1}^n (\alpha_i + \beta_i) \leq B \quad \& \quad \alpha_i + \beta_i \leq x_i.size \quad (7)$$

n represents the number of regions where the target addresses are generated. Our objective function f represents the hit rate of the active address within the target address budget B .

$$f = \frac{\sum_{i=1}^n \alpha_i}{\sum_{i=1}^n \alpha_i + \beta_i} \quad (8)$$

A feasible solution $x \subseteq X$ that satisfies Formula (7), then the most effective solution x^* is only if $f(x^*) \geq f(x), \forall x \subseteq X$.

C Seed Number vs. Probing Efficiency

State-of-the-art address generation algorithms learn the structural and distributional characteristics of seeds to generate target addresses that are more likely to survive. However, these techniques are overly dependent on the quality, quantity, and distribution of seeds. Theoretically, seed address-based target address generation algorithms cannot work in target regions with no seeds, nor can they work efficiently in target regions with few seeds. Next, we further explore the impact of

Figure 11: The effect of the number of seeds on the efficiency of active IPv6 address probing.

the number of seeds on the efficiency of active IPv6 address probing.

From the previous measurements, we find that DET [47] has better probing efficiency than 6Tree [33], 6Gen [36], and Entropy/IP [15]. Therefore, we randomly select a different number of active addresses as seeds in any announced prefix with a sufficient number of seeds, and use DET to generate target addresses, with a budget of 10K.

Figure 11 shows the hit rate of active address probing for DET with a different number of seeds. We find that the hit rate of the active address is the lowest when the extreme case of the seed address is 1. At this point, the address probing strategy is the same as 6Tree and fixed-space brute force

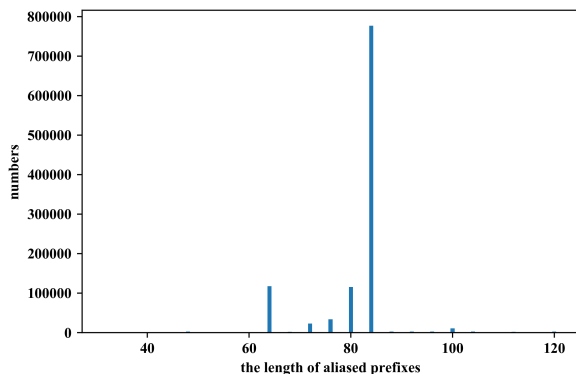

Figure 12: The length distribution of aliased prefixes.

scanning. It builds a hierarchical space tree and prioritizes randomly generates target addresses in low nybble space, so the probing efficiency of this active address is poor (the hit rate is less than 0.01%). As the number of seeds increases, the hit rate of active address probing increases. When the number of seeds in the target region exceeds 100, the active address hit rate exceeds 10%. When the number of seeds exceeds 1000, the hit rate of active addresses remains stable. Therefore, the seed address-based target address generation algorithms are very dependent on seeds and cannot effectively perform global active IPv6 address probing when the number of seeds is insufficient. In this paper, we divide the global active IPv6 address probing task into three sub-tasks according to the number of seeds in the announced prefix spaces, including scenarios with no seeds, scenarios with few seeds, and scenarios with sufficient seeds. We empirically classify the announced prefix spaces. When the number of seeds in the announced prefix space exceeds 1000, we classify the announced prefix space with sufficient seeds. We classify the announced prefix space with few seeds when the number of seeds is not greater than 10. Solutions are designed for each of the above scenarios, effectively solving the global active IPv6 address probing problem.

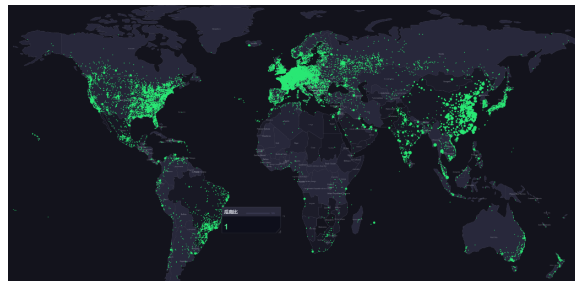

Figure 13: The location distribution of IPv6 hitlist.

D Verification of AddrMiner-S

Figures 10(a) to 10(e) show how the hit rate of active addresses and the number of merged nodes vary with the number of reinforcement learning iterations. *AddrMiner-S* can find more optimal address regions by merging nodes to discover active addresses (exploration) and generate target addresses (exploitation) in high-density regions. When the node space is fully explored, the node merging operation can further expand the address search space. During the exploration process, the hit rate of active addresses does not drop suddenly, ensuring the efficiency of active address probing and discovering new high-density regions. Thus, *AddrMiner-S* strikes a balance between exploration and exploitation. In Figure 10(c), the sampling bias of the seeds is small, so the hit rate is less volatile. In Figure 10(e), the sampling bias is obvious. As the number of iterations increases, high-density regions of the actual network are discovered, which effectively improves the efficiency of address probing.

E Aliased Prefix Analysis

During our evaluation process, we found that aliased prefixes profoundly impact the generation of IPv6 addresses. Because the entire prefix is configured on the same network device, when we do not judge the aliased prefix, all addresses in the aliased prefix space will return an ICMPv6 response packet. These addresses will consume probing resources and cause a lot of false active addresses. Therefore, in our probing system, we consciously detect the aliased prefix and remove aliased

addresses.

Figure 12 shows the length distribution of aliased prefixes. We found that the length of aliases prefix is mostly between /64 and /84. We also surprisedly found that 2,685 aliased prefixes are announced prefixes, such as 2401:5e40:8000::/33, assigned to Japan Network Information Center. We further analyzed and found that the target network opened FTP and Telnet ports and took anti-probing measures. Therefore, we inferred that the device where the prefix 2401:5e40:8000::/33 was located could be a honeypot, a decoy network, or a clustered storage system.

The aliased prefix, especially the entire announced prefix as an aliased prefix, may bring the following security problems: First, heuristic active address probing will guide a large number of probes into the aliased prefix space for probing (if there is no ability to remove the aliased prefix), it will cause excessive load on the network device configured with the aliased prefix, and even multiple normal probers will cause DDoS attacks. In addition, it may also affect the performance of the upper network.

F IPv6 Hitlist Introduction

We further analyze the organizational distribution and address location distribution of the IPv6 hitlist in Table 6 and Figure 13, respectively.

Co-opting Linux Processes for High-Performance Network Simulation

Abstract

Network experimentation tools are vitally important to the process of developing, evaluating, and testing distributed systems. The state-of-the-art simulation tools are either prohibitively inefficient at large scales or are limited by nontrivial architectural challenges, inhibiting their widespread adoption. In this paper, we present the design and implementation of *Phantom*,¹ a novel tool for conducting distributed system experiments. In Phantom, a discrete-event network simulator directly executes unmodified applications as Linux processes and innovatively synthesizes efficient process control, system call interposition, and data transfer methods to co-opt the processes into the simulation environment. Our evaluation demonstrates that Phantom is up to $2.2\times$ faster than Shadow, up to $3.4\times$ faster than NS-3, and up to $43\times$ faster than gRaIL in large P2P benchmarks while offering performance comparable to Shadow in large Tor network simulations.

1 Introduction

Network experimentation tools promote the progression of network science: they aim to *realistically* reproduce the effects of distributed networks at *scale* in a *controlled* environment, enabling the scientific evaluation of performance and security across a range of system characteristics. Experimentation tools are particularly useful for *large-scale* distributed systems that are deployed in the real world, such as the globally expansive domain name system [50], peer-to-peer and content distribution networks [14], decentralized data-storage networks [52], and overlay networks [17]. Due to the sizes of these deployments and the internet's great heterogeneity and rapid change [19], it would be extremely difficult to run scientifically controlled, replicable experiments with them in the real world. Tools that enable realistic, scalable, and controlled experimentation of large-scale distributed systems can help accelerate research, development, and education.

Large-scale distributed systems are often characterized by a complex set of algorithms and protocols that run in *application-layer* software. Previous work has found that it is prudent to *directly execute* this software as part of the experimentation process to promote realism [30, 54, 62]. However, there are nontrivial architectural challenges in designing tools that meet the scalability and realism requirements. Emulators such as Mininet [45] do not support large-scale systems because they are vulnerable to time distortion during periods of overload [44]. Simulators such as NS-3 [26] run *application abstractions* in place of real software which can cause unrealistic behavior and lead to invalid results [54].

To meet the large-scale distributed system requirements, the state-of-the-art tools are designed with hybrid architectures wherein a network simulator directly executes application code. However, tools that load and execute applications in *plugin namespaces* (i.e., NS-3-DCE [62] and Shadow [30]) suffer from compatibility and correctness issues and high maintenance costs: applications must be recompiled as plugins, complex code is required to load and run them, and the system calls they make often leak outside of the simulation. On the other hand, tools that run applications as *Linux processes* (i.e., gRaIL [54]) incur considerable inter-process overhead: we have measured at least a $10\times$ performance penalty in running gRaIL due to inefficient process control, system call interposition, and data transfer mechanisms. No existing network simulator simultaneously overcomes the compatibility, correctness, maintenance, and performance challenges found in the state-of-the-art tools.

Introducing Phantom: We present *Phantom*,¹ a novel, multi-process network simulator that: (i) precludes the compatibility, correctness, and maintenance issues that have plagued plugin-based designs; and (ii) overcomes the performance challenges of existing multi-process designs by innovatively synthesizing efficient process control, system call interposition, and data transfer mechanisms. In Phantom, a discrete-event network simulation core directly executes unmodified

Approved for public release: distribution is unlimited.

¹We use *Phantom* as a codename in this paper, but our design is merged into the open-source Shadow simulator and synonymous with Shadow v2 [4].

applications as Linux processes, allowing us to take advantage of native Linux process isolation and management. Phantom co-opts the Linux processes into a simulation environment by (i) preloading a shim library (via `LD_PRELOAD`) that is used to establish efficient mechanisms for process control and function interception; (ii) installing a secure computing (i.e., `seccomp`) filter in the processes to guarantee interposition on system calls that are not preloadable; and (iii) using a novel inter-process memory mapper that allows us to directly read and write process memory without incurring inter-process communication (IPC) overhead. Once the processes are co-opted, Phantom efficiently emulates system calls they make and facilitates communication over a simulated network.

Novel Contributions: This paper makes the following novel contributions to the state of the art in network simulation:

- The innovative design of Phantom, which for the first time shows how to minimize inter-process overhead in a hybrid, multi-process network simulator.
- A high-performance implementation of Phantom.
- An extensive evaluation of Phantom through which we find that it is up to $2.2\times$ faster than Shadow, up to $3.4\times$ faster than NS-3, and up to $43\times$ faster than gRaIL in large P2P benchmarks while offering performance comparable to Shadow in large Tor network simulations.
- A verification of Phantom’s accuracy in small LAN and WAN networks and in large Tor overlay networks.

Impact: This work has high potential for broad impact across multiple communities for the purposes of research, development, and education. First, researchers building software prototypes can use Phantom to quickly evaluate their new distributed system designs in a large-scale network without needing to worry about complicated deployments that are difficult to manage. Second, Phantom can be built into developers’ testing frameworks so that new code can be continuously tested and discovered bugs can be identically reproduced. Third, with facilities to introduce network events (e.g., intermittent delays or failures), Phantom could help teach network and distributed systems courses. The Tor Project has already started using Phantom to develop and test new congestion control protocols before deploying them to the Tor network [57].

Availability: Phantom is merged into the open-source Shadow project as of v2 [4] and our artifacts are publicly available [3].

2 Background and Motivation

We motivate the need for Phantom by identifying the key requirements, existing architectures, and challenges for realistically simulating large-scale distributed systems. (See Appendix A for extended background on related tools.)

2.1 Requirements

Scalability: Recent work finds that it is imperative to run network experiments as close as possible to the deployed scale because reducing the scale can lead to a significant loss

of confidence in the experimental results [40]. Although some statistical confidence can be recovered with repeated trials, it can take many more trials at a smaller scale to achieve the same confidence as larger scale simulations [40].

To increase the scale at which we can run network experiments, a correct and valid execution of the simulation workload should not depend on the computational abilities of, or passage of time on, the host machine. Decoupling the simulation from time and computational constraints allows us to scale without introducing artifacts in the results due to over-provisioning and time-distortion [44].

Realism: Distributed systems are often composed of a diverse set of applications that each contain complex logic. We should directly execute these applications in order to guarantee that our experiments identically replicate their logic and obtain the highest application fidelity possible [30, 54, 62].

Deployed system software is often under active development to fix bugs and develop enhancements. We should execute applications the same way they would be executed in deployment; we should not require recompilation or the maintenance of application patches or abstractions. Running unmodified applications enables us to decouple the application logic and programming language from that of the simulation.

Control: Large-scale distributed systems contain many variables, and changing any one of them can have cascading network effects that can lead to unexpected behaviors or results. We should support deterministic execution to obtain scientific control and to guarantee that the results produced by an experiment can be independently and identically replicated.

2.2 Traditional Architectures

Tools implementing strictly traditional architectures are unsuitable for evaluating large-scale distributed systems with logic primarily contained in *application-layer* software.

Simulation: Network simulators such as NS-3 [26] scale independently of the wall-clock time [67] and offer precise experimental control due to deterministic execution [13]. However, simulators traditionally run application *abstractions* in place of real software which can cause unrealistic behavior and lead to invalid results [54]. As a result, traditional simulators do not fulfill the application realism requirement.

Emulation: Network emulators such as Mininet [45] directly execute applications using real kernel network stacks and therefore offer better application realism. However, emulators lack perfect scientific control due to non-determinism [12]. Moreover, emulators are generally unable to scale independently of computational constraints: if the experiment host machine is overloaded, time distortion will exacerbate reproducibility issues [44]. We confirm this claim with an experiment in which we find that as the host machine becomes more loaded with virtual peers, *its packet forwarding capacity is limited* and a decreasing fraction of the sent packets are correctly forwarded (see §5.4 and Figure 14 for details). As a result, traditional emulators are useful only at small scales.

Table 1: Properties of Network Experimentation Architectures

Architecture	Example Tool	Scalability*	Realism†	Control‡
Emulation	Mininet [45]	○	●	○
Simulation	NS-3 [26]	●	○	●
Hybrid	This Work	●	●	●

* Experiments scale independent of time or computational constraints.

† Unmodified applications can be directly executed without recompilation.

‡ Results can be deterministically replicated with the same RNG seed.

2.3 Hybrid Architectures and Challenges

A hybrid architecture is characterized by the ability to directly execute applications to promote realism while still running them in the context of a cohesive network simulation. As a result, a hybrid architecture enjoys the advantages of both emulation and simulation and offers the best opportunity to fulfill the scalability, realism, and control requirements discussed in §2.1 (see Table 1). However, there are numerous challenges with hybrid architectures that we believe have inhibited tools implementing them from achieving widespread adoption. We describe these challenges by the method for executing applications: *plugin namespaces* and *processes*.

Plugin Namespaces: In this approach, the simulator loads each application into a new plugin namespace (e.g., using `dlmopen`) and directly executes the application in the context of that namespace while using function interposition (via `LD_PRELOAD`) to hook the loaded applications into the simulation environment. A plugin design is implemented in both NS-3-DCE [62] and Shadow [30] and has several limitations:

- *Compatibility:* The domain of supported applications is limited to those that are compiled as position-independent libraries (PIC) or executables (PIE) that export their symbols to the dynamic symbol table (`rdynamic`), are dynamically linked to `libc`, and make all system calls through `libc`. Rebuilding is tedious and impossible if the source code is not available (e.g., closed-source software or malware).
- *Correctness:* Relying solely on preloading is unreliable because only dynamically linked functions (e.g., those in `libc`) can be intercepted using `LD_PRELOAD`; system calls invoked via statically linked code or assembly instructions will leak outside of the simulation and cause errors.
- *Maintainability:* A custom dynamic loader [63] is required to load more than 16 namespaces at once, and a portable threading library [48] is used to support multi-threaded applications (these account for 62k LoC in Shadow; see §4). `libc` functions with nontrivial functionality must be reimplemented in order to intercept the system calls they make.

These challenges have limited Shadow’s use to Tor network simulation [40] while work on simulating Bitcoin has been abandoned [48] and work on NS-3-DCE has mostly stalled.

Processes: In this approach, applications are executed as standard Linux processes and hooked into the simulation through the system call interface using standard kernel facilities. This design overcomes many of the limitations of the plugin ap-

proach: (i) the simulator can execute any existing application without rebuilding it; (ii) kernel subsystems guarantee reliable process isolation and correct system call interception; and (iii) the maintenance of a custom loader, threading libraries, and reimplemented `libc` functions is no longer required. However, the naïve way of connecting multiple processes in a cohesive simulation as demonstrated in gRaIL [54] requires the kernel’s process control (`ptrace`) subsystem and is significantly less performant than the plugin approach: we show in §5.4 that the run time of gRaIL (which extends NS-3) is 13× that of NS-3 alone, and 43× that of Phantom in experiments with fixed P2P messaging workloads. Worse performance in gRaIL’s multi-process design can be attributed to:

- *Process control:* The simulator needs to control the execution state of the processes as they progress through simulated time. The `ptrace` process control mechanism (`PTTRACE_ATTACH` or `PTTRACE_TRACEME`) incurs overhead that is *quadratic* in the total number of attached processes, limiting scalability (see Appendix B.1).
- *System call interposition:* The simulator needs to intercept system calls made in the processes so they can be emulated. The `ptrace` system call mechanism (`PTTRACE_SYSCALL`) requires *at least 4* context switches *for every system call*, contributing substantial overhead relative to a same-process function call (see Appendix B.2).
- *Data transfer:* The simulator needs to access system call arguments referencing process memory (e.g., data buffers). The `ptrace` memory access mechanism (`PTTRACE_PEEK` and `PTTRACE_POKE`) requires an additional system call and mode transition *for each word of memory*, making it inefficient for large structs and buffers (see Appendix B.3).

Ideally, we want a simulator with the higher performance of the uni-process, plugin-based Shadow design (which does not incur inter-process overhead) *and* the improved compatibility, correctness, and maintainability of the multi-process gRaIL design. However, it was previously unknown if this ideal is attainable due to the multi-process challenges; indeed, we show throughout §5 that even a more efficient use of `ptrace` (see Appendix B) is still less performant than a uni-process design.

3 Design

In this section we describe the novel multi-process Phantom design that eliminates the limitations of the state-of-the-art plugin-based architecture and overcomes the performance challenges of the state-of-the-art process-based simulator.

3.1 Overview

The main component in Phantom is a discrete-event simulator which drives the simulation (see Figure 1). After initialization, the simulator directly executes the real applications of an experiment as Linux processes while using inter-process communication channels (IPC) between the application and simulator processes. Phantom co-opts the applica-

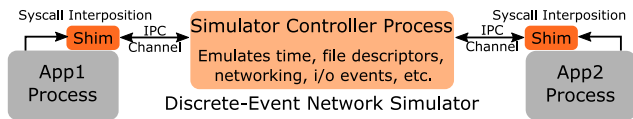

Figure 1: Overview of the Phantom design. Phantom directly executes application processes, intercepting system calls and handling them using a shim and an inter-process communication channel.

tion processes into the simulation by intercepting all system calls they make (e.g., `socket`, `listen`, `connect`, `send`, `recv`, `poll`, etc.) rather than allowing them to be handled by the Linux kernel. Phantom handles intercepted system calls by internally simulating common kernel functionalities that most applications expect to be available, such as networking facilities (e.g., buffers, protocols, and interfaces), event notification facilities (e.g., `select`, `poll`, and `epoll`), and file descriptor facilities (e.g., files, sockets, and pipes). As a result, Phantom emulates a Linux kernel to the applications while connecting them through a virtual, simulated network, and the applications need not be aware that they are running in a simulation.

3.2 Components

3.2.1 Simulation Controller Process

Phantom is a parallel, conservative-time, discrete-event network simulator that emulates a Linux kernel to the applications it executes. Simulations are driven by a single controller process which has two primary functions that occur successively during an *initialization* phase and an *execution* phase.

Initialization Phase: During initialization, the controller reads and processes configuration inputs. The inputs specify a number of virtual hosts that should be simulated, a network graph model that should be used to model network characteristics such as routing, latency, and packet loss between the virtual hosts, and the file paths and arguments needed to directly execute the applications on the virtual hosts. The controller initializes internal simulation state accordingly.

Execution Phase: Simulation work is organized into *events* that each occur at a discrete simulation time. Each event is assigned to a virtual host and stored in a host-specific *event queue*: a min-heap that sorts events by their simulation time.

The controller manages the global simulation clock and synchronizes simulation time by using time barriers to establish discrete *execution rounds*: time intervals during which events may be safely executed in parallel. The time barrier in a round is set such that no event that is executed for any host in that round will enqueue a new event for any other host in the same round. This conservative-time algorithm guarantees that simulation time always advances on each host, even when concurrently executing distinct hosts' events. When the next event time in every host's event queue exceeds the time barrier for the current round, the controller updates the global clock and advances the execution round.

3.2.2 Parallel Worker Threads

Phantom concurrently executes the events in each execution round using *worker threads* (workers) that are managed with high level abstractions we call *logical processors* (LPs). Phantom allows a configurable number of LPs and controls the state of an independently configurable number of workers such that only a number of workers equal to the number of LPs are concurrently active.²

The following algorithm employs a work stealing [10, 65] strategy to schedule the worker threads, ensuring that each LP will always be running a worker thread as long as one with remaining work exists. When an execution round begins, one worker thread starts *running* for each LP while the remaining workers remain *waiting*. While running, a worker dequeues and executes all events that occur within the current round (as set by the controller) for all hosts assigned to it. When a worker completes all outstanding events for the current round, it: (i) starts running another waiting worker that has yet to run in this round (if any exist); and (ii) starts waiting to be run again during the following round. An execution round ends when all workers have entered the waiting state.

3.2.3 Direct Application Execution

During initialization, each virtual host is configured to directly execute some number of applications. Phantom internally creates virtual process and thread data structures to store the state needed to manage the execution of the applications (e.g., file descriptor tables and standard input/output handles). **Managed Processes and Threads:** Phantom directly executes specified application binaries and allows for configuration of the command-line arguments and the start time within the simulation. Each application is launched by a Phantom worker with a `vfork+execvpe` sequence.

The application execution procedure results in the creation of one or more Linux processes and threads that are *managed* by their parent Phantom worker. Each worker (i) uses our preload shim library to co-opt their managed processes into the simulation, and (ii) uses our inter-process communication mechanisms to modulate the running state of the managed processes such that only one of a worker and its managed processes are running at any time (thus maintaining that only one task per LP is concurrently active).

Preload Shim: In order to assist with controlling the managed processes and threads, we create a custom shared library, subsequently referred to as “the shim”, which is loaded into each managed process's address space using the `LD_PRELOAD` environment variable. We use the shim to: (i) execute initialization code in the shim's constructor functions and establish an inter-process communication channel (see §3.2.6); and (ii) intercept functions defined in libraries that are dynamically linked to the applications (e.g., `libc`; see §3.2.4).

²Limiting the number of LPs to be at most the number of available CPU cores avoids performance degradation caused by CPU oversubscription.

Figure 2: Control flow when intercepting system calls in Phantom.

3.2.4 System Call Interposition

Phantom co-opts processes into the simulation by intercepting functions at the system call interface using two interception strategies: *preloading* and *seccomp* (see Figure 2).

Primary Strategy: Preloading: Recall from §3.2.3 that Phantom preloads a shared library shim into each process it executes using the `LD_PRELOAD` environment variable. Because the shim is preloaded, the dynamic loader loads the shim before all other shared objects linked to the managed process and the shim is the first library searched when attempting to dynamically resolve symbols. This feature allows us to selectively override functions in other shared libraries by supplying identically named functions with alternative implementations inside the shim. Preloading is efficient, as it changes only the address of the instruction that is next executed when a dynamically-linked function is invoked. Therefore, we use preloading as our primary interception strategy.

Notice that preloading works by intercepting *shared library functions*, not *system calls*. While preloading can interpose dynamically linked calls to `libc` system call wrapper functions made from outside of `libc`, it cannot interpose the statically linked calls made from *inside* of `libc` (e.g., internal calls from `printf` to `write`).³ If using preloading alone, we would need to reimplement `printf` and any other `libc` functionality we wanted to support and not just the system call wrappers—an untenable engineering burden. Preloading alone would also fail to intercept system calls made without using `libc` at all, e.g., those made by directly using a `syscall` instruction.

Secondary Strategy: seccomp: Phantom intercepts system calls that are not handled by the preloading strategy using the kernel’s `seccomp` (secure computing) facility. The `seccomp` facility enables a process to set a filter on the system calls that are made by the process and to associate an action with the filter. We install a `seccomp` filter that traps all system calls except for: (i) `sigreturn`; and (ii) system calls originating from Phantom’s own preloaded shim. We install a `SIGSYS` signal handler for system calls trapped by the `seccomp` filter; whenever a system call matching the filter is invoked, the kernel traps it and instead calls our signal handler function.

We use `seccomp` as our *secondary* interception strategy because, although it can intercept all system calls, it is less efficient than preloading; it requires: (i) a mode transition

³APIs that invoke vDSO functions (e.g., `time`) rather than make system calls can either be preloaded or we can dynamically rewrite the vDSO to guarantee that it makes interoperable system calls [55].

from the process to the kernel when the system call is invoked; (ii) execution of the `seccomp` filter; and (iii) a mode transition back to the process to invoke the shim callback function. Because most system calls are preloadable, we infrequently incur the additional overhead from `seccomp` in practice.

3.2.5 Emulating System Calls

Both system call interception strategies from §3.2.4 result in a `syscall` handler function being executed in the shim, i.e., within the managed process. System calls can be emulated either directly in the shim or in the controller (see Figure 2).

In the Shim: Frequently made system calls that can be emulated using little state from the controller can be serviced directly in the shim without incurring additional overhead related to IPC. For example, the shim directly handles the `time`, `gettimeofday`, and `clock_gettime` system calls by arranging for the controller to share and maintain the current simulation time in a shared memory control block that is accessible to the shim as described in §3.2.6.

In the Controller: The remaining system calls are serviced in the simulator controller process. The system call number and arguments are sent to the controller using the IPC control channel as described in §3.2.6. The controller handles the system calls internally using lightweight implementations that effectively form a simulated kernel that completely replaces the functionality normally provided by the Linux kernel. The simulated kernel (re)implements (i.e., simulates) important system functionality, including: the passage of time; input and output operations on file, socket, pipe, timer, and event descriptors; packet transmissions with respect to transport layer protocols such as TCP and UDP; and aspects of computer networking including routing, queuing, and bandwidth limits. (See Appendix D for additional details.) Importantly, this approach enables us to establish a private, simulated network environment that is completely isolated from the real network, but is internally interoperable and entirely controllable.

Determinism: Phantom uses a pseudorandom generator that is seeded with a configurable seed as its single source of randomness throughout the simulation. Care is taken to ensure that all random bytes that are needed during the simulation are initiated from this source, including during the emulation of system calls such as `getrandom` and when emulating reads from files like `/dev/*random`. This approach allows Phantom to produce deterministic simulations, improving scientific control over the experimentation process and enabling experimental results to be replicated.

3.2.6 Managed Process-to-Controller Communication

We use control channels to exchange *fixed-size* messages with each managed process (e.g., system call arguments), and a memory manager to exchange *dynamic* amounts of data (e.g., a buffer passed to a `send` system call; see Figure 3).

Control Channel: Phantom establishes a control channel with the shim of each managed process by allocating an initial block of shared memory and sharing the handle to this

Figure 3: Phantom uses shared memory as a control channel, modulating control using semaphores. The app1 shim intercepts `send()`, writes its arguments into the shared syscall registers, and then uses semaphores to pass control. The controller reads the registers, uses the memory manager to directly copy the send buffer into simulated packets, and schedules an event so the packets arrive at the receiver following network semantics. The controller writes the return register and passes control back so app1 continues running. An analogous process occurs when app2 calls `recv()` (or any other system call).

memory during process startup using an environment variable. This *control block* uses a fixed data structure layout that includes semaphores and messaging state (e.g., system call arguments). The semaphores provide a safe and efficient way for a message sender to signal that a new message is available and for a message receiver to wait for a new message; the controller uses this functionality to modulate the execution state of the process (see §3.2.7). We use shared memory and semaphores because we found this combination to perform better than alternative approaches (see Appendix C).

Memory Manager: We designed an inter-process memory access manager to enable the controller to directly and efficiently read and write the memory of each managed process without extraneous data copies or control messages. The memory manager tracks the memory mappings that are active across various regions of a process’s memory, which are analogous to the mappings found in the `/proc/<pid>/maps` file. Upon initialization, the memory manager creates a sparse memory file for each process, where a virtual address in the process corresponds to the same offset in the file. The memory manager initially *remaps* the process’s stack and heap memory regions into this file. As the process runs, the memory manager brokers all read, write, or other mapping requests that involve managed process memory in order to: (i) also map requests for anonymous private regions (such as those made when serving large allocation requests) into the shared file; (ii) maintain a consistent view of the process’s address space; and (iii) simplify system call handling by translating memory pointers to shared memory pointers as needed. Whenever the memory manager receives an access request for an address that is not mapped into the shared file, it utilizes the kernel’s `process_vm_readv` and `process_vm_writev` facilities to directly transfer data between the controller and the managed process’s address space without copying it into kernel space.

3.2.7 Managed Process/Thread Scheduling

We use the IPC control channel from §3.2.6 to control the execution state of each managed process. When a process

first loads, it immediately waits on the channel semaphore to receive a message from Phantom before starting. When a Phantom worker runs (following the algorithm in §3.2.2), the worker initially sends a start message to the process it manages and waits to receive a message back from the process. The process then runs until it invokes a system call that is interposed as described in §3.2.4, sends a system call request message back through the control channel to the waiting Phantom worker, and waits to receive the system call result message from Phantom.

There are two possible scheduling outcomes when a Phantom worker handles a system call requested by a managed process. For system calls that can be handled immediately (non-blocking calls, or blocking calls for which a result is ready), the Phantom worker returns the result over the control channel and the scheduling cycle continues. For system calls that cannot be handled immediately (blocking system calls whose result is not ready), the Phantom worker must wait for some condition to become true (e.g., a packet to arrive or a timeout to occur). Such conditions are internally registered, and then the worker leaves the managed process in an idle state while it continues executing simulation events (and advancing simulation time). When the condition later becomes true (e.g., a timeout occurred), the worker executes an event that causes it to check the system call state and return the timeout result to the process over the control channel. The process continues executing and the scheduling cycle continues.

The effect of this scheduling process is that each Phantom worker only allows a single thread of execution across all processes it manages; each of the remaining managed processes/threads will always be idle, waiting for a result message from the worker for the previously requested system call. Using this scheduling process, Phantom has precise control over the execution state of all managed processes and guarantees nonconcurrent access of managed processes’ memory through the memory manager from §3.2.6.

3.2.8 Linux CPU Scheduling

Phantom is designed to work with the Linux CPU affinity (i.e., CPU pinning) scheduling feature. CPU affinity is a scheduling attribute associated with running Linux processes. A process’s CPU affinity can be adjusted to restrict the process to run only on a specified subset of CPUs (e.g., a single CPU). CPU pinning can improve performance by reducing the frequency of cache misses, CPU migrations, and context switches. In particular, Linux semaphores shared between two same-core processes incur fewer context switches than when shared between cross-core processes (see Appendix C). Recall that Phantom will run either a worker thread or one of its managed processes, but never both at the same time. This design choice enables us to naturally pin each worker and all of its managed processes to the same core in order to capitalize on the CPU pinning performance benefits.

4 Implementation

We implement Phantom using the plugin-based Shadow as a basis because: (i) we will show in §5.4 that Shadow outperforms other simulators; and (ii) it will be fairer to compare the plugin- and process-based architectures using tools that share the same foundation. See Appendix A.3 for Shadow details.

Transforming Shadow: We forked Shadow v1.14.0 and identified the components that are no longer necessary for Phantom. Of the 94,259 lines of code (LoC) in Shadow v1.14.0,⁴ we removed 47,959 LoC (50.9%) containing a custom version of the GNU portable threads library that was used to simulate application threading [48], 14,498 LoC (15.9%) containing a custom loader that dynamically loads plugins using `dlopen` [63], and 6,559 LoC (7.0%) that implemented the interface between Shadow and the `libc` functions it preloads. We also found that 6,315 LoC (6.7%) implemented tests and 2,123 LoC (2.3%) implemented tools, leaving just 16,805 LoC (17.8%) implementing core simulator functionality that Phantom integrates (see Appendix D for more details).

Implementing Phantom: We implemented Phantom’s design from §3 on top of our stripped down version of Shadow. Our full Phantom implementation supports 164 system calls and contains 56,742 LoC: tests account for about 15,653 LoC (27.6%), tools account for 1,956 LoC (3.4%), and the remaining 39,133 LoC (69.0%) implements core functionality.

5 Evaluation

We evaluate Phantom by running micro- and macrobenchmarks, by verifying its simulation accuracy, and by comparing it to related tools. (See Appendix E for additional details.)

In our benchmarks, we compare three distinct state-of-the-art simulator architectures (see Appendix A): (i) multi-process, `seccomp` (Phantom); (ii) multi-process, `ptrace` (gRaIL); and (iii) uni-process, plugin namespaces (Shadow). For fairness, we compare all three architectures running on top of an identical simulator framework and network stack (i.e., Shadow’s), thus ensuring that we can isolate performance differences and attribute them *exclusively* to the change in architecture and not to, e.g., differently inefficient code running in independent code-bases.⁵

All experiments use CPU pinning and our primary interception strategy (preloading) unless otherwise noted. All simulations were repeated ten times with unique seeds; we present the results as the mean across the ten trials with 99% CIs.

⁴LoC are counted with the `scc` tool: <https://github.com/boyter/scc>

⁵Because gRaIL was originally implemented on top of NS-3, we ported the design to Shadow by implementing `ptrace` as an optional alternative to the `seccomp` secondary interposition strategy. We found and mitigated many sources of `ptrace` overhead (see Appendix B) and our implementation should be considered an optimized, near-best-case version of gRaIL.

Figure 4: Time to execute blocking, nonblocking, and io-based system calls using several interception methods, compared to Shadow’s uni-process preload-based design.

5.1 Performance: Microbenchmarks

Setup: We anticipate that one of the major sources of overhead in a multi-process design is due to inter-process communication and context switching, which in Phantom occurs whenever a system call is executed. There are three main types of system calls: (i) blocking calls that require the simulator to update state (e.g., advance time) before returning; (ii) nonblocking calls that can return immediately; and (iii) input/output (io) calls that involve reading or writing a dynamically sized buffer. We benchmark these operations using a small program that either invokes the `nanosleep` system call (with a timeout of 1 for blocking or 0 for nonblocking), or invokes a `write` and then a `read` operation on a pipe. The program loops repeatedly for 10k iterations and measures the time required to complete each benchmark after timing 10k iterations of a no-op as a baseline. We report the difference between the mean time to execute each of the three benchmarks and the mean time to execute the no-op baseline.

Results: We ran the benchmarks in our multi-process architecture using several alternative interception methods, and in Shadow’s uni-process preload-based architecture. Figure 4 shows similar trends across all three benchmarks. First, we notice that using preloading and `ptrace` together is slightly slower than using `ptrace` alone; this is because the shim intercepts the system call and then (since it does not have a handler) it invokes the `system` function to pass control to `ptrace`, which adds a few instructions relative to the standard use of `ptrace`. Second, `seccomp` with preloading is significantly faster than `seccomp` alone (and both `ptrace` modes), because preloading allows us to intercept system calls without incurring the overhead of a mode transition and the execution of the `seccomp` filter. Third, the uni-process design is the fastest of all methods tested; while the blocking and io-based system calls incur some overhead due to switching portable threads (using `set jmp` and `long jmp`), a non-blocking system call is effectively a function call.

Figure 5 shows the results from running our io-based benchmark while setting the buffer size to 1k, 4k, 16k, and 64k bytes. Phantom with the relatively simple approach of using `process_vm_readv` and `process_vm_writev` is the

Figure 5: Time to execute io-based system calls using Phantom’s `process_vm_read` and `process_vm_write` fallback facilities compared to its primary inter-process memory mapping design.

Figure 6: Time to execute our microbenchmarks in Phantom when using the Linux CPU pinning and realtime scheduling features.

slowest. This is partly from the context switch overhead between Phantom and the managed thread for each `read` and `write` call, and the kernel/user mode transition overhead of making the `process_vm` system calls. While these overheads are not dependent on the buffer size, and are amortized for larger buffer sizes, the `process_vm` system calls have significant per-page overhead for validating permissions, pinning each page in memory before doing the copy, and then unpinning them. Hence, the `process_vm` approach gets significantly *worse* than the alternatives as the buffer size increases.

While Phantom’s `mmap`-based approach (§3.2.6) still has the fixed overhead of context switches between Phantom and the managed thread for each `read` and `write`, it uses an interval-map of mapped *regions* (not *pages*) to validate and translate each pointer. Since this cost is fixed, rather than per-page as with the `process_vm` calls, its overhead relative to the uni-process approach is amortized for larger buffers and becomes less than the uni-process overhead for 64 KB buffers.

Figure 6 shows the time to execute our benchmarks using the Linux CPU pinning feature described in §3.2.8 in addition to the `sched_fifo` Linux realtime scheduler. We observe that CPU pinning significantly improves Phantom’s performance while mixed results are obtained when using realtime scheduling. Run time under realtime scheduling decreases by 48–73% when adding CPU pinning, indicating that the primary benefit is from pinning. CPU pinning improves performance particularly well in Phantom due to our design in which a worker modulates its running state and that of each of its managed processes such that no two of these run con-

currently. Therefore, workers and their managed processes will effectively share the same CPU core, improving caching and limiting cross-core migration. We also tested Phantom using `ptrace` and Shadow’s uni-process design and found that pinning provides comparable or better performance than other modes (see Appendix E.1 for more details).

5.2 Performance: Macrobenchmarks

While microbenchmarks enable us to test the effects of system call operations in isolation, macrobenchmarks provide us with a more wholistic understanding of performance while simulating a larger distributed network.

5.2.1 Setup

To run our macrobenchmarks, we write a simple peer-to-peer (P2P) messaging application whose behavior is inspired by the parallel hold (PHOLD) model commonly used to benchmark discrete-event simulators [20].⁶ Our P2P application uses standard UDP sockets for network communication and works as follows. Each peer first creates and sends some number m of messages at startup using `sendto` and then uses `poll` to wait for incoming messages to arrive. Whenever a message is received with `recvfrom`: (i) a number c of AES encryptions and c AES decryptions are performed to produce computational load; and (ii) a new message with a 1k payload is created and sent to produce network load. Whenever a peer sends a message, it makes a weighted choice of the destination peer where peers’ weights are drawn from a configurable probability distribution W ; we use W to create unbalanced workloads across peers.

To benchmark performance we create distributed networks with p peers, each running our P2P application on a distinct virtual host. The network latency between each pair of hosts is set to 50 ms and each host’s bandwidth is unrestricted. All peers start at the same time and run for ten simulated seconds, resulting in 200 communication rounds. Unless otherwise mentioned, our experiments use defaults of $p=1k$ peers, $m=100$ messages, $c=0$ AES (encrypt, decrypt) sequences, and W is the exponential function e^{-3x} for $x \in [0, 1]$ (to produce unbalanced peer workloads).

5.2.2 Results

Interception Strategy and LP Count: We run experiments that vary the interception strategy and LP count to investigate their effects on performance. Our results in Figure 7 show that the uni-process Shadow simulation completes faster than the multi-process Phantom simulations when using 14 or fewer LPs (consistent with our microbenchmark results). However, when the number of LPs exceeds 14, the `seccomp` interception strategy (with or without preloading) performs better than both the `ptrace` strategy and the uni-process design. We observe diminishing returns and performance regressions

⁶We modify the PHOLD model because it is shown to lead to well-balanced workloads that are not representative of real-world networks [11].

Figure 7: The time to complete our P2P benchmark across a varying set of interception strategies and number of logical processors (i.e. concurrently active worker threads). The y-axis is in log scale.

Figure 9: Performance of our P2P benchmark using Phantom’s `process_vm_read` and `process_vm_write` fallback facilities compared to its primary inter-process memory mapping design.

Figure 8: Time to complete our P2P benchmark when using the Linux CPU pinning and realtime scheduling features.

Figure 10: Performance of our P2P benchmark when Phantom (`seccomp`) and Shadow (`uni-proc`) are configured to use one worker thread per virtual host or one worker per logical processor (LP).

with `ptrace` and the `uni-process` design when using more than 14 LPs (the number of cores available on each of the two CPUs), while `seccomp` is able to make effective use of additional LPs. Finally, using a large number of LPs causes more than a $7\times$ slowdown in `ptrace` (from 79s with 14 LPs to 581s with 56 LPs) which we speculate is due to inefficient kernel facilities. We observed similar trends in the initialization time—the time for Phantom to launch all processes or Shadow to load all namespaces: Phantom with `seccomp` is more than $3\times$ as fast (0.84s) as both `ptrace` (3.5s) and the `uni-process` design (2.6s) at initializing processes when using 28 LPs (see Appendix E.2 for more details).

We conclude from our results that using a combination of the preloading and `seccomp` interception strategies leads to the best performance in Phantom: preloading with `seccomp` improves performance over `seccomp` alone because it reduces the overhead from mode transitions and executions of the `seccomp` filter. As in the microbenchmarks, preloading has little effect when used with `ptrace` as expected. Finally, using a number of LPs equal to the number of CPU cores (i.e., half of the available hyper-threads) produces reasonable performance for both Phantom and Shadow. Hence, we use 28 LPs and enable preloading in the remaining experiments.

Linux CPU Scheduling: Figure 8 shows the results of our investigation into the effects of Linux CPU scheduling on the performance of our macrobenchmark. As in our microbenchmarks, we find that CPU pinning has a positive effect on performance: Phantom with `seccomp` completes the benchmark $2.5\times$ faster with CPU pinning than with standard scheduling.

Pinning has a similar but slightly smaller relative effect on `ptrace`, and a positive but minor effect on the `uni-process` design. We observe in our measurements that pinning reduces the number of CPU migrations that occur during the simulation from 5.8M to 8.6k for Phantom with `seccomp`, from 3.6M to 8.1k for Phantom with `ptrace`, and from 180k to 5.7k for Shadow’s `uni-process` design. Realtime scheduling again shows mixed results, but always performs better than standard scheduling when combined with pinning. We conclude that pinning provides a consistently positive effect on performance, and enable it in the remaining experiments.

Inter-Process Memory Manager: Figure 9 shows the performance of Phantom’s inter-process memory mapping design across three metrics. First, we find that Phantom completes the benchmark in comparable time when: (i) using the primary `mmap`-based approach; and (ii) being restricted to the fallback approach of using `process_vm_read` and `process_vm_write`. Recall that our P2P macrobenchmark sends messages with 1k payloads, and in our microbenchmark we found that the performance of the memory mapping approach improves relative to the fallback mechanism as the payload size increases. Second, we observe that the memory mapping design uses slightly more RAM and causes slightly more page faults because it requires additional state to track the memory mappings. Phantom always finishes the benchmark sooner than Shadow’s `uni-process` design ($<70\%$) while using less RAM ($<65\%$) and causing fewer page faults ($<35\%$). (We find that the same general trends hold when running Phantom with `ptrace`; see Appendix E.2 for details.)

Figure 11: Performance of our P2P benchmark when scaling the number of hosts from 1k to 64k hosts (i.e., processes in Phantom or namespaces in Shadow). Both axes are plotted in log scale on all subplots. Running 32k or more hosts in Shadow exceeded the machine’s RAM (256 GiB).

Worker Thread Scheduling: Figure 10 shows the performance of our work-stealing worker thread scheduling design (described in §3.2.2) in which we run one worker thread per virtual host, compared to a work-stealing algorithm from Shadow that runs one worker thread per logical processor (LP). The benchmark completes more quickly when using one worker thread per host (i.e., 1000 workers in our benchmark) than when using one worker per LP (i.e., 28 workers in this experiment), for both Phantom and Shadow. We observe that by using additional threads, we increase the maximum RAM used and the number of CPU migrations that occur while running the benchmark. (We again find that the same general trends hold when running Phantom with `ptrace`; see Appendix E.2 for details.) We conclude that using more threads should be done in consideration of available RAM.

Peer Workload: We conducted an investigation into the effects of varying peer workloads by varying the number of messages m , the number of AES (encrypt, decrypt) sequences c , and the peer weight distribution W . As expected, increasing m and c resulted in a roughly linear increase in benchmark times in both Phantom and Shadow, while the workload distributions we tested had minor effect on performance. We present more details in Appendix E.2 due to space constraints.

Distributed Network Scale: We investigate the performance of our P2P benchmark while scaling the network size from 1k to 64k hosts. Our results in Figure 11 show that Phantom with `seccomp` outperforms `ptrace` and Shadow’s uni-process design in terms of benchmark time, while initialization time (the time to launch all processes in Phantom or load all namespaces in Shadow) and memory usage both scale more efficiently in Phantom than in Shadow. (Running 32k or more hosts in Shadow exceeded the machine’s RAM (256 GiB).)

Figure 11a shows that the benchmark time exhibits growth that is nearly linear in the number of hosts (`ptrace`: $r = 0.999$, `seccomp`: $r = 0.995$, `uni-process`: $r = 0.994$, where $r = 1$ indicates perfect correlation) with 91ms per host for `ptrace`, 51ms per host for `seccomp`, and 96ms per host for `uni-process`. Accordingly, `uni-process` completes the 16k benchmark in 25m compared to 21m for `ptrace` and 10m for `seccomp` despite running the 1k benchmark in 55s compared to 78s for `ptrace` and 33s for `seccomp`. Phantom with `seccomp` completed the benchmark fastest for all tested network sizes.

Figure 11b shows how the initialization time changes as the host count increases. Here, clear separation between Phantom’s design (which launches multiple processes) and Shadow’s uni-process design (which loads multiple namespaces) can be observed through visual inspection. Despite a slight shift in growth between 4k and 16k hosts for `seccomp`, we find that Phantom is more efficient and scalable than Shadow at initializing virtual hosts’ processes. For example, at 16k hosts Shadow completed initialization in about 8m while Phantom completed it in less than 1.5m.

Figure 11c shows that Phantom uses significantly less RAM to complete the benchmark than Shadow. At 1k hosts Shadow uses 2.3 GiB but Phantom with `seccomp` only uses 1.5 GiB (~65%), while at 16k hosts Shadow uses 90 GiB but Phantom with `seccomp` only uses 26 GiB (~29%). Phantom’s relatively lower memory usage allows us to scale the number of hosts in the P2P benchmark to 4× the size of the largest network in which a benchmark was successful in Shadow.

Conclusions: We draw two primary conclusions from our benchmarks. First, Phantom outperforms the state-of-the-art uni-process Shadow design by effectively mitigating the multi-process performance challenges identified in §2.3. Second, Phantom consistently outperforms a simulator built around our implementation of `ptrace` (which we argue in Appendix B outperforms `gRaLL`’s use of `ptrace`).

5.3 Accuracy: Verification

In this section, we verify that Phantom can accurately simulate basic network characteristics as well as more complex Tor overlay networks [17]. Recall that, as described in §4, Phantom integrates the network stack from Shadow; we do not claim the design or implementation of this network stack as a contribution of this paper. Shadow’s network has already been extensively validated in previous work [30, 32, 37, 40]. Therefore, our primary focus is to verify that Phantom does not *reduce* the accuracy of the simulated network relative to Shadow; we consider our verification successful if Phantom and Shadow produce similar simulated network results.

Basic Network Verification: We evaluate the extent to which Phantom can accurately simulate basic network characteristics that are typical of LAN and WAN networks. Our evaluation considers two nodes that communicate over a single link.

Figure 12: Our basic network verification experiments show that Phantom and Shadow produce identical `iperf` results across a range of configured bandwidths and latencies and that Phantom achieves comparable or higher link utilization than our baremetal setup.

We configure the link with a latency and bandwidth capacity, and then use `iperf` and a UDP ping application to measure the available network bandwidth and latency, respectively, between the nodes. We conducted the experiment across a range of latency and bandwidth settings in Phantom, Shadow, and using two baremetal machines in our lab connected by a 10 Gbit/s physical link (where we used `netem` to emulate the configured latency and bandwidth). Our results in Figure 12 show that: (i) Phantom and Shadow produce indistinguishable results across all tested bandwidths and latencies; and (ii) Phantom generally achieves comparable or higher link utilization than the `netem`-based baremetal setup. (See Appendix E.3.1 for more details, including a description of our latency verification which shows a maximum error of 3%.)

Tor Network Verification: We evaluate the extent to which Phantom can accurately simulate more complex Tor networks using the state-of-the-art Tor modeling tools and methods [40]. We configure a Tor network using a total of 12,232 Linux processes to generate a total of 74 Gbit/s of network traffic, which is equivalent to the expected combined traffic of about 238k users and represents a scale of about 30% of the public Tor network (more explanation is provided in Appendix E.3.2).

We run 10 Tor simulations for 60 simulated minutes each in both Phantom and Shadow and find that: (i) both tools require 27 real hours to run each simulation; and (ii) Shadow uses at most 1116 GiB of RAM while Phantom uses at most 1032 GiB (92.5% relative to Shadow). We measure no significant difference in the simulated network performance across 6 metrics including circuit build time, circuit round trip time, circuit goodput, and Tor network transfer times for 50 KiB, 1 MiB, and 5 MiB files: Figure 13 shows that the performance distributions from Phantom and Shadow are within CI bounds. We conclude that Phantom does not reduce the accuracy relative to Shadow in conducting network experiments.

Figure 13: Our Tor network verification experiments show that Phantom and Shadow produce nearly identical Tor performance results (within CI bounds) since they share a network stack.

See Appendix E.3.2 for additional analyses and performance comparisons across a total of 6 network scale factors.

5.4 Comparison to Related Tools

In this section, we compare Phantom to popular tools implementing emulation, simulation, and hybrid architectures.

Mininet: Mininet is a network emulator that creates (i) a network of virtual hosts that run applications as Linux processes; (ii) virtual network interfaces within the Linux kernel; and (iii) virtual switches, controllers, and links that are managed by Mininet [45]. (See Appendix A.1 for more details.)

Mininet’s network emulation architecture offers poor control and scalability because the host kernel is responsible for handling packet events, and the packet routing process is unpredictable and sensitive to load. If the host machine becomes overloaded, Mininet will experience time distortion that will degrade experiment realism and control.

We demonstrate Mininet’s limitations by running a peer-to-peer benchmark (see §5.2.1) while scaling the number of peers in the experiment. Because each peer introduces a constant number of packets into the experiment, the expected number of packets and work to perform in the experiment grows linearly with the number of hosts. However, we find that load and network congestion on the host machine affects the outcome of the experiment. Figure 14 shows the average number of packets received per second by the virtual hosts (averaged over 10 trial runs). As the host machine becomes more loaded with virtual peers, *its packet forwarding capacity is limited*, and fewer packets than expected are forwarded. In contrast, Figure 14 shows that Phantom produces the expected packet throughput in simulated time (Phantom may run faster or slower than real time as necessary to achieve correctness).

NS-3 and gRaIL: NS-3 is a popular network simulator that simulates all aspects of networking *and* all application logic [26], while gRaIL extends NS-3 by enabling simulated nodes to directly execute applications as standard Linux processes managed by the kernel’s `ptrace` facility [54]. (See Appendix A.2 for more details.)

Figure 14: Average packet forwarding rate of a fixed P2P messaging workload in Phantom and Mininet as the number of hosts is varied.

Figure 15: Runtime of a fixed P2P messaging workload in Phantom, Shadow, NS-3, and gRaIL as the number of hosts is varied.

We evaluate the performance cost of running our P2P benchmark from §5.2.1, replicating its logic so that it could also run as an NS-3 application. We configured the benchmark with $m=100$ messages, $c=0$ AES operations, and W =uniform distribution. We vary the number of hosts while configuring 50 ms pairwise latencies and 1 Gbit/s network bandwidths, and run experiments using multiple simulation tools.

Figure 15 shows the real time (mean of 10 trial runs) required to complete 10 seconds of network simulation parallelized across all cores on a blade server (see Appendix E.1) as the number of hosts is varied.⁷ In our 1k host experiment, we find that (i) Phantom is $2.2\times$ and $3.4\times$ faster than Shadow and NS-3, respectively; and (ii) gRaIL’s inefficient multi-process design is about $13\times$ slower than NS-3 alone, and $43\times$ slower than Phantom, demonstrating that Phantom effectively eliminates IPC overhead as a performance bottleneck and overcomes the multi-process challenges from §2.3.

Shadow: Shadow [30] implements a hybrid, uni-process architecture in which applications are directly executed in plugin namespaces and preloading is used (via `LD_PRELOAD`) to intercept `libc` function calls and hook the applications into the simulation. (See Appendix A.3 for more details.)

Although Figure 15 shows that it performs well, Shadow’s plugin architecture is limited in its compatibility, correctness, and maintainability: as shown in Table 2, applications running in Shadow must be compiled as position-independent, must be dynamically linked to `libc`, and must not make system calls via statically linked or assembly code (or else they will not be interceptable). Because we cannot guarantee that

⁷Runtimes are normalized by the amount of work performed (i.e., packets delivered) by each simulator; this resulted in runtime adjustments of $< 5\%$ for all but gRaIL, which delivered only 56% of the expected packets and thus had its runtime adjusted by a factor of 1.8.

Table 2: Application Properties Supported in Hybrid Simulators

Application Property	Shadow	Phantom
Multiple threads (e.g., support for <code>pthread</code> s)	●	●
Multiple processes (e.g., support for <code>fork</code>)	◐	◐
Not position-independent (i.e., PIC or PIE)	○	●
Not dynamically linked to <code>libc</code>	○	●
Symbols not exported to dynamic symbol table	○	●
System calls made in statically linked code	○	●
System calls made in assembly (i.e., avoiding <code>libc</code>)	○	●
100% statically linked (e.g., some go programs)	○	◐

○ Does not work in tool or architecture ● Works in tool & architecture
◐ Not implemented in tool (as of writing) but supported by architecture

`libc` functions will not internally issue multiple unique system calls, Shadow’s design requires reimplementing *both* the kernel system calls *and* the `libc` functions that invoke them.

Phantom overcomes Shadow’s limitations by running applications as standard Linux processes, allowing us to take advantage of the kernel’s high-performance process isolation features. Moreover, Phantom uses `seccomp` to guarantee that system calls can be intercepted no matter how the application initiates them (see Table 2), enabling us to reduce the emulation scope to the system call interface and support a much larger set of applications; Phantom’s supported application set is primarily limited by the system calls and protocols implemented in its simulated kernel, which can be extended over time (our design could also be incorporated into other simulators, such as NS-3). Phantom enjoys these advantages while also meeting or exceeding Shadow’s performance (as we have shown throughout §5).

6 Conclusion

We have designed, implemented, and thoroughly evaluated Phantom, a novel, high-performance network simulator for large-scale distributed systems. Phantom’s multi-process design eliminates the compatibility, correctness, and maintainability limitations that we believe have inhibited the widespread adoption of existing plugin-based simulators. With our innovative synthesis of efficient process control, system call interposition, and data transfer mechanisms, Phantom also overcomes the inter-process performance challenges of the state-of-the-art multi-process simulator. Through our extensive evaluation, we have demonstrated that Phantom achieves better performance and is more scalable than alternative simulators across a variety of important benchmarks.

Acknowledgments: We thank our shepherd and the anonymous reviewers for their valuable feedback. We thank Steven Engler for discussions about design and support during development. This work has been partially supported by the Office of Naval Research (ONR), the Defense Advanced Research Projects Agency (DARPA), and the National Science Foundation (NSF) under award CNS-1925497.

Appendices

A Background Details for Related Tools

In this appendix we provide extended background on existing tools for network experimentation. We consider popular tools from the architecture categories listed in §2.2 and §2.3: Mininet [45] (emulation), NS-3 [26] (simulation), gRaIL [54] (hybrid, multi-process, `ptrace` controller), and Shadow (hybrid, uni-process, plugin namespaces) [30].

A.1 Mininet

Mininet is a popular network emulator that implements a common design approach for network experimentation tools. Mininet creates a network of virtual hosts that run applications as standard Linux processes, virtual switches that support OpenFlow for custom routing and software-defined networking, and virtual controllers and links. Mininet executes application binaries and routes network packets through virtual network interfaces created within the Linux kernel [45]. The packets are routed by virtual switching and routing appliances managed by Mininet. Network attributes, such as link bandwidth and latency, are emulated using Linux’s traffic control (`tc`) facilities.

Mininet’s design is very flexible: most any application can be run directly without the need of explicitly programmed network simulation routines, making it easy to spin up a new network and quickly start testing software. However, Mininet offers poor control and scalability because the host kernel is responsible for handling packet events, which is unpredictable and sensitive to load as we show in §5.4.

A.2 NS-3 and gRaIL

NS-3 is one of the most widely-used network simulation tools used by network researchers. NS-3 simulations are composed of virtual nodes running application and routing software that are implemented entirely within NS-3’s application logic (written in C++). NS-3 experiments offer a high degree of control and reproducibility, because all aspects of the networking—from generating a packet within an application to physically transmitting the packet’s bits over physical media—are simulated. However, a serious drawback of NS-3’s design is that real applications cannot be run within the simulation. For example, to run `ping` between two NS-3 nodes, a `ping` application simulator must be hand-crafted within NS-3 application code (as opposed to directing the nodes to execute a `ping` binary). Although this requirement may be acceptable to simulate simple applications, generating realistic simulations of complex protocols (e.g., Tor [17]) is difficult due to engineering complexities (e.g., the Tor codebase contains tens of thousands of lines of code).

Two NS-3 modules have been developed that do allow for real application execution within NS-3 simulations: (i) direct-code execution (DCE) mode [62], and (ii) the discrete event

protocol emulation vessel (gRaIL) [54]. In the more recent gRaIL approach, NS-3 nodes are configured to run real application binaries (e.g., `/usr/sbin/ping`) which are forked and executed as genuine Linux processes. The progress of these processes are managed by Linux’s process tracing facility `ptrace`, which allows the NS-3 process to intercept system calls made by the applications and translate them into NS-3 simulation events. Configuring NS-3 with gRaIL improves simulation realism, but has a very high performance cost as we show in §5.4.

A.3 Shadow

Shadow is a hybrid, uni-process network experimentation tool that incorporates aspects of both simulation and emulation [30]. At its core, Shadow is a conservative-time discrete-event network simulator that simulates network protocols (e.g., TCP and UDP), threading (using GNU portable threads [48]), and other kernel operations. Shadow dynamically loads applications into their own namespaces (using `dlopen` and a custom loader [63]) and directly executes application code in the simulator process. Shadow hooks the applications into the simulation using function interposition, but emulates a Linux environment so that application code functions as if it was running in Linux.

Shadow represents the state-of-the-art hybrid network simulator tool for directly executing applications in large-scale distributed system simulations. A primary reason is that Shadow is designed to be high-performance: it runs as a single process (with multiple threads) to avoid inter-process overhead and unnecessary data copies. This has led Shadow to become the standard tool for simulating the Tor anonymity network [40]. However, Shadow has not had widespread use outside of the niche Tor application; Shadow has been shown to simulate Bitcoin networks [48], but that work has since been abandoned due to compatibility, correctness, and maintainability issues as we describe in §5.4.

B Interposing System Calls with `ptrace`

As described in §4, we implemented a system call interposition strategy based on `ptrace` to better understand the performance limits of a simulator designed around `ptrace`. Our `ptrace` implementation provides an alternative to Phantom’s `seccomp` secondary interposition strategy (see §3.2.4).

gRaIL [54] is designed solely around the use of `ptrace` to control processes, system calls, and data transfer. Unfortunately, during our `ptrace` implementation and evaluation, we learned that the way that gRaIL uses `ptrace` (which is a standard and intuitive way to use `ptrace`) results in several scalability and performance problems that significantly reduce the performance of a hybrid network simulator. Since we wanted to understand the performance limits of `ptrace`, we developed enhancements to make `ptrace` more efficient and work around its bottlenecks.

In this appendix, we describe what we learned about making a `ptrace`-based system more performant and scalable. We argue that our improvements make our application of `ptrace` in a simulator significantly more performant and scalable than `gRaIL`'s. Moreover, our implementation inside of Phantom enables us to more fairly evaluate and compare *the best version of gRaIL that it could be* rather than its inefficient prototype.

B.1 Scaling `waitpid` to Many Tracees

In initial evaluations, we were surprised to find that when adding n hosts to a PHOLD [20] simulation, in which the total number of messages passed scales linearly with the number of hosts, the simulation time grew *quadratically* with n instead of linearly. This turned out to be because the `waitpid` syscall, which is used by a `ptrace` tracer to wait for the next `ptrace` stop from a given tracee, performed a linear scan of child tasks, making its performance $O(n)$ in the number of processes in the simulation; i.e. adding a process with some fixed amount of work to the simulation not only added that amount of work, but also made the management of every other process in the simulation slower.

Since this behavior of `waitpid` is potentially surprising, and could hurt performance for other large-scale uses of `ptrace`, we implemented a kernel patch making it $O(1)$ instead of $O(n)$. That patch was accepted, and first included in Linux kernel version v5.13-rc1 [56].

Since we wanted good performance in today's Linux distributions without needing to install a custom kernel, we also implemented a workaround in Phantom's `ptrace` code. Initially we worked around this with a dedicated "fork proxy" thread to initially fork each managed process. This way the (at the time) one-per-CPU "worker thread" weren't parents of the managed processes. However, `waitpid` also performed an $O(n)$ linear scan of *tracees*. This meant that when switching from running one managed thread to another, the worker thread needed to `ptrace-detach` from the blocked thread (sending it a `SIGSTOP` to prevent it from running), and `ptrace-reattach` to the next thread to run. This workaround added substantial overhead, but was an overall performance improvement for simulations involving more than around 1000 managed threads per worker thread.

We were later able to remove the fork-proxy workaround when we moved to the logical-processor-based scheduler described in §3.2.2. Since each worker thread only manages the processes and tasks of a single simulated host, `waitpid` does not become more expensive as hosts are added.

B.2 Reducing Per-syscall `ptrace` Stops

Many `ptrace`-based systems, including `gRaIL` [53, 54] use the `PTRACE_SYSCALL` command to execute the tracee until its next syscall. When the tracee makes a syscall, the tracee is put into a `syscall-enter-stop`. The tracer can then fetch the memory registers of traced program to examine the syscall arguments using a `PTRACE_GETREGS` command (and memory

referenced by those parameters as per Appendix B.3). In the case where the tracer desires to *emulate* the syscall, as is usually the case in Phantom, the tracer can:

1. issue a `PTRACE_SETREGS` command to change the syscall-number being requested to an invalid one;
2. issue another `PTRACE_SYSCALL` command to allow the tracee to execute the syscall, which will result in the issuing of an `ENOSYS` signal that puts the tracee into a `syscall-exit-stop`;
3. overwrite the error result to emulate the original syscall using `PTRACE_SETREGS` etc.; and
4. allow the tracee to continue running again with another `PTRACE_SYSCALL` command.

Using this approach, there are a minimum of 4 context-switches per syscall (assuming the tracee and tracer are executing on the same CPU):

1. tracee to tracer at the `syscall-enter-stop`;
2. tracer to tracee to execute the (no-op) syscall;
3. tracee to tracer at the `syscall-exit-stop`; and
4. tracer to tracee to resume the tracee's execution.

The `ptrace` syscall has an alternative command for when syscalls are to be *emulated* instead of just monitored: the `PTRACE_SYSEMU` command. As with `PTRACE_SYSCALL`, the tracee enters `ptrace-enter-stop` when first encountering a syscall. If the tracer continues again using `PTRACE_SYSEMU`, there is no `syscall-exit-stop`, saving 2 context-switches.

The primary downside of using `PTRACE_SYSEMU` is that if we *really do want* the managed process to execute the original syscall (perhaps with modified arguments), we can no longer just resume the original syscall, because the kernel does not execute the syscall when using `PTRACE_SYSEMU`. In Phantom we instead first get out of the `ptrace-enter-stop`, with a `PTRACE_SINGLESTEP` command, overwrite the instruction pointer to "rewind" it to point to the `syscall` instruction again, and then `PTRACE_SINGLESTEP` again to actually execute it. This adds an extra `ptrace-stop` relative to the case where we would use `PTRACE_SYSCALL`, but this tradeoff is worthwhile when *most* syscalls are being emulated (as is the case in Phantom).

B.3 Efficiently Accessing Tracee Memory

The mechanism for accessing tracee memory via `ptrace` itself is `PTRACE_PEEK` and `PTRACE_POKE`. This is the mechanism used by many `ptrace`-based systems, including `gRaIL` [53, 54] and `DetTrace` [55]. Unfortunately, this mechanism requires a separate syscall and accompanying mode transition to access *each word* of memory, making it inefficient for large structs and buffers.

We could reduce the number of syscalls required for large memory accesses by instead reading and writing the `/proc/[pid]/mem` pseudo-file. After opening the file (which requires already being `ptrace-attached`), accessing a contiguous buffer can be done with a single `pread` or `pwrite` syscall

and multiple buffers can be accessed at the same time with `preadv` and `pwritev`.

However, we instead make use of the `process_vm_readv` and `process_vm_writev` syscalls, which are analagous to `preadv` and `pwritev` but are specialized for accessing the memory of another process. They are a bit simpler to use, since they take the `pid` of the target process instead of needing to open and maintain a file descriptor. They also do not require the caller to be `ptrace`-attached to the target process—a feature that Phantom utilizes in order to use the same code for accessing managed process memory no matter if we are using the `ptrace`- or `seccomp`-based syscall interception strategies.

As discussed in §3.2.6, in Phantom we make most memory accesses even more efficient by remapping some of the tracee’s memory regions into a shared memory file, which is also mapped into Phantom. As we show in Figure 5, this further increases cross-process data transfer performance.

B.4 Enabling Work Stealing

In Shadow, there is roughly one worker thread per-CPU, and in each round of the simulation, each worker thread processes a queue of simulated hosts. When a worker thread’s queue is empty, it *steals* hosts from another worker’s queue.

Unfortunately, when using `ptrace`, only the thread that originally `ptrace`-attached a traced thread is permitted to issue `ptrace` commands; other threads in the process are not. This means that one worker thread cannot steal a simulated host from another worker thread and control its managed processes while the original worker thread is still attached.

We briefly pursued patching the kernel to lift this restriction, but it would involve a fair bit of complexity, and there is understandable hesitancy from kernel developers to add further complexity to the already quite complex `ptrace` subsystem in order to support a somewhat niche use-case.

We initially solved this problem by detaching `ptrace` from each managed thread in a host when done processing that host’s events for the round, and re-attaching each thread the first time we need to control it each round. This process had substantial overhead, which was incurred even if the host and its threads were executed by the same worker the next round.

Phantom’s logical-processor-based scheduler design described in §3.2.2 addresses this problem. In Phantom’s scheduling architecture, worker threads are stolen by logical processors, but hosts never move between worker threads. Therefore a worker thread can stay attached to its managed threads for the entire simulation.

B.5 Avoiding `ptrace` Stops on Some Syscalls

As shown in Figure 4, intercepting a syscall via `LD_PRELOAD` and servicing it via IPC is significantly faster than intercepting and servicing it via `ptrace`. Unfortunately it is difficult to create a hybrid approach that uses `LD_PRELOAD` but falls back to `ptrace`, because `ptrace` stops for *every* syscall. Even if we avoid a `ptrace`-stop by intercepting a

syscall via `LD_PRELOAD`, any syscall we make to communicate with Phantom will still generate a `ptrace`-stop, negating the performance benefit.

We prototyped a solution that worked around this problem by never making a syscall to perform IPC; after sending a message in the shared memory segment, we would do a busy-wait to receive the response instead of making a `futex` syscall. This approach actually worked well for simulations that otherwise had idle cores to spare—the Phantom worker thread could service the syscall on one CPU while the managed thread spun in its loop on another. However, since this effectively halved the maximum concurrency, we ultimately discarded this approach.

A better solution to this problem is to use a `seccomp` filter to have some syscalls generate a `SECCOMP_RET_TRACE` event, and then use `ptrace` to catch those instead of stopping on every syscall [55].

In Phantom we similarly leveraged `seccomp`, but configured `seccomp` to trap to a signal handler (`SECCOMP_TRAP`) in the managed thread. The signal handler uses IPC if needed to communicate with Phantom, doing away with `ptrace` altogether. We have not performed a direct performance comparison between this `SECCOMP_TRAP` approach and the `SECCOMP_RET_TRACE` approach, but expect it to have similar or better performance: while `SECCOMP_RET_TRACE` skips the transfer from control in the kernel to the managed thread before context-switching to the tracing thread, using memory-based IPC from the `SECCOMP_TRAP` handler lets us transfer the register values more cheaply than `PTRACE_GETREGS` and `PTRACE_SETREGS`. More importantly, we can service some syscalls from the `SECCOMP_TRAP` handler without having to context-switch to Phantom at all, as described in §3.2.5.

C Context Switching Performance

In Phantom’s process-oriented architecture, control and messages must be exchanged between Phantom’s worker processes and managed application processes via interprocess communication (IPC). Linux and the POSIX standard offer many facilities for exchanging data across process boundaries and synchronizing processes. In this appendix, we examine the cost associated with a process context switch when facilitated by a given synchronization method. The control flow being measured is as follows, for a communicating parent process and child process pair:

1. The child waits for control from the parent;
2. The parent signals to the child that it should run, and waits for the child;
3. The child gains control, immediately signals back to the parent that it should run, and goes into the wait state; and
4. The parent wakes up and regains control.

In other words, this benchmark measures the latency required to perform a context-switch round-trip from a parent process to a child process and then back to the parent.

Figure 16: Time required to perform a process context-switch round trip under various synchronization mechanisms and process CPU affinity values.

Four synchronization mechanisms are included in the benchmark:

1. An `_Atomic_Bool` flag placed in shared memory. Waiting is performed by repeatedly checking if the value is `true` (i.e., spinning), and signaling is performed by setting the flag's value to `true`.
2. A POSIX semaphore placed in shared memory. Waiting is performed with `sem_wait` and signaling is performed with `sem_post`.
3. A Unix domain socket with ends shared by the parent and child process. Waiting is performed with `recv` called on the socket's file descriptor and signaling is performed with `send` called on the descriptor.
4. A POSIX message queue shared by the processes. Waiting is performed by calling `mq_recv` and signaling is performed with `mq_send`.

In addition to the mechanism, in this benchmark we also vary the CPU affinity of the parent and child processes. The cost of context switching varies depending upon which processors are executing the processes. The benchmark tests three cases: (i) when the parent and child are pinned to the same CPU core; (ii) when the parent and child are pinned to separate cores on the same CPU; and (iii) when the parent and child are pinned to separate cores on separate NUMA nodes and CPUs.

We ran these benchmarks on a machine with two 14-core Intel Xeon E5-2697 CPUs clocked at 2.60 GHz (the same machine used in our §5 experiments). The machine was running CentOS 7 and Linux kernel version 5.11.6-1. Figure 16 shows the average context-switch round-trip time taken over 100k repeated trials. (99% confidence interval ranges are drawn at the top of each bar, but in every case the interval size is almost zero.) These results show that POSIX message queues and semaphores slightly outperform Unix domain sockets, and that semaphores are the most efficient synchronization method when the processes are pinned to the same core (which is the case in Phantom). Cross-core and cross-node context switching is significantly more expensive than same-core, with the exception of the atomic boolean flag; when using this syn-

chronization mechanism, having two CPUs that can spin in parallel minimizes latency. However, spinning can waste CPU cycles and is not economical when the CPU is under load. Hence, we find that POSIX semaphores are the most performant mechanism to synchronize control between Phantom and its managed, child processes.

D Simulated System and Network Facilities

In this appendix, we describe at a high level the system and network facilities that Phantom simulates. These simulated components are mostly borrowed from Shadow (see §4), but significant attention was required to integrate these with Phantom's new system call interposition, memory manager, and process scheduling interfaces.

Time: As a simulator, Phantom has complete control over simulated time. Attempts by managed processes to obtain the current time are handled by returning the simulated time (relative to a recent epoch) instead. (Because retrieving time is a hot-path function, time-related system calls are handled in the shim as described in §3.2.5.)

Input/Output: Phantom simulates file descriptors and tracks them using a lookup table for each managed process. This ensures a consistent mapping of file descriptor numbers to the internal objects needed to operate on them. Files are simulated internally by using real OS files and translating between the simulated and real file descriptor numbers. Other descriptors can be completely simulated internally, including sockets, pipes, timers, and events. Event notification facilities (e.g., `select`, `poll`, and `epoll`) can also be simulated by tracking the state of each simulated descriptor and triggering callback events when those states change in a way that requires action. Both blocking and non-blocking operations are supported as described in §3.2.7.

Transport: Phantom is a packet-level simulator that implements simulated versions of protocols such as TCP and UDP. Although packet-level semantics are simulated with respect to the associated socket protocols, packet payloads (application data) sent by the managed processes are copied only once into internal buffers. Transferring this data between virtual hosts across the simulated network amounts to transferring the memory address of the original data location, minimizing overhead when transferring simulated packets.

Network: Phantom simulates DNS using a simple name to virtual IP address mapping. Routing is simplified to running shortest path over a configurable network graph to compute end-to-end latency and packet loss. In addition to these network characteristics, packets sent over the simulated network will also be subject to: (i) virtual host bandwidth limits which are simulated using token buckets; and (ii) network queuing semantics which are simulated using an implementation of the CoDel (controlled delay) network scheduling algorithm.

Figure 17: Time to execute our microbenchmarks from §5.1 when Phantom is configured to run with the `ptrace` interception strategy and the Linux CPU pinning and realtime scheduling features.

Figure 18: Time to execute our microbenchmarks from §5.1 in the uni-process, preload-based Shadow architecture when using the Linux CPU pinning and realtime scheduling features.

E Extended Evaluation

In this appendix, we include some extended evaluation details and results that we were unable to include in the main body of the paper (in §5) due to space constraints.

E.1 Extended Microbenchmarks

We conducted the evaluation here and in §5.1 using a blade server cluster in which each blade contained identical hardware: 256 GiB of RAM and 2×14 core Intel Xeon E5-2697v3 CPUs (56 total hyper-threads) running at 2.6 GHz. Each blade machine was running CentOS 7 and Linux kernel version 5.11.6-1. We configured our experiments to run in docker containers to ensure that we were running identical software stacks across the blade machines.

Figure 17 shows the effect of Linux CPU scheduling features when running Phantom with a `ptrace` interception strategy. We find that CPU pinning alone performs the best and that adding realtime scheduling along with CPU pinning has an adverse effect. Running with realtime scheduling alone only slightly improves performance over using the standard Linux scheduling mechanisms.

Figure 18 shows the effect of Linux CPU scheduling features on a uni-process design. The choice of Linux CPU scheduling feature has little effect on the nonblocking `nanosleep` benchmark, since it is effectively a function call and already incredibly efficient. Interestingly, realtime scheduling reduces performance for both the blocking and io-

Figure 19: Initialization time is the time for Phantom to launch all managed processes (or for uni-process Shadow to load all namespaces) and run them until the first blocking system call.

Figure 20: Performance of our P2P benchmark with Phantom using `ptrace` interception with `process_vm_read` and `process_vm_write` fallback facilities compared to its primary inter-process memory mapping design.

based benchmarks, and adding pinning and realtime scheduling together does not mitigate these effects.

E.2 Extended Macrobenchmarks

We conducted the evaluation here and in §5.2 using the same blade server cluster that we used for the microbenchmarks (see Appendix E.1).

Interception Strategies: Figure 19 shows the initialization time for Phantom with various interception strategies compared to the uni-process Shadow design. As expected, preloading has an insignificant effect on launch/load times. When using `seccomp`, Phantom completes the initialization process the faster than the uni-process design. Initialization takes the longest when using `ptrace`, and scales the worst as the number of LPs increases.

Memory Manager: Figure 20 shows that, when configured to use the `ptrace` interception strategy, the inter-process memory mapping design performs comparably to `process_vm_read` and `process_vm_write` fallback facilities despite using slightly more RAM and causing slightly more page faults. Phantom’s memory manager uses less RAM than Shadow’s uni-process design in all cases.

Thread Scheduler: Figure 21 shows the performance of the work-stealing thread schedulers when running Phantom with the `ptrace` interception strategy compared to the performance when using the schedulers in the uni-process Shadow design. Consistent with our results from §5.2, we find that

Figure 21: Performance of our P2P benchmark when our worker thread scheduler uses one thread per virtual host or one thread per logical processor (LP).

using one worker thread per virtual host decreases the time to complete the P2P benchmark relative to using one worker thread per LP despite using more RAM and causing more CPU migrations.

Peer Workload: We investigated the performance effect of varying the workloads in our P2P benchmark. In §5.2.1 we described the configurable parameters in our benchmark: each peer sends m messages, when receiving a message a peer performs c AES (encrypt, decrypt) sequences before sending another message, and message destinations are selected according to a peer weighting function W .

Figure 22a shows the results when varying c in the range $[0, 3]$. In Phantom with `seccomp` interception and in Shadow’s uni-process design, we observe a roughly linear increase in the benchmark time when increasing the number of AES operations that must be performed upon receipt of every message as expected. Interestingly, the linear constant appears to be slightly larger for `seccomp` than for uni-process, and much larger for `ptrace`. We speculate that the observed performance may be due to caching differences.

Figure 22b shows the results when varying m in the set $\{1, 10, 100, 1k\}$. After subtracting the baseline initialization time (represented roughly by the 1 msg/host case), we observe a linear increase in the benchmark time as we increase the message load; this is the expected result since increasing the message load also increases the amount of work the simulator must perform.

Figure 22c shows the results when varying the workload distribution. In addition to the exponential function defined in §5.2.1 as e^{-3x} for $x \in [0, 1]$, we also consider a “uniform” distribution where each peer has an equal probability of being selected as the destination for any message, and a “ring” distribution where each peer simply selects its closest neighbor as the destination of its outgoing messages. We can see from Figure 22c that these alternative workload distribution functions have minor effect on performance in our simulations.

E.3 Extended Network Verification

In this appendix, we present extended details and results from our evaluation of Phantom’s ability to accurately represent network characteristics from §5.3.

(a) The effects of varying CPU load

(b) The effects of varying message load

(c) The effects of varying peer load distribution

Figure 22: Performance of our P2P benchmark in Phantom using the `seccomp` and `ptrace` interception strategies and in Shadow’s uni-process design while varying the benchmark CPU and network load parameters.

E.3.1 Extended Basic Network Verification

We verify that Phantom accurately models networked application behavior when those applications are run in different networks with a variety of bandwidth and latency properties. We use two test applications, iPerf and a UDP echo application, to measure Phantom’s simulated bandwidth and latency characteristics. We compare the measurements collected from Phantom to a set of baremetal measurements we collected by running the same applications on two physically-networked servers with emulated bandwidth and latency properties. Additionally, we collected iPerf bandwidth measurements using Shadow so that we could verify that Phantom does not simulate network activity differently than Shadow does. Below we describe the experimental setup and the results from our two experiments.

Setup: To collect simulated bandwidth measurements, we ran a series of iPerf(v2) simulations with Phantom and Shadow. In each simulation, a single client and server communicate

using iPerf’s single-threaded TCP benchmark. The client sends traffic for 10 s, and the server runs until all the data from the client is received. Bandwidth is recorded from the server, which is receiving the traffic, in three-second intervals. Each simulation uses a network configured with a different bandwidth and one-way latency. For these experiments, we consider bandwidth values between 1 Mbit/s and 1 Gbit/s, and one-way latency values between 1 ms and 175 ms. We determined that 175 ms was a realistic upper-bound on latency in wide-area networks by examining RIPE Atlas ping measurements from Jan. 11, 2021: we found that the maximum latency reported by the probes for all built-in measurements was 173.5 ms after removing outliers.

To collect simulated latency measurements, a custom UDP echo application is ran between a client and a server with Phantom. The echo application simply measures the time required for the client to echo a UDP packet sent by the server, which estimates the round-trip time between the server and the client. We consider the same range of latency values in these experiments as in the bandwidth experiments.

To collect emulated baremetal measurements for comparison, we ran the same applications on two physically-networked servers. The machines had 2×Intel Xeon E5-2697 v3 CPUs, 256 GiB of RAM, and ran Debian 11 with Linux Kernel v5.10.0-8. They were both connected with NetXtreme II BCM57810 10 Gigabit Ethernet NICs through a 10 Gbit/s switch. We used Linux’s `netem` facilities to configure each machine’s NIC with a specified bandwidth rate limit and packet latency. Additionally, we set the machine’s TCP stack to use the Reno congestion control algorithm, which is also implemented in Shadow and Phantom.

iPerf Bandwidth Measurements: Figure 12 in §5.3 compares iPerf-reported bandwidth from the baremetal measurements, Phantom, and Shadow. In the left three plots, latency is held constant (at either 10 ms, 75 ms, or 175 ms) and iPerf-reported bandwidth is plotted versus the experimentally-configured bandwidth limit. In the right three plots, bandwidth is held constant (at either 10 Mbit/s, 100 Mbit/s, or 1 Gbit/s) and iPerf-reported bandwidth is plotted versus the experimentally-configured packet one-way latency. These plots show the bandwidth reported by iPerf during the 3-second interval closest to the half-way point of the transfer, which estimates the sustained maximum bandwidth achieved between the client and the server. We find that Phantom does not change modeling accuracy relative to Shadow, and that Phantom-reported performance matches baremetal-reported performance in most network conditions. With more extreme bandwidth and latency values, Phantom is able to achieve higher link-utilization than baremetal. These differences may be accounted for by different parameterizations of Phantom’s TCP stack and Linux’s (e.g., different initial window sizes). Extending and tuning Phantom’s TCP stack to more closely approximate the behavior of Linux’s networking facilities is a promising direction for future work.

Table 3: The Number of Virtual Hosts, Processes, and the Amount of Traffic in each Simulated Tor Network of the Given Scale

Network Scale	5%	10%	15%	20%	25%	30%
Clients	436	871	1307	1742	2178	2614
Relays	349	694	1039	1385	1732	2076
Servers	40	79	119	158	198	238
Total Virtual Hosts	825	1644	2465	3285	4108	4928
Tor	785	1565	2346	3127	3910	4690
OnionTrace	785	1565	2346	3127	3910	4690
TGen	476	950	1426	1900	2376	2852
Total Processes	2046	4080	6118	8154	10196	12232
Simulated Gbit/s*	12	24	37	49	62	74
Equivalent Tor Users	39.6k	79.2k	119k	158k	198k	238k

* Mean across 20 total simulations for each network scale.

Latency Measurements: Both the Phantom and baremetal measured RTT latency values matched nearly identically with the value specified in the experiment for all configured latencies. The largest percent-error between the simulated and emulated results (taking the emulated measurements to be ground-truth) was 3%, which occurred at the lowest configured one-way latency (1 ms): the Phantom-measured RTT was 2 ms, whereas the baremetal measured RTT was 2.07 ms. The difference can be accounted for by software processing time, which Phantom does not simulate.

E.3.2 Extended Tor Network Verification

We consider large-scale Tor network simulation as a practical use case for Phantom. By supporting Tor, we believe Phantom will have broader impact particularly among researchers in the privacy-enhancing technologies community since they commonly use simulation [5, 7–9, 15, 16, 18, 21–25, 27–29, 31, 33–37, 39, 41–43, 46, 47, 49, 51, 58–61, 64, 66, 68, 69] to explore Tor performance and security research problems [6]. Moreover, the Tor Project has recently adopted the use of simulation in their own network planning and performance analyses [2], and Phantom has already been used to guide these efforts [57].

The Tor anonymity network [17] contains over 6k relay nodes [1] and about 800k users that are simultaneously active, i.e., running a Tor client and generating network traffic [38]. Constructing a simulated Tor network that is representative of the real Tor network involves a significant modeling and configuration effort [40]. Important factors that must be considered include the number of virtual hosts running Tor clients and relays, traffic generator clients and servers, the network latency between these hosts, the bandwidth available to these hosts, and the configured behavior of the clients, relays, and traffic generators. Fortunately, recent foundational work on Tor network experimentation has contributed methods and tools to guide our experimentation process [40]. We use these tools directly to create Tor network configs and run experiments in both Phantom and Shadow (Tor network modeling is outside the scope of this paper).

Figure 23: The time and memory required to complete each Tor network simulation in Phantom (using `seccomp` interception) and in Shadow’s uni-process design as the network model scale increases. (b) and (c) show performance relative to Shadow’s baseline.

Setup: We generate 10 unique Tor network configs for each of 6 network scale factors using Tor network state from 2021-01; Table 3 shows the total number of virtual hosts and Linux processes used at each scale. Each client host runs three processes: (i) a TGen traffic generator process that generates traffic according to Markov models created by measuring the real Tor network [38]; (ii) a Tor process in client mode that forwards the TGen traffic into our private Tor network; and (iii) an OnionTrace process that connects to Tor to gather statistics and log information. Each relay host runs a Tor process in relay mode that forwards traffic in our private Tor network, and an OnionTrace process that gathers statistics and logs. Each server host simply runs a TGen server process that coordinates with TGen clients to generate traffic. Table 3 also shows the total volume of traffic being simulated at each scale, and the equivalent expected number of Tor users that it would take to generate that traffic in the public Tor network.

We run each of the resulting 60 Tor networks using Tor v0.4.5.9 in Phantom (using `seccomp`) and in Shadow (the state-of-the-art Tor network simulator). We conducted the evaluation using a blade server cluster in which each blade contained identical hardware: 1.25 TiB of RAM and 4×8 core Intel Xeon E5-4627v2 CPUs (without hyper-threading support) running at 3.30 GHz. For all experiments, we enable CPU pinning, disable realtime scheduling, and use 32 LPs (one LP per core) following our results from §5. We present the results as the mean across the ten networks at each scale with 95% confidence intervals (CIs).

Verification Results: We analyze the performance characteristics in each simulation, e.g., the simulated time to transfer data through the simulated Tor network. Recall from §5.3 that our primary goal is to validate that Phantom does not *reduce* the accuracy of the simulated network stack that it integrates and that we consider our validation successful if Phantom and Shadow produce similar simulated network results.

Figure 13 in §5.3 shows the simulated Tor performance results from using both Phantom and Shadow to each simulate the ten 30% scale Tor networks. Shown are several Tor performance metrics, including: circuit build times; circuit round trip times (time from data request to first byte of response); circuit goodput (transfer rate for range [0.5 MiB, 1 MiB] over 1 MiB and 5 MiB transfers); and client download times for

transfers of 50 KiB, 1 MiB, and 5 MiB. The shaded areas represent 95% confidence intervals that were computed following recently published methods [40]. We do not find a significant difference in performance measured in the simulated Tor network across several metrics when comparing Phantom to Shadow. Again, this is the desired and expected result since both Shadow and Phantom share a network stack implementation. We conclude that Phantom maintains the same level of simulator accuracy that Shadow provided; i.e., Phantom’s multi-process design does not degrade the level of accuracy that can be provided by a simulated network.

Performance Results: Figure 23 shows the simulators’ performance when running the Tor network simulations.

Figure 23a shows that the absolute time to complete a 60 simulated minute experiment is roughly linear in the network scale, where Phantom completed the experiment in the 10%, 20%, and 30% networks in 9, 18, and 27 hours, respectively. Phantom’s run time is remarkably similar Shadow’s, even though Phantom incurs IPC overhead while Shadow does not; this demonstrates the efficiency of Phantom’s design even when simulating somewhat complex distributed systems.

We plot simulation run time relative to Shadow’s baseline in Figure 23b. Although there is large uncertainty in small network scales (consistent with prior work [40]), we observe that Phantom is competitive to Shadow’s uni-process performance at smaller scales and comparable at larger scales: at 30% scale, Shadow’s performance falls within Phantom’s 95% CI.

Figure 23c shows the max RAM used by Phantom to simulate each network scale relative to Shadow’s baseline. We observe that Phantom is more memory-efficient than Shadow: while Shadow used 178, 357, 540, 727, 919, and 1116 GiB at network scales of 5%, 10%, 15%, 20%, 25%, and 30%, respectively, Phantom used at least 90.4% (at 5% scale) and at most 92.5% (at 30% scale) of RAM relative to Shadow.

We conclude that Phantom effectively overcomes the multi-process performance challenges identified in §2.3: Phantom’s multi-process design offers comparable performance to Shadow’s uni-process design while being more memory efficient. In addition to its performance, Phantom offers significant improvements over Shadow because its multi-process design precludes Shadow’s compatibility, correctness, and maintainability limitations that we identified in §2.3.

KSG: Augmenting Kernel Fuzzing with System Call Specification Generation

Abstract

Kernel fuzzing is a dynamic testing technique that has successfully found numerous kernel vulnerabilities. However, existing kernel fuzzers, such as Syzkaller, depend on system call specifications to generate test cases. Writing such specifications requires an immense amount of domain knowledge while being extremely laborious. Meanwhile, automated generation of the specification is still an open problem due to the complexity of the kernel, including entry function extraction and input type identification. As a result, the current amount of system call information is insufficient to test the entire kernel code base thoroughly. Syzkaller covers an average of 38% of Linux kernel code with current Syzlang specifications for a prolonged time of fuzzing.

In this paper, we propose KSG to generate system call specifications for kernel fuzzers automatically. First, it utilizes probe-based tracing to extract entry functions accurately. Then, it uses path-sensitive analysis to collect precise input types and range constraints in each execution path of entry functions. Based on the aforementioned information, KSG generates specifications in the domain language Syzlang, which is used by most kernel fuzzers. We evaluated KSG on several versions of the Linux kernel. It automatically generated 2433 unique specifications. Leveraging the newly generated specifications, Syzkaller and Moonshine achieved coverage improvements of 22% and 23% respectively. Furthermore, our approach assisted fuzzers to discover 26 previously unknown bugs, where 13 and 6 bugs were fixed and assigned with CVEs, respectively.

1 Introduction

The operating system kernel is one of the most complex components and forms the foundation of the software system. It is responsible for core functionalities, such as communication and IO of userspace applications. The security of the kernel is crucial as kernel bugs can lead to huge impacts easily, e.g.,

causing userspace applications to be unresponsive [24] and allowing an attacker to completely compromise a target system [22]. Fuzz testing [19] is a popular technique for automatically discovering security vulnerabilities and has already been applied to the kernel domain. For instance, Syzkaller [33], one of the most widely used kernel fuzzers, has been integrated into Linux testing pipeline. It has reported thousands of kernel bugs [31] up until now, demonstrating the effectiveness of applying fuzzing to kernel testing.

The driving force of the kernel fuzzer's bug discovery capability is system call specifications, which provide a rich set of system call information. As shown in Figure 2, a system call can accept parameters with different types based on underlying submodules' requirements. The prototype of system calls are written in C, a weakly typed language, that does not provide much information of system calls' arguments, e.g., many parameters are defined as *void**. Therefore, it is difficult for fuzzers to generate inputs that satisfy the submodules' structural constraints without additional information, resulting in low fuzzing efficiency. To address this issue, existing kernel fuzzers, such as Syzkaller, use a domain language called Syzlang [34] to encode system call specifications. Syzlang is a strongly typed language and can specialize system calls to specific submodules with precise input types, as shown in Figure 1. With this domain knowledge, fuzzing efficiency can be improved significantly. Meanwhile, the amount of specifications has a significant impact on the performance of fuzzers. Fuzzers can generate inputs to test kernel submodules that are well-encoded in the specifications, but they have difficulty reaching kernel code that is not encoded. Therefore, many researchers have to manually write numerous specifications to test the kernel thoroughly.

However, encoding system call specifications requires an immense amount of domain knowledge, resulting in significant time costs and insufficient number of specifications. Many system calls in the Linux kernel are an abstraction over corresponding functionalities of kernel submodules, which are responsible for dispatching the user input to submodules' operations. The actual types of the system call's param-

^{*}Yu Jiang is the corresponding author of this paper.

ters depend on the specific invoked submodule. Therefore, most specifications are encoded for specific submodules, e.g., *dev_loop.txt* in Syzkaller is specifications for *loop* device. In order to encode specifications manually, the following different aspects of domain knowledge are required: (1) the precise input types of system call used by the submodule; (2) the range constraints on specific input parameters; (3) the domain language used by fuzzers for specifications. However, the large amount of kernel submodules and the complexity of the input types make it difficult to encode specifications for a wide range of kernel functionalities. Consequently, most specifications are written by kernel experts, but the extensive manual effort required has caused specification shortage. Based on the coverage data reported by Syzbot's dashboard [32], Syzkaller covers an average of 38% of Linux kernel code with the current Syzlang specifications for a prolonged time of fuzzing. Several recent works perform automatic specification generation [4, 6, 11], but they are either designed for particular system calls or close-sourced scenarios. In order to further reduce manual efforts, we need to generate specifications for more system calls and their corresponding submodules.

Source code analysis can be used to generate specifications effectively, but several challenges need to be addressed due to the complexity of the Linux kernel. First, extracting entries that should be analyzed is difficult because entries can be registered dynamically. In order to generate specifications for specific submodules, we need to analyze submodules' operations invoked by system calls, and we refer to these operations as *entries*. However, entries can be registered dynamically in many scenarios, for instance, during kernel initialization and module loading. Consequently, it is challenging to extract entries using current static analysis methods. Second, the input types of entries can vary in different execution paths, resulting in difficulties identifying them. The functionalities of kernel submodules are complex, while the number of entries for accessing them is limited. In consequence, the submodules' entries can accept different input types across execution paths. We need to collect input types and corresponding range constraints in each execution path of every entry, which poses significant complexity to the analysis. Finally, to generate specifications in domain languages used by kernel fuzzers, we need to perform syntax mapping and semantic encoding based on the collected information.

To address the aforementioned challenges, we propose KSG (Kernel Specification Generator) to automatically generate system call specifications for kernel fuzzers. KSG mainly contains three steps. First, in order to extract submodules' entries without being bound to their implementation details, KSG utilizes a probe-based tracing with Linux *eBPF* [2] and *kprobe* [13]. Based on the extracted entries, KSG uses path-sensitive analysis to collect precise input types and range constraints in each execution path of entries, which is based on Clang Static Analyzer (CSA) [20]. Finally, based on the gathered information, KSG generates system call specifica-

tions in domain language Syzlang, which is used by most kernel fuzzers, to improve the fuzzing efficiency. We evaluated KSG on multiple versions of Linux kernel. It generates 8 specialized calls per minute, with a total of 2433 specialized calls generated in 5 hours, 1460 of which are new to existing specifications. Leveraging the generated specifications, Syzkaller and Moonshine's [23] coverage are improved by 22% and 23%, respectively. Furthermore, KSG assisted fuzzers to discover 26 previously unknown bugs, with 13 and 6 were fixed and assigned with CVEs, respectively.

Overall, we make the following technical contributions:

- We propose an analysis approach for system call specification generation. It incorporates multiple techniques to precisely collect submodules' entries and their types and range constraints on each execution path.
- We designed and implemented KSG, which extracts submodules' entries with *eBPF* and *kprobe* and performs path-sensitive analysis based on Clang Static Analyzer. Leveraging the collected information, KSG generates specifications in Syzlang for kernel fuzzers.
- The evaluation result shows that KSG generated 2433 specifications in total, which can improve the coverage of Syzkaller and Moonshine by 22% and 23% respectively, and assisted fuzzers to find 26 new bugs.

2 Background and Related Works

2.1 Kernel Fuzzing

Fuzz testing is an automated vulnerability discovery approach. Its idea is to continuously generate input to trigger program crashes with the assistance of various sanitizers [27, 28]. Within each fuzz loop, the fuzzer selects the seed from the given corpus with certain guided strategies [5, 25]. Then, it mutates the seed by combining multiple mutation operators, and feeds the generated input to the target program for execution [7, 16]. Meanwhile, the fuzzer collects interesting program behavior, e.g., coverage [3], to determine whether an input is valuable for further mutations, thus continuously optimizing the fuzzing campaign. Take AFL [15] for instance. It is a coverage-guided userspace program fuzzer that has found hundreds of vulnerabilities in widely-used libraries. Many works optimize each part of the fuzz loop [1, 17, 18, 36, 40]. For instance, RIFF [37] moves computations done originally at runtime to instrumentation time, thus reducing the instrumentation code while utilizing vector instructions to improve throughput. Consequently, its coverage measurement mechanism can reduce fuzzing overhead significantly.

The overall process used in kernel fuzzing is similar to that used in userspace, but each specific part can be different due to the complexity of the kernel. Specifically, the idea of kernel fuzzing is to generate high-quality input to trigger

kernel crash assisted with kinds of kernel sanitizers [8, 9], which is the same as a standard fuzz loop. However, unlike userspace fuzzing, the input structure of system calls can be complicated, and the cost of each test case execution is expensive. Therefore, the inputs generated by kernel fuzzers need to satisfy the structural and range constraints; otherwise, it would be rejected early by input validation, thus wasting huge amounts of fuzzing time. Existing fuzzers use specifications to encode input information of system calls to address this. Based on this domain knowledge, the performance of kernel fuzzers can be improved considerably.

Syzkaller is a state-of-the-art kernel fuzzer developed by Google. In order to generate high-quality input, it utilizes the domain language Syzlang to encode system call specifications manually. Although the encoding process brings substantial costs, they enable Syzkaller to discover thousands of bugs in the Linux kernel. Meanwhile, many works improve each part of kernel fuzzing [12, 14, 21, 26, 29, 35, 38]. Take Moonshine [23] as an example, it proposes a seed distillation algorithm to collect system call sequences from real-world applications and provide initial seeds for kernel fuzzers. Healer [30] optimizes input synthesis with system call influence relations and utilizes a dynamic learning algorithm to identify such relation between calls. Although both works improve the fuzzing performance significantly, their performance, like Syzkaller, depends on the quality and abundance of Syzlang specifications.

2.2 System Call Specification

Many system calls in Linux are an abstraction over corresponding functionalities of kernel submodules, and they are responsible for dispatching the user input to submodules' operations. A system call can accept parameters with different types based on submodules' expectations. As shown in Figure 1, the input types of socket-related calls can vary for different underlying protocols. The type of parameter `val` in `setsockopt` is `void*`, where it becomes `struct tcp_repair_window` when protocol is TCP, while other protocols can define different types. The structure of `val` can be very complex since each protocol supported by the Linux kernel can utilize different types. Besides, the original type of `val` (`void*`) does not provide any structural information to fuzzer. Without further input information, fuzzer cannot test `setsockopt` effectively since most generated inputs do not satisfy the requirements of specific protocols and will be rejected by input validation.

Kernel fuzzers utilize specifications written in domain language to generate input. For instance, Syzkaller utilizes Syzlang to encode specifications for specific submodules. Within each submodule's specification, kernel experts first define the resource type corresponding to the submodule. The resource type in Syzlang infers that the value of a parameter can only be constructed by the kernel and represents a kind of kernel resource. Then, kernel experts specialize system calls

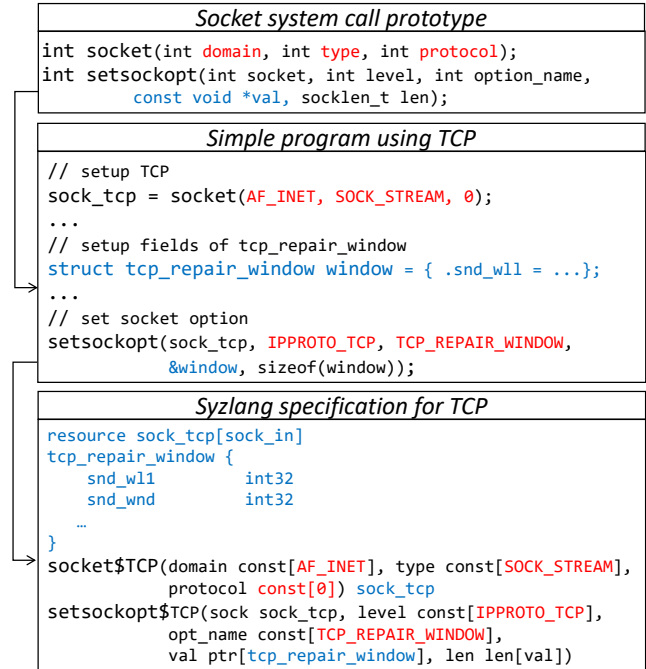

Figure 1: The input types of socket-related calls can vary for different protocols. The type of parameter `val` is `void*`, it becomes `struct tcp_repair_window` when the protocol is TCP, and other protocols can define different types. With Syzlang (the bottom part), calls can be specialized to specific protocol with range constraints (highlighted in red) and precise types (highlighted in blue).

that can access the submodule to multiple simplified calls via adding range constraints and qualifying the input type. Take Figure 1 as an example, it demonstrates parts of specifications written for TCP. The resource type `sock_tcp` represents a created TCP socket. Each parameter of the specialized call `socket$TCP` is qualified as a constant value (highlighted in red), which guides kernel fuzzers to set up TCP socket correctly. The parameter `val` of `setsockopt$TCP` is qualified as `tcp_repair_window`, which is the correct type corresponding to `TCP_REPAIR_WINDOW` option. Using Syzlang, these socket-related calls can be specialized to specific protocols with range constraints and precise types. Kernel fuzzers can use specialized calls to considerably improve their efficiency.

However, manually encoding specifications can be time-consuming due to the required domain knowledge mentioned in Section 1. Several works propose to generate specifications for specific system calls or particular scenarios. DIFUZE [6] is dedicated to generating specifications for system call `ioctl` of Android drivers and is the most relevant work to ours. It first finds all uses of `file_operations` related structures to identify the handle of `ioctl`. DIFUZE then tries to extract the device name from specific registration functions in the kernel. Finally, it detects the command values and correspond-

ing parameter structures with LLVM’s analysis capabilities, e.g., range analysis. With the above steps, DIFUZE can generate correct usages of `ioctl` from different drivers. However, most submodules’ operations are registered dynamically with unpredictable manners, which results in false negatives in DIFUZE. Besides, its pattern-based method can only be used to analyze `ioctl`. Meanwhile, Syzgen [4] and IMF [11] propose to generate specifications for close-sourced components of macOS. They capture system calls issued by userspace applications and generate specifications by analyzing the parameters’ value of captured calls. Nevertheless, both approaches do not utilize the available source code in open source scenarios to generate more effective system call specifications.

3 Challenges

3.1 Extracting Entries of Submodules

In order to generate specifications for specific submodules, we need to analyze the submodules’ entries that are invoked by system calls. Specifically, Linux defines the operations that submodules should implement with structures containing function pointers, e.g., `file_operations` and `proto_ops` as shown in Figure 2. Submodules implement these operations and register them to the kernel. We refer to these operations as entries. The responsibility of many system calls is to dispatch the input to the registered operations via indirect function call; thus, they do not contain much input information of the specific submodules. The submodules’ entries define the input types to the system calls for accessing themselves. Therefore, we need to analyze specific entries to obtain concrete input types to generate high-quality specifications. Take Figure 1 as an example, `val`’s type is `void*` and the system call `setsockopt` does not make any restriction on its concrete type. In TCP scenarios, `setsockopt` passes `val` to the entry `tcp_setsockopt`, which requires `val`’s type should be `struct tcp_repair_window*` when the option is `TCP_REPAIR_WINDOW`. We need to analyze the entry `tcp_setsockopt` to generate specifications for `setsockopt` in TCP scenarios.

However, the submodules’ entries can be registered dynamically in many situations, making it difficult to extract them. Submodules implement operations and store the function pointers in the corresponding structures, which are registered to the kernel with kinds of registration functions. The process mentioned above occurs at various times, such as kernel initialization and module loading. However, identifying the pointer’s target is challenging with current static analysis approach. The various registration points further increase the engineering efforts. For example, Figure 2 shows the definitions of `file_operations` and `proto_ops`, which contain the operations for kinds of files and sockets. Device drivers can implement `file_operations` according to their needs and register the structure to VFS during module loading.

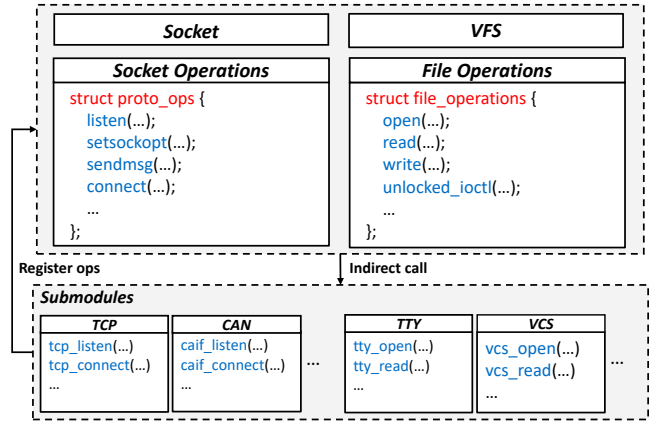

Figure 2: The definitions of `file_operations` and `proto_ops` contain the operations for files and sockets. Device drivers can implement `file_operations` as their needs and register this structure to VFS. Different protocols can register their own operations to socket layer in different ways.

Different protocols can register their `proto_ops` operations to the socket layer in different ways during kernel initializing. In order to generate specifications for submodules, we need to extract their entries and address the aforementioned dynamism.

3.2 Identifying Input Types of Entries

The second challenge is that each entry’s input type can be different across execution paths, which further increases the complexity of the analysis. As mentioned above, the kernel defines the operations that submodules need to implement via various structures containing function pointers. The number of such function pointers in each specific structure is limited, while each submodule can be very complex. Consequently, many submodules’ entries accept different input types in different execution paths to satisfy their functional requirements. In other words, the input type to the submodule’s entry is not fixed; some of the input parameters are responsible for controlling the execution path, while other parameters or fields have different types depending on the value of the former. Figure 3 shows the TCP submodule’s implementation of system call `setsockopt`, which is registered with `proto_ops` structure. The value of the parameter `optname` is mainly used to determine the different execution paths, while `optval` has different types based on the value of the former. In order to generate specifications, we need to identify the parameters’ type and collect corresponding range constraints in each execution path of the entries.

However, variables can be aliased with each other and cast to different types by different means, resulting in the difficulty in identifying their types and collecting corresponding range constraints in each execution path. To demonstrate the former

```

static int do_tcp_setsockopt(struct sock *sk, int level,
                           int optname, sockptr_t optval, unsigned int optlen)
{
    struct tcp_sock *tp = tcp_sk(sk);
    ...
    switch (optname) {
        case TCP_CONGESTION: {
            char name[TCP_CA_NAME_MAX];
            Path1: ➔ // type of `optval` is char[TCP_CA_NAME_MAX]
                    strncpy_from_sockptr(name, optval, ...);
        }
        case TCP_MAXSEG:
            int val;
            Path2: ➔ // type of `optval` is int*
                    copy_from_sockptr(&val, optval, sizeof(val));
                    tp->rx_opt.user_mss = val;
        case TCP_REPAIR_WINDOW:
            struct tcp_repair_window opt;
            Path3: ➔ // type of `optval` is tcp_repair_window*
                    if (copy_from_sockptr(&opt, optval, sizeof(opt)))
                        return -EFAULT;
    }
    return err;
}

```

Figure 3: `do_tcp_setsockopt` is TCP’s implementation of `proto_ops`. The type of parameter `optval` varies for different value of `optname`. This demonstrates that the input type of submodule’s entry can be different across execution paths

case, the value of variable `p0` with scalar type can be assigned to another variable `p1`. Meanwhile, `p1` can be cast to a pointer, which infers that `p0` represents an address. We will miss this kind of information without handling the alias between variables. To demonstrate the latter case, as shown in Figure 3, although parameter `optval` is declared as `sockptr_t` type, it is converted to different types under different cases of switch statement using different cast methods. For instance, `optval` is cast to `void*` type with C-style cast expression before the switch statement. `optval` is treated as `int*` type on *Path 2*, because `copy_from_sockptr` calls `copy_from_user` to copy `sizeof(val)` bytes from userspace, while variable `val` is `int` type. The above pattern is common in the kernel, thus we need to adequately handle the aliasing issue and type casting to properly collect types and ranges constraints.

4 Key Techniques

Figure 4 shows the overall workflow of KSG. First, the kernel source code is compiled based on the given configuration, which outputs a bootable kernel image and a series of files containing the Clang AST. The AST provides the kernel with code information for each stage of the analysis. When the kernel boots, the entry extraction module hooks multiple probes dynamically before and after specific kernel functions. KSG then scans various device files and network protocols, thus triggering the execution of hooked kernel functions, which can be captured by the probes. Consequently, the probes can detect and extract the submodules’ entries. Based on the AST and entries, KSG analyzes the range constraints and input types in

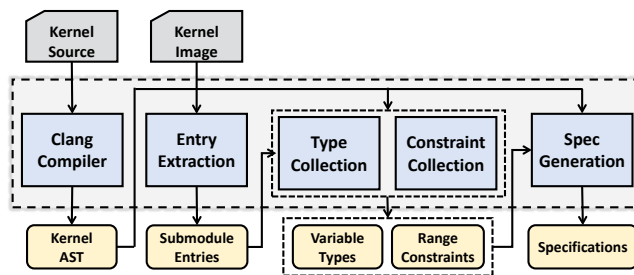

Figure 4: Workflow of KSG. The kernel code is compiled to a bootable image and files containing the clang AST. Sub-modules’ entries can be detected and extracted by the entry extraction module. Based on the AST and entries, KSG collects the range constraints and input types in each execution path of each entry with path-sensitive analysis. Finally, KSG generates specifications based on the collected information.

each execution path of each entry with path-sensitive analysis. Finally, based on the collected information, KSG generates specifications in domain language Syzlang for fuzzers, where the syntax mapping and semantics encoding are performed. The specifications can be generated with the aforementioned process, and the effectiveness of fuzzers can be improved with the generated specifications.

4.1 Entry Extraction

As mentioned above, we need to analyze the submodules’ entries for specification generation. However, the entries can be registered in many scenarios, causing difficulties in locating them. To address this, KSG utilizes a probe-based tracing to extract the entries. Although entries of different submodules can be registered with unpredictable manners, they are eventually stored into the specific data structures’ fields in the kernel. For instance, entry `file_operations` is stored into the `f_ops` field of `struct file`, which is maintained by virtual file system (VFS). In another instance, different protocols of the net subsystem store entry `proto_ops` into field `ops` of `struct socket`. Therefore, instead of analyzing the entries’ registration points, KSG extracts entries by capturing data structures containing the respective submodules’ entries, which we refer to as target structures.

Figure 5 shows the workflow of entry extraction. When the kernel boots, KSG hooks multiple probes before and after specific kernel functions utilizing Linux *eBPF* and *kprobe* (1). *eBPF* and *kprobe* enable KSG to hook our custom functions into any kernel function. We refer to these extended functions as probes and to hooked kernel functions as target functions. The target functions we choose are a mandatory part to access the submodules and are responsible for constructing target structures, thus they enable the probes to capture the execution of them and access target structures. Then, KSG scans the kernel resources corresponding to submodules from userspace.

Figure 5: Workflow of entry extraction. KSG hooks probes before and after the target kernel functions. Then, it scans resources and traps into kernel space. The target functions are executed, and the whole process is captured by the probes, which extract submodules' entries and save their addresses. Finally, KSG symbolizes addresses of the entries in userspace.

For instance, KSG opens device files and specific network protocols via system calls `open` and `socket` to access `VFS` and `net` submodules (2 & 3). After trapping into kernel space, these system calls invoke the target functions, which construct the target structures (4). Then the whole process is captured by the probes, which extract the submodules' entries via accessing certain field of the target structures (5 & 6). The entries are then stored into data structures provided by eBPF so that the extracted entries can be accessed from userspace (7 & 8). Finally, KSG reads the entries via `bpf` system call, and symbolize entries to the corresponding kernel symbols with Linux `/proc/kallsyms`. The above process enables KSG to extract submodules' entries accurately.

Take device drivers for instance, the probes will be hooked after the execution of kernel function `do_filp_open`, which is called by system call `open` and is responsible for opening files used by `VFS`. Then, KSG accesses files in specific directories of the system recursively, e.g., `/dev` and `/proc`. After capturing the execution of `do_filp_open`, the probe first filters the threads, thus ensuring that only KSG's execution is captured. The probe accesses the kernel data `struct file`, which represents the state of an opened file, and reads the field `f_ops` of it. Field `f_ops` is `filer_operations` type and contains the submodule's entries. KSG saves `f_ops` into eBPF maps so that entries can be read and symbolized in userspace. Since Linux treats almost everything as a file and most submodules are accessible from `VFS`, the above procedure can extract most submodules' entries. For sockets, KSG scans all the protocols supported by the kernel and captures the kernel function `__sock_create`, which is called by system call `socket`. KSG extracts the entry `proto_ops` of each protocol by accessing the field `ops` in the `struct socket`.

4.2 Types and Constraints Collection

With submodules' entries being extracted, KSG needs to collect input information from them for specification generation. However, the parameters' types of each entry can vary across execution paths. To identify parameters' types of each execution path, KSG needs to check if a parameter, originally declared in scalar type, is cast to pointer, and collect the most precise type of each pointer. Overall, KSG utilizes the symbolic execution of Clang Static Analyzer (CSA) to perform intra-procedural, path-sensitive analysis on submodules' entries. During symbolic execution, KSG checks all expressions that can determine the parameters' types of each execution path and associate the most precise type with each parameter.

To correctly identify parameters' types, KSG first needs to handle the alias between variables. CSA associates variables with unique symbolic values and allocates a memory region for each variable based on its memory model [39]. Aliasing issue can be handled with this mechanism because CSA guarantees that variables that are aliased with each other either have the same symbol or point to the same memory region during symbolic execution. Specifically, if the symbolic value of a variable is `sym0`, then the symbolic value of variables that are assigned with the former will also be `sym0`. Variables with pointer type that have the same address during concrete execution always point to the same memory region during symbolic execution. CSA itself associates the gathered range constraints to symbolic value instead of particular variables. Since symbolic value is associated with variables and is updated accordingly during symbolic execution, range constraints can be collected and propagated by CSA.

Based on the mechanism mentioned above, we associate the type information with symbols and memory regions to collect and propagate them properly. Specifically, for variables that are originally declared in scalar type but are cast to pointers, KSG maps the symbolic value of these variables to the memory regions of pointers in `SymRegionMap` (Line 1) as shown in Algorithm 1. For pointers, KSG associates the most precise type that is known with the best effort in specific program point with their memory regions, which is stored in `RegionTypeMap` (Line 2). A special map `RegionMap` (Line 3) is used to record the connections between regions in a pointer to pointer cast. `RegionMap` is needed because CSA creates new element region for this kind of cast, while these regions represent the same variable semantically. The above three global maps can be used to record and propagate the collected type information during symbolic execution.

KSG collects input types in each execution path during CSA's symbolic execution procedure. Specifically, whenever CSA executes the type cast expression, including explicit C-style casts and implicit casts, and kernel functions with copy

Algorithm 1: Collecting Types

```
1 SymRegionMap := ∅
2 RegionTypeMap := ∅
3 RegionMap := ∅
4 for CastExpr ∈ Entry do
5   S := SourceSym(CastExpr)
6   T := TargetSym(CastExpr)
7   if IsIntegerToPtr(CastExpr) then
8     R := Region(T)
9     SymRegionMap[S] := R
10    continue
11  if !IsPtrToPtr(CastExpr) then
12    continue
13  R0 := Region(S)
14  R1 := Region(T)
15  Record(R0, R1, RegionMap)
16  STy := KnownType(R0, RegionTypeMap)
17  TTy := KnownType(R1, RegionTypeMap)
18  if IsMorePrecise(STy, TTy) then
19    updateRegionType(R1, STy)
20  else
21    updateRegionType(R0, TTy)
```

semantics, such as `copy_from_user`, KSG obtains the type information from the expressions and updates the global maps mentioned above based on the comparison rules shown in Table 1. As shown in Algorithm 1, KSG records the mapping between the symbolic value of the scalar and the memory region of the pointer, which handles the integer to pointer casts (Lines 8 to 10). The recorded mapping can be used to retrieve the region of a pointer that is declared in scalar type. For a pointer to pointer cast, the algorithm first gets the respective regions of the source pointer and the target pointer (Lines 13 to 14), and records the connection between these regions into `RegionMap` (Line 15). Then it identifies the current known type of regions with `RegionTypeMap`, and the declared type of region is used if it has not been recorded (Lines 16 to 17). Based on the rules in Table 1, the algorithm updates the regions with the more precise type (Lines 18 to 21). For kernel functions with copy semantics, KSG utilizes a similar approach. Take `copy_from_user` as an example, KSG gets the current known type of the source pointer and the target pointer, and performs the type comparison first. Then, it checks if the last parameter is a unary expression `sizeof`, if so, KSG performs an additional comparison with the corresponding type. KSG updates the `RegionTypeMap` with the most precise type. Furthermore, KSG records the data flow direction of pointers based on the analyzed kernel functions. For example, `copy_from_user` infers the `In` direction and KSG associates this information with the corresponding memory region.

To associate the memory region with the most precise type in each execution path, KSG utilizes type comparisons. As shown in Table 1, the algorithm divides the types into four categories. First, `void` or `void*` is less precise than all other types because they do not encode any structural information. Scalar type that has longer bit width is more precise than another scalar type. Both scalar and compound type are less precise than pointer type, because it’s a common use case in kernel to store the pointer value to scalar or pointer-sized compound type. For pointer types, the algorithm applies the above rules to the underlying type recursively. With the procedure above, KSG can identify the concrete type of each parameter and field of compound type.

Table 1: Rules for comparison between source type and target type. ‘>’ represents that the source type is more precise than the target type, ‘<’ is the opposite. *Size* means that the result depends on the size of comparison types. *Underlying* means comparing the underlying type recursively.

	Void	Scalar	Compound	Ptr
Void	=	<	<	<
Scalar	>	<i>Size</i>	<	<
Compound	>	>	<i>Size</i>	<
Ptr	>	>	>	<i>Underlying</i>

Figure 6 shows a running example of `do_tcp_setsockopt` with Algorithm 1. First, CSA marks the input parameter `optname` and `optval` as symbol `sym0` and `sym1`, respectively. After the first case condition, it collects range constraint of `sym0`, indicating that `optname` equals to `TCP_REPAIR_OPTIONS` on the current execution path. Algorithm 1 is invoked when CSA enters the kernel function `copy_from_sockptr` since it calls `copy_from_user` eventually. Symbolic value `sym1` is associated with memory region `region0`, which is recorded in `SymRegionMap`, because `optval` (integer type) is cast to a pointer. The mapping from `region0` to `struct tcp_repair_opt` is also recorded in `RegionTypeMap`. Finally, CSA captures another range constraint of `opt`’s field `opt_code`. In this way, KSG knows the concrete type of `sym1` based on the information in `SymRegionMap` and `RegionTypeMap`. This example demonstrates that the types and range constraints can be collected properly and the second challenge can be addressed by combining CSA and type collection.

4.3 Specification Generation

Leveraging the above approach, KSG can collect parameters’ types and range constraints in each execution path of submodules’ entries. Based on the collected information, KSG generates specifications in domain language `Syzlang` for kernel fuzzers. The generation procedure needs to accomplish two

Figure 6: Running example for Algorithm 1. CSA first marks `optname` and `optval` as symbolic value `sym0` and `sym1`. Then it captures range constraint on symbolic value `sym0`. Algorithm 1 maps `sym1` to memory region `region0` since `optval` is cast to pointer type. Finally, CSA further captures another range constraint of `sym2`, symbolic value of `opt`'s field `opt_code`.

major goals: syntax mapping and semantic encoding. The former performs the mapping from C language AST to Syzlang AST and the latter encodes the collected range constraints into the generated specifications.

KSG divides the generation process into two steps. The first step generates the definitions of Syzlang resource type corresponding to the submodule, and the system calls that are responsible for creating the former. As mentioned in Section 4.1, KSG scans device files and protocols to extract submodules' entries. Meanwhile, the needed information for accessing the submodule is recorded. For instance, the file paths are saved for device drivers and the `domain`, `type` and `proto` are saved for specific sockets. Based on this information, KSG defines *resource* type for each submodule, and the name of the defined *resource* type follows specific rules. For example, resource types for device and socket are prefixed with `fd` and `sock`, respectively. For TCP submodule shown in Figure 1, `sock_tcp` is defined in this step. Then, KSG generates the corresponding system calls that create the resource type. For example, KSG generates the system call `open` for device drivers, and the input path of `open` is qualified to the file path of the device. The specialized version of system call `socket` is generated for each protocol, e.g., `socket$TCP` shown in Figure 1.

The second step generates the specialized calls for the remaining entries of a submodule. Specifically, KSG generates a specialized call for each execution path of each entry. The duplicated calls are filtered, and the parameters' types of each generated specialized call are qualified to the corresponding type in the execution path. Specifically, for a variable de-

clared in scalar type, KSG first checks if it is a pointer via querying `SymRegionMap` and maps it to Syzlang pointer if so; otherwise, KSG obtains its bit size according to the AST information and maps it to the corresponding numeric type with same bit size in Syzlang. Meanwhile, KSG checks whether the symbol of the scalar has range constraints by querying the program state of CSA. The corresponding constraint is represented as Syzlang's `const` type or ranged integer type. For array type, KSG first maps its element type to Syzlang type recursively, then queries CSA whether its length has range constraints. KSG constructs the corresponding Syzlang array type based on the mapped element type and length information. For pointer type, KSG first gets the memory region of the pointer from CSA, and queries the concrete type associated with the region from `RegionTypeMap`. KSG then maps the type of pointee recursively, and queries data flow direction associated with the memory region. KSG constructs the Syzlang pointer type with the mapped pointee's type and collected data flow direction. Finally, KSG maps each field of compound type to Syzlang type and generates the corresponding compound type in Syzlang. Based on the above mapping rules, KSG can generate specifications for submodules' entries based on the collected types and range constraints.

Take Figure 1 as an example, KSG generates three specialized system calls for each path of `do_tcp_setsockopt`. The type of `optname` is mapped to `const` type in Syzlang based on range constraints of each path. In the meantime, the type of `optval` is mapped to `array`, `int32`, and `struct`, respectively. Listing 1 in the Appendix shows part of generated specifications for driver `/dev/pts`, which manual specifications do not cover. Listing 2 shows part of generated specifications for the socket `X25`.

5 Implementation

Entry extraction. We implement eBPF programs based on BCC [10] and hook them as kprobe into target kernel functions. Two probes are used to capture the entries of device drivers' and protocols' operations, respectively. We currently utilize a userspace program to trigger the extraction process. The program first attaches the probes to the kernel. It then scans kernel-provided resources, such as opening files in `/dev`, mounting all the supported file systems, opening files in different file systems, and creating all the supported sockets of the kernel. These operations allow us to extract the implementation of the corresponding file operations and socket operations for different submodules.

Types and Constraints. We implement the types and constraints collection based on Clang13. Algorithm 1 is implemented as multiple CSA checkers that are hooked after each time CSA simulates execution of cast expression and before the execution of functions with copy semantics, e.g., `copy_from_user`. These checkers read the symbol values and memory regions of the expressions in the hooked opera-

tions from current program state, and update the type information stored in the global maps based on the type comparison rules in Table 1. For better intra-procedure analysis, we utilize the cross translation unit (CTU) analysis of CSA based on pre-dumped AST and compilation database. We customized the analysis configuration, e.g., increasing the max number of imported translation units, limiting the loop time since it does not provide new information for specification generation but reduces efficiency. Besides, we also modeled a larger number of kernel library APIs via implementing CSA checkers for better symbolic execution, including `kmalloc`, string manipulation functions, etc. These checkers observe the symbolic execution of the kernel and actively participate in modeling the program behavior via modifying the region bindings and range constraints stored in the program state.

Specification Generation. The generation procedure is implemented as plugins too that are hooked into CSA at the end of each execution path’s simulation. We first implement AST to fully support Syzlang language. Based on the type information stored in the global maps and the range constraints of each symbol in the CSA, the translation of KSG maps the C language AST to Syzlang AST. In order to generate the specifications, the mapped AST is serialized into text format that conforms to the syntax rules of Syzlang, thus allowing kernel fuzzers to use the generated specifications and speed up the entire fuzzing campaign.

6 Evaluation

In this section, we evaluate the effectiveness of KSG on recent versions of Linux and fuzzers. Specifically, we chose Linux-5.15, 5.10, and 5.4 as our target versions. Linux 5.15 is the latest version prior to submission, whereas 5.10 and 5.4 are widely used by many distributions. To evaluate the effectiveness of the generated specifications in improving fuzzers’ performance, we took the generated specifications as input to Syzkaller and Moonshine, and compared the code coverage and bug finding capabilities to their original version. We chose Syzkaller because it is the state-of-the-art kernel fuzzer. Moonshine improves Syzkaller’s fuzzing efficiency by distilling high-quality seeds for it and is a representative fuzzer. We design experiments to address the following questions:

- **RQ1:** How does KSG perform in generating system call specifications in terms of efficiency and quality?
- **RQ2:** How effective are the generated specifications in improving the coverage of kernel fuzzers?
- **RQ3:** How effective are the generated specifications in assisting kernel fuzzers to find bugs?

Experiment Settings The experiments were conducted on a Linux server with a 16-core Intel i7-10700K CPU and

32 GiB of memory. Each version of the kernel uses the same compilation configuration. Specifically, `CONFIG_BPF` and `CONFIG_KPROBE` were enabled for entry extraction. We also enabled `CONFIG_KCOV` to collect code coverage. We extended fuzzers with the generated specifications, and we refer to those extended fuzzers as Syzkaller+ and Moonshine+, respectively. All 4 fuzzers were configured with the same parameters in terms of QEMU configurations and base system call specifications. Specifically, we started all experiments simultaneously and distributed the resources evenly, including 2 cores and 4 GiB of memory for each virtual machine. All 4 fuzzers adopted the same base version of the Syzlang specifications. To reduce statistical errors, each experiment was repeated 3 times and executed over a period of 72 hours, and the average results were reported.

6.1 Specification Generation

We executed KSG on three versions of the Linux kernel and the whole process of specification generation is automatic. Table 2 shows the results of this process. During entry extraction, KSG scanned 1098 unique device files and 78 different sockets in total, and extracted 572 and 222 entries, respectively. Note that the number of entries is not equal to the number of scanned files and sockets multiplied by the number of function pointers defined in `file_operations` and `proto_ops`. This is because: first, the registered operations of different files and sockets can be the same; second, each submodule does not need to implement all the operations; finally, KSG de-duplicates the extracted entries and verifies the extracted addresses. Besides, we manually verified the correctness of extracted entries by reading the source code corresponding to the submodule. The result shows that KSG can correctly extract the entries of all files and sockets that are accessible from userspace. Furthermore, since KSG performs entry extraction dynamically based on eBPF after kernel booted and all submodules loaded, the correctness of the extracted entries can also be guaranteed.

Table 2: KSG extracted 792 entries by scanning 78 sockets and 1098 device files. After path-sensitive analysis in 5h, KSG generated specifications containing 2433 specialized calls, and 1460 of them are new to existing specifications.

	Scanned	Entries	Specs	New Specs
Socket	78	222	923	+586
Driver	1098	572	1510	+874
Overall	1176	794	2433	+1460

By performing path-sensitive analysis on submodules’ entry, KSG generates 8 specialized calls per minute, with a total of 2433 specialized calls generated in 5 hours. Of this total, 1510 specialized calls are generated from device drivers while 923 specialized calls corresponded to sockets. Specifically, for

64% of the extracted entries, the number of generated specialized calls is less than 2. This is because the input types remain consistent across the execution paths. For instance, KSG generates one specialized call for system call `bind` of each type of socket. The input address is qualified to the type defined by the corresponding socket type, while the type of such parameter in C prototype does not constrain the input structure. Although the number of specialized calls for this 64% of the entries is limited, encoding specifications for them requires extensive domain knowledge, whereas KSG can automate this process leveraging the source code analysis. For 36% of the extracted entries, the number of generated specialized calls is more than 2 because the input types of these entries can vary in different execution paths. The average number of specialized calls for these entries is 4, and KSG generates up to 29 specialized calls for system call `getsockopt` of X25 socket. For those 36% of the entries, the manual efforts of writing specifications would be vast, while the automation of KSG can significantly reduce the time cost of this process.

Compared with the existing specifications that contains 1204 specialized calls for the drivers and sockets scanned by KSG, 1460 generated calls are new, of which 586 and 874 are generated from the analyzed sockets and drivers, respectively. In order to further verify the correctness of the generated specifications, we manually checked if the range constants match the collected parameter types by reading the source code of submodules. The final result shows that KSG can correctly extract the input types and the corresponding range constraints in each execution path of submodules' entries.

6.2 Coverage Improvement

To answer **RQ2**, we took 1460 new specialized calls as input to Syzkaller and Moonshine, while monitoring the fuzzing process and sampling each fuzzer's statistics in the 72-hour run. Figure 7 shows the comparison of branch coverage between fuzzers and Table 3 lists detailed statistics. The base specifications used by Syzkaller and Moonshine contain 4144 specialized calls in total, including specifications encoded for submodules that have not been handled by KSG. With 1460 new specialized calls, Syzkaller+ and Moonshine+ achieved 22% and 23% coverage improvement, respectively.

As shown in Figure 7, both Syzkaller+ and Moonshine+ can achieve higher coverage statistics than their original version in the same amount of time. Specifically, all tools show significant growth in the first 8 hours, where the advantage of the generated specifications is not obvious. After fuzzing for 8 hours, the coverage growth of Syzkaller and Moonshine starts to slow down, whereas that of Syzkaller+ and Moonshine+ is significantly faster than the former. This is because KSG does not improve kernel fuzzers' throughput or efficiency, but rather enables fuzzers to reach more modules and code with additional generated specifications. Therefore, all fuzzers perform at similar rates before 8 hours since they have yet

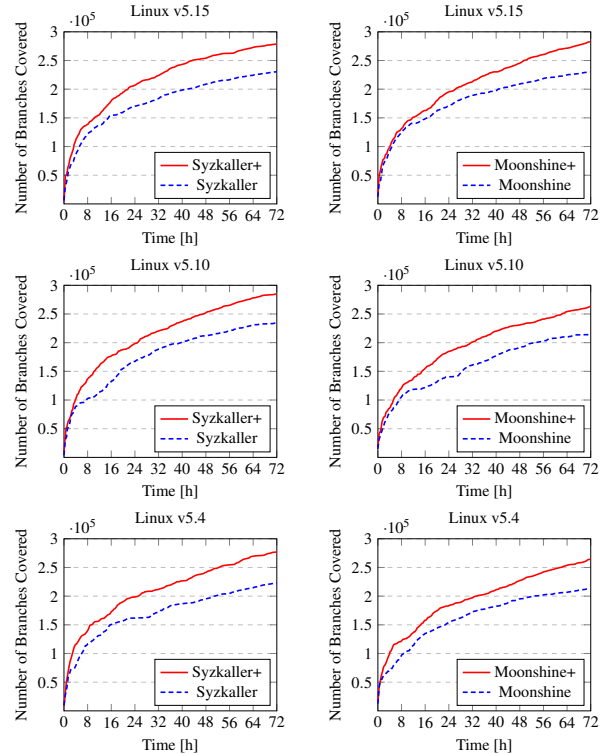

Figure 7: Coverage growth of Syzkaller and Moonshine with generated system call specifications on three versions of Linux kernel over 72 hours. In all kernel versions, Syzkaller+ and Moonshine+ achieve the higher coverage statistics.

to cover the code reachable using manually-written specifications. They diverge after 8 hours as the manually-written specifications cannot provide the kernel fuzzers with more low hanging fruit, while the generated specifications allow the fuzzers to continue finding more code in more modules.

In principle, fuzzers utilize the generated specifications to generate test cases. In order to further demonstrate the reason behind the improvement, we analyzed the output corpus of all fuzzers and calculated the percentage of test cases that contain the newly generated calls in the whole corpus. At the end of 72-hour experiment, the average percentage of such inputs in the corpus is 28%. Therefore, the reason behind the coverage improvement is that the generated specifications provide new test portals for fuzzers. Syzkaller+ and Moonshine+ can synthesize test cases based on the new specifications thus covering kernel code that used to be unreachable. Meanwhile, the improvement can demonstrate the quality of the generated specifications, since specifications with low quality, e.g., range constraints mismatch input types, can even hinder fuzzers' capabilities. The above results prove that the generated specifications can assist fuzzers in exploring more code in the kernel.

Table 3: Coverage statistics of fuzzers compare to their original versions. Columns “min-impr” and “max-impr” present the minimum / maximum improvement.

(a) Syzkaller+ vs. Syskaller			
Version	min-impr	max-impr	Average
5.15	+18%	+24%	+21%
5.10	+19%	+25%	+22%
5.4	+20%	+28%	+24%
Overall	+19%	+25%	+22%

(b) Moonshine+ vs. Moonshine			
Version	min-impr	max-impr	Average
5.15	+19%	+24%	+22%
5.10	+20%	+25%	+23%
5.4	+20%	+26%	+24%
Overall	+19%	+25%	+23%

6.3 Bug Finding and Case Studies

To answer **RQ3**, we tested the Linux kernel with Syzkaller+ and Moonshine+ for two weeks. As a result, we found 138 unique vulnerabilities in total and 26 were confirmed by maintainers as previously unknown bugs, of which 13 and 6 were fixed and assigned with CVEs, respectively. Table 4 lists the details of those vulnerabilities. Most of these vulnerabilities are critical. For instance, KSG assisted fuzzers to discover a vulnerability with a 7.0 CVSS score (CVE-2021-4028). Although Syzkaller has been testing the Linux kernel continuously with large amounts of computing resources, these 26 vulnerabilities have not been reported. The reason why KSG assisted Syzkaller+ and Moonshine+ to discover 26 previously unknown vulnerabilities is that the generated specifications provide fuzzers with more information of system calls. Based on this domain knowledge, Syzkaller+ and Moonshine+ can generate test cases to test kernel code that used to be difficult for fuzzers to reach. The above result shows that the specifications automatically generated by KSG can improve the fuzzers’ vulnerability detection capabilities.

Case Study: CVE-2021-4148 KSG assisted fuzzers to discover a vulnerability in VFS. As shown in Figure 8, `block_invalidatepage()` would throw BUG due to assertion failure if `stop` is greater than `PAGE_SIZE`. However, the input generated by the fuzzer is a huge page, and the length is the size of the huge page due to the read-only FS THP support. This triggers kernel crash directly and Figure 8 shows a fix for this. However, the root cause of this vulnerability is complicated. Specifically, the kernel isn’t supposed to get a writable file descriptor on a file that has huge pages added to the page cache without the filesystem’s knowledge. VFS should have truncated the page cache when it found THPs in the cache. Except for the fix mentioned, this vulnerabil-

Table 4: KSG assisted fuzzers to discover 26 previously unknown vulnerabilities. All of these vulnerabilities have been confirmed by maintainers; 13 of these bugs have been fixed by corresponding patches and another 6 have been assigned with CVEs.

<code>blk_mq_get_tag</code>	logic bug	Fixed

ity was fixed properly with additional patches. Leveraging the newly generated specifications, the fuzzer synthesized the corresponding test cases thus triggering the assertion failure.

7 Discussion and Limitations

During the experiments, we found a total of 231 specialized calls from existing specifications that are encoded for the submodules scanned by KSG, but are nonexistent in the generated specifications. We believe there are three major reasons for this. First, KSG mainly considers range constraints while handwritten specifications encode other parameters semantics, e.g., defining parameters that are checksums of other fields as instances of the `csum` type in Syzlang. Second, kernel experts can redefine original input types from system call definitions to other types with the same memory layout to generate argument values more efficiently. For instance, some submodules use the high 16 bits and low 16 bits of a `u32` number for different purposes, and kernel experts redefine them as two `u16` types so that fuzzer can generate and mutate values for them individually. For these two limitations, we can improve KSG further by hooking more kernel functions during

Figure 8: When the size of the `stop` is greater than `PAGE_SIZE`, `block_invalidatepage()` would throw BUG. Fuzzer triggered this crash by passing a huge page, where the length is the size of huge page due to FS THP support. This figure shows a direct fixing patch for CVE-2021-4148.

path-sensitive analysis to collect more parameters’ semantics as well as redefining input types based parameters’ usage. Finally, the kernel code contains low-level operations, e.g., inline assembly, which may not be well modeled by CSA, thus leading to the range constraints and type information being missed during the analysis procedure. To address this, we can construct checkers to simulate common low-level operations so that the related information can be collected and propagated properly.

Currently, we mainly apply KSG to generate specifications for drivers and sockets. Since many resources in Linux are represented as files in VFS, using file-operation-relevant system calls allows us to extract entry information for many submodules. Meanwhile, in principle, KSG is generalizable. For other multiplexing system calls, we can adapt entry extraction to the target through a slight analysis of the internal implementation to find the kernel functions that need to be injected; then, we can apply the rest of KSG. For other system calls, we can directly execute the collecting algorithm of KSG and generate specifications based on gathered information since these steps only depend on the source code information. Take system call `prctl()` as an example, KSG can collect the argument constraints directly from `sys_prctl()`.

8 Conclusion

In this paper, we propose KSG to automatically generate system call specifications for kernel fuzzers based on entry

extraction and types and constraints collection. The evaluation shows that KSG generates 8 specialized calls per minute, with a total of 2433 specialized calls generated in 5 hours. Leveraging the generated specifications, Syzkaller and Moonshine’s coverage were improved 22% and 23%, respectively. Furthermore, KSG assisted fuzzers to discover 26 previously unknown bugs. The above result demonstrates that KSG is effective in generating system call specifications, and the generated specifications can improve the fuzzers’ performance.

For future work, we will extend KSG to other system calls or submodules to generate more specifications since some submodules are not covered by KSG yet, and submodules like drivers can change over time, which potentially involves making modifications to entry extraction. More importantly, we can augment KSG to infer semantic information of system calls’ parameters, thus significantly improving the generated specifications, which can be implemented with multiple CSA checkers encoded carefully with domain knowledge.

Acknowledgments

We sincerely appreciate the guidance from our shepherd. We would also like to thank the anonymous reviewers for their valuable comments and input to improve our paper. 9.1 Generated Specifications

Listing 1 shows part of generated system call specifications for `/dev/pts`. During entry extraction, KSG extracts `struct file_operation` of device `/dev/pts` via accessing device files under `/dev/pts` directory. KSG then performs path sensitive analysis on each extracted entry to collect types and range constraints. During the first step of generation, KSG defines the resource type `fd_dev_pts_0`, where the name of resource type is generated based the accessed file. `openat$dev_pts_0_0` is also generated during this step and the target file path is qualified to `/dev/pts/0`. After the second step of the generation, the rest of specialized calls and related types were generated based on the collected types and range constraints.

Listing 1: Generated specifications for `/dev/pts` driver

```
resource fd_dev_pts_0[fd]
openat$dev_pts_0_0(fd const[AT_FDCWD], file
  ptr[in, string["/dev/pts/0"]], flags flags
  [open_flags], mode flags[open_mode])
fd_dev_pts_0
...
ioctl$dev_pts_0_16(fd fd_dev_pts_0, cmd const
  [0x5413], arg ptr[in, winsize])
ioctl$dev_pts_0_11(fd fd_dev_pts_0, cmd const
  [0x80045440], arg ptr[in, int32])
ioctl$dev_pts_0_3(fd fd_dev_pts_0, cmd const[0
  x541f], arg ptr[in, serial_struct])

DLOS: Effective Static Detection of Deadlocks in OS Kernels

Shi-Min Hu
Tsinghua University

Abstract

Deadlocks in OS kernels can cause critical problems like performance degradation and system hangs. However, detecting deadlocks in OS kernels is quite challenging, due to high complexity of concurrent execution and large code bases of OS kernels. In this paper, we design a practical static analysis approach named DLOS, to effectively detect deadlocks in OS kernels. DLOS consists of three key techniques: (1) a *summary-based lock-usage analysis* to efficiently extract the code paths containing distinct locking constraints from kernel code; (2) a *reachability-based comparison method* to efficiently detect locking cycles from locking constraints; (3) a *two-dimensional filtering strategy* to effectively drop false positives by validating code-path feasibility and concurrency. We have evaluated DLOS on Linux 5.10, and find 54 real deadlocks, with a false positive rate of 17%. We have reported these deadlocks to Linux kernel developers, and 31 of them have been confirmed.

1 Introduction

Concurrent execution improves the performance of OS kernels, but can inevitably introduce concurrency bugs. Some studies [37, 38, 51] have shown that a large part of reported OS bugs are related to kernel concurrency. Deadlock is a common kind of concurrency bugs, caused by a locking cycle in different threads. For example, one thread acquires the locks A and then B , while the other concurrent thread acquires the locks B and then A , and thus a deadlock caused by the ABBA locking cycle occurs. Deadlocks in OS kernels are dangerous, because they can infinitely block the involved threads, causing performance degradation and even system hangs.

To find deadlocks, many existing approaches [5, 9–11, 15, 21, 27, 28, 31, 33, 44, 45, 55] dynamically monitor thread execution and lock-related operations to detect locking cycles. These approaches have shown promising results in both user-level applications and OS kernels. For example, Lockdep [33] is a widely-used lock-usage validator integrated in the Linux

kernel. It detects deadlocks, double locks and other locking issues, by dynamically tracking the state of each lock class and checking the dependencies between different lock classes. However, dynamic analysis approaches require well-constructed workloads or substantial test cases to cover the code containing bugs, and thus their detection coverage is often limited in runtime testing.

To improve detection coverage, some approaches [30, 41, 42, 46, 52] use static analysis to detect deadlocks in user-level applications. However, these approaches are ineffective in detecting deadlocks in OS kernels, for two main reasons. First, these approaches requires a fixed entry point (such as a `main` function) to start dataflow analysis; but an OS kernel consists of many kernel modules, each of which has no such a fixed entry point [4, 43]. Second, these approaches need to identify concurrent code and perform concurrency alias analysis according to thread-creation function calls (such as the calls to `pthread_create`) and related arguments; but the concurrency of OS kernel is often determined by the concurrent execution of specific interface functions in each kernel module [2], not explicitly calling thread-creation functions.

To our knowledge, RacerX [19] is the sole existing static analysis approach to systematically detect deadlocks in OS kernels. It uses *locking constraint* to describe the locking situation when each lock is acquired, e.g., if a code path acquires the locks A and then B , its locking constraint is $A \rightarrow B$. RacerX performs flow-sensitive and inter-procedural analysis to identify the code paths containing locking constraints (such code paths are referred to as *target code paths* subsequently) from OS kernel code, and then recursively compares between each two target code paths with their locking constraints to detect locking cycles as deadlocks.

However, RacerX still has some limitations. First, though using some heuristic techniques (like result ranking), RacerX still has a high false positive rate of 46%, due to neglecting the feasibility and concurrency of code paths. Second, RacerX neglects alias relationships, causing both false positives and negatives. Finally, RacerX simply compares between each two target code paths with their locking constraints in a recursive

way to detect locking cycles. This method works well for old OS kernels (like Linux 2.5.62 checked in its paper), but can be inefficient for modern OS kernels (like Linux 5.10 checked in our evaluation) that are much larger and more complex. Since the RacerX paper published in 2003, no new static approach has been proposed to systematically detect deadlocks in OS kernels. Thus, it is important to design a new static approach to perform effective deadlock detection in modern OS kernels.

In this paper, we design a practical static analysis approach named DLOS, to effectively detect deadlocks in OS kernels. DLOS consists of three key techniques:

(1) DLOS uses a *summary-based lock-usage analysis* to efficiently extract the code paths containing distinct locking constraints from kernel code. Our analysis uses function summaries to avoid repeated code analysis in the same functions, and it also drops the target code paths containing repeated locking constraints. To improve accuracy, our analysis is flow-sensitive and inter-procedural with the consideration of alias relationships, and it also uses a light-weight method to validate code-path feasibility with an SMT solver.

(2) DLOS uses a *reachability-based comparison method* to efficiently detect locking cycles from locking constraints. We observe that there are substantial target code paths containing distinct locking constraints in modern OS kernels (like Linux 5.10). Thus, when detecting locking cycles, simply comparing between each two target code paths with their locking constraints in a recursive way is quite time-consuming. To solve this problem, for each target code path, our method maintains a constraint reachability graph to store the locking constraints that are reachable starting the comparison from this code path, and the involved target code paths. By using constraint reachability graphs, our method can reduce repeated comparison of locking constraints, to improve the detection efficiency. If a locking cycle is found, it is considered as a possible deadlock, with the involved target code paths and locking constraints.

(3) DLOS uses a *two-dimensional filtering strategy* to effectively drop false positives, by validating the feasibility and concurrency of target code paths for each possible deadlock. On the one hand, as using an SMT solver to completely validate the feasibility of each code path is quite time-consuming, our strategy validates code paths in a phased way. Specifically, during locking-constraint extraction, as substantial code paths are required to be validated, making the validation efficiency more important, our strategy uses a simple and light-weight path-condition checking method to drop obviously infeasible code paths containing locking constraints; and then after locking-cycle detection, as the code paths of possible deadlocks should occupy a very small proportion of all the code paths, making the validation accuracy more important, our strategy uses a complete and heavy-weight path-condition checking method to drop false deadlocks. On the other hand, for each possible deadlock, our strategy checks the concurrency of its code paths, by analyzing their call graphs and looking for common locks acquired in these code paths.

Figure 1: DLOS workflow.

Overall, DLOS has three main stages shown in Figure 1. In Stage 1, DLOS uses our summary-based lock-usage analysis to extract the code paths containing distinct locking constraints. In Stage 2, according to the extracted code paths and locking constraints, DLOS uses our reachability-based comparison method to detect possible deadlocks. In Stage 3, DLOS uses our two-dimensional filtering strategy to check possible deadlocks and drop false positives. After these stages, DLOS reports the final reports of the found deadlocks.

Compared to RacerX, DLOS has two main advantages. First, DLOS can achieve better accuracy than RacerX, by validating code-path feasibility with an SMT solver, considering alias relationships and checking the concurrency of the involved code paths for reported deadlocks. Second, DLOS can spend less time than RacerX, by extracting and comparing locking constraints more efficiently.

We have implemented DLOS with LLVM [32] and Z3 [54]. DLOS performs automated static analysis on the LLVM bytecode of the checked OS kernel. Overall, we make three main contributions in this paper:

- We analyze the challenges of static deadlock detection in OS kernels, and propose three key challenges to address these challenges: (1) a *summary-based lock-usage analysis* to efficiently extract the code paths containing distinct locking constraints from kernel code; (2) a *reachability-based comparison method* to efficiently detect locking cycles from locking constraints; (3) a *two-dimensional filtering strategy* to effectively drop false positives by validating code-path feasibility and concurrency.
- Based on these three key techniques, we design a practical static analysis approach named DLOS, to effectively detect deadlocks in OS kernels.
- We evaluate DLOS on Linux 4.9 and 5.10, and find 46 and 65 deadlocks, respectively. We manually check these deadlocks, and find that 39 and 54 deadlocks are real. 21 of the real deadlocks found in Linux 4.9 have been fixed in Linux 5.10. We have reported the 54 real deadlocks found in Linux 5.10 to Linux kernel developers, and 31 of them have been confirmed.

The rest of this paper is organized as follows. Section 2 introduces the background and motivation. Section 3 introduces the challenges of static deadlock detection in OS kernels and our key techniques to address these challenges. Section 4 introduces DLOS. Section 5 shows our evaluation. Section 6

makes a discussion about DLOS. Section 7 presents related work, and Section 8 concludes this paper.

2 Background and Motivation

We first introduce deadlock and its detection, then explain the concurrency model of OS kernels, and finally motivate our work using a real deadlock in the Linux kernel.

2.1 Deadlock and Its Detection

To protect critical data from concurrent accesses, several kinds of synchronization primitives are designed and used. Locks are the most frequently-used synchronization primitives in real-world programs, to guarantee atomicity and prevent data races. However, if locks are incorrectly used, a deadlock can occur when one thread holds a lock that other concurrent threads want to acquire and vice versa.

Locking cycles in concurrent threads can cause deadlocks. The most common case is the ABBA lock in two threads, as shown in Figure 2(a). Namely, one thread acquires the locks A and then B ($A \rightarrow B$), while the other concurrent thread acquires the locks B and then A ($B \rightarrow A$), causing a locking cycle ($A \rightarrow B, B \rightarrow A$). In three or more threads, deadlocks can also occur due to such locking cycles, as shown in Figure 2(b).

Figure 2: Deadlock examples.

For dynamic analysis, deadlock detection has two basic steps, namely extracting locking constraints in concurrent threads and then comparing these locking constraints to detect locking cycles. For static analysis, deadlock detection is similar but more complex. On the one hand, without exact runtime information about thread execution, static analysis has to identify locking constraints from each code path and validate the concurrency of code paths. On the other hand, without exact values of accessed variables, static analysis has to validate the feasibility of code paths using an SMT solver.

2.2 Concurrency Model of the OS Kernel

A modern OS kernel consists of many kernel modules, including filesystems, network modules, device drivers, etc. Each kernel module has some specific interface functions that are called by upper-level programs, including other kernel modules via function-pointer calls and user-level applications via system calls. Figure 3 shows some examples of interface functions that are assigned to function-pointer fields. These interface functions form the entry points of the kernel module,

```
FILE: linux-5.10/fs/gfs/file.c
1108. file_operations gfs2_file_fops = {
1109.     .llseek = gfs2_llseek,
1110.     .read_iter = generic_file_read_iter,
1111.     .write_iter = gfs2_file_write_iter,
1112.     .unlocked_ioctl = gfs2_ioctl,
1123. }

FILE: linux-5.10/drivers/net/wan/lmc_main.c
808. struct net_device_ops lmc_ops = {
809.     .ndo_open = lmc_open,
810.     .ndo_stop = lmc_close,
811.     .ndo_change_mtu = hdlc_change_mtu,
812.     .ndo_start_xmit = hdlc_start_xmit,
816. }
```

Figure 3: Examples of interface functions in kernel modules.

and all other functions defined in the kernel module are called by them [4, 43]. Due to this execution model, the concurrency of OS kernel is often determined by the concurrent execution of specific interface functions in each kernel module [2]. In fact, a kernel module can also explicitly call thread-creation functions (such as `kthread_create` in the Linux kernel), but such operations are not common in kernel module code.

Different from the OS kernel, each user-level application has a fixed entry point (like a `main` function) and explicitly calls thread-creation functions (like `pthread_create`) to start concurrent execution. Accordingly, to detect deadlocks in user-level applications, existing static approaches [30, 41, 42, 46, 52] start dataflow analysis from this fixed entry point, and identify concurrent code for concurrency alias analysis according to thread-creation function calls and related arguments. Due to the difference between the concurrency models of OS kernels and user-level applications, these approaches are ineffective in detecting deadlocks in OS kernels.

2.3 Motivating Example

Figure 4 presents a real and already fixed deadlock in the `btrfs` filesystem, and this bug is found by our approach DLOS in the evaluation of checking Linux 4.9. When the function `btrfs_read_chunk_tree` is executed on the code path $P1$, it acquires the locks `root->fs_info->chunk_mutex` and then `orig->device_list_mutex`; when the function `btrfs_remove_chunk` is executed on the code path $P2$, it acquires the locks `fs_devices->device_list_mutex` and then `root->fs_info->chunk_mutex`. During filesystem execution, the functions `btrfs_read_chunk_tree` and `btrfs_remove_chunk` are able to be concurrently executed at runtime, and the locks `orig->device_list_mutex` and `fs_devices->device_list_mutex` can be identical, and thus an ABBA deadlock can occur. This deadlock was introduced by the commit `57ba4cb85bff` [16] in Linux 4.7, and it was found by Lockdep [33] and fixed by the commit `01d01caf19ff` [17] in Linux 5.9, after over 4 years later. In fact, Lockdep is integrated in the Linux kernel for dynamic deadlock detection, but it took Lockdep such a long time to find this deadlock, because the interleaving of the code paths $P1$ and $P2$ are infrequent in real execution.

This example illustrates why deadlocks occur in OS kernels. First, determining concurrent code paths and identifying the same locks in these code paths require substantial knowledge of OS kernels. In the example, without deep understanding of filesystems and extensive testing, it may

```

Code Path P1:
// FILE: linux-4.9/fs/btrfs/volumes.c
btrfs_read_chunk_tree
-> lock_chunks [Line 6803]
-> mutex_lock(&root->fs_info->chunk_mutex) [Line 517]
-> read_one_dev [Line 6833]
-> open_seed_devices [Line 6601]
-> clone_fs_devices [Line 6558]
-> mutex_lock(&orig->device_list_mutex) [Line 734]
      A→B
Code Path P2:
// FILE: linux-4.9/fs/btrfs/volumes.c
btrfs_remove_chunk
-> mutex_lock(&fs_devices->device_list_mutex) [Line 2844]
-> lock_chunks [Line 2857]
-> mutex_lock(&root->fs_info->chunk_mutex) [Line 517]
      B→A

```

Figure 4: A real deadlock in Linux 4.9 *btrfs* filesystem.

be difficult to know code paths *P1* and *P2* can be concurrently executed, and the locks `orig->device_list_mutex` and `fs_devices->device_list_mutex` can be identical. Second, incorrect fixing of known bugs can introduce new and hard-to-find concurrency bugs. In the example, the commit 57ba4cb85bff introducing the deadlock aimed to fix a harmful data race in the functions `btrfs_remove_chunk` and `btrfs_dev_replace_finishing`, but this commit incautiously introduces a locking cycle in the functions `btrfs_remove_chunk` and `btrfs_read_chunk_tree`. Finally, multiple functions (including concurrent functions and the functions called by them) and variables in these functions need to be considered.

By scanning the reported deadlocks in the Linux kernel, we find that most of them are found in stress testing and kernel fuzzing. But the detection coverage of runtime testing heavily relies on the provided workloads, causing many real deadlocks to be missed. Static analysis can conveniently achieve high detection coverage without actual execution of the OS kernel. However, as the sole existing static approach of systematically detecting deadlocks in OS kernels, RacerX [19] still has many false positives, and its concurrency analysis can be inefficient to modern OS kernels (like Linux 5.10 checked in our evaluation) that are much larger and more complex than old OS kernels (like Linux 2.5.62 checked in the RacerX paper). Thus, it is important to design a new static approach to perform effective deadlock detection in modern OS kernels.

3 Challenges and Key Techniques

To detect deadlocks, static analysis needs to first extract the code paths containing distinct locking constraints (such code paths are referred to as *target code paths* subsequently) from kernel code, and then compare these code paths with their locking constraints to detect locking cycles as deadlocks. However, performing these steps for checking OS kernel code has three main challenges:

C1: Extracting locking constraints. A modern OS kernel is very large and complex, because it has many kernel modules and lots of functions with complicated call graphs. Thus, extracting locking constraints in OS kernel code can be quite time-consuming and inaccurate.

C2: Detecting locking cycles. Due to the large and complex code base of the OS kernel, there are substantial target code paths containing distinct locking constraints. Thus, when detecting locking cycles, simply comparing between each two target code paths with their locking constraints in a recursive way is quite inefficient.

C3: Dropping false bugs. On the one hand, without validating the feasibility of code paths, static analysis can extract many infeasible target code paths and thus report many false bugs. On the other hand, each deadlock involves two or more target code paths that should be able to concurrently executed. Thus, without validating the concurrency of these target code paths, static analysis can report many false bugs whose target code paths cannot be concurrently executed.

To solve the above challenges, we propose three key techniques. For *C1*, we propose a *summary-based lock-usage analysis* to efficiently extract the code paths containing distinct locking constraints from kernel code. For *C2*, we propose a *reachability-based comparison method* to efficiently detect locking cycles from locking constraints. For *C3*, we propose a *two-dimensional filtering strategy* to effectively drop false positives by validating code-path feasibility and concurrency. We will introduce these techniques as follows.

3.1 Summary-Based Lock-Usage Analysis

Our summary-based lock-usage analysis has two basic stages: (S1) performing a dataflow analysis to collect target code paths containing distinct lock-acquire/release operations; and then (S2) performing a static lockset analysis to compute locking constraints for each target code path.

S1: Collecting target code paths. In this stage, the dataflow analysis has some properties: 1) this analysis is flow-sensitive and inter-procedural with the consideration of alias relationships, which can improve the accuracy; 2) this analysis uses function summaries to reduce repeated analysis, which can improve the efficiency; 3) this analysis drops the target code paths containing repeated lock-acquire/release operations, which can reduce repeated comparison in locking-cycle detection; 4) this analysis uses a light-weight method to validate the feasibility of each analyzed code path, which can reduce false positives of deadlock detection. This dataflow analysis traverses the code paths in the analyzed function *func*.

Figure 5 shows the main procedure of this dataflow analysis, which is represented as *DataFlowAnalysis*. It creates a function summary *func_sum*, which stores basic information about *func* (like function name and function-definition location) and the target code paths in *func*. This function summary is initialized with no target code path (line 1). This analysis handles each code path *code_path* in *func* with three steps (lines 2-30). First, it creates a data structure *tar_path* to collect the lock-acquire/release function calls and analyzed basic blocks in *code_path* (line 3), and then checks each function call *call* in *code_path* (lines 4-26). If *call* is used to acquire

```

DataFlowAnalysis(func)
Input: func – the analyzed function
Output: func_sum – function summary storing basic information about func
and the target code paths in func
-----
1: func_sum->tar_path_set :=  $\emptyset$ ;
2: foreach code_path in GetCodePathSet(func) do
3:   tar_path := CreateTargetCodePath(code_path);
4:   foreach call in GetCallSetInPath(code_path) do
5:     called_func := GetCalledFunction(call);
6:     if CheckLockFunction(called_func) then
7:       AddLockVector(call, tar_path->lock_vec);
8:     else
9:       // Use function summary to reduce repeated analysis
10:      called_func_sum := FindFuncSummary(called_func);
11:      if called_func_sum == NULL then
12:        called_func_sum := DataFlowAnalysis(called_func);
13:      end if
14:      // Top-down analysis of all target code paths in the callee
15:      called_tar_path_set := called_func_sum->tar_path_set;
16:      foreach called_tar_path in called_tar_path_set do
17:        tar_path_tmp := SplicePathInfo(tar_path, called_tar_path);
18:        if LightPathCheck(tar_path_tmp) == TRUE then
19:          AddPathSet(tar_path_tmp, func_sum->tar_path_set);
20:        end if
21:      end foreach
22:      // Bottom-up analysis of one target code path selected in the callee
23:      rand_tar_path := RandomSelect(called_tar_path_set);
24:      tar_path := SplicePathInfo(tar_path, rand_tar_path);
25:    end if
26:  end foreach
27:  if LightPathCheck(tar_path) == TRUE then
28:    AddPathSet(tar_path, func_sum->tar_path_set);
29:  end if
30: end foreach
31: DropRepeatTargetCodePath(func_sum->tar_path_set);
32: return func_sum;
-----

```

Figure 5: Dataflow analysis of collecting target code paths.

or release a lock, it is added into the lock-operation vector *lock_vec* of *tar_path* (line 7); otherwise this analysis handles its called function *called_func*. If *called_func* has been already analyzed, its function summary is gotten and stored as *called_func_sum* (line 10); otherwise, *DataFlowAnalysis* is recursively used to compute its function summary as *called_func_sum* (line 12). Then, from *called_func_sum*, this analysis gets and handles the target code paths in *called_func* (lines 15-21) in a top-down manner. For each such target code path *called_tar_path*, this analysis splices it with *tar_path* to form a new and possible target code path *tar_path_tmp*. This analysis uses a light-weight method (will be explained in Section 3.3) to validate the code-path feasibility of *tar_path_tmp*; if the code path is feasible, *tar_path_tmp* is considered as a possibly real target code path in *func* and added into the function summary *func_sum*->*tar_path_set* (lines 18-20). To avoid the explosion of bottom-up code paths from the callee function *called_func*, this analysis randomly selects one of the target code paths in this function and splices it into *tar_path* (lines 23-24). Before the code path ends, this analysis uses the light-weight method again to validate the code-path feasibility of *tar_path*; if the code path is feasible, *tar_path* is considered as a possibly real target code path in *func* and added into the function summary *func_sum*->*tar_path_set* (lines 27-29). After handling each code path, this analysis checks *func_sum*->*tar_path_set* to drop the target code paths containing identical lock-operation vectors (line 31), which can

reduce repeated comparison of target code paths in locking-cycle detection. Finally, this analysis returns the function summary *func_sum* (line 32), which can be used to analyze other functions that call *func*.

Besides the procedure shown in Figure 5, this dataflow analysis also performs an intra-procedural, flow-insensitive and Andersen-style alias analysis [1] to identify all variables aliased with the lock argument of each lock-acquire/release function call. The alias analysis can help to improve the accuracy of computing locking constraints in S2. Moreover, each function summary stores the information about arguments and global variables, and drops the information about local variables, which are never used outside the function.

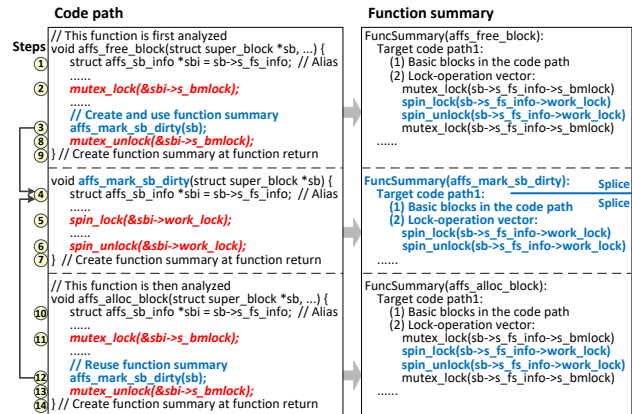

Figure 6: Example of summary-based dataflow analysis.

Example. We illustrate this dataflow analysis using the simplified code of the Linux *affs* filesystem in Figure 6. This figure shows three functions and partial code paths of them. According to the function position order, this analysis first analyzes the function *affs_free_block* and then *affs_alloc_block*, the analysis steps are represented as ①. This dataflow analysis also considers the alias relationships at ①, ④ and ⑩. At ③, there is a function call to *affs_mark_sb_dirty*, so this dataflow analysis first handles this function, then creates its function summary, and finally splices the target code path of this function summary into the analyzed target code path of *affs_free_block*. At ⑫, the function *affs_mark_sb_dirty* is called again, so its function summary is reused, and the target code path of this function summary is spliced into the analyzed target code path of *affs_alloc_block*. By using the function summary, the analysis efficiency can be effectively improved.

Note that to avoid path explosion caused by bottom-up code paths of each callee function, this dataflow analysis uses a partial bottom-up analysis. Specifically, it randomly selects one of the target code paths in its function summary, and splices this path into the analyzed target code in the caller function, as shown at lines 23-24 in Figure 5. However, this method can miss other target code paths of the callee function, which can cause false negatives of deadlock detection. Even

Figure 7: Example of the traditional comparison.

so, compared to RacerX [19] that only has top-down analysis without bottom-up analysis, this dataflow analysis is more accurate by using partial bottom-up analysis. In the future, we will implement a more complete and low-complexity bottom-up analysis, by referring to some existing approaches [39, 40].

S2: Computing locking constraints. This step uses a static lockset analysis to compute locking constraints in the target code paths collected in S1. This lockset analysis is similar to dynamic lockset analysis proposed in Eraser [47] for race detection, but in a static way. For each target code path, this lockset analysis maintains a lockset storing the held locks, and it handles lock-acquire and -release function calls.

When encountering a lock-acquire function call, this analysis first creates and adds related locking constraints in the analyzed target code path, according to the locks in the lockset and the acquired lock of this call; and then it adds this acquired lock into the lockset. For example, when this analysis handles the function call acquiring the lock X , if the lockset LS stores the held locks A and B , it first creates two locking constraints $A \rightarrow X$ and $B \rightarrow X$, then adds these locking constraints into the analyzed target code path, and finally adds X into LS . When encountering a lock-release function call, this analysis looks for and drops the involved lock in the lockset.

3.2 Reachability-Based Comparison Method

After extracting target code paths, we need to compare them to detect locking cycles as possible deadlocks. During comparison, we use a field-based analysis to identify the same locks in different code paths, if the lock variables' data structure types and fields are identical, which is similar to RacerX [19] and DCUAF [2]. Moreover, because a locking cycle can involve multiple target code paths (like the example deadlock in Figure 2(b)), the traditional method (used by existing static approaches like RacerX [19]) starts the comparison from each locking constraint in each target code path, and then recursively compares between each two target code paths with their locking constraints. Specifically, this method compares the current locking constraint with each locking constraint of each unhandled target code path. If they are matched, the current locking constraint is replaced with the matched locking constraint, and the comparison continues; if they are not matched, the comparison selects other target code paths. If all target code paths have been handled, the comparison stops. Once a locking cycle is found, this method reports a deadlock.

Figure 8: Example of our reachability-based comparison.

Example with the traditional comparison. We illustrate this traditional method using an example in Figure 7, containing four target code paths ($TP1$, $TP2$, $TP3$ and $TP4$), each of which contains one locking constraint. This method first starts the comparison from the locking constraint $A \rightarrow B$ in $TP1$ (namely $TP1\{A \rightarrow B\}$), and then starts the comparison from the locking constraint $D \rightarrow A$ in $TP2$ (namely $TP2\{D \rightarrow A\}$). The detailed comparison steps are also shown in the figure.

In Figure 7, we find that when starting the comparison from $TP2\{D \rightarrow A\}$, some steps (marked in blue and bold font) perform repeated comparison that has been done when starting from $TP1\{A \rightarrow B\}$. In fact, such repeated comparison of locking constraints are common in locking cycle detection, because many code paths handle the same locks but have different locking orders, leading to different locking constraints. Thus, if such repeated comparison can be reduced, the locking cycle detection can be much more efficient.

Based on this idea, we propose a reachability-based method to efficiently compare locking constraints for locking-cycle detection. During comparison, this method maintains a constraint reachability graph for the target code path that the comparison starts from. This reachability graph contains some reachable nodes, each of which indicates an *indirect* locking constraint used for subsequent comparison:

$$\bigwedge_{i=1}^n (TP_i\{A_i \rightarrow A_{i+1}\}) \Rightarrow TP_{indirect}\{A_1 \rightarrow A_{n+1}, TP_{set}\}$$

$$TP_{set} = \{TP_1, TP_2, \dots, TP_n\}$$

This indirect locking constraint is added in the handled target code path. When our method finishes the comparison starting from all the locking constraints in this target code path, its reachability graph is completely built. The indirect locking constraints in this reachability graph are used to reduce repeated comparison involving the handled target code path. Specifically, if any locking constraint (direct or indirect) in this target code path is matched, the comparison stops and checks whether there is a locking cycle. Note that our method assumes a target code path is never concurrently executed with itself, because static analysis has insufficient information to infer whether a code path can be concurrently executed with itself. This assumption is also followed by existing static approaches, such as RacerX [19] and DCUAF [2].

Example with our reachability-based comparison. To illustrate our method, we still use the example in Figure 7. The key steps performed by our method are marked in red and bold font. Our method still first starts the comparison from the locking constraint $TP1\{A \rightarrow B\}$. Because $TP1\{A \rightarrow B\}$ matches $TP3\{B \rightarrow C\}$ and $TP4\{B \rightarrow E\}$, our method creates two indirect locking constraints $TP1\{A \rightarrow C, [TP3]\}$ and $TP1\{A \rightarrow E, [TP4]\}$ and adds them in the target code path $TP1$. After $TP1$ is handled, its reachability graph is completely built. When our method starts the comparison from the locking constraint $TP2\{D \rightarrow A\}$, the three locking constraints (including two indirect ones) in $TP1$ are matched. Because the reachability graph of $TP1$ is complete, the comparison stops when these locking constraints are handled, which can avoid the repeated steps performed by the traditional comparison method in Figure 7. In this way, our method can effectively reduce the time usage of locking-cycle detection.

Besides, for each indirect locking constraint, our method also stores the related original locking constraints and target code paths. During comparison, if a locking cycle is found as a possible deadlock, our method can conveniently recover the information about the involved locks and their code paths, which is used for false-positive filtering in Section 3.3.

3.3 Two-Dimensional Filtering Strategy

For a possible deadlock, our strategy checks whether it is a false positive, in two dimensions, namely validating the feasibility and concurrency of its target code paths.

D1: Validating code-path feasibility. For a given code path, we can use an SMT solver to validate the satisfiability of all the branch conditions and variable accesses (including read and write operations) in this code path. For deadlock detection, there are two possible stages where code-path validation can be performed: (S1) during the dataflow analysis extracts target code paths in Section 3.1, we can validate the feasibility of each extracted target code path; (S2) after locking-cycle detection in Section 3.2, we can validate the feasibility of the target code paths for each possible deadlock.

In S1, because the dataflow analysis needs to handle substantial code paths, if we perform complete and accurate validation of these code paths, the time cost will be quite high. In S2, we believe that the code paths of possible deadlocks should occupy a very small proportion of all the target code paths extracted in the dataflow analysis, and thus it is acceptable to perform complete and accurate validation of these code paths. An alternative way is to just perform code-path validation in S2. However, without the validation in S1, lots of infeasible target code paths will be extracted for locking-cycle detection, which can also introduce high time cost.

Based on the above consideration, our strategy uses a staged and balanced way. In S1, our strategy uses a simple and light-weight path-condition checking method to efficiently check the extracted target code paths. This method checks only

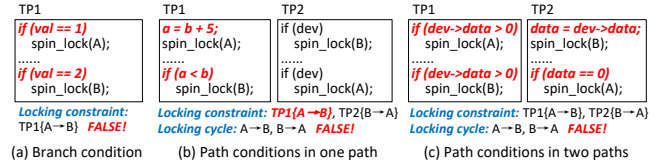

Figure 9: Examples of code-path feasibility validation.

Figure 10: Examples of code-path concurrency checking.

branch conditions in each code path, without handling variable accesses outside branch conditions. Thus, this method is fast but relatively inaccurate, and it can quickly drop many target code paths that are obviously infeasible. Figure 9(a) shows an example target code path that can be dropped by this method. In S2, our strategy uses a complete and heavy-weight path-condition checking method to accurately check the code paths of possible deadlocks. This method checks both branch conditions and variable accesses in each code path. Thus, this method is relatively slow but accurate, and it can effectively drop false deadlocks involving complex path conditions.

In fact, because a deadlock contains two or more code paths that are interleaved in concurrent execution, these code paths may access some shared variables that should have identical values. Thus, for each possible deadlock, the heavy-weight method in S2 performs code-path validation in two ways. First, for each code path of this deadlock, the method validates its feasibility; if any code path is identified to be infeasible by an SMT solver, this deadlock is considered to be false and dropped. Second, the method extracts shared variables having identical data structure types and fields in each two code paths, then identifies the variable accesses and branch conditions that are related to these shared variables in the code paths, and finally translates the identified operations into SMT constraints of an SMT solver. If these SMT constraints are computed to be unsatisfiable, this deadlock is considered to be false and dropped. Figure 9(b) and Figure 9(c) show two example false deadlocks that can be dropped in these two ways, respectively.

D2: Checking code-path concurrency. For a deadlock, its target code paths should be able to be concurrently executed; otherwise, this deadlock is false. For each possible deadlock, our strategy checks the concurrency of its target code paths in two ways. First, our strategy checks whether there is a common lock acquired before the involved lock-acquire operations in any two of the target code paths. If so, these code paths cannot be concurrently executed, so this possible deadlock is considered to be false and dropped. Second, our strategy extracts the call graph of each target code path, and checks whether any two of these call graphs have common parts. If so,

Figure 11: DLOS architecture.

it indicates that the related two code paths may be sequentially executed at different time points of the same thread, so this possible deadlock is considered to be false and dropped. Figure 10(a) and Figure 10(b) show two example false deadlocks that can be dropped in these two ways, respectively.

4 DLOS Approach

Based on the three key techniques in Section 3, we design a practical static approach named DLOS, to detect deadlocks in OS kernels. We have implemented DLOS with Clang [13] and Z3 [54]. DLOS automatically performs static analysis on the LLVM bytecode files of the OS kernel. Figure 11 shows the architecture of DLOS, which has four phases:

P1: Source-code compilation. The *Clang compiler* compiles the kernel source files into LLVM bytecode files, and then the *information collector* handles each function in LLVM bytecode to collect the function’s information (including function name, function-definition position, etc.). The information is used for inter-procedural analysis across source files.

P2: Locking-constraint extraction. The *lock-usage analyzer* uses our summary-based lock-usage analysis to handle LLVM bytecode files. This analysis starts at the entry of each function in the kernel code, to extract target code paths containing distinct locking constraints.

P3: Locking-cycle detection. The *locking-cycle detector* uses our reachability-based comparison method to check the extracted target code paths with locking constraints, and detects locking cycles as possible deadlocks. We observe that a kernel module often acquires private locks that are not accessible for other kernel modules, and thus the detector focuses on checking target code paths in the same kernel module.

P4: False-positive filtering. The *deadlock validator* uses our two-dimensional filtering strategy to check possible deadlocks and drop false positives. Besides, two possible deadlocks may have identical problematic locking operations but differ in code paths. To drop such repeated bugs, for a new possible deadlock, the validator checks whether it has the same problematic locking operations with any already detected deadlock; if so, it is considered to be repeated and dropped.

Implementation details. DLOS performs lock-usage analysis and path validation from the entry of each function in OS code, so it can handle different execution contexts like interrupt handling. However, DLOS does not handle function-pointer calls

at present, so it cannot detect deadlocks across kernel modules connected by function pointers. Besides, DLOS cannot analyze RCU locks, as RCU lock-acquiring/release functions (like `rcu_read_lock` and `rcu_read_unlock`) have no argument. Finally, to accelerate deadlock detection, DLOS can support the parallelism of handling multiple kernel modules using multi-thread execution.

5 Evaluation

To validate the effectiveness of DLOS, we evaluate it on the Linux kernel. To cover different kernel versions, we select an old version 4.9 and a recent version 5.10. Table 1 shows the basic information about these kernel versions, and source code lines are counted by CLOC [14]. We run the experiments on a regular x86-64 PC with eight Intel i7-3770@3.40G CPUs and 16GB memory. We use the kernel configuration *allyesconfig* to enable all kernel code for the x86-64 architecture.

Description	Linux 4.9	Linux 5.10
Release time	December 2016	December 2020
Source files (.c)	23.7K	29.4K
Source code lines (.c)	11.4M	14.7M

Table 1: Basic information about the checked OS kernels.

5.1 Bug Detection

We configure DLOS with common lock-acquiring/release functions (like `spin_lock` and `spin_unlock`) according to the Linux kernel documents [34], and then run DLOS to automatically check the kernel source code. We manually check all the deadlocks found by DLOS to identify real bugs. Table 2 shows the results, and we have the following findings:

Code analysis. DLOS can scale to large code bases of OS kernels. Specifically, it analyzes 8.5M and 11.7M source code lines in 14.5K and 19.9K source files in Linux 4.9 and 5.10, respectively, within 7 hours. The remaining 2.9M and 3.0M source code lines in 9.2K and 9.5K source files are not analyzed, because they are not enabled by *allyesconfig* for the x86-64 architecture.

Efficiency improvement. DLOS improves the analysis efficiency from two aspects:

First, when extracting target code paths containing locking constraints, our lock-usage analysis uses function summaries to reduce repeated code analysis in the same functions. Specifically, around 93% of the times DLOS handles a function call is able to reuse an existing function summary, without the need of analyzing the function’s definition again.

Second, when detecting locking cycles, our reachability-based comparison method uses constraint reachability graphs to reduce repeated comparison of locking constraints. Specifically, with 196K and 222K indirect locking constraints created by our method, 851K and 946K times of repeated comparison are reduced in Linux 4.9 and 5.10, respectively.

	Description	Linux 4.9	Linux 5.10
<i>Lock-usage analysis</i>	Source files (analyzed/all)	14.5K/23.7K	19.9K / 29.4K
	Source code lines (analyzed/all)	8.5M/11.4M	11.7M/14.7M
	Times of handling functions	4,102K	5,032K
	Times of reusing function summaries	3,816K	4,682K
	Extracted distinct target code paths	102K	117K
	Extracted locking constraints	323K	439K
<i>Locking-cycle detection</i>	Created indirect locking constraints	196K	222K
	Times of reducing comparison	851K	946K
	Possible deadlocks	465	539
<i>False-positive filtering</i>	Dropped infeasible target code paths	464K	524K
	False bugs due to infeasible paths	220	258
	False bugs due to common locks	78	94
	False bugs due to call graphs	101	122
	Total false bugs	419	474
<i>Deadlock</i>	Found bugs	46	65
	Real bugs	39	54
<i>Time usage</i>	Lock-usage analysis	265m	294m
	Locking-cycle detection	85m	96m
	False-positive filtering	22m	28m
	Total time	372m	418m

Table 2: Deadlock-detection results.

False-positive dropping. DLOS uses our two-dimensional filtering strategy to drop false positives from three aspects:

First, when extracting target code paths containing locking constraints, our strategy uses a simple and light-weight code-path validation method to drop 464K and 524K infeasible target code paths in Linux 4.9 and 5.10, respectively. In addition, by dropping these target code paths, the related unnecessary locking-constraint comparison can be avoided in locking-cycle detection, which also improves the efficiency of deadlock detection.

Second, after locking-cycle detection reports possible deadlocks, our strategy uses a complete and heavy-weight code-path validation method to drop 220 and 258 false bugs in Linux 4.9 and 5.10, respectively. Indeed, these false bugs' code paths are failed to be dropped in our lock-usage analysis, because the light-weight code-path validation method used in this analysis is efficient but relatively inaccurate. To improve accuracy, the heavy-weight code-path validation method completely checks both branch conditions and variable accesses in the code paths of each possible deadlock, and thus it successfully drops these false bugs after locking cycle detection.

Finally, our strategy checks the concurrency of possible deadlocks, and drops 179 and 216 false bugs in Linux 4.9 and 5.10, respectively, because their target code paths are considered to be non-concurrent. Specifically, 78 and 94 bugs are dropped due to holding a common lock in target code paths; 101 and 122 bugs are dropped due to containing common parts in the call graphs of target code paths.

Deadlock finding. DLOS reports 46 and 65 deadlocks in Linux 4.9 and 5.10, respectively. We spent eight hours on checking all these 111 reported deadlocks. We identify 39 and 54 deadlocks are real in Linux 4.9 and 5.10, respectively. 21 real deadlocks in Linux 4.9 have been fixed in Linux 5.10, including the deadlock in the *btfs* filesystem shown in Figure 4. Thus, DLOS can find known deadlocks. Moreover, we have reported the 54 real deadlocks in Linux 5.10 to Linux

kernel developers, and 31 of them have been confirmed. We are still waiting for the reply of the remaining ones. Thus, DLOS can find new deadlocks.

We infer that these real deadlocks are missed by Lockdep in extensive kernel testing, because their thread interleavings are infrequent to occur, and constructing workloads to cover these thread interleavings is difficult. Thus, DLOS can indeed find many deadlocks that are hard to find in runtime testing.

Besides, we believe that DLOS is helpful to deadlock reproduction, because it produces the detailed code paths of the found deadlocks. With these code paths, time delays can be strategically injected and carefully controlled, to cover specific thread interleavings and reproduce the found deadlocks. We have manually performed this way for several deadlocks in kernel modules that we can run, including the two deadlocks in Figure 4 and Figure 12(a), and these deadlocks can be successfully reproduced at runtime.

Deadlock details. Among the 93 real deadlocks in Linux 4.9 and 5.10, 78 (33 in Linux 4.9 and 45 in Linux 5.10) occur in device drivers, and 15 (6 in Linux 4.9 and 9 in Linux 5.10) occur in filesystems. This result indicates that device drivers remain a significant source of OS bugs [49]. Besides, for 86 deadlocks (35 in Linux 4.9 and 51 in Linux 5.10), DLOS reports two code paths for each of them, indicating it is caused by two locks in two threads; for the remaining 7 deadlocks, DLOS reports three code paths for each of them, indicating it is caused by three locks in three threads.

5.2 False Positives and Negatives

False positives. DLOS reports 7 and 11 false bugs in Linux 4.9 and 5.10, resulting the false positives rates of 15% and 17%, respectively. By manually checking these false bugs, we find that they are reported for three main reasons:

First, the field-based analysis in locking-cycle detection can make mistakes when identifying the same locks in different code paths. This analysis identifies the same locks if the locks variables have the same data structure types and fields; but two different lock variables can also have the same data structure types and fields, and their data structure variables are different. This analysis cannot handle such cases at present. This reason causes DLOS to report 3 and 5 false bugs in Linux 4.9 and 5.10, respectively.

Second, although DLOS uses Z3 to validate path feasibility, it can still make mistakes when handling some complex cases, such as complicated arithmetic conditions and data dependence across multiple functions. This reason causes DLOS to report 2 and 3 false bugs in Linux 4.9 and 5.10, respectively.

Finally, the alias analysis in our lock-usage analysis is intra-procedural and flow-insensitive, and thus can identify wrong alias relationships across function calls, causing mistakes in locking-constraint extraction. This reason causes DLOS to report 2 and 3 false bugs in Linux 4.9 and 5.10, respectively.

False negatives. DLOS may still miss some real deadlocks for three main reasons:

First, our lock-usage analysis performs incomplete bottom-up analysis of each callee function, to avoid path explosion of inter-procedural analysis. Specifically, it randomly selects one of the target code paths in the callee function, and splices it into the analyzed target code in the caller function. Although the other target code paths in the callee function are handled in top-down analysis, they are neglected in bottom-up analysis, causing some locking constraints in the target code paths of the caller function to be missed.

Second, DLOS does not analyze function-pointer calls, and thus it cannot build complete call graphs for inter-procedural analysis. As a result, DLOS may miss real deadlocks involving the code that is reached through function-pointer calls.

Finally, DLOS considers that a target code path is never concurrently executed with itself. Indeed, to reduce false positives, DLOS validates two code paths' concurrency by checking their common locks and call graphs. However, this validation is infeasible for two identical code paths, and thus DLOS does not detect deadlocks occurring in the same target code path of different execution contexts.

5.3 Case Studies of the Found Deadlocks

Figure 12 shows two deadlocks found by DLOS in Linux 5.10, and they have been confirmed by Linux kernel developers.

Deadlock in SysRq command handling for filesystems. In Figure 12(a), when the function `do_thaw_all_callback` is executed on the code path *P1*, it first acquires the read-write semaphore `sb->s_umount` and then the mutex lock `bdev->bd_fsfreeze_mutex`; when the function `freeze_bdev` is executed on the code path *P2*, it first acquires the mutex lock `bdev->bd_fsfreeze_mutex` and then the read-write semaphore `sb->s_umount`. During SysRq commands [50] are handled for filesystems, the functions `do_thaw_all_callback` and `freeze_bdev` can be concurrently executed, and thus an ABBA deadlock can occur.

Deadlock in the LPFC SCSI driver. In Figure 12(b), when the function `lpfc_nvmet_unsol_fcp_issue_abort` is executed on the code path *P1*, it acquires the spinlocks `ctxp->ctxlock` and then `phba->sli4_hba.abts_nvmet_buf_list_lock`; when the function `lpfc_sli4_nvmet_xri_aborted` is executed on the code path *P2*, it acquires the spinlocks `phba->sli4_hba.abts_nvmet_buf_list_lock` and then `ctxp->ctxlock`. During driver execution, the functions `lpfc_nvmet_unsol_fcp_issue_abort` and `lpfc_sli4_nvmet_xri_aborted` can be concurrently executed, and thus an ABBA deadlock can occur.

From the feedback of kernel developers, the confirmed deadlocks found by DLOS require infrequent and special test cases to find at runtime, which indicates that DLOS is useful to detecting hard-to-trigger deadlocks via static analysis.

```

5.4 Comparison Experiment

We aim to experimentally compare to RacerX [19], which is the sole existing static approach to systematically detect deadlocks in OS kernels. However, RacerX is not open-source, and Linux kernel 2.5.62 checked in its paper is too old to be normally compiled by Clang. Thus, we have to try our best to implement a RacerX-like tool according to its paper.

RacerX [19] performs code analysis with summary caches, which seems similar to function summaries used in our lock-usage analysis. However, RacerX lacks the other two key techniques used in DLOS, namely the reachability-based comparison method to improve the efficiency of locking-cycle detection, and the two-dimensional filtering strategy to drop false positives. To validate the value of these two techniques in comparison, we implement three tools by modifying DLOS: (1) $DLOS_{reach}$ that uses the traditional comparison method in RacerX for locking-cycle detection to replace the reachability-based comparison method in DLOS; (2) $DLOS_{filter}$ that removes the two-dimensional filtering strategy in DLOS; (3) *RacerX-like* that both uses the traditional comparison method for locking-cycle detection and removes the two-dimensional filtering strategy in DLOS.

We run these three tools to check the whole Linux 5.10 code, but the $DLOS_{reach}$ and *RacerX-like* tools run for over 60 hours, without finishing their detection. Thus, for more clear comparison, we select six kernel modules in Linux 5.10, and run these tools and DLOS to check the source code of these kernel modules. These six kernel modules include: two ones (*sb* and *lpfc*) that has real deadlocks found by DLOS, two ones (*fpga* and *ocfs2*) that has false deadlocks found by DLOS, and two ones (*jfs* and *bcache*) that has no deadlock found by DLOS. Table 3 shows the results, and we find that:

	Description	DLOS _{reach}	DLOS _{filter}	RacerX-like	DLOS
<i>sb</i>	Found bugs (real/all)	6/6	6/14	6/14	6/6
	Time usage	30s	14s	27s	16s
<i>lpfc</i>	Found bugs (real/all)	7/7	7/25	7/25	7/7
	Time usage	524s	162s	501s	181s
<i>fpga</i>	Found bugs (real/all)	0/2	0/5	0/5	0/2
	Time usage	21s	9s	18s	11s
<i>ocfs2</i>	Found bugs (real/all)	0/2	0/10	0/10	0/2
	Time usage	936s	214s	892s	253s
<i>jfs</i>	Found bugs (real/all)	0/0	0/0	0/0	0/0
	Time usage	305s	101s	280s	122s
<i>bcache</i>	Found bugs (real/all)	0/0	0/3	0/3	0/0
	Time usage	78s	28s	71s	33s

Table 3: Comparison results of six Linux kernel modules.

First, the DLOS_{reach} tool achieves the same accuracy with DLOS, but it spends more time on locking-cycle detection. Thus, our reachability-based comparison method is more efficient than the traditional comparison method in RacerX, when performing locking-cycle detection.

Second, the DLOS_{filter} tool reports many more false bugs than DLOS, though it finds the real deadlocks found by DLOS. Thus, our two-dimensional filtering strategy is useful to dropping false positives in deadlock detection. Moreover, we observe that the DLOS_{filter} tool spends less time than DLOS. Indeed, without validating the feasibility or concurrency of target code paths, the DLOS_{filter} tool can decrease time usage; but this tool extracts many infeasible target code paths for locking-constraint comparison, which also increases the time usage of locking-cycle detection. As a whole, the decreased time usage is more than the increased time usage in the experiment, and thus the DLOS_{filter} tool has less time usage than DLOS.

Finally, the RacerX-like tool spends less time than the DLOS_{reach} tool, because it does not validate the feasibility or concurrency of target code paths, but causing more false bugs to be reported. The RacerX-like tool spends more time than the DLOS_{filter} tool, because it detects locking cycles with the traditional comparison method, which is less efficient than our reachability-based comparison method; but it achieves the same accuracy with the DLOS_{filter} tool, because neither of them drops false positives. Compared to the RacerX-like tool, DLOS achieves better accuracy in deadlock detection with less time usage.

6 Discussion

Interleaving model. DLOS identifies each target code path from the entry of each function in OS code, and then it considers that two different target code paths identified by our lock-usage analysis can be concurrently executed. To reduce false positives, DLOS validates their concurrency by checking common locks and call graphs using our two-dimensional filtering strategy. As this strategy is infeasible in handling the case that a target code path is concurrently executed with itself, DLOS cannot detect deadlocks occurring in this case.

Detecting deadlocks in other OS kernels. Besides the Linux kernel, DLOS can also check other OS kernels to detect their deadlocks. However, doing so has some practical difficulties. For example, some APIs used in DLOS have different usages between these Oses and Linux, and these Oses have different processes of kernel-code compilation from Linux. At present, we have preliminarily run DLOS in NetBSD to check its kernel source code, and found one real deadlock in the *sysmon* kernel module without false positive. This deadlock has been confirmed by NetBSD kernel developers.

Detecting deadlocks involving waiting queues. Besides the deadlocks caused by locking cycles, incorrect operations on waiting queues can also cause deadlocks in OS kernels. For example, one thread waits for the event E_1 and then triggers the event E_2 , while the other concurrent thread waits for the event E_2 and then triggers the event E_1 , so a deadlock can occur for these two threads. In kernel code, waiting queues and locks can be used together to cause deadlocks, which are more difficult to detect. At present, no static approach (including RacerX) can detect such deadlocks, and thus we plan to extend DLOS to detecting them.

Detecting other locking issues. We believe that DLOS can be extended to detecting other locking issues, such as double locks and using sleep-able locks while holding spinlocks. Indeed, computing locksets and validating code-path feasibility are two important steps in detecting locking issues, and our lock-usage analysis and filtering strategy can effectively perform these steps, respectively.

Limitations and future works. DLOS can be strengthened in some aspects. First, DLOS does not handle function-pointer calls in its lock-usage analysis, and thus it may miss deadlocks involving the code that is reached through function-pointer calls, especially the deadlocks across kernel modules connected by function pointers. To relieve this limitation, we plan to apply existing function-pointer analysis [3, 36] in DLOS to detect more deadlocks and reduce false negatives. Second, to reduce the complexity of analyzing loops and recursive calls, DLOS unrolls each loop and recursive call just once, causing soundness loss in static analysis. Such soundness loss can introduce both false positives and negatives, when DLOS analyzes the code involving loops and recursive calls. To relieve this limitation, we plan to adapt existing loop-oriented analysis [35, 48] in DLOS to soundly handle loops and recursive calls. Thirdly, DLOS does not handle some special cases at present, such as RCU locks, memory barriers, assembly instructions and concurrent execution of the same code path, which may also cause false positives and negatives in deadlock detection. To relieve this limitation, we plan to consider these special cases in our static analysis, to further improve analysis accuracy. Finally, we plan to port DLOS to detecting deadlocks in other OS kernels, and to extend DLOS to detecting deadlocks involving waiting queues as well as other locking issues.

7 Related Work

7.1 Dynamic Analysis of Deadlocks

Many approaches [5, 9–11, 15, 21, 27, 28, 31, 33, 44, 45, 55] dynamically monitor thread execution and lock-related operations to detect locking cycles. Most of them are used for user-level applications. For example, Pulse [31] is an operating system mechanism to detect deadlocks in applications. It periodically identifies long-sleeping application processes and the events they are waiting for, then uses high-level speculative execution to a general resource graph about each identified application process, and finally detects cycles in the graph as deadlocks. UnDead [55] is an efficient dynamic approach for deadlock detection. It uses several techniques to reduce runtime overhead, such as only recording unique lock dependencies (identical to locking constraints in this paper) for every thread during the execution and dropping unnecessary information in runtime recording.

Lockdep [33] is a kernel lock-usage validator, which can find different kinds of lock-related bugs, such as double locks and deadlocks. Lockdep performs runtime monitoring and checking based on the granularity of lock class, which describes a group of locks that are logically the same with respect to locking rules. Specifically, Lockdep dynamically tracks the state of each lock class and checks the dependencies between different lock classes. If any state or dependency is incorrect when lock-related operations are performed, Lockdep will report related bugs at runtime.

By using exact runtime information about thread execution and lock-related operations, dynamic analysis approaches can effectively reduce false positives in deadlock detection. However, dynamic analysis requires substantial test cases to achieve high testing coverage and reduce false negatives, and it also introduces runtime overhead for the tested programs.

7.2 Static Analysis of Deadlocks

Some approaches [30, 41, 42, 46, 52] use static analysis to detect deadlocks in user-level applications, without actually running the applications. Naik et al. [30] design a sound static approach to check deadlocks in C programs. For the checked program, this approach performs context-sensitive and thread-sensitive analysis on its inter-procedural control flows, based on abstract interpretation. During the analysis, this approach checks lock-related operations to extract lock dependencies and detect locking cycles as possible deadlocks. This approach also uses a non-concurrency analysis to drop false positives, by checking common locks and thread-creation/joining operations. Santhiar et al. [46] design a static approach to detect deadlocks in asynchronous C# programs. This approach uses a new representation of the mixed synchronous and asynchronous control flows, and constructs a deadlock detection graph based on this representation. However, OS kernels and

user-level applications have different concurrency models (described in Section 2.2), and thus these approaches are ineffective in detecting deadlocks in OS kernels.

To our knowledge, RacerX [19] is the sole existing static analysis approach to systematically detect deadlocks in OS kernels. However, it has a high false positive rate of 46%, due to neglecting the feasibility and concurrency of code paths; and its locking-cycle detection method is simple and inefficient. Compared to RacerX, DLOS checks the feasibility and concurrency of code paths to achieve better accuracy, and uses a reachability-based comparison method in locking-cycle detection to achieve higher efficiency. Besides, we also note that Breuer et al. [6–8] have several works that focus on detecting deadlocks caused by sleeping while holding spinlocks. As these works have no systematic technique of detecting deadlocks caused by locking cycles, we do not particularly introduce and compare to these works in this paper.

7.3 Detection of Kernel Concurrency Bugs

Besides deadlocks, OS kernels also suffer from other kinds of concurrency bugs, such as data races and atomicity violations. To detect these kernel concurrency bugs, some approaches [2, 12, 18, 47] use static or dynamic lockset analysis to track shared variables and lock-related operations, and some approaches [20, 25, 29] perform sampling to monitor concurrent memory accesses. Moreover, to actually cover infrequent thread interleavings and detect hard-to-find concurrency bugs, some approaches [22–24, 26, 53] perform random thread scheduling or coverage-guided thread-interleaving exploration in runtime testing. Though these approaches do not target deadlocks, some of their techniques (like lockset analysis) are useful for DLOS in deadlock detection.

8 Conclusion

Deadlocks in OS kernels are dangerous and hard-to-find. To detect these bugs, we design a practical static analysis approach named DLOS. It has three key techniques, including a summary-based lock-usage analysis to efficiently extract code paths containing distinct locking constraints, a reachability-based comparison method to efficiently detect locking cycles, and a two-dimensional filtering strategy to effectively drop false positives. In the evaluation, DLOS finds 54 real deadlocks in Linux 5.10, and 31 of them have been confirmed.

Abstract

While there exist many consistency models for distributed systems, most of those models seek to provide the basic guarantee of convergence: given enough time and no further inputs, all replicas in the system should eventually converge to the same state. However, because of *Convergence Failure Bugs* (CFBs), many distributed systems do not provide even this basic guarantee. The violation of the convergence property can be crucial to safety-critical applications collectively working together with a shared distributed system. Indeed, many CFBs are reported as major issues by developers. Our key insight is that CFBs are caused by divergence, or differences between the state of replicas, and that a focused exploration of divergence states can reveal bugs in the convergence logic of real distributed systems while avoiding state explosion. Based on this insight, we have designed and implemented Modulo, the first Model-Based Testing tool using *Divergence Resync Models* (DRMs) to systematically explore divergence and convergence in real distributed systems. Modulo uses DRMs to explore an abstract state machine of the system and derive schedules, the intermediate representation of test cases, which are then translated into test inputs and injected into systems under test (SUTs). We ran Modulo to check ZooKeeper, MongoDB, and Redis and found 11 bugs (including 6 previously unknown ones)

1 Introduction

The emergence of cloud-scale applications has driven the need for distributed storage systems to support them. To provide availability and scalability, those systems replicate data across several replicas, which may be distributed in a single datacenter or even globally across several datacenters [1–5, 32, 39, 50, 57, 62]. To tolerate network partitions and delays, many of these systems adopt weaker-consistency guarantees [58, 59], allowing them to replicate data asynchronously. This means that clients connected to different replicas may observe different states of the data. The exact order and delay of concurrent operations on replicated data is

governed by a “consistency model,” which attempts to strike a balance between intuitive behavior (favoring stronger consistency guarantees) and scalability and partition tolerance (favoring weaker guarantees).

Regardless of these differences, most of consistency models in practice guarantee a common property, which is that given enough time and no further modifications to the data, all replicas will eventually arrive at the same contents for the data—something we call the *convergence guarantee* also known as eventual consistency. However, distributed systems are inherently designed to be *temporarily inconsistent* so that they may continue to respond to requests, even as they *converge* to a consistent state by replicating data among the replicas. We call this temporary inconsistency *divergence*. Yet, divergence can cause more than temporary inconsistency in the presence of failures. Divergence in the presence of failures may also lead to *conflicts*, where different replicas have incompatible states, which can only be resolved by truncating or removing data from one or more of the replicas. While it is not the sole cause, we find that a major cause of systems failing to converge is defects in the convergence logic after the failure recovery. Such bugs leading to convergence failures are named *Convergence Failure Bugs* (CFBs).

Looking into bug databases of a couple of systems for the period from 2010 to 2017, we found about 10 bugs that are already reported and fixed by developers and external users [23, 31, 33, 34, 51, 55, 56, 60, 64]. They are all marked by developers as either “Blocker”, “Critical” or “Major” in terms of severity. This demonstrates that CFBs are perceived by developers as real, prevalent and important bugs to find and fix. In some case, the convergence failure is noticed by developers as visible to clients [31], which can directly cause clients to make incorrect decisions leading to serious consequences. Thus, a convergence failure can be crucial to safety-critical applications collectively working together through a shared distributed system.

To exercise distributed systems’ convergence logic, more divergence than would naturally occur during regular use needs to be generated. This paper presents *Modulo*, the first Model-Based Testing tool that systematically explores differ-

ent divergence states by alternately injecting events that cause divergence and convergence into the real distributed systems.

Modulo overcomes limitations in previous solutions for detecting CFBs in distributed systems. On one hand, distributed systems model-checkers [27, 29, 35, 41, 42, 44, 52, 61] aim to provide formal verification of a distributed system, and as such must ensure that they exhaustively explore the state space of the system under test (SUT). To achieve exhaustive exploration, they must tightly control all nondeterministic events so as to drive the SUT through all possible states. Unfortunately, tightly controlling all events leads to the well-known “state-explosion problem,” as the number of states grows exponentially with the number of events that are controlled. To reduce the severity of state-explosion, a smart and insightful abstraction of target behavior is needed. None of existing model-checkers has explored the state-space consisting of divergence and convergence.

On the other hand, random testing approaches, such as Jepsen [38], do not aim for formal verification but rather simply to find bugs, and thus they need not exhaustively explore all states. This frees them from having to control all nondeterministic events. Instead, random testing approaches inject a targeted set of external events (randomly of course) and, rather than controlling all other events, allow the SUT to randomly visit states depending on how events interleave naturally during execution. Random testing approaches typically do not record the states explored, so they cannot provide any guarantee or measure of state-space coverage. Moreover, because they do not know which events are important, they may not be able to provide a sequence of inputs that can reliably reproduce the bug.

Modulo’s key contributions stem from our observation that *many CFBs arise from flaws in the convergence logic of distributed systems, and are orthogonal to other functions of the system*. Thus, CFBs can often be reproduced purely by partially controlling only the few events that lead to convergence and divergence. This partial control allows Modulo to significantly reduce the severity of the state explosion problem, while still enabling it to deeply explore different divergence states of the SUT.

Different distributed systems have different techniques to converge replicas after a failure. To abstract these differences so that it can generalize across different systems, Modulo introduces *Divergence Resync Models* (DRMs), which consist of an *Abstract Execution Model* (AEM) and a *Concrete Execution Model* (CEM). The AEM describes abstract conditions for convergence and divergence events. For example, systems like ZooKeeper and MongoDB require quorum before they can accept client requests that could cause divergence between replicas. The AEM for these systems thus specifies the conditions under which the systems quorum will have been achieved (i.e., the majority of replicas are available). The CEM maps the AEM conditions, as well as divergence and convergence events, to API calls for a specific SUT. Mod-

ulo uses the AEM to generate schedules of abstract events that alternate between divergence and convergence and the CEM to execute these schedules on the SUT to search the convergence code of the system for CFBs.

We ran Modulo on ZooKeeper, MongoDB, and Redis as SUTs and found 11 CFBs, including 6 new ones that had not been found before. For each of these bugs, Modulo provides a schedule of inputs that deterministically triggers the bug. To find these CFBs, we used 5 DRMs—1 for ZooKeeper, 1 for MongoDB, and 3 for Redis, which range from 72-782 lines of code in size.

We made the following novel contributions:

- As far as we know, Modulo is the first systematic test generation system, specifically designed to discover CFBs.
- We introduce the concept of Divergence Resync Models (DRMs) that inject events specifically designed to elicit and discover the existence of CFBs.
- We design, implement and evaluate Modulo, a system that uses DRMs to find CFBs in real distributed systems.
- We perform an empirical study to demonstrate the effectiveness of the proposed approach by integrating the prototype to 3 mature open-source distributed systems: ZooKeeper, MongoDB, and Redis. Modulo was able to find several critical CFBs in them.

§2 gives the overview of divergence and convergence, the core concepts of Modulo and DRMs, and provides an example CFB that Modulo can find. §3 describes the architecture of Modulo and the 5 DRMs we use in this study. We then document our experience and empirical results of applying Modulo to mature open-source distributed systems in §4. Subsequently, we present further discussion on Modulo compared to previous proposals in §5 and discuss related work in §6. Finally, we draw our conclusions in §7.

2 Overview

2.1 System Model

We model a distributed storage system as a set of replicas, each of which is a key-value store. In an idealized system, the storage system consists of one replica, and each write would transition the key-value store in the system from one state to the next. However, in the distributed implementation of the system, each write is applied to one of the replicas, and then the distributed storage system asynchronously replicates the write to the remaining replicas until every replica converges to the same state. Thus, at any given time, there can be several replicas that differ from our idealized single replica. Our target system should manage updates and resolve conflicts to maintain the convergence of replicas. That is, our proposed

approach is not designed to test those systems allowing multi-master updates with gossip protocols where the convergence property is not guaranteed.

Our approach injects failures into the system-under-test to drive it into corner cases. Failures are erroneous states where synchronization between replicas is interrupted, so convergence does not occur without reverting to the normal state via failure recoveries. Failures may be caused by several reasons, such as crash of replicas, suspension of replicas, and links failures between replicas. After recovering from failures, convergence should occur and replicas must have identical structure in terms of write sequences contained in their log. Regarding the convergence property, we focus on those systems that are partially synchronous, although there is nothing stopping us from applying Modulo to eventually consistent systems such as Cassandra, which is left as a future work. Quorum-based systems we tested with Modulo require a quorum to elect a leader, but may ingest writes expecting failures will be recovered soon. In contrast, Redis does not use leader election, so it does not require a quorum to start servicing clients. It lets the sync source to replicate any changes down to the sync targets recursively.

2.2 Divergence and Convergence

We formally define *divergence* as the total number of writes that need to be applied across all replicas to make their key-value stores equal to the single idealized replica. *Convergence* is simply the complement of divergence (i.e., $convergence = -divergence$), where the replicas are said to be converged when divergence is zero. *Resynchronization* (resync) is an operation implemented by distributed storage systems to achieve convergence after a failed replica recovers. Resync reduces divergence by replicating writes from a replica to the recovered replica and may implement *conflict resolution* to eliminate write operations that prevent the replicas from achieving convergence. Conflict resolution is particularly complex as it usually results in data loss, which storage systems seek to avoid unless absolutely necessary.

Divergence occurs in the natural course of the operation of a distributed system as writes are applied to replicas. However, under normal circumstances, the amount of divergence is usually small, as systems aim to replicate writes fairly quickly, subject to standard networking and processing delays. However, failures may further increase divergence. For instance, replica crashes and network outages can prevent replicas from replicating operations for an extended period of time. This will trigger defects related to assumptions about the resources needed to track outstanding operations or about the length of time that replicas may be unavailable. Repeated failures may result in replicas changing leader or master roles, which can result in conflicts, allowing Modulo to exercise the conflict resolution logic of distributed systems.

A simple example illustrating the concept of divergence

Figure 1: **Divergence and convergence.** Replicas A, B and C diverge their states upon failures of B and C. Since the leader replica A is alive, the latest state of A can be replicated to replicas B and C upon their recovery, resulting in the state *convergence*.

and convergence is given in Figure 1. The divergence example starts in an initial state where A is the leader replica and B and C are non-leader replicas. At time 1, a write of v_0 to k , $W(k, v_0)$, is sent by a client to A, A applies the operation and then replicates it to B and C. At time 2, B fails and, another write, $W(k, v_1)$, is sent to A. Only A and C can apply the write, thus there is some amount of temporary divergence among replicas. At time 3, C fails, and another write, $W(k, v_2)$, is sent to A. Only A can apply the write, resulting in even more divergence among the 3 replicas. Convergence can simply be regarded as the decrease of divergence in the system. At time 4, B recovers from the failure and rejoins the distributed system. Most distributed systems implement resync procedures that attempt to bring B up to date with the most recent state on the other replicas. Thus, B can converge with A by replicating $W(k, v_2)$. At time 5, C recovers and resyncs with A by replicating $W(k, v_2)$, resulting in full convergence among the 3 replicas. Now, there is no divergence in the system. (i.e., all replicas have the same key-value stores).

2.3 An Example Bug

To illustrate the type of bugs Modulo will find, we give an example of a new bug that Modulo discovered in ZooKeeper version 3.4.11 [8]. ZooKeeper requires a quorum of replicas to be online to operate, where quorum is defined as more than one-half the total number of replicas. In each epoch, which is a predefined period of time, the replicas in the quorum elect one of them as the “leader.” All write operations are serialized through the elected leader, and all other replicas (called “followers”) replicate operations from the leader.

ZooKeeper replicas employ 2 mechanisms to save data so that it can be recovered after a crash. First, the replicas use a write-ahead transaction log that can be replayed after a failure to recover the state of data that did not properly persist. Transactions are appended into the log as they get committed. Because all changes caused by transactions are

Figure 2: **Running example (ZooKeeper Bug#1)**. The replica B fails to truncate the past log ($k3: v8$) upon recovery with the SNAP resync (see, §2.3). To observe this bug, another failure and recovery step is required right after the bug is triggered (6). Modulo successfully formulated the exact sequences of steps to trigger this previously unknown CFB.

sequentially logged, replaying transactions in the log will restore the state of a replica. Second, replicas periodically clear the transaction log and persist a snapshot of in-memory data to disk, which can then be reloaded into memory after a failure. Taking a snapshot of memory is considerably slower than writing transactions into the write-ahead log as they occur, so ZooKeeper only takes snapshots after the transaction log has grown to some point or after resync following a failure depending on the resync logic. For example, in ZooKeeper 3.4.11, taking snapshot occurs on followers if they resync with a new leader via SNAP or by sending a truncation request, which are further explained in following paragraphs. The example is replica C taking a snapshot after the resync at time 2 in Figure 2.

ZooKeeper uses 2 mechanisms to resync replicas after replicas have recovered from a failure. One mechanism is DIFF resync, where another replica transfers all missing operations from its transaction log to the recovered replica. The other mechanism is SNAP resync, where another replica sends its entire key-value store to the recovered replica. ZooKeeper picks DIFF resync if the leader’s log contains all transactions required for resync. However, this can lead to problems as old log entries may be purged by an earlier snapshot. If ZooKeeper’s resync logic determines the leader does not have all required transactions in its log, then the SNAP mechanism will be selected. For example, in ZooKeeper version 3.4.11, when followers resync with the leader that does not have a log containing entries that are newer than its snapshot, the SNAP mechanism is used (e.g., SNAP resync at time 3 in Figure 2).

The base case that can happen during the resync is replicating operations that have not been replicated to those replicas recovered from a failure. Moreover, it may be necessary for a recovering replica to *truncate* its local write-ahead log and remove conflicting operations. During resync, a leader sends a truncation request (TRUNC) to a follower. Conflicting operations may exist if one replica had been the leader and committed some operations that had not yet been replicated

to other replicas before failing, and another replica is subsequently elected as the new leader and commits another set of operations, resulting in two conflicting sets of operations.

We illustrate the example bug in Figure 2. Suppose we initially have replicas A, B and C and the epoch is at 4. Both A and B have the same set of key-value pairs $k1: v1, k2: v2, k3: v3, k4: v4$ and $k5: v5$. Also, their log contains entries for all writes creating the key-value set. C has the same key-value set except for $k1: v6$ and its log additionally contains the entry for the write, $W(k1, v6)$. Currently, A and B are up and C is down. B is the leader of the epoch 4.

At time 1, A crashes and a write, $W(k3, v8)$, is made, which B accepts and commits¹. Then, B crashes. At time 2, A and C restart and resync using TRUNC. C restores its key-value set by replaying its truncated log and takes a snapshot. Note that neither A nor C has seen the write, $W(k3, v8)$, yet at this point. Then, A and C crash and B and C restart. C becomes the new leader. At time 3, because C has no log entry newer than its snapshot, C resync with B using the SNAP mechanism. Yet, C does not send a truncation request to B, so B accepts and restores using the C’s snapshot but fails to truncate the write, $W(k3, v8)$, from its log, which is the root cause of the bug. However, at this point, the bug is not apparent yet. At time 4, B crashes and another write, $W(k5, v10)$, is committed on C. Then, C crashes and B and C restart. Now, C becomes the leader. At time 5, B and C use DIFF resync to replicate $W(k5, v10)$ from C to B. At time 6, B replays its log and restores $k3: v8$, while C still has $k3: v3$. Because of the failure to truncate the log entry for $k3: v8$ on B, the replicas believe they have converged when in fact they have not, and the system fails to reach convergence.

This example illustrates several key features of the CFBs that Modulo is designed to discover. First, a long series of very specific steps is required to trigger the bug—far larger than are likely to happen simply due to randomized stress testing. The series of steps is essentially the alternating sequence of

¹ $W(k2, v7)$ injected at the epoch 3 and $W(k4, v9)$ injected at the epoch 5 are not shown in the figure.

Figure 3: Modulo Architecture. Gray boxes are input and output of Modulo. Blue boxes are Modulo components. Yellow boxes are DRM components.

convergence and divergence that causes the CFB to surface. Modulo specifically targets the generation of such sequences using DRMs, which we discuss in Section 3. Second, because the sequence is very deep, it would be very difficult to find such bugs through a naïve search of the entire state space of all the replicas. However, the root cause and nature of the bug make it orthogonal to the detailed internal state of the replicas, which can be influenced by internal events such as thread interleaving and the order of lock acquisitions. Instead, it is the generation of divergence and convergence events between the replicas in ZooKeeper that triggers the bugs, which are the events that Modulo seeks to explore. By focusing only on controlling events related to divergence and convergence, such as replica failure and recovery, Modulo is able to explore deep sequences such as these without being constrained by state explosion.

3 Modulo

As shown in Figure 3, Modulo consists of 2 core components: a schedule generator and a concrete executor. To use Modulo, the user provides a DRM and 2 parameters: *numReplicas*, which indicates the number of replicas, and *numOps*, which indicates the total number of writes that will be applied to the SUT. Modulo then uses the DRM to produce a schedule of divergence transitions ($\mathcal{D} \rightarrow$) and convergence transitions ($\mathcal{C} \rightarrow$), which are then executed by the concrete executor on the SUT. $\mathcal{D} \rightarrow$ cause more divergence in a system while $\mathcal{C} \rightarrow$ cause SUT convergence among available replicas. After executing each schedule, the concrete executor waits for the SUT to be quiescent after pre-configured time duration. Then, it checks whether all replicas in the SUT have converged (i.e., have identical state) by reading values of each key and compare those across replicas. Finally, the result is recorded in a file for more detailed analysis.

A DRM contains 2 subcomponents: an Abstract Execution Model (AEM) and a Concrete Execution Model (CEM). The

AEM describes the conditions under which $\mathcal{C} \rightarrow$ and $\mathcal{D} \rightarrow$ may take place. For example, an SUT may require a quorum of replicas to be available before write operations will be accepted and divergence may occur, which would be specified in the AEM. AEMs describe such requirements abstractly in terms of the AEM state, given in Table 1, such that a single AEM may be used to test multiple SUTs. For example, both ZooKeeper and MongoDB require quorums, so an AEM that models quorums is used to test both, while an AEM that does not model quorums may be needed to test systems that do not rely on quorum. The output of the schedule generator in Modulo is a set of schedule files, which are consumed by the concrete executor. We describe this further in §3.3. The concrete executor uses the CEMs to map $\mathcal{C} \rightarrow$ and $\mathcal{D} \rightarrow$ in the schedules to concrete operations that drive a SUT into the states dictated by the schedule. As such, CEMs are necessarily specific to the SUT.

An AEM specifies a finite state machine of the system-under-test and the CEM translates transitions in the AEM into corresponding transitions on the system-under-test. The user is required to abstract away unnecessary details in the AEM to limit the state space being tested to interesting states. The relationship between the AEM and the CEM can thus be viewed as the AEM specifying the state space to test and the CEM translating tests specified by that state space into concrete tests to run on the actual SUT. Modulo exhaustively explores the AEM’s finite state machine. Failures are detected directly on the SUT when it fails to converge after a certain amount of time. There are differences in the DRMs to test each SUT differently. For instance, Redis’s DRMs need a way to model the link failures and recoveries between pairs of replicas, different from ZooKeeper’s and MongoDB’s DRM.

We describe the most generic form of AEMs and CEMs below, which can be flexibly extended to more sophisticated models. Table 1 and 2 are for the baseline AEM used for ZooKeeper and MongoDB. Our baseline AEM abstract away the role of replicas, but the leader is distinguished during concrete execution of CEM to find out to which replica a write should be injected. For more complex AEMs like the one used for Redis, we need to extend states and transitions of AEM to model the network link failures.

3.1 Abstract Execution Model

The AEM specifies a state machine, whose state space Modulo explores to produce the schedule of $\mathcal{C} \rightarrow$ and $\mathcal{D} \rightarrow$. At each state, Modulo systematically performs $\mathcal{C} \rightarrow$ and $\mathcal{D} \rightarrow$ depending on whether the guard conditions specified in the AEM are met or not. The guard conditions are boolean functions over the state of the AEM. During $\mathcal{D} \rightarrow$, Modulo simulates a client that sends zero or more write operations from the sequence of write operations $W : \langle w_n | n \in \{0..numOps\} \rangle$, where *numOps* is the parameter specified as part of the test configuration. The term *replicaState* is a vector of length

Variable	Description
replicaState	List of non-negative integer values. State of all replicas that defines the latest write operation applied
onlineStatus	List of boolean values. Status of the replica indicating if the replica is online or offline

Table 1: AEM State Description.

$numReplicas$, with each element indicating the index of the latest write operation in W that a particular replica has observed. The term $onlineStatus$ is also a vector of length $numReplicas$, which stores the status of each replica as either *online*, meaning that the replica is available, or *offline*, meaning that the replica is unavailable because it has failed for reasons such as a crash or a link failure.

Modulo performs $C \rightarrow$ and $\mathcal{D} \rightarrow$ on the AEM according to the transition descriptions given in Table 2. For $\mathcal{D} \rightarrow$, Modulo fails zero or more replicas, followed by zero or more write operations from the write sequence (though obviously there should be either non-zero replica failures or non-zero writes). For example, consider the replicaState of a 3-replica system, which can be represented by a tuple $[R_A, R_B, R_C]$ with each element corresponding to a replica’s replicaState. Recall that the replicaState is the index of the latest write that the replica has ideally replicated. Thus, a divergence transition that applies a write to replica A, which is replicated to replica B, will change the replicaState from $[1, 1, 1]$, to $[2, 2, 1]$. Because replica C did not replicate the write due to a failure, its replicaState does not increase. For $C \rightarrow$, Modulo returns one or more replicas back to operation and initiates resync. In cases where resync is automatic, the AEM will simply model all online replicas as achieving the latest write index. However, some systems, like Redis, allow manual resync between a subset of replicas, in which case the AEM may explore states with different subsets of replicas resynchronizing. In general, if the type of resync or failure that can occur depends on the abstract AEM state, then the AEM model will specify the type of resync or failure for each $C \rightarrow$ and $\mathcal{D} \rightarrow$ in the generated schedules accordingly. If it does not, then the CEM will run the SUT several times with the same schedule, trying out the different SUT-specific failure and resync methods. The CEM, which we discuss in §3.2, specifies many of the details on how replica failures are caused and how Modulo can tell if resync is complete.

Modulo’s schedule generator applies symmetry reduction [15] to remove schedules that have identical states. For example, in a system with replicaState of $[3, 3, 1]$, where replicas A and B have replicated up to write #3 while replica C has only replicated up to write #1, failing replica A or replica B is symmetrical, so Modulo will only produce one schedule for both of those cases. One notable caveat is that some systems, such as ZooKeeper, distinguish one leader replica from the others. We can extend AEMs in a straightforward way by

Transition	Description
convergence	replicaState: set each online replica’s write index to the latest write that the replica can resynchronize to onlineStatus: set one or more replicas to online
divergence	replicaState: increase replica’s write index based on number of writes applied onlineStatus: set zero or more replicas to offline

Table 2: AEM Transition Description.

adding a state variable to track which replica is the leader, and a leader and the non-leader will be considered not identical for the purposes of symmetry reduction.

An AEM produces schedules for a CEM to interpret and inject events to a SUT. The following is the schedule we used to find our example ZooKeeper bug, which was generated by using Q/C/Z-DRM (see §3.3) with the modulo parameters $numOps = 5$ and $numReplicas = 3$. The example Figure 2 illustrates what happens between ⑤ and ⑩. Note that we use integer values to indicate the degree for divergence but to identify replicas for convergence (i.e., 0 for A, 1 for B and 2 for C).

$\mathcal{D} \rightarrow$: Divergence, $C \rightarrow$: Convergence
① $\mathcal{D} \rightarrow [0, 0, 1]$ // introducing divergence by making C commit a write $W(k1, v6)$ while other replicas are failed; then fail C
② $C \rightarrow [0, 1]$ // introducing convergence by recovering failures of A and B and having them resync; C remains failed
③ $\mathcal{D} \rightarrow [0, 1, 0]$
④ $C \rightarrow [0, 1]$ // epoch 4 begins; B becomes a leader
⑤ $\mathcal{D} \rightarrow [0, 1, 0]$ // $W(k3, v8)$ is committed on B
⑥ $C \rightarrow [0, 2]$ // resync TRUNC; C takes a snapshot
⑦ $\mathcal{D} \rightarrow [1, 0, 0]$ // skipped in the figure
⑧ $C \rightarrow [1, 2]$ // SNAP resync; truncation fails (Bug)
⑨ $\mathcal{D} \rightarrow [0, 0, 1]$ // $W(k5, v10)$ is committed on C
⑩ $C \rightarrow [1, 2]$ // resync DIFF; Bug manifests
⑪ $C \rightarrow [0]$

3.2 Concrete Execution Model

The purpose of a CEM is to translate the abstract $C \rightarrow$ and $\mathcal{D} \rightarrow$ in the schedules generated from an AEM into concrete actions that can be performed on an SUT, to drive it down the individual schedules. For example, a $\mathcal{D} \rightarrow$ may indicate that one of the replicas advances its write index while the others do not, which the CEM may translate as failing 2 replicas and then injecting a write into the SUT. As such, the concrete executor and CEM share some similarities with concrete model-checkers, except that the Modulo’s concrete executor only explores $C \rightarrow$ and $\mathcal{D} \rightarrow$ sequences specified by the schedules generated by the AEM, and thus only control the aspects of the concrete state that map onto the abstract state

of the AEM, namely whether replicas are online or offline, and what writes are replicated by each replica.

In most cases, $C \rightarrow$ and $\mathcal{D} \rightarrow$ can be mapped to a set of SUT-specific APIs to write keys in the SUT and to check if resync has completed. In some cases, CEMs may also need to monitor log files to infer whether the certain aspects of resynchronization, such as leader election, have completed. Finally, in some extreme cases, we may need to instrument the SUT itself to reveal such interfaces to the CEM. For example, if we wanted to make the leader replica explicit when the system does not provide such information, we can replace the default leader election protocol with the one that can explicitly report the result of the leader election to our tool. Different SUTs have different requirements that must be met before they can accept writes. For example, some systems require a leader to be elected before they can ingest writes. These requirements must also be encoded in the CEM so that writes specified in the abstract schedule are correctly applied to the concrete SUT.

For each type of transition specified by the AEM, the CEM may have several ways of realizing that transition, allowing multiple concrete test sequences to be generated from a single abstract schedule. For example, some SUTs treat different types of failures differently (i.e., replica crash vs a network partition). The CEM may run the same schedule but select a different failure type at each $\mathcal{D} \rightarrow$. Similarly, there can be different options during $C \rightarrow$. Another place where CEM may have several options is what concrete set of writes, in terms of key names and values, will be used to realize the abstract writes in the AEM. In most cases, a set of unique values to a small set of keys suffices.

Below we show how our Q/C/Z-DRM's CEM interprets and injects events into a SUT for realizing divergence and convergence transitions to manifest our example bug. `setData(<k>, <v>)` sets <k> to <v>.

To realize, $\mathcal{D} \rightarrow [0, 1, 0]$:

- ① Crash A // no need to crash C, as it is already down
- ② `setData(<k3>, <v8>)` to B
- ③ Wait for commit on B
- ④ Crash B

To realize, $C \rightarrow [0, 2]$:

- ① Restart A
- ② Restart C
- ③ Wait for resync completion

3.3 DRM Examples

Overview. Table 3 shows the description of DRMs we have implemented to test ZooKeeper, MongoDB, and Redis in our experiments. We name the DRMs according to the following format: The first letter indicates whether the SUT requires a quorum of replicas (i.e., more than one-half of the replicas must be online) to receive write requests or not. Our DRM

models support both systems that require quorum (Q) and those that are stand-alone (S). The second is how replica failures are injected in the model. For failure methods, Modulo can forcibly kill replicas with the signal `SIGKILL` to simulate crash failures (C), suspend replicas with the signal `SIGSTOP` to simulate systems stalled due to a sudden burst of heavy load (S), prevent replicas from communicating to simulate link failures (L) or decommission replicas from a cluster to simulate replica replacement (D). The third is which SUT it is written for, either ZooKeeper (Z), MongoDB (M), or Redis (R). Models are named using the scheme `<quorum_requirement>/<failure_modes>/<SUT>`.

Also, the user-specified portion of each DRM is presented in Table 3. We had to manually write between 72 to 782 lines of code, which is the result of the effort trying to reduce the manual effort required for each DRM. We put the majority of the code overlapped across DRMs into library or template classes that users can use or extend. We believe we can further reduce the number of codes to write manually. Even for S/CL/R-DRM which required the largest codes for us to write has a large portion of the code that can be further implemented as a library or a template class. Therefore, we think the manual effort required to use DRMs is not heavy and it can become even lighter as the library and templates get mature.

Methodology. In implementing DRMs, we learned a couple of key lessons. First, one should write DRMs in a top-down approach. Think about the most general behavior first. Then, one can extend it by inheriting the most part while overriding only for differences. By doing so, users can reduce the amount of the code they need to write significantly. For instance, write a DRM that injects only one type of failure first. Then, users can write a DRM that can inject multiple types of failures by reusing many lines of code.

Second, focus on the behavior that matters to find target bugs. Users may have a specific type of CFBs they want to find foremost. For instance, ZooKeeper has suffered from errors in transaction log handling. To create more complicated cases, crashing and restarting is important because transaction log is backed by files where a new file is created everytime a new epoch begins. However, focusing on crash failures may not be effective for other systems that rely heavily on full resync using a single transaction log file or that may always use a snapshot resync. For those systems, exploring various network partition failures may be more effective.

Third, pay attention to configuration parameters. Distributed systems rely on various configuration parameter values and their behaviors depend on them. For example, Redis maintains a log of transactions failed replicas missed for a certain timeout period in case a failed replica comes back. Normally, this speeds up resync if the replica returns before the timeout. Modelling divergence behavior to wait longer than the timeout before triggering resync will cause the log to be prematurely discarded and replication fail silently without

attempting to use full resync or SNAP resync.

We now describe some interesting aspects of some models we built in more detail below.

Q/C/Z-DRM. This model is used for ZooKeeper, which requires a quorum of replicas to be online to start servicing requests. This DRM only models crash failures. Since a quorum is required, a $\mathcal{D} \rightarrow$ is only allowed when enough replicas to form a quorum are online, but at the same time $\mathcal{C} \rightarrow$ are not enabled when all replicas are online because there is no divergence to resolve. This model simply uses `kill -9` to send a `SIGKILL` signal, simulating crash failures. Since a quorum is required, the model is restricted in that it must ensure a quorum of replicas is available before it can start injecting write operations, otherwise the write operation will be rejected by the SUT. Also, after $\mathcal{C} \rightarrow$, it needs to pause before executing the next $\mathcal{D} \rightarrow$ in order to ensure that resync is complete. In ZooKeeper prior to version 3.5, log messages are scanned to confirm the existence of a leader that guarantees the resync completion. As of 3.5, it is not the case, so we use timeout.

Q/C/M-DRM. We reuse the same AEM as the Q/C/Z-DRM's. This demonstrates how AEMs can be reused for different SUTs. To confirm the resync completion, we use an MongoDB API call to query the internal document, "replSetGetStatus," to retrieve the timestamp of the latest transaction committed on each replica. Then, we wait until those timestamps of every replica becomes same. In case replicas never converge, potentially due to a CFB, it uses an internal time out.

S/S/R-DRM. This DRM does not require a quorum to start servicing clients. It models a chain replication where any replica can become a *sync source* and a *sync target*². Any write committed by a sync source will be replicated to its sync targets. Sync targets cannot have more than one sync source, but sync source can have multiple sync targets. This DRM considers suspend failures instead of crash failures. Also, this DRM starts with an initial state where no replica is connected with another replica. For recovery, we check if the replica is connected with another one and, if not, then we establish new links with other replicas. This model uses `kill -STOP` and `kill -CONT` to suspend and resume Redis processes, respectively. To confirm the completion of resync, this model employs the hybrid of 2 methods. First, it uses the `info` API call to read the `master_link_status`, `master_sync_in_progress`, `aof_rewrite_in_progress` and `rgb_bgsave_in_progress` variables that indicate whether resync is complete. Second, we found that just relying on these variables can cause the CEM to miss some cases when resync is complete. Thus, the CEM also uses a timeout to ensure forward progress. We believe this reduces unnecessarily long timeout, and demonstrates how flexible Modulo

²See: <https://redislabs.com/ebook/part-2-core-concepts/chapter-4-keeping-data-safe-and-ensuring-performance/4-2-replication/4-2-3-masterslave-chains/>

can be. Unlike ZooKeeper and MongoDB where resync is automatically triggered by recovering failures, Redis does not automatically trigger resync after a new replica joins. Instead, Redis requires a `slaveof` API call to be explicitly invoked to trigger resync. Thus, this CEM explicitly has replicas establish links between sync sources and a sync targets using the API call, as specified in schedules by its AEM.

S/L/R-DRM. This DRM models link failures only, causing a replica stop replicating data from its sync source. When it recovers a partitioned replica, it considers all possible scenarios of re-establishing replication links. This model simulates link failures using the Redis API command `slaveof no one`, which tells a replica that it has no sync source, causing it to stop replicating data from its sync source. When a link is re-established, the `slaveof` API is used.

S/CL/R-DRM. This model uses both crash and link failures. In addition, $\mathcal{C} \rightarrow$ can pick one of 2 kinds of resync strategies. One is *online resync* and the other one is *offline resync*. Online resync is a built-in resync mechanisms of Redis that gets triggered by re-establishing links between sync sources and sync targets. Offline resync, on the other hand, is a manual resync procedure that can be performed by an administrator. An administrator may manually copy the snapshot of a sync source to a sync target and then may have the sync target start off on the snapshot copy. Because, it considers both types of failures, it generates a larger state-space than the previous AEMs.

3.4 Implementation

Modulo is implemented in Java and comprises roughly 8.4K lines of code. Schedule generation is implemented in about 281 lines of code, and concrete execution takes about 766 lines of code. Our DRMs total 7.3K lines of code where the AEMs and CEMs consist of 2.8K and 4.6K lines of code, respectively, including DRM examples, a library and templates.

A significant part of the DRM implementation consists of SUT log parsing, API interaction and analysis code to infer the state of SUT replicas. To give a concrete example, ZooKeeper records whether a replica is a leader or not in its log message file as follows:

```
LEADING - LEADER ELECTION TOOK - 230
Follower sid: 0 : info : ...
Synchronizing with Follower sid: 0 ...
```

Similarly, a follower replica will log the following messages:

```
FOLLOWING - LEADER ELECTION TOOK - 217
Resolved hostname: 127.0.0.1 to address: ...
Getting a diff from the leader 0x100000009
```

Thus, the DRM can scan log message files of ZooKeeper looking for messages containing either LEADING or FOLLOWING

Name (Parameters)	AEM	CEM	Lines of Code (AEM/CEM/Total)
Q/C/Z-DRM ($numOps = \{1..5\}$, $numReplicas = \{3..5\}$)	Only considers crash failures. $C \rightarrow$ ensures the quorum exists before $\mathcal{D} \rightarrow$. Crashes all replicas at the end of $\mathcal{D} \rightarrow$	Using kill -9 to send SIGKILL for crash failures. Confirm the quorum exists before writes. Using log scanning to confirm the leader for versions before 3.5, but, as of 3.5, relying on timeout.	USER 54/59/113 LIB 339/620/959
Q/C/M-DRM (same as above)	Same as Q/C/Z-DRM	Using an API to retrieve “replSetGetStatus” and compare timestamps of the last transaction on each replica to wait for resync completion	USER 54/117/171 LIB 339/907/1246
S/S/R-DRM ($numOps = \{1..2\}$, $numReplicas = \{4\}$)	Only considers suspend failures. Considers all replicas initially partitioned. As recovering suspend failures, establish links between the recovered replica and an online replica.	Using kill -STOP and kill -CONT to simulate suspend and resume. Using the ‘info’ API and timeout to wait for resync completion. Using the ‘slaveof’ API to trigger resync	USER 33/39/72 LIB 955/1240/2195
S/L/R-DRM ($numOps = \{1\}$, $numReplicas = \{3\}$)	Only considers link failures between an arbitrary pair of replicas. Considers replicas initially connected in a single ‘slave chain.’	The ‘slaveof’ API is used for link failures and recoveries. Initially, forming links as a single slave chain.	USER 0/110/110 LIB 955/1240/2195
S/CL/R-DRM ($numOps = \{1, 2\}$, $numReplicas = \{2\}$)	Considers both link and crash failures. Considers two types of resync strategies: online resync and offline resync.	For the offline resync strategy, a script copying over snapshots and starting up a replica with the snapshot is used.	USER 405/377/782 LIB 955/1240/2195

Table 3: The summary/comparison of DRM Examples. The naming convention indicates the quorum requirement, failure modes, and the target SUT. Below the name, we also present modulo parameter values we used. AEM and CEM give more detailed descriptions of each subcomponent of the given DRM example. Only the differences of each DRM compared to the one above is specified. The rightmost column shows the lines of code (LOC) for user-specified portion of DRMs (USER) and for a library and templates users use (LIB)—only the part directly interfacing with user-specified portion is counted. Since each DRM may use different template, there can be difference in LOC for LIB.

indicating which role they have switched to. The DRM needs to keep track which replica is the leader in order to successfully inject write operations to cause divergence, because only the leader replica can ingest write operations.

4 Evaluation

We present our results from running Modulo on 3 mature, open-source, distributed storage systems: ZooKeeper, MongoDB, and Redis.

4.1 Bug Discovery

In Table 4, we summarize the CFBs found and tabulate the time Modulo took to find each of the bugs, as well as the number of transitions of the schedule manifesting the bug. More detailed description is provided in Appendix A. Those bugs labelled with “New!” had not been reported until we discovered. Our evaluation study has been conducted between 2017 and 2020—ZooKeeper Bug #1 and ZooKeeper Bug #2 were found in 2017, while ZooKeeper Bug #3, ZooKeeper Bug #4, and ZooKeeper Bug #5 were discovered in 2020. We note that some bugs are quite complex, requiring a specific sequence of more than 10 transitions to trigger the bug. Also, DRM state space is evaluated in terms of the number of schedules generated for different DRMs and different modulo parameter

values. Lastly, we show the state coverage measurement over time for the setting used to test the most recent ZooKeeper version.

4.2 Testing Performance

Table 4 also shows how much time our prototype took to find each bug mentioned above. The performance was measured on a machine with an 2.83GHz Intel Core2 Quad CPU and 8GB of RAM. We found that the limiting factor for the testing speed of Modulo is (1) the speed of the underlying distributed system and (2) how easily Modulo can infer that the system has converged after a $C \rightarrow$ so that it can inject a $\mathcal{D} \rightarrow$. In general, distributed systems do not prioritize speed during replication operations, and the lack of interfaces to infer when they are done can lead to slower testing as in the case of MongoDB. Without an interface that allows the CEM to tell if convergence had been achieved, Modulo had to check the timestamp of the keys on every replica to see if they were the same. In addition, MongoDB can take a long time to achieve convergence, forcing the CEM to use a very high timeout value (10 minutes in our experiments). In contrast, the CEMs for ZooKeeper and Redis can infer that convergence has occurred in other ways that do not require either checking or a timeout. We believe it should be possible to modify MongoDB to allow Modulo to infer whether convergence has

Bug ID	DRM	Root Cause	Elapsed Time	Time/Schedule	# of Trans.
ZooKeeper Bug #1(New!) [8]	Q/C/Z-DRM	Fail to truncate operations due to missing invocation	11 hours	33 sec	11
ZooKeeper Bug #2(New!) [9]	Q/C/Z-DRM	Fail to truncate operations due to file handling mistake	2 hours	39 sec	11
ZooKeeper Bug #3(New!) [10]	Q/C/Z-DRM	Fail to replicate operations due to an incomplete log	23 min	33 sec	7
ZooKeeper Bug #4(New!) [11]	Q/C/Z-DRM	Fail to truncate operations due to a pointer handling mistake	47 min	30 sec	10
ZooKeeper Bug #5(New!) [12]	Q/C/Z-DRM	Fail to truncate operations due to missing invocation	20 hours	37 sec	10
MongoDB Bug #1	Q/C/M-DRM	Fail to truncate operations due to incomplete timestamp information	18 min	6 min	3
MongoDB Bug #2(New!) [36]	Q/C/M-DRM	Fail to replicate operations due to incomplete protocol design	4 hours	5 min	5
Redis Bug #1 [25]	S/S/R-DRM	Fail to invoke snapshot sync due to incomplete protocol design	6 hours	6 min	6
Redis Bug #2 [53]	S/CL/R-DRM	Fail to replicate operations due to lacking resync related information	11 min	14 sec	4
Redis Bug #3 [53]	S/CL/R-DRM	Fail to replicate operations due to lacking resync related information	2 min	6 sec	3
Redis Bug #4 [22]	S/L/R-DRM	Fail to truncate operations due to incomplete protocol design	2 min	33 sec	2

Table 4: CFB Analysis Summary.

Table 5: DRM State Space Size (# of Schedules).

occurred without the needing to rely on timeouts and intend to explore this in the future.

4.3 DRM State Exploration

Table 5 shows several examples of the DRM state space size in terms of the number of schedules generated. As the number of *numOps* or *numReplicas* increase, the number of schedules generated quickly grows. The largest number of schedules were generated for Q/C/Z-DRM with *numOps* = 5 and *numReplicas* = 3 which we used to test ZooKeeper 3.4.11 and found the example bug. Nevertheless, as we reason in §5, the state space for Modulo to search is much smaller than explicit state model-checkers.

In Figure 4, we measured how state space coverage is increased during our evaluation finding bugs in the version of ZooKeeper, 3.7. We fixed *numReplicas* at 3 and varied *numOps* from 1 to 4, which increases the time taken. For each *numOps* setting, we ran tests separately one after another. Bugs can be found by schedules with no particular probability distribution. Considering this, it is important to run each test exhaustively not to miss any bug. Our design choice to split AEM and schedule generation from the con-

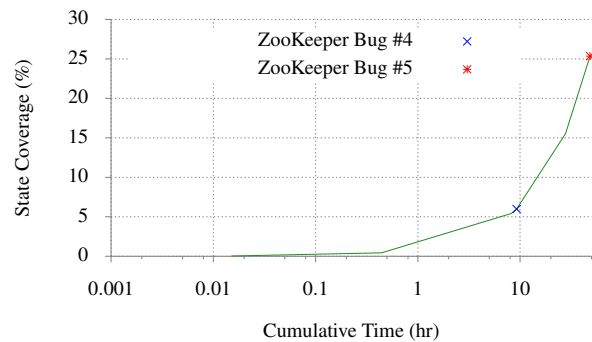

Figure 4: DRM State Coverage graph. We show the state coverage measurements from testing ZooKeeper 3.7. X-axis shows the cumulative time and Y-axis shows the state coverage ratio based on the number of schedules executed. Also, we mark when we found ZooKeeper Bug #4 and ZooKeeper Bug #5.

crete test execution by CEM also enables easy parallelization. Indeed, we when parallelize our tests, we get a linear increase in throughput.

5 Discussion

Modulo is designed to detect CFBs efficiently by only exploring system states that are relevant to its DRMs, which only model states and events relevant to $C \rightarrow$ and $D \rightarrow$ state transitions. In contrast to traditional system model-checking [27,29,35,41,42,44,52,61], Modulo is less complete, meaning it may miss bugs that manifest due to events like lock acquisition and thread interruption, as these are not captured by $C \rightarrow$ and $D \rightarrow$ in DRMs. However, by abstracting away states and events not relevant to DRMs, Modulo is able to explore considerably deeper bugs that, in some cases, take 10 or more transitions to manifest. Furthermore, Modulo finds

these bugs in real, concrete systems rather than in abstract models, making reproduction and confirmation of bugs much simpler.

Compared to distributed systems random testing, such as that employed by Jepsen [38], Modulo is more systematic, complete and exhaustive. Random testing can find many crucial bugs by randomly injecting external events; however, it is neither systematic, complete nor exhaustive for the following reasons. First, it does not model how the underlying distributed system works, including key concepts such as divergence and convergence. Hence, random testing may miss corner cases regarding divergence and convergence. Second, fuzzing does not control nondeterministic events. For instance, without delaying the timing of a crash-failure injection, a replica may crash before ensuring a write injected before the crash is committed. Third, random testing cannot reproduce bugs the way Modulo can, making the analysis and reproduction of bugs more challenging.

Modulo significantly reduces the severity of state explosion by taking a simple abstract model and mapping it onto transitions on a real concrete system. This allows Modulo to find deeper bugs than systems that attempt to explore more complex state spaces. To illustrate, Modulo's AEM's typically model 3-replica systems with between 1 and 5 writes. Before each write in the sequence, a replica can typically (1) do nothing, (2) receive or replicate the write operation, or (3) failure/recovery (e.g. crash/restart). Since replicas may have an arbitrary number of transitions where they may do nothing, we typically cap the maximum number of transitions in a replica an AEM may have at around 8. Thus we can estimate a rough upper bound for the state space of such a system as $3^{(8 \times 3)}$ or roughly 300 million. In practice, the number of reachable states is far less, because replicas can accept writes only when they are online, and other AEM-specific restrictions such as quorum requirements further limit the transitions that replicas may execute. In practice, Modulo's targeted approach leads to have AEMs produce anywhere from few schedules to tens of thousands of schedules, which is about 10 to 10^5 of states. In comparison, models checked by explicit state model checkers may contain more than 10^{20} or even 10^{250} states [17]. Our relatively small DRMs mean that Modulo is able to explore more scenarios than traditional model checkers could in given time, increasing the likelihood of finding target bugs, without exploring states that are irrelevant to find those specific types of bugs.

Meanwhile, we also note that a targeted approach can be seen as a disadvantage for finding many of various types of bugs. Indeed, as Modulo is targeted to find a specific type of CFBs, the number of bugs we found from our evaluation is relatively low. Nevertheless, we envision that the number of bugs found by Modulo can be increased, as developers who are more expert of each SUT can develop a larger collection of DRMs that are more effective to explore corner cases.

We acknowledge that Modulo does depend on domain

knowledge of the system-under-test to specify DRMs, and this would also be required to apply Modulo to other types of distributed systems. In our experience, a single user without previous experience may conservatively take about 2 weeks to learn about the system-under-test and 2 weeks to write the first DRM. When we first applied Modulo to Redis, using the same model as ZooKeeper and MongoDB did not lead to bugs, because Redis, started as an in-memory key-value store, has a simpler persistent storage mechanism. Subsequently, we found exploring suspend or link failures enabled Modulo to trigger more complex functionality. Modulo's methodology, abstraction and concrete execution, is not necessarily restricted to key-value stores but can be applied to other distributed systems. Paxos-based systems can be effectively tested using Modulo by modelling message/thread interleaving alongside failure injections.

Our main limitation is that the schedules generated by the abstract model must be run on the real SUT, which executes much slower than an abstract model would. In addition, many operations require pauses and timeouts before they can complete. For example, a system may not consider a replica failed until a certain time has passed, and leader election must complete after replicas recover before writes can be ingested by the system. Since they are not always possible to avoid, in practice we find that these timeouts are the ultimate limit on how fast Modulo can find bugs. We think virtualizing clocks and fast-forwarding time may help [42].

6 Related Work

Distributed Systems Testing. Some previous proposals for distributed systems testing employ state-space exploration. However, their state-spaces are more focused on interleaving concurrent internal events, such as thread scheduling or network message delivery [20, 28]. Also, previous work presents a tool for injecting network-partitioning failures for cloud systems [7], yet it does not inject crash failures, and it requires an OpenFlow-capable hardware component to simulate network-partitioning. Jepsen is an open-source testing tool that injects various types of failures into distributed database systems [38]. However, unlike Modulo, Jepsen randomly generates inputs, which implies that the state space for input sequences cannot be efficiently reduced without missing corner cases and, in some cases, reproducing bugs may be very difficult due to the nondeterministic ordering of events that Jepsen does not control. Furthermore, Jepsen does not record any information about the state exploration, therefore it cannot provide any guarantee about the state-space coverage. There has been a work that focuses on interleaving low-level file system operations across distributed replicas along with crash failures [6], but it is limited to crash injection only and does not test the divergence and convergence behaviors of distributed systems.

Model-based testing systematically derives test cases from

an abstract model of the SUT [14, 37, 45, 48, 49, 54]. Dalal et al. [18] devised a method that can generate various input parameter values for tests from the abstract model called the Test Data Model. A technique that can derive test cases for system testing from an UML statechart was developed by Offutt et al. [47]. Also, Gargantini et al. [24] propose to use model checking to derive test cases from an abstract model. In addition, Andrews et al. [13] came up with a technique that models a web application as a finite state machine to generate tests. Also, Yang et al. [63] applied model-based testing to find security flaws in about 500 implementations of OAuth 2.0. More recently, Davis et al. [19] used model-based testing to ensure specification-implementation conformance of distributed systems. However, previous proposals for model-based testing do not look for CFBs. Also, none of the existing model-based studies test the divergence and convergence of replicated distributed storage systems as the SUT.

Distributed Systems Model Checking. Model checking has been extensively studied and used to prove the correctness of complex systems and to find bugs in them. Clarke and Emerson [16] were the first to propose model checking, which exhaustively explores the state space of abstract models specified in temporal logic. Dill developed a model checker called Murphi [21], which is used to prove the correctness of various systems, including distributed shared memory systems. SPIN is another popular abstract model-checking tool [30]. More recently, Lamport [40] developed TLA+, a specification language, and TLC, a model checker for TLA+, which has been used by Amazon, showing the practicality of model checking in the industry. Nevertheless, abstract model-checking cannot find bugs in implementations directly.

Concrete model-checking is used to employ an implementation as a model to explore directly. Musuvathi et al. [44] proposed a concrete model-checker using implementations as the model to verify. Godefroid [26] also proposed the same idea around the same time. Killian et al. [35] devised a technique that enables checking for not only safety properties but also liveness properties. Lin et al. [42] developed a black-box concrete model-checker that does not need to know about the source code by interposing events at the interface layer between the target system and the underlying operating system. Model checking not only proves the correctness of the system but also predicts if the implementation execution is driving the system to faulty states, steering the system execution away to prevent this [61]. Simsa et al. [52] explored the generalization of concrete model-checking to provide the flexibility for determining the level of controls for nondeterminism. Recently, concrete model-checkers have been improved to detect deep bugs by exploring scenarios involving multiple failures [41, 43]. Unlike Modulo, previous concrete model-checkers explore various tightly controlled sequences of concurrent internal events.

7 Conclusion

Modulo mitigates the traditional state-explosion problems of systematic model-checking approaches to find CFBs by abstracting away all states and state transitions that are not related to the concepts of convergence and divergence. Modulo applies schedules derived from state explorations of small abstract models of such systems to real distributed systems. Our work identified several factors that lead to such bugs, which include (1) employing several resync or failure-handling mechanisms whose interactions are difficult to foresee, (2) hard limits or inadequate designs for handling large amounts of divergence, and (3) assumptions about length of time that replicas may have failed and failures that span events like leader transitions. While it is beneficial to generate counterexamples that trigger the bugs on real systems, we find that this also slows down the speed at which Modulo can find bugs, as it must examine the state of the system at to determine if it can inject the next input or not, and it must wait for the distributed system itself to complete its replication operations before adding divergence.

A Bug Description

A.1 ZooKeeper Bugs

We discovered 5 new bugs in ZooKeeper by finding 2 new bugs in version 3.4.11, 1 new bug in version 3.5.8 and 2 new bugs in version 3.7.0. We reported them to the ZooKeeper developers and reported bugs were designated as ZooKeeper Bug #1, ZooKeeper Bug #2, ZooKeeper Bug #3, ZooKeeper Bug #4 and ZooKeeper Bug #5 [8–12]. We got confirmation for ZooKeeper Bug #1 and ZooKeeper Bug #3. ZooKeeper Bug #1 is described in §2.3. All our experiments used 3 replicas. Initially, all 3 replicas are online and synchronized with a initial key-value set. Also, the Q/C/Z-DRM implementation for ZooKeeper crashes all replicas after each $\mathcal{D} \rightarrow$ and implements $C \rightarrow$ by restarting replicas in the quorum, which automatically triggers resync between each replica and the elected leader.

As described earlier, ZooKeeper implements 2 different resync mechanisms: DIFF resync and SNAP resync. Conflict-resolution logic often fails to correctly truncate transaction logs when SNAP resync is used, which results in persistent inconsistency. This problem is further exacerbated by an apparent reluctance on the part of the developers to truncate transaction logs, perhaps out of a conservative preference not to lose data unless absolutely necessary, which results in cases where logs should have been truncated but were not. Other complexities, such as using multiple log files instead of a single log file and incorrect assumptions about those files, contributed to other bugs. We saw similar bugs are recurring and stem from the similar portion of the resync implementation. It shows that the complexity of the resync mechanisms in ZooKeeper has been the major source of CFBs.

A.2 MongoDB Bugs

We run Modulo on MongoDB version 3.0.0 and discovered 2 bugs. One was fixed in later versions of MongoDB by upgrading their replication protocol, Replica Set Protocol (version), from Protocol Version 0 to Protocol Version 1. The

other one was new and we reported it on the MongoDB Bug Database [36]. We used 3 replicas in the DRM and the same initial state as we did with ZooKeeper.

The first MongoDB bug we discussed occurred because the developers failed to anticipate the situation where a primary commits some operations that have not been replicated to other replicas, operations only the primary is thus aware of. Modulo found the bug and the bug had never previously reported. However, the bug does not manifest on the latest version of MongoDB. On further inspection, we found that Replica Set Protocol Version 0, which had this bug, was replaced by Replica Set Protocol Version 1, which was implemented in MongoDB version 3.2 and became the default protocol after version 3.6. Thus, this particular bug was not fixed directly by developers, but instead eliminated when the afflicted protocol was replaced by a completely new protocol. With Modulo's bug report, we estimate that the bug could have been fixed by changing 10's of lines of code, but instead was fixed when the entire protocol was re-implemented, which required changing 12 files containing roughly 7.4K lines of code.

The second bug demonstrates the perils of simultaneously using several resync mechanisms. Having several resync mechanisms allows MongoDB to select among them to improve efficiency, but the mechanisms have slightly different side effects, which, under the right circumstances, can combine to put the system into an unrecoverable state.

A.3 Redis Bugs

Modulo found 4 CFBs [22, 25, 53] in Redis versions 2.8.0 and 4.0.0. Upon further examination, we found all had been previously reported.

In Redis, crash failures always lead to the SNAP resync, which simply replicates the entire state of the sync source to the sync target. As mentioned earlier, this trivially guarantees convergence since the sync target is now a mirror of the sync source. To trigger more complex resync mechanisms, Modulo required DRMs that could exercise other replication and failure recovery mechanisms that Redis provides. Unlike Zookeeper and MongoDB, this required the development of 3 different DRMs, and each DRM was responsible for finding at least 1 CFB. We found it useful to have separate DRMs as each DRM could separately exercise some of Redis' features, while combining them would have resulted in a larger state space and more schedules to explore.

In terms of time and effort, Redis took the most: a novice Redis user took a couple of weeks to initially write each DRM, where most of the time was spent understanding Redis' mechanisms and API. The Redis DRMs are also roughly 2-3 times larger and more complex than ZooKeeper and MongoDB DRMs because replicas may specify any sync source to resync from, giving more possibilities. Qualitatively, we feel the effort to construct DRMs is similar to that of writing a

specification in a formal specification language such as TLA+, which has been cited as an acceptable cost by developers at Amazon [46]. The user needs to understand the important properties of the system they want to test, and be able to abstract them away from implementation details. In addition, the user must also be able to reduce a system to a smaller number of replicas and smaller number of keys to reduce the state space. However, unlike model checkers such as TLA+, which run on an abstract state machine representation of the SUT, Modulo marries the advantages of a reduced state space produced by the manual abstraction, with the ability to reproduce the bugs found using a counter-example of real inputs that can be run on the concrete system.

SoftTRR: Protect Page Tables against Rowhammer Attacks using Software-only Target Row Refresh

Abstract

Rowhammer attacks that corrupt level-1 page tables to gain kernel privilege are the most detrimental to system security and hard to mitigate. However, recently proposed software-only mitigations are not effective against such kernel privilege escalation attacks.

In this paper, we propose an effective and practical software-only defense, called SoftTRR, to protect page tables from all existing rowhammer attacks on x86. The key idea of SoftTRR is to refresh the rows occupied by page tables when a suspicious rowhammer activity is detected. SoftTRR is motivated by DRAM-chip-based target row refresh (ChipTRR) but eliminates its main security limitation (i.e., ChipTRR tracks a limited number of rows and thus can be bypassed by many-sided hammer [17]). Specifically, SoftTRR protects an unlimited number of page tables by tracking memory accesses to the rows that are in close proximity to page-table rows and refreshing the page-table rows once the tracked access count exceeds a pre-defined threshold. We implement a prototype of SoftTRR as a loadable kernel module, and evaluate its security effectiveness, performance overhead, and memory consumption. The experimental results show that SoftTRR protects page tables from real-world rowhammer attacks and incurs small performance overhead as well as memory cost.

1 Introduction

Rowhammer is a software-induced dynamic random-access memory (DRAM) vulnerability that frequently accessing (i.e., hammering) DRAM aggressor rows can induce bit flips in neighboring victim rows. An attacker can hammer aggressor rows to corrupt different types of sensitive objects on victim

rows without access to them, breaking memory management unit (MMU)-based memory protection, achieving privilege escalation [13,46,62] or leaking sensitive information [11,37]. Of the many sensitive objects that have been corrupted by the rowhammer attacks, page table corruption is the most detrimental to system security, making kernel privilege escalation attacks the mainstream [57]. To date, kernel privilege escalation attacks [13,22,46,53,59,62] focus on corrupting level-1 page table entry (L1PTE) and some of them have been demonstrated to gain kernel privilege from unprivileged applications [13,46,62], or even from JavaScript in webpages [22].

Multiple software-only mitigation schemes [12,34,57] can be used to mitigate the kernel privilege escalation attacks. Compared to hardware defenses [30,38,40,49], software-only schemes have the appeal of compatibility with existing hardware, allowing better deployability. However, existing software-only mitigations require modifications to memory allocator and they are not effective against all the kernel privilege escalation attacks. Specifically, CATT [12] and CTA [57] are vulnerable to a recent privilege escalation attack (PThammer [62]) that targets L1PTE. ZebRAM [34] assumes that bit flips occur in a victim row that is one-row from hammered aggressor row(s), making itself unable to defend against (kernel privilege escalation) rowhammer attacks where a victim row is no less than 2-row from the hammered rows [32,62]. To this end, we ask:

Is there an effective and practical software-only defense that protects page tables against rowhammer attacks?

Our Contributions. In this paper, we provide a positive answer to the question. We propose a new software-only defense that defends against all existing kernel privilege escalation attacks on x86, called SoftTRR. SoftTRR is motivated by

a hardware defense, i.e., ChipTRR (known as TRR in the DRAM standards [30, 40]). ChipTRR is designed to count rows' activations and refreshing adjacent rows to suppress bit flips if the activation counts reach a pre-defined threshold. ChipTRR was believed to eliminate the rowhammer effect in present-day DDR4-based systems, until it was completely circumvented by [17].

We observe that the root cause of failure of ChipTRR is that it tracks a limited number of rows. Thus, bit flips are still possible when multiple rows are being hammered and the number of hammered rows is larger than the tracked rows (i.e., *many-sided hammer* [17]). SoftTRR addresses this limitation by monitoring and tracking all rows neighboring (victim) rows containing page tables. SoftTRR leverages MMU-enforced virtual memory subsystem to frequently track memory accesses to any rows adjacent to page-table rows, and refreshes page-table rows when necessary, making SoftTRR effective in preventing rowhammer from breaking page table integrity.

Specifically, MMU is an essential component of modern processors that supports OS kernel to enforce memory isolation. With the assistance from MMU, the kernel, configures page tables, mediates every memory access from user space, and captures any unauthorized access that triggers a hardware exception. On top of that, the kernel can capture the memory access where relevant page tables have an unused `rsrv` bit set (see page fault handler in Section 4.3). With this observation, SoftTRR uses the kernel as the root of trust and frequently configures page tables with the `rsrv` bit set to track memory accesses to rows that neighbor rows of page tables. When the tracked memory-access counters reach a pre-determined limit, corresponding page-table rows will be refreshed. By SoftTRR's design, an adjacent or neighboring row can be multiple-row from a page-table row, thus voiding the above assumption of one-row-distance between victim and aggressor rows made by ZebRAM [34]. In our implementation, the adjacent rows are up to 6-row away from the aggressor rows, the largest row distance that has been observed so far [32].

Our prototype implementation of SoftTRR is a loadable kernel module (LKM) without any modification to the kernel. The LKM has about 1700 source lines of code and it has been deployed into three Linux systems where underlying hardware have either DDR3 or DDR4 modules. We evaluated SoftTRR-deployed systems in terms of security effectiveness, performance, memory consumption and robustness. The experimental results show that SoftTRR is effective in mitigating kernel privilege escalation attacks. Besides, SoftTRR incurs low overhead on the tested benchmarks and its memory consumption is within hundreds of KiB in a real-world use case of LAMP (i.e., Linux, Apache, Mysql and PHP). We also validate the robustness of a SoftTRR-enabled system using system-call stress tests, results of which show that the system runs as stable as a vanilla system.

In summary, the main contributions are as follows:

- We introduce SoftTRR to defend against rowhammer at-

tacks on page tables. Compared to prior works, SoftTRR is an effective and practical software-only mitigation scheme.

- We implement a lightweight SoftTRR prototype to collect page tables, track memory access, and refresh target page tables by leveraging MMU and OS kernel features.
- We evaluate SoftTRR's effectiveness against 3 representative rowhammer attacks, its performance overhead and memory consumption. The experimental results show that SoftTRR successfully protects page tables against the attacks, and incurs negligible overhead and memory cost.

2 Background and Related Work

In this section, we first describe DRAM and its address mapping. We then present the rowhammer vulnerability as well as its hardware and software defenses. Please refer to [42, 63] for rowhammer surveys.

2.1 DRAM

The main memory of most modern computers uses DRAM. Memory modules are usually produced in the form of dual inline memory module (DIMM), where both sides of the memory module have separate electrical contacts for memory chips. Each memory module is directly connected to the CPU's memory controller through one of the two channels. Logically, each memory module consists of two ranks, corresponding to its two sides, and each rank consists of multiple banks. A bank is structured as arrays of memory cells with rows and columns.

Every cell of a bank stores one bit of data whose value depends on whether the cell is electrically charged or not. As the charge stored in the cell disperses over time, every cell's charge must be restored or refreshed periodically in a specified time period (i.e., t_{REFW}), a typical value of which is 64 milliseconds (ms).

DRAM Address Mapping. The memory controller decides how physical-address bits are mapped to a DRAM address. A DRAM address refers to a 3-tuple of *bank*, *row*, *column* (DIMM, channel, and rank are included into the *bank* tuple field). As this mapping is not publicly documented on the Intel processor platform, it has been reverse-engineered by multiple works [44, 45, 55, 59].

2.2 Rowhammer Vulnerability

Kim et al. [33] are the first to perform a large scale study of rowhammer on DDR3 modules, results of which have shown that the vulnerability can be triggered by software accesses, that is, frequently accessing rows of $i + 1$ and $i - 1$ (i.e., aggressor rows) cause bit flips (i.e., charge leakage) in row i (i.e., victim row).

There are four hammer patterns in existing works. First, *double-sided hammer* refers to a case where two adjacent rows of the victim row are hammered simultaneously, which is the most effective hammer pattern in inducing bit flips on DDR3 modules [46]. Second, *single-sided hammer* randomly picks two aggressor rows in the same bank and hammers them [46]. Third, *one-location hammer* selects a single aggressor row for hammer. This hammer pattern only applies to certain systems where the DRAM controller employs an advanced policy (i.e., the closed-page policy) to optimize performance [21]. Last, *many-sided hammer* chooses more than two aggressor rows within the same bank for hammer. The aggressor rows are usually separated by one row and two out of them are adjacent to the victim row [17, 29].

2.3 Rowhammer Defenses

Hardware Solutions. Existing hardware solutions employed by the industry can be summarized into three main categories. The first is to decrease the DRAM refresh period [33] to refresh all DRAM rows more frequently. For instance, three computer manufacturers (HP [25], Lenovo [39] and Apple [3]) deployed firmware updates to decrease the refresh period from 64 ms to 32 ms. However, *clflush-free* rowhammer attacks [5] still induce bit flips in the reduced refresh period. Decreasing the refresh period by more than 7x can make the rowhammer impossible but it will impose unacceptable overhead to the systems [33]. The second one is proposed by Intel [28] that leverages Error Correcting Code (ECC) memory to correct single-bit errors and detect double-bit errors. However, ECC has been reverse engineered and is vulnerable to rowhammer [15]. The last is to track row's activation count and various approaches have been proposed [30, 33, 38, 40, 43, 47–49, 60]. Among them, ChipTRR [30, 40] was adopted by recent DDR4 manufacturers but it has been reverse-engineered and defeated [17, 23, 29]. None of other approaches are widely deployed due to their limitations (e.g., significant area cost or performance downsides) [7].

Software Defenses. Software defenses include both mitigation and detection techniques. As sensitive data is required to be within victim rows for exploitation, existing mitigation techniques modify memory allocator and enforce DRAM-aware memory isolation at different granularity [9, 12, 34, 52, 54, 57]. CATT [12] implements DRAM isolation between user and kernel memory. CTA [57] provides a dedicated DRAM region for level-1 page tables. ZebraRAM [34] isolates rows of sensitive data in a zebra pattern. These defenses can prevent page tables from being hammered. Albeit on different hardware, SoftTRR has an averaged overhead of 0.75% on SPECint 2006 (see Appendix A), similar to that of CATT [12] and CTA [57]. However, ZebraRAM has a much higher overhead of 4%–5%. ALIS [52] isolates DMA memory to prevent the remote rowhammer attack [52] targeting a memcached application. RIP-RH [9] provides DRAM

isolation for local user processes.

Anvil [5] utilizes CPU performance counters to monitor cache miss rate and detects a rowhammer attack, as typical rowhammer attacks incur frequent cache misses. However, Anvil is prone to false positives [12, 57]. Besides, its current implementation cannot detect the PThammer attack [62]. The other detection technique is RADAR [61]. As rowhammer attacks exhibit recognizable rowhammer-correlated sideband patterns in the spectrum of the DRAM clock signal, RADAR leverages peripheral customized devices to capture and analyze the electromagnetic signals emitted by a DRAM-based system.

3 SoftTRR: Software-only Target Row Refresh

We discuss threat model and assumptions in Section 3.1, design principles in Section 3.2 and design overview in Section 3.3. Section 4 describes implementation details.

3.1 Threat Model and Assumptions

Our primary goal is to protect page tables and guarantee that an adversary cannot corrupt them to gain kernel privilege through rowhammer on x86 architectures. In our implementation of SoftTRR, we focus on protecting level-1 page tables (LIPTs), the same goal as in CTA [57], because all existing page-table-oriented rowhammer attacks aim at corrupting LIPTs. Even when higher levels of PTs are corrupted, they are hard to be exploited (see details in CTA [57]). In spite of that, SoftTRR can be extended to protect other levels of page tables and we discuss it in Section 7.

We assume the kernel as the root of trust, and the kernel module implementing SoftTRR is well protected. We consider threats coming from both local adversaries and remote adversaries. A local adversary resides in a low privilege user process and thus can execute arbitrary code within her privilege boundary. A remote adversary stays outside by launching an attack, e.g., through a website with JavaScript.

The DRAM address mappings and in-DRAM address remappings can be reverse-engineered using prior works [14, 44, 55, 59] and they are assumed to be available. Besides, previous software-only rowhammer defenses [9, 12, 34, 57] consider that hammering row_i only affects row_{i+1} and row_{i-1} , which however is not consistent with a recent work by Kim et al. [32]. Particularly, they performed a comprehensive study of 1580 DRAM chips (300 DRAM modules in total) from three major DRAM manufacturers and found that bit flips can occur in rows that are up to 6-row away from the hammered row_i . SoftTRR by design protects rows of page tables from being flipped by rows that are N-row away and its current implementation allows that the distance between an adjacent row and an LIPT row ranges from 1-row to 6-row, the largest row distance observed by Kim et al. [32].

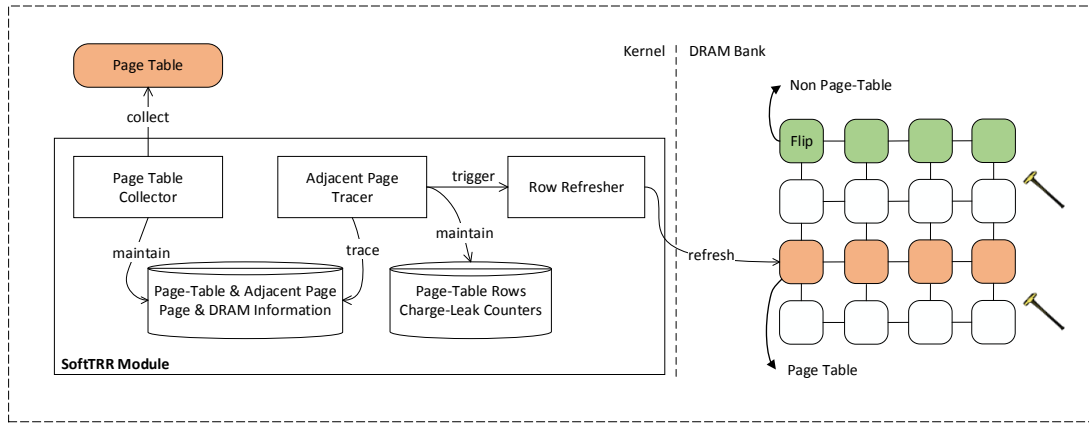

Figure 1: SoftTRR Overview. SoftTRR is a kernel module and has three main components. *Page Table collector* maintains information about page-table pages and their adjacent pages in close proximity. *Adjacent Page Tracer* traces access to the maintained adjacent pages and updates charge-leak counters for relevant rows of page-table pages. When the counters reach a pre-determined limit, *Row Refresher* is triggered to refresh desired rows hosting page-table pages. In comparison, non-page-table rows (highlighted in green) are vulnerable to bit flips.

3.2 Design Principles

SoftTRR follows the security and practicality design principles described below. The security principle is to guarantee SoftTRR can defend against all existing rowhammer attacks targeting page tables. The practicality principles aim to make SoftTRR applicable to real-world systems.

- **DP1:** SoftTRR should be effective in protecting ALL page tables. Without this completeness guarantee, an attacker can gain kernel privilege by compromising the integrity of page tables that are not protected by SoftTRR.
- **DP2:** SoftTRR should be compatible with OS kernels. It neither modifies/adds kernel source code nor breaks kernel code integrity through binary instrumentation, which hinders its adoption in practice.
- **DP3:** SoftTRR should have small performance overhead to a protected system.

3.3 Design Overview

SoftTRR, residing in the kernel space, collects all page tables, and monitors their entire life cycle from page-table creation to page-table release. For each collected page-table page, SoftTRR identifies all its adjacent pages in DRAM and traces memory accesses to the adjacent pages. Thus, SoftTRR is aware of which adjacent page is accessed. When the traced access count reaches a pre-determined limit, SoftTRR knows which page-table page is at the risk of being flipped and promptly refreshes the page (satisfying **DP1**).

All existing software-only mitigation techniques (see [Section 2](#)) deeply hack into the memory allocator to become

DRAM-aware and add extra allocation/deallocation constraints. Unlike them, SoftTRR only acquires offline domain knowledge (e.g., DRAM address (re)mappings of physical addresses), without requiring a new memory allocator or changing legacy allocator logic (satisfying **DP2**).

When paging is enabled, memory accesses are performed through page tables or relevant TLB entries, and SoftTRR flushes TLB and configures page tables to trace memory accesses to those adjacent pages. Thus, the access to an adjacent page raises a hardware exception, which is captured by SoftTRR for the tracing purpose. If no such access occurs, no overhead is introduced. Thus, the accesses to non-adjacent pages are at full speed, isolating the performance overhead caused by the accesses to adjacent pages (satisfying **DP3**).

As shown in [Figure 1](#), SoftTRR has three critical components. *Page Table Collector* actively collects all page tables and maintains their page and DRAM information. It also collects and maintains *adjacent pages*. Besides being accessible to unprivileged users, a page is considered as adjacent when itself or its corresponding page-table page is adjacent to (N-row from) another page-table page. This is based on an observation from Zhang et al. [62]. In particular, rowhammer attacks corrupting page tables are classified into two categories. For *explicit* attacks [13, 46], they require attacker-accessible memory adjacent to L1PT pages. For *implicit* attacks [62], they only need mutual adjacency among L1PT pages.

Adjacent Page Tracer keeps a close watch over memory accesses to collected adjacent pages, and maintains a charge-leak counter for a row where a page-table page resides. If any one row of adjacent pages has been accessed, the charge-leak counters of nearby page-table rows are updated accordingly, indicating that the page-table rows leak charge once.

Row Refresher remains dormant if charge-leak counters do not reach a pre-determined limit. If yes, a rowhammer attempt is believed to be taking place and the above tracer triggers row refresher, which will promptly refreshes desired rows whose charge-leak counters reach the limit.

4 Implementation

As stated in [Section 3.1](#), SoftTRR implements L1PT protection and a row of adjacent pages can be up to 6-row away from a row of L1PT pages. Our prototype implementation is a loadable kernel module (LKM) without modifications to the kernel. The LKM consists of around 1700 source lines of code and works with Ubuntu installation running a default Linux kernel 4.4.211. Before we talk about the three aforementioned components of SoftTRR, we first introduce important data structures as below.

4.1 Data Structures

We reuse the kernel's red-black tree structure [16], an efficient self-balancing binary search tree that guarantees searching in $\Theta(\log n)$ time (n is the number of tree nodes). As shown in [Table 1](#), we have three red-black trees and a ring buffer, i.e., `pt_rbtree`, `adj_rbtree`, `pt_row_rbtree` and `pte_ringbuf`, respectively.

Specifically, `pt_rbtree` stores L1PT page information while `adj_rbtree` stores information of pages that are adjacent to L1PT pages. For the two trees, a physical page number (PPN) is used as the node key and thus a new node will be allocated when information of a new L1PT page or adjacent page needs to be stored. Besides, `pt_row_rbtree` stores DRAM information about L1PT pages. For this tree node, `row_index` works as the node key and a node can have one or more bank structures (i.e., `bank_struct`). One bank structure stores `bank_index` that one or more L1PT pages own (e.g., multiple L1PT pages share the same row of the same bank). Also note that a page can span across multiple banks [55] and thus an L1PT page can have multiple `bank_struct`. `pt_count` records the number of L1PT PPNs that are in the same row of the same bank. `leak_count`, short for the charge-leak counter in [Section 3.3](#), stores the number of accesses to rows that are adjacent to a row of `row_index` in the same bank. For a given DRAM module, we leverage a publicly available algorithm [55] to reverse-engineer its DRAM address mapping, and embed the mapping into the kernel before acquiring a physical page's DRAM information. We allocate each node of each tree using the slab allocator [10], which is an efficient memory management mechanism intended for the kernel's small object allocation compared to the buddy allocator.

`pte_ringbuf` stores information of leaf page table entries (PTEs) that are collected by adjacent page tracer (see [Section 4.3](#)). These PTEs point to either adjacent pages them-

selves or *huge pages* containing adjacent pages. If the adjacent page is a 4 KiB page, the PTE is an L1PT entry. If the adjacent page is part of a huge page (i.e., 2 MiB or 1 GiB), the PTE is either an L2PT entry or an L3PT entry. Each node of `pte_ringbuf` is a structure that has three main fields also shown in [Table 1](#). Particularly, `pte` is a pointer to the leaf PTE. `vaddr` is a virtual address referring to an adjacent page or its corresponding huge page. `mm` is a pointer to a kernel structure (i.e., `mm_struct`) about a process's address space where `vaddr` belongs. The adjacent page tracer combines `vaddr` and `mm` to flush the TLB entry that stores the adjacent page's virtual-to-physical address mapping.

4.2 Page Table Collector

For user processes/threads that are already in the main memory before our module is loaded, page table collector enumerates the list of `task_struct` to find every existing process/thread, as Linux kernel uses `task_struct` for existing user processes/threads. It then performs page-table walk for every virtual page in each valid virtual memory area (VMA) of each user process to collect information of L1PT pages and their adjacent pages. Specifically, `pt_rbtree` and `pt_row_rbtree` store distinct L1PT pages, and their DRAM bank and row indexes, respectively. To build `adj_rbtree`, the collector finds out all user pages that are adjacent to L1PT pages in DRAM. It also selects all L1PT pages from `pt_rbtree` that are adjacent to each other and puts all PPNs pointed by selected L1PT pages' valid entries into `adj_rbtree`. For free pages that are adjacent to L1PT pages and allocated for use later (e.g., a free page is allocated and mapped to the user space right after the collector finishes collecting all adjacent pages), the adjacent page tracer handles them appropriately (see [Section 4.3](#)).

For L1PT pages that are dynamically allocated or freed after the above collection, we perform dynamic inline hooks to multiple kernel functions. Inline hook is called trampoline or detours hook, which is a method of receiving control when a hooked function is called. Dynamic kernel hook only requires loading a kernel module without kernel recompilation or binary rewriting, making itself easy to deploy in practice (e.g., Kprobes, Kpatch [19, 35, 36]).

We leverage a library¹ to hook two kernel functions, i.e., `__pte_alloc` and `__free_pages`. `__pte_alloc` traces newly allocated L1PT pages. `__free_pages` monitors dynamically released pages. The collector hooks these two functions to update the three red-black trees as follows:

- For a newly allocated L1PT page, its page, bank and row indexes will be updated into `pt_rbtree` and `pt_row_rbtree`, respectively. If there are new user pages that are adjacent to the L1PT page, they are added into `adj_rbtree`.

¹https://github.com/cppcoffee/inl_hook

Data Structures	Main Fields in A Node	Descriptions	
pt_rbtrees	PPN (key)	A unique page frame number of an LIPT page.	
adj_rbtrees	PPN (key)	A unique page frame number of an adjacent page.	
	row_index (key)	A row index of one or more LIPT pages.	
pt_row_rbtrees	bank_struct	bank_index	A bank index of one or more LIPT pages.
		pt_count	The number of LIPT pages that have the same indexes of bank and row.
		leak_count	The number of accesses to rows adjacent to a row of row_index and bank_index.
	pte	A pointer to a page table entry relevant to an adjacent page.	
pte_ringbuf	vaddr	A virtual address relevant to an adjacent page.	
	mm	A pointer to mm_struct relevant to a process where vaddr resides.	

Table 1: Data structures used by SoftTRR.

- If an adjacent page is freed, it will be removed from `adj_rbtrees`.
- If an LIPT page is freed, it will be removed from `pt_rbtrees`. Also, the collector acquires a node in `pt_row_rbtrees` that has the freed page's row index. Within the node, `pt_count` in each `bank_struct` corresponding to the freed page is decremented by one. If every `pt_count` for the node becomes 0, then the node is deleted from `pt_row_rbtrees`. Besides, the freed page's adjacent pages in `adj_rbtrees` are removed.

4.3 Adjacent Page Tracer

To trace memory accesses to adjacent pages at runtime, the adjacent page tracer leverages page fault handler.

Page Fault Handler. A page fault is a type of hardware exception. Whenever a user access to a virtual page violates access permissions dictated by one PTE, a page fault arises and will be captured by the MMU. As a response, the MMU will switch the process context to the kernel, which invokes the page fault handler to handle the fault based on an error code. The error code is generated by hardware and there are 7 page-fault error codes [27]. For instance, when a memory access to a virtual address that is marked as non-present in the PTE (i.e., `present` bit is cleared), the access triggers a non-present page fault with `P` bit in the error code set to 0. To handle this page fault, the page fault handler can allocate a new physical page for the virtual address and marks the address as present in the PTE, the so-called *demand paging*.

Leverage Page Fault. The adjacent page tracer can trace the memory access to a page by configuring flag bits in a PTE and hooking the page fault handler (i.e., `do_page_fault` function in the kernel space). As the memory access can be *read*, *write* or *instruction fetch*, not every flag bit can be leveraged. For instance, a physical page becomes read-only when its corresponding PTE has `RW` bit cleared. Once write-access to the page occurs, a page fault is generated with `W/R` bit of the error code set to 1. Thus, we experimented with each flag bit, results of which show that both `present` bit and `rsrv` bit in a PTE can be used for the tracing purpose. Next, we discuss why the tracer chooses `rsrv` bit rather than `present` bit.

Particularly, configuring `present` bit to trace the memory

access causes a kernel crash, as the kernel performs active checks of `present` bit in a leaf PTE in multiple cases. For instance, when a process is forking a new child process, the kernel checks `present` bit in the process's leaf PTEs. If one of the PTEs points to a physical page that is traced, `present` bit in the PTE is set to 0 by the tracer. When such a case occurs to the kernel check, the kernel will abort, because the tracer is unaware of when the forking occurs and it cannot restore `present` bit to 1 to pass the kernel check.

On top of that, we observe that one PTE has multiple `rsrv` bits in x86 which are unused and set to 0 by default. An access to a page with one `rsrv` bit in the PTE set to 1 will trigger a page fault and generate an error code with `RSVD` bit set to 1 (this `RSVD` error has been leveraged in prior works [2, 6, 8, 18, 56] for different purposes). In contrast to the `present` bit check, the kernel does not check against leaf PTEs' `rsrv` bits. For instance, if an adjacent page is a part of a huge page of 2 MiB, its leaf PTE is an L2PT entry and the kernel does not inspect any `rsrv` bit in the entry. As the page table management is a core component of the kernel, its code logic remains relatively stable. Take a recent stable Linux kernel version (i.e., 5.10.4) as an example, there is no check against any `rsrv` bit, either. It is probably because that `rsrv` bits remain unused in leaf PTEs. In our implementation, the tracer chooses a `rsrv` bit, i.e., bit 51 in the PTE.

Trace Adjacent Page. Upon the tracer has configured `rsrv` bits in relevant PTEs pointing to the adjacent pages or the huge pages containing the adjacent pages, and flushed desired TLB entries, subsequent access to an adjacent page or its huge page will trigger a page fault. As `do_page_fault` is hooked, the tracer captures a faulting (huge) page with an expected error code of `RSVD` and collects complete DRAM information from the faulting (huge) page. Thus, the tracer updates `leak_count` of LIPT pages that are adjacent to either the captured (huge) page or its leaf page-table page. As an LIPT page may have multiple `bank_struct`, `leak_count` of each `bank_struct` for the LIPT page should be updated accordingly. If the `leak_count` reaches a pre-determined limit in Figure 2, row refresher will be triggered (see Section 4.4).

We note that the tracer clears `rsrv` bit before transferring control back to the user space to resume the memory access. However, any subsequent access to the same adjacent page

or its huge page is no longer traced as `rsrv` bit is cleared. To address this issue, the tracer sets up a periodic timer to configure `rsrv` bit in a fixed interval and thus traces the accesses as frequently as possible. Specifically, when a timer comes, the tracer leverages kernel's *reverse mapping* feature to translate a PPN in `adj_rbtree` to a set of virtual addresses, as a PPN can be mapped to multiple virtual addresses. For each address, the tracer performs page-table walk, sets `rsrv` bit in its leaf PTE and flushes its cached TLB entry.

It is clearly inefficient to do the reverse-mapping and page-table walk for every PPN in `adj_rbtree` in every timer event. To improve the efficiency, the tracer sets `rsrv` bit in PTEs relevant to the pages in `adj_rbtree` and then frees corresponding nodes in `adj_rbtree` in the first timer. If page faults with the error code of `RSVD` occur, the tracer captures them and stores the faulting addresses' PTE information into a dedicated ring buffer (i.e., `pte_ringbuf`). When subsequent timer events come, the tracer sets `rsrv` bits in PTEs stored in `pte_ringbuf`, and handles remaining nodes in `adj_rbtree` which are updated by the page table collector.

For any new page that is allocated for the user space in the default page fault handler, the tracer checks if its PPN or its LIPT page's PPN (if exists) is adjacent to any PPN in `pt_rbtree`. If so, its leaf PTE information is inserted into `pte_ringbuf`.

Particularly, `pte_ringbuf` maintains two pointers for updates, i.e., `head` and `tail`. If a new PTE is inserted to `pte_ringbuf`, the `head` pointer is updated and points to the empty node next to the node of latest inserted PTE. If one PTE is removed from `pte_ringbuf` (i.e., its `rsrv` bit has been configured), the `tail` pointer is updated and points to the least recently inserted PTE. When the `head` and the `tail` point to the same ring buffer node, the buffer becomes empty. The ring buffer size is pre-determined empirically. When the node number between the `tail` and the `head` pointers is no less than 80% of the total node number of the ring buffer, the tracer allocates a larger ring buffer (e.g., four times of the old ring buffer size in our implementation), which will store newly inserted PTE. The old ring buffer will be freed when its stored PTEs are all consumed by the tracer.

As shown in [Figure 2](#), the time interval between two consecutive timer events (denoted as `timer_inr`) should be small enough to keep adjacent pages under close surveillance and `leak_count` is updated promptly. On the other hand, our system might experience unacceptable overhead if the timer is too frequent and causes numerous context switches between user and kernel. To this end, we discuss how to decide `timer_inr` in [Section 4.5](#) to keep SoftTRR's security guarantee while minimize its performance impacts.

4.4 Row Refresher

Direct-physical Map. Linux systems and paravirtualized hypervisors (e.g., Xen) map the whole available physical mem-

Figure 2: The adjacent page tracer sets up tracing to adjacent pages in each time point from $t_0, t_1, t_2, t_3, \dots, t_n$ and the interval between two adjacent time points is `timer_inr`. The tracer captures the first memory access (highlighted in green) and ignores subsequent memory accesses in each interval of `timer_inr` and updates `leak_count`. Whenever `leak_count` reaches `count_limit`, the row refresher starts.

ory directly into the kernel space [31, 58] in order for the kernel to access any data or code in the physical memory. Thus, every physical page allocated for the user space has been mapped to at least two virtual pages, i.e., a user virtual page and a kernel virtual page. While for a kernel's physical page, it is mapped to a single kernel virtual page.

Refresh Desired Rows. If `leak_count` in `bank_struct` reaches a pre-determined limit (denoted as `count_limit`), the row refresher refreshes desired rows specified by relevant `bank_struct`. As each node in `pt_row_rbtree` provides bank indexes and row indexes, the refresher leverages them to reconstruct a physical address. Based on the direct-physical map, the refresher finds out a kernel virtual address mapped to the physical address. As a read-access to a row can automatically re-charge the row and prevent potential bit flips, the refresher flushes CPU caches of the kernel virtual address, reads the virtual address, and resets `leak_count` to 0 at last.

If `count_limit` is set too small (e.g., 1), the refreshing cost may become unacceptable as many unnecessary refreshes are introduced by regular memory accesses to adjacent pages. If `count_limit` is too large, the refresher is unable to promptly refresh a row before it is flipped. Thus, `count_limit` should be no less than 2 and we decide its value in the next section.

4.5 Offline Profile

SoftTRR decides realistic and reasonable `timer_inr` and `count_limit` to keep its security and practicality design principles. As illustrated in [Figure 2](#), the adjacent page tracer only captures the first memory access to an adjacent page within each `timer_inr` and updates `leak_count`. The subsequent memory accesses within `timer_inr` to the same page will be ignored by the tracer. Thus, the maximum time period (denoted as `threshold`) for hammer before the page is refreshed has such an equation: $threshold = timer_inr \times (count_limit - 1)$. This means that SoftTRR must carefully set `threshold` short enough to ensure that no bit flip occurs within `threshold`.

We decide `threshold` based on the equation:

Machine Model	Hardware Configuration			Attack	SoftTRR Bit Flip Failed?
	CPU Arch.	CPU Model	DRAM (Part No.)		
Dell Optiplex 390	KabyLake	i7-7700k	Kingston DDR4 (99P5701-005.A00G)	Memory Spray [46]	✓
Dell Optiplex 990	SandyBridge	i5-2400	Samsung DDR3 (M378B5273DH0-CH9)	CATTmew [13]	✓
Thinkpad X230	IvyBridge	i5-3230M	Samsung DDR3 (M471B5273DH0-CH9)	PThammer [62]	✓

Table 2: Each rowhammer attack targets n (e.g., 50 in our experiments) victim pages of L1PTEs. With SoftTRR enabled, each attack fails to induce bit flips in these pages, indicating that those attacks have been mitigated.

$threshold = t_{RC} \times \#ACT$, where t_{RC} is the time interval between two successive ACT commands and $\#ACT$ is the number of activations for all the hammered rows that is required to induce the first bit flip. Thus, we guarantee that no bit flip occurs within the time interval of $threshold$. We learn from Kim et al. [32] that t_{RC} is around 50 ns and $\#ACT$ per row is in the order of 20 K on DDR3 modules and 10 K on DDR4 modules. Compared to DDR3 modules that require at least 1 aggressor row, no less than 2 aggressor rows are required in DDR4 modules due to the ChipTRR. As such, $\#ACT$ for triggering the first bit flip is around 20 K for both DDR3 and DDR4 modules. To this end, $threshold$ is set to 1 ms, below which DRAM modules are believed to be rowhammer-free. As both $timer_inr$ and $count_limit$ for SoftTRR are unsigned integers, $timer_inr$ is set to 1 ms and $count_limit$ is set to 2.

5 Security Evaluation

We now turn to evaluate the security effectiveness of SoftTRR on three different hardware configurations, summarized in Table 2, all running Ubuntu.

We deploy SoftTRR into each system against one representative kernel privilege escalation attack, i.e., Memory Spray [46] that hammers user memory adjacent to L1PTEs, CATTmew [13] that hammers device driver buffer adjacent to L1PTEs, and PThammer [62] that implicitly hammers L1PTEs adjacent to other L1PTEs. Both Memory Spray and CATTmew are explicit rowhammer attacks with two different types of memory accessible to unprivileged users. PThammer is the only published implicit rowhammer attack.

5.1 Defeating Memory Spray

Background. The Memory Spray [46] is the first rowhammer attack targeting L1PTEs. It is a probabilistic attack, as it sprays numerous L1PT pages into the memory with the hope that some L1PT pages are placed onto victim rows adjacent to attacker-controlled rows. As such, exploitable bits in L1PTEs can be flipped, resulting in kernel privilege escalation.

Evaluation Details. We test the effectiveness of SoftTRR against the Memory Spray on the Dell Optiplex 390. In this

machine, traditional 2-sided hammer pattern cannot trigger any bit flip and instead we use the 3-sided hammer identified by TRRespass². We first conduct 3-sided hammer to randomly identify n (e.g., 50 in our evaluation) vulnerable pages that have reproducible bit flips, that is, a vulnerable page has at least one victim physical address (P_v) and hammering three aggressor addresses P_a , P_b and P_c will flip bits in P_v .

We then optimize the attack by using the kernel privilege to put page tables onto vulnerable pages in a deterministic way. Specifically, we spray n pages of L1PTs by creating a virtual memory region of $2n$ MiB, ask the kernel to copy the content of the n pages of L1PTs into the n vulnerable pages, which are then used to translate the virtual memory region. The vulnerable pages now contain L1PTs and the original L1PTs are removed. By doing so, an attacker will definitely corrupt any one of the L1PTs pages by hammering three relevant aggressor addresses. When SoftTRR is enabled to collect and protect the n pages of L1PTs, we re-start the optimized attack for n hours (one-hour hammer for one vulnerable L1PT page) and observe no single bit flip in those n pages of L1PTs by checking their integrity, indicating that the Memory Spray attack has been successfully defeated.

5.2 Defeating CATTmew

Background. As mentioned in Section 2, CATT [12] enforces physical user-kernel isolation. CATTmew [13] breaks CATT’s security guarantee by identifying device (e.g., SCSI Generic) driver buffers that are kernel memory but can be accessed by unprivileged users. CATTmew exploits the driver buffers to ambush adjacent L1PT pages for hammer, with the hope that these L1PT pages are prone to bit flips.

Evaluation Details. We use 2-sided hammer to search n vulnerable pages on the Dell Optiplex 990. A vulnerable page has at least one victim physical address (P_v) and hammering two aggressor addresses (P_a and P_b) flips bits in P_v .

We then rely on the kernel privilege to convert CATTmew into a deterministic attack. Specifically, we spray n L1PT pages and copy their entries onto the n vulnerable pages as what we did in the optimized Memory Spray attack. On top of that, we apply for the SCSI Generic (SG) buffer using

²<https://github.com/vusec/trrespass>

Linux user APIs. In this test machine, we can apply as large as 123 MiB and only 8n KiB of the SG buffer are enough. We instruct the kernel to copy the allocated SG buffer’s content into the 2n aggressor pages and change the buffer’s address mappings accordingly. To this end, hammering the buffer will induce bit flips in the vulnerable L1PT pages. However, when SoftTRR is set active, no single bit flip has been observed in those L1PT pages after n hours of hammering, indicating that SoftTRR is effective in defeating the CATTmew attack.

5.3 Defeating PThammer

Background. Rowhammer attacks before PThammer [62] are explicit rowhammer that require access to an exploitable aggressor row (e.g. adjacent to a row of L1PTs). PThammer voids this requirement. By spaying L1PT pages and placing some onto victim rows with a high probability, PThammer exploits page-table walk to produce frequent loads of some L1PTes from aggressor rows (i.e., “implicitly hammering L1PTes”), which will induce bit flips in other L1PTes in victim rows.

Evaluation Details. We optimize PThammer by using the kernel privilege to present a more efficient and deterministic attack on the Thinkpad X230. Specifically, PThammer uses eviction sets to flush TLB entries and CPU caches of desired L1PTes and user memory loads trigger the page-table walk to implicitly hammer the L1PTes. However, the eviction-based flush is probabilistic. In our test, the kernel assists PThammer in performing the flush through explicit instructions (i.e., `invlpg` for TLB flush and `clflush` for L1PTes flush). Thus, its hammer instruction sequence is kernel-assisted flush with a user memory load, which is less efficient than the aforementioned 2-sided hammer that applies `clflush` for user data flush. In such a case, we cannot use the traditional 2-sided hammer to identify vulnerable pages, as these pages may become non-flippable to the kernel-assisted hammer. To address this issue, we add a certain number of NOP (e.g., 180) instructions into the 2-sided hammer instruction sequence to meet the time cost taken by the kernel-assisted hammer. By doing so, n vulnerable pages of interest can be discovered.

As PThammer massages L1PTes onto vulnerable pages with a probability, we instead spray 3n L1PT pages by creating a virtual memory region of 6n MiB. We then ask the kernel to copy all entries of the L1PT pages into the n vulnerable pages and the 2n aggressor pages. The kernel then changes the address mappings of the created virtual memory region by using the new 3n L1PT pages. As such, the optimized PThammer successfully induces bit flips in the n vulnerable L1PT pages by using the kernel-assisted hammer against the 2n aggressor L1PT pages. In comparison, we enable SoftTRR before starting the optimized PThammer. As each 2 aggressor L1PT pages is adjacent to a vulnerable L1PT page in `pt_rbtrees`, SoftTRR traces memory accesses to the created virtual pages pointed by the L1PT page entries. Considering

Benchmarks	Programs	SoftTRR Overhead	
		$\Delta_{\pm 1}$	$\Delta_{\pm 6}$ (default)

Table 3: Benchmark results for SPECspeed 2017 Integer, Phoronix and memcached.

that the PThammer still requires frequent memory loads of the created virtual pages for page-table walk, it cannot bypass the tracing. After n hours of hammering the 2n aggressor pages, no bit flip occurs, meaning that SoftTRR has mitigated PThammer.

6 Performance Evaluation

We evaluate the performance impacts induced by SoftTRR, i.e., SoftTRR’s runtime overhead, memory consumption and system robustness are evaluated in Section 6.1, Section 6.2 and Section 6.3, respectively. The experiments are conducted in a DDR4-based system. The system is Ubuntu running on top of a Dell Desktop with Intel i7-7700K and Samsung 16 GiB DDR4 (part number: M378A2G43AB3-CWE). By default, the row distance implemented by SoftTRR between adjacent rows and L1PT-page rows is up to 6-row, denoted by $\Delta_{\pm 6}$. In comparison, we also measure its impacts in the scenario of only one-row-distance that previous works (e.g., [34]) assume, denoted by $\Delta_{\pm 1}$. The results show that SoftTRR

Figure 3: The memory consumed by SoftTRR in both $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ for the LAMP production environment.

Figure 4: The numbers of protected LIPT pages and traced adjacent pages in both $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ for the LAMP production environment.

in both scenarios of $\Delta_{\pm 6}$ and $\Delta_{\pm 1}$ incurs an average slow-down within 0.83% indicating that the row distance may have a relatively small impact on the performance overhead. We note that the cost of initially loading SoftTRR into the kernel is around 28 ms and it occurs only once. We also validate the system robustness of SoftTRR, results of which show that SoftTRR does not affect the stability of the protected system, making itself practical.

6.1 Benchmark Runtime Overhead

We measure SoftTRR-induced runtime overhead using two popular benchmarks and an industrial memory-intensive application, i.e., SPECspeed 2017 Integer [50], Phoronix test suite³ and memcached⁴.

³<https://github.com/phoronix-test-suite/phoronix-test-suite>

⁴<http://memcached.org/latest>

SPEC CPU 2017 is an industry standard benchmark package that contains CPU-intensive programs for measuring compute-intensive performance. It has 43 benchmarks in total and is organized into 4 suites, among which SPECspeed 2017 Integer has been used. This suite launches 10 integer programs with a specific configuration file customized from *Example-linux-gcc-x86.cfg* and the benchmark results are summarized in Table 3. As we can see from the table, the overhead of $\Delta_{\pm 6}$ (0.83%) and $\Delta_{\pm 1}$ (0.07%) are less than 1%.

Phoronix is a free and open-source benchmark software for mainstream OSes (e.g., Linux, MacOS and Windows). It allows for testing performance overhead against common applications in an automated manner. As this suite has a large number of programs testing different aspects of a system, we select a subset of the available programs to stress-test performance of CPU, memory, network I/O and disk I/O. As shown in Table 3, the average performance overhead is 0.22% for $\Delta_{\pm 1}$ and 0.24% for $\Delta_{\pm 6}$, respectively, indicating that the Phoronix overhead is negligible in both scenarios.

memcached is a pervasively used in-memory data storage system and can consume as much memory as possible. To evaluate the performance impacts of SoftTRR on memcached, we start memcached as a memory-intensive process, that is, 13 out of 16 GiB are allocated for memcached, to stress-test SoftTRR. We then run memaslap [1] for 5 times (with 5 minutes in each time) to benchmark the memcached process. The memaslap tool is a load generation and benchmark for memcached-based servers and allows generating various workloads. In our experiments, memaslap specifies default workloads for memcached (i.e., the task window size is 10 K, the thread for startup is 1 and each thread has 16 self-governed concurrencies to handle socket connections). As shown in Table 3, the average overhead of Ops, TPS and Net_rate are only 0.39%, 0.39% and 0.46% for $\Delta_{\pm 1}$ and 0.18%, 0.15%, and 0.31% for $\Delta_{\pm 6}$, respectively.

6.2 LAMP Runtime Memory Consumption

We use a real-world use case to measure runtime memory consumption of SoftTRR, that is, a LAMP server (i.e., Linux, Apache, MySQL and PHP). We run a common tool (i.e., Nikto [51]) in another machine for 60 minutes to stress test the LAMP server. Nikto is a web server scanner that tests the LAMP server for insecure files and outdated server software. It also carries out generic and server type specific checks.

The memory cost induced by SoftTRR within the 60 minutes is shown in Figure 3. The memory consumption is a total memory size of three red-black trees (i.e., pt_rbtrees, pt_row_rbtrees and adj_rbtrees) and the ring buffer (i.e., pte_ringbuf). We note that the pre-allocated pte_ringbuf is 396 KiB. As shown in the figure, the memory costs in both $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ increase gradually and reach a relatively stable level in the last 15 minutes. Both $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ have a similar and low memory cost (i.e., less than 600 KiB).

Linux Test Project	Vanilla System	SoftTRR	
		$\Delta_{\pm 1}$	$\Delta_{\pm 6}$ (default)
File	open	✓	✓
	close	✓	✓
	ftruncate	✓	✓

	prctl	✓	✓
	vhangup	✓	✓

Table 4: System-call stress tests from Linux Test Project (✓: the stress test does not report any problem.).

Protected and Traced Page Number. When computing the memory consumption, we also collect the unique page numbers that SoftTRR protects and traces, respectively. Figure 4 shows that both protected L1PT page number and traced adjacent page number in $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ increase and become stable within the 60 minutes. We note that the protected L1PT page numbers in $\Delta_{\pm 1}$ and $\Delta_{\pm 6}$ are in the same order of magnitude as the overall system activities in both scenarios are similar to each other. As an L1PT-page row in $\Delta_{\pm 6}$ can have up to 12 adjacent rows, 6 times the adjacent row number that an L1PT-page row can have in $\Delta_{\pm 1}$, more adjacent pages are expected to be collected in $\Delta_{\pm 6}$. Figure 4 shows that the traced adjacent page number in $\Delta_{\pm 6}$ is higher than that in $\Delta_{\pm 1}$.

6.3 System Robustness

To evaluate the robustness of our test system after deploying SoftTRR, we select 20 system calls of different types and perform stress tests for each selected system call on both the vanilla system and the SoftTRR-based system. The stress tests come from Linux Test Project (LTP)⁵ and they are used to identify system problems. Particularly, we follow the LTP’s quick guide to run a single test each time using the default configuration without explicitly specifying any parameters (e.g., binding the test onto one or more CPU cores. As such, we first run all the tests on the vanilla system, results of which are used as the baseline to compare with that of SoftTRR. As can be seen from Table 4, the stress test results clearly

⁵<https://github.com/linux-test-project/ltp>

show that there is no deviation for the SoftTRR-based system compared to the vanilla system. Besides, we do not observe any issue when executing previous benchmarks. As a result, the test system runs stably with SoftTRR enabled.

7 Discussion

Other Data Objects Protection. If critical data structures of SoftTRR are targeted, we can easily extend SoftTRR to protect them. Similar to the L1PT protection described in Section 3.3, SoftTRR treats its own data structures as protected objects. To protect sensitive user objects (e.g., binary code pages of `setuid` processes or DNN model weight pages) against existing attacks [21, 24], RIP-RH [9] is effective by physically isolating trusted user processes. Orthogonal to RIP-RH, SoftTRR can also be extended to defeat such attacks. Particularly, trusted users pass specified objects to SoftTRR through a provided user API (e.g., `netlink`) and SoftTRR thus uses a similar mechanism to protect those objects.

Level-1 and Higher-level Page Table. Existing kernel privilege escalation attacks focus on corrupting L1PTs, and there is no demonstrated attack that has successfully exploited higher-level page tables [57]. If such an attack may be feasible in the future, we can easily extend our SoftTRR to protect higher-level page tables. For instance, when SoftTRR is extended to protect L2PT pages, SoftTRR collects desired user pages if they or their corresponding L1PT or L2PT pages are adjacent to either L1PT or L2PT pages. SoftTRR traces the collected user pages by setting `rsrv` bits in their leaf PTEs and refreshes relevant page-table pages when necessary. As the number of higher-level PT pages is significantly smaller than the number of L1PT pages (e.g., an L2PT page can point up to 512 L1PT pages), we believe that the additional performance overhead will not be high.

DMA-based Kernel Privilege Escalation Attack. There is NO existing DMA-based kernel privilege escalation attack on x86. Such attack is demonstrated on ARM (Drammer [53]), and it has been defeated by GuardION [54] that enforces DMA memory isolation. In the future, if such attacks on x86 prove to be feasible, we can take the following two ways to solve. One is to integrate SoftTRR with existing orthogonal defenses. In particular, ALIS [52] on x86 physically isolates DMA memory using guard rows and bit flips are thus confined to DMA memory of attackers.

Alternatively, SoftTRR can leverage IOMMU [26] to monitor remote access to DMA memory by configuring I/O page tables, similar to MMU-based page tables. Specifically, SoftTRR collects (I/O) page tables and their adjacent DMA memory pages that are allocated to users. By configuring I/O page tables, SoftTRR traces accesses to the collected DMA pages. When IOMMU is widely available on x86, we believe that SoftTRR can leverage it to defend (I/O) page tables against unknown DMA-based kernel privilege escalation attacks.

Half-Double Attack. Inspired by [17], Google recently proposes a new hammer technique, called Half-Double [20], which induces bit flips in a target victim row that is 2-row away from a row being hammered. Specifically, Half-Double observes that some ChipTRR implementations in DDR4 modules will refresh a row’s two neighboring rows if the row is detected to be hammered. With this key observation, Half-Double hammers a row (known as Far Aggressor), which enables ChipTRR to frequently refresh the row’s neighboring rows (known as Near Aggressor). As such, Half-Double can combine the frequent refreshes and a few activations against Near Aggressors to induce bit flips in victim rows that are 2-row away from a Far Aggressor.

However, we believe that Half-Double is unlikely to bypass SoftTRR and break page tables. In order to induce the first bit flip, #ACT required by Half-Double to hammer one Far Aggressor is about 296K, whereas SoftTRR assumes that the minimum #ACT is 20K for the first bit flip based on Kim et al. [32]. Thus, SoftTRR can detect Half-Double’s hammering and refresh page-table rows (if any) from being flipped by a 2-row-distance Far Aggressor. In the current implementation of SoftTRR, it can protect page-table rows from being corrupted by a Far Aggressor that is up to 6-row away.

Possible Performance Degradation Attack. We did not observe a high performance impact in our real-world applications and it might rarely occur that memory accesses concentrate on locations adjacent to LIPTEs. The system performance can be badly affected (as a kind of DoS attack [41]) if an adversary stresses SoftTRR by causing many additional page faults and refreshes. To alleviate such attack, SoftTRR can count the number of refreshes. If the count reaches a threshold, it can raise an alarm and leverage the scheduling information to narrow down the list of potentially malicious processes.

Support for ARM Architecture. Although there are reserved bits in page table entries in the ARM architecture, setting these bits will not trigger any hardware fault [4]. If we extend SoftTRR to provide ARM support, a possible solution is to disable the page table walk and capture the address-translation fault. However, this solution may introduce a larger performance overhead, as each memory access to a process triggers the fault if the process has pages adjacent to LIPT pages. Alternatively, we can leverage the present bit rather than the reserved bit in both x86 and ARM. As discussed in Section 4.3, the kernel performs active checks of the present bit in a leaf PTE. To address this issue, we can leverage the approach [56] to find all the functions where the kernel performs the check. By hooking these functions, we can restore the present bit and bypass the kernel check.

Support for Hardware-assisted Virtualization . SoftTRR, by design, works in a bare-metal system. To adapt itself to work in the guest OS kernel of a VM, SoftTRR needs the mappings of guest physical addresses to DRAM addresses. As

host physical addresses to DRAM mappings and in-DRAM address remappings can be reverse-engineered through prior works [14, 44, 55, 59], SoftTRR requires the guest-to-host memory mapping that is managed by the hypervisor. To this end, SoftTRR can register a virtual interrupt to communicate with the hypervisor. Particularly, upon the VM’s physical memory is allocated, SoftTRR obtains the guest-to-host memory mapping through the registered interrupt. If the VM’s physical memory is updated at runtime, the hypervisor notifies the SoftTRR of the updated mapping. If the hypervisor maintains mostly consecutive mapping (e.g., the Xen hypervisor uses 1 GiB huge-pages by default), we do not think maintaining the mapping would cause a major issue (e.g., SoftTRR only maintains a mapping of 1K entries even if the VM’s memory is up to 1 TiB).

8 Conclusion

In this paper, we proposed a software-only defense, named SoftTRR, that protects level-1 page tables against rowhammer attacks on x86. SoftTRR is a loadable kernel module and compatible with commodity Linux systems without requiring any kernel modification.

We evaluated the security effectiveness of SoftTRR-enabled systems using three kernel privilege escalation attacks. Also, we measured SoftTRR’s performance overhead, memory cost, and stability using multiple benchmark suites and a real-world use case. The experimental results indicate that SoftTRR is effective in defending against all the mentioned attacks, and practical in incurring low performance overhead and memory cost. Besides, it does not affect the system stability.

Acknowledgments

We thank our anonymous reviewers and shepherd for their insightful comments and suggestions.
