A SPECint 2006

SPECint 2006 is an industry standard benchmark suite intended for measuring the performance of CPU and memory. For this suite, we launch 12 integer programs with a specific configuration file (i.e., *linux64-amd64-gcc43+.cfg*) and summarize the benchmark results in Table 5. As we can see from the table, the overhead of $\Delta_{\pm 6}$ (i.e., 0.75%) is a bit higher than that of $\Delta_{\pm 1}$ (i.e., 0.04%) although the row distance of $\Delta_{\pm 6}$ is an order of magnitude larger than that of $\Delta_{\pm 1}$.

Programs	SoftTRR Overhead	
	$\Delta_{\pm 1}$	$\Delta_{\pm 6}$ (default)
perlbench	0.47%	1.42%
bzip2	-0.61%	1.52%
gcc	0.00%	0.51%
mcf	-2.08%	-2.08%
gobmk	0.30%	0.60%
hmmer	0.41%	0.83%
sjeng	0.00%	0.26%
libquantum	0.00%	0.59%
h264ref	0.00%	0.89%
omnetpp	0.32%	0.00%
astar	0.97%	2.60%
xalancbmk	0.63%	1.89%
Mean	0.04%	0.75%

Table 5: SPECint 2006 benchmark results.

B Artifact

Abstract

This artifact contains a prototype implementation of SoftTRR that protects level-1 page tables from rowhammer attacks. It works as a loadable Linux kernel module without any modifications to the kernel.

Scope

This artifact is effective and practical in protecting level-1 page tables from being corrupted by rowhammer attacks. Particularly, it leverages realistic and reasonable software refreshes to mitigate a rowhammer attack where a hammered row can be up to 6-row away from a targeted row hosting level-1 page tables.

Contents

This artifact has 6 main source files, which are briefly introduced as follows. *defense.c* is to initialize our kernel module such as registering dynamic hooks to relevant kernel functions (we rely on a third-party inline hook library

https://github.com/cppcoffee/inl_hook that resides in the directory of *inl_hook* in our repository). *victim_handler.c* collects level-1 page-table pages and their physically adjacent pages. *pgfault.c* monitors `do_page_fault` to trace memory accesses to pages that are physically adjacent to level-1 page-table pages. *rbtree.c*, *dramaddr.c* and *kernel_symbol.c* provide some helper functions such as maintaining important data structures and DRAM address mappings, parsing relevant kernel symbols, etc. We refer the readers to our repository for more details.

Hosting

This artifact is available at <https://doi.org/10.6084/m9.figshare.19721692>.

Hardening Hypervisors with Ombro

Ethan Johnson, Colin Pronovost, and John Criswell
Department of Computer Science, University of Rochester

Abstract

This paper presents Ombro, a low-level virtual instruction set architecture (vISA) which enforces compiler-based security policies on real-world commodity hypervisors. We extend the Secure Virtual Architecture (which itself extends the LLVM compiler’s Intermediate Representation) to support the full set of hardware operations needed to run an x86 commodity hypervisor used in some of the world’s largest public clouds, namely, the Xen 4.12 hypervisor, running in full hardware-accelerated mode using Intel’s Virtual Machine Extensions (VMX). We have ported Xen 4.12 to the Ombro vISA and demonstrated that it can run unmodified guest VMs of real-world relevance (namely, Linux guests under Xen’s HVM and PVH modes). Furthermore, to demonstrate Ombro’s ability to harden hypervisors from attack, Ombro implements control flow integrity and the first protected shadow (split) stack for x86 hypervisors. Our performance results show that Ombro achieves this protection without imposing measurable overheads on most application benchmarks.

1 Introduction

Various ideas have been proposed and demonstrated that can improve hypervisor security against low-level attacks such as memory safety vulnerabilities. One such approach would be to re-implement the hypervisor in a safe language such as Rust [1], but this is considered prohibitively labor-intensive for real-world hypervisors such as Xen [3], VirtualBox [46], or Hyper-V [42]. Another is to provide a whole-VM trusted execution environment (TEE) that protects VMs from a compromised hypervisor by isolating and removing most of the hypervisor from the trusted computing base [32, 41, 55, 56]; this approach is powerful and promising but tends to impose heavyweight requirements (e.g. moving the non-trusted portion of the hypervisor into VMX/SVM’s non-root (guest) mode, which imposes high overheads e.g. on VM exit handling) [41, 56] or substantial modifications to hardware [32, 55]. Enclave-based TEEs such as Intel’s SGX [30] offer similar benefits but provide a more functionally limited operating environment compared to whole-VM TEEs. Designs such as HyperSafe [51], which adds lightweight control flow integrity (CFI) protection to the hypervisor, make hypervisors more resilient against attack but face an “arms race” of rapidly evolving attacks [7, 8, 27, 29], necessitating the addition of further defenses such as a shadow stack (HyperSafe [51] is vulnerable to attacks that corrupt return addresses) to remain viable.

When applied to kernel-mode software like hypervisors, hardening approaches such as CFI must account for the fact

that the raw hardware/software interface provided by the native ISA is much “messier” than the execution environment user-mode applications can expect. Low-level operations which are typically thought of as transparent and orthogonal, such as context switches, VMX/SVM guest entry/exit, page table updates, and control register modifications, are fully exposed to host-kernel-mode software. These operations present numerous opportunities for security invariants such as CFI enforcement to be undermined when software logic has been corrupted by a memory safety exploit.

Prior work on the Secure Virtual Architecture (SVA) [15, 17] addresses this issue by extending the LLVM compiler’s Intermediate Representation (IR) with *virtual instructions* (a.k.a. *intrinsic*s) that encapsulate these low-level hardware/software interactions with principled, higher-level abstractions intended for use by kernel-mode code. Program state discontinuities that could break security enforcement are prevented, since operations such as context switches and paging updates are handled safely by a thin, trusted layer of code provided by the compiler to implement the virtual instructions, whose behavior cannot be compromised by bugs in a kernel or hypervisor built upon them. To date, SVA has been used to successfully enforce security policies such as memory safety [16] and CFI [13] on commodity Linux and FreeBSD OS kernels. Initial support for hardware-accelerated virtual machines via Intel VMX has been added to SVA [34], but it lacks several key features needed to support real production hypervisors such as Xen [3], VirtualBox [46] and Hyper-V [42], and also lacks SMP (multiprocessor) support, a necessity in the modern cloud.

In this paper, we present *Ombro*, a low-level virtual instruction set architecture (vISA) designed to support the efficient and complete implementation of compiler-based security mitigations in real-world commodity hypervisors. We extend SVA to support the full set of hardware features needed to support the Xen 4.12 hypervisor [3], including virtual APIC support, model-specific register (MSR) virtualization, and I/O port virtualization. We also add the first SMP support to SVA (benefiting non-hypervisor designs as well that are based on it) and make several key design improvements to SVA’s existing VMX support [34] to address shortcomings in performance and its ability to integrate with the Xen codebase. We have ported Xen 4.12 to the Ombro vISA and demonstrate that it can run unmodified guest VMs of real-world relevance (Linux guests under Xen’s HVM and PVH modes) with negligible performance impacts on most application benchmarks. Additionally, as a case study in the kinds of hypervisor security mitigations whose design and implementation Ombro sup-

ports, we demonstrate the implementation of control flow integrity with return address protection (shadow/split stack) using the tools provided by Ombro, and that these mitigations add no further performance impacts to guest operations.

To summarize, our contributions are as follows:

- We have enhanced the SVA vISA developed in Shade [34] to support a full-featured production-quality hypervisor (namely, Xen). We have also added symmetric multiprocessing (SMP) support to the SVA vISA.
- We have developed techniques that ensure that bugs in hypervisors cannot break return address and control flow integrity. We have created a prototype of a system, dubbed Ombro, that uses our enhanced SVA vISA to enforce these policies on a production-quality hypervisor.
- We have ported the Xen hypervisor to Ombro. This is the first full port of a full-featured production-quality hypervisor to the SVA virtual instruction set.
- We have evaluated the performance of Ombro and found that the vISA imposes negligible performance impacts on most guest application benchmarks. We have also found that the addition of CFI and return address protection imposes no measurable overheads.

2 Background

Ombro employs *virtual instruction set computing* (VISC) [5, 16] to ensure that its security guarantees (which mitigate control-flow hijacking) are not bypassed via low-level interactions between the hypervisor and the x86 hardware. Here, we present background information on VISC, the VISC-based Secure Virtual Architecture (SVA), and its features and limitations relevant to Ombro.

2.1 Virtual Instruction Set Computing

Virtual instruction set computing (VISC) [5] is a system design in which the instruction set to which software is compiled (the *virtual instruction set* or *vISA*) is decoupled from the instruction set implemented by the processor (the *native instruction set*). A trusted code generator translates code from the virtual instruction set to the native instruction set. This translation can occur at any time (at compile time, link time, install time, boot time, or just-in-time during program execution). The defining characteristic of VISC is that all software in the system must be translated from virtual instruction set code to native instruction set code. In an idealized theoretical VISC system, this includes applications as well as system software (e.g. operating system kernels and hypervisor executives), i.e., all code on the system must target the virtual ISA rather than the native ISA. Practical designs may elect to relax this requirement within specific domains (e.g. applications or guest VMs running in less-privileged hardware modes) to maintain support for existing native-code applications.

Secure Virtual Architecture (SVA) [15, 16] is a VISC infrastructure that leverages the trusted code generator to enforce security policies on all software in the system stack, including the OS kernel and (optionally) library and application code. Because software must be translated by SVA’s trusted code generator, SVA can instrument code during native code generation to enforce security policies. SVA’s virtual instruction set is an extended version of the original LLVM Intermediate Representation (LLVM IR) [39], allowing SVA to use aggressive static analysis to optimize away provably unnecessary run-time security checks.

SVA extends LLVM IR with new virtual instructions (called *intrinsic*s) to support low-level privileged operations such as I/O, MMU configuration, and context switching in kernel-mode software without the need for native assembly code or direct access to privileged in-memory hardware data structures (page tables, etc.) [15]. These *intrinsic*s are implemented by a small library of trusted code (the “SVA-OS runtime”) which is, architecturally, considered part of the compiler, and linked or inlined into the target program as necessary during translation from virtual to native code. The resultant vISA provided to kernel programmers is designed to make it impossible to express computations that would violate the security policies specified for the system. To the extent that goal cannot be ensured statically, the SVA-OS implementation vets inputs and sanitizes outputs at runtime to prevent raw hardware functions from being used in unsafe ways.

To prevent attacker-compromised kernel-mode software from simply bypassing the vISA by executing native code, newer versions of SVA [13–15, 22, 34] enforce code segment integrity on the kernel by using software fault isolation [50] to prevent it from utilizing any kernelspace page-table mappings that are both writable and executable. This ensures that all native code has been translated or validated by the SVA code generator (either ahead of time or by request at runtime) and contains any necessary instrumentation while not containing privileged native instructions that would bypass the vISA.

Because it is possible to fully implement kernel-mode system software (e.g., OS kernels or hypervisors) using the SVA vISA’s virtual instructions, compiler-based security transformations such as control flow integrity (CFI) [4], software fault isolation (SFI) [50], or memory safety [20] enforcement can be performed on it at the LLVM IR level without “blind spots” arising from opaque native assembly or instructions with privileged side effects. SVA has been used to safely and efficiently support a variety of security policies and popular OS kernels over the years. The original SVA prototype enforced both spatial and temporal memory safety on the Linux 2.4 kernel [15, 16]. Subsequent iterations exchanged full memory safety for low-overhead CFI enforced on the FreeBSD 9.0 kernel [13] and explored a novel application of lightweight SFI instrumentation on the kernel to protect userspace applications from a compromised kernel [14]. Other SVA derivatives have explored adding protection against cache and speculative

side-channel threats against protected userspace applications in a Virtual Ghost system [21, 22, 34].

2.2 Kernel-Mode Memory Protection in SVA

Starting with the *Virtual Ghost* project [14], SVA has supported protecting designated sections of the host-virtual address space against tampering by kernel-mode (Ring 0) code using software fault isolation (SFI) [50]. This protection can be used as a foundation for multiple security policies and can optionally protect portions of userspace as well as kernelspace (lower and upper halves of the address space).

The SVA native code translator instruments all load and store instructions within host-kernel-mode code with SFI checks that determine whether the access references a virtual address within the protected region. If so, the check detects a violation and generates a trap, allowing the SVA VM to take corrective action, such as alerting the system administrator or terminating system execution. Otherwise, the load or store is allowed to proceed normally [14].

SVA's SFI checks can be implemented using traditional bitmasking instructions [50] or a fast scheme developed for Apparition [22] based on Intel's Memory Protection Extensions (MPX) [30]. The architecture is flexible and can be readily adapted to other hardware protection mechanisms such as segmentation [30] or memory protection keys [28, 30].

The memory region(s) protected by these SFI checks can be used to store user or kernel secrets where they cannot be seen or modified by the kernel/hypervisor. Depending on the needs of particular threat models, enforcement designs, and system performance, SFI checks can be omitted on loads so as to protect data against tampering even if it does not need to be secret [14].

SVA uses this memory protection in its design to make its other enforcement mechanisms complete while maintaining high performance. For instance, SVA maintains its own direct map (one-to-one mapping of all physical memory) within the kernelspace SFI-protected region, allowing intrinsics to write to page tables and code pages while leaving the kernel's mappings to them read-only; this avoids the need to expensively switch page tables or mappings on every such intrinsic call [22]. SVA likewise uses its SFI to ensure the integrity of its own metadata, such as tables tracking the permitted and current usage types of each physical memory frame [15, 22].

In Virtual Ghost [14], Apparition [22], and Shade [34], a userspace SFI-protected region is used to hide application secrets from a compromised OS kernel. In Ombro, we will use SVA's SFI to protect hypervisor control stacks and enforce return address integrity (Section 7).

2.3 VMX Support in SVA

Shade [34] added initial support for Intel VMX to SVA. *Shade* extended the SVA *vISA* with intrinsics and conceptual idioms for management of hardware-accelerated guest VMs—specifically, VM entry and exit (world switches), extended

paging, and VMCS management—while ensuring that these newly introduced capabilities would not compromise SVA's ability to enforce the security policies introduced in prior work (specifically Virtual Ghost [14] and Apparition [22]).

VMX facilitates *world switches* (the host/guest context switches associated with VM entry and exit) by giving the hypervisor open-ended control over each state element—instruction pointer, control and segment registers, etc.—as an individual field within a special in-memory data structure called the Virtual Machine Control Structure (VMCS) [30]. Different state elements are handled differently according to their importance in maintaining consistent system operation, and this behavior can (to an extent) be controlled by the hypervisor via flags in the VMCS. Some fields can be bidirectionally saved/restored by the processor as part of the host/guest-mode transition; for others, the hypervisor is expected to load an arbitrary value into the VMCS to which the register will be reset on VM exit. Others, such as the general purpose registers, are untouched by entry and exit, requiring the hypervisor to save and restore them itself.

This makes security enforcement on hypervisors challenging because the architecture implicitly assumes the hypervisor can be trusted. The ability to set host-state fields and entry/exit control flags in the VMCS affords countless opportunities for a compromised hypervisor to exploit VM exit to escape CFI enforcement and other security measures. Besides the instruction pointer itself, fields such as the stack pointer, segment registers, and control registers (which can disable security features such as protected mode, No-Execute (NX) pages, and SMEP [30]) can completely redefine the hypervisor's environment, rendering many protections useless.

Shade addresses these issues in SVA by encapsulating the VM entry/exit process (*VMLAUNCH/VMRESUME*) into an SVA intrinsic, *runvm*, which handles switching of sensitive state during world switches [34]. *runvm* has the semantics of a self-contained function call, contrasting with the broad, open-ended modification of system state possible with the native interface. *Shade* keeps context-switched guest state for the host and each guest VM within SFI-protected SVA internal memory (Section 2.2), providing access to individual guest state fields only through targeted intrinsics. The VMCS itself is likewise stored in protected memory and accessible to the hypervisor through intrinsics (*read/writenvmcs*) which only permit access to non-sensitive fields (or *vet/sanitize* input/output for partially sensitive fields). VMCS fields related to features that SVA needs to control at a higher level (e.g. extended paging) are blocked by *read/writenvmcs*, forcing the hypervisor to use the appropriate higher-level intrinsics.

While *Shade* laid important high-level groundwork for safely supporting the use of VMX acceleration in an SVA-based system, it fell short of being able to support a full-scale commodity hypervisor like Xen (or even a lightweight virtualization support driver like KVM [36]). *Shade* was developed and evaluated with a minimalist “toy” hypervisor that exer-

cised core VMX operations without the complexity of a full hypervisor. This facilitated the initial design and debugging of complex intrinsics such as `runvm`, but precluded an end-to-end performance evaluation and left unclear the question of whether the design choices made in the vISA would truly be conducive to porting a real hypervisor without invasive code changes or performance impacts. Shade also lacked support for key VMX features important to real-world hypervisors such as accelerated interrupt controller (APIC), model-specific register (MSR), and I/O port virtualization [30], and only supported vetting of a small subset of VMCS fields. Our work remedies these shortcomings, allowing us to port Xen 4.12 to the SVA vISA and use it to enforce and evaluate a security policy of real-world interest (return address protection for CFI) on a real-world hypervisor.

3 Threat Model

Our threat model assumes that we have a system running a single bare-metal hypervisor, such as Xen, on the hardware. This hypervisor hosts one or more guest virtual machines running various operating systems. The hypervisor is benign but may have exploitable memory safety errors that permit control-flow hijacking attacks such as return-to-libc [49] and return-oriented programming (ROP) [47] attacks. As we want to mitigate advanced control-flow hijacking attacks [7, 8, 18, 27], our defense must protect the integrity (but not necessarily confidentiality) of return and return-from-interrupt addresses. Non-control data attacks [9], Data-Oriented Programming (DOP) attacks [29], and other memory safety attacks that do not corrupt return addresses, function pointers, and other control data are out of scope.

4 Design

In this work, we present three major design contributions:

1. We extend and improve upon the SVA virtual instruction set architecture (vISA) of the Shade [34] project to efficiently support the full set of hardware features needed to run the Xen 4.12 hypervisor [3] in support of guest VMs accelerated using the Virtual Machine Extensions (VMX) [30] features of modern Intel x86-64 processors.
2. We extend the SVA vISA to support symmetric multiprocessing (SMP), an essential feature of modern systems that historical SVA designs notably lacked.
3. We present a design for an efficient and straightforward scheme enforcing forward-edge control flow integrity (CFI) with return address integrity (i.e. backward-edge CFI). This serves as a case study in how the SVA vISA can be used to support sound and efficient enforcement of security policies on commodity hypervisors, and also represents an advancement in its own right on the state of the art [51] as the first efficient protected shadow stack design for a hypervisor.

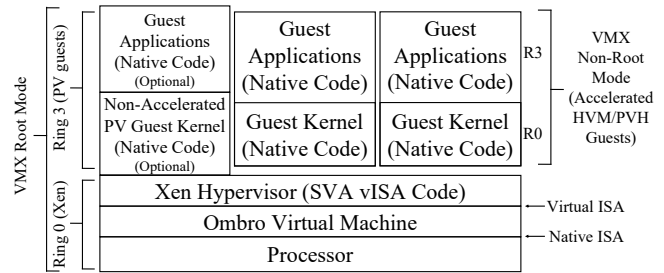

Figure 1: Ombro Architecture

Figure 1 depicts the overall architecture of Ombro as used to enforce security policies on the Xen 4.12 hypervisor.¹ Ombro permits the hypervisor to run in the processor’s highest-privileged mode—Ring 0 of VMX root mode—without relying on hardware privilege isolation to enforce security policies on the hypervisor. The hypervisor is compiled to the SVA vISA rather than native code, preventing computations from being expressed that could violate security policy. The *Ombro Virtual Machine’s*² SVA-OS runtime support library—a thin layer of trusted native code provided by the SVA native code translator (i.e. the compiler; see Section 2.1) to implement the dynamic security checks required to safely implement the vISA on native hardware—runs alongside the hypervisor in this fully privileged mode, having been linked or inlined directly into the compiled hypervisor by the SVA native code translator. Software fault isolation (SFI) [50] (Section 2.2) and control flow integrity (CFI) [4] provided by SVA ensure that the hypervisor, despite running with full hardware privileges, cannot compromise the Ombro Virtual Machine or escape the vISA to run unrestricted native code.

Notably, Ombro does *not* require guest VM code (or host userspace application code for an OS-resident hypervisor) to be compiled to the SVA vISA. The hypervisor/host OS continues to employ standard x86 privilege isolation features (namely, privilege rings and VMX root/non-root modes) to isolate guest VMs and userspace applications from the hypervisor/kernel and each other, allowing guests and applications to run unmodified native code. Only the hypervisor/host kernel itself must be ported to the SVA vISA so that it can be safely controlled within the processor’s most privileged mode.

Section 5 presents the extensions and improvements we make to the Shade [34] version of the SVA vISA to support a full commodity hypervisor (Xen 4.12). Section 6 describes specific enhancements to the SVA design that are necessary to support multi-processor systems, addressing a weakness in prior SVA work. Section 7 presents a design that utilizes the SVA vISA to efficiently and soundly enforce return address

¹Our design supports any x86-64 hypervisor in principle, including those integrated with a host OS kernel; for concreteness, we focus on Xen in this work. In an OS-resident hypervisor, host userspace applications take the place of non-accelerated paravirtual guests in Ring 3 of VMX root mode.

²“Virtual machine” here refers to the language-theoretic sense of the term, not to the concept of a “guest virtual machine” provided by hypervisors. We aim to consistently use “guest VM” to refer to the latter throughout this work.

integrity on Xen to defend the hypervisor against advanced control-flow hijacking attacks.

Guest Virtualization Modes Supported. The Xen 4.12 hypervisor, for legacy reasons, supports a variety of operating modes for guest VMs on the x86-64 platform, which can be used simultaneously for different guests [54]. These represent a continuum of hardware acceleration usage and guest OS support, ranging from the traditional non-accelerated paravirtualization described in the original Xen paper [23] (referred to as “PV” mode in Xen’s documentation [54]), to VMX-accelerated full virtualization supporting native guests (“HVM” mode), to a modern paravirtual approach utilizing VMX acceleration with Xen-aware guests (“PVH” mode).

Because classic PV mode is being de-emphasized by the Xen project and likely to be phased out in the future [54], Ombro’s design only supports VMX-accelerated guests (i.e. HVM and PVH) and does not provide a complete set of intrinsics for the hypervisor to support PV guests running in usermode (host Ring 3). However, doing so would be a straightforward extension of the existing SVA vISA, which fully supports [14–16, 22, 34]) OS kernels with userspace applications in Ring 3. Our prototype (Section 8) does exactly this (in a limited way with some shortcuts) for implementation convenience. At times, we refer to PV concepts in design sections for the sake of clarity to readers familiar with Xen. They are not, however, relevant to our security design, as the design is intended for a modern Xen installation utilizing HVM/PVH for all guests including the control domain (*dom0*).

Terminology: Guest VMs, Domains, vCPUs, etc. SVA interfaces (following Intel’s convention) use the term “guest virtual machine” to refer to a singular guest CPU virtualized by a hypervisor. Each such guest CPU exists in one-to-one correspondence with a Virtual Machine Control Structure (VMCS) [30]. From the physical CPU’s and SVA’s perspective, it does not matter how the hypervisor may choose to group those virtual CPUs together. However, this distinction is important to Xen, which refers to the overall VM (which may include multiple emulated CPUs) as a “domain” and individual virtualized CPUs as “vCPUs”. Each vCPU thus corresponds to exactly one VMCS, and to one “guest VM” from SVA’s perspective. Xen performs context switches on a per-vCPU basis, not per-domain (different vCPUs from the same or different domains are context switched as independent entities), which is in line with Intel’s and SVA’s perspective. In this paper, we sometimes refer to “vCPUs” rather than “guest VMs” when this distinction is important.

5 vISA Additions and Improvements

Our experience porting Xen to the SVA vISA developed for Shade [34] led us to extend and improve upon the vISA, adding missing support for hardware virtualization elements used by Xen and mitigating disruptions to Xen’s performance and code structure. We describe these improvements below.

5.1 Securing Higher-Level VMX Features

The Intel VMX feature set is controlled primarily through control and state fields in a large (page-sized) in-memory, per-vCPU data structure called the Virtual Machine Control Structure (VMCS) [30]. Most VMX settings and subfeatures are controlled straightforwardly via individual VMCS fields or bits within a field consolidating similar controls. Some subfeatures, however, are more complex and are spread across multiple VMCS fields; some even utilize subsidiary control pages that the hypervisor must provide and link into the main VMCS by storing (host-)physical pointers into specific fields.

Shade’s vISA support for the VMCS (Section 2.3) is insufficient to manage multi-field controls and substructures because its `read/writevmcs` intrinsics operate on individual fields and cannot readily account for behavioral dependencies between them (e.g. fields activated by bits in other fields, or structure pointers that must be set prior to enabling a feature in a different field). Thus, Shade must err on the side of caution wherever invalid field combinations could lead to security holes or undefined behavior: it categorically blocks the hypervisor from writing to such fields and forces the features they control to be disabled or utilized in a hardcoded fashion preconfigured by the SVA runtime.

While this achieved Shade’s goal of ensuring security for the host system while supporting basic VMX functionality, it locks the hypervisor out of performance- and functionality-critical VMX features such as extended paging, interrupt controller (local APIC) virtualization, and MSR³ and I/O port virtualization. Shade provided higher-level intrinsics supporting extended paging by extending SVA’s existing support for vetting host page table updates [34] but did not attempt to design vISA support for APIC, MSR, or I/O port virtualization.

Ombro extends the design of the vISA to support APIC, MSR, and I/O port virtualization as first-class idioms; Table 1 summarizes the new intrinsics. As all three of these features entail both multi-VMCS-field dependencies and substructures linked into the VMCS (and APIC virtualization interacts with MSR virtualization), we address them via similar techniques.

MSR and I/O virtualization are the more straightforward of these to support. By default, VMX guests are blocked from accessing MSRs or performing port I/O (i.e., `rd/wrmsr` and port I/O instructions cause VM exits) [30]. When MSR or I/O virtualization is enabled in the VMCS, the processor will selectively allow guests to read or write particular MSRs or I/O ports based on whether their corresponding bits are set in the *MSR* and *I/O bitmaps*, which are substructures linked via host-physical pointers in the VMCS. This hardware design has multiple security implications in an SVA system.

Firstly, as MSRs control privileged processor features (including crucial security features like long mode and page-

³*Model-specific registers* (MSRs) are a class of indexed control and information registers used extensively in the x86 ISA to manage privileged processor features [30]. They have widely varying semantic and security implications and represent a substantial portion of the x86 ISA’s complexity.

Table 1: APIC, MSR, and I/O Virtualization Intrinsics

Name (Arguments)	Description
<code>vlapic.enable</code> (<code>paddr virtual_apic_page</code> , <code>paddr apic_access_page</code>)	Enable APIC virtualization for the active VM using the xAPIC (MMIO) interface
<code>vlapic.enable_x2apic</code> (<code>paddr virtual_apic_page</code>)	Enable APIC virtualization for the active VM using the x2APIC (MSR) interface.
<code>vlapic.disable</code>	Disable the currently active VM's local APIC (or use exit-based virtualization).
<code>posted.interrupts.enable</code> (<code>u8 vector</code> , <code>paddr descriptor</code>)	Enable posted interrupt processing for the currently active VM.
<code>posted.interrupts.disable</code>	Disable posted interrupt processing for the currently active VM.
<code>msr.intercept.{get,set,clear}</code> (<code>int vmid</code> , <code>u32 msr</code> , <code>enum rw</code>)	Get, set, or clear an MSR intercept for the specified VM.
<code>io.intercept.{get,set,clear}</code> (<code>int vmid</code> , <code>u16 port</code>)	Get, set, or clear an I/O port intercept for the specified VM.

level execute permissions [30]), the vISA cannot allow untrusted host software (e.g. the hypervisor or host kernel) to access them arbitrarily. Thus, neither of the `rdmsr` or `wrmsr` instructions are present in the SVA vISA; relevant processor features are managed through higher-level vISA idioms or controlled directly by SVA. A guest VM, however, can execute native (non-vISA) kernel-mode code; its access to MSRs is therefore constrained only by the MSR bitmaps. Therefore, it is necessary for Ombro to constrain the settings of the MSR bitmaps on a per-MSR level.

Secondly, the bitmaps themselves, being VMCS substructures addressed via raw host-physical pointers, would represent a security hole if the hypervisor were allowed to control them directly. A compromised hypervisor could configure the processor to use bitmap addresses corresponding to arbitrary physical memory, including SVA-protected pages (Section 2.2), allowing it to trick SVA into overwriting protected memory (since SVA must write to the bitmaps to ensure guests exit when accessing security-sensitive MSRs) or infer the contents of protected memory based on a guest's behavior.⁴

Ombro addresses these issues by allocating and taking ownership of the MSR and I/O bitmaps itself in protected memory, as it does with the VMCS (Section 2.3). The `msr_intercept.clear` intrinsic (Table 1) checks the provided MSR index against a whitelist of known-safe MSRs that guests can access without compromising Ombro's security policies. `io_intercept.clear` does not need to impose any restrictions under Ombro's threat model, as the only need is to prevent abuse of the bitmap substructure (per-port filtering is available for potential use under other threat models).

APIC virtualization (APICv) poses similar challenges but is more complex. Modern processors support both legacy *xAPIC mode* (in which the APIC is controlled via a memory-mapped I/O (MMIO) interface) and the newer *x2APIC mode* (which is controlled via MSRs) [30]. Traditionally, hypervisors would

⁴While Ombro's threat model (Section 3) does not require confidentiality of SVA-protected memory, other SVA-based systems such as Virtual Ghost [14] and Shade [34] do, making this a relevant design consideration.

configure VMX to force a VM exit on all APIC accesses, either via extended paging (for the xAPIC MMIO interface) or by configuring the MSR bitmaps to force exits for APIC-related MSRs (for x2APIC). This allows the hypervisor to fully emulate the APIC in software, but is slow.

APICv allows certain common APIC accesses by the guest to be virtualized in hardware without a VM exit. The hypervisor provides a *virtual-APIC page* in memory whose fields stand in for the real APIC's registers when a guest attempts to access them [30]. Guest reads to APIC registers via the MMIO (xAPIC) or MSR (x2APIC) interfaces see the values provided by the hypervisor in the virtual-APIC page. Guest APIC writes are virtualized by hardware without a VM exit in situations involving the task- and processor-priority registers, end-of-interrupt signaling, and self-IPIs; unvirtualizable writes are stored to the virtual-APIC page followed by a VM exit so the hypervisor can handle them conventionally.

Relatedly, *posted-interrupt processing* [30] allows a hypervisor to send interrupts to a guest running on a different processor without forcing that guest to VM exit. When a processor in guest mode receives a (real) inter-processor interrupt to a specified *notification vector*, it will (without exiting) check an in-memory *posted-interrupt descriptor* to see if one or more virtual interrupt records have been deposited within (e.g. by the hypervisor on the sending CPU), and if so, deliver them to the running guest through its virtual APIC.

Both features effectively map pages of host-physical memory into a guest's address space with (limited) write access, posing a clear security risk under our threat model, as this could be used to defeat SVA-protected memory (e.g. the return address stacks described in Section 7). Unlike with MSR and I/O port virtualization, it is not convenient to simply have Ombro take ownership of the virtual-APIC page and posted-interrupt descriptor in protected memory, as the hypervisor needs to frequently read and write to them for normal operation. Thus, to allow the hypervisor to safely control these pages, our APICv intrinsics (Table 1) check and record the VMCS's references to them in SVA's memory metadata tables (which track the usage of every 4-kB physical memory frame; see Sections 2.2 and 6.1) as if they were page mappings accessible to the hypervisor. The hypervisor is thus only allowed to use non-sensitive pages it "owns" as APICv VMCS substructures. Additionally, Ombro ensures that the vector used for posted-interrupt notifications does not overlap with any intercepted by SVA.

5.2 Guest Context Switching Optimizations

The x86 platform supports context switching of floating-point unit (FPU) state using the `XSAVE` and `XRSTOR` instructions [30]. These instructions save or load a processor's entire FPU state, as well as that of several non-FPU features such as vector and memory protection extensions, as a several-kB monolithic data structure; system software is thus architected to perform these slow operations as infrequently as possible.

Xen refrains from using the FPU during its own execution, leaving guest state untouched and allowing Xen to only perform `XSAVE/XRSTOR` when context switching from one guest vCPU to another.

Shade [34] took the straightforward but inefficient approach of context switching FPU state on every VM entry/exit. This provided a clean abstraction wherein no guest state is ever active on the processor in host mode or vice versa, but porting Xen to the SVA vISA for Ombro showed this to be a flawed design, yielding more than 200% overhead over baseline (non-SVA) Xen in our no-op hypercall (VM entry/exit) microbenchmark and unacceptably high overheads of up to 60% on VM-exit-heavy guest workloads (Section 10).

Ombro eliminates this source of overhead by extending the SVA vISA's existing *thread* abstraction, which can be context switched independently of processor privilege level transitions, to include guest VM (VMX non-root mode) state in addition to userspace host process (Ring 3) state as in prior SVA work [14, 16]. This better matches how real-world hypervisors like Xen model context switching and allows FPU state to be switched on vCPU context switches instead of requiring it on every VM entry/exit. Because slow-switching elements of the guest's state (the FPU, some MSRs, etc.) are thus active even while the system is in host mode, this provides a slightly less flexible programming model to the hypervisor than in Shade, but these limitations are non-issues in practice and can be worked around: Xen already avoids using the FPU in hypervisor context; an OS-integrated hypervisor would simply allocate separate SVA threads for guest VMs and host processes; and a hypervisor could free up the FPU for itself by context switching to a dummy SVA thread not associated with a guest VM or host process.

5.3 VMCS Management Optimizations

Ombro makes two additional improvements to the SVA vISA to eliminate overheads related to VMCS management induced in Xen by the Shade [34] design. The foremost of these is that, unlike the native ISA, Shade only permits a single VMCS to be loaded on a CPU at a time. The native ISA only permits one VMCS to be *active* at a time, but others need not be unloaded to load a new one [30], allowing them to remain cached by the hardware for future context switches. This distinction is crucial to performance; we found via an informal benchmark that modifying Xen to explicitly clear (flush) the outgoing VMCS in every context switch induces unacceptably high (over 4x) runtime overhead on guests when the machine's physical CPUs are oversubscribed (i.e., when vCPU context switches are frequent). Ombro addresses this limitation by loosening the vISA to allow multiple loaded VMCSes to coexist, relying on the mutex in the SVA thread structure (Sections 5.2 and 6.1) to ensure a VMCS cannot be loaded on multiple CPUs at once (which is undefined behavior in the native ISA [30]).

The second improvement changes VMCS initialization (the `allocvm` intrinsic) to provide benign defaults for all security-sensitive VMCS and guest state fields rather than requiring the hypervisor to specify them up-front. While VMCS construction is not performance-critical for Xen, it occurs early in vCPU creation before Xen has determined most of the guest's initial state, making it awkward to port Xen to use Shade's interface. Ombro's interface is more general and agnostic to hypervisor design choices.

6 SMP Support in SVA

Ombro adds symmetric multiprocessing (SMP) support to SVA that all previous SVA systems [13–16, 21, 22, 34] lacked. This required several changes to the internal design of the SVA runtime library to make it thread-safe and to add support for multi-processor TLB coherency. However, we made *no* changes to the outward-facing SVA-OS virtual instruction set; the original design [15–17] proved general enough to be applicable to both uni- and multi-processor systems.

6.1 Thread Safety and Reference Counting

SVA maintains several data structures in its internal protected memory (Section 2.2) to track system state that it maintains on behalf of the hypervisor/OS kernel and to ensure that its intrinsics are not used to configure the system in a way that could undermine other security protections. These include thread structures used for context switching host processes [16] and guest vCPUs (Section 5.2) and a table tracking typed references to each physical memory frame to prevent host-kernel-mode software from using its control over the MMU to evade SVA's memory protections or code integrity enforcement [15].

As these structures must be thread-safe in a multi-processor system, Ombro adds locking to SVA's thread structures and to each entry in the frame usage table. Intrinsic calls attempting to load or save a thread or to change a frame's usage type must obtain the relevant lock to prevent races. Incrementing/decrementing a frame's reference count in the table when a page mapping is updated is a lock-free operation utilizing an atomic compare-exchange loop to perform the update while checking for integer overflow/underflow.

Additionally, Ombro expands the frame reference counts themselves to separately count read-only and writable page mappings to each frame. Prior SVA work [15, 22, 34] did not allow system software to create *any* mappings to SVA-protected frames even when they only require tamper-protection and not confidentiality (e.g. kernel code or page tables). This required ad-hoc (and OS-specific) handling in SVA of special cases like the kernel's direct map and read access to page tables. Ombro allows these to be handled through ordinary intrinsic calls, making SVA more system-agnostic and allowing Xen to continue supporting non-VMX PV guests under Ombro.

6.2 TLB Shootdowns

In an SVA system, physical memory frames used for security-sensitive purposes such as page-table pages, host-kernel-mode code, or SFI-protected memory (e.g. return address stacks in Ombro—see Section 7) are tracked by SVA so it can prevent system software from mapping them into the virtual address space with inappropriate permissions or outside the SFI-protected region [14, 15, 22]. To prevent use-after-free attacks based on stale TLB entries, SVA flushes the TLB whenever a frame’s usage type changes and one or both of the types involved are security-sensitive (because x86 does not support selective TLB flushes based on physical addresses [30], a full TLB flush must be used).

On multiprocessor systems, this TLB flush must include *all* processors, necessitating *TLB shootdowns*. Ombro implements this by broadcasting an inter-processor interrupt (IPI) [30] to all processors at a reserved interrupt vector, which is received by an SVA handler that performs each local TLB flush. The processor initiating the shutdown will not release its lock on the frame’s usage type until all other processors have acknowledged completion of the flush, ensuring that software cannot create a conflicting mapping based on the new type that would violate security policy.

7 Return Address Integrity

To defend against advanced control-flow hijacking attacks as described in our threat model (Section 3), Ombro must protect the integrity of return and return-from-interrupt addresses in Xen. We address this by using the vISA primitives provided by SVA to implement a *split stack* in Xen, where return addresses are stored on one stack (called the *control stack*) while local variables are stored on a separate stack (called the *data stack*). The control stack is protected against tampering using SVA’s kernel-mode memory protection mechanism (Section 2.2), while memory writes utilizing dynamic pointers or offsets that could be controlled by an attacker are only permitted to access the data stack in ordinary (unprotected) Xen memory.

7.1 Security Guarantees

Ombro ensures return address integrity (all functions return control flow to their dynamic callers) by enforcing the following invariants on the hypervisor at runtime:

Invariant 1. *Function calls always save the return address on the control stack, or do not save any return address (e.g. tail calls).*

Invariant 2. *Returns will always retrieve the return address from the correct location on the control stack, i.e. into which the return address was saved by the matching dynamic caller.*

Invariant 3. *Control stacks cannot be corrupted by any code outside of trusted SVA-OS intrinsics, even when memory safety errors are exploited.*

Invariant 4. *System software cannot use an SVA-OS intrinsic to tamper with a control stack’s contents or a control stack pointer on its behalf.*

7.2 Enforcement Design

In a split stack design, the control and data stack are tracked by separate stack pointers that can be incremented and decremented independently [10, 59]. In Ombro, we use the native x86 stack pointer register, `RSP`, for the control stack, so that call and return instructions naturally use the control stack for return addresses. This maintains Invariant 1 and contributes to Invariant 2. The data stack is tracked by a free general-purpose register reserved from the callee-saved set (`R15` in our prototype). The compiler is modified accordingly to facilitate this; function prologues and epilogues create and destroy stack frames using the data stack pointer, leaving the control stack pointer to be adjusted only by the return-address pushes and pops performed by call and return instructions.

Call and return instructions are the only ones permitted to modify the control stack pointer `RSP` outside of SVA-OS intrinsics. They always respectively decrement or increment `RSP` by exactly 8 bytes (the Ombro compiler will not emit returns that pop additional values off the stack), ensuring that only the relevant return address is affected. No other data is stored on the control stack besides the single return address pushed by each call and popped by the corresponding return; the data stack is used for local variables, argument passing, and callee-saved registers. As forward-edge CFI prevents functions being entered except through a call (non-tail-call jumps can only target another location within the current function), calls and returns are guaranteed to occur in correctly nested (matching) order. Hence Invariant 2 is ensured.

Because calls and returns occur in nested order, underflow of the control stack pointer cannot occur. Overflow is addressed by placing a guard page at the end of each control stack; guard pages are marked as invalid in the page tables, ensuring that any attempt to read or write beyond the space allocated for a control stack will be intercepted and prevented by an SVA fault handler.

Ombro instruments all host-Ring-0 code outside of SVA-OS intrinsic implementations with SFI checks on memory stores (Section 2.2), ensuring that any attempts to write to a protected virtual address region will be caught and prevented. SVA’s enforcement of code segment integrity (Section 2.1) in conjunction with forward-edge CFI [13, 22] ensures that these SFI checks cannot be bypassed even in the presence of memory safety errors. The control stack is allocated within the SFI-protected virtual address region by SVA on Xen’s behalf. Only call and return instructions are exempted from SFI checks (so that they can access the control stack as intended); these are generated by the compiler such that they always access the stack using a predictable static offset from `RSP`, so they cannot be used to access any other location in service of an exploit. Hence Invariant 3 is ensured.

The SVA vISA provides no means for system software to set or adjust the host-Ring-0 control stack pointer `RSP`, or to write to any location on a control stack, except pushing/popping from it via calls and returns. SVA allocates a control stack for each CPU (Xen allocates hypervisor stacks on a per-physical-CPU basis) and points `RSP` to it as a side effect of SVA’s boot-time per-CPU initialization; thereafter, SVA maintains the integrity of `RSP` across all intrinsic calls, context switches, and VM entry/exit. Per our threat model (Section 3), the hypervisor is considered benign prior to exploitation by a memory safety error; SVA initialization occurs during early boot before significant attack surfaces become available (there is no network yet, nor have any guest VMs been started, including the `dom0` control domain). The SVA-OS intrinsic implementations themselves are part of the trusted computing base and thus assumed to correctly implement the vISA, ensuring that Invariant 4 is upheld after initialization.

8 Implementation

The prototype we built to evaluate Ombro is based on source code for the SVA-OS runtime support library (see Section 2.1, Figure 1, and Section 4) inherited from the Shade [34] project and other previous SVA work [14–16, 22]. We significantly modernized and refactored the codebase to address limitations of prior work, which included adding multi-processor support and overhauling the page reference tracking system to be more flexible (Section 6). Overall, we improved the code to be substantially less fragile and more maintainable, and generalized aspects of the code that were specific to using SVA with OS kernels (and FreeBSD in particular), such that it could support a bare-metal hypervisor like Xen while retaining support for OS kernels (including those with integrated hypervisors). We upgraded SVA to be based on the LLVM 10.0.0 compiler [2] instead of LLVM 3.1 as in Shade [34] and prior work. In parallel, we ported the x86-64 implementation of Xen 4.12 [3] to target Ombro’s version of the SVA vISA, linking it at compile time with the SVA-OS runtime support library (as in prior SVA work).

Our software trusted computing base (TCB) relative to our threat model (Section 3) consists of the SVA runtime library (11,453 lines of code (LOC)), our CFI and SFI passes added to the LLVM compiler (792 LOC), and non-pass modifications to LLVM implementing our split stack transformation (497 LOC added/changed), totaling 12,742 LOC.⁵

Porting Xen 4.12 to the SVA vISA and supporting Ombro’s split stack transformation entailed adding/changing $\leq 3,389$ LOC⁶ (out of 313,377 total in Xen—about 1%), mostly in low-level code dealing with page tables, VM entry/exit, VMCSes,

⁵We counted non-comment/whitespace lines using `sloccount` [52] for the SVA library and passes and manually from `git diff`s for the rest.

⁶Most changes are gated behind `#ifdefs`, leaving the original code in place; we took the difference between vanilla Xen and the Ombro port using `sloccount` and added twice the number of removed lines from `git diff` as an upper bound on the undercount.

and system boot. By comparison, prior work’s port of Linux 2.4.22 to SVA [16] modified 5,066 LOC out of 632,469 total (0.8%). This shows that the difficulty of an SVA port scales roughly but not exactly with the scope of the system.

As Section 4 describes, Ombro’s security design assumes that all domains are used only in VMX-accelerated modes (HVM and PVH), but our prototype retains partial support for classic PV mode. Although Xen 4.12 supports a PVH `dom0`, we found it useful to use a PV `dom0` in order to have a working, debuggable environment while porting VMX-related components to SVA, as the `dom0` is responsible for controlling Xen and providing hardware drivers. We did not attempt to fully port Xen’s PV code to SVA, leaving some native assembly and unsafe (to our threat model, not Xen’s) workarounds in place, though this could be completed with a little extra work and minor enhancements to the SVA vISA. Since we benchmarked (Section 10) within a PVH `domU`, we do not expect significant performance differences between a PV and PVH `dom0`, especially since we used the same configuration for both Ombro and baseline Xen.

Further Implementation Experience Discussion. Some readers may be interested in further discussion of our experience porting Xen to the SVA vISA and how that experience, as well as our incremental performance evaluations throughout, fed back into our design process and motivated specific design changes. For reasons of space, that discussion is deferred to Appendix B.

9 Security Analysis

Prior work [7, 8, 18, 25, 27] has shown that defenses relying on CFI [4] to mitigate memory safety attacks must *prevent* the corruption of return addresses in order to repel advanced control-flow hijacking attacks, as static determination of the call sites to which control flow may return leaves sufficient loopholes for an attacker to perform arbitrary computation [8]. To this end, Ombro implements a split control/data stack in Xen (Section 7) and uses SVA’s SFI-based kernel-mode memory protection facility (Section 2.2) to protect the control stack (and hence return addresses) from tampering.

Zhou et al. [58] proposed a framework for evaluating the attack surface exposed by a security policy providing return-address protection, drawing from Göktaş et al.’s [27] taxonomy classifying the different types of control-flow “gadgets” that can be used by an attacker to assemble a code-reuse attack in the presence of CFI. *Call-site* (CS) gadgets begin at a return point following a call instruction, and *Entry-point* (EP) gadgets begin at the entry point to a function. Orthogonally, they classify the methods by which gadgets can be linked together to form a “chain” useful for computation: by corrupting return addresses on the stack (*return-oriented programming*), indirect jump targets (*jump-oriented programming*), or function pointers (*call-oriented programming*). Depending on the CFI policy in effect and the availability of gadgets in the target

program, it may be possible and/or necessary to mix different gadget types and chaining methods to achieve a practical chain. Pure call-oriented programming, in which only function pointers are manipulated to link gadgets, turns out to be difficult or impractical to achieve in many cases, particularly in scenarios where it is not possible for the attacker to repeatedly exploit memory safety errors; return- or jump-oriented gadget linking must typically be used to perform initial setup before the attacker can pivot to a call-oriented chain [7, 27].

Because Ombro’s split stack design prevents any corruption of Xen’s control stack (which includes return as well as return-from-interrupt addresses), return-oriented gadget linking is categorically precluded. Additionally, the SVA vISA does not include LLVM’s indirect jump (`indirectbr`) instruction and does not need it to support Xen, the Linux kernel [16], or the FreeBSD kernel [13, 14]. Thus, jump-oriented gadget linking is precluded. Cumulatively, this severely limits the ability of an attacker to assemble a useful gadget chain, particularly in single-exploit scenarios, as only call-oriented chaining is possible. That, in turn, is further limited by Ombro’s forward-edge CFI protection.

Ombro’s label-based forward-edge CFI scheme is based on that of KCoFI [13]; it is relatively coarse-grained, allowing indirect calls to target any valid function entry point (but nowhere else). Since the protected control stack already prevents return-oriented gadget chaining, and the prohibition of `indirectbr` prevents jump-oriented chaining, the net effect of adding this forward-edge CFI enforcement is to limit an attacker to a restricted form of pure call-oriented programming: only entry-point (EP) gadgets can be used and they can only be chained together via corrupted function pointers.

Ombro may be susceptible to the pure-call-oriented “Control Jujutsu” attack described by Evans et al. [25], who showed that, in popular programs, common function pointer coding patterns make it possible to assemble purely call-oriented chains of EP gadgets even when return addresses are fully protected and strong static analysis is used to limit forward-edge control flow transfers to those intended by normal program operation. Specifically, they noticed that this was possible in Apache and Nginx due to extensive use of function pointers to provide C++-style runtime polymorphism in C, which exacerbates the lack of context-sensitivity in static (label-based) CFI. We observe that Xen frequently utilizes similar code patterns, using function pointers to delegate at runtime to method implementations specific to particular virtualization modes, hardware capabilities, etc. Hence, similar attacks might be possible against Xen protected by Ombro. It is unclear, however, whether such attacks can work in practice against a bare-metal hypervisor like Xen. Evans et al. relied on the proliferation of arbitrary-code-execution system calls such as `system()` and `execve()` to invoke a shell rather than attempting to achieve arbitrary computation through code reuse alone; these elements do not exist in Xen, and similarly desirable functionality from an attacker’s perspective (e.g.,

giving the attacker’s domain *dom0* privileges or mapping a victim domain’s memory into the attacker’s) is not necessarily invoked from as many places in the codebase.

Although our prototype implementation only restricts indirect calls to calling any valid function, it would be straightforward to extend our label-based CFI approach to utilize a more precise control flow graph based on more advanced static analysis. Because Xen is a monolithic executable and does not support run-time module loading, whole-program analysis could be used to identify functions that are never address-taken (i.e. never indirectly called) and refrain from emitting CFI labels for them, eliminating them as viable targets for gadget chaining. While such functions might be reachable “downstream” of other functions that *are* called indirectly, this could make return-to-library [49] and similar short-chain code-reuse attacks more difficult, furthering the goal of making it difficult to reach functionality of ultimate interest to an attacker. (Most indirectly-called functions in Xen are focused on low-level platform-specific and scheduling-related functionality, and do not interact directly with code manipulating sensitive high-level fields such as access controls.)

Since it is built using SVA, Ombro prevents many attacks (such as code injection) even if an attacker successfully diverts control flow. Because SVA prevents tampering with host-kernel-mode code pages (i.e. Xen or SVA code) to ensure that all privileged code is compiled with the trusted vISA translator (Section 2.1), it is impossible for an attacker to pivot from code reuse to a more flexible code-injection attack, which is typically the goal of code-reuse payloads in practice [27, 35]; attackers must perform *all* malicious computation via code reuse. While ROP “compilers” do exist (e.g. [48]), they are incapable of compiling complex high-level payloads, particularly for the restrictive code-reuse modalities necessary to defeat Ombro’s CFI. This effectively limits attackers to non-control data and data-oriented programming (DOP) attacks, which are outside our threat model’s scope (Section 3). DOP could also face practical headwinds similar to Control Jujutsu.

10 Performance Evaluation

To evaluate Ombro’s performance, we selected a portfolio of real-world application macrobenchmarks (Section 10.1) that we believe are reflective of typical cloud workloads. We used the Phoronix Test Suite’s `pts/kernel` suite [40, 44] as a starting point, with the following adjustments:

- We excluded benchmarks that failed to compile or run on our test system running unmodified Xen (see system details below). We used a more recent version (2.4.48) of the Apache benchmark rather than exclude it due to its real-world importance and use by related work [41].
- Because the full `pts/kernel` suite takes days to run and includes numerous configurations of the same applications with minor differences, we ran a single configuration of

each application, selecting the longest-running one that completed in less than five minutes. Our full suite runs in approximately three hours. Phoronix runs each benchmark at least three times and until the standard deviation of all runs is less than 3.5% or a benchmark-specific cut-off threshold is met; the result reported for each benchmark is the (arithmetic) mean of these runs [45].

- We chose to add a Memcached benchmark (v1.6.9, also from Phoronix) because it is used by related work [41] and represents a stress test for Ombro’s overheads. We used the “Get” configuration with four connections.

We also developed and ran microbenchmarks (Section 10.2) for hypercall latency (VM entry/exit), EPT fault handling, and inter-processor interrupts (IPIs); our selection of microbenchmarks parallels related work [41].

For all of our experiments, we used a Dell Precision 7820 workstation with an Intel Xeon Silver 4208 (Cascade Lake) CPU (8 cores/16 threads at 2.10 GHz with 11 MB L3 cache) [11], 32 GB 2666 MHz DDR4 memory, a 256 GB M.2 NVMe SSD, and a 2 TB SATA 7200 RPM hard drive. All disk I/O for the experiments used the SSD (the hard drive was unused); the *dom0* (control VM) had direct access to the SSD and the *domU* (guest VM)’s virtual disk was directly backed by a physical partition (not a file-based disk image).

For our baseline, we ran unmodified (“vanilla”) Xen 4.12 with an Arch Linux (kernel 5.15.12-arch1-1, packages updated 2022-01-04⁷) *dom0* running in PV (traditional paravirtualization) mode. The benchmarks ran within a *domU* running the same Linux distribution in PVH (VMX-accelerated with paravirtual optimizations) mode. The *domU* was allocated 16 vCPUs and 24 GB of RAM. We used GCC 11.1.0 to compile the benchmark applications. We disabled Spectre [37] mitigations such as IBRS [30] for all benchmark runs to provide a fair comparison, since our prototype did not implement them (for reasons of time). We likewise enabled eager FPU saving in vanilla Xen as Ombro saves FPU state on every vCPU context switch (Section 5.2).

We evaluated Ombro using the implementation described in Section 8, i.e., Xen 4.12 ported to the SVA vISA and compiled with CFI, SFI, and split-stack transformations. All other configurations were the same as for the baseline.

10.1 Macrobenchmark Results

Table 2 summarizes our macrobenchmark results comparing baseline unmodified Xen (labeled “vanilla”) with Ombro. As Table 2 shows, Ombro incurs no detectable overheads (differences are within or close to noise margins) on most benchmarks, even though we selected a predominantly I/O-intensive (i.e. challenging to virtualize) benchmark set. Several exceptions, particularly Memcached, RocksDB, and LevelDB, are discussed further in Section 10.3 and Appendix A.1.

⁷Arch Linux is a “rolling” distribution without versioned releases, so the package date stands in lieu of a version number.

Table 2: Macrobenchmark Results

Benchmark	Units (↑↓ is better)	Vanilla		Ombro	
		Result	Std. Dev.	Ovhd.	Std. Dev.
PostgreSQL	TPS ↑	4266.496	26.7%	-17.84%	18.5%
PostgreSQL	ms (avg. lat.) ↓	61.644	21.0%	-16.72%	18.9%
MBW	MiB/s ↑	6694.581	0.3%	-2.88%	0.1%
BenchmarkMutex	ns ↓	39.967	0.9%	-0.67%	0.0%
PostMark	TPS ↑	4335.000	1.0%	-0.58%	1.0%
pmbench	μs ↓	0.113	4.5%	-0.55%	4.2%
OSBench (Create Files)	μs/event ↓	24.270	0.3%	-0.07%	0.8%
ctx_clock	clocks ↓	240.000	0.0%	0.00%	0.0%
OpenSSL (RSA 4096)	signs/s ↑	1516.867	0.3%	0.05%	0.2%
StressNG (RdRand)	bogo ops/s ↑	250298.447	0.0%	0.06%	0.0%
Apache	req/s	212698.913	0.4%	0.34%	0.1%
t-test1	s ↓	23.587	0.9%	0.75%	0.6%
iPerf (TCP)	Mbits/s ↑	28029.667	2.3%	0.75%	1.1%
SQLite	s ↓	83.164	0.8%	1.06%	0.7%
Hackbench	s ↓	140.056	0.8%	4.53%	1.8%
Schbench	μs ↓	18762.667	0.7%	4.59%	8.0%
IPC (TCP Socket)	messages/s ↑	473697.400	13.3%	4.63%	12.1%
LevelDB	μs/op ↓	428.367	0.1%	12.62%	0.3%
RocksDB	ops/s ↑	34557.667	0.1%	12.82%	0.3%
Memcached	ops/s ↑	46960.733	0.2%	21.81%	2.1%
Geometric mean				0.87%	

Table 3: Microbenchmark Results (TSC cycles)

Benchmark	Vanilla		Ombro		
	Cycles	Std. Dev.	Cycles	Std. Dev.	Ovhd.
No-op hypercall	750	18.5%	1465	14.2%	95%
EPT fault	4180	10.0%	5693	8.88%	36%
vCPU self-IPI	1731	12.9%	2353	14.6%	36%
IPI (vCPU→vCPU)	2966	14.6%	3531	14.4%	19%

We also ran our benchmarks with Ombro’s split stack, CFI, and SFI transforms disabled to determine if Ombro’s security instrumentation contributes significant performance overhead. Our results show no discernible difference, i.e., nearly all of Ombro’s overhead comes from the vISA itself, not the instrumentation. Appendix A.2 contains detailed results.

10.2 Microbenchmarks

Table 3 summarizes our microbenchmark results for key hypervisor operations. We ran 2²⁸ timed iterations of each benchmark (reporting the arithmetic mean) after 2¹² untimed warmup iterations. Results are in hardware timestamp counter (TSC) cycles measured using the `rdtsc` instruction (with Xen’s `rdtsc` interception disabled) before and after the operation (or sending/receiving on the respective CPUs for IPIs; our processor synchronizes the TSC across cores [30]).

Each microbenchmark includes a VM entry/exit cycle, which is minimally exercised by the no-op hypercall benchmark. Ombro’s base hypercall overhead is substantially greater than the overhead of more complex operations, which are themselves greater than our macrobenchmark overheads in Section 10.1. This indicates that VM entry/exit is the primary source of Ombro’s overhead. Since hardware acceleration is designed to make VM exits relatively rare, Ombro’s overhead only substantially impacts difficult-to-virtualize workloads that incur frequent VM exits.

10.3 Overhead Sources and Their Remedies

Prior work [41] illustrated that Memcached’s performance is highly sensitive to changes in VM entry/exit latency be-

cause it is frequently bottlenecked by the need to send inter-processor interrupts (IPIs) between guest vCPUs, e.g. by Linux’s implementation of the `futex()` system call. IPIs are efficient on a “bare-metal” (unvirtualized) system but expensive to virtualize because hypervisors cannot safely expose the interrupt controller (local APIC) to guests, requiring a VM exit to virtualize the APIC in software whenever an IPI is to be sent. Although VMX currently provides exit-free hardware-virtualized *delivery* of virtual interrupts (Section 5.1), the *sending* of them is not yet virtualized, making this a major pain point for virtualizing popular applications like Memcached. Besides Memcached, our RocksDB and LevelDB benchmarks are of a similar nature (multi-threaded in-memory databases) and exhibit the same sensitivity.

To confirm our hypothesis that Ombro’s overheads come almost exclusively from VM entry/exit overheads (Section 10.2) and that this is responsible for our three macrobenchmark outliers, we conducted an informal experiment where we modified vanilla Xen to add artificial (busy-wait) overhead after each VM exit. With this modification, vanilla Xen’s macrobenchmark results closely matched those of Ombro (the same benchmarks showed similar slowdowns).

We conclude, therefore, that Ombro’s overheads on these outliers are not of great concern, as the IPI virtualization problem is shared with vanilla Xen (and x86 virtualization in general). We explore this further in Appendix A.1, where we compare vanilla Xen with a bare-metal (unvirtualized) system; we observe that baseline Xen’s overheads on Memcached, RocksDB, and LevelDB (and others) far outweigh the additional impact of Ombro on Xen. We note also that Intel has announced plans to introduce hardware-accelerated *IPI virtualization* in future processors [12] to address this issue; we expect this will eliminate Ombro’s overheads on these workloads as it will eliminate the underlying VM exits.

As Appendix A.2 details, none of Ombro’s effective overhead is attributable to its compile-time security instrumentation (split stack, CFI, and SFI). This bodes well for the prospects of using the SVA approach and infrastructure to implement stronger security hardening, such as full memory safety [20, 43, 57], on hypervisors, as hypervisor execution evidently does not represent a sufficient fraction of system run-time to make instrumentation on it costly in absolute terms.

11 Related Work

Compiler-based virtual machines decouple the instruction set used to express computation from the instruction set implemented by the hardware. Ombro builds directly upon prior work with the Low Level Virtual Architecture [5, 17] and Secure Virtual Architecture [16], described in Section 2.

Previous work has enforced CFI and/or return address integrity on systems code, but none have enforced return address integrity for hypervisors. KCoFI [13] and KCFI [26] enforce control flow integrity on OS kernel code but do not provide return address integrity. Silhouette [58] provides CFI and a

protected shadow stack for application code running in privileged mode on embedded systems and inspired our attack surface analysis (Section 9). Kage [24] uses compiler-based techniques similar to Ombro’s to provide CFI and a protected shadow stack for an embedded real-time OS while splitting the kernel into trusted and untrusted layers. IskiOS [28] provides a protected shadow stack for the Linux kernel by utilizing Intel’s Memory Protection Keys feature [30] but does not enforce it on hypervisor code. Ombro could incorporate IskiOS’s technique in lieu of SVA’s MPX-based SFI enforcement option if Intel deprecates MPX as planned [31].

HyperSafe [51] enforces control flow integrity on hypervisor code and controls how the hypervisor configures the MMU to prevent attackers from corrupting page tables, hypervisor code pages, or CFI labels. Unlike Ombro, it does not provide return address integrity and is therefore susceptible to advanced ROP attacks [7, 8, 18, 27]. The HyperSafe authors designed and evaluated a shadow stack variant in conjunction with their CFI scheme but found it to have high overhead (over 300%) due to its reliance on the x86 platform’s WP bit as an isolation mechanism [51]. In contrast, Ombro’s use of SFI for kernel-mode isolation provides efficient control stack protection. HyperSafe also does not appear to constrain VMX features (e.g., by protecting the VMCS) whereas Ombro does.

Whole-VM trusted execution environments (TEEs) that protect guest VMs from compromised hypervisors, such as CloudVisor [41, 56], H-SVM [32, 33], and HyperCoffer [55], are an orthogonal approach to hardening the hypervisor itself against attack. Ombro’s SVA-based VISC approach could readily lend itself to implementation of a whole-VM TEE using SFI and vISA restrictions in lieu of the hardware-based isolation mechanisms used by prior work, similar to Virtual Ghost’s [14] and Apparition’s [22] approach for OS kernels. In such a system, a whole-VM TEE could be *combined* with Ombro-style hypervisor hardening for additional defense-in-depth with (we believe) minimal cumulative overhead.

12 Future Work and Conclusions

Several interesting directions for future work exist. We can explore additional security policies that SVA-based systems could enforce on hypervisor code, such as code pointer integrity [38] and memory safety [20, 43, 57]. We can also explore replacing hardware-enforced security enforcement and isolation with compiler instrumentation techniques. For example, we could explore whether compiler-based enforcement could allow us to create hypervisors with isolated components as previous work [53] does using hardware isolation features.

In conclusion, we have expanded the SVA vISA and ported the Xen hypervisor to it, have used the vISA to implement the first protected shadow (split) stack for a hypervisor, and have demonstrated its efficiency on real-world benchmarks.

We thank the anonymous reviewers and shepherd for their helpful feedback. This work was supported by NSF grant CNS-1629770 and ONR award N00014-17-1-2996.

A Additional Benchmarks

In this appendix, we provide results and discussion of additional benchmarks that we conducted in order to shed light on the main results presented in Section 10. We did not include these results in the main body of the paper because they either served to demonstrate existing issues known from prior work that we do not claim as novel results, or presented no statistically significant contrast and thus could be summarized adequately in the main text without detailed results.

A.1 Unmodified Xen vs. Unvirtualized

In Section 10.1, we observed that a few benchmarks from our subset of the Phoronix suite, particularly Memcached, RocksDB, and LevelDB, exhibited non-negligible overheads (unlike most of our macrobenchmarks) under Ombro as compared to baseline (“vanilla”) Xen. Through further experimentation (Section 10.2) and reference to existing literature in the field [41], we were able to conclude (Section 10.3) that the primary cause of these particular benchmarks’ poor behavior was likely due to the fact that they frequently send inter-processor interrupts (IPIs) to communicate between threads running on different virtual CPUs (vCPUs), which on current Intel processors requires taking a VM exit [12, 30].

As VM exits are expensive (slow) operations for hypervisors to handle due to the substantial amount of processor state that must be saved and loaded during a world switch, hypervisor and hardware design generally tries to make them infrequent as a share of total execution time. Workloads that do not make that possible (such as these problematic benchmarks) can therefore expect to incur substantial overheads simply from being virtualized in the first place.

To illustrate this issue, we re-ran our macrobenchmark suite (Section 10.1) on our test machine in a “bare-metal” (i.e. unvirtualized) configuration and compared the results to that of vanilla Xen, as shown in Table 4. For consistency with our main results, vanilla Xen is retained as the baseline, with the bare-metal results compared to it, yielding negative “overheads”, i.e. speedups, for bare metal. As can be seen, the benchmarks that showed non-negligible overheads under Ombro in Section 10.1 all run substantially faster on bare metal than under vanilla Xen, the difference between the two being far greater in magnitude than the difference between Ombro and vanilla Xen. In fact, most of the benchmarks, including the ones to which Ombro added no or negligible overhead over vanilla Xen, show significant gaps between unvirtualized and virtualized execution.

Our methodology for the bare-metal benchmark runs was to boot a copy of the same Linux installation used for the *domU* (unprivileged guest domain) in Xen-based benchmark runs directly from the system bootloader instead of through Xen. As it is the same system except for the addition of a few driver packages needed to support running on physical hardware, this minimizes differences between the configurations,

but the comparison is nonetheless imperfect: the bare-metal runs had access to the system’s full 32 GB of RAM, whereas the Xen-based runs were limited to 24 GB in the *domU*, as we needed to leave some of the system’s memory for Xen and the *dom0*. This, as well as effects such as the difference between virtualized and unvirtualized disk I/O, could potentially amplify the difference measured between vanilla Xen and bare metal. We therefore do not attempt to draw strong quantitative conclusions from the detailed results of this comparison and suffice to note qualitatively that the outliers in our Ombro benchmarks are clearly especially difficult cases for vanilla Xen as well. This is consistent with the conclusions of prior work [41] and the fact that Intel is planning to introduce *IPI virtualization* to future processors so that workloads such as these no longer need to incur frequent VM exits [12].

A.2 Ombro without Instrumentation

As part of our performance evaluation (Section 10), we wished to measure whether Ombro’s control flow integrity (CFI), software fault isolation (SFI), and split stack transformations had measurable impacts on performance. This would allow us to separate overheads due to instrumentation from those incurred simply by porting Xen to the SVA virtual instruction set (vISA).

To this end, we set a flag in the compiler that instructed it to not add CFI and SFI checks to the generated code or to perform the split stack transformation when building Xen in the Ombro configuration. This results in a build of Ombro which does not have functional hardening protections beyond vanilla Xen but still uses SVA intrinsics rather than native assembly to perform low-level operations. Thus, it measures any overheads from extra data copying or code indirection entailed by routing through the virtual instructions as well as the overheads of any runtime security checks performed by the intrinsics themselves.

We ran our macrobenchmark suite on this “no-instrumentation” build of Ombro/Xen and compared it with vanilla Xen, as summarized in Table 5. As in Appendix A.1, we use vanilla Xen as our baseline for consistency with our main results in Section 10.1. The overheads listed for “Ombro without instrumentation” can therefore be compared head-to-head with the “Ombro” numbers in Section 10.1.

As can be seen, the results for Ombro without instrumentation do not exhibit a clear contrast from the Ombro results in Section 10.1 that rises above the noise floor. (In fact, the geometric mean for Ombro without instrumentation shows *higher* overhead than ordinary Ombro, which can be clearly attributed to experimental noise given the high standard deviations on the benchmarks that turned out the most favorably for ordinary Ombro, particularly the PostgreSQL benchmarks.) We therefore conclude that the CFI and SFI instrumentation and the split stack transformation add no measurable overhead to the “core” vISA port. This makes sense in light of our conclusion from Sections 10.2 and 10.3 that Ombro’s overheads

are driven primarily by an increase in VM entry/exit latency, not by overheads on Xen’s own execution (e.g. scheduling and VM-exit handling such as hardware emulation).

The observation that CFI, SFI, and split-stack enforcement on Xen do not measurably impact overall performance indicates that Ombro’s increased VM entry/exit latency is coming from the extra data copying and operations performed by SVA’s implementation of VM entry/exit, rather than from Xen itself being slowed down by the compile-time security transformations. As our Ombro benchmarks were conducted with SVA’s standard bitmasking SFI implementation selected (Section 2.2) instead of the optional MPX-accelerated SFI implementation from Apparition [22] (which is in principle faster), this leads to a secondary conclusion that optimizing SVA’s CFI and SFI instrumentation is neither necessary nor worthwhile for Ombro, even though it has been for past SVA-based systems.

B Implementation and Porting Experience

Section 8 describes our prototype implementation of Ombro (i.e. the SVA compiler and runtime library plus our port of the Xen hypervisor to the SVA vISA) as used in our performance evaluation (Section 10). However, as the construction of this prototype represents a great deal of the work involved in this project, this appendix discusses that experience further for the benefit of interested readers. We discuss practical observations from the experience of building the prototype (B.1) as well as how our observations of the prototype’s performance fed back into the design process (B.2).

B.1 Engineering Observations

The process of porting Xen to SVA took two programmers (a PhD student and a research programmer) roughly two years to complete. This includes the substantial infrastructural improvements to SVA described in Section 8; qualitatively, we improved SVA from a minimally functional research prototype (previous SVA systems could not even run large-scale applications like the Apache web server without crashing) to one that, while perhaps not “production-grade”, can confidently run a complete Xen system with multiple guests hosting a full spectrum of complex end-user applications. These include a fully working MATE desktop GUI under the Ubuntu-based Linux Mint and a Wayland-based window manager (Sway) under Arch Linux (we used Arch for our benchmarks but exercised both distributions heavily during development); web browsers like Firefox and Chrome; development tools like Clang and GCC; and a full Phoronix suite of kernel-intensive real-world macrobenchmarks (Section 10). Notably, we did not need to exclude *any* benchmarks for lack of compatibility with Ombro, although a few failed to compile on the unmodified baseline system, likely due to the system compiler being too new.

We expect that, particularly with these SVA infrastructure improvements in place, an experienced hypervisor developer

could repeat our port of Xen (or port another hypervisor) to SVA/Ombro in substantially less time than we took, as we spent a lot of those two years learning about hypervisor and VMX inner workings and debugging opaque low-level issues.

Once we completed the port of Xen to SVA and had a fully working system, it was relatively straightforward to implement return address protection via a compile-time split stack transformation (Section 7). The split-stack-related changes to the compiler, SVA runtime library, and Xen were relatively small (see LOC numbers in Section 8) and took only about a month to complete, during which we also began the performance evaluation and writing of the paper.

We believe this success highlights the power and flexibility of the SVA approach. SVA provides a well-defined interface for low-level software/hardware interactions along with a robust toolkit of primitives useful for enforcing confidentiality and integrity policies, such as kernel-mode memory protection and mediation of hardware data structures (e.g. page tables and VMCSes). This foundation gives security researchers a proven framework within which they can experiment with novel security policies and enforcement mechanisms, allowing them to focus on the security and performance tradeoffs of their contributions rather than reinventing and reimplementing solutions to the myriad known pitfalls of securing kernel-mode code.

B.2 Performance-Driven Design Changes

As our performance analyses (Section 10 and Appendix A) show, the entirety of Ombro’s statistically significant overhead (only seen on certain IPI-heavy benchmarks) comes from the basic port of Xen to the SVA vISA, not from its compile-time security instrumentation on Xen (CFI, SFI, and split stack). In earlier versions of our vISA design, its overheads were substantially larger, and appeared on more benchmarks, than in the final version presented in this paper. These overheads yielded insights that drove several design changes to the vISA which dramatically improved performance to bring Ombro more in line with a non-SVA baseline.

Active vs. Loaded VMCSes in the vISA. The first such change, detailed in Section 5.3, corrected a limitation of the Shade [34] version of the vISA that was not previously evident because Shade’s hypervisor support was not sufficiently sophisticated to support a real-world hypervisor or evaluate performance at any level higher than microbenchmarks that exercised the functionality of individual VMX instructions. Shade interpreted Intel’s concept of there only being one “active VMCS” at a time on a processor [30] as meaning that a previous VMCS had to be explicitly unloaded (using the VMCLEAR instruction) before a different one could be loaded (via VMPTRLD). While porting Xen, however, it quickly became clear that Xen expects to be able to maintain multiple *loaded* VMCSes even as it switches between different *active* ones in vCPU context switches—i.e. to perform subsequent

VMPTLDRs on multiple VMCSes within a working set without VMCLEARING any of them until the respective vCPU is ready to be torn down or migrated to a different physical CPU.

To see how much impact Shade’s more restrictive interface would have on real-world performance, we modified Xen to explicitly flush the outgoing vCPU’s VMCS on every context switch and informally measured the impact on a *domU* guest running a context-switching stress test program we had created for debugging. If the (single-threaded) guest was the only significant load on the machine, no slowdown was evident compared to vanilla Xen—unsurprising, since few context switches were occurring. However, when we forced context switches by running a CPU-intensive application on all cores in the *dom0*, we found that the *domU*’s performance dropped precipitously, by over 4x.

Clearly, the hardware is able to take significant advantage of Xen’s default behavior by retaining multiple VMCSes in on-chip cache across vCPU context switches. Ombro therefore (Section 5.3) improves the vISA to support calling the `loadvm` intrinsic on a new VMCS without having to first call `unloadvm` on a then-current one. While this (slightly) complicates the vISA’s conceptual model of VMCS behavior compared to Shade, the performance improvements are well worth it, demonstrating that this facet of the native ISA is indeed essential to preserve at the vISA level.

Tying Guest State to SVA Thread Switches vs. VM Entry/Exit. The sole remaining source of vISA overhead that appeared in our benchmarks (Section 10 and Appendix A) is attributable to overhead on VM entry and exit. While entry/exit overheads should ideally not be performance-critical due to hardware-accelerated virtualization that makes VM exits rare, real systems fall short of this ideal. As our performance analysis in Section 10.3 explains, this is particularly true for IPI-heavy workloads that incur frequent VM exits. It is therefore desirable to minimize the SVA vISA’s impact on entry/exit latency as much as possible.

As Section 5.2 discusses, Shade’s version of the `runvm` intrinsic [34] was designed to present a conceptually clean abstraction wherein no guest state is ever active on the processor when running in host mode (outside of the `runvm` intrinsic itself) or vice versa. This necessitated that `runvm`’s implementation context-switch *all* system state elements, on every entry and exit, that could be modified by a guest and which could affect host software’s view of system state.

While porting Xen, we realized that this design decision was overly prescriptive on hypervisor and host-OS design and negatively impacted performance, since it forced heavy-weight state components such as the FPU and MSRs to be switched on every VM entry/exit. In practice, the hypervisor/kernel is not expecting SVA to completely hide the guest’s existence from it; rather, it will save and restore its own state on higher-level context switches (between guest vCPUs or host userspace threads) to accommodate the guest’s occupation of the processor. This allows the hypervisor/kernel to

minimize unnecessary copying by refraining from disturbing major state components like the FPU except when it decides to schedule a different vCPU or thread to run; it also allows it to implement lazy FPU saving [6] if desired.

Since its original versions [16, 17], SVA has provided vISA primitives to assist OS kernels in safely transitioning between their own execution state and that of userspace threads as they handle interrupts, traps, and system calls and make context switches. This, we realized, is exactly the model used by real-world hypervisors for making context switches between vCPUs. It was therefore natural to eliminate Shade’s excessive orthogonality between userspace-thread and guest-vCPU context switches in favor of unifying them under SVA’s existing *thread* abstraction [13, 14]. As described in Section 5.2, guest vCPU state is now stored in the same fields within SVA’s thread context structures as used for userspace threads, the only difference being that the hypervisor/OS kernel chooses to enter that context via a call to the `runvm` intrinsic (VM entry to VMX non-root mode) rather than via SVA’s `iret` function (return to host Ring 3 from interrupt/trap/syscall handler).

Besides streamlining the SVA vISA, this conceptual change improved Ombro’s VM entry/exit overhead from over 200% to just 95% (Section 10.2) and macrobenchmark overhead on the worst IPI-heavy outlier from 60% to 21.81% (Section 10.1). Based on further informal experimentation, we believe reducing the overhead further may be possible, but the current implementation has reached a point of diminishing returns, making it more profitable to focus on eliminating the root cause of excessive VM exits in the outlier benchmarks, e.g. through Intel’s upcoming hardware IPI virtualization support [12] as discussed in Section 10.3 and Appendix A.1.

C Background on the Name *Ombro*

For readers who are curious what the name *Ombro* signifies, it is a word meaning “shade” or “shadow” in the constructed international auxiliary language Esperanto [19]—the only artificial language that has successfully become a “living” human language. This follows a loose tradition within our research group of naming systems after a general theme of “ghosts” or “shadows”, which originated with systems building on the Virtual Ghost [14] project. These initially included Apparition [22] and Shade [34] (direct descendants of Virtual Ghost) and expanded to include some non-SVA-based shadow stack projects such as Silhouette [58], IskiOS [28], and Kage [24] (the latter two translating “shadow” in Greek and Japanese respectively). *Ombro* was doubly appropriate for the work presented in this paper as it can be interpreted either as a translation of “Shade” (the project we directly extend) or as referring to the “shadow stacks” we provide for Xen to protect return addresses.

The Esperanto origin of *Ombro* is also apropos to the nature of a virtual instruction set computing (VISC) system like SVA, as Esperanto is an academically-constructed yet practically-purposed human language designed to streamline

second language learning by minimizing irregularities and exceptions—much as the SVA virtual instruction set architecture (vISA) does in relation to native hardware ISAs to make analysis and protection of low-level system software easier. Like SVA’s role in mediating the interface between hardware ISAs and low-level software, Esperanto is not meant to *replace* native languages but to supplement them in situations where they struggle to fulfill their communication goals.

The *Ombro* name was selected by the lead author (Ethan Johnson) who studied and learned Esperanto as a hobby during the development of this work. He has attained intermediate proficiency in the language and welcomes correspondence either in English *ăŭ en Esperanto*.

Abstract

A number of trusted execution environments (TEEs) have been proposed by both academia and industry. However, most of them require specific hardware or firmware changes and are bound to specific hardware vendors (such as Intel, AMD, ARM, and IBM). In this paper, we propose HyperEnclave, an open and cross-platform process-based TEE that relies on the widely-available virtualization extension to create the isolated execution environment. In particular, HyperEnclave is designed to support the *flexible enclave operation modes* to fulfill the security and performance demands under various enclave workloads. We provide the enclave SDK to run existing SGX programs on HyperEnclave with little or no source code changes. We have implemented HyperEnclave on commodity AMD servers and deployed the system in a world-leading FinTech company to support real-world privacy-preserving computations. The evaluation on both micro-benchmarks and application benchmarks shows the design of HyperEnclave introduces only a small overhead.

1 Introduction

In recent years, trusted execution environments (TEEs) are emerging as a new form of computing paradigm, known as confidential computing, due to the high demand for privacy-preserving data processing technologies that can handle massive data samples. TEEs provide hardware-enforced memory partitions where sensitive data can be securely processed. Existing TEE designs support different levels of TEE abstractions, such as process-based (Intel's Software Guard eXtensions (SGX) [55]), VM-based (AMD SEV [45]), separate worlds (ARM TrustZone [16]), and hybrid (Keystone [49]). Currently, the most prominent example of TEEs is Intel SGX, which is widely available in commercial off-the-shelf (COTS) desktop and server processors.

Motivations. Most of today's TEE technologies are close-sourced and require specific hardware or firmware changes

that are difficult to audit, slow to evolve, and thus are inferior to cryptographic alternatives (such as homomorphic encryption), which are based upon public algorithms and widely available hardware. Moreover, most existing TEE designs restrict the enclaves (i.e., the protected TEE regions) to run only in fixed mode.¹ It is difficult to support the performance and security requirements of various types of applications that need to be protected by TEEs. For example, Intel SGX enclaves run in the user mode and cannot access privileged resources (such as the file system, the IDT, and page tables) and process privileged events (interrupt and exceptions). As a result, running I/O-intensive and memory-demanding tasks leads to significant performance degradation.

To fill the gap, in this paper we propose the design of HyperEnclave to support *confidential cloud computing* that can run securely on both legacy servers readily available in the cloud, and on the rising ARM (or RISC-V in the future) servers, without requiring specific hardware features. For this purpose, our design provides a process-based TEE abstraction using the widely available virtualization extension (for isolation) and TPM (for root of trust and randomness etc.). To better fulfill the needs for specific enclave workloads, HyperEnclave supports the *flexible enclave operation modes*, i.e., the enclaves can run at different privilege levels and can have access to certain privileged resources (see Sec. 4 for more details).

Design details. In our design, the system runs in three modes. A trusted software layer, called RustMonitor (security monitor written in Rust), runs in the *monitor mode*, which is mapped to the VMX root mode. RustMonitor is responsible for enforcing the isolation and is part of the trusted computing base (TCB). The untrusted OS (referred to as the *primary OS*) provides an execution environment for the untrusted part of applications; the untrusted OS and application parts run in the *normal mode*, which is mapped to the VMX non-root mode. The trusted part of application (i.e., *enclave*) runs in the *secure mode*, which can be mapped *flexibly* to ring-3 or ring-0 of the VMX non-root mode, or ring-3 of the VMX root mode.

¹An exception is CURE [20], which however requires hardware changes to the CPU core and the system bus to support the flexible enclaves (Sec. 9).

*Corresponding author: Wenhao Wang (wangwenhao@ie.ac.cn).

Memory isolation is enforced with hardware-based memory protection of the memory-management unit (MMU). As we observe that existing process-based TEEs (e.g., Inktag [38] and Intel SGX [55]) are vulnerable to page-table-based attacks [74], our memory isolation scheme chooses to manage the enclave’s page table and page fault events entirely by the trusted code, removing the involvement of the primary OS. The design also prevents certain types of enclave malware attacks (Sec. 3.2).

To minimize the attack surface, we adopt an approach called *measured late launch*: the primary OS kernel is first booted; then a chunk of special kernel code, implemented as a kernel module in the primary OS, runs to initiate RustMonitor in the most privileged level (i.e., the monitor mode) and demotes the primary OS to the normal mode. All booted components during the booting process are measured and extended to the TPM Platform Configuration Registers (PCRs). Since the TPM attestation guarantees that PCRs cannot be rolled back, the design ensures that RustMonitor is securely launched; otherwise, a violation of the TPM *quote* would be detected during remote attestation.

We have implemented HyperEnclave on commodity AMD servers. In total RustMonitor consists of about 7,500 lines of Rust code. The APIs of our enclave SDK are compatible with the official SGX SDK. As a result, code written for SGX could be easily ported to run on HyperEnclave by recompiling the code with little (or no) source code changes. We have ported a number of SGX applications, as well as the Rust SGX SDK [71] and the Occlum library OS [64] to HyperEnclave. The micro-benchmarks show that the overheads for ECALLs and OCALLs are < 9,700 and < 5,260 cycles respectively (14,432 and 12,432 cycles respectively on Intel SGX). The evaluation on a suite of real-world applications shows that the overhead is small (e.g., the overhead on SQLite is only 5%).

Contributions. In summary, the paper proposes the design of HyperEnclave, with the following contributions:

- An open² and cross-platform process-based TEE with minimum hardware requirements (virtualization extensions and TPM) that can run existing SGX programs with little or no source code changes, which enables the reuse of the rich toolchains and ecosystem for Intel SGX.
- Supporting the flexible enclave operation modes to fulfill the diverse security and performance requirements of enclave applications without hardware or firmware changes.
- A memory isolation scheme that the enclave’s page table and page fault are managed entirely by the trust code, which mitigates the page-table-based attacks and the enclave malware attacks.
- A measured late launch approach, combined with the TPM-based attestation to reduce the attack surface.
- An implementation on commodity servers (mostly) using the memory safe language Rust, and an evaluation on real

hardware and applications, demonstrating that the proposed design is practical and only has a small overhead.

2 Background

2.1 Trusted Execution Environment

A Trusted Execution Environment (TEE) is designed to ensure that sensitive data is stored, processed, and protected in an isolated and trusted environment. The isolated area could be a separate system apart from the normal operating system (such as the TrustZone [16] secure world), a part of a process address space (such as an Intel SGX [55] enclave), or a stand-alone VM (such as a virtual machine protected by AMD SEV [45] or Intel TDX [41]). To resist the privileged attacker, TEE needs to thwart not only the OS-level adversary but also the malicious party who has physical access to the platform. To this end, it offers hardware-enforced security features including isolated execution, integrity, and confidentiality protection of the enclave, along with the ability to authenticate the code running inside a trusted platform through remote attestation.

Isolation. At the core of a TEE is the memory isolation scheme, which guarantees that code, data, and the runtime state of the enclave cannot be accessed or tampered with by untrusted parties. For Intel SGX, the protected memory (i.e., the *enclave*) is mapped to a special physical memory area called Enclave Page Cache (EPC), which is encrypted and cannot be directly accessed by other software, firmware, BIOS, and direct memory access (DMA).

Attestation. The goal of remote attestation is to generate an attestation *quote*, which includes the measurement of the software state, signed with the attestation key embedded in the hardware. The remote user verifies the validity of the quote by checking the signature (which reflects the hardware identity) and the measurement (which proves the software state).

2.2 Trusted Platform Module

Trusted Platform Module (TPM) is both an industry-standard [36] and an ISO/IEC standard [4] for a secure cryptoprocessor. It is used by nearly all PC and server manufacturers. Firmware TPMs (fTPMs) are firmware-based (e.g. UEFI) TPM implementations. At the time of this writing, Intel, AMD, and Qualcomm all have implemented fTPMs.

TPM has a set of Platform Configuration Registers (PCRs), which can be used for the measurement of the booted code during the boot process. PCRs are reset to zero on system reboot or power on-off. During every boot process, the PCRs can only be extended with the new measurement (called PCR extend), and thus cannot be set to arbitrary values.

Every TPM ships with a unique asymmetric key, called the Endorsement Key (EK), embedded by the manufacturer as the root of trust. The TPM can generate a quote of the PCR

²The code will be available at <https://github.com/HyperEnclave>.

values, signed using the TPM Attestation Identity Keys (AIK), while the AIK is generated inside TPM and certified using EK. Any modifications of the booted code would be reflected in the quote. Upon receiving the quote, the remote party can validate the signing key comes from an authentic TPM and can be assured that the PCR digest report has not been altered.

2.3 Threat Model

Like the other TEE proposals [23, 49], we trust the underlying hardware, including the processor establishing the virtualization-based isolation, the System Management Mode (SMM) code, as well as the TPM. We assume that the Core Root of Trust for Measurement (CRTM) is trusted and immutable. HyperEnclave mitigates certain physical memory attacks, such as cold boot attacks and bus snooping attacks with the hardware support for memory encryption. We don't fully trust the operator and assume the attacker cannot mount physical attacks during the boot process, i.e., we assume that the system is initially benign (during system boot), and the early OS during the boot stage is part of the TCB. This can be achieved in two ways.

- *Firstly*, the power-on event can be secured with a hardware device, such as an HSM (i.e., hardware security module). The platform enters the boot process only with the engagement and supervision of a trusted party, who owns the HSM. After that, the operators for maintenance are not trusted.
- *Secondly*, the boot process can be enhanced to defend against adversaries with physical accesses. To prevent I/O attacks, we can harden the OS to remove unnecessary devices and disable the DMA capability of peripherals before IOMMU is enabled. We can enable memory encryption at an early stage (e.g., in the BIOS, before any off-chip memory is used) to prevent physical memory attacks.

However, after RustMonitor is launched, the primary OS is demoted to the normal mode, and can be under the control of the attacker, who may try to compromise the RustMonitor or enclaves, e.g., try to access the protected memory directly or through DMA. We consider the enclave code may be malicious or controlled by an attacker due to memory bugs. Our design needs to prevent a compromised enclave from contaminating the other enclaves or the RustMonitor. We also prevent the attacks against the primary OS or the application code, such as those presented in [63]. Similar to other TEEs, in this paper we do not focus on the prevention of denial of service (DoS) attacks or side channel attacks, such as cache timing and speculative execution attacks [48].

3 Design

HyperEnclave is designed to support confidential cloud computing without requiring specific hardware features. Therefore, HyperEnclave is built upon the widely available virtual-

Figure 1: System Overview.

ization extension. In particular, HyperEnclave is designed to support the process-based TEE model (similar to Intel SGX) for the following reasons.

- *Minimized TCB.* To protect an application using the process-based TEE, the TCB includes only the protected code itself, while in the other forms of TEE, much more code must be included, such as the guest operating system for VM-based TEEs.
- *Established ecosystem.* Since Intel SGX is currently the most prevalent TEE supported in the cloud (major CSPs, including GCP, Azure, and Aliyun, provide SGX-based instances [9, 62]), a rich set of toolchains and applications have been developed. Supporting the SGX model reduces the porting effort and makes it easy to deploy confidential computing tasks in the cloud.
- *Cloud computing trends.* We have witnessed a clear trend towards running container-based serverless applications in the cloud. Protecting these applications against untrusted clouds using TEEs is important. Considering that such computing tasks are typically short-lived, and favor a short start-up time, maintaining a VM seems to be too heavy-weight.

In this section, we introduce HyperEnclave using x86 notations, as we prototyped HyperEnclave on AMD servers.

3.1 System Overview

HyperEnclave supports the following modes: the monitor mode, i.e., VMX root operation mode; the normal mode for the primary OS and untrusted part of applications, i.e., ring-0 and ring-3 of the VMX non-root operation mode respectively; and the secure mode for the enclave, which could be ring-3 and ring-0 of the VMX non-root operation mode, or ring-3 of the VMX root operation mode, depending on the *enclave operation mode*. We will introduce the flexible operation mode supported by HyperEnclave in Sec. 4. As illustrated in Figure 1, HyperEnclave consists of the following components:

- *RustMonitor* is a lightweight hypervisor running in the monitor mode that manages the enclave memory, enforces the memory isolation, and controls the enclave state transitions. It works as a resource monitor, while complicated tasks are offloaded to the primary OS.
- RustMonitor creates a *unique* guest VM (referred to as the *normal VM*) that runs the *primary OS* (such as Linux) and hosts the untrusted part of applications in the normal mode. The primary OS is still in charge of process scheduling and I/O devices management, but it is not trusted by the RustMonitor and enclaves.
- *Application* is the untrusted part of the application which runs in the primary OS.
- *The kernel module*. We provide a kernel module in the primary OS to load, measure, and launch RustMonitor, as well as to invoke the emulated privileged operations.
- To ease development, HyperEnclave provides an *enclave SDK* with APIs compatible with the official Intel SGX SDK [12], including both the untrusted runtime and trusted runtime (i.e., SDK uRTS and SDK tRTS). As such, most SGX programs can run on HyperEnclave with little or no source code changes.
- *Enclave* is the trusted part of the application running in the secure mode.

3.2 Memory Management and Protection

Challenges. For process-based TEEs, the enclave runs in the user mode and is not able to manage its own page table. Existing designs (e.g., Intel SGX, TrustVisor [54]) allow the untrusted OS to manage the enclave’s page table. To prevent memory mapping attacks (i.e., attacks by manipulating the enclave’s address mappings, as shown in Figure 9, Appendix A.1), the design of SGX extends the Page Missing Handler (PMH) and introduces a new metadata called EPCM for additional security checks on TLB misses [32]. Without secure hardware support, a prevalent software solution [19, 54, 75] is to make the page tables write-protected by setting the page table entries (PTEs) for pages holding the page tables, i.e., any update to the page table traps to the hypervisor and then be verified. However, on x86 platforms the updates of access and dirty bits of the PTEs also trap into the hypervisor, leading to non-negligible overhead. Even-worse, since the enclave page fault is also processed by the OS, the above designs are still vulnerable to the page table-based attacks, such as the controlled-channel attacks [74].

The design becomes more challenging to support enclave dynamic memory management (i.e., EDMM on SGX2 platforms [34]), i.e., dynamically adding or removing enclave pages, or changing the enclave page attributes or types after the enclave is initialized. Without EDMM, all physical memory that the enclave might ever use must be committed before enclave initialization. Therefore, EDMM reduces en-

clave build time and enables new enclave features, such as on-demand stack and heap growth, and on-demand creation of code pages to support just-in-time (JIT) compilation. On SGX2 platforms, the enclaves need to send the EDMM request to the SGX driver through OCALLs, who then makes the requested changes. Since the driver is untrusted by the enclaves, the changes need to be explicitly checked and accepted by the enclaves to take effect, which involves heavy enclave mode switches.

HyperEnclave memory management. We observe that the above challenges are rooted in the fact that the enclave’s page table and page faults are both managed by the primary OS. In HyperEnclave, though the enclave is still part of the application’s address space, we create a separate page table for the enclave and let RustMonitor manage the enclave’s page table and page fault without the involvement of the primary OS³, while the page tables in the normal VM are still managed by the primary OS. However, the design faces new challenges: since the enclave can access the application’s entire address space, upon a change to the mapping of the page tables in the applications, e.g. due to page swapping, the updated mapping needs to be synchronized to the enclave’s page table managed by RustMonitor.

To eliminate the overhead for synchronization, we pre-allocate a *marshalling buffer* in the application’s address space, which is shared with the enclave. The mappings of the marshalling buffer are fixed during the entire enclave life cycle by pre-populating the physical memory and pinning it in the memory. All data exchanged between the enclave and the application must be passed through the marshalling buffer. The application’s memory mappings (except those for the marshalling buffer) are not needed by the enclave and are not included in the enclave’s page table. Such a design also mitigates the known enclave malware attacks [63], as the enclave cannot access the application’s address space but the marshalling buffer (Sec. 6 for more details). We remind the attacker may manipulate the marshalling buffer, however it does not cause additional security issues, since the buffer is untrusted by design where the developer is responsible to ensure that the data transmitted through the buffer is authentic and protected (same as the SGX model).

When the enclave accesses a virtual address that is not committed with a physical page (e.g., due to page swapping or EDMM), a page fault is raised and the enclave traps to RustMonitor. RustMonitor picks up a free page from the enclave memory pool, inserts a new mapping to the enclave’s page table, and resumes the enclave’s execution. When the enclave requests changing the page permissions, the enclave issues a hypercall to RustMonitor to update the permissions in the enclave’s page table and clear the corresponding TLB entries.⁴

HyperEnclave memory isolation. Figure 2 shows the mem-

³P-Enclave can manage its own guest page table (Sec. 4.3).

⁴P-Enclave can change the page permissions by itself (Sec. 4.3).

Figure 2: Memory isolation.

ory mappings of the applications within the normal VM and the enclaves. The application’s memory within the normal VM is managed with nested paging, while the enclave’s memory could be managed through nested paging or through normal 1-level address translation, determined by the corresponding operation mode (Sec. 4). As a result, HyperEnclave enforces the following security requirements.

- **R-1:** The primary OS and applications are not allowed to access the physical memory belonging to RustMonitor and the enclaves.
- **R-2:** The enclave is not allowed to access physical memory belonging to RustMonitor and other enclaves. It is designed to have access to only a specific memory region shared with the untrusted application for parameter passing (i.e., the marshalling buffer).
- **R-3:** DMA accesses from malicious peripherals to the physical memory belonging to RustMonitor and the enclaves are not allowed. In order to prevent such attacks, HyperEnclave restricts the physical memory used by the peripherals with the support of the Input-Output Memory Management Unit (IOMMU) in modern processors.

Memory encryption. To thwart physical memory attacks, such as cold boot and bus snooping attacks, HyperEnclave may leverage hardware memory encryption (such as AMD SME [44] and Intel MKTME [42]) to encrypt partial physical memory at the page granularity. If the platform does not support hardware memory encryption, HyperEnclave may consider to apply software approaches [76] to encrypt the isolated memory. This approach, however, may impose substantial overhead compared with hardware based solutions.

3.3 Trusted Boot, Attestation and Sealing

Measured Late Launch. The boot process of HyperEnclave is shown in Figure 3. On system boot, a static and immutable piece of code, known as the Core Root of Trust for Measurement (CRTM), executes first to bootstrap the process of building a measurement chain for subsequent firmware and software, including the BIOS, grub, the primary OS kernel, and initramfs. The measurements are stored to TPM PCRs

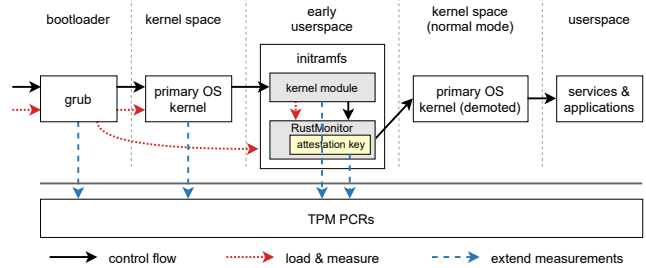

Figure 3: Measured Late Launch.

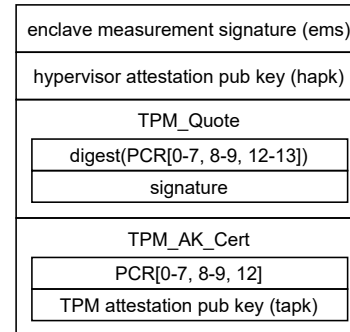

Figure 4: The HyperEnclave quote structure.

for each boot component, so that any modification will be reflected in the attestation quote.

To reduce the attack surface from the primary OS, we put the RustMonitor image into the initramfs. The kernel measures the RustMonitor image and extends the value to TPM PCRs, then it launches RustMonitor in *early userspace*, i.e., before any userspace program that relies on the disk file system starts to run. Along with the measured boot, it ensures that the software state when RustMonitor is loaded is trusted.

After RustMonitor is loaded, the execution continues at the pre-defined entry. RustMonitor sets up its own running context (such as the stack, page table, IDT, etc.) and prepares the virtual CPU (vCPU) configurations for each CPU. Then RustMonitor launches the normal VM and demotes the primary OS to the normal mode. Returning to the kernel module, the kernel continues to boot in the normal mode and is unaware of the existence of RustMonitor.

HyperEnclave applies the above approach (referred to as *measured late launch*) so that RustMonitor is loaded as a type-2 hypervisor (like KVM) while runs as a type-1 hypervisor (like Xen). In this way, RustMonitor does not need to trust the primary OS anymore after the primary OS is demoted to the normal mode.

Remote Attestation. With the measured late launch, all booted components are measured and extended to the TPM. After RustMonitor is booted, it needs to extend the trust to the enclaves. For this purpose, RustMonitor derives an attestation key pair which is used to sign the enclave measurement. Then RustMonitor extends the derived public key to the TPM

PCR, and the private key never leaves RustMonitor which is protected by memory isolation and encryption.

During enclave creation, all pages added to the enclave (including the corresponding page content, page type, and RWX permissions) are measured by RustMonitor to generate the enclave measurement. The (intermediate) measurement is stored in RustMonitor's memory, which is invisible to the enclaves and the primary OS.

Similar to TPM and Intel SGX, HyperEnclave adopts a SIGn-and-MAC (SIGMA) attestation protocol for the remote attestation flow. As shown in Figure 4, we denote the public key of RustMonitor's attestation key by the hypervisor attestation public key (`hapk`). The enclave measurement is signed using RustMonitor's attestation key to form the enclave measurement signature (`ems`). The TPM quote `TPM_Quote`, which is signed using the TPM attestation key, includes the PCRs for the measurement of all booted code, and the measurement of `hapk`. Upon receiving the attestation report, the remote user can verify the report by comparing the measurement of booted code (including the CRTM, BIOS, grub, kernel, initramfs, and hypervisor) and the enclave, as well as verifying the certificate chain for generating the signature.

Secret key generation. When RustMonitor is initialized for the first time, it generates a root key K_{root} from the random number generator (RNG) module of the TPM. K_{root} is stored outside the TPM using TPM's seal operation. During the booting process on system reset, RustMonitor decrypts K_{root} using TPM's unseal operation, which guarantees that K_{root} can only be unsealed with the exactly same TPM chip with matching PCR configurations. Furthermore, RustMonitor floods the PCRs with a constant before transferring control to the primary OS to prevent it from retrieving K_{root} . All other key materials, including the enclave's sealing key and report key are derived from both K_{root} and the enclave's measurement.

3.4 The Enclave SDK

Porting existing applications to the enclaves can be cumbersome since TEEs usually expose limited hardware and software interfaces and provide additional security services (e.g., attestation and sealing). For process-based TEEs, the applications need to be partitioned into the trusted and untrusted parts, and the interfaces need to be carefully designed to avoid various security pitfalls [27, 46, 69]. A lot of effort has been spent and many tools have been developed for Intel SGX, due to its dominant position in the market, including library OSes [64, 67], containers [18], automatic partition and protection tools [50, 68], WebAssembly Micro Runtime [57], and interface protection [65]. Consequently, Intel SGX has supported securely running applications written in C/C++, Rust, Java, Python, etc., without expensive code refactoring.

We provide the enclave SDK with APIs compatible with the official Intel SGX SDK to ease the development of applications on HyperEnclave. The enclave SDK is retrofitting the

official SGX SDK. By replacing the SGX user leaf functions (e.g., `EENTER`, `EEXIT`, and `ERESUME`) with hypercalls, SGX programs can run on HyperEnclave with little or no source code changes. Once the enclave executes these user leaf functions, it traps to RustMonitor and RustMonitor emulates the functionalities of the corresponding SGX instructions.

The enclave is compiled as a trusted library of the application, while the application itself runs in the primary OS. The enclave life cycle is managed through the emulation of a set of privileged SGX instructions (i.e., `ECREATE`, `EADD`, `EINIT`, etc.). To this end, the kernel module running in the primary OS provides similar functionalities by invoking RustMonitor through hypercalls, and exposes the functionalities to the applications by the `ioctl()` interfaces. By emulating the privileged SGX instructions, RustMonitor is responsible for the management of the enclave's life cycle (Sec. 4).

To be compatible with the official Intel SGX SDK, most data structures involved in HyperEnclave (such as the `SIGSTRUCT` structure, the `SECS` page, and the `TCS` page) are similar to that of SGX. With the HyperEnclave design, it is straightforward to support dynamic enclave management in an enclave, since the enclave memory and page fault are all managed by RustMonitor. Multi-threading within the enclave is supported by associating one `TCS` page for each enclave thread within the enclave. Exception handling within the enclave is supported by setting more than 1 `SSA` page for each `TCS`. The details are omitted due to space constraints and we refer the readers to the SGX manual [11] for more details.

4 Flexible Enclave Operation Mode

A wide range of existing applications can be offloaded to the TEEs, such as computing-intensive tasks (machine learning [60]), input and output (IO)-intensive tasks (such as the Apache and Nginx web server [18]), memory-intensive tasks (Redis and Memcached [18]), and tasks which favor in-enclave exception handling and privilege separation [21]. Most TEEs support running the enclaves only in fixed mode, Intel SGX (also TrustVisor [54] and Secage [51]) enclaves in particular, as part of the application address space, run in user mode. As a result, the user mode enclave is not allowed to access the privileged resources (such as the IDT and page tables) and process the privileged events (interrupt and exceptions). It must switch to the untrusted code to gain access to privileged resources and handle the events. The I/O-intensive and memory-intensive tasks essentially involve the frequent world switches which are expensive and introduce non-negligible performance losses, even though both software and hardware optimizations have been proposed trying to reduce the context switch latencies [61, 66, 73]. In this section, we introduce the three enclave operation modes supported by HyperEnclave, as shown in Figure 5. The world switches in different enclave operation modes are shown in Figure 6.

Figure 5: Comparison of the enclave operation modes supported by process-based TEEs. (a) Intel SGX runs enclaves in the host user mode (or guest user mode in the virtualization environment). (b) TrustVisor runs the protected code (Pieces of Application Logic, PALs) in the guest user mode. (c) HyperEnclave supports 3 coexisting enclave operation modes: ① GU-Enclaves running in guest user mode; ② P-Enclaves running in guest privileged mode and optional guest user mode; ③ HU-Enclaves running in host user mode.

4.1 Guest User Enclaves

Guest user enclave (GU-Enclave) is the basic enclave operation mode which is typically running computing-intensive tasks. The enclave runs in the guest user mode (i.e., guest ring-3 of the VMX non-root operation mode).

During the enclave creation, RustMonitor prepares a vCPU structure which contains a guest page table (GPT) and a nested page table (NPT) for GU-Enclave. On entry and exit between the normal VM and the enclave VM, RustMonitor switches the vCPU states (e.g. the instruction pointer, thread pointer, NPT, and GPT) accordingly.

To handle the interrupts and exceptions during the enclave running, RustMonitor configures the vCPU to trap all interrupts and exceptions to the monitor mode. RustMonitor then saves the enclave’s context, forwards the interrupt or exception to the normal VM. After the primary OS completes handling the interrupt or exception, the application invokes the ERESUME hypercall, which traps to RustMonitor to restore the enclave’s context and resume the execution of the enclave.

4.2 Host User Enclaves

Host user enclave (HU-Enclave) is running in host user mode. It delivers the optimal world switch efficiency by substituting the mode switch (hypercalls: ~ 880 CPU cycles on our platform) with the ring switch (syscalls: ~ 120 CPU cycles

Figure 6: World switches for the supported enclave operation modes. (a) Using hypercalls to enter and exit GU-Enclave and P-Enclave. (b) Using syscalls and syscall returns to enter and exit HU-Enclave.

on our platform) (Figure 6). It further eliminates the extra virtualization overhead (e.g. vCPU context switching and two-dimensional page walking) in GU-Enclave. HU-Enclave may benefit the I/O-intensive workload according to our evaluation in Sec 7. By comparison, running enclaves in the guest user mode provides more defensive depth.

When loading the HU-Enclave, RustMonitor prepares a process context, e.g. creates a level-1 page table. On enclave entry, RustMonitor updates the CPU state and invokes the system call return instruction (i.e., SYSRET on x86 platforms) to enter the HU-Enclave. Correspondingly, on enclave exit, HU-enclave invokes the system call instruction (i.e., SYSCALL on x86 platforms) and traps into RustMonitor. The ENCLU leaf instructions (e.g., EGETKEY, EREPORT) are emulated as a system call. Interrupts and exceptions within the HU-Enclaves also trap into the RustMonitor. The procedures are similar to those for the GU-Enclaves described in Sec. 4.1.

4.3 Privileged Enclaves

Inspired by the VM-based TEEs, such as AMD SEV [45], HyperEnclave supports privilege enclaves (P-Enclaves) which run in guest privileged mode. P-Enclave is permitted to access the GDT, IDT, and level-1 page table which benefits a wide variety of applications, as demonstrated by Dune [21]. One such example is the garbage collector, an essential feature for Java applications (existing works port the JVM to enclaves [26, 43]). The garbage collector frequently changes page permissions to trigger page faults in order to track the page status. For user mode enclaves (e.g., GU-Enclaves and HU-Enclaves), it has to involve the primary OS to update the page table and handle the page fault which suffers huge performance loss due to world switches. P-Enclaves eliminate the world switch by supporting in-enclave exception handling and level-1 page table management. More specifically, P-Enclaves configures its own exception handler to handle certain exceptions (such as page fault). RustMonitor passes

through the white-list exceptions to the P-Enclave and forwards others to the primary OS. Furthermore, P-Enclaves can also support page-table-based in-enclave isolation schemes, e.g., sandboxing untrusted third-party libraries.

With the ability to receive interrupts within the enclaves, P-Enclaves may also detect abnormal interrupt events by counting the frequency, before requesting RustMonitor to route them to the primary OS. As such, existing interrupt-based side channel attacks [24, 37, 40, 58, 59, 70] could be detected and mitigated. We leave further exploration in this direction to future work due to space constraints.

5 Implementations

We report our implementation of HyperEnclave on an AMD platform that supports hardware virtualization technology and memory encryption. In the current implementation, RustMonitor consists of about 7,500 lines of code written mostly in Rust, and the kernel module for the primary OS has about 3,500 lines of C code. Also, we made about 2,000 lines of code changes to the official Intel SGX SDK (version 2.13).

5.1 RustMonitor

RustMonitor runs at the highest privilege level and enforces the isolation for the enclaves. To reduce the risks caused by memory corruption or concurrency bugs, we implemented RustMonitor mostly in Rust, a memory-safe language, with only a few lines of assembly code used for context switches. Compared with existing hypervisors such as KVM [47] and Xen [29], RustMonitor is much smaller and thus easier to be formally verified. We are working on the formal verification of RustMonitor and plan to release the result as a separate report.

When the platform is booted, we configure the kernel command line parameters in the grub to reserve regions of physical memory, which are exclusively used by RustMonitor and the enclaves. RustMonitor manages the reserved physical memory by maintaining a list of free pages. When an enclave page is needed, e.g., when adding an enclave page during enclave creation, a free page is retrieved from the pool; when the enclave page is freed, the page is attached to the list again. Moreover, RustMonitor also manages the enclave's page tables and processes the page fault.

5.2 The Kernel Module

The kernel module is loaded by the primary OS during the booting process. Then it loads, measures, and launches RustMonitor, with the measurement extended to the TPM PCR as part of the TPM quote. When the kernel module is loaded, a device file is created and mounted at `/dev/hyper_enclave`. The application can open it and issue the `ioctl()` to invoke the emulated privileged operations.

5.3 The Enclave SDK

HyperEnclave retrofits the official SGX SDK as follows.

Supporting the SGX SDK APIs. We replace the SGX user leaf functions (e.g. `EENTER`, `EEXIT`, `ERESUME`, etc.) in the SGX SDK with hypercalls or system calls. Our implementation retains the same parameter semantics and orders as SGX for compatibility purposes.

Parameters passing with the marshalling buffer. In HyperEnclave, the enclave can only access its own address space and the marshalling buffer shared with the application. The size of the marshalling buffer can be configured in the enclave's configuration file, with a default size. The data needs to be transmitted to the marshalling buffer before invoking edge calls. We modified SGX SDK to handle the transitions, which are thus transparent to the developer.

We modified the untrusted runtime library in the SDK (i.e., `libsgx_urts.so`), such that during enclave initialization a marshalling buffer is allocated using `mmap()` with `MAP_POPULATE` flags set. As a result, the GPAs for the marshalling buffers are pre-populated. Then an `ioctl()` is issued to request the primary OS not to compact or swap out the physical pages of the marshalling buffers during the enclave's lifetime. When the application invokes the emulated `EINIT` instruction to mark the initialization of the enclave, the base address and the size of the marshalling buffer are passed to RustMonitor, who will add the mapping of the marshalling buffer in the enclave's page table. In this way, the marshalling buffer is now shared between the enclave and the untrusted application. The base address and the size of the marshalling buffer are also passed to the trusted runtime library to transmit data from the marshalling buffer to the enclave.

The current `OCALL`'s implementation in the SGX SDK invokes the `sgx_ocalloc()` within the enclave to allocate a buffer on the stack area of the untrusted application, which is then used for cross-enclave data transmission. As such, we only need to modify the `sgx_ocalloc()` function to allocate a memory area in the marshalling buffer. To support parameter passing through the marshalling buffer for `ECALLs`, we modified SGX's `Edger8r` tool to automatically generate code that copies the transmitted data into the marshalling buffer.

The SGX programming model supports passing parameters with the `user_check` attribute. For such parameters, the SDK tool will not generate code to check the address range or perform data movement. Since the enclave code could access the entire process's address space, some enclave programs may use a pointer with the `user_check` attribute to manipulate the data buffer outside the enclave directly, without accounting for the overhead for copying the data across the enclave boundary. To deal with it, we added an interface for the developer to allocate the buffer within the marshalling buffer, in the cases when the developer may use parameters with the `user_check` attribute.

The remote attestation flow is similar to SGX, following

the same SIGn-and-MAc (SIGMA) protocol. We extended the `sgx_quote_t` structure in the SDK to include the HyperEnclave quote, and the modification is transparent to the enclave code.

With the above design, most SGX programs could run on HyperEnclave without source code changes. Furthermore, to ease the development of HyperEnclave applications, we have also ported the Rust SGX SDK [71] and the Occlum library OS [64] to HyperEnclave.

6 Security Analysis

Trust Establishment. HyperEnclave relies on measured boot to bootstrap the trust of RustMonitor, a common approach for the design of TEEs (e.g., TrustZone [16] and Keystone [49]). All the components during booting (including the CRTM, BIOS, grub, kernel, and initramfs) are measured and extended to the TPM PCRs. As a result, any tampering of the booted code will be reflected and audited through remote attestation.

We consider HyperEnclave is deployed in a controlled environment (i.e., the data center in the cloud computing scenario) such that the attacker has limited physical access to the platforms. To reduce the attack surface and minimize the TCB, we put the RustMonitor image into the initramfs, and RustMonitor is loaded and measured in early userspace. In this phase, the primary OS kernel does not accept external inputs from the user, and the peripherals such as network connection are disabled. With the measured late launch approach, RustMonitor does not need to trust the primary OS anymore after the OS is demoted to the normal mode.

Enclave memory isolation. As presented in Sec. 3.2, the enclave’s memory and page tables are maintained by RustMonitor, which are inaccessible to the primary OS. The TLBs are cleared upon world switches to prevent illegal memory accesses using stale TLB entries. RustMonitor prevents the primary OS to access the reserved physical memory by removing the corresponding mappings from its NPT. RustMonitor also configures the IOMMU to prevent unauthorized device accesses to the reserved physical memory.

Our design prevents the memory mapping attacks since the primary OS cannot interfere with the enclave’s address mappings. We introduce the marshalling buffer to support memory sharing between the enclave and the application. The application pre-allocates a marshalling buffer in normal memory and passes the base address and size of the buffer to RustMonitor during enclave initialization. In case the application may pass crafted addresses (e.g., to overwrite the enclave memory), before adding the mapping of the marshalling buffer to the enclave’s page table, RustMonitor ensures the address range of the marshalling buffer is outside the enclave address range.

Defense Against Compromised Enclaves. Previous work demonstrates that enclave malware may steal secret data or hijack the control-flow of the application outside the enclave [63]. HyperEnclave is designed to confine potentially

malicious enclaves as follows.

- *Preventing arbitrary memory accesses to the application.* The SGX enclave could access the entire address space of the application, and it is possible for attacks such as leaking the secret keys or stack canaries, or tampering with the code pointers for control flow attacks. In HyperEnclave, the enclave can only access its own memory and the marshalling buffer, which is only used for parameter passing.
- *Preventing arbitrary control flows after EEXIT.* The SGX design allows the enclave to jump to arbitrary addresses by setting `rbx` before executing the EEXIT instruction (i.e., exiting the enclave), opening door to enclave malware attacks [63]. In our design, since the EEXIT instruction is emulated by RustMonitor, it is easy to prevent such attacks by adding the validity check when EEXIT is invoked.

Physical attacks. Hardware memory encryption techniques such as AMD SME could be used to protect the enclave from physical attacks such as cold boot attacks or bus snooping attacks. With memory encryption, data are always encrypted in the memory or on the memory bus, and are only decrypted within the CPU. The memory encryption key is generated randomly on system boot and stored in the CPU, which cannot be accessed explicitly by software.

Side channel attacks. Compared with SGX, HyperEnclave can mitigate certain types of side channel attacks. Since the enclave’s guest page tables and page fault events are processed by RustMonitor without primary OS involvement, the latter cannot mount page-table-based attacks [25, 72, 74]. We leave the protection against micro-architectural attacks such as speculative execution attacks as future work.

7 Evaluation

We deployed HyperEnclave on a server with two AMD EPYC 7601 CPUs (2 threads per core, total of 128 logical cores) with 512 GB DDR4 RAM. We configure 2 GB reserved memory for RustMonitor, and 24 GB for EPC memory. The primary OS is Ubuntu 18.04 LTS with Linux kernel 4.19.91. For comparison, we run the same experiments on an Intel Xeon E3-1270 v6 CPU with SGX enabled, with 64 GB DDR4 RAM, running the same OS. The SGX SDK version for both HyperEnclave and the native SGX hardware are 2.13. All programs are compiled with GCC 7.5.0 and the same optimization level.

We tried to rule out differences between hardware. Except where explicitly stated, the evaluations didn’t exceed the EPC size, so as not to trigger excessive page swapping. All evaluations were performed in single-threaded mode. For micro-benchmarks (Table 1 and Table 2), we compare HyperEnclave on AMD hardware with SGX on Intel hardware using the same SGX SDK. We measured the core cycles to avoid the influence of CPU frequencies. For real-world workloads, we set the baselines as the counterparts with no security protections on Intel and AMD platforms respectively, and compare

	EENTER	EEXIT	ECALL	OCALL
Intel SGX	-	-	14,432	12,432
HU-Enclave	1,163	1,144	8,440	4,120
GU-Enclave	1,704	1,319	9,480	4,920
P-Enclave	1,649	1,401	9,700	5,260

Table 1: Latency of SGX primitives on HyperEnclave and Intel (in CPU cycles).

	Intel SGX	GU-Enclave	P-Enclave
#UD	28,561	17,490	258
#PF	-	2,660	1,132

Table 2: Average CPU cycles of handling an #UD and #PF exception inside the enclaves.

the *relative slowdowns* introduced by SGX and HyperEnclave. Since we only compare the relative slowdowns, we stress that the *absolute* performance results are on dissimilar platforms and are not directly comparable. All HyperEnclave evaluations were measured with memory encryption enabled.

We’ve been careful in ensuring HyperEnclave implements the TEE functionality correctly. Still, memory encryption between SGX1 and HyperEnclave is different, i.e., Merkel tree and AES-CTR versus AES-XTS (see Figure 11 in Sec. A.3 for the evaluation of memory encryption overhead), which may explain the improvement for memory-intensive workloads. Besides, world switches for HyperEnclave (especially, HU-enclave) are faster, which explains the improvement for I/O-intensive workloads.

7.1 World Switches Performance

We measured the latency of edge calls (i.e., ECALLs and OCALLs) on both HyperEnclave (under different enclave operation modes) and Intel SGX. The test code runs empty edge calls with no explicit parameters 1,000,000 times and takes the median value. We also measured the instruction-level latency for the emulated EENTER and EEXIT instructions on HyperEnclave. We were not able to measure the instruction-level latency on SGX since the `RDTSCP` instruction is not supported within the enclaves on our SGX platform.

The results are shown in Table 1. It shows that HU-Enclave has the optimal edge calls performance as it reduces a mode switch (~ 880 cycles) to a ring switch (~ 120 cycles) while P-Enclave is slower than GU-Enclave for it needs to switch more privileged states during the world switches. All of the results are comparable with Intel SGX.

7.2 Enclave Exception Handling

We used the undefined instruction exception (#UD) and the page fault exception (#PF) to evaluate the enclave exception handling performance. In the #UD benchmark, the test code

Figure 7: Marshalling buffer overhead for ECALLs and OCALLs with various data size, and with the marshalling buffer (marked as `ms_buf`) enabled and disabled.

executes an undefined instruction in the enclave to trigger the exception 1,000,000 times. The exception handler advances the instruction pointer and returns. For P-Enclave, the exceptions are captured and handled entirely within the enclaves, without enclave mode switches. For GU-Enclave and SGX, an exception causes an asynchronous enclave exit (AEX) and switches the CPU to the untrusted OS, then executes a two-phase exception handling [7]. The result shows that the exception handling within P-Enclaves is about $68\times$ and $110\times$ faster than GU-Enclave and Intel SGX respectively (Table 2).

We further simulated a typical garbage collector (GC) scenario that the test code first allocated a large memory buffer, then the write permissions to the buffer were revoked by changing the enclave’s page table. After that, the enclave accessed the buffer to trigger the page faults. In the exception handler, the write permission is restored. The result (Table 2) shows that P-Enclave is about $2.3\times$ faster than GU-Enclave, for P-Enclave updates the page table and handles the page faults by itself, while GU-Enclave needs to trap into RustMonitor to update the page tables. Note that we did not evaluate GC on Intel SGX, since our SGX1 platform does not support page permission modifications after the enclave initialization.

7.3 Marshalling Buffer Overhead

To measure the overhead of introducing the marshalling buffer, we constructed a GU-Enclave variant that does not use the marshalling buffer as the baseline. We measured the overhead for both ECALLs and OCALLs with various sizes of the transferred data while varying the directions for data movement (i.e., “in”, “out” and “in&out”). We ensure the data to be transferred is not cached using the `CLFLUSH` instruction. We evaluated the performance for transferring the same data on SGX for comparison.

Figure 7 provides the results for ECALLs and OCALLs respectively. It shows that the overhead increases almost lin-

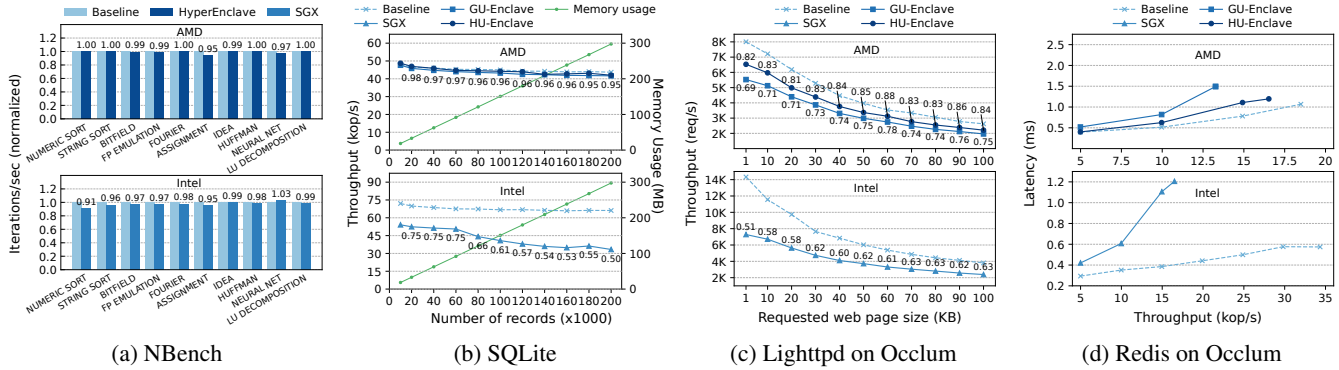

Figure 8: Performance of NBench, SQLite, Lighttpd, and Redis on AMD (with HyperEnclave) and Intel (with SGX).

early with the data size. For ECALLs, the overhead for “in”, “out” and “in&out” directions is 8%, 11% and 21% respectively for transferring 16 KB data, due to the extra memory copy. For OCALLs, the overhead is negligible, since it allocates a buffer on the marshalling buffer without additional memory copy (Sec. 5.3). We remind that data transfers in ECALLs contribute a small portion to the processing time for many real-world computation workloads, especially for computation or memory intensive tasks.

7.4 Real-world Workloads

The evaluations were conducted on four real-world applications: an algorithm benchmark suite **NBench** [53], a lightweight web server **Lighttpd** [13], two popular databases **SQLite** [14] and **Redis** [15], as representations for CPU intensive, I/O-intensive, and memory-intensive tasks. We ported the library OS Occlum [64] (v0.21) to the enclave SDK to reduce the porting effort for Lighttpd and Redis. We measured the performance on both HyperEnclave and Intel SGX, using the same code compiled under the SDK simulation mode as the baseline (providing no security guarantees).

NBench. NBench measures the performance of a system’s CPU, FPU, and memory system, without I/O and system calls involved. We used an adaptation of NBench to SGX, i.e., SGX-NBench [8] with no source code modification for our evaluation. As shown in Figure 8a, the overhead introduced by HyperEnclave and SGX is about 1% and 3% respectively.

SQLite. We ported SQLite (v3.19.3) with the enclave SDK, and evaluated it on both Intel SGX and HyperEnclave (GU-Enclave and HU-Enclave) using the YCSB [30] workload A (50% reads, 50% updates). In this evaluation we focused on the memory performance, so we configured the database as in-memory and embedded the client into the enclave to avoid I/O operations. We increased the number of records and measured the time for 100,000 database operations. As shown in Figure 8b, on SGX the throughput is about 75% of the baseline for small memory usage. When the memory usage exceeds the EPC size (about 90 MB), the performance drops to 50% due to page swapping. On HyperEnclave, both

GU-Enclave and HU-Enclave have almost the same performance as the baseline (< 5% overhead). We speculate that it’s because the memory encryption performance for AMD SME (without integrity protection) is faster than SGX.

Lighttpd. We ran a Lighttpd (v1.4.40) server with Occlum on both SGX and HyperEnclave (GU-Enclave and HU-Enclave modes). We used the Apache HTTP benchmarking tool [10] and ran 100 concurrent clients over the local loopback to fetch various sizes of web pages to evaluate the throughput. In this evaluation, the overhead mainly comes from the frequent enclave mode switches (Table 1). As shown in Figure 8c, HU-Enclave delivers the best performance as expected (81% ~ 88% of the baseline). GU-Enclave achieves 69% ~ 78% of the baseline, while SGX achieves 51% ~ 63% of the baseline.

Redis. We use Redis to evaluate the performance under the comprehensive scenarios where both memory and I/O are intensive. We ran a Redis (v6.0.9) database server with Occlum on both SGX and HyperEnclave (GU-Enclave and HU-Enclave modes). Similar to SQLite, we configured the database as in-memory and used the YCSB workload A. For the evaluation, we first loaded 50,000 records (in total 50 MB data) and then performed 100,000 operations from 20 clients over the local loopback. We increased the request frequency and measured the latency under different throughput. As shown in Figure 8d, HU-Enclave achieves 89% of the maximum throughput of the baseline, while GU-Enclave and SGX are about 72% and 48% of the baseline, respectively.

8 Discussions

HyperEnclave on other platforms. HyperEnclave requires the virtualization extension (specifically, two-level address translation) for isolation and TPM for the root of trust and randomness, etc. Virtualization is supported on many ARM servers (such as the ARMv8 platforms [2]). The RISC-V H-extension specification has evolved to v0.6.1 in 2021. Both ARM and RISC-V virtualization support two-level address translation. Certain TPM products already support ARM servers. Research has been conducted to support firmware TPM on RISC-V [22]. As such, signs are promising that

HyperEnclave can be adapted to run on ARM and RISC-V platforms.

However, porting HyperEnclave to ARM and RISC-V platforms requires non-trivial engineering effort, considering that the instruction set architectures (ISAs) are totally different. Take the ARMv8 architecture as an example. The software modules can be mapped to different exception levels (ELs): The monitor mode for RustMonitor can be mapped to EL2; The normal mode for the primary OS and untrusted part of the applications can be mapped to EL1 and EL0 respectively; The secure mode for enclaves can be mapped flexibly to EL1 or EL0. Memory isolation can be supported similarly with the support of stage 2 address translations. Furthermore, the official Intel SGX SDK only supports x86 platforms. In particular, the transitions across enclave boundaries are handled with platform-dependent assembly code, and need to be rewritten according to the application binary interface (ABI) of the targeted platforms. We leave the further exploration of adapting HyperEnclave to other platforms as future work.

Attack surfaces under different enclave operation modes.

The untrusted primary OS still runs within the VM and the attack surface from the primary OS to enclaves does not change. Running the enclaves in privileged mode or in the host, however, may expose more attack surfaces to a malicious enclave. For example, it may make the enclave malware easier to escalate to host ring-0, if the enclave runs in the host already.

9 Related Works

Most existing TEEs require specific hardware or firmware changes [17, 33, 39, 39, 41, 45, 55]. Specifically, CURE [20] changes the CPU core to support the enclave identifier (eid), and modifies the system bus to support the memory and peripheral arbiters for memory and peripheral access control according to the eid. Then the trusted security monitor can configure the hardware primitives to support the flexible enclaves. In contrast, HyperEnclave supports flexible enclave modes on commodity hardware without hardware or firmware changes.

A line of research has been conducted to build the isolated execution environment (e.g., PAL for TrustVisor and HAP for InkTag) using virtualization extensions, including TrustVisor [54], InkTag [38], Overshadow [28], AWS Nitro Enclaves [3], Microsoft Defender Credential Guard [5] and Hyper-V Shielded VMs [6]. TrustVisor makes the PAL page table pages read-only to prevent memory mapping attacks. The design introduces much overhead during PAL registration and switches from/to PALs. Even worse, it triggers many NPT violations in high memory pressures scenarios, due to the updates to the access and dirty bits of the PAL page tables, introducing huge overhead [52]. In Inktag, the HAP page tables are managed by the hypervisor. It allows the untrusted OS to request the hypervisor to update the HAP page tables. Both TrustVisor and InkTag are susceptible to page-table-based attacks [72, 74]. Furthermore, these designs usually contain a

large code base in the TCB, including device drivers, guest IO emulation, network and block device virtualization, etc. For example, AWS Nitro Enclaves [3] are constructed by the host KVM and Linux, and thus the host Linux kernel is always trusted. We made the design choice to minimize the TCB of RustMonitor, which performs basic CPU/memory virtualization and enclave management. The primary OS kernel only needs to be trusted during the boot process and is demoted after RustMonitor starts.

Komodo [35] implements an SGX-like enclave protection model in the TrustZone environment. Keystone [49] supports customizable TEEs on RISC-V platforms. Komodo enclaves run in secure user mode, while Keystone enclaves run in U-mode and S-mode. In comparison, HyperEnclave supports flexible enclave mode (guest ring-3, guest ring-0/ring-3, and host ring-3). Both Komodo and HyperEnclave use page-table-based memory isolation, while Keystone uses PMP (physical memory protection) for memory isolation.

Recently, ARM introduced the Realm Management Extension (RME) in the forthcoming ARMv9-A architecture [1]. The monitor (running at EL3) enforces physical memory isolation among the secure, non-secure, and Realm worlds. The trusted Realm Management Monitor (RMM), which executes at EL2 in Realm security state (R-EL2), isolates the Realms from each other through the stage 2 page tables. Similar to HyperEnclave, the RMM is much simpler than a typical hypervisor and relies on the non-secure hypervisor for device emulation etc. RME requires architectural extensions, while HyperEnclave does not. Moreover, HyperEnclave decouples its trust chain from the CPU as much as possible to construct an open and cross-platform TEE.

10 Conclusion

In this paper, we proposed HyperEnclave, an open TEE that can run on various platforms with minimum hardware requirements. It supports the process-based TEE model, and SGX programs can run on HyperEnclave with little or no code changes. Moreover, HyperEnclave supports the flexible enclave operation modes to fulfill various enclave workloads. We implemented HyperEnclave on commodity AMD servers and deployed the system internally for real-world computations. We are working on the formal verification of the implementation and plan to open source to the community.

A Supplementary Materials

A.1 Mapping Attacks

See Figure 9.

A.2 Virtualization Overhead

We’d like to evaluate the virtualization overhead on the normal VM. We ran SPEC CPU 2017 INTSpeed benchmarks [31], LMBench [56], and Linux kernel (v5.15) building when enabled and disabled RustMonitor. The result shows that the virtualization overhead is less than 1% in most benchmarks (see Figure 10 and Table 3). HyperEnclave avoids massive VM-exits by pass-through most devices to the normal VM and installs huge pages in NPT when possible to relieve the TLB pressure.

	LMBench (μ s)						Kernel Build (s)
	null call	fork	ctxsw	mmap	Page Fault	AF UNIX	
Native	0.1195	196.3	3.13	66,125	0.2433	5.73	1,410
Normal VM	0.1192	197.9	3.22	66,407	0.2461	5.69	1,417
Overhead	-0.25%	0.82%	2.88%	0.43%	1.15%	-0.70%	0.50%

Table 3: Virtualization overhead on LMBench (null syscall, fork, context switches among 16 processes with 64KB working set, mmap, page fault, and unix socket) and building the Linux kernel.

A.3 Memory Encryption Overhead

We evaluate the memory encryption overhead by measuring the memory access latency with and without encryption in sequential and random access patterns. The buffer size is varied from 16 KB to 256 MB. Figure 11 illustrates the result on HyperEnclave and SGX. When the buffer size is smaller than the LLC size (8 MB), the overhead on both platforms is negligible. When the buffer size is over the LLC size, the overhead for sequential accesses and random accesses can be over $2.4\times$ and $25\times$ respectively on HyperEnclave, while on SGX is $3\times$ and $30\times$ respectively. When the buffer size exceeds the EPC size (93 MB), the overhead for sequential accesses and random accesses is $45\times$ and $1000\times$ slow on SGX, due to the EPC page swapping, while on HyperEnclave the overhead is still less than $30\times$ since we reserve 24GB as enclave memory in our test.

Figure 9: Mapping attacks. (a) Two guest virtual addresses within the enclaves are mapped to the same guest physical address; (b) A non-enclave virtual address is mapped to the physical address belonging to the enclave.

Figure 10: Virtualization overhead on SPEC CPU 2017.

Figure 11: Memory encryption overhead for sequential and random memory accesses on HyperEnclave (with AMD SME) and Intel SGX (with Intel MEE). The LLC size is 8 MB, and the available EPC size on Intel SGX is about 93 MB.

B Artifact Appendix

Abstract

HyperEnclave can support existing SGX toolchains and run SGX applications on AMD CPU with security guarantees. This artifact contains the binaries of the RustMonitor, and documentations on how to setup the HyperEnclave environment. We provide two containers to reduce the environment configuration efforts. Specifically, the server container includes the pre-installed enclave SDK, the Occlum LibOS, and the benchmarks along with their dependencies⁵. The client container includes pre-installed client side benchmark scripts for Lighttpd and Redis.

Scope

The artifact includes benchmarks for edge calls (i.e., ECALLs and OCALLs), and benchmarks for the real-world workloads, including NBench, SQLite, Lighttpd and Redis. We provide scripts to reproduce the results in the paper (summarized in Table 4).

Contents

- `README.md` describes the artifact and provides a road map for evaluation.
- `host/` contains RustMonitor binary, the Linux kernel module binary, and the scripts to install and enable HyperEnclave.
- `server/` contains the source code (or patches) and scripts of all experiments to run within the enclaves. We also provide a docker container with all dependencies installed.

⁵The artifact is based on SGX SDK v2.15, Occlum LibOS v0.27, and GCC 9.4.0. The versions have little effect on the performance results.

Experiments	Figure/Table	Which container	Estimated time	Description
edge-calls	Table 1	server	10s	The latency of EENTER/EEXIT and ECALLs/OCALLs.
exception	Table 2	server	20s	Handling exceptions inside the enclaves.
NBench	Figure 8a	server	10m	Performance scores of NBench inside the enclaves.
SQLite	Figure 8b	server	15m	Throughput of in-memory SQLite database with different number of records, under YCSB A workload.
Lighttpd	Figure 8c	server/client	10m	Throughput of Lighttpd web server inside Occlum LibOS with different request sizes.
Redis	Figure 8d	server/client	20m	Latency-throughput curve of Redis in-memory database server inside Occlum LibOS with increasing request frequencies. The client uses YCSB A workload.

Table 4: Summary of the benchmarks included in the artifact.

- `client/` contains the benchmark scripts for network-based experiments (Lighttpd and Redis) to run on the client side. We also provide a docker container with all dependencies installed.
- `plots/` contains plotting scripts to generate figures from the experiment results.
- `paper-results/` contains the results shown in the paper.

Hosting

Check out <https://github.com/HyperEnclave/atc22-ae> (tag: `atc22-ae`, commit ID: `d1be8ab`).

Requirements

Hardware requirements:

- A 64-bit AMD platform with SVM enabled. Optionally, we recommend that the platform should support SME for the protection against physical memory attacks.
- RAM \geq 16 GB.
- Free disk space \geq 30 GB.

We disabled TPM and IOMMU features in RustMonitor binary for artifact evaluation to minimize the hardware requirements. These features do not affect the performance results.

Software requirements:

- Linux with the specified kernel version (i.e., `5.3.0-28-generic`) to match our given kernel module binary. We recommend Ubuntu 18.04.4 LTS which uses this version of kernel as the default.
- Docker.
- Git.
- GCC and Linux kernel headers (for building the `enable_rdfsbase` kernel module).

PRIDWEN: Universally Hardening SGX Programs via Load-Time Synthesis

Abstract

A growing class of threats to Intel Software Guard Extensions (SGX) is Side-Channel Attacks (SCAs). As a response, numerous countermeasures have been proposed. However, it is hard to incorporate them to protect SGX programs against multiple SCAs simultaneously. A naïve combination of distinct countermeasures does not work in practice because some of them are 1) *undeployable* in target environments lacking dependent hardware features, 2) *redundant* if there are already defenses with similar functionalities, and 3) *incompatible* with each other by design or implementation. Identifying all of such conditions and preparing potential workarounds before deployment are challenging, primarily when an SGX program targets multiple platforms that abstract or manipulate their configurations.

PRIDWEN is a framework that selectively applies essential SCA countermeasures when loading an SGX program based on the configurations of the target execution platform. PRIDWEN allows a developer to deploy a program in the form of WebAssembly (Wasm). Upon receiving a Wasm binary, PRIDWEN probes the current hardware configuration, synthesizes a program (i.e., a native binary) with an optimal set of countermeasures, and validates the final binary. PRIDWEN supports both software-only and hardware-assisted countermeasures, and our evaluations show PRIDWEN efficiently, faithfully synthesizes multiple benchmark programs and real-world applications while securing them against multiple SCAs.

1 Introduction

Conducting *confidential or private computing* in a shared computing environment (e.g., the public cloud) is challenging [1, 2]. Intel Software Guard Extensions (SGX) [3, 4] has thus been proposed and adopted by leading cloud service providers to help ensure even system software and hardware cannot compromise the authenticity, confidentiality, and integrity of applications running inside SGX *enclaves* [5–7]. Nevertheless, Intel SGX is susceptible to Side-Channel Attacks (SCAs) [8], which are threats to shared cloud environments in which it aims to be deployed. Researchers

*The two lead authors contributed equally to this work.

Attack	Known Countermeasures
Cache	Cache flushing [21], cache eviction detection [23]
Page	Page fault detection [24], frequent exception monitoring [26, 27]
HT	HT disabling [21], co-location detection [25, 26]
Branch prediction	Branch obfuscation [28]
Speculation	Branch prediction control [29], lfence [30]
L1TF	Cache flushing and HT disabling [21]
MDS	HT disabling [22]

Table 1: Known side-channel attacks against SGX and countermeasures. HT: Hyper-Threading; L1TF: L1 Terminal Fault; MDS: Microarchitectural Data Sampling.

have shown that SGX is vulnerable to various SCAs utilizing cache [9–13], page table [14–18], and transient execution [19, 20], which can infer sensitive control flows or exfiltrate secret data. To defend against individual SCAs, software- and/or hardware-based countermeasures have been proposed, such as cache flushing [21, 22] or eviction detection [23], page fault detection [24], and Hyper-Threading Technology (HT) disabling [21, 22] or co-location detection [25, 26] (Table 1).

However, multiple side channels can co-exist in a vulnerable program; protecting SGX programs from multiple known SCAs is difficult, not to mention the existence of unknown ones. One way is collectively applying existing countermeasures against individual SCAs, but naïvely doing so fails due to the unawareness of diverse target execution platforms or co-existing mitigation techniques, which may make such countermeasures 1) *undeployable* due to different hardware settings, 2) *redundant* because of over-protection, and 3) *incompatible* due to conflicts among different mitigations. Another way is adopting a comprehensive countermeasure, i.e., oblivious execution [18, 31], that is effective to many SCAs except for speculative execution. However, even the state-of-the-art oblivious execution incurs average slowdown of $51\times$ [31], largely downgrading the cost-effectiveness of cloud computing. A practical alternative, data-location (re-)randomization [32], incurs relatively small slowdown ($8\times$), but it is still heavy and does not cover control-flow leakage.

One conventional approach to solve such issues is to create a *bloated* application incorporating independently compiled object files for each architecture and runtime detection code, to selectively activate them according to different hardware configurations [33]. This approach, however, is not suitable for Intel SGX: First, checking hardware configurations is sup-

ported by system software outside the Trusted Computing Base (TCB); malicious system software can provide misinformation about hardware configurations to SGX applications. Second, the secure memory that enclaves share, Processor Reserved Memory (PRM), is limited [4]; bloated SGX applications can easily occupy a huge portion of it.

PRIDWEN. To practically protect SGX programs from various SCAs, we argue that the decision of the SCA mitigations to be applied should be delayed as close to the final execution as possible to best fit the target SGX platform as well as co-existing mitigation techniques. Therefore, instead of adopting the static compilation approach, in this paper, we propose PRIDWEN, a framework that uses *load-time synthesis* to dynamically harden SGX programs by selectively applying different mitigation techniques according to the configurations on the target execution platform. While ensuring the security, PRIDWEN maintains the cost-effectiveness of cloud computing by minimizing the extra effort required for preparation on the tenant side, and the runtime overhead of program synthesis on the cloud side.

PRIDWEN has a universal loader that securely loads and hardens a given SGX program inside an enclave based on four components: 1) Prober that identifies the target platform’s hardware and system configurations using SGX exception handling logic and remote attestation; 2) PassManager that manages and determines an optimal set of feasible instrumentation passes based on the identified configurations; 3) Synthesizer that hardens a given SGX program with the chosen instrumentation passes before loading it in the target enclave; and 4) Validator that verifies whether the final executable is hardened as expected, and provides a functionality for developers to remotely verify both the process of synthesis and the hardened binary before execution.

To make PRIDWEN 1) *platform-independent*, 2) *instrumentation-friendly*, and 3) *lightweight*, we develop a new instrumentation framework using WebAssembly (Wasm) [34, 35] as the Intermediate Representation (IR). The size of PRIDWEN in binary is only 1.26 MiB, which only adds a slim footprint to the enclave TCB. Existing Wasm runtimes for SGX [36–39] only *interpret* Wasm binaries without any *instrumentation support*. Furthermore, unlike existing Wasm instrumentation frameworks for non-SGX programs [40, 41], PRIDWEN can comprehensively transform Wasm binaries at both Wasm IR and native code levels. PRIDWEN also supports multiple high-level languages; users only need to compile their SGX programs once with a Wasm compiler backend (e.g., Emscripten [42]).

To showcase the capability and practicality of PRIDWEN, we integrate four mitigation passes into PRIDWEN: 1) T-SGX [24] to prevent a page-fault SCA with a hardware support; 2) Varys [26] to mitigate cache-timing, page-fault-, and HT-based attacks in a software-only manner; 3) QSpec-tre [30] to mitigate the Spectre attack; and 4) fine-grained Address Space Layout Randomization (ASLR) [43] as a

general-purpose mitigation. We first detail the steps to integrate the four passes into PRIDWEN, then we demonstrate how PRIDWEN produces the optimal set of passes based on the runtime configurations with minimal manual effort.

Performance. PRIDWEN poses moderate performance overhead on top of the original mitigation techniques and retains faithfulness of execution semantics (§6). The average slowdown of hardened real-world applications (Lighttpd, libjpeg, and SQLite) was $2.1\times$ with hardware-assisted non-redundant mitigation techniques and $3.6\times$ with software-only mitigation techniques for outdated microcode (i.e., no hardware-level mitigation), which closely conforms to the originally reported performance overhead of the selected countermeasures. Also, PRIDWEN faithfully compiled and ran all 73 programs from the official Wasm specification test suite [44]. Program synthesis completed within 0.5 s with a temporary usage of less than 25 MiB of enclave memory across tests.

PRIDWEN is designed to be an easily-extensible universal framework that respects the diversity of computing platforms. PRIDWEN is publicly available as an open-source project ¹, allowing communities to test, use, and contribute. We envision that the growing PRIDWEN framework should serve as a hub for the SCA-resistant SGX ecosystem, and potentially other mitigations as well.

Contributions. This paper makes the following contributions:

- **The first platform-aware load-time synthesis framework for SGX programs.** To the best of our knowledge, PRIDWEN is the first framework that dynamically synthesizes and hardens SGX programs by applying optimal hardware- and/or software-based mitigations according to the target platform.
- **Attestable in-enclave Wasm instrumentation and compilation toolchain.** A comprehensive instrumentation and compilation toolchain based on Wasm is implemented inside the SGX enclave to enable dynamic program synthesis with attestation. PRIDWEN can instrument Wasm both at IR and native level.
- **Extensive evaluation.** We study the performance of PRIDWEN extensively using benchmarks and real-world applications. The results suggest that PRIDWEN only introduces moderate runtime overhead while preserving the execution semantics.

2 Background and Related Work

In this section, we present the background and related work. Additional related work can be found at [Appendix A](#).

Intel SGX. Intel SGX is a hardware-based Trusted Execution Environment (TEE) that securely runs a userspace application in an untrusted remote environment, such as the public cloud. Through remote attestation [45], Intel SGX allows a user to

¹<https://github.com/sslab-gatech/Pridwen>

load his/her signed program into a remote environment, while helping ensure that the program binary has never been altered. To help secure the code and data of SGX programs, Intel SGX provides an enclave to each program, which is a dedicated secure region of the main memory. The enclave is isolated from any other software including an OS. The code and data stored in the enclave are always encrypted by the Memory Encryption Engine (MEE), and decrypted only when they are loaded into a CPU package (i.e., the cache), to help prevent physical attacks such as a cold boot attack [46].

Exceptions in SGX. Conventionally, exceptions are delivered to system software such as OS for further investigation. However, Intel SGX cannot adopt traditional exception handling because system software is untrusted. Instead, Intel SGX defines two mechanisms, Asynchronous Enclave Exit (AEX) and Custom Exception Handler (CEH) [47, 48]. Whenever an exception is generated during an enclave execution, the CPU exits from the enclave asynchronously. During AEX, the original exception number and register context are stored into the State Save Area (SSA) inside the enclave and then overwritten by synthetic data. Further, SGX allows developers to define CEHs to process exceptions inside an enclave; These CEHs can retrieve the SSA to check the stored exception number (`GPRSGX.EXITINFO.VECTOR`) and registers (`GPRSGX.<registers>`), and update them (e.g., `GPRSGX.RIP`) to resume the execution.

SGX side channels. SCAs against SGX have been actively studied. Traditional cache SCAs work against Intel SGX with different configurations [9–13, 49]. Recent studies show that page access patterns [14–18], interrupt execution time [50, 51], branch prediction behaviors [28, 52], speculative execution [19, 20] and Intel’s internal buffers [53–55] can all be used to infer sensitive information inside enclaves. In response, countermeasures that cope with the fundamental characteristics of the SCAs have been proposed. T-SGX [24] and Cloak [23] use Transactional Synchronization Extensions (TSX) to accurately recognize page faults and cache evictions inside an enclave, respectively. Varys [26] and Déjà Vu [27] aim to detect frequent interrupts or AEXs. Also, since HT enables concurrent SCAs without interrupts, Varys [26] and HyperRace [25] try to prevent an SGX hyperthread from being co-located with other hyperthreads. Disabling HT and/or flushing the L1 cache are also necessary to mitigate recent speculative or transient SCAs [21, 22]. In addition, SGX-LAPD [56] leverages a huge page to degrade the accuracy of the page-level SCA. Lastly, oblivious code execution and data access techniques for Intel SGX [18, 31, 57–60] have been proposed as a general countermeasure against SCAs, but they incur overly high performance overhead. The state-of-the-art ORAM-based system Klotski [61] improves the performance significantly. However, it only defeats controlled-channel attacks [14, 18]. In contrast, PRIDWEN focuses on universally hardening SGX applications by automatically and selectively applying multiple defenses against different SCAs together.

WebAssembly (Wasm). The World Wide Web Consortium (W3C) proposes Wasm [34] as a platform-independent compilation target for various high-level languages (e.g., C/C++ and Rust). A Wasm binary has language-like syntax and structure that are suitable for compilation and instrumentation. The basic executable unit of code in Wasm is a module that consists of multiple sections, where each section contains specific definitions of the module such as global variables, functions and a sequence of instructions of each function. Wasm instructions execute on a stack machine, and Wasm supports only the structured control flow such as `if-else` and `loop` without `goto` statements, enabling single-pass fast compilation.

Memory safety in Wasm. Wasm maintains a linear memory with a configurable size dedicated to all the memory accesses except for local and global variables. The linear memory is disjoint from other memory regions such as the code section and the call stack. As a result, given a buggy Wasm program (e.g., originating from a C program with a memory corruption bug), an attacker can only interfere with the data in the linear memory, but cannot tamper with its control flow.

PRIDWEN and Wasm. Because the Wasm binary is well-structured and friendly for efficient Just-In-Time (JIT) compilation, PRIDWEN adopts Wasm as IR for supporting load-time synthesis. PRIDWEN also benefits from Wasm’s memory-safety feature, mitigating code-reuse attacks against SGX [62, 63]. Moreover, the minimal footprint of Wasm fits PRIDWEN’s demand for a compact yet flexible instrumentation and compilation toolchain inside an enclave. Although existing compilers (e.g., LLVM) can fit into enclaves with extended size in new scalable CPUs [64], the TCB size will largely increase, and the migration effort would be significant as well.

3 Overview

Scenario. In this paper, we consider the widely-used *confidential-computing* scenario on the cloud, where the user wants to utilize the Intel SGX on the cloud to protect his/her data and applications. In this scenario, there are two entities: the cloud and the user. The user runs his/her applications inside enclaves, and wants to protect his/her data against side-channel attacks using PRIDWEN.

Threat model. Our threat model is similar to the threat models in other SGX-related studies [14, 24, 26]. Our TCB consists of an SGX enclave provided by an Intel CPU and everything inside the enclave, including PRIDWEN, a target Wasm binary prepared by the user, and the PRIDWEN pass selection policy. We assume that the user uses remote attestation to verify the validity of the CPU and PRIDWEN, and establish a secure channel with PRIDWEN to securely transmit his/her binaries. We assume that adversaries have already compromised the underlying privileged system software (e.g., OS) to attack PRIDWEN and the target binary. Any threats due to poten-

Figure 1: Overview of PRIDWEN. ❶ A user compiles a program into a Wasm binary and transmits it to PRIDWEN via a secure channel. ❷ PRIDWEN probes the hardware configurations. In this example, the CPU enables TSX and IBRS while disabling HT. ❸ PRIDWEN selects mitigation passes. Here, it chooses T-SGX and ASLR because the CPU enables TSX (for mitigating page-fault attacks) and IBRS (for mitigating Spectre variants). ❹ PRIDWEN synthesizes and hardens a native binary based on chosen passes. ❺ PRIDWEN validates the final synthesized native binary. A report is sent back to the user to attest the final binary.

tial vulnerabilities of the CPU and the code running inside enclaves are out of scope.

Goals. PRIDWEN is designed to achieve the following goals:

1) *Adaptivity.* PRIDWEN selects mitigation techniques that conform to the capabilities of the target execution platform on demand. PRIDWEN needs to optimally combine multiple mitigation techniques without causing conflicts or failures.

2) *Attestability.* The second goal of PRIDWEN is to support the remote attestation of the dynamically generated binary inside SGX; Native SGX only supports attesting static binaries. PRIDWEN should allow users to verify the integrity of the final executable running inside an enclave, as well as obtain the genuine information regarding whether the executable is faithfully generated by PRIDWEN (e.g., the selection and application of the mitigation schemes).

3) *Extensibility.* Another goal of PRIDWEN is to be extensible, so that it can support forthcoming mitigation techniques against SCAs besides existing ones. Moreover, it should support multiple platforms due to the diversity of practical computing platforms. The extensibility of PRIDWEN should also allow for smooth integration of legacy mitigation techniques.

Architecture. Figure 1 shows an overview of PRIDWEN. The core of PRIDWEN is an in-enclave loader that implements key ideas with corresponding components: *user-mode hardware probing* (Prober), *optimal pass selection* (PassManager), *load-time program synthesis* (Synthesizer), and *post-synthesis validation & final binary attestation* (Validator). Given that each countermeasure may depend on specific hardware features, Prober interacts with the platform and dynamically determines the availability of these features. Based on the probing results, PassManager determines an optimal set of countermeasures (i.e., instrumentation passes) and finalizes the order of applying them based on user policies. Next, PassManager informs Synthesizer about the final selection. Synthesizer takes a Wasm binary (provided by the user via a secure network channel) as an input and compiles it into a native one. During the com-

```

1 #define UD 6 /* Invalid opcode exception */
2 bool tsx_support = false;
3 check_tsx_support:
4   _xbegin();
5   tsx_support = true;
6   _xend();
7 exception_handler:
8   if (SSA.GPRSGX.EXITINFO.VECTOR == UD &&
9       SSA.GPRSGX.RIP == check_tsx_support) {
10    GPRSGX.RIP = skip_tsx_check;
11  }

```

Figure 2: Exception-based probing code for TSX. If a CPU does not support TSX, there will be a #UD exception that needs to be handled by an in-enclave exception handler to proceed execution (i.e., changing GPRSGX.RIP).

pilation, Synthesizer hardens the binary with the optimal pass set provided by PassManager. Validator takes the synthesized binary as an input, and verifies that 1) each countermeasure is correctly enforced, and 2) no conflict exists among the enforced countermeasures. Validator also provides the functionality of attestation on the final binary.

4 PRIDWEN

4.1 Prober

The goal of Prober is to identify hardware capabilities of the target execution platform, which is needed by PassManager to determine the optimal set of mitigation schemes to enforce. This *hardware probing* step typically requires interactions with the system software, such as retrieving privileged registers (i.e., Model-Specific Register (MSR) and control registers) and executing the cpuid instruction. However, we cannot rely on these approaches because the system software is not trusted in our threat model. SGX provides an attribute field called XSAVE-Feature Request Mask (XFRM) to determine whether some hardware features are enabled at enclave creation, but it only covers a few instructions (e.g., AVX and MPX [48]). To solve this, PRIDWEN leverages exception handling and remote attestation to securely probe hardware configurations while running inside an enclave.

Exception-based instruction probing. The instruction probing identifies whether PRIDWEN can use hardware-assisted mitigation techniques relying on specific instructions. A CEH for SGX (§2) can be used to determine whether a target system supports or enables the required instruction. Specifically, the probing code executes the specific instruction demanded (e.g., TSX) inside SGX, and then checks whether it results in a #UD exception by inspecting the exception information (Figure 2). If it does—i.e., the target platform does not support the instruction, PRIDWEN adopts a software replacement of the hardware-assisted mitigation if available, or omits it otherwise. The CEH then advances GPRSGX.RIP to continue execution.

Attackers can disrupt this type of probing, but it only results in Denial-of-Service (DoS) that they can always trigger without special attacks: 1) Attackers can simply resume the

onFunctionEnd(CCTX *c)	End of a function
onControlStart(CCTX *c)	Beginning of a control statement
onControlEnd(CCTX *c)	End of a control statement
onInstrStart(CCTX *c)	Before a IR-level instruction
onInstrEnd(CCTX *c)	After a IR-level instruction
onMachineInstrStart(CCTX *c, MI *i)	Before a native instruction
onMachineInstrEnd(CCTX *c, MI *i)	After a native instruction

Table 2: The APIs for the instrumentation. CCTX: CompilerContext. MI: MachineInstr. MCTX: MachineContext. MB: MachineBasicBlock.

enclave execution right after the #UD exception without invoking the CEH. However, GPRSGX.RIP still points to the invalid instruction, and it is impossible to manipulate it or the exception number outside the enclave. Therefore, this only incurs repeated #UD exceptions. 2) Attackers can selectively enable a specific hardware instruction *only during probing* and disable it during the actual execution. This trick can deceive the probing, but it only introduces #UD exceptions during runtime, resulting in another DoS.

Remote attestation for hardware configuration. The remote attestation determines whether a target platform is vulnerable to SCAs that utilize certain hardware features. SGX remote attestation allows PRIDWEN to accurately determine several hardware configurations, i.e., HT and Indirect Branch Restricted Speculation (IBRS). If a remote device turns on HT, an attestation verification report will contain CONFIGURATION_NEEDED in the `isvEnclaveQuoteStatus` field since API version 3 [65, 66]. PRIDWEN can leverage this information to selectively adopt mitigations for preventing hyperthread co-locations [25, 26]. Also, if a remote device does not install the microcode update for indirect branch control mechanisms, a remote attestation protocol will indicate `GROUP_OUT_OF_DATE` [67]. If users still want to securely run their code on such an outdated device, they can adopt software-based approaches [30] against speculative SCAs. Without learning such hardware information, unnecessary performance overhead might be paid for applying redundant protections. It is worth mentioning that updating microcode and changing HT configuration require system reboot in general; As a result, malicious system software cannot manipulate these hardware configurations during the execution of hardened programs.

4.2 PassManager

PassManager is in charge of selecting and integrating multiple mitigation schemes. PassManager provides a set of high-level APIs that allows developers of side-channel mitigation schemes to implement their instrumentation passes and plug them into the PRIDWEN loader. During the load time, PassManager 1) maintains a list of plugged-in passes, 2) determines the optimal set of passes for Synthesizer to execute, and 3) resolves the correct application order of each selected pass to avoid conflicts.

Pass APIs. Table 2 lists the high-level APIs for implementing instrumentation passes. For instrumentation, we expose all the hooks as APIs. To reflect the structure of a Wasm module, we classify the IR-level hooks into the granularity of functions, controls, and instructions. Each hook can obtain the information about the hooking IR instruction and the current states of compilation via the `CompilerContext` (CCTX) data structure. For the native level, the hook should consult the information of the native instruction via the `MachineInstr` (MI) data structure, as the `CompilerContext` data structure does not track such information.

Pass selection and ordering. When being plugged into the PRIDWEN loader, each pass is associated with a configuration file that specifies the type of SCA to mitigate, hardware features or other passes that it depends on, and a list of passes incompatible with it. Each pass can also specify its weakly dependent passes, which indicates that the pass depends on these weakly-dependent passes only when they are available. During the initialization phase, PassManager adds all the plugged-in passes into a pass queue. For better flexibility, PRIDWEN also allows a user to customize the pass queue by providing a pass selection policy (P), which contains descriptions of all plugged-in passes and their dependencies. We detail our implementation of a pass selection policy in §5.2.

To select the optimal set of passes, PassManager takes the following steps: 1) It consults Prober about the current hardware configuration. 2) It checks the dependency of each pass in the queue, and drops a pass if the required hardware feature is not available. 3) It checks the types of side channels that each active pass mitigates; if PassManager identifies more than one passes targeting the same SCA, it retains the one with the highest priority value specified in P . If not specified, it will first assign a priority value to each of them based on several criteria including performance overhead. 4) To determine the application procedure of active passes, PassManager builds a dependency graph of all the passes given the dependencies specified in P . Next, PassManager uses the topological order of the graph as the application order. PassManager may drop passes if their strong dependencies are not satisfied or incompatible passes are in the active pass set². If all passes are independent, PassManager uses the order in the pass queue as the application order. Here we assume the graph contains no circular dependencies; otherwise, PRIDWEN will terminate the execution.

4.3 Synthesizer

Synthesizer uses *load-time synthesis* to dynamically generate a final binary hardened with the optimal set of mitigation passes (§4.2) for the current hardware configuration, and loads

²Note that we did not come across any SCA mitigations that are mutually exclusive. If such cases emerge in the future, programmers can specify this situation in the pass selection policy (P) and mark the involved mitigation passes as mutually exclusive; the pass with higher priority will be applied by default. Users may override the policy to choose a custom priority.

the binary into memory for execution. Synthesizer adopts a Wasm binary as the input, and takes three steps, i.e., parsing, compilation, and instrumentation, to achieve this goal. We extend the compilation chain to support both IR- and native-level instrumentation so that it is flexible enough to integrate various types of SCA mitigation schemes with PRIDWEN.

Parsing. In the parsing step, Synthesizer performs standard decoding on a Wasm binary and converts it into Wasm IR. During decoding, Synthesizer also validates the format of the binary with several checks (e.g., type checking of functions) to guarantee that the binary follows the specification. Any modification to the binary before parsing can thus easily result in an immediate rejection. For example, inserting an instruction that causes the inconsistency on the stack machine renders the binary invalid.

Compilation. To generate the native binary inside the enclave given Wasm IR, Synthesizer performs a single-pass compilation over each function (similar to the baseline compilation of SpiderMonkey [34] and V8 [68]). During the compilation of a function, Synthesizer virtually executes each instruction based on the execution model of the Wasm stack machine and generates the corresponding native code. Synthesizer also keeps track of the metadata about each value (e.g., actual location and data type) on the operand stack to help correctly generate the native code and facilitate type-checking. In addition to the operand stack, Synthesizer maintains a control stack that keeps track of the control flow of the function. Pushing a value to the control stack indicates the function initiates a new control statement (e.g., block, if, or loop instruction), while popping a value from the control stack implies reaching the end of the current statement (e.g., an end instruction). The control stack provides sufficient information for Synthesizer to resolve the target of a branch (e.g., a br instruction). After finishing the native code generation of all functions, Synthesizer performs relocation. This process patches all the unresolved address values in the native instructions, such as call and those for memory accesses.

Instrumentation. To support flexible instrumentation, we extend the design of the compilation to provide hooks at both IR- and native-level. For IR-level hooks, we place them both before and after the position that Synthesizer processes an IR instruction to support code insertion, modification, and deletion. For each hook, we provide sufficient information about the corresponding instruction and the states of the compilation at the given point, such as the operands and the control stacks. Since Synthesizer may generate more than one native instruction for a single IR instruction, we provide similar hooks at the native level (i.e., surrounding the generation of native instructions) to support mitigation schemes that require the information about native instructions. To support the insertion or the modification of native instructions that require relocation, we provide the option to mark such instructions with symbols. A symbol refers to a target location that allows

Synthesizer to recognize and resolve it during the relocation phase.

Reproducible synthesis. Since both the compilation and instrumentation are *deterministic*, Synthesizer has a nice property: the synthesis process is reproducible. This property ensures that given the same Wasm code and hardware configuration, the same version of PRIDWEN loader always generates the same final binary.

4.4 Validator

The flexibility of instrumentation indicates that an instrumentation pass can arbitrarily modify the binary. Such modifications can potentially disturb the already applied instrumentation passes or break the binary itself. To avoid such cases, Validator supports *post-synthesis validation* to validate whether the synthesized executable is hardened as expected. Also, since the runtime behavior of PRIDWEN cannot be determined beforehand, Validator provides *final binary attestation* to allow users to remotely verify both the process of synthesis and the hardened binary before execution. Both *post-synthesis validation* and *final binary attestation* are necessary to ensure the correctness of the final binary. In addition, they are conducted *only* once before running the program, and thus will not affect the runtime performance.

Post-synthesis validation. In post-synthesis validation, Validator conducts static analysis over a synthesized binary. Unlike typical binary analysis that assumes a stripped binary, post-synthesis validation enables more sophisticated analyses by taking advantage of the metadata (e.g., the control-flow information) provided by Synthesizer. Post-synthesis validation takes in the form of validation passes coupled with each instrumentation pass. Based on the control-flow information, Validator executes validation passes at the basic-block level. Validator iterates through all functions in the binary and invokes a procedure implemented in each validation pass at the beginning of each basic block, which performs a series of checks based on the content of the basic block (i.e., raw bytes). For example, a procedure can determine whether specific instrumentation is applied based on pattern matching. If any of the validation passes fails, Validator rejects the binary. Optionally, the procedure can utilize other metadata such as the original IR instructions that map to the basic block to facilitate the analysis beyond binary scanning.

Final binary attestation. In addition to using remote attestation for hardware probing (§4.1), PRIDWEN uses remote attestation to attest the dynamically synthesized binary inside the enclave. SGX does not natively support the attestation of dynamic enclave content; instead, traditional remote attestation measures only the static code and data that are initially inside an enclave, which is used as a piece of evidence throughout the process of remote attestation. To attest dynamic content, PRIDWEN incorporates a two-step scheme that extends the attestation of static content.

Attack surface	SW-only Mitigation	HW-assisted Mitigation
Cache timing	Interrupt (Varys)	Cache flushing (microcode)
Page fault	Interrupt (Varys)	T-SGX
HT	Co-location (Varys)	HT disabling (microcode)
Speculative execution	QSpec	IBRS (microcode)
Static layout	ASLR	N/A

Table 3: Attack surfaces and software-only or hardware-assisted mitigation schemes PRIDWEN implements. CPUs with recent microcode update do not have some of the attack surfaces.

In the first step, a user uses the SGX standard procedure to attest the static part of PRIDWEN and establishes a secure channel [45]. Then, the user sends a Wasm binary `p.wasm` to PRIDWEN via the secure channel and PRIDWEN starts to synthesize the final binary based on the hardware configuration (`hw_config`) of the execution platform. In the second step, PRIDWEN sends the user: 1) the measurement of the synthesized binary `p.code` (i.e., the hash of native code blocks `hash(p.code)`) and 2) the `hw_config`. The user can then validate `hash(p.code)` thanks to a PRIDWEN’s property: *reproducible synthesis* (§4.3). With the reproducible synthesis, the user can validate the final binary based on both `p.wasm` and `hw_config`.

5 Implementation

We implement a prototype of PRIDWEN with 25k lines of C code on top of the Intel Linux SGX SDK 2.5.102. The size of PRIDWEN in binary is only 1.26 MiB, maintaining a slim footprint of trusted computing base (TCB). For native code generation, we implement an x86 backend to support the full Wasm instruction set.

Runtime support. Our prototype provides an Emscripten-compatible runtime support that allows to run fairly large, complex applications such as Lighttpd, as shown in §6. The application is directly compiled from unmodified C source code to a Wasm binary using the Emscripten compiler.

Attestation of synthesized binaries. Our prototype supports *final binary attestation* mentioned in §4.4. Also, the prototype provides a tool that allows users to locally validate the measurement of the synthesized binary.

5.1 Example Passes

To illustrate the capability and practicality of PRIDWEN, our prototype implementation integrates four SCA mitigation schemes (ASLR [43], Varys [26], T-SGX [24], and QSpec [30]) into PRIDWEN using provided APIs, and *simultaneously* cover five important SCA surfaces (cache timing, page fault, HT, speculative execution, and static layout) (Table 3) based on the probed hardware configuration (§4.1). Although the four mitigation schemes were not originally introduced by this work, they are selected to demonstrate how to integrate existing mitigation techniques using PRIDWEN. Because the control-flow information (including the definition of basic

blocks in the binary) is required by most of the passes, we implement a control-flow analysis pass to share the information with other passes, eliminating the overhead posed by repetitive analyses. PRIDWEN helps to prioritize hardware-assisted mitigations with lower overheads if the execution platform supports them (e.g., TSX for T-SGX), and safely avoid redundant countermeasures if the platform is free from the corresponding SCAs thanks to recent microcode or hardware updates [21, 22, 29, 69].

5.1.1 Example Pass #1: Fine-grained ASLR

Many SCAs rely on accurate memory layout information to improve the granularity of leaked information. Thus, PRIDWEN enables fine-grained ASLR by default, which randomizes the location of every basic block, as a general mitigation scheme against SCAs.

Integration. We adopt the similar compiler-level scheme from SGX-Shield [43] by inserting a `jmp` instruction at the end of every basic block. First, the pass uses the `onControlStart` and `onControlEnd` APIs (Table 2) to identify the structure of a basic block. Next, the pass inserts a `jmp` with a symbol that points to the succeeding basic block if it does not end with a `jmp`. The pass also updates the targets of other branches accordingly by using the `onMachineInstrEnd` API. Later, Synthesizer shuffles the placement of each basic block if the ASLR pass is enabled. During the relocation, the generated symbols allow Synthesizer to resolve the target of each branch to a basic block at a randomized location.

Post-synthesis validation. We integrate a validation pass that performs the following checks: 1) whether a basic block terminates with a `jmp` and 2) whether each branch points to the correct target based on the control-flow information.

5.1.2 Example Pass #2: T-SGX

SGX allows the OS to handle page faults. Page-fault SCAs [14] exploit this design decision by intentionally making enclave pages inaccessible and observing which pages are accessed. To defeat this SCA, T-SGX [24] hides page faults from the OS by running an enclave spitted as small code blocks inside TSX transactions. As a result, all page faults occurring during the execution are suppressed (i.e., not delivered to the OS).

Integration. Our T-SGX pass has cache usage and execution time analyzers for native instructions using the `onMachineInstrEnd` API. Based on the analysis results, the pass determines the scale of a code block. Next, the pass replaces branch instructions at the end of the block with the instructions redirecting to the springboard (i.e., a `lea` for saving the address of the next code block and a `jmp` to the springboard). Similar to the fine-grained ASLR pass, the T-SGX pass identifies basic blocks in the binary by using the `onControlStart` and `onControlEnd` APIs. To support the springboard, the pass places the springboard code before

the entry function (e.g., main) of the binary by using the `onFunctionStart` API.

Post-synthesis validation. The validation pass for T-SGX checks 1) the presence of the springboard, 2) the presence of the instructions to jump to the springboard at the end of every code block, and 3) whether the target of the instructions in step 2 correctly points to the springboard. Optionally, the pass can re-analyze cache usage and execution time to ensure the correctness of the code splitting.

5.1.3 Example Pass #3: Varys

SCAs usually require frequent interrupts or HT to accurately identify the execution context (e.g., which pages are accessed) or to attack in-core cache and speculation units. Varys [26] is a software-based approach to detect such behaviors.

High-frequency AEX detection and cache eviction. Varys identifies the occurrence and frequency of interrupts during the enclave execution by analyzing AEXs. Specifically, whenever an AEX occurs, SGX updates the corresponding field in the SSA. Thus, by counting the number of instructions executed at every basic block and periodically polling the SSA, Varys can estimate the frequency of AEXs. In addition, Varys explicitly evicts cache lines upon detecting AEXs to mitigate cache-based SCAs.

Co-location test. To prevent scheduling victim and attack threads to the same HT core, Varys prepares a pair of SGX threads and checks whether they are in the same core via an L1-cache-based covert timing channel. Varys performs this co-location test whenever it observes an AEX.

Integration. PRIDWEN's Varys pass inserts the checking code at the beginning of every basic block by using the `onControlStart` and `onControlEnd` APIs. Unlike the original Varys that counts the number the instructions at the LLVM IR level, our pass counts the number of native instructions with the help of the `onMachineInstrEnd` API. For the SSA polling routine, the pass inserts the code before the entry function of the binary via the `onFunctionStart` API. The pass also adds the co-location test code to the SSA polling routine (i.e., after detecting an AEX).

Post-synthesis validation. The validation pass verifies 1) the presence of the checking code, 2) the correctness of the instruction number added to the counter, 3) the presence of the SSA polling code, and 4) whether the target of the `call` in the checking code points to the SSA polling routine.

5.1.4 Example Pass #4: QSpectre

One software-based approach to mitigate the Spectre attack is to use serializing instructions (e.g., `lfence`) to prevent the CPU from speculatively executing instructions beyond the intended placements. Following this idea, Microsoft Visual Studio has adopted a compiler-based scheme, QSpectre [30],

```
1 [ { "name": "tsgx",
2   "sca": [ "page" ],
3   "dependency": { "hw": [ "tsx" ], "weak": [ "aslr" ] },
4   "priority": "high"
5 },
6 { "name": "cotest-tsgx",
7   "sca": [ "ht" ],

which finds potentially vulnerable code patterns and inserts `lfence` instructions During compilation.

Integration. Instead of inserting `lfence` instructions based on pattern matching, which can be bypassed [70], PRIDWEN's instrumentation pass for QSpectre adopts a simple, yet effective strategy: inserting `lfence` instructions to all `if-else` structures. More concretely, the pass inserts an `lfence` instruction right after the conditional branch in the code of an `if-else` structure. This pass uses the `onMachineInstrEnd` API and determines if a conditional branch is in an `if-else` structure by consulting the `CompilerContext` data structure.

Post-synthesis validation. The validation pass simply checks the presence of the `lfence` instruction in every `if-else` structure.

5.2 Pass Coordination

PassManager selects the optimal set of passes and resolves potential conflicts following the steps mentioned in §4.2. To incorporate the four passes into PRIDWEN, we specify the pass selection policy P (shown in Figure 3). Note that the policy P is just an example; PRIDWEN can transparently support any developer-provided policies by design.

Pass selection. First, PassManager selects all feasible passes according to hardware dependencies. For example, it selects the QSpectre pass if IBRS is disabled and HT is enabled (Line 13). Next, it prunes passes that target overlapping SCAs based on the priority. We prioritize T-SGX (hardware-based) over Varys (software-based) in P such that if PassManager has selected the T-SGX pass because TSX is available, it will omit the Varys pass. Then, PassManager checks the unprocessed

passes in P and includes those whose dependencies are all satisfied (e.g., co-location test for T-SGX `cotest-tsgx`), or without any dependency (e.g., ASLR).

Pass ordering. Based on the dependencies specified in P , PassManager also determines the order of applying passes to resolve potential conflicts among them. For example, the ASLR and T-SGX passes can compete with each other to instrument branches at the end of basic blocks. To avoid such conflicts, a weak dependency between the two passes is indicated in P (Line 3). Accordingly, PRIDWEN serves the ASLR pass first and then applies the T-SGX pass with slight modification (e.g., instrument `jumps` inserted by the ASLR pass to make it point to the T-SGX springboard). Also, PRIDWEN must apply the T-SGX co-location test pass `cotest-tsgx` after the T-SGX pass itself to correctly insert the testing code at the springboard, which is indicated in P as a strong dependency (Line 8). As passes without dependencies (e.g., QSpectre) can be applied at anytime, PRIDWEN simply applies them after serving passes with dependencies.

6 Evaluation

We evaluate PRIDWEN on successful mitigation of individual targeted SCAs (§6.1), the semantic correctness of the input Wasm program (§6.2), the performance characteristics of the PRIDWEN loader (§6.3), and the performance overhead of PRIDWEN-synthesized binaries (§6.4).

Experiment setup. We ran all the experiments on a machine with a 4-core Intel i7-6700K CPU (Skylake microarchitecture) operating at 4 GHz with 32 KiB L1 and 256 KiB L2 private caches, an 8 MiB L3 shared cache, and 64 GiB of RAM. The machine was running Linux kernel 4.15. The PRIDWEN loader is compiled with `gcc 5.4.0` and executed on top of the Intel Linux SGX SDK 2.5.102.

Applications and test suites. We use three real-world applications or libraries (Lighttpd 1.4.48 [71], libjpeg 9a [72], and SQLite 3.21.0 [73]) as a macro-benchmark suite representing large, complex applications, as well as a micro-benchmark suite, PolyBenchC [74]. The benchmark suite consists of 23 small C programs with only numerical computations (i.e., no `syscall`) that are used to evaluate the runtime performance of just-in-time compiled Wasm binaries against native C binaries [34]. We compile the original source code of each micro- or macro-benchmark program into Wasm using Emcripten [42], an LLVM-based compiler. We also directly port all of the programs using SGX SDK to serve as baseline versions. We use the official Wasm specification test suite [44] to test the correctness of the synthesis of PRIDWEN (§6.2).

Methodology. For each run of experiments, we take the compiled Wasm binaries as input to PRIDWEN. To evaluate PRIDWEN-synthesized binaries with distinct sets of defense schemes enforced, we manually configure PRIDWEN before each run. We use **BASE** to represent the configuration of base-

line compilation (i.e., synthesis without instrumentation) and the name of defense schemes to represent the configuration of enforcing the corresponding schemes. For example, **TSGX** indicates the configuration with T-SGX enforced. For the ease of comparing Varys and T-SGX, the rest of the section uses **VARYS**, to represent its original design with the co-location test, respectively. **QSpectre** or **QS** represent QSpectre. To measure the execution time of each application, we use the `rdtsc` instruction via an `0Ca11` inside an enclave. The reported results are averaged over 10 runs.

6.1 Security Analysis

In addition to statically checking the enforcement of each mitigation scheme via validation passes, we also manually verify whether the integrated versions of example passes are effective and compatible by running simplified SCAs against them and building a test suite (§6.2). After hardening a test binary over the SCA surfaces with different combinations, we introduce frequent page faults and interrupts, manipulate processor affinity, and run a simple Spectre attack [19]. We confirm that the T-SGX pass suppresses page faults during runtime, the Varys pass detects frequent interrupts and thread co-location (if HT is enabled), and the QSpectre pass disrupts speculation (if IBRS is disabled). In addition, combining the ASLR pass and frequent interrupt detection (the Varys pass) can effectively mitigate or slow down an attacker's attempts to infer the fine-grained memory layout.

6.2 Correctness

To validate whether the synthesized program behaves as expected, we use the official Wasm specification test suite [44], which provides comprehensive test cases for all Wasm instructions. The test suite consists of 73 programs. Each program includes a set of functions and test cases that specify the expected outputs with given inputs. We ran the test suite on PRIDWEN with all hardening configurations and reported the results in terms of *pass* or *fail* on each program. In addition to the test suite, we also record intermediate values of all benchmark programs (by manually inserting `printf`) for both baseline and PRIDWEN-synthesized version and compare them.

Results. The results show that programs with all hardening configurations successfully pass all the test cases, which indicates that 1) the baseline compilation of PRIDWEN (**BASE**) faithfully follows the specification of Wasm, and 2) the enforcement of schemes does not modify the behavior of the program. Moreover, there is no difference when comparing intermediate values between **BASE** and the synthesized binaries.

6.3 Performance of PRIDWEN

To show both runtime and memory overheads of the PRIDWEN loader, we measured the execution time that PRIDWEN takes to generate native C binaries and the additional memory that it allocates during the entire process (by

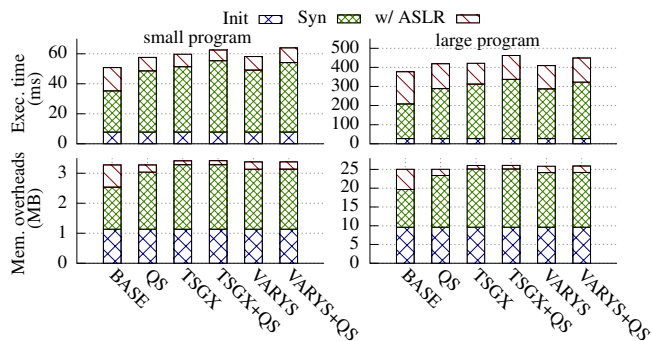

Figure 4: The top and bottom figures show runtime overheads and memory overheads, respectively, of PRIDWEN on program synthesis.

hooking `malloc`). To demonstrate the impact on the size of input, we used one small (2mm, 52 kB) and one large (`lighttpd`, 462 kB) Wasm binaries as inputs. We also ran experiments with different configurations of PRIDWEN to show the impact of enforcing different mitigations. As the co-location test depends on either T-SGX or Varys and requires only adding a piece of code to each scheme, we do not include it in the selected configurations. Note that the overhead only needs to be paid once during the first initialization and synthesis.

The results are shown in [Figure 4](#). We divide each bar into three parts: the initialization stage (blue), the synthesis stage (green), and additional overhead when the ASLR is enforced on top of the corresponding configuration (red). The initialization stage includes the time spent on hardware probing, PassManager initialization, and Wasm parsing. The synthesis stage represents the time spent on compilation and instrumentation in Synthesizer.

Runtime performance. For the runtime overhead ([Figure 4](#)), it is clear that given the same program, the execution time of the initialization stage is fixed regardless of the configurations. For the large program, PRIDWEN spends more time during the initialization stage, which is mostly due to the process of parsing the Wasm binary; however, the proportion of the execution time spent in the initialization stage decreases, which indicates that PRIDWEN spends more time on the synthesis stage for the large program. Also, enabling ASLR for the large program incurs higher overhead since it has more basic blocks. In addition, enforcing more schemes incurs higher overheads as expected. Overall, the one-time overhead of PRIDWEN is acceptable (less than 500 ms for the large program).

Memory overhead. For the memory overhead ([Figure 4](#)), the results show that PRIDWEN requires a fixed amount of memory during the initialization stage for the same program. PRIDWEN requires more memory for the large program, since the majority of the required memory is used to store the IR of the input program during the parsing process. We also observe similar memory requirements for PRIDWEN with the **BASE** configuration in the synthesis stage, since it needs more memory to maintain the metadata during compilation for the large program. Also, enabling ASLR on top of **BASE** incurs

Figure 5: The runtime performance of PRIDWEN-synthesized Wasm programs compared to native C binaries.

the highest overhead. The reason is that the instrumentation passes of each scheme all depend on the pass that manages the control-flow graph (CFG) information. As the ASLR pass can share the CFG information with other passes and can directly reuse such information during runtime, enabling ASLR on top of them incurs less overhead; when enabling just ASLR in **BASE**, it needs to generate the CFG information itself, resulting in a large memory overhead. Note that the memory overhead is only imposed once before the execution of the synthesized binary; thus it does not affect the memory usage of the binary in run-time.

6.4 Performance of Synthesized Binaries

We measure the runtime and memory overheads of PRIDWEN-synthesized binaries. We compare the results with those of native C binaries ported directly into SGX enclaves. In addition, we measure the performance overhead of the PRIDWEN-synthesized version of the defense schemes by comparing the results with those of the **BASE** configuration, and match it to that of the original implementations (i.e., the overhead indicated in the original papers). We confirm that the overheads are mainly inherited from the original design of the countermeasures; PRIDWEN only imposes minimal amount of overheads in the binaries.

Runtime performance. [Figure 5](#) shows the results of running the PolybenchC with the **BASE** configuration, which are normalized to the execution time of the native C programs. Our results indicate that PRIDWEN-synthesized binaries have negligible slowdown or are even faster than the native C binaries, without any mitigation schemes enforced. The execution time of PRIDWEN-synthesized binaries are $0.7\times$ – $1.0\times$ of that of the native C binaries. Likewise, the very initial evaluation [34] of the in-browser Wasm compiler reports similar execution overhead results on PolybenchC programs ($0.5\times$ – $1.4\times$ of that of native C). The runtime performance of PRIDWEN-synthesized Wasm programs is comparable to or even better than that of C programs. This might be due to the small size of PolybenchC programs, with only numerical computations. Therefore, the synthesized Wasm programs are fairly compact and similar to native binaries. Furthermore, the difference between compilers (i.e., Emscripten and GCC) may also contribute to the results. When programs get more complex, performance overhead increases as their Wasm forms

Figure 6: The top and bottom figures show the runtime performance and memory overheads, respectively, of PRIDWEN-synthesized programs secured with different mitigation schemes, compared to **BASE**.

no longer maintain the similarity to native binaries (e.g., the number of instructions with one-to-many mappings grows).

Figure 6 demonstrates the results of running PolybenchC with defense schemes enforced. The bar on the figure represents the relative execution time of the program to the **BASE** configuration. **ASLR** incurs various overheads due to different numbers of randomized basic blocks being executed, which is not cache-friendly. Similarly, **QSpectre** also incurs various but smaller overheads, which result from the number of `lfence` instructions being executed.

Regarding T-SGX and VARYS, **TSGX** incurs less overhead than **VARYS** does. Especially, **VARYS** suffers from high overhead when it needs to check AEXs inside a loop structure (see an example in [Appendix B](#)). **VARYS** cannot avoid this issue without compromising its security guarantees. In contrast, **TSGX** supports loop optimization, which puts an entire loop into single transaction when possible.

Memory overhead. **Figure 6** shows how much memory each mitigation demands on top of the binaries with **BASE**. On average, the memory overheads of the synthesized binaries are about $1.2\times$ compared to the baseline binaries, which is moderate.

Real-world applications. We use three real-world applications as case studies to show that PRIDWEN provides sufficient support for large, complex programs. In addition to the *Lighttpd* (a web server), the other two applications are based on *libjpeg* and *SQLite* libraries. The *libjpeg* application supports both compressing and decompressing a *jpeg* image and the *SQLite* application supports basic database operations, including insert, select, update, and delete. We use the HTTP benchmarking tool, *wrk*, for evaluating the throughputs of the *Lighttpd*. For the other two applications, we measure the execution time of each supported operation and report the average values over 10 runs.

Figure 7 shows the results of *Lighttpd*. The slowdown of **BASE** is $1.5\times$ to the native version. **TSGX** incurs less over-

Figure 7: The performance of *Lighttpd*; QS: QSpectre.

Figure 8: The performance of synthesized *libjpeg* and *SQLite*; each left bar illustrates hardware-assisted passes, while each right bar illustrates software-only passes.

heads compared to **VARYS** ($1.9\times$ versus $2.6\times$), demonstrating the advantage of hardware-assisted mitigation schemes over software-only ones. **ASLR** incurs significant overhead because *Lighttpd* has a large number of small-sized basic blocks; This shortens the gap between **TSGX** and **VARYS** when they are enforced with **ASLR**. When enforcing multiple mitigation schemes, the slowdown of *Lighttpd* is up to $4.6\times$ compared to the native binary.

Figure 8 presents the performance of *libjpeg* and *SQLite* applications. We use stacked bars to represent the incurred overheads when applying the optimal set of mitigations on top of a viable hardware configuration. The runtime overhead of **BASE** is $1.2\times$ – $1.7\times$ compared to the native versions. The overheads of individual mitigation schemes are similar to the results of PolyBenchC presented in **Figure 6** (e.g., **TSGX** in-

curs less overheads than **VARYS**). The average slowdown of hardware-assisted mitigation schemes is 1.9× while that of software-only mitigation schemes is 3.4×. Depending on hardware configurations, hardware-assisted mitigation schemes are 2.1×–5.4× faster than software-only ones.

Again, as PRIDWEN only aims to integrate multiple mitigation techniques, most of the performance overheads are inherited from the original design of the countermeasures, while PRIDWEN itself does not impose significant overheads.

7 Discussion

Adding new defenses to PRIDWEN. PRIDWEN is designed with future scenarios in mind. Thanks to the high-level instrumentation APIs provided by PRIDWEN (Table 2), new instrumentation-based defense techniques can be easily added to PRIDWEN as a pass. PRIDWEN pass APIs offer different instrumentation granularity with sufficient information about the corresponding instruction on both IR- and native-level, which should meet all instrumentation needs. We recommend to develop new defenses directly with PRIDWEN to save the hassle of replacing heterogeneous instrumentation APIs with PRIDWEN versions during integration. The developer will also need to provide the type of side-channel attack targeted by the new defense, and the possible dependency on specific hardware features or existing techniques in the pass selection policy. This allows Prober and PassManager to resolve potential incompatibility issues and conflicts, and correctly enforce the new defense. Compared to the effort needed to write a new pass, writing a pass selection policy should be much simpler.

Upgrade PRIDWEN. Modern hardware is evolving quickly with updated features useful for security purposes and PRIDWEN is designed to keep up with the hardware evolution. It is necessary for PRIDWEN to allow probing of new hardware features for defense techniques built with such features. The probing logic for the specific hardware feature will need to be added by PRIDWEN developers using either exception-based instruction probing or trusted remote attestation (§4.1) to bypass untrusted privileged software. Novel and secure techniques are also welcomed to probe the hardware capability of the platform. We hope that PRIDWEN can motivate hardware manufacturers to provide official secure probing helpers for hardware features. Upgrade of PRIDWEN is the effort of both the hardware and the software communities. The power of PRIDWEN is truly unleashed when equipped with the most updated inclusion of hardware features and mitigation schemes.

The recent SmashEx attack [75]. A recent paper presents the SmashEx attack targeting the SGX SDKs; the targeted SDKs do not properly handle *re-entrancy* in their asynchronous exception handling logic, which allows the attacker to compromise the integrity of the SSA region and modify GPRSGX.RIP. PRIDWEN is built on top of the trusted Intel

SGX SDK. The vulnerability of asynchronous exception handling in SGX (SmashEx) is rooted in the SGX SDK, and it was already mitigated by recent patches [76, 77]. That is, the enclave-specific SSA that hosts the GPRSGX.RIP cannot be compromised with the attack in the latest SDK. PRIDWEN should work with the latest SGX SDK because it does not heavily rely on or modify a certain SDK version.

Program synthesis on the cloud side vs. the user side.

PRIDWEN makes the design decision of conducting program synthesis on the cloud side to minimize the extra effort required for preparation on the user side. An alternative solution would be deploying a dedicated program on the cloud to report the hardware configuration back to the user, then the user in return synthesizes and caches the hardened binary themselves and sends the binary to the cloud for deployment. Synthesizing and caching the binaries of different configurations at the user side can save compilation cost on the cloud side; however, this puts more burden on the user. In addition, it would be difficult to update the binaries on the cloud side when the configuration changes, since the server has to wait for the user to compile and transmit the updated version. In contrast, when the configuration on the server is changed (e.g., after reboot), PRIDWEN automatically re-synthesizes the application and applies the change upon restarting. It is also possible to optimize PRIDWEN in a similar way by caching the synthesized programs of different configurations on the cloud side to reduce the compilation overhead.

8 Conclusion

PRIDWEN is a framework to dynamically synthesize a secure SGX program that is optimally hardened against various SCAs simultaneously, while preventing any *deployability*, *redundancy*, or *incompatibility* problem. To overcome the restrictions of the static deployment model of SGX, PRIDWEN adopts Wasm as the IR, and supports smooth integrations of instrumentation passes for both hardware-assisted and software-only mitigations. PRIDWEN selects an optimal set of mitigations to be applied at runtime according to the hardware configurations of the target platform, and provides means for the user to validate and attest the final synthesized binary. We implement a prototype of PRIDWEN, which integrates four SCA defenses. Through extensive evaluation, we show that PRIDWEN efficiently hardens SGX programs with chosen defenses, while incurring moderate performance overhead.

9 Acknowledgment

We would like to thank the anonymous reviewers and our shepherd for their helpful feedback. We also would like to thank Scott Constable and Yuan Xiao from Intel for constructive discussions. This research was funded by Intel and the NSF award NSF-1563848.

enforcing fine-grained ASLR. VC3 [78] and SGXElide [79] deploy encrypted SGX code while decrypting it within an enclave. Obfuscuro [31] obfuscates SGX code with Oblivious RAM. For the deployability, some loaders abstract the interface between SGX code and the outside. Ryoan [80] implements a two-way sandbox to securely execute untrusted code inside an enclave. Haven [81], Graphene-SGX [82], and SGX-LKL [83] run a library OS inside an enclave to execute unmodified programs. Similarly, SCONE [84] abstracts system call interfaces and Panoply [85] abstracts POSIX interfaces to run unmodified programs with SGX. Unlike these approaches, PRIDWEN focuses on how to instrument SGX applications according to the hardware features to improve their security.

SGX and Wasm. To the best of our knowledge, there are a few initial efforts to execute Wasm interpreters inside an enclave. Rust-SGX [36] can be configured to use Wasm as a backend. Se-Lambda [37] executes serverless functions written in Wasm inside an enclave. Also, Intel and Red Hat are developing Wasm runtime for SGX [38, 39]. However, unlike PRIDWEN, these approaches only run existing Wasm interpreters without improving their functionalities.

Wasm instrumentation. Other studies also instrument Wasm binaries to detect security attacks. SEISMIC [40] instruments Wasm binaries to inject an inline monitor for detecting cryptojacking. Wasabi [41] is a Dynamic Binary Instrumentation (DBI) tool that statically instruments Wasm binaries to inject hooks and dynamically runs JavaScript-based analysis code on them to find potential bugs. However, unlike PRIDWEN, they do not consider instrumenting native binaries compiled from Wasm binaries, which is necessary to adopt low-level security mitigations sensitive to machine code.

Abstract

Executing complex, memory-intensive deep learning inference services poses a major challenge for serverless computing frameworks, which would densely deploy and maintain inference models at high throughput. We observe the excessive memory consumption problem in serverless inference systems, due to the large-sized models and high data redundancy.

We present TETRIS, a serverless platform catered to inference services with an order of magnitude lower memory footprint. TETRIS’s design carefully considers the extensive memory sharing of runtime and tensors. It supports minimizing the runtime redundancy through a combined optimization of batching and concurrent execution and eliminates tensor redundancy across instances from either the same or different functions using a lightweight and safe tensor mapping mechanism. Our comprehensive evaluation demonstrates that TETRIS saves up to 93% memory footprint for inference services, and increases the function density by 30× without impairing the latency.

1 Introduction

Serverless computing has seen its popularity explode in recent years, due to the ease of use, cost efficiency, resource management-free, and autoscaling advantages. Serverless inference, i.e., deploying deep learning (DL) inference services atop a serverless platform, is continuously adopted in the backend of the internet of things (IoT), mobile and web applications [1, 6, 11, 65, 74]. Some typical explorations include the Amazon Alexa [5], Facebook Messenger bot [49], and Netflix media transformation [38].

Inference services are commonly memory-intensive, consuming a substantial amount of memory throughout the computation. If performing inference in a serverless environment, we find that the current serverless platforms (e.g., AWS Lambda [2]) do not support inference computation well. First,

Figure 1: Schematic overview of memory consumption in serverless inference systems.

they cannot accommodate large inference models. For example, AWS Lambda limits the memory footprint of functions to $\leq 10\text{GB}$ [2], whereas the recent MT-NLG language model [36] even needs 2TB memory to load its 530 billion parameters. Second, these platforms cause a significant waste of memory resources. The "one-to-one mapping policy" of request to function instance by commercial platforms [2] introduces significant memory redundancy. The memory footprint of language runtime, libraries, and even tensors is repeated across function instances. On the other hand, serverless functions are usually *short-lived*. While the CPU processing of inference requests takes only a short time (e.g., 75% execute for less than 10 seconds in Microsoft Azure [60]), the memory is kept occupied without working for long due to the early reservation or keep-alive caching after completion (e.g., 15-60 minutes in AWS Lambda) [20, 58, 60]. Hence, how to improve the memory efficiency of serverless inference has become a crucial problem.

To reduce the memory footprint, prior works have proposed the *runtime sharing* method [16] (Figure 1), i.e., multiple requests share the same function instance runtime with increased instance concurrency. In serverless inference, *runtime sharing* can also be enabled through *batching*, which aggregates multiple inputs into a single batch submission for more efficient execution [1, 71, 74]. We study the memory footprint of serverless inference and observe that the *tensor redundancy* problem (i.e., tensors in the computational graphs of infer-

*Corresponding author: laiping@tju.edu.cn.

ence models are highly duplicated across function instances) still severely degrades memory efficiency. Such duplication is commonly caused by either replicated function instances or identical parts generated by pervasive pre-trained models or transfer learning [15, 52, 61, 62, 73]. We summarize 768 machine learning (ML) models utilized by 58.com, the China’s largest local life service website, finding that tensor redundancy exists in 67.5% of natural language processing models, 26.7% of image classification models, 30.1% of recommendation models.

The *tensor redundancy* problem can be mitigated through operating system kernel-level page merging methods (e.g., [3, 33, 47]), which scan for duplicate content in the memory and merge the content into a single physical page. However, they incur nonnegligible scanning overhead (e.g., 5 minutes scanning time) and thereby work well only for deduplicating fairly static memory pages, contradicting with *short-lived* nature of serverless functions. Since the scanning process occurs after applications are loaded, they can neither accelerate the function startup nor solve the *startup failure* problem caused by the out-of-memory (OOM) error. Moreover, their implementations require modifications to the operating system kernel, which is heavy and may introduce risks of side-channel attacks [42].

In this paper, we explore improving the memory efficiency of serverless inference system through both *runtime-level sharing* and *tensor-level sharing*. As illustrated in Figure 1, *the colocated function instances share tensor-memory pages with identical content*. Tensor sharing introduces several challenges that need to be addressed. (1) *Non-harming performance*: The sharing method should not impair the inference latency. (2) *Safe sharing*: The sharing process should not introduce data leakage risks. (3) *First-time sharing*: The sharing method should start working as long as the inference functions are activated, to accelerate the function startup and reduce the OOM errors. (4) *Low overhead*: The sharing method should be lightweight for easy integration with serverless frameworks, and transparent to tenants.

To overcome these challenges, we build TETRIS, a domain-specific serverless platform that caters to DL inference as backend-as-a-service (BaaS) offerings with high memory efficiency. For example, *after using TETRIS, the memory footprint of the LaBSE model (a multilingual BERT embedding model [18]) reduces from 1.97GB to merely 141.7MB, and the instance density also increases from 64 to 911 per 128GB-server without any modifications to the model*. TETRIS provides a complete solution for the memory bottleneck problem in serverless inference through automating runtime sharing, tensor sharing, memory reclaiming, and instance scheduling. It enables tensor sharing through a user-space page deduplication method, which has no pollution to the underlying systems and is thus incredibly lightweight and easy to implement. It is also highly efficient and supports to guarantee the Service Level Objectives (SLOs). DL developers would significantly

benefit from TETRIS, as it can save tremendous memory as well as monetary costs, or the freed memory can be reused for other purposes like caching.

Our contributions can be summarized as follows:

- We observe the *tensor redundancy* problem in serverless inference systems and propose the corresponding *tensor sharing* idea for memory efficiency.
- We design a lightweight, user-space tensor mapping-based sharing method, eliminating the tensor redundancy problem in serverless inference systems.
- We implement a prototype system of TETRIS, which is built with the open-source OpenFaaS [17] and TensorFlow Serving [51], supporting memory sharing, memory reclaiming, and instance scheduling.
- We extensively evaluate TETRIS using a comprehensive set of benchmarks and production workloads. The experimental results reveal that TETRIS can save up to 93% of memory and increase the function density by 30×, compared to the state-of-the-art approaches.

The rest of the paper is structured as follows. We study the data redundancy problem in serverless inference (§2), and use the findings to guide the design (§3) and implementation (§4) of TETRIS. We then evaluate the performance of TETRIS (§5), discuss related work (§6), and conclude (§7).

2 Background and Motivation

2.1 Inference on Serverless

The use of machine learning is divided into two phases: training and inference. While model parameters are continuously updated throughout the training phase, they remain fixed during the inference phase. In DL frameworks (e.g., TensorFlow), models are organized as computational graphs, and data in the graph are stored as *tensors*. The nodes represent operators or variables and edges denote the direction in which the tensor flows. In particular, the variable nodes of parameters and intermediate tensors produced on edges consume the most memory. The parameterized tensors may also be identical across different models, due to the pervasive usage of pretraining and transfer learning. As an example, we investigate the VGGish-based audio classification models that assist the telephone customer service in the local life service website, which are used for detecting various noises, non-human voices, dialects, etc. We find that these models share the bottom embedding layers, accounting for over 90% of the model parameters.

In serverless inference, each deep learning model is typically deployed into a separate function instance (e.g., a Docker container [45]). The function instances automatically scale in or out according to the fluctuation of requests. In the case of scaling out, an identical instance is created and its runtime, library, and model parameters are loaded into the memory repeatedly.

2.2 Motivations

To improve memory efficiency, we study the memory footprint of typical serverless inference models. The benchmarks are selected from TensorFlow Hub [22], with an average of 6.8k downloads. All of them are implemented and deployed on an OpenFaaS [17] testbed (Table 3).

Observation #1: Memory-intensive startup: *The loading of massive model parameters dominates the inference function instance startup.*

Figure 2: Request processing time and memory breakdown for various inference models.

The DL inference functions require numerous model parameters to load at startup, typically saved in a serialized model file. In particular, before the function can conduct the inference, the model loading thread continuously reads the parameter tensors from the disk and then deserializes and populates them into the corresponding node in the computational graph. With the memory page cache enabled to accelerate the startup, we measure the time of the three phases during request processing (Figure 2(a)): *sandbox and runtime initialization*, *model loading*, and *inference computation*. The *function startup* time is significantly longer than the *inference computation* time. Especially in the Bert-QA model case (with 1,300MB parameters), only 3.73% of the time is spent on computation. Even for the small model of Resnet50 (with 102MB parameters), the inference computation time still only accounts for 13.37%. If merely considering the startup, the majority of time is further spent on loading model parameters. For example, the ratios exceed 89% for both Electra and Bert-QA.

Observation #2: Memory-intensive computing: *The inference computation requires a substantial amount of memory, with the model parameters consuming the most.*

Figure 3: Analysis of the compressed model size and download times of deep learning models from TensorFlow Hub.

The memory footprint of an inference process can be divided into the following sections: *program code*, *libraries*, *the model* (for loading parameters in the form of tensors), *the function call stack*, *intermediate tensors* (i.e., generated at runtime) and *the network buffers* (i.e., allocated for receiving function requests). The *model* itself consumes the majority of memory.

We measure the memory consumption of different types of inference models at runtime and present the results in Figure 2(b). The model parameters occupy a major portion of all memory consumption (e.g., for VGG19, storing the parameter tensors accounts for more than 93% of the total memory consumption). We also compile a list of 625 machine learning models from TensorFlow Hub [22] and analyze their compressed model file sizes (Figure 3). In addition, 42% of the compressed model file sizes surpass 100MB, such as the popular text-embedding model *universal sentence encoder* (downloaded 1.4M times), which has a compressed model size of 0.89GB and consumes 1.72GB memory at runtime. Typically, the text processing models employing large embedding layers are substantially larger than the image, audio, and video processing models.

Observation #3: Runtime redundancy: *The inference runtime is replicated in memory due to the multilaunched instances. While both concurrent execution and batching enable runtime sharing, how to use them in combination is challenging.*

Figure 4: Average inference latency increases over batch size and concurrency.

Multilaunched instances lead to duplicated runtime memory consumption. The memory footprint can be reduced by packing multiple requests into an instance for sharing the runtime resources (e.g., ML model, framework, and network buffers.). In serverless inference, runtime sharing can be implemented in two ways: *batching* and *concurrent execution*. Given the same benchmarks and resource configurations, we evaluate the inference latency under both implementations. Figure 4 illustrates that both implementations increase the latency significantly: *batching* increases the latency due to the increased computing load, whereas *concurrent execution* increases latency due to the increased resource contention among threads, i.e., as concurrent requests compete for the computing threads in TensorFlow, the interleaved computation of operators increases the average latency.

We further measure memory consumption under various combinations of *batching* and *concurrency* (Figure 5). In par-

ticular, we generate a constant 200 requests per second (RPS) toward DenseNet169 [30] and Lstm [27] and specify their latency SLOs at 200ms and 30ms, respectively. After omitting combinations that do not guarantee the SLOs, we find that solely increasing either the concurrency or batch size leads to sub-optimal memory efficiency. For DenseNet169, increasing only the batch size quickly causes SLO violations due to the long waiting time in the batch queue, whereas increasing the concurrency does not. For the Lstm model, a larger batch size ($batchsize = 6$) achieves the least memory consumption under the SLO guarantee. As various combinations of batch size and concurrency may lead to completely different memory efficiency, selecting the best among them is essential.

Figure 5: Normalized memory consumption of function instances under various combinations of batch size and concurrency.

Observation #4: Tensor redundancy: *The tensors of the constants, model parameters, are extensively replicated across function instances.*

Besides the runtime redundancy, parameterized tensors are also replicated across instances from the same function, i.e., *tensor redundancy*. We summarize 768 DL models at 58.com, finding that tensor redundancy also commonly exists across distinct functions. There are presently 27 business lines in 58.com, including jobs, housing, vehicles, cellphones, home services, resumes, etc. These businesses have common demands on DL inferences (e.g., image, text, video, and audio processing) but with different datasets (e.g., pictures of houses, cars, people, and smartphones). Primarily, there are two scenarios that cause tensor redundancy across distinct functions [15, 40, 52, 61, 62, 73]:

(1) *Multi-versioned functions.* In production scenarios, a DL model is frequently reused directly in various business contexts. As online web services have strict latency requirements (e.g., < 100 milliseconds), models with pipeline dependencies are commonly deployed together within a function to avoid the excessive network communications. In such cases, although these pipelines vary across businesses, tensors within the shared models stay identical. For example, the Optical Character Recognition (OCR) pipeline and the image moderation pipeline share the same text line identification and recognition models (e.g., Resnet), whereas the image moderation pipeline incorporates an extra model for keyword detection. Moreover, DL models are also commonly deployed

with specific pre- and post-processing modules for processing data in different formats, thus generating multi-versioned model pipelines.

(2) *Pretraining & transfer learning.* It refers to training a model with massive datasets for one task, where the learned parameters could be reused in other related tasks. In such way, new models could significantly benefit from prior knowledge to accomplish new tasks rather than from scratch. At 58.com, pre-trained models or transfer learning are widely used for reducing development costs. For example, in the house leasing business, webchats are recorded and different DL models are called to identify the status of the landlord (e.g., whether the house was leased) and tenant (e.g., a genuine renter or housing agent) respectively. In the telephone customer services, there are also distinct models to assess the recruitment, rental and housekeeping intentions of users, respectively. These models with similar tasks are all built from a pretrained Bert model. Instead of fine-tuning all parameters of a model, it is common to directly reuse partial parameters and only fine-tune a small set of model layers for two reasons: (i) It is able to significantly decrease the training overheads of similar downstream tasks, enabling rapid development; (ii) Fine-tuning the whole model may result in overfitting if the target dataset is small and the number of parameters is huge [23, 28, 34, 44, 48]. It even improves the accuracy in case of insufficient training samples (e.g., sporadic noises). For example in the advertising business, a Resnet50 model with only the top layers retrained achieves an accuracy of > 98% in classifying QR codes.

It is highly empirical to determine which layers should be reused in practice. For tasks like sentiment classification, reusing the initial 12-16 layers of Bert even outperforms fine-tuning all layers on the SST-2 dataset [39]. The VGGish-based audio classification model for detecting noises with retained bottom embedding layers also achieves an accuracy of > 93%. Table 1 summarizes the representative deep learning models used for image, text, and audio processing in our website, as well as their applications, potential redundant parts and redundancy ratios.

Table 1: Tensor redundancy at 58.com.

Application Domains	Image	Text	Audio
Representative Models	Resnet50	Bert	
	EfficientNet	Roberta	VGGish
	MobileNet	Albert	
		GPT	
Applications	Advertising	Reading Extraction	Audio Classification
	Housing	Text Summary	
	Secondhand Trading	Text Classification	
Redundant Part	Bottom Layers	Embeddings Middle Layers	Embeddings
Redundancy Ratio	>70%	>31%	>90%

Observation #5: Cache redundancy: *Both the runtime and tensor redundancy are exacerbated by the widespread usage of in-memory caches in both the serverless platform and DL library.*

To alleviate the cold-start overhead, serverless platforms [20, 60] often keep function alive and warm after the execution

is finished (a.k.a. caching). Caching exacerbates the runtime and tensor redundancy problem.

Moreover, caching also exists in DL frameworks. For example, TensorFlow makes use of high-performance computing libraries, such as MKL-DNN [32] to accelerate the execution of computational graphs. The internal tensor representation of TensorFlow is not identical to MKL-DNN when performing operations such as convolutions; thus, the convolutional kernel data in TensorFlow format must be converted into MKL-DNN format. These converted parameters are usually cached in memory for subsequent usage [4] (e.g., 87.7% of parameters are cached for Resnet50). Hence, these caches also increase tensor redundancy.

2.3 Implications

Due to the memory-intensive nature of startup and computing in DL inference (**Observation 1** and **Observation 2**), the main memory can be easily and massively harvested in serverless inference systems. Reducing the memory footprint of serverless inference needs to be addressed immediately. We study the in-memory data redundancy in serverless inference systems, and observe that the redundancy problem primarily derives from three aspects: *runtime redundancy* (**Observation 3**), *tensor redundancy* (**Observation 4**) and *cache redundancy* (**Observation 5**).

Table 2: Comparison of existing systems.

	KSM [33]	Photons [16]	INFless [71]	TETRIS
Runtime sharing	✓	concurrency	batching	✓
Tensor sharing	✓	✗	✗	✓
Func. Cache sharing	✓	✗	✗	✓
No-harming perf.	✓	limited	limited	✓
First-time sharing	✗	✓	✓	✓
N.F. Running level	kernel	container	container	container
Imple. difficulty	high	low	low	low

Prior works [3, 16, 33, 47, 71] have proposed reducing the in-memory data redundancy through *page merging* or *runtime sharing* (Table 2). The *page merging* methods, such as KSM [3, 33, 47], support memory-saving deduplication through searching and merging equal physical pages of memory. However, it is a Linux kernel-level feature; therefore, its implementation is relatively difficult. It also does not support *first-time sharing* during the startup of function instances. *Runtime sharing* can be enabled through either *concurrent execution* (e.g., Photons [16]) or *batching* (e.g., INFless [71]). However, they only partially solve the *runtime redundancy* problem and their optimal combination is still worth further exploration. Moreover, the *tensor redundancy* and *cache redundancy* still exist and severely degrade the memory efficiency.

3 System Design

In this section, we present the design of TETRIS.

3.1 System Overview

The insight of TETRIS is that memory efficiency can be improved through the combined optimization of tensor

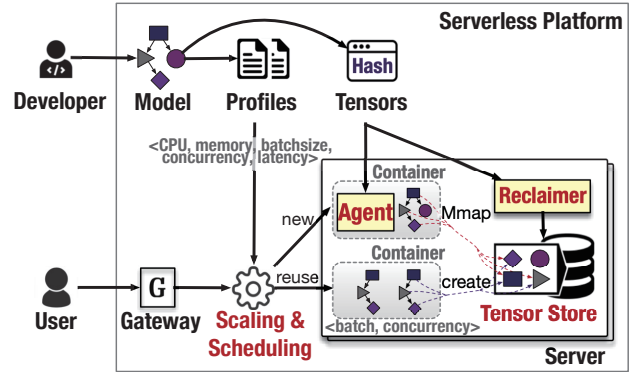

Figure 6: An overview of TETRIS.

sharing and runtime sharing. Figure 6 illustrates the overall architecture of TETRIS, which enables runtime sharing through its *scaling and scheduling* engine and supports tensor sharing through the *agent* in each container and the *tensor store* in each server. When a developer submits a trained DL model to the platform, TETRIS extracts the tensor information (including tensor sizes and hash values) and profiles the inference latency under various batch sizes and concurrency settings. The tensor information is used for directing *tensor sharing*, and the profiles are used by the *scaling and scheduling* module to determine the best *runtime sharing* configuration.

When the user submits requests to the *gateway*, the *scaling and scheduling* engine first decides whether to scale out new instances or reuse existing ones according to the workloads. First, in the case of scaling out instances, the engine derives the batch size and concurrency configurations, minimizing the memory footprint under the SLO guarantee. Then, the new instances are launched on servers with maximum *tensor similarity*. TETRIS supports *first-time sharing* of tensors through a special *agent* in each sandbox. The *agent* parses the computational graph of the model and reads the *hash* value of the tensors. Then, the agent checks whether the *tensor store* has already stored it. If so, the *agent* only maps the memory address of the tensor to its local process using the syscall of *Mmap*, and the reference number of the tensor is increased by 1. Otherwise, the agent loads the tensor from the model file into memory directly and creates a new item in the *tensor store*. Each *agent* is only active during the startup of a new instance. In contrast to DL training where tensors may be updated every iteration, tensors in inference are fixed during its service time. Hence, we set them to be only readable to ensure safe memory access across functions. Second, in the case of reusing existing instances, requests are forwarded to instances following the load balancing principle.

When the workload decreases, the *scaling and scheduling* engine also selectively releases the least-loaded instances without violating the SLO. After release, the reference number of its tensors decreases by 1. In each server, there is a *memory reclaimer* periodically validates the reference number of each

tensor and reclaims the memory pages with reference = 0 so that the released functions no longer occupy memory. A *keep-alive* policy can be adopted to avoid reclaiming oscillation.

3.2 Scaling and Scheduling

The *scaling and scheduling* engine relies on the model profile and requests per second (RPS) to make the scaling decision.

Profiling: We develop an automatic profiler that measures the inference latency of each model under various configurations. Specifically, we define the profile of each model as a 5-tuple $\langle c, m, b, p, l \rangle$, where $c \in C$ denotes the number of allocated CPUs, $m \in M$ denotes the memory configuration for the inference, $b \in B$ indicates the maximum batch size for that instance to process requests, $p \in P$ represents the number of concurrent inference threads, and l represents the inference latency under previous configurations. Since current serverless platforms typically use CPUs for function computation and DL inference on CPUs typically uses small batches (e.g., $B = \{1, 2, 4\}$) and low concurrency (e.g., $P = \{1, 2, 3, 4\}$) to achieve low latency. Thus, we profile only these combinations to narrow the profiling space. Since allocating excessive memory does not lower inference latency, we assign each configuration the bare minimum. Finally, we obtain $n = |C||M||B||P|$ 5-tuples characterizing the model, which are stored in the database.

In the profiling phase, TETRIS also computes and stores the hashes of tensors using the cyclic redundancy check (CRC) code, which is utilized in checking the memory status during *tensor sharing*.

Runtime-shared scaling: The scaling engine monitors the real-time RPS and judges whether the existing instances are sufficient to serve these requests. If not, it dispatches parts of requests to existing instances and launches new instances to process the residual ones. Given the model profile and residual RPS (denoted by R), the scaling engine explores the optimal configurations of new instances, to minimize memory usage while guaranteeing their latency SLO. We define an integer variable $x_i, \forall i \in [1, \dots, n]$, which indicates the configuration i is adopted for x_i new instances. Hence, the optimal configuration can be found by solving the following integer programming problem:

$$\text{minimize : } \sum_{i=1}^n m_i x_i \quad (1)$$

$$l_i \leq t_{slo}, \quad \forall i \wedge x_i \geq 1 \wedge b_i = 1 \quad (2)$$

$$l_i \leq t_{slo}/2, \quad \forall i \wedge x_i \geq 1 \wedge b_i > 1 \quad (3)$$

$$\sum_{i=1}^n x_i b_i p_i / l_i \geq R, \quad \forall i \quad (4)$$

$$x_i \in \mathbb{N} \quad (5)$$

Objective (1) defines the memory occupied by the instances. Constraints (2) and (3) ensure that the latency SLO is satisfied: For $b_i = 1$ (i.e., no batch queue exists for an inference thread), the inference latency l_i should not exceed the SLO; For $b_i > 1$ (i.e., requests must wait in a queue to saturate the batch), we have $t_{wait}^i + l_i \leq t_{slo}$, where t_{wait}^i denotes the waiting time in the batch queue. Suppose the RPS distributed to instance i is r_i , then we have $t_{wait}^i = b_i p_i / r_i$. Since $r_i \leq b_i p_i / l_i$ must be

Algorithm 1: DTS Algorithm

Input:

Requests R ; profile $O = \{ \langle c, m, b, p, l \rangle \}; t_{slo}$;

Output:

S : the set of selected instance configurations;

```

1  $S = \emptyset$ ;
2 sort  $O$  in descending order of  $(b_i p_i) / (l_i m_i), \forall i \in [1..n]$ ;
3 while  $R > 0$  do
4   for each configuration  $o_i \in O$  do
5     if  $b_i = 1 \wedge t_{exec}(c_i, b_i, p_i) > t_{slo}$  then
6        $\lfloor$  continue;
7     if  $b_i > 1 \wedge t_{exec}(c_i, b_i, p_i) > t_{slo}/2$  then
8        $\lfloor$  continue;
9      $R \leftarrow R - (b_i p_i) / l_i$ ;
10     $S \leftarrow S \cup \{o_i\}$ ;
11    break;
```

established (otherwise, if the request arrival rate exceeds the batch processing rate, requests will be dropped), we obtain $l_i \leq t_{slo}/2$. Constraint (4) ensures that the residual RPS can be fully processed by the new instances. Constraint (5) refers to the domain constraint.

This problem can be reduced to the NP-Complete knapsack problem [54]. Hence, we design a heuristic algorithm, called Decreased Throughput Selection (DTS) to determine the instance configuration efficiently. Algorithm 1 presents the details. In line 2, we sort the configurations in O in descending order by normalized throughput. Then, we greedily select the configuration with higher normalized throughput as long as the latency SLO is satisfied (lines 3-11). The DTS algorithm can also be easily extended to balance CPU usage by normalizing the throughput with $m_i + \alpha c_i$, where α denotes the equilibrium factor.

Scheduling: Once the scaling engine has determined the configurations of new instances, the scheduler deploys them to the appropriate servers. To reduce cluster-level memory consumption through *tensor sharing*, TETRIS always tries to dispatch them on servers with maximum *tensor similarity* (denoted by θ). Specifically, for instance i , TETRIS first filters out servers that do not meet resource requirements (e.g., CPU and memory). Then, it derives the similarity value between a model i and a server j using $\theta_{ij} = Mem(T_i \cap T_{store}^j) / Mem(T_i)$, where T_i represents the set of tensors in instance i , T_{store}^j represents the set of tensors already stored in server j , and $Mem(T_i)$ represents the aggregated memory of tensors in T_i .

3.3 Tensor Sharing

After an instance is scheduled on a server, TETRIS first launches a sandbox (e.g., container) on the target server to accommodate it. Then, an *agent* is activated in the sandbox to load the model into the main memory. For a tensor that has

previously been loaded into the *tensor store*, the *agent* maps its memory address to the instance. Otherwise, it creates a new item for it in the *tensor store*.

```

1  Status LoadTensor(Tensor& tensor, TensorReader& reader) {
2      // Get tensor hash value.
3      std::string tensor_hash = GetHash(reader, tensor);
4      // Get or create tensor lock in
5      // Shared Tensor Store atomically.
6      TensorLock lock = CreateOrGetTensorLock(tensor_hash);
7      // Obtain ownership of a tensor lock.
8      lock.Lock();
9      // Check if the tensor in Shared
10     // Tensor Store already exists.
11     if(!TensorExists(tensor_hash)) {
12         // Allocate the tensor memory in
13         // Shared Tensor Store and load

21     // Release the lock.
22     lock.Unlock();
23     return Status::OK();
24 }

```

Listing 1: Simplified code snippet for loading tensors.

Agent: The agent is a lightweight, user-space process for sharing tensors across function instances. Whenever loading a model into memory, the *agent* reads the computational graph metadata stored in the model file and parses the tensors that need to be loaded into memory. As illustrated in Listing 1, the *agent* reads the hash value of a tensor using the interface *GetHash()* and checks whether the *tensor store* has already had the tensor. If the *TensorExists()* returns *FALSE*, the *agent* allocates memory for the tensor and puts it in the *tensor store*. Otherwise, it calls *MmapTensor()* to map the memory address of the existing tensor to the model. The *agent* maintains a loading queue for tensors. To ensure that the *tensor store* correctly behaves when it is accessed by multiple concurrent *agents*, we employ locks: an *agent* must acquire a lock before writing to the store (line 8) and release it after writing completion (line 22).

The *agent* is only active during the startup of an instance. It does not require modifications to the underlying operating system or virtualization layer and does not degrade inference performance.

Tensor store: The *tensor store* holds all tensor memory (parameters, constants, etc.) that need to be shared across all function instances on a server. Every function instance on the server can access tensors in the *tensor store*. Each tensor is uniquely identified by a hash value, calculated from the tensor content and dimensions. We use hash values because they are independent of the models and underlying frameworks. There is also a corresponding lock for each tensor to ensure their safe operation of constructing, mapping, or reclaiming. The *tensor store* is initially empty and does not hold any tensors or locks. During the running of the system, the *agent* continuously adds tensors into it. Each tensor is associated with a *reference number* initialized with 1 after its creation.

Whenever the *agent* adds a new mapping to an existing tensor, the *reference number* is increased by 1. Similarly, whenever an instance is released after completion, the *reference number* is decreased by 1. The tensor memory is reclaimed after the *reference number* is set to 0.

While the *tensor store* is shared by all function instances by default, TETRIS also supports building a *dedicated tensor store* for a subset of functions at the local server (e.g., functions belonging to the same tenant). The tensors in a *dedicated tensor store* cannot be accessed by functions without permission.

3.4 Memory Reclaiming

When a function instance is released, the tensor that it maps from the *tensor store* is not instantly deleted, as it may still be referenced by other instances. To appropriately reclaim the memory of shared tensors, TETRIS runs a *memory reclaimer* on each server, which periodically detects and reclaims the memory of tensors with *reference number* = 0.

The *reclaimer* also supports *tensor caching* policies, which keep tensors in the *tensor store* even after their *reference numbers* become 0. Currently, we have added two caching policies in the *reclaimer*: (1) *keep-alive window*: it is a timeout threshold to determine how long a tensor is kept alive; (2) *Least Recent Used (LRU)*: it only keeps the recently or often-used tensors in the *tensor store* after the *tensor store* is full. The cached tensors can accelerate the startup of function instances. Although TETRIS only supports these two policies at this time, other caching policies [20, 60] can be easily integrated into it. When a tensor’s memory is reclaimed, the *reclaimer* is also required to obtain its lock. To sum it up, Figure 7 depicts the lifecycle of tensors in TETRIS.

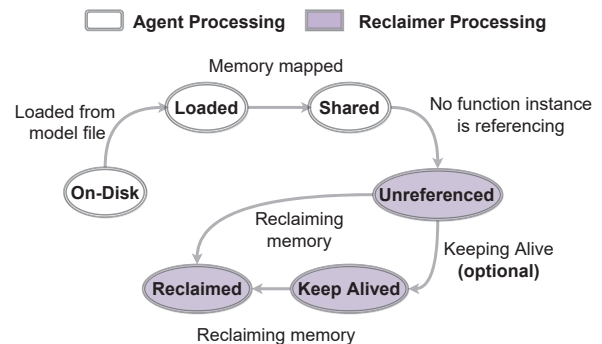

Figure 7: Overview of the tensor lifecycle in TETRIS.

4 System Implementation and Discussion

TETRIS is implemented in the open-source serverless platform OpenFaaS [17] with the DL inference framework TensorFlow Serving [22]. In particular, the *runtime sharing* ability is added to OpenFaaS by modifying its modules including *request dispatching*, *autoscaling*, *scheduling* and *instance creating*; The *tensor sharing* ability is implemented by modifying the TensorFlow Serving framework. We further implement

the *reclaimer* as a separate daemon. The entire system runs on Kubernetes. Overall, TETRIS’s implementation introduces negligible pollution to the existing software stack except for the newly added module *reclaimer*.

Tensor store: Since maintaining a cluster-level global tensor store is costly due to frequent tensor access during inference and high network latency, TETRIS maintains a shared tensor store on each server for performance guarantee while minimizing cluster memory consumption through instance scheduling. The tensor store on each server is implemented as a shared memory region, which can be accessed by all *agents* and the *reclaimer* at the local server. Although shared memory can be enabled by Docker through setting the `-ipc=host` option at the container creation time, allowing all containers to share the host *ipc* namespace, this introduces significant risks of malicious activities or misoperations. Hence, we instead implement the shared memory by mounting a memory-based *tmpfs* [64], in which the tensor store is just a directory. Then, it could be mounted to each container during its creation time using command like `docker -v`. Tensors are stored as files under the mounted *tmpfs* directory and their hash values are set as the filenames. In this way, we can build multiple dedicated tensor stores flexibly, just by creating different mounted directories.

Agent: The *agent* is integrated into the existing loading process of the TensorFlow Serving system. In particular, we modify the *RestoreOp* interface and provide a new tensor memory allocator to manage the shared memory mappings using the *open* and *Mmap* syscalls. After a tensor is created and initialized, its memory pages are tagged as read-only to prevent modifications. File locks are leveraged to synchronize *agents*, avoiding manipulating tensors simultaneously. In the case of concurrently loading models, we pre-randomize the list of loaded tensors to reduce lock conflicts. Besides, we replace the *malloc* interface in the TensorFlow Serving framework with *tcmalloc* [59] to reduce the memory waste.

Scaling & scheduling: The scaling and scheduling engine is integrated into the *faas-netes* module of OpenFaaS. In particular, we modify its *autoscaling* module to implement the DTS algorithm. While OpenFaaS originally uses the default scheduler of Kubernetes, we also modify it using the *tensor similarity*-based scheduling algorithm. To enable both *runtime sharing* and *tensor sharing*, we directly create Kubernetes pods for instances and mount the *tmpfs* directory in the instance creating process.

Reclaimer: The *Reclaimer* is implemented as a Kubernetes DaemonSet. Although Linux provides *fuser* or *lsof* for identifying whether or not a tensor has been referenced by processes, these tools are highly inefficient. Instead, the *Reclaimer* retrieves the set of running functions on a server through Kubernetes’ API, then infers the set of referencing tensors (denoted by T_{warm}) by querying the profile database. Then, the tensor set to be reclaimed (denoted by T_{cold}) can be derived using $T_{cold} = T_{all} \setminus T_{warm}$, where T_{all} represents the set of tensors

residing in the Tensor Store. Such an implementation also ensures fault tolerance, i.e., unreferenced tensors can be detected even when *agents* crash.

GPU Inference: Although the current serverless platforms typically use CPUs for function computation, TETRIS is still effective for GPU inference since frameworks like TensorFlow usually keep a copy of tensors in CPU memory. TETRIS is also suitable for large models which cannot fit into GPU memory. As GPU memory could also be shared through *cudaIpc* [50] APIs, TETRIS can be extended to the GPU inference scenario by developing a specialized manager for maintaining GPU tensor mappings.

5 Evaluation

5.1 Methodology

Table 3: Experimental testbed configurations.

Machine Type	Type 1	Type 2
CPU Device	Intel(R) Xeon(R) CPU E7-4820 v4	Intel Xeon Silver-4215
Number of Sockets	4	2
Processor BaseFreq	2.0 GHz	2.50 GHz
CPU Threads	80 (40 physical cores)	32 (16 physical cores)
Memory Capacity	256 GB	128 GB
Shared LLC Size	25 MB	11 MB
Operating System	Ubuntu 16.04	Ubuntu 16.04
Kubernetes Version	v1.19.2	v1.20.0

Testbed: We evaluate TETRIS using an 8-server testbed consisting of two types of machines: 2 machines are equipped with 80 cores and 256GB of memory while 6 others are equipped with 32 cores and 128GB memory. The machines are interconnected via a 100 Gbps, full-bisection bandwidth Ethernet. Table 3 lists the hardware and software details.

Figure 8: Production workload trace examples.

Workloads: We collect a comprehensive set of benchmark DL models with high heterogeneity from both TensorFlow Hub [22] and the real-world local life service website (Table 4). The benchmark suite is comprised of 21 inference models, ranging in model sizes from 11MB to 3.5GB, varying in download times from 310 to 1.1M, and covering application domains including text, image, audio, etc. Based on these models, we further construct four real-life applications: A *second-hand vehicle trading (SVT) application* adopts the SSD model for object detection and two Resnet152 models for classifying cars and motorcycles. An *audio question & answering (QA-Audio) application* employs the Stt, Use-qa and Fastspeech2 models for speech-to-text translation, QA

Table 4: Inference benchmark suite.

DL Model	Size	Description	Download times
Bit-M [37]	3.5GB	Feature vector extraction	1.4k
LaBSE [19]	1.8GB	Sentence Embedding	24.9K
Bert-qa [14]	1.3GB	Question Answering	501
Electra [10]	1.3GB	Discriminator	6.1K
Use [7]	980MB	Sentence Encoder	1.4M
Centernet [75]	731MB	Object Detection	12.8K
Use-qa [72]	568MB	Question Answering	16.3K
Use-large [7]	563MB	Sentence Encoder	1.1M
Vgg19 [63]	549MB	Image Classification	commercial
Bert [14]	392MB	Text Processing	197.5K
EfficientNetB7 [68]	255MB	Image Processing	2.2K
Resnet152 [26]	231MB	Image Processing	1.6K
InceptionResnetV2 [66]	214MB	Image Processing	6K
Stt [69]	176MB	Speech-To-Text	398
Resnet101 [26]	171MB	Image Processing	1.6K
FastSpeech2 [57]	119MB	Text-To-Speech	310
InceptionV3 [67]	92MB	Image Processing	11.6K
SSD [43]	29MB	Object Detection	commercial
Dssm [29]	25MB	Text Processing	commercial
Lstm [27]	23MB	Text Processing	commercial
Textcnn69 [9]	11MB	Text Processing	commercial

and text-to-speech translation, respectively; A *semantic similarity computation (SS) application* uses the *Use* model for semantic similarity computation; A *text question & answering (QA-Text) application* uses Textcnn69, Lstm, and Dssm for understanding user questions and finding matched answers.

These services are triggered by dynamic invocations simulated using the production trace from the Azure Function [46], where the invocations per hour illustrate diurnal and weekly patterns. Figure 8 displays all the three typical types of production traces used: stable, periodic, and bursty.

Competing approaches: We compare TETRIS with *INFless* [71], *Photons* [16], and the runtime sharing-only version of TETRIS: *Tetris-RO*. *INFless* is a state-of-the-art serverless inference system that natively supports batching and fine-grained CPU-GPU allocation for low-latency, high-throughput inference on serverless. *Photons* supports runtime sharing through concurrent execution in each instance. Since *Photons* is not serverless inference oriented and provide no SLO guarantee, we redevelop it atop OpenFaaS and extend it with function profiles while greedily selecting instance

configurations with the maximum concurrency under SLO constraints. *Tetris-RO* is a variant of TETRIS that disables the tensor sharing part.

5.2 Tensor Sharing Evaluation

We first evaluate the tensor sharing effectiveness by solely activating the TETRIS’s *agent*, and compare the memory footprint to that in the native OpenFaaS system. In particular, the memory footprint under tensor sharing can be derived by $M_{ts} = M_{tensor} + I \times M_{others}$, where M_{tensor} denotes the memory for parameterized tensors, M_{others} indicates the memory for runtime, libraries and others that cannot be shared across instances, and I represents the number of colocated instances in a server. Likewise, the memory footprint under the native OpenFaaS system can be derived by $M_{baseline} = I \times (M_{tensor} + M_{others})$.

Memory footprint: Sharing tensors across instances of an inference function saves memory by up to 93%. Figure 9(a) depicts the memory reduction rate by various models under various number of instances (from 2 to 32). Clearly, the memory reduction rate benefits more from increasing the number of colocated instances. The reduction rate depends on the percentage of memory that can be shared. Basically, the more parameters a model contains (i.e., M_{tensor}) and the less other memory (i.e., M_{others}) a model requires lead to a higher memory reduction rate. For example, the memory reduction rate of VGG19 (i.e., with $M_{tensor} = 549MB$ and $M_{others} = 95.4MB$) reaches to 82% when colocating 32 instances. For models with fewer parameters and relatively larger temporary memory footprints, Lstm for example, the memory reduction rate is limited to 4.4% in the 2-instance co-locating scenario. When deploying 32 function instances, the memory reduction rates of large models like LaBSE and Use even exceed 91% and 93%, respectively. For the model of Bit-M, TETRIS reduces its memory consumption by 108.5GB, because TETRIS only keeps a single copy of the model parameters in memory. Even with only two instances, the memory footprint can still be reduced by an average of 28%.

Memory footprint: Sharing tensors across functions can further reduce memory by up to 36.3%. We collect model variants which are generated by transfer learning from the InceptionV3, EfficientNetB7, Resnet101, Resnet152, Vgg19,

and InceptionResnetV2 models for applications in housing rental, recruitment, second-hand products, travel, and catering businesses. They are commonly only retrained the top dense layers. Figure 11(a) reveals that, as the number of model variants increases, the system memory can be further reduced for all models by up to 36.3%, and at least by 18.8%. Among these models, the memory reduction rate for Vgg19 is relatively limited since merely 77MB parameters are shared among its variants, although it still achieves 13.8% under the co-location of 32 variants.

Higher function density: Tensor sharing reduces the memory consumption of functions, improving the function density by up to 30 \times . Figure 10 presents the increasing rate of function density under various memory configurations. For the LaBSE model with 1.8GB parameters that consume 1.9GB memory, the function density is improved by 20 \times . In the case of the Use model, it even achieves an improvement of 30 \times . For large models, such as Bit-M, a server with 64GB of memory is only capable of maintaining 14 instances. After sharing tensors, the density increases to 74, i.e., more than 60 instances can be accommodated in the same machine. Tensor sharing still significantly improves function deployment density for models with small memory footprints. For instance, 1161 and 1720 additional instances can be created on a 256GB-memory server for Dssm and Textcnn69, respectively.

Figure 10: Function density improvement under various machine memory capacities.

Accelerating startup: The first-time sharing of tensors reduces the startup overhead of inference functions, accelerating the startup speed by 91.56%. The loading of tensors dominates the startup process. Directly mapping an existing tensor address to a new instance is much faster than loading and decoding it from the file on disk; thus, the first-time tensor sharing feature of TETRIS can significantly accelerate the startup process. Figure 9(b) demonstrates that tensor sharing from the same function’s previous instance can significantly speed up the startup process. For example, the model loading time of Bit-M exceeds 15 seconds in a native system whose page cache is disabled, which remains to be 7.9s with page cache acceleration, while tensor sharing can reduce its startup time to 2.8 seconds. Even for models with fewer tensors, such as SSD and Textcnn69, the speedup from tensor sharing still achieves 17.3% and 32.8%, respectively.

Besides the acceleration from sharing tensors of the same function, cross-function tensor sharing could accelerate

startup even when the model has never been loaded. Although it may be slower than that from the same function’s instance due to less redundancy across functions, the speedup still achieves an average of 46.9% (Figure 11(b)). For Vgg19, the startup process is still accelerated by 12.3% when compared with the page cache.

5.3 Overall Evaluation

We further evaluate the overall efficiency of TETRIS by deploying four applications: *SVT*, *QA-Audio*, *SS* and *QA-Text*, and requests towards them are generated using three types of production traces in Figure 8.

Memory footprint: TETRIS outperforms both *INFless* and *Photons* significantly in memory consumption. Figure 13 presents the normalized mean, median and peak memory consumption by TETRIS, *INFless* and *Photons*. We find that *INFless* consumes most of the memory in all experiments for two reasons: (1) *INFless* can only reduce memory consumption when the model supports batching. However, for the applications *QA-Audio* and *SS*, there are models (i.e., *FastSpeech2* and *Use*) that do not support batching. (2) Batching introduces additional queuing time. While the inference computation on CPU is slow and the SLO is tight, we are not able to configure a much larger batch size even for batch-enabled models. (3) *INFless* prefers to use the fragmented resources spanning over multiple servers for better accommodating the residual load and improving the resource utilization, which exacerbates memory consumption. For the four applications *SVT*, *QA-Audio*, *SS* and *QA-Text* under a *stable* request load, TETRIS can reduce the mean memory footprint by more than 86%, 64%, 69%, 65%, respectively, and reduce the peak memory consumption by more than 87%, 68%, 71% and 65%, respectively. In particular, TETRIS achieves the best memory

Figure 13: Normalized memory consumption by four applications under stable, period and bursty workloads.

efficiency in the SVT case because its Resnet152 models benefit more from tensor sharing as they are built from the same set of pretrained parameters. Resnet152 is also computationally intensive and limits the chance for packing requests to share runtimes. *Photons* consumes much less memory than *INFless* since it executes requests concurrently within the same instance without batch queuing time, however tensor redundancy across function instances still exists. Because of tensor sharing, TETRIS can further decrease the mean memory consumption by more than 68%, 33%, 37%, and 21%, and the peak memory consumption by more than 67%, 43%, 39%, and 22% for the applications, respectively.

Efficient runtime sharing: The combined optimization of batching and concurrent execution in TETRIS outperforms either *INFless*'s batching or *Photons*'s concurrent execution. As illustrated in Figure 13, *Tetrtris-RO* can reduce more memory footprint than *INFless* and *Photons* in cases of SVT, QA-Audio, and QA-Text: *Tetrtris-RO* can select configurations flexibly by exploring the various combinations of batch size, concurrency and CPUs. Taking SVT as an example, *Photons* only chooses to execute at most 2 concurrent requests within each instance due to its fixed mapping between concurrency and CPUs, while *Tetrtris-RO* can greedily activate 3 concurrent threads. For the QA-Audio application, although *Photons* greedily packs 4 requests into the same instance, *Tetrtris-RO* could further decrease runtime redundancy by concurrently executing 2 requests with a batch size of 6. For the QA-Text application consisting only of small models, the average memory consumption is still reduced by 21% from the runtime sharing.

Although *Tetrtris-RO* consumes more memory than *Photons* in the SS application case, *Tetrtris-RO* requires much fewer CPU resources. Figure 12 illustrates that *Tetrtris-RO* and *INFless* allocate CPU resources averagely by 42% and 39% less than *Photons*. This outcome is because each time *Photons* increases concurrency, it also requires a fixed amount of additional CPUs, resulting in excessive CPU allocations.

SLO guarantee: TETRIS can guarantee the latency SLO of inference workloads. Figure 14(a) demonstrates that both TETRIS and *INFless* achieve a low SLO violation rate (< 4%)

for all applications. For SVT and SS, TETRIS outperforms *INFless* since more CPUs are allocated for each instance in TETRIS to support concurrent processing. For QA-Audio and QA-Text, the SLO violation rate of TETRIS is slightly higher than that of *INFless* since it uses a larger batch size in runtime sharing, introducing additional batch queuing time. Overall, TETRIS achieves significant improvement in memory efficiency at the cost of a negligible increase in the SLO violation rate.

Cost savings: The reduction of memory consumption by TETRIS saves considerable monetary cost for inference service providers. To further demonstrate the benefits of TETRIS, we conduct a large-scale simulation with a combination of the mentioned applications, and gradually increase the RPS from 100 to 5000. As illustrated in Figure 14(b), TETRIS reduces memory of 61.5GB and 20.2GB per 100 requests, compared to that of *INFless* and *Photons*, respectively. If following the pricing model of \$0.0504 per hour according to the r6g.medium service at AWS EC2, such memory reduction can be transformed into \$0.000861 and \$0.000283 cost savings per 100 requests. If considering the local life website, which serves 1.9 billion requests per day, TETRIS could reduce the monetary cost by \$16,359 per day, about \$5.97 million per year.

5.4 Overhead

The implementation of TETRIS does not require modifications to the ML model, the virtualization sandbox, or the underlying operating system. Developers are simply required to submit the model (instead of the function code) as the model itself contains sufficient information for deployment.

Profiling overhead: TETRIS relies on the offline profiling phase to estimate latency under various CPU, batch size, and concurrency configurations. Since inference on CPU typically incurs high latency, the exploration space of combinations of batch size and concurrency is actually limited. The automatic profiler can test each inference model under various configurations and generate profiles within several minutes. In a real system, as inference services are invoked repeatedly, the profiling only generates a one-time cost and the profiles can

Figure 14: (a) SLO violation rate. (b) Memory consumption and financial cost per 100 requests under varying workloads. (c) Average profiling time for models used in the evaluation. (d) Inference latency distribution. (e) Average loading latency over the number of concurrent loading function instances with models from Table 4.

be reused for later invocations. As depicted in Figure 14(c), profiling an inference model takes an average of 12 minutes.

Inference latency: The memory address mapping method in TETRIS does not introduce latency overhead. We measure the latency distribution of the models in Table 4. Figure 14(d) demonstrates that, compared to the latency yielded by deploying on the TensorFlow Serving framework directly, there is no performance degradation observed after using TETRIS.

Lock contention: When multiple instances are created simultaneously, the contention on the tensor lock may cause startup overhead. We measure the average model loading latency without page cache and compare it with the baseline of the TensorFlow Serving framework. Figure 14(e) indicates that TETRIS still outperforms the baseline by employing randomization in the tensor loading process, thereby reducing much of the lock contentions. Once a tensor is loaded into memory successfully, TETRIS need only to map the memory address for newly launched instances, whereas the baseline still requires expensive file reading and decoding.

6 Related Work

Memory deduplication: Prior works [3, 8, 21, 47, 70] have proposed eliminating redundant data loaded in memory by scanning, comparing, and merging duplicated pages. However, such page-level scanning methods could incur colossal overhead and lag for large, high-density serverless inference functions. As they are effective at the kernel level, TETRIS is compatible with these methods and can be used in conjunction to reduce memory consumption further.

Model compression: Large inference models can also be substantially compressed through fine-grained model design, pruning and quantization techniques (e.g., [24, 25, 31, 56]). However, unlike TETRIS, these methods involve model modifications. The compressing process may also reduce inference accuracy, resulting in side effects for businesses [53]. TETRIS and model compression can coexist.

Inference runtime optimizations: The memory footprint of inference can also be reduced by optimizing memory allocation during inference runtime [13, 35, 40, 41, 55]. However, these optimizations are either framework-specific or require model conversion, whereas TETRIS is orthogonal to these optimizations and can be employed together to further reduce

memory consumption. Moreover, they may require developers to redesign or retrain the model, increasing the development burden, whereas TETRIS requires no model modifications.

Serverless inference: The existing serverless inference systems [1, 6, 71, 74] generally focus on improving inference throughput without violating the SLOs. Instead of improving memory efficiency, they primarily optimize the allocation of computational resources (e.g., CPU and GPU). TETRIS explores solving the memory efficiency problem in serverless inference and can be integrated into such systems. Trims [12] accelerates the data shipping between CPU and GPU through sharing existing models in GPU memory, whereas TETRIS explores sharing tensors among function instances.

7 Conclusion

Modern applications (such as IoT data processing, advertising recommendations, autonomous driving, and e-commerce) continuously rely on inference services. It is expected that serverless inference can reduce the maintenance cost for service providers, however, memory resources can be easily and massively harvested in existing serverless inference systems. Our proposal, TETRIS, can significantly reduce the memory footprint of inference services through runtime sharing and tensor sharing. TETRIS can be easily integrated into serverless platforms as a user-space plugin. With TETRIS, cloud providers can deploy an order of magnitude more instances in each server without violating the SLOs, thus significantly decreasing the deployment and maintenance costs. The prototype of TETRIS is available at <https://github.com/JelixLi/Tetris>.

In the future, we would like to further optimize the GPU memory efficiency of serverless inference systems.

Acknowledgments

We thank our shepherd and other anonymous ATC reviewers for their extremely insightful comments and suggestions that have significantly improved the quality of this paper. We also thank Dr. Tao Li for his significant contribution to this work. Abstract

Deploying large-scale Transformer models under the conventional *pre-train-then-fine-tune* paradigm is impractical for multi-task serving, because a full model copy for each downstream task must be maintained, quickly exhausting the storage budget. Recent algorithmic advances in Parameter-Efficient Transformers (PETs) have shown enormous potential to mitigate the storage overhead. They share the pre-trained model among tasks and only fine-tune a small portion of task-specific parameters. Unfortunately, existing serving systems neither have flexible PET task management mechanisms nor can efficiently serve queries to different tasks in batches. Therefore, we propose PetS, the first unified framework for multi-task PETs serving. Specifically, different PET tasks are expressed by a unified representation in the same framework, which enables flexible PET task management. Based on the unified representation, we design a specialized PET inference engine to batch different tasks' queries together and execute them with task-agnostic shared operators and task-specific PET operators. To further improve system throughput, we propose a coordinated batching strategy to deal with arbitrary input queries. We also develop a PET operator scheduling strategy to exploit parallelism between PET tasks. Comprehensive experiments on Edge/Desktop/Server GPUs demonstrate that PetS supports up to $26\times$ more concurrent tasks and improves the serving throughput by $1.53\times$ and $1.63\times$ on Desktop and Server GPUs, respectively.

1 Introduction

Recently, large-scale pre-trained Transformer models have revolutionized the field of artificial intelligence. Benefited from the practical *pre-train-then-fine-tune* paradigm, Transformer models such as Bert [9], GPT-2/3 [3, 45], Roberta [31], XLNet [59], T5 [46], and some other variants [28, 29] have achieved the leading-edge performance on various NLP (Natural-Language-Processing) tasks, including question-answering, sentiment-classification, text classification and machine translation, etc. Besides NLP tasks, some recent works also apply transformers to computer vision tasks [4, 11, 25, 32, 55, 61], which demonstrate comparable or even superior

[†]Work done during Zhe Zhou's internship at Alibaba DAMO Academy.

*Corresponding author.

performance against conventional Convolutional Neural Networks (CNNs). In brief, Transformers have been recognized as a milestone of artificial intelligence.

To date, a standard workflow has been shaped to apply Transformers to real-world applications. As is depicted in Figure 1, big companies like Google first pre-train the Transformer models like Bert [9] and GPT [3, 45] with large-scale datasets (Step ①). The unsupervised pre-training usually lasts for days to months, even trained on TPU clusters [3, 9]. The pre-trained models with rich task-agnostic knowledge are provided to application developers, who then fine-tune the pre-trained models on their private datasets in a supervised manner (Step ②). The fine-tuned task-specific models are finally deployed to cloud or edge servers (Step ④) to process different input queries. Such a workflow, however, is faced with the poor scalability issue in the pervasive multi-task serving scenarios [18, 19, 34, 40, 48, 53]. Since application developers fine-tune and maintain a full model copy for each downstream task, the storage overhead is proportional to the number of deployed tasks. Considering the enormous parameters (e.g., several hundred millions to several thousand millions of parameters) of Transformer models, the storage overhead will be huge. What is worse, conventional serving frameworks have to swap in and out models frequently if the GPU memory cannot hold all the invoked tasks, resulting in much lower serving throughput. Also, since the input queries are associated with different models, we cannot inference them in batches for higher serving throughput [7, 12, 16, 50].

Recent algorithmic advances in Parameter-Efficient Transformers (PETs) have shown enormous potential to solve these problems partially. They share the pre-trained model weights among tasks and only fine-tune a small portion of task-specific parameters for each downstream task [14, 20, 23, 24, 41, 62, 64]. By this means, the storage overhead is substantially mitigated, while the model accuracy is still comparable or even superior to the full-model fine-tuning counterparts. These methods, however, cannot run efficiently with existing Transformers serving frameworks [12, 37, 56]. On the one hand, due to the lack of PET task management mechanism and PET-oriented inference engine, we have to merge PET parameters into the shared model and still send full model copies to the frame-

Figure 1: The conventional workflow VS. *PetS* workflow for developing and deploying Transformer-based applications. ①: Large-scale unsupervised pre-training. ②: Full-model fine-tuning on customized datasets for different tasks. ③: Parameter-efficient fine-tuning. ④: Serving the input queries with conventional frameworks. ⑤: Serving the input queries with *PetS*.

works. Thus, the GPU memory footprint is not mitigated. On the other hand, queries to different tasks cannot be processed in batches due to both the inter-task weight differences and inter-algorithm representation differences.

To take full advantage of parameter-efficient Transformers, in this paper, we propose *PetS*, a unified framework for multi-task PETs serving with extraordinary scalability and performance. To this end, we first express the state-of-the-art PET algorithms by a unified representation, which decouples any PETs into task-agnostic shared operations and task-specific PET operations. Based on the unified representation, we design a PET tasks management mechanism, which enables the service providers to register and load PET tasks flexibly. We then develop a high-performance PET Inference Engine (PIE) to batch different tasks' queries and execute them with shared operators and light-weighted PET operators, substantially improving the serving throughput. We also propose several optimization strategies to improve the system's throughput further. To be specific, we propose a Coordinated Batching strategy to deal with arbitrary input queries (i.e., queries with different sequence lengths and PET types). To exploit parallelism between PET operators, we apply a PET Operator Scheduling strategy to properly put concurrent PET operators to different CUDA streams. We comprehensively evaluate *PetS* on Edge/Desktop/Server GPU platforms. Compared to conventional frameworks, *PetS* supports up to $26\times$ more concurrent Transformer tasks and improves the serving throughput by $1.53\times$ and $1.63\times$ on Desktop and Server GPUs, respectively. Therefore, *PetS* shows great potential to reduce the service deployment cost and improve the service quality in multi-task Transformers serving scenarios.

2 Background & Motivations

2.1 Transformer Models

As illustrated in Figure 2, Transformer models are generally built by stacking several homogeneous Transformer blocks. A standard Transformer block consists of three key components:

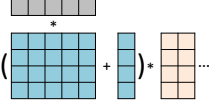

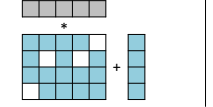

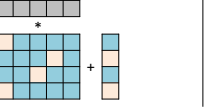

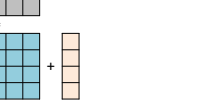

Figure 2: Bert Architecture.

Multi-Head Attention (MHA), Feed-Forward Network (FFN) and Normalization Layers (Norm). For each block, the input is a sequence of n vectors (tokens), denoted as $X \in \mathbb{R}^{n \times d_{in}}$, where n and d_{in} are the sequence length and the input feature dimension. Three linear projection weights $\{W_Q, W_K, W_V\} \in \mathbb{R}^{d_{in} \times d}$ project the input tensor X to Query, Key and Value tensors, denoted as $\{Q, K, V\} \in \mathbb{R}^{n \times d}$ (Step ① in Figure 2), where d represents the hidden feature dimension. The Q, K, V tensors are split to multiple "Heads" (Step ②) to perform softmax-based self-attention respectively (Step ③). The self-attention results are then concatenated (Step ④) and linear-transformed (Step ⑤) to generate the MHA results. After skip-connection and layer-normalization, the hidden feature X is then fed into the FFN layer, which computes with two fully-connected layers (Step ⑥ and ⑦). The GELU activation function [22] is applied to the first layer's output. One block's output serves as the input of the next block. On top of the last block, there is usually a classification layer to generate the final results for a given downstream task.

Traditional neural-networks like CNNs and LSTMs all involve "prior" in their models to enhance the performance (i.e., a CNN model assumes the 2D images have spatial locality, while an LSTM model assumes that the information should be either remembered or forgotten). In comparison, Transformers have no such priors and learn all the useful information

Table 1: Comparisons of State-of-the-Art Parameter-Efficient Transformers.

Model Type	Adapters [23]	MaskBert [64]	Diff-Pruning [20]	Bitfit [62]
Main Computation. Pre-trained Parameters Are Marked Blue				
Formula	$Y_t = X_t \cdot W + b,$ $Y_t = Y_t + \sigma(Y_t \cdot W_{down}) \cdot W_{up}$	$Y_t = X_t \cdot (W \odot M_t) + b$	$Y_t = X_t \cdot (W + \delta_t) + (b + b_t)$	$Y_t = X_t \cdot W + b_t$
Additional Parameters	7.3%	3%	0.5%	3.8%

purely through unsupervised pre-training. To achieve this, not only the pre-train datasets are large in scale, the models also contain enormous parameters to guarantee a high knowledge capacity. For instance, Bert-base and Bert-large have 110M and 340M parameters, respectively, while some recent models even have billions [3, 51] or trillions of parameters [13]. The explosion of such large-scale Transformer models brings both opportunities and challenges. On the one hand, real-world tasks get benefited from their superior performance compared to traditional DNNs. On the other hand, it is challenging to deploy Transformer models to resource-constrained scenarios due to the storage/memory capacity limit, especially when multiple tasks should be served simultaneously.

2.2 Multi-Task Transformers Serving

In real-world scenarios, a server usually runs multiple tasks (here a *task* refers to a distinct DNN model) concurrently for serving different queries [2, 48, 50] (each query invokes at least one of the DNN models). According to the standard workflow shown by steps ①-②-④ in Figure 1, for multi-task transformers serving, every downstream task has its own fine-tuned model. That is to say, the storage/memory overhead is proportional to the number of tasks. In the figure, three tasks occupy $3 \times$ storage. More importantly, all the models should be buffered in GPU memory for quick response to different queries. As the number of tasks increases, it will easily exceed the GPU's memory. Alternatively, we can swap in and out models once some tasks are invoked. Such a method, however, will downgrade the system's performance due to the considerable model swapping overhead [19, 48, 53]. Also, if each task only has limited input queries, the computation resources will be under-utilized because of the small batch size.

Although previous serving systems/frameworks like IN-FaaS [48], Nexus [50], Rafiqi [53], Triton [40], Tensorflow Serving [18] and many DNN accelerators [2, 6, 17, 26, 27] have emphasized the multi-task DNN serving ability, to implement multi-task Transformers serving is still challenging. Reasons are mainly two-folded. First, Transformers usually contain enormous parameters to guarantee their sufficient knowledge capacity. Thus, the storage and memory overhead is much heavier than traditional DNNs, limiting the number of served tasks. Second, previous multi-task inference frame-

works/accelerators assume that the computation/bandwidth requirements vary among concurrent DNNs. Thus, they execute computation-bounded and memory-bounded models (or layers) together to fully utilize the hardware resources. However, since the Transformer blocks are homogeneous among different tasks, there is little room for improving system throughput by co-locating heterogeneous models.

2.3 Parameter-Efficient Transformers

A potential solution to the multi-task Transformers serving problem is directly training a multi-task model like T5 [46]. However, such a method is infeasible in real scenarios since all the application developers have to provide their private datasets to train such a one-for-all model. Recently, Parameter-Efficient Transformers (PETs) have emerged as another promising way to deal with the problem. PETs are based on the assumption that pre-trained models have learned rich knowledge from large-scale pre-train datasets [44, 47]. Thus, we can adapt the pre-trained model to downstream tasks by only fine-tuning a small portion of task-specific parameters rather than the whole model. As illustrated in Figure 1, through parameter-efficient fine-tuning (Step ②), only the PET parameters should be stored for each downstream task. For example, four representative PETs, namely Adapters [23], MaskBert [64], Diff-Pruning [20], and Bitfit [62] only use 0.5% to 7.3% additional parameters for each task. However, they still achieve comparable or even higher accuracy against the full-model fine-tuning counterparts. We summarize them in Table 1 and introduce them as follows:

Adapters: Adapters [23] proposes to inject trainable, task-specific "adapter" modules between some layers of the pre-trained model, while the pre-trained weights are shared among tasks. Formally, assume the linear layers in a pre-trained model compute the hidden feature Y_t with input feature X_t and pre-trained parameters W (weight) and b (bias), namely $Y_t = X_t \cdot W + b$, then an adapter module manipulates the hidden features with two learnable weights $W_{down} \in \mathbb{R}^{d \times d_m}$ and $W_{up} \in \mathbb{R}^{d_m \times d}$, namely $Y_t = Y_t + \sigma(Y_t \cdot W_{down}) \cdot W_{up}$, where σ is the activation function. Since the bottleneck dimension $d_m \ll d$, the Adapter modules are small in size. Each task only requires about 7.3% of new parameters (including a task-specific classification layer).

MaskBert: Based on the lottery ticket hypothesis on Bert [5, 43], MaskBert [64] adapts the pre-trained model to downstream tasks by learning binary masks for each weight matrix. As shown in Table 1, for each task, the pre-trained model (including the classification layer) is frozen. Only the binary masks with about 5% of zero elements are learned for each weight matrix. Since the masks are binary, MaskBert only incurs about a 3% per-task storage overhead. For each linear layer, the computation is represented as $Y_t = X_t \cdot (M_t \odot W) + b$, where M_t denotes the task-specific mask.

Diff-Pruning: Diff-Pruning [20] also shares the pre-trained model among tasks and only fine-tunes a small portion of "difference" for each downstream task. As shown in Table 1, the orange elements in both weight and bias represent the fine-tuned "difference", which only incur about 0.5% of new parameters for each task. During inference, these difference parameters, denoted as δ_t and b_t , are merged with the pre-trained model to construct a task-specific model. Thus, the main computation is $Y_t = X_t \cdot (W + \delta_t) + (b + b_t)$.

Bitfit: Besides a task-specific classification layer, Bitfit [62] only fine-tunes the linear and normalization layers' bias-terms, which also achieves competitive accuracy on some tasks in the standard GLUE benchmark [54]. As shown in Table 1, the linear layers in Bitfit compute with $Y_t = X_t \cdot W + b_t$ where b_t is the only task-specific parameter.

There are still many other emerging PET algorithms [14, 24, 33, 41]. Their workflows are similar to at least one of the above PETs. Therefore, in this paper, we conduct the discussion mainly based on these four representative PETs.

2.4 Challenges of Multi-Task PETs Serving

When serving T different tasks, PETs reduce the storage overhead from original $T \times \gamma$ to $T \times \eta + \gamma$, where γ and η denote the amount of full-model parameters and PET parameters, respectively. Since $\eta \ll \gamma$, using PETs can significantly reduce the storage overhead. However, we notice that the algorithmic advantages of PETs can hardly translate to real speedup with conventional Transformers serving frameworks, mainly due to the following challenges:

Challenge #1: Current frameworks cannot support various PET algorithms flexibly. We present the leading GLUE tasks of each PET algorithm in Table 1. As we can see, all PETs have their advantageous tasks. None of the four PETs can serve as the one-for-all choice. That is to say, the application developers tend to choose the best PETs for their downstream tasks [33]. Therefore, the serving framework has to support multiple types of PETs. However, current serving frameworks are not optimized for diverse PETs. They lack the mechanism to register and manage different PETs flexibly, considering their distinct algorithmic representations.

Challenge #2: The GPU-memory footprint is still not mitigated. To serve PETs like MaskBert and Diff-Pruning using conventional inference frameworks, we have to merge the task-specific PET parameters into the shared model. Af-

Figure 3: Unified representation of PETs. ①: Adapters ②: MaskBert ③: Diff-pruning ④: Bitfit.

ter that, we load the newly constructed models to inference frameworks for serving. Thus, concurrent tasks still occupy $O(T \times \gamma)$ GPU memory, limiting the system's scalability. As discussed before, we can swap in/out models among tasks to deal with the GPU capacity issue, which will result in low throughput due to the model swapping overhead [19, 48, 53].

Challenge #3: It is still hard to improve the system's serving throughput, especially when each task only has limited queries. It is well-known that batched inference is a practical technique to improve a DNN serving system's throughput [7, 12, 16, 50]. However, due to the differences in PET parameters and PET algorithms, conventional frameworks can hardly batch different tasks' queries (even though the tasks may belong to the same PET algorithm) for higher throughput. Such a problem will be more prominent when each concurrent task only has a few queries to process.

3 PetS Framework

To address the challenges outlined above, we propose PetS, a unified framework for efficient multi-task PETs serving. We first propose a unified representation to put all PETs into one framework. Based on this, we develop a flexible PET tasks management mechanism and a specialized PET Inference Engine (PIE) that enables both inter-task and inter-algorithm query-batching. Details are introduced as follows.

3.1 Unified Representation of PETs

As Table 1 shows, state-of-the-art PETs have different algorithmic representations, resulting in a "fragmentation" problem. We propose a unified representation, which expresses PETs with task-agnostic and task-specific operations, to help put them into one framework and enable batched inference. As illustrated in Figure 3, for each PET, we decouple the main computation (linear layers) into three operations: (1) Dense Matrix-Vector-Multiplication (MVM) operation using shared pre-trained weights. (2) Bias vector addition (Vadd) using shared or task-specific bias. (3) Sparse/dense MVM operations using task-specific PET parameters. Since all PETs share the same pre-trained weight matrix W , the first operation, namely $X_t \cdot W$ can be batched together. Though the task-

specific computation with PET parameters cannot be batched among PETs, it only involves light-weighted operations.

Adapters and Bitfit naturally fit into such a representation, since the PET operations are already decoupled from the shareable operations. For Diff-Pruning and MaskBert, we need to perform some equivalent transformations. As Figure 3 shows, for Diff-Pruning, the computation concerning the shared weight and "difference" are conducted separately. Then the results are added up, namely $X_t \cdot (W + \delta_t) = X_t \cdot W + X_t \cdot \delta_t$. For MaskBert, we use an equivalent transformation: $M_t \odot W = (1 - \bar{M}_t) \odot W$, where \bar{M}_t denotes the bit-wise inversion of binary mask M_t . Thus, the original MVM operation is converted to $X_t \cdot W - X_t \cdot (W \odot \bar{M}_t)$. The $W \odot \bar{M}_t$ term can be treated as the sparse weight differences similar to Diff-Pruning's. Since δ_t and $W \odot \bar{M}_t$ are sparse matrices with high sparsity (typically 95% - 99.5%), these PET operations can be efficiently computed with sparse kernels. Considering that the Vadd operations concerning bias terms only have little overhead, we mainly focus on operations (1) and (3), namely the sparse and dense MVM operations.

The unified representation brings two main advantages. First, the queries from different tasks can be batched together at step (1), regardless of the PET types. Let us consider an extreme case: assume we have T tasks, each having a single query. The execution latency is changed from $\sum_{i=0}^{T-1} \alpha(1)$ to $\sum_{i=0}^{T-1} \beta_i + \alpha(T)$, where $\alpha(n)$ denotes the latency of running a Transformer model (without PET) with a batch of n queries. β_i denotes the latency of PET operations for query i . The throughput is improved if we have:

$$\sum_{i=0}^{T-1} \beta_i + \alpha(T) < \sum_{i=0}^{T-1} \alpha(1) \quad (1)$$

The inequality always holds since $\beta_i \ll \alpha(1)$ (the PET operations are light-weighted compared to the shared operations) and $\alpha(T) \ll \sum_{i=0}^{T-1} \alpha(1)$ (batched inference can greatly reduce the average latency [7, 12, 16, 50]).

Second, such a unified representation simplifies the PET tasks management. Each task can be registered by identifying its shared model tag, PET type, and PET parameters. The inference engine can then load these PETs in a unified way.

3.2 Framework Overview

Based on the unified representation, we then present the PetS serving framework to support the management and serving of PET tasks. Figure 4 illustrates the proposed PetS framework. PetS has three main components: a Task Manager, a Parameter Repository, and a PET Inference Pipeline. PetS works as follows: ❶: The framework first registers the PET tasks submitted by developers. For each PET task, the developers are required to provide the Pre-trained Model Tag (such as bert-base-cased), PET Parameters (in compressed format) and PET Type (e.g., MaskBert). ❷: Task Manager registers PET tasks, which assigns a unique Task_id to each submitted task. The PET parameters and the

Figure 4: PetS System Overview.

pre-loaded shared model parameters are all stored in the Parameter Repository (❸). After registration, the PET Inference Engine (PIE) is responsible for processing the input queries (❹) through an optimized PET Inference Pipeline (❺).

3.3 Managing PET Tasks

One of the key features of PetS is the flexible and efficient PET task management mechanism, which is powered by the Task Register and Task Loader modules.

Task Register: The Task Register module registers a PET task according to the user-provided information denoting its shared model, task-specific parameters, and PET type. A triplet $\langle \text{Task_id}, \text{Shared_model_tag}, \text{PET_type} \rangle$ is formed to bind each task with its corresponding pre-trained model and the supported PET type, where the Task_id is unique to identify each PET task. All these triplets are organized as a map structure, with the Task_id as the key and the $\langle \text{Shared_model_tag}, \text{PET_type} \rangle$ pair as the value. Therefore, we can index the metadata of each task given the Task_id of a query. Once a PET task completes registration, its PET parameters are stored in the Parameter Repository. Note that for PETs like MaskBert and Diff-Pruning, the PET parameters are stored in a compressed format to save storage. **Task Loader:** Before a PET task is invoked by the inference engine, the Task Loader module firstly loads the shared model parameters if they have not been loaded yet. Otherwise, the Task Loader indexes the Parameter Repository and accesses the PET parameters according to the Task_id of each invoked task. Considering that the PET parameters are small in size and the shared model only has one copy, all the parameters can be buffered into the GPU memory for quick invoking.

3.4 PET Inference Pipeline

At the core of PetS framework is the PET Inference Pipeline, which processes queries with three pipelined steps including Preprocessing, Batch Scheduling and PET Inference.

3.4.1 Preprocessing

The preprocessing module fetches queries from standard HTTP/gRPC data plane similar to conventional inference serving frameworks [18, 40]. Then it analyzes input data

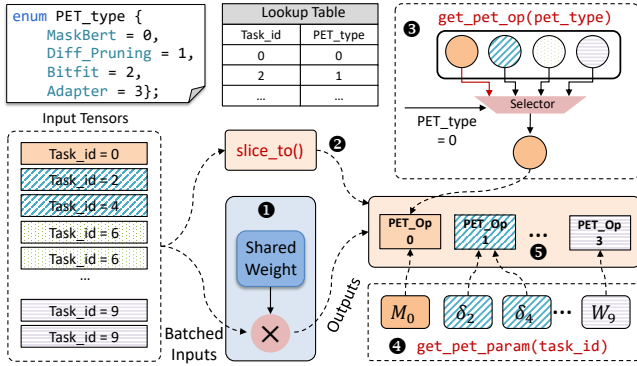

Figure 5: Base PET inference engine workflow.

and reformats them for the next query-batching step. Firstly, the input data is classified according to the shared model (Shared_model_tag). The metadata of each query is extracted, such as the invoked task’s id, sequence length, PET type, etc. Some preliminary data preprocessing operations are then performed according to the extracted metadata, such as grouping the queries of the same PET task. In order to improve the performance of sparse PET operations, the input tensors’ data layout is also reformatted according to the compression format of the corresponding sparse PET parameters. Finally, the preprocessed input queries together with the extracted metadata are dispatched to different queues for further scheduling, according to their targeting shared models.

3.4.2 Batch Scheduler

As discussed before, batching is an effective way to improve system throughput. Though `PetS` enables both inter-task and inter-algorithm batching through the proposed unified representation, the heterogeneity of queries in terms of PET type and sequence length still prevents batching efficiently. The batch scheduler module is used to overcome the challenge posed by query heterogeneity. Taking preprocessed queries as input, the batch scheduler tries to maximize the benefit of batching PET operators and minimize the padding overhead of batching shared operators with different sequence length at the same time. It leverages an accurate performance model to help make batching decisions. The details of the scheduling policy will be described in Section 4.1.

3.4.3 PET Inference Engine

PIE Workflow: The batched queries are finally fed into the PET Inference Engine (PIE). Figure 5 illustrates the base workflow of PIE. In the Figure, we use different colors to indicate the queries’ PET types in the batch. For example, task 0 belongs to MaskBert, while tasks 2,4 belong to Diff-Pruning. PIE starts the computation of each Transformer layer as follows: ❶: PIE performs batched GEMM computation using the input tensor and shared weights W . ❷: PIE gets the `PET_type` attributes of each query by searching in the lookup table with its `Task_id`. The batched inputs are also sliced into several mini-batches (intra-task batching) according to the task id. Then PIE gets the PET operators (❸) and PET

Figure 6: Coordinated Batching Strategy

parameters (❹) according to the obtained PET types. ❺: PIE executes the PET operators successively on each sliced mini-batch. These PET operators are also responsible for adding the PET results to the shared outputs if needed. Note that the remaining operations like self-attention are also performed by PIE but are not shown in the figure.

PET Operator Library: According to the unified representation in Figure 3, the PET tasks rely on different PET operations. MaskBert and Diff-Pruning involve sparse matrix-matrix multiplication (SpMM) as their PET parameters contain high sparsity. Adapters perform light-weighted dense GEMM. While Bitfit only requires a Vadd operation. Therefore, PIE provides an operator library containing high-performance implementations of both dense and sparse operators. The sparse operators are tuned specifically for the sparse patterns and parameter sizes of the target models. We can also implement new PET operators for other emerging PET algorithms if they can fit into the unified representation.

PET Task Scheduler: During the inference of each layer, the PET operations of different tasks have no data dependency and can therefore run in parallel. Given the system allowed parallelism, e.g., the number of CUDA streams on GPU, the PET task scheduler schedules the PET operations to utilize the parallelism as much as possible. The PET operator scheduling strategy is introduced in Section 4.2.

4 Optimization Strategies

4.1 Coordinated Batching

In real scenarios, the input queries usually have variable sequence lengths. If we batch short queries and long queries, the short ones have to be zero-padded, incurring useless computation. Previous frameworks like TurboTransformers [12] pay much attention to solve such a problem. However, for `PetS`, we have to consider both the shared operations and PET operations. Therefore, we propose a Coordinated Batching (CB) strategy to coordinate these two parts during batching.

Problem Formulation: Assume there are R queries, namely $Q = \{x_0, x_1, \dots, x_{R-1}\}$ associated with T different tasks. We divide queries into M batches. For each batch, we use $\alpha[N][L]$ to denote the shared model latency when batching N queries with a maximum length of L . In the meantime, a PET operator

Algorithm 1: Coordinated Batching Strategy

```
1 Input: Number of tasks  $T$ , queries  $Q = \{x_0, x_1, \dots, x_{R-1}\}$ , Shared  
   Op latency model  $\alpha$ , PET Op latency model  $\beta$ ;  
2 Step 0: Pre-processing  
3 Cluster input queries to the same task and generate  
    $Q = \{X_0, X_1, \dots, X_{T-1}\}$ , where  $X_i$  contains  $n_i$  queries;  
4 Step 1: Intra-task batching  
5 for  $i \leftarrow 0$  until  $T$  do  
6   Create DP state vector  $state[n_i + 1]$ ,  $state[0] = 0$ ;  
7   Sort queries in  $X_i$  according to the sequence length in an  
   ascending order;  
8   Create  $split\_idx\_list[n_i + 1]$ ,  $pt = get\_pet\_type(i)$ ;  
9   for  $j \leftarrow 1$  to  $n_i$ ;  $min\_cost = INF$  do  
10    for  $k \leftarrow 1$  to  $j$  do  
11      $tmp = state[k - 1] + \beta[pt][j - k + 1][X_i[j].len]$ ;  
12     if  $tmp < min\_cost$  then  
13       $min\_cost = tmp$ ,  $split\_idx = k - 1$ ;  
14      $state[j] = min\_cost$ ,  $split\_idx\_list[j] = split\_idx$ ;  
15   Split queries into mini-batches  $MB$  using  $split\_idx\_list$ ;  
16 Step 2: Inter-task batching  
17 Sort mini-batches according to their max sequence lengths;  
18 Create DP state vector  $state[\#mini\_batch + 1]$ ,  $state[0] = 0$ ;  
19 Create  $sum[\#mini\_batch + 1]$ ,  $sum[i]$  records the total queries of the  
   first  $i$  mini-batches;  
20 for  $i \leftarrow 1$  to  $\#mini\_batch$ ;  $min\_cost = INF$  do  
21   for  $j \leftarrow 1$  to  $i$  do  
22     $batch\_size = sum[i] - sum[j - 1]$ ;  
23     $tmp = state[j - 1] + \alpha[batch\_size][MB[i].max\_seq\_len]$ ;  
24    if  $tmp < min\_cost$  then  
25      $min\_cost = tmp$ ,  $split\_idx = j - 1$ ;  
26    $state[i] = min\_cost$ ,  $split\_idx\_list[i] = split\_idx$ ;  
27 Split mini-batches into macro batches using  $split\_idx\_list$ ;  
28 Return: The scheduled macro batches
```

takes $\beta[pt][n][l]$ seconds to process the PET terms of n queries, whose PET_type is shortened to pt , and l is the max length of these n queries. Then, the estimated execution latency is:

$$Batch_Latency(B_i) = \alpha[N_i][L_i] + \sum_{j=0}^{t_i-1} \beta[pt_{ij}][n_{ij}][l_{ij}]. \quad (2)$$

In the formula, we use B_i to denote the i -th batch, and assume there are t_i different tasks in the batch. For the j -th task in batch i , there are n_{ij} queries that shape a mini-batch, which is processed by a PET operator indexed by pt_{ij} . The longest sequence length of the n_{ij} queries is l_{ij} . Since all the M batches, namely $\mathcal{B} = \{B_0, B_1, \dots, B_{M-1}\}$ are executed successively, we can further estimate the total latency as:

$$\begin{aligned} Total_Latency(\mathcal{B}) &= \sum_{i=0}^{M-1} Batch_Latency(B_i) \\ &= \sum_{i=0}^{M-1} \alpha[N_i][L_i] + \sum_{i=0}^{M-1} \sum_{j=0}^{t_i-1} \beta[pt_{ij}][n_{ij}][l_{ij}] \end{aligned} \quad (3)$$

As we can see, the total latency is jointly determined by the shared and PET operators. To coordinate these two parts, we propose a two-step Coordinated Batching strategy. As illustrated in Figure 6, in the first step, we generate "mini-batches" for each task (intra-task batching), which only considers the effect of batching PET operators using a profiled β -model. In the second step, we generate "macro-batches" by combining these mini-batches among tasks (inter-task batching), which

Algorithm 2: PET Operator Scheduling Strategy

```
1 Input: PET operator set  $\mathcal{O}$  of a macro-batch, stream set  $\mathcal{S}$ ,  
   latency model  $\beta$  and bandwidth model  $\omega$   
2 Output:  $\mathcal{O}$  to streams assignment  $\Phi(\mathcal{O} \rightarrow \mathcal{S})$   
3  $I \leftarrow \emptyset$   $\triangleright$  operational intensity of  $\mathcal{O}$ ;  
4 for  $o \in \mathcal{O}$  do  
5    $op\_intensity \leftarrow (\frac{o.FLOPs}{\beta(o)}) / \omega(o)$ ;  
6    $I.append(op\_intensity)$ ;  
7 Sort  $\mathcal{O}$  in an ascending order according to  $I$ ;  
8 for  $o \in \mathcal{O}$  do  
9    $stream\_idx \leftarrow \lfloor o.idx / |\mathcal{S}| \rfloor$ ;  
10   $\Phi(\mathcal{O}[o.idx]) \leftarrow \mathcal{S}[stream\_idx]$ ;
```

only considers the effect of batching shared operators using a profiled α -model. In both steps, we sort the queries and use dynamic programming (DP) to find the optimal splitting positions with low time-complexity.

Algorithm 1 details this strategy. The queries with the same task id are firstly clustered and sorted according to the sequence length. At the first step, we use $state[i]$ to record the minimum latency of PET operations when batching the first i queries. We use $split_idx_list$ to record the splitting positions. Equation 4 shows the Bellman equation:

$$state[i] = \min_{0 < j \leq i} (state[j - 1] + \beta[pt_{ij}][i - j + 1][l_{ij}]) \quad (4)$$

With the DP algorithm, we divide the queries of each task into mini-batches. At the second stage, the Bellman equation only considers the shared operators, whose latency is estimated by the α model. Instead of scheduling each single query, the second step schedules the mini-batches:

$$state[i] = \min_{0 < j \leq i} (state[j - 1] + \alpha[batch_size][L_j]) \quad (5)$$

Where $state[i]$ records the minimum latency of batching the first i mini-batches. L_j denotes the max sequence length of the j -th mini-batch. $batch_size$ denotes the number of total queries from mini-batches i to j . After dynamic programming, the mini-batches are assigned to multiple macro-batches.

4.2 PET Operator Scheduling

In addition to the coordinated batch scheduling, PET operators can be executed in parallel to further improve hardware utilization and performance. To achieve the PET-task-level parallelism on GPU, PET operators in a macro-batch (as shown in Figure 6) can be assigned to multiple CUDA streams. However, naively assigning a unique stream to each PET task may not get the ideal speedup, because if we assign computation-intensive operators to different streams (or memory-intensive operators), they can hardly be executed in parallel, since they are bounded by the same resources. Therefore, we propose a light-weighted online scheduling strategy to dynamically assign PET tasks to streams. The scheduling algorithm is shown in Algorithm 2. The input includes the set of PET operators to be scheduled, and the set of streams on which the PET operators execute. The algorithm also requires the PET latency model β used in Algorithm 1, as well as a bandwidth

Table 2: PET data structures and interfaces

Data Structure	Interface
PETModel	load_shared_model(model_url) load_pet_task(pet_type, param_url)
PETLayer	load_pet_params(pet_type, pet_layer_param)

model ω generated together with β . The algorithm outputs the assignment from the PET operator set to the stream set. The first step (lines 3–6) of Algorithm 2 computes the operational intensities of all the PET operators. Operational intensity is a metric to measure the compute to memory access ratio of an operator [57]. The achieved intensity of an operator is computed by its FLOPs divided by the utilized bandwidth. The second step (lines 7–10) then assigns a stream for each PET operator. The rationale is to put operators with differentiated operational intensities to different streams, in order to minimize resource conflict between streams.

Though the PET operator level parallelism contradicts the assumption that the PET operators are executed sequentially in Coordinated Batching. Experiments in Section 6 demonstrates that the coordinated batching still works well with parallel PET execution. Involving a more accurate performance model for parallel PET execution can help generate better scheduling results. We leave this as our future work.

5 Implementation

We implement `PetS` with a Python front-end to describe shared model and PET tasks management, and a C++ backend to perform query scheduling and inference serving.

5.1 PET Description

The description of PET tasks is based on the HuggingFace Transformers framework [58]. We extend HuggingFace Transformers library mainly with two data structures and three interfaces to manage PET tasks, as shown in Table 2. `PETModel` is the base structure to implement a model with PET tasks. `PETLayer` is defined in `PETModel` to describe PET operations, apart from the shared operations. The first interface of `PETModel` in Table 2, `load_shared_model`, loads the shared parameters as traditional HuggingFace tasks do. The `load_pet_task` interface is used to load PET parameters, given PET type and PET parameters URL. It will call `load_pet_params` defined in `PETLayer` to finish the underlying load operations for each layer. Users can inherit and implement these interfaces according to specific tasks.

5.2 Inference Serving

The three modules of the `PetS`'s PET Inference Pipeline in Figure 4 are deployed in individual processes to process input queries in a pipelined manner.

Inference Engine: Inference frameworks compatible with HuggingFace Transformers library can be plugged into `PetS` as its backend engine, such as TurboTransformers [12], LightSeq [56], FastTransformers [37], etc. Modifications should be done to support PET operators and the PET Task

Code Listing 1: User Interface

```
server = PetS() # create a PET server
# Register PET tasks
server.register_task("Adapter", "bert-base", pet_param_url_0)
server.register_task("MaskBert", "bert-base", pet_param_url_1)
# Register other PET tasks ...
# Load shared model parameters and PET tasks
server.load_shared_model("bert-base")
server.load_pet_tasks(pet_task_ids)
# Fetch queries from input query queue and run inference.
queries = server.fetch(input_query_queue)
results = server.inference(queries)
```

Table 3: Shared Model Configurations

Bert Type	#Layer	#Head	Hidden Size	Inter-Size	# Params
DistillBert	6	12	768	3072	66 M
Bert-base	12	12	768	3072	110 M
Bert-large	24	16	1024	4096	340 M

Scheduler. Without loss of generality, `PetS` implements the backend inference engine based on TurboTransformers*. It leverages cuBLAS to compute the shared dense MVM operators. We leverage a high-performance SpMM implementation [15] to implement the sparse PET operators.

5.3 User Interfaces

We use a code sample as shown in Code 1 to demonstrate how users can launch `PetS`, load models and process queries with only a few lines of Python code.

After creating a `PetS` server, it firstly registers PET tasks through the `register_task` interface. It will write the user-provided PET parameters to Parameter Repository and get the assigned task ids. Then the server loads the shared models by calling standard HuggingFace Transformers API and loads PET tasks using the assigned task ids to index the Parameter Repository. Once fetching a group of queries from the input query queue, the `PetS` server runs the PET inference pipeline and returns the inference results.

Currently, we only implement the four aforementioned PET algorithms in the `PetS` framework. A new PET algorithm can work with `PetS` as long as it meets two requirements: (1) The PET operations are separable (with necessary equivalent transformations) from the shared operations. (2) The separated PET operations are light-weighted. Then, to support a new algorithm, the developers should first identify its PET operations. Then the related functions introduced in this section should be extended accordingly.

6 Evaluation

6.1 Experimental Setup

Shared Models: We choose Bert-base, Bert-large [9], and DistillBert [49] as the shared pre-trained models, whose configurations are listed in Table 3. We do not include generative Transformer models such as GPT-2 [45] because GPT-like models have not been well-studied by the PET algorithms discussed above. We leave the evaluation on GPT-like models as our future work and focus on Bert-like models in this

* Shared by CPU and GPU

paper. Note that although in Section 2 we mainly use a single layer for illustration, the evaluations in this section are all conducted on entire models.

PET Tasks: The configurations of four PET algorithms are summarized in Table 4. For Adapter, we set the hidden size (d_m) of the adapter modules to 64. For MaskBert and Diff-Pruning the PET parameters’ sparsity is set to 95% and 99.5%, respectively (we use the equivalent transformation proposed in Section 3.1 to obtain the 95% sparsity for MaskBert). For all PETs, we reproduce the algorithm on HuggingFace Transformers to obtain the trained PET parameters.

Platforms: We evaluate PetS on Edge/Desktop/Server platforms, namely Jetson TX2 (8GB memory, shared by CPU and GPU), GTX-1080Ti-11GB (Intel Xeon E5-2690 CPU), and Tesla-V100-32GB (Intel Xeon Golden 5220 CPU, two sockets). The V100 platform installs CUDA-10.1. The 1080 Ti platform installs CUDA-11.3. The TX2 platform is flashed with Jetpack 4.4.1 containing CUDA-10.2.

6.2 Main Results

6.2.1 Maximum Number of Supported Tasks

We first demonstrate PetS’s scalability by comparing the maximum number of supported tasks with conventional Sequential Serving Systems (SeqS) [1, 7, 12]. Without loss of generality, here we use the unmodified TurboTransformers framework as a representative for SeqS. SeqS loads full-model copy for each task, while PetS works on light-weighted PET tasks. For each platform, we load T tasks (for PetS, each task belongs to a random PET type). If the system can process a batch of

32 randomly-generated queries (each query has a length of 128) without the out-of-memory (OOM) issue, we assume the system can support at least T tasks. We increase T repeatedly to test the limit. The maximum supported tasks are listed in Table 5. Compared to conventional SeqS systems, PetS supports $4\times$ (Bert-large on TX2) to $26\times$ (DistillBert on V100) more concurrent tasks, thanks to the proposed unified representation and efficient PET tasks managing mechanism. Therefore, PetS can substantially save the hardware cost when deploying multiple Transformer-based applications to scenarios from edge computing to cloud computing. Also, it avoids the notoriously slow model swapping [19, 48, 53] even when hundreds to thousands of tasks are invoked.

6.2.2 Throughput Improvement

As stated before, PetS achieves both inter-task and inter-algorithm batching through the unified representation and a specialized PET Inference Engine (PIE). Therefore, we evaluate PetS’s throughput (measured in Queries-Per-Second, QPS) under different situations. As shown in Figure 7, we load 4~32, 16~64 and 32~128 random tasks on TX2, 1080 Ti and V100 platforms, respectively. For each task, we generate queries with three fixed shapes. All queries with the same shape are executed in one batch. We adopt SeqS running a single task as the baseline. Note that here we do not include the two optimizations introduced in Section 4 and adopt a simple fixed-batch policy in the batch scheduling step. We assume that there are no dependencies between tasks.

As we can see, on the 1080 Ti and V100 platforms, PetS achieves up to $1.87\times$ and $1.86\times$ higher throughput, $1.53\times$ and $1.63\times$ on average, compared to the single-task serving baseline. We notice that PetS fail to achieve meaningful speedup than single-task serving on TX2. This is because TX2 only has limited computation resources (256 CUDA cores) and therefore can hardly get benefited from batched inference. Similarly, on 1080 Ti and V100, we observe lower speedup on Bert-large models than Bert-base/DistillBert. This is because Bert-large has a larger layer size (see Table 3), which saturates the GPUs’ computation resources more easily, diminishing the benefits of batched inference.

6.2.3 Comparison with ParS

Apart from Sequential Serving Systems (SeqS), several previous serving systems are built to support concurrent execution of multiple tasks in parallel [18, 40, 48], which belong to the

Figure 8: Throughput Comparison with SeqS and PARS.

Parallel Serving System (PARS). We compare PetS’s throughput over conventional PARS to examine the performance. To implement PARS, we modify the original TurboTransformers framework and put each task-specific model to a unique CUDA stream to run all models in parallel. Note that in this experiment, we adopt Bert-base as the shared model and do not consider model swapping. All results are collected on the GTX-1080 Ti platform.

As shown in Figure 8, we evaluate multiple query configurations represented by a pair of per-task batch size and sequence length ($\{BS, SL\}$) to illustrate the PetS’s generality. We run each query configuration on a different number of tasks for SeqS, ParS, and PetS. All results are normalized to the SeqS baseline. When the number of tasks is small (1~4), PetS cannot outperform ParS. For one thing, PetS has extra PET operations, as illustrated in Figure 3. For the other, tasks of ParS run in parallel. Although the shared weight part of PetS can also utilize parallel hardware, the overhead of PET operations cannot be offset by the limited parallelism. As the number of tasks increases, the benefit of PetS begins to manifest. PetS has an average 17.7% speedup over ParS when the number of tasks reaches 16 on all four configurations. Neither SeqS nor ParS could run too many concurrent tasks due to OOM, while PetS is still able to scale to 32 tasks and even more (refer to Table 5). As we can find in the figure, benefited from the higher hardware utilization, the QPS of PetS improves with the increased total batch size (i.e., $\#tasks \times BS$). As the number of tasks further increases to 256 or more (not shown in the figure), the QPS improvement curve will reach a plateau since a large batch saturates the GPU resources.

6.3 Performance Analysis

6.3.1 Execution Time Breakdown

To figure out why PetS outperforms the baseline systems in serving throughput, we break down the execution time of both PetS and SeqS on GTX-1080 Ti. We set two workloads (i.e., per-task batch size = 1, sequence length = 64 and per-task batch = 2, sequence length = 32) and evaluate eight random tasks with Bert-base and Bert-large models. Therefore, the two workloads issue 8 and 16 queries each time. As we can see in Figure 9, PetS speeds up the Non-PET operators (including the attention operations and the computation of shared linear layers) by $2.17\times$ to $3.28\times$, thanks to the batched execution of shared operators. Due to the adoption of SpMM library, the PET operators only take up 27.4% to 41.3% of the total execution time. Therefore, the end-to-end execution

Figure 9: Execution Time Breakdown.

Figure 10: GPU Memory Footprint Comparison.

time is still much less than SeqS.

6.3.2 Memory Footprint Breakdown

We also profile the memory footprint of PetS and SeqS on 1080 Ti to understand why PetS has outstanding scalability. Taking the configuration of $\{BS, SL\} = \{1, 128\}$ as an example, we plot the consumed GPU memory by both model weights and data under different task numbers in Figure 10.

We can see that a single task has about 0.35GB weight parameters. The memory consumption of SeqS grows linearly with the number of tasks. The weight parameters exceed 11GB for 32 tasks on SeqS, causing OOM on GTX-1080 Ti. On the contrary, for PetS, only the memory footprint of the PET parameters, which normally occupies less than 5% of the shared weight, increases with the number of tasks. As a result, the total memory footprints of 64 tasks occupy less than 40% of total GPU memory, demonstrating that PetS can support much more tasks. Note that the memory footprints of 16 and 32 tasks are the same, but 64 tasks consume three times more data memory than 32 tasks. This is because we use NVIDIA CUB device memory allocator [36] for dynamic data memory management, and the allocated device memory is not strictly proportional to data size, but aligned according to some rounding rules.

6.3.3 Effect of PET Operator Scheduling

In Section 4.2, we introduce a PET Operator Scheduling strategy to properly schedule PET operators to multiple CUDA streams. To demonstrate the benefits of such a strategy, we also profile the speedup using Bert-base on GTX-1080 Ti GPU. We set the sequence length from 4 to 64. For each test case, we put the same 1024 random queries in the pool and process them with a batch of 128. As shown in Figure 11, when 32 tasks are served, increasing the number of streams to 32 brings the optimal performance for all input configurations and reduces up to 15% of execution latency. However, we observe that as the number of tasks keeps growing to 64 and 128, using more than two streams even downgrades the performance under the Seq = 4 configuration. The main inferred

Figure 11: PET Operator Scheduling Performance.

reason is that, as the number of tasks increases, each task’s batch size gets smaller. When the input queries also have limited sequence lengths (i.e., seq = 4), the execution time is too short for the GPU’s scheduler to overlap concurrent streams. Thus, launching too many streams will only incur non-negligible synchronization overhead.

For PIE, the number of CUDA streams can be dynamically set before each batch’s inference. Therefore, we can add a rule to the PET operator scheduler: for tasks with short sequence lengths and small per-task batch size, we set a small stream number such as one or two. For tasks with a long sequence length, we set a large stream number such as 32. We obtain the threshold on each GPU platform by profiling in advance.

6.4 Performance on Arbitrary Inputs

As stated before, in real-world multi-task serving scenarios, the input queries usually have variable sequence lengths and PET types. Naïvely batching these queries may not bring the ideal throughput. Our proposed Coordinated Batching (CB) strategy is aimed to improve *PetS*’s performance on arbitrary inputs by coordinating shared operations and PET operations during batching. To evaluate the effect of CB, we test on workloads with variable sequence lengths and PET types, and then compare CB with three baseline batching strategies:

Fixed-Sized Batching: We put queries in the pool to fix-sized batches, regardless of their PET types and sequence lengths.

α -only Batching: We dynamically batch the queries only using the α model. This strategy is similar to TurboTransformers’ smart batching. To implement the α -only Batching, we treat every single query as a mini-batch and only conduct the inter-task batching (step 2) in Figure 6.

β -only Batching: We dynamically batch the queries only using the β model. That is to say, in Figure 6, only the first step will be performed. The obtained mini-batches will be directly sent to PIE for execution.

To simulate real-world cases, we assume that the queries’ lengths obey the Gaussian Distribution. Without loss of generality, we set the mean value to 32 and set the standard deviation from 1 to 8. The concurrent tasks are set from 32 to 128. Each task is assigned to a random PET type. For each case, we put 1024 queries in the query pool. For each query in the pool, we randomly assign it to a registered task.

As shown in Figure 12, the proposed CB strategy achieves on average $1.52\times$ and $1.27\times$ speedup over Fixed-Sized Batching and β -only Batching, respectively. When the std values

Figure 12: Comparison of Batching Strategies

are set from 1 to 4, CB also achieves up to $1.14\times$ ($1.06\times$ on average) speedup over α -only Batching. For input queries with large variance, Coordinated Batching achieves lower QPS than α -only Batching. We infer that the first step guided by the β model may put some queries with certain length difference into one batch, which is acceptable by Step 1. Such a difference, however, may be amplified in Step 2, since the shared operators usually take up the majority of total execution time (see Figure 9). On the contrary, if the input queries have middle or small variances, the batching of both the two steps is near-optimal. Therefore, to get the highest performance on arbitrary inputs, we can measure the std value of the queries in the pool and choose to use Coordinated Batching (for low-std inputs) or α -only Batching (for high-std inputs).

7 Limitations & Future Work

As revealed by the evaluation results, *PetS* favors the scenarios where the number of tasks is large, while each task has few input queries. If there are only a few tasks, but each task has a large batch, using a traditional SeqS framework may also achieve good throughput. Also, as shown in Figures 8 and 9, when there are only a few tasks, the overhead of *PetS* (i.e., computing PET operators and shared dense operators separately) will outweigh the benefits, since the shared operators cannot achieve enough speedup in these cases to cover the overhead of PET operators.

Currently, the proof-of-concept *PetS* implementation only supports downstream tasks sharing the same pre-trained model. However, with the increasing of tasks adopting transformers as their backbones, there will be more and more shared models registered in *PetS*. The ability to simultaneously serve multiple pre-trained models from various task fields is needed. On the other hand, giant pre-trained models with trillions of parameters exceeding the capability of a single GPU have emerged to achieve significant accuracy gain, such as [13, 52, 63]. Partitioning a single giant model with PET tasks and different shared models on multiple GPUs is challenging for *PetS*. Moreover, for online queries with latency and cost constraints, how to balance *PetS*’s performance and QoS should also be taken into consideration. We leave the model partitioning and QoS-aware query scheduling as *PetS*’s future work.

8 Related Work

Parameter-Efficient Transformers: Apart from the four representative PETs discussed in the paper, there are many

other PET variants like AdapterFusion [41], LoRA [24], LeTs [14] and Prefix-tuning [30], etc. As stated in Section 5.3, these PETs can also work with `PetS` with some necessary extensions. We also notice that there are some works trying to put PETs into one framework such as UniPELT [33] and MAM-Adapter [21]. However, they belong to training frameworks designed from the user’s angle. Their main goal is to combine multiple PET techniques into one model to achieve better accuracy. On the contrary, `PetS` is designed from a service provider’s angle. It batches different fine-tuned tasks provided by users regardless of their PET algorithms and parameters. Therefore, these techniques are orthogonal to `PetS`. Besides, we also notice that Adapter-Hub [42] shares many ideas with `PetS`. It provides an easy way to train and share adapters for different downstream tasks based on Huggingface Transformers. A recent work named OpenDelta [10] further supports fine-tuning more types of PETs. However, the two frameworks are mainly designed for algorithm developers and not optimized for model serving. `PetS` mainly focuses on improving the multi-task serving efficiency from the system implementation and optimization perspectives. We believe that it will be promising to adopt `PetS` as the inference serving backend of these training frameworks.

Inference Serving Systems: As illustrated in Section 6, previous inference serving systems can be classified as `SeqS` and `ParS`. Rafiqi [53] and Clipper [7] deploy a model in an exclusive container, and introduce caching, batching, and model selection techniques to reduce model swapping overhead. Clockwork [19] reduces GPU inference latency variability by ordering queries based on their service level objectives (SLOs) and only running one query at a time, while TurboTransformers [12] batches queries to a single model to improve system throughput. Compared to the `SeqS` running each model sequentially, `ParS` systems enable concurrent execution of multiple models. INFaaS [48] proposes to automatically select models for multiple queries in order to maximize throughput. NVIDIA’s MPS [39] and recent MIG [38] techniques enable efficient GPU resource sharing through hardware partition or full isolation. There exist other systems [8, 40, 60] featured with GPU sharing techniques.

Transformers Inference Engines: With the prevailing of Transformers, some inference engines are designed specifically for efficient Transformer inference. FastTransformers [37] and DeepSpeed [35] are two frameworks featured with multi-GPU inference. LightSeq [56] is a light-weighted inference engine performing some input-aware optimization techniques, such as smart batching and padding minimization, so does the inference engine of TurboTransformers [12].

Leveraging parameter-efficient Transformers, `PetS` saves storage, mitigates model swapping overhead and also improves system throughput by co-design and co-optimization between inference serving system and inference engine.

9 Conclusion

This paper presents `PetS`, a unified framework for efficient multi-task Parameter-Efficient Transformers (PETs) serving. To enable flexible PET task management and high-throughput serving, we first propose a unified representation to put different PETs into the same framework. Then we design a specialized PET inference engine to execute different tasks’ queries in batches. We also propose a coordinated batching strategy to deal with arbitrary input queries and develop a PET operator scheduling strategy to exploit parallelism between PET tasks. Experiments on Edge/Desktop/Server GPUs demonstrate that `PetS` can support up to $26\times$ more concurrent tasks and improves the serving throughput by $1.53\times$ and $1.63\times$ on Desktop and Server GPUs, respectively.

A Artifact Appendix

Abstract

The artifact contains PetS’s code and its setup&running descriptions. We provide instructions and click-to-run scripts for reproducing the main results in this paper.

Scope

This artifact is used for reproducing the main results in Section 6. Specifically, we produce click-to-run scripts to reproduce the results of Figures 7,8,9,11,12 and Table 4.

Contents

- **Code Base:** The code base of the artifact includes the PetS inference framework. It contains the coordinated batching and PET operator scheduling components to demonstrate PetS’s performance optimization strategies.
- **Benchmarking Scripts:** We provide click-to-run benchmarking scripts to evaluate PetS’s performance. The script `run_pets_main_results.sh` can conduct all the main experiments, while you can also run each experiment individually using other provided scripts like `eval_batching_strategies.sh`, `eval_multi_stream.sh`, etc.
- **Instructions:** We provide a detailed README to guide the environment setup, evaluation and code reuse, etc.
- **Reference Results:** We provide the experiment results on two GPU platforms for reference use.

Hosting

The [†] artifact is archived in Zenodo.

Requirements

- **Hardware:** The artifact can run on a server or embedded platform equipped with at least one NVIDIA GPU. We tested NVIDIA Jetson TX2, GeForce GTX 1080 Ti, and NVIDIA Tesla V100.
- **Compilation and Runtime:** The experiments are performed on three platforms with GPUs mentioned above. The compilers and operating systems on the platforms are: on platform with 1080 Ti GPU, g++ 7.5.0 and nvcc 11.3, Ubuntu 20.04; Tx2: Jetpack 4.4.1 with CUDA-10.2. V100: Ubuntu 18.04, CUDA-10.1. g++ 7.5.0.

Many other GPU platforms (e.g., 2080Ti, P100, K80, etc.) may also be compatible with this artifact. However, the Ampere architecture (e.g., A100, A6000) is not currently supported by the sputnik library.

[†]<https://doi.org/10.5281/zenodo.6534753>

Evaluation and Expected Results

After setting up the environment, you can run the two-step evaluation procedure: experiments running and results validating. The first step generates the performance numbers, and the second step draws figures. Please refer to `README.md` for detailed evaluation flow. The full evaluation lasts for about one hour. You can find the plotted results in the `research/reproduced_figures` folder.

Known Issues: Some AE reviewers have reported that in their running environments with V100 GPUs, they failed to get the same curve as Figure 11 (though Figure 11 is based on the 1080-ti GPU). We tested two machines with V100 GPUs. One can get even better results (a local machine, driver version = 510), but the other (an AliCloud instance, driver version = 460) got worse results than 1080-ti. We infer that this is due to the hardware and driver differences. The exact cause is still under investigation.

How to Reuse Beyond Paper

A PET algorithm can work with PetS as long as it meets two requirements:

- Its PET operations are separable (with necessary equivalent-transformations) from the shared operations.
- The separated PET operations are light-weighted.

To support a new algorithm, we should first identify its PET operations. Then three steps are required to add the new PET algorithm to PetS:

- Step-1. Register a new PET type and implement the PET operations using Pytorch APIs in `python/turbo_transformers/layers/modeling_pets.py`.
- Step-2. Deal with the PET parameters loading. Add new loading functions in `modeling_shared_bert.py` and `pet_manager.h`, respectively.
- Step-3. Implement the new PET operators in `shadow_op.cpp/shadow_op.h`
- Step-4. If the new PET operators should be called at places that are different from the four PETs in the paper, you should also modify the bert layers backends, e.g., `bert_output.cpp`

Campo: Cost-Aware Performance Optimization for Mixed-Precision Neural Network Training

Abstract

Mixed precision training uses a mixture of full and lower precisions for neural network (NN) training. Applying mixed precision must cast tensors in NN from float32 (FP32) to float16 (FP16) or vice versa. The existing strategy greedily applies FP16 to performance-critical operations without quantifying and considering the casting cost. However, we reveal that the casting cost can take more than 21% of NN operation execution time, and in some cases surpasses the performance benefit of using low precision. In this paper, we introduce Campo, a tool that improves performance of mixed-precision NN training with the awareness of casting costs. Campo is built upon performance modeling that predicts the casting cost and operation performance with low precision, and introduces a cost-aware graph rewriting strategy. Campo is user-transparent, and enables high performance NN training using mixed precision without training accuracy loss. Evaluating Campo with six NN models, we show that compared to TensorFlow using TF_AMP (a state-of-the-art performance optimizer for mixed precision training from Nvidia), Campo improves training throughput by 20.8% on average (up to 24.5%) on RTX 2080 Ti GPU and by 20.9% on average (up to 23.4%) on V100 GPU, without training accuracy loss. Because of using the cost-aware mixed precision training, Campo also improves energy efficiency by 21.4% on average (up to 24.2%), compared to TensorFlow using TF_AMP.

1 Introduction

Training Neural network (NN) can be resource-demanding: it consumes many compute cycles and requires high memory bandwidth and capacity. One promising approach to lower the resource requirements is to use mixed precision training [1]. Mixed precision is a computational method using a mixture of full and lower precisions. Mixed precision can deliver significant computational speedup by executing operations in a lower precision format as much as possible, while storing critical information in the full-precision format to preserve task-specific accuracy. The mixed precision training

has shown significant speedup over the single (full) precision training on a variety of NN [2–4], especially with tensor cores (TC) available on some GPU architectures.

In NN training frameworks like TensorFlow and PyTorch, the mixed precision training is implemented via a graph rewrite process [5]. This process casts tensors referenced in certain operations in NN from float32 (FP32) to float16 (FP16), or vice versa. This process adopts a greedy strategy that applies FP16 execution to performance-critical operations, most of which are matrix multiplication and convolution, based on an implicit assumption that using low precision *always* leads to performance improvement, and hence the casting cost can be always justified.

However, our detailed performance analysis reveals that the above common assumption is not true. We observe that the casting cost can take more than 21% of operation execution time, depending on the input tensor size of the operation using mixed precision. In some cases (e.g., the operation `MatMul` with an input data size of (64, 1001, 1001, 2048)), the casting cost surpasses the performance benefit of using low precision. As a result, using mixed precision training (even with TC) may not be performance-beneficial and even leads to performance loss (22.7% in the example of `MatMul`). Hence, the casting cost must be considered and quantified when deciding precision for operations.

Deciding whether using low precision for an operation is performance-beneficial is challenging, because the operation time and casting cost are affected by input data size, whether TC is used, and performance characterization of operation (e.g., memory access pattern and compute intensity). Also, using low precision should not impact NN model accuracy. Hence, making the decision of using low precision is a multi-dimensional problem.

In this paper, we introduce a cost-aware performance optimization tool, named Campo, aiming to improve performance of mixed-precision NN training with the awareness of casting costs. Campo assigns the low or full computation precision to each operation in NN to maximize performance while preserving the NN model accuracy. Campo is built upon perfor-

mance modeling that predicts the casting cost and operation performance with low precision. The performance modeling is operation-specific and captures events (such as L2 cache misses and global loads/stores on GPU) critical to the performance of low precision and collected through dynamic profiling in full precision. Using dynamic profiling, the performance modeling is also able to capture the impact of input data size on performance.

Leveraging the performance modeling, Campo introduces a cost-aware graph rewriting strategy. This strategy avoids applying low precision to those operations that cannot get performance benefit, and minimizes the casting cost when applying low precision to a group of operations. Furthermore, Campo does not impact NN model accuracy, because it only applies low precision to those operations identified as numerical safe by the traditional algorithm for low precision assignment. In addition, some operations can benefit from low precision but cannot run on TC because their input data sizes cannot meet the requirement of TC. For those operations, Campo pads the input tensors without programmer participation to maximize the utilization of TC for high performance.

We summarize major contributions as follows.

- We conduct a comprehensive performance characterization on operations in NN training and quantify casting costs. In contrast to the traditional methods that decide precision assignment without considering the casting cost, we reveal that the casting cost can outweigh the performance benefit of using low precision. This observation is unprecedented.
- We develop novel and practical performance modeling to predict casting cost and the performance of operations in low precision.
- We propose Campo, a performance optimization tool that enables high-performance mixed precision training without losing training accuracy. Campo uses a graph traverse algorithm and performance modeling to assign low or high precision to each operation.
- We implement Campo within TensorFlow, and evaluate it with six NN models on Nvidia GeForce RTX 2080 Ti and V100 GPUs. Our evaluation shows that compared to TensorFlow using TF_AMP (a state-of-the-art performance optimizer for mixed precision training from Nvidia), Campo improves training throughput by 20.8% on average (up to 24.5%) on RTX 2080 Ti and by 20.9% on average (up to 23.4%) on V100, without losing training accuracy. Because of using cost-aware mixed precision training, Campo improves energy efficiency by 21.4% on average (up to 24.2%), compared with TensorFlow using TF_AMP.

2 Background

2.1 Mixed Precision Training

A dominant programming paradigm, commonly adopted by machine learning frameworks such as TensorFlow and Py-

Figure 1: The workflow of mixed precision training.

Torch, is to represent an NN model as a static dataflow graph, where computation functions (e.g., Conv2D, and MatMul) in the NN model are associated with nodes in the graph, and input and output tensors of the computation map to edges. The architecture of the NN model (i.e., the dataflow graph) is defined using symbolic expressions by the programmer; The common computation functions are defined as *operations* by the machine learning framework.

The mixed precision training makes precision assignment decisions per node. Some nodes (i.e., operations) in the dataflow graph use full precision (i.e., FP32), and those nodes are essential to maintain training accuracy. Other nodes use lower precision, which is useful to save memory capacity and bandwidth and enable faster math operations (especially on GPUs with TC support). As a result, the mixed precision training can harvest the best of both worlds: maintaining training accuracy and having fast execution.

In TensorFlow and PyTorch, only FP16 is considered as lower precision for the mixed precision training because of FP16’s commonality in various GPU architectures, although some GPU architectures (such as Turing and Ampere) support other lower precisions, such as INT8 and INT4. Like TensorFlow and PyTorch, we only consider FP16 as lower precision in this paper, because of FP16’s commonality.

Figure 1 depicts the workflow of using the mixed precision training in TensorFlow and PyTorch. In general, it includes two steps: (1) identifying which nodes should be changed to FP16 and inserting casts between FP32 nodes and FP16 nodes by a mixed precision graph optimizer, and (2) adding loss scaling to preserve small gradient values by an automatic loss-scale optimizer. We focus on (1) in this paper.

The mixed precision graph optimizer decides the assignment of low precision to operations by classifying operations into multiple lists based on operation’s numerical safety. The numerical safety refers to how an NN model’s quality is affected by the use of low precision. An operation is numerical unsafe, if using low precision during the operation execution leads to worse training accuracy, compared with using FP32. In TensorFlow, there are four lists, discussed as followed.

- **Allowlist:** operations (e.g., MatMul and Conv2D) in this list are considered numerically-safe for execution in FP16, and also performance-critical. These operations are always converted to use FP16.
- **Denylist:** operations (e.g., Exp and SoftMax) in this list are considered numerically-dangerous in FP16 and their effects may also be observed in a downstream operation node. For example, using FP16 in the operation sequence of Exp ->Add, the Add is unsafe due to the unsafe Exp.

Figure 2: A snippet of the dataflow graph from BERT using mixed precision. The tuple on each edge represents a tensor with its shape (i.e., the size of each dimension).

- **Inferlist:** operations (e.g., `BiasAdd`) in this list are considered numerically-safe in FP16, which may be, however, made unsafe by an upstream *denylist* operation.
- **Clearlist:** operations (e.g., `Max` and `Min`) in this list do not have numerically-significant effects in the sense that they can be executed either in FP16 or in FP32.

Compared with TensorFlow, PyTorch use three lists because the operations in the *clearlist* and the *inferlist* are classified into a single list.

Using the above lists, the mixed precision graph optimizer uses low precision for an operation, if any of the following three conditions is true: (1) The operation is in the *allowlist*; (2) the operation is in the *clearlist*, and its immediate ancestor(s) and immediate descendent(s) are using low precision; (3) the operation is in the *inferlist* and there is no upstream *denylist* operation. The mixed precision graph optimization works online by re-writing the dataflow graph via inserting casts before the iterative training of NN model happens.

Figure 2 shows a mixed-precision graph snippet taken from BERT [6] (a transformer-based model). To enable FP16 for `MatMul` and `BiasAdd` while ensuring numerical safety, two FP32-to-FP16 cast operation nodes and one FP16-to-FP32 cast operation node are inserted into the graph. Take the FP32-to-FP16 cast operation node with the input data size (64, 1024) as an example. The number of scalar elements in the input data (tensor) is 65536 (i.e., 64×1024) in this example.

2.2 Tensor Core Acceleration

Since Volta architecture, Nvidia introduces specialized hardware arithmetic units into its GPU products, called Tensor Cores (TC). Compared to regular CUDA cores, TC is more performant and energy-efficient. TC is used to accelerate FP16 matrix multiplication and convolution operations. In TensorFlow, these operations refer to `MatMul`, `Conv2DBackpropFilter`, `Conv2DBackpropInput` and `Conv2D`, which are usually the most fundamental and time-consuming operations in NN models.

TC is automatically activated to run an operation when two conditions are met: (1) the operation is either matrix multiplication or convolution using FP16, and (2) the input tensors of the operation satisfy the shape requirements. For (2), TC requires certain dimensions of the tensor to be a multiple of 8. If the condition (1) is met, we say the operation is a *TC candidate*. Such an operation can run on regular CUDA cores

with low precision when the condition (2) is not met.

Besides the above discussion on the mixed precision training and TC, we target on those NN models whose dataflow graphs are static, which indicates that the dataflow graph does not change its structure across training samples and hence each training step goes through the exactly same computation graph. This implies that once the training batch size is determined, the input data size and shape (i.e., the size of each dimension) of operations are known before the training happens. Such NN models are very common and have been a research target in many recent efforts [7–13].

3 Observation and Motivation

To motivate the design of Campo, we characterize the performance of operations under full precision and low precision, and study the casting cost. Table 1 shows the performance results for six operations. These operations can be commonly found in NN models. The first four operations in the table (`MatMul`, `Conv2D`, `Conv2DBackpropFilter`, and `Conv2DBackpropInput`) are candidates to run on TC. These four operations can easily account for most of the NN training time. For example, in ResNet50, the four operations take more than 90% of the total training time. The four operations fall into the *allowlist*, and hence are always converted for FP16 execution. The last two operations in the table (i.e., `BiasAdd` and `MaxPool`) fall into the *inferlist* and *clearlist*, respectively, of which the numerical precision chosen for the operations is usually context-dependent. We do not study the operations in the *denylist* because they are always executed in FP32. Besides the six operations in Table 1, we study other operations in the three lists, but do not show them in Table 1 for brevity.

We develop two microbenchmarks for each operation to run it with FP16 and FP32 respectively. The input data sizes for each operation are collected from Resnet-50, Inception3 and DCGAN by dlprof [14]. Among those input data sizes, some of them meet the TC requirement on tensor shape, and hence the corresponding operations run on TC. In our study, we use TensorFlow 1.15 and Nvidia RTX 2080 Ti GPU. We run each operation with each input data size 100 times and report the average result. In Table 1, “FP16 Exe. time” and “FP32 Exe. time” do not include casting cost.

Overall, we study the impact of data precision, TC, casting cost, and input data size on operation performance.

Table 1: Performance comparison of some of the representative operations in NN training.

NN Operations	Input Data Size	FP16 Exe. Time (ms)	FP16+Cast Exe. Time (ms)	FP32 Exe. Time (ms)	Using TC
MatMul	(2048, 8, 8, 1024)	0.312	0.353	0.323	yes
	(64, 1001, 1001, 2048)	0.412	0.524	0.427	no
	(2048, 1024, 1024, 1024)	0.414	0.584	0.888	yes
Conv2D	(64, 35, 35, 48)	2.707	2.795	3.664	yes
	(64, 147, 147, 32)	28.965	29.249	29.487	no
	(64, 299, 299, 3)	57.879	58.944	60.098	no
Conv2DBackpropFilter	(64, 299, 299, 3)	8.690	9.773	10.246	no
	(64, 149, 149, 32)	6.013	7.988	7.011	no
	(64, 35, 35, 192)	0.786	0.948	0.871	yes
Conv2DBackpropInput	(64, 37, 37, 96)	3.954	4.049	6.943	yes
	(64, 149, 149, 32)	15.561	16.828	15.696	no
	(64, 35, 35, 192)	5.234	5.939	10.060	yes
BiasAdd	(64, 1001, 1001)	0.252	0.317	0.255	no
	(64, 4096, 4096)	0.294	0.323	0.298	no
	(64, 9216, 9216)	0.299	0.342	0.311	no
MaxPool	(64, 35, 35, 288)	1.849	2.072	1.793	no
	(64, 17, 17, 768)	1.399	1.542	1.402	no
	(64, 8, 8, 2048)	0.825	1.128	0.981	no

1) *Performance variance with different data precisions.*

Table 1 shows that across operations, FP16 consistently outperforms F32, regardless of using TC or not (and without consideration of casting cost). For example, despite not using TC, MatMul with FP16 performs slightly better (3.5%) than with FP32 for the input data size (64, 1001, 1001, 2048).

Furthermore, when the input shape meets the requirement of using TC, the performance gain of using FP16 over FP32 is more significant. For example, Conv2DBackpropInput with FP16 performs significantly better (48%) than with FP32 for the input data size (64, 35, 35, 192).

Observation 1. Without TC, using F16 leads to slightly better performance than using F32. Using TC for FP16 magnifies the performance benefit of F16.

2) *Impact of input data size on performance gains from FP16.* Training an NN model can invoke many instances of an operation in a training step. Different instances of the operation can use different input data sizes. Table 1 shows that as we change the input data size of an operation, the performance gain of using FP16 over using FP32 varies significantly. For example, for MatMul with FP16, the performance gain is 3.6% and 114.5% for the input data sizes (64, 1001, 1001, 2048) and (2048, 1024, 1024, 1024) respectively. In this example, such a large performance variance comes from whether TC is utilized. Even if TC is not utilized for TC candidate operations, we observe large performance variance across different input data sizes. For example, Conv2DBackpropInput with input data sizes (64, 149, 149, 32) and (64, 37, 37, 96) have 75.6% and 0.9% performance gains when using FP16.

The above observation holds true for the non-TC candidate operations as well. For example, BiasAdd with input data sizes (64, 9216, 9216) and (64, 1001, 1001) have 40.1% and 11.9% performance gain when using FP16.

The reason for the above result is because of smaller memory bandwidth consumption and smaller number of FP operations with smaller input data size, which offers less opportunity for FP16 to tap and improve performance.

Observation 2. The performance gain of using FP16 varies largely across input data sizes.

3) *Impact of casting cost.* Comparing “FP16+Cast Exe. Time” and “FP16 Exe. Time” in Table 1, we see that the cast operation introduces 3% - 29% overhead, diminishing the performance benefit of FP16. As a result, using FP16 can perform worse than FP32. For example, considering the casting cost, MatMul using a TC-satisfied input data size (2048, 8, 8, 1024) and a TC-unsatisfied input data size (64, 1001, 1001, 2048) with FP16 performs worse than with FP32 by 9.3% and 22.7% respectively, and the casting cost takes 11.6% and 21.4% of the operation execution time, which is large.

The casting cost stems from (1) the time to initialize the cast operation node in the dataflow graph, and (2) the time to do bitcast and numerical truncation for each scalar element in the input tensor as well as construct the output.

Observation 3. The cast operation introduces non-negligible overhead. Considering the casting cost, it is not always performance-profitable to convert FP32 to FP16 regardless of using TC or not.

In addition to the NVIDIA GeForce RTX 2080 Ti, we get the same three observations on Nvidia V100.

Implications of observations. The effectiveness of using low precision for an operation is impacted by input data size, casting cost, and the usage of TC. Optimizing the assignment of low precision to operations is a multi-dimensional problem, not just one dimensional problem as assumed in the existing solutions.

Figure 3: Overview of Campo.

4 Design

4.1 Overview

Campo includes an offline component and an online component, as illustrated in Figure 3. The offline component is used to build performance modeling to predict performance of operations in FP16. The performance modeling is used by the online component, and makes performance prediction using performance events (e.g., L2 cache misses and global memory load/store throughput) collected from operation execution in FP32. The performance modeling uses correlation analysis to decide which events are the most important for accurate performance prediction. The performance modeling is based on statistical regression modeling, which is built only once by the offline component but repeatedly used by the online component.

The online component includes graph profiling, graph traverse to make per-node precision decision, insertion of cast operation, and input transformation. The graph profiling uses one iteration to run operation nodes in FP32 and collect events needed by performance modeling. The graph traverse makes four passes on the dataflow graph of the NN model and uses performance modeling to decide if each operation should use FP16 or not based on the estimation of performance benefit and cost of using FP16. The input transformation pads the input tensors to make TC candidates meet the requirement of TC on input shape and thus improves the utilization of TC. The online component is lightweight and enables cost-aware mixed precision optimization with guarantee on performance improvement without training accuracy loss.

4.2 Performance Modeling

We build performance modeling to decide whether low or full precision should be employed for a given operation with a given input data size. The performance modeling predicts (1) the casting cost based on the input data size, and (2) execution time of the operation with low precision.

4.2.1 Predicting Casting Cost

The casting cost for a cast operation includes two parts: (1) the time to initialize the cast operation node in the dataflow graph, denoted by C_I , and (2) the time to do the conversion (i.e., the cost to do `bitcast` and numerical truncation for each scalar element in the input tensor as well as construct the output tensor), denoted by C_C .

C_I is modeled as a constant, because C_I comes from a couple of memory allocations and variable assignments for the object initialization of the cast operation node in the dataflow graph. C_C is proportional to the number of scalar elements in the input tensor of the cast operation node. This proportion is represented as a ratio, r . Given the same number of scalar elements, we observe that there is no performance difference between converting from FP16 to FP32 and from FP32 to FP16.

Hence, the casting cost is modeled in Equation 1, where $tensor_size$ is the input data size of the cast operation node. Taking the operation `Add` with an input data size (64, 1024) for conversion as an example, $tensor_size$ is 65536 (i.e., 64×1024).

$$casting_cost = r * tensor_size + C_I \quad (1)$$

To use the above model, we must know r and C_I . They are obtained using linear regression where r and C_I are the slope coefficient and intercept. In particular, by profiling 500 FP32-to-FP16 cast cases and 500 FP16-to-FP32 cast cases, we collect a total of 1000 training samples, each of which includes a pair of measured $casting_cost$ and $tensor_size$ from a cast operation. We use the method of least squares to find the values of r and C_I that minimize the sum of the squared errors.

4.2.2 Predicting Execution Time of Operation

We adopt an operation-specific modeling method, which means that we build a performance model for each individual operation. We do not build a general model for all the operations to predict performance, because the operations exhibit a variety of performance characteristics in terms of memory access patterns and computation intensity. Building a single, general model does not give good prediction accuracy. In our experience, we build a general model using the similar method as building operation-specific models, but can achieve only 43% prediction accuracy, which leads to 21% longer execution time, compared with using operation-specific models. Furthermore, although the total number of operations in the *allowlist*, *inferlist*, and *clearlist* is 143, which is large, the operation-specific performance models are built offline for once, and then can be reused for all NN models. Hence, operation-specific modeling is practical.

Why not using dynamic profiling to measure performance in low precision? Our performance modeling predicts

the execution time of an operation using low precision on regular CUDA cores and TC (if the operation is an TC candidate). We could use dynamic profiling to measure the execution time. In particular, we use three training iterations of the NN model: one iteration running all operation nodes in FP32, one running all operation nodes in FP16 on regular CUDA cores, and one iteration running TC candidate nodes in FP16 on TC.

However, the dynamic profiling using training iterations has limitations. In particular, the dynamic profiling uses FP16 for many operations to measure execution time, regardless of the impact of those operations on training convergence. To avoid slow convergence of the training process after dynamic profiling, one has to discard the three training iterations and restart the training process. This complicates the training pipeline. Even worse, for those downstream training tasks that use a pre-trained model, the number of training iterations is limited. Using dynamic profiling can lead to a large increase in training time. For example, training (fine-tuning) a small NN model Audio2Vec [15] can take about ten iterations, and losing three iterations for dynamic profiling leads to more than 20% increase in training time.

Modeling intuition. The performance of an operation in FP32 and FP16 has correlation. For example, using FP16 reduces the working set size, compared with using FP32, which can lead to less cache misses and in turn decrease execution time. Our intuition is that using execution time in FP32 and a handful of performance-critical events measured in FP32, we can predict execution time in FP16. The parameters (coefficients) in our performance modeling should capture the performance correlation between FP32 and FP16.

Performance modeling. Based on the above intuition, we build the performance model as follows.

$$OP_{LP} = OP_{FP32} \cdot \left(\sum_{i=1}^N w_i \cdot PC_i \right) + \sigma \quad (2)$$

where OP_{LP} is the execution time on either regular CUDA cores or TC using FP16, OP_{FP32} is the execution time on regular CUDA cores using FP32, PC_i is a performance-critical event measured during the execution of FP32, N is the number of performance critical events, and w_i and σ are coefficients. Each operation has up to two performance models: one for regular CUDA cores and the other for TC.

A performance-critical event is a model feature. We use hardware performance counters on GPU to collect those events. There are about 100-200 events collectable on GPU. We choose those events that are the most correlated to the operation performance in FP16, using the following method.

Selection of model features. We use the Spearman's rank correlation coefficient [16] (or Spearman's ρ) to select events. The Spearman's ρ is a method to quantify how well the relationship between two variables can be described using a monotonic function [16]. The Spearman correlation between two variables is high when observations have a similar rank

between the two variables, and low when observations have a dissimilar rank between the two variables.

In our case, an event is a variable and the operation performance using FP16 is the other variable. We make many observations by running tests. If the observations on the event and the observations on the F16 performance have the similar rank (i.e., relative position label of the observations within the event or F16 performance), then the event is monotonically correlated (either monotonically increasing or monotonically decreasing) with the FP16 performance. In our case, we use a threshold of 0.75 for ρ . When $|\rho|$ for an event is larger than 0.75, then we choose it as a model feature.

In particular, given an operation OP , we use the following method to select features to build the performance model for FP16 on TC. Using 1000 different TC-satisfied inputs, we run OP in FP32 1000 times to collect execution time and each collectable event. Then, using the same 1000 inputs, we run OP in FP16 1000 times to collect execution time. As such, we construct 1000 samples, each of which consists of measured FP32 execution time, the value of each collectable event, and FP16 execution time. For each event, we use the 1000 samples to run the Spearman's rank correlation analysis and calculate ρ . If ρ is larger than the threshold, then the event is selected.

To select the features to build the performance model for FP16 on regular CUDA cores, we use the same method as above but the operation inputs do not necessarily meet the TC requirement.

We select events for each operation using the above approach. We discuss the most common events across operations as follows.

- **Global memory load/store throughput** indicates intensiveness of global memory access. If an operation has higher throughput in global memory load/store, the operation may get larger performance benefit by using FP16.
- **Instruction executed per cycle** indicates compute intensity. Using FP16 can be helpful for those floating point intensive operations, because of higher throughput of FP16 instructions.
- **GPU occupancy** indicates how many warps are able to be active during operation execution. An operation with low GPU occupancy will be sensitive to whether FP16 or FP32 is used, because using FP16 or not causes difference in global memory accesses and the operation with low GPU occupancy has lower thread-level parallelism to hide long global-memory access latency.
- **L2 cache accesses and misses and L1 cache accesses** indicate memory access locality in the operation. Compared with an operation with bad reference locality, an operation with good reference locality can take advantage of the cache hierarchy and is not sensitive to global memory bandwidth, hence less sensitive to the global memory bandwidth savings due to the use of FP16.

Getting model coefficients w_i and σ . For each operation-specific performance model, we run the operation 1000 times

with 1000 inputs with different sizes, using FP32 and FP16 respectively. That generates 1000 samples, each of which includes FP32 execution time, the values of events collected in FP32, and FP16 execution time. Using the 1000 samples, we use the method of least squares to find the values of coefficients w_i and σ that minimize the sum of the squared errors. To generate 1000 inputs with different sizes, we profile the input data size of the operations from 11 NN models (including GoogLeNet, UNet-3D, DLRM, DCIGN, BiLSTM, SSD-MobileNet-v1, ShuffleNet, SSD, DenseNet, Mask R-CNN, RNN-T) from the MLPerf benchmark suite [17] using 100 training steps with various batch sizes.

Building performance models for an operation is not time-consuming. For example, building the two models for the operation `Conv2D` (including generating samples to get the model coefficients) takes about 1.5 hours. Building performance models for 143 operations takes about 112.5 hours.

Justification of modeling method. In essence, our modeling method is linear regression. Before we used it, we asked if other modeling methods (such as using a machine learning model) can work. We built a multilayer perceptron model (MLP) taking the same input and output as our linear regression model. The MLP has four layers (one input, one output and two hidden layers) and has 800 neurons in total. However, we do not see any benefit of using such a model in terms of prediction accuracy: the prediction accuracy for the MLP is 71%, while it is 94.2% for the linear regression model. The low prediction accuracy of using MLP is largely due to the fact that our problem nature exhibits near-linear correlation between features and MLP seems to be prone to get stuck in a local optimum for this problem. Furthermore, the MLP takes 10x more training samples than the linear regression model. Hence, we do not use MLP.

Furthermore, we asked if basic heuristics can work. In fact, compared with using dynamic profiling (a basic heuristic), using performance modeling reduces training time by 20% for `Audio2Vec`. Compared with using the same precision for all instances of each operation (another basic heuristic), using performance modeling reduces training time by 35% for `BERT-large`. Our performance models are repeatedly used for NN models, which amortizes the construction cost.

Our modeling method considers the impact of operation input on operation performance, because it uses dynamic profiling in FP32 to measure performance with the given operation input, based on which to make prediction for FP16 performance with the same operation input.

Furthermore, our modeling method is operation-specific, which greatly simplifies model construction, because the operation type itself provides much of implicit information on operation characteristics. For example, the operation name `MatMul` indicates strided memory accesses, and hence the operation-specific performance model does not need to explicitly model such a memory access pattern to make performance prediction. As a result, our performance model can

focus on capturing the correlation between the performance of FP32 and FP16.

4.3 Runtime Graph Rewriting

The runtime graph rewriting decides (1) data precision for each operation, and (2) which operations to be converted together to reduce the number of cast operation nodes. By graph rewriting, Campo aims to reach the following goals: (1) minimizing the training time; (2) minimizing the casting cost; and (3) no adverse impact on the numerical safety (compared with the traditional mixed-precision training).

The graph rewriting in Campo includes graph profiling, graph traverse to determine the precision assignments, and insertion of cast operation nodes, discussed as follows.

Graph profiling. Given an NN model, Campo uses a single training step (or iteration) running in FP32 to collect execution time and events needed by performance modeling for those operations in *allowlist*, *inferlist*, and *clearlist*. The graph profiling is triggered right after the first few training steps used by TensorFlow for warmup (i.e., determining system configurations).

Graph traverse happens after graph profiling, and performs four times on the dataflow graph. Each graph traverse follows the data flow in the NN training to analyze operation nodes in the dataflow graph. During the graph traverses, Campo uses two lists, *allow_nodes* and *deny_nodes*, to record those operation nodes determined to run in FP16 and in FP32 respectively. We depict the four-time traverse as follows.

Traverse #1. During the traverse, when an operation node is encountered, Campo checks if it is in *allowlist*. If yes, then Campo uses performance modeling to decide if the casting cost plus FP16 execution time of the operation (on regular CUDA cores or TC) is smaller than the counterpart FP32 execution time. If yes, then the operation node is put into *allow_nodes*; If no, then it is put into *deny_nodes*. During the traverse, only those operations that are numerical safe in FP16 (i.e., in *allowlist*) are considered, in order to maintain the training accuracy of the NN model.

Traverse #2. During this traverse, Campo checks the remaining operation nodes. For each node, Campo checks if it is either numerically-unsafe (i.e., in *denylist*) or on a path from a node in *denylist* to another node in *denylist* or *inferlist* through some operation nodes in *inferlist* or *clearlist*. If yes, then the checking node is added to *deny_nodes*. This traverse aims to prevent numerically-unsafe operation nodes and their downstream operation nodes from being changed to FP16, in order to maintain the training accuracy.

Traverse #3. During this traverse, Campo checks each remaining operation node. If the node (called the target node in the remaining discussion) is in *inferlist* or *clearlist*, then Campo put the target node into *allow_nodes*. After Traverse 2, such a node should be safe to use FP16. It is possible that the immediate upstream or downstream node(s) of the target

node is in *allow_nodes*. For such a case, the cast operation to convert target node for FP16 or FP32 is saved for higher performance.

Traverse #4. During this traverse, Campo checks each remaining operation node. If the node (called the target node in the remaining discussion) is in *clearlist* and connected to a node in the *allow_nodes* via other nodes in *clearlist*, then Campo uses performance modeling to decide whether the casting cost is smaller than the performance benefit of using FP16 (on regular CUDA cores or TC) for the target node and other connecting nodes. If yes, then the target node is put into *allow_nodes*.

Insertion of cast operation nodes. After the four-time graph traverse, Campo changes the type attribute of operation nodes according to their FP16 or F32 assignments, and then inserts a cast operation node at the boundary between any FP16 node and its neighbour FP32 node (or vice versa) by using the API `ChangeTypeAttrsAndAddCasts` provided by TensorFlow.

4.4 Usage of Tensor Cores

For any operation node in FP16 decided in the graph rewriting process, Campo is able to use performance modeling to decide if using regular CUDA cores or TC is more performance beneficial. If using TC is better, then Campo makes the best efforts to run the operation on TC.

In particular, in each training step, Campo checks the input shape of each TC candidate. If the input shape of a TC candidate cannot meet the TC requirements, Campo pads the input tensor by adding zero-filled rows or columns. For example, for `Conv2D`, Campo pads its input to make the dimension size of each channel a multiple of 8. Compared to the traditional padding method recommended by `dlprof`, our method is implemented inside the training framework, and thus transparent to the users and does not need to modify NN models.

Overhead analysis. Zero padding adds overhead to computation and memory consumption. For an operation decided to use FP16 on TC by performance modeling, the computation overhead (with casing cost) is easily surpassed by the performance benefit: in our evaluation, an operation decided to use FP16 on TC by performance modeling can typically gain about 2x performance improvement (compared with using FP32 on regular CUDA cores), while padding usually leads to less than 20% performance overhead. To consider the performance overhead of zero padding in performance modeling, we can introduce a threshold, which is an empirical estimation on the padding overhead. Only when the casting cost plus this threshold is smaller than performance benefit, we use FP16 on TC.

The memory overhead of padding is usually less than 1%, which is very small. This is because in practice, the number of zero-filled rows or columns via padding is less than 8 and the number of dimensions requiring padding is typically at most

2, while the total number of rows or columns is hundreds.

5 Implementation

Campo extends the mixed precision graph optimizer and runtime system in TensorFlow v1.15. Such an extension includes 235 C++ LOC. The extension is used to decide if an operation should use FP16 based on performance modeling. We add APIs `CheckAllowListOps` and `CheckIfAllowThroughClear` to implement the first and fourth graph traverses. The other two traverses extend the existing implementation for assigning precision to operations in TensorFlow. In TensorFlow's `op_kernel` module, we add an API `InputShapeTranform` to implement input padding and meet the TC requirements on the input shape. Besides the above extension, Campo includes graph profiling and performance modeling (including offline tools to build performance models). In total, Campo is written in 2570 LOC.

6 Discussions

Differences between using performance modeling and static profiling. The static profiling is an alternative approach to get performance of operations in low precision. Using static profiling, the user must collect the information on tensor shapes from operators, and then use the collected information to run operators in low precision offline. We discuss the differences between performance modeling and static profiling as follows.

There are two differences. First, the static profiling has to be done for each NN model and is not scalable, while the performance modeling, once built, can generally work for most NN models. Second, when the number of tensor shapes and operations in an NN model for profiling is small, the static profiling is a better solution to get operation performance in low precision. However, the profiling cost must be small enough to enable practical deployment of static profiling. In contrast, the performance modeling does not incur deployment cost for most of NN models. The performance models can be repeatedly used for NN models, which amortizes the model construction cost.

Portable performance modeling. Our performance modeling is architecture-dependent, because it collects architecture-dependent performance events as the model features. This means that we must build different performance models for different GPU architectures. How to reduce human efforts to build performance models remains to be studied. In addition, it would be interesting to extend Campo to lower precisions (e.g., INT8 and BF16) using the same methodology in Campo. We leave them as our future work.

Figure 4: Training throughput with FP32, TF_AMP and Campo on RTX 2080 Ti.

Figure 5: Training throughput with FP32, TF_AMP and Campo on V100.

Table 2: Hardware configurations

CPU	Intel Xeon CPU E5-2648L v4@ 1.80GHz
Main Memory	64 GB DDR4
CPU Cores	2 sockets, 14 cores per socket
GPU	NVIDIA GeForce RTX 2080 Ti (Turing)
CUDA Cores	4352 CUDA cores (68 SMs, 1.54GHz)
Tensor Cores	544 tensor cores
L1 Cache	64 KB (per SM)
L2 Cache	5.767 MB
GPU Device Memory	11 GB GDDR6
GPU	NVIDIA Tesla V100 (Volta)
CUDA Cores	5376 CUDA cores (84 SMs, 1.53GHz)
Tensor Cores	672 tensor cores
L1 Cache	128 KB (per SM)
L2 Cache	6.144 MB
GPU Device Memory	32 GB HBM2

7 Evaluation

7.1 Experimental Setup

Experimental Platforms and Tools. We use a multicore machine equipped with two TC-supported GPUs (i.e., Nvidia GeForce RTX 2080 Ti and V100) and Intel Xeon CPU listed in Table 2. The two GPUs are attached to the server by PCIe 3.0. We use CUDA 9.0 [18], NVIDIA cuDNN 8.0, and Ubuntu 18.04. We use dlprof [14] and Nvidia Nsight Compute [19] to collect performance statistics. We measure system power for GPU, CPU and DRAM by using a collection of industry-standard tools including NVIDIA System Management Interface [20] and Intel Running Average Power Limit (RAPL) Interface [21]. We use the number of samples processed per second and training throughput per Watt as metrics to quantify training throughput and energy efficiency respectively. Unless indicated otherwise, the reported results are collected on V100 and all tests use the default GPU setting.

Benchmarking Methodology. We evaluate six NN mod-

Figure 6: The number of cast nodes of NN models trained with TF_AMP and Campo, respectively.

els including AlexNet [22], Inception3 [23], Vgg16 [24], ResNet50 [25], DCGAN [26], and BERT-large [6]. We only evaluate BERT-large on V100 because of the out-of-memory error on RTX 2080 Ti. For the first four models, Imagenet is used as the training dataset [27]. For DCGAN and BERT-large, we use CelebA [28] and SQuAD [29] as the training dataset, respectively. The training batch size for AlexNet and other models on GeForce RTX 2080 Ti GPU is 256 and 64 respectively, according to the model configurations in related work [30]. The training batch size for BERT-large and other models on V100 is 10 and 256 respectively, according to the model configurations in related work [31].

We run each NN model training experiment ten times and then report the average results. We use TensorFlow v1.15 and its performance optimizer “TF_AMP” for mixed precision training. TF_AMP is our baseline for performance comparison. TF_AMP in TensorFlow v1.15 is the state-of-the-art solution and *the most recent* performance optimizer for mixed precision training. To preserve small gradient values, we adopt the automatic loss-scale optimizer in TF_AMP. To evaluate model accuracy, We test both the Top-1 and Top-5 accuracy on the ImageNet-1k validation set for AlexNet, ResNet50, Inception3 and Vgg16, and the celebA validation set for DCGAN. For BERT, we test the F1 score on the SQuAD v1.1 validation set.

Figure 7: TC utilization of NN models trained with TF_AMP and Campo, respectively.

7.2 Training Throughput

Figures 4 and 5 show the training throughput of Campo, TF_AMP, and single precision training (using FP32). To calculate speedup, the throughput of using the single precision training is used as the baseline.

Using mixed precision training, TF_AMP and Campo achieve large speedup (1.28x - 3.05x) over FP32 on both GPUs. Furthermore, Campo outperforms TF_AMP by 20.8% on average (up to 24.5%) on RTX 2080 Ti, as well as by 20.9% on average (up to 23.4%) on V100. The performance benefit of Campo over TF_AMP comes from two perspectives: reducing the number of cast operation nodes in the dataflow graph and using TC more often, discussed as follows.

7.3 Performance Breakdown

Number of cast operation nodes. Figure 6 quantifies the number of cast operation nodes. Campo reduces the number of cast operations nodes for higher performance. Campo uses 27.7% less cast operation nodes on average (up to 31.3%) than TF_AMP.

TC utilization is defined as the percentage of training time when TC is busy. Figure 7 shows TC utilization. Campo increases the utilization of TC by 29.4% on average (up to 37.9%), which indicates that Campo uses TC more often.

Contribution quantification of the graph rewriting and improving TC utilization. We disable our method of improving TC utilization but keep the graph rewriting to quantify its contribution to the performance improvement (compared with TF_AMP). Then we enable our method of improving TC utilization along with the graph rewriting to quantify the contribution of improving TC utilization. Figure 8(a) and Figure 8(b) show the results on two GPUs. The two figures reveal that the graph rewriting contributes more than improving TC utilization: 84.5% of the overall performance improvement (on average) comes from the graph rewriting.

We also notice that V100 benefits 38.1% more (on average) from TC, compared with RTX 2080 Ti. This is because of two reasons. (1) V100 has more computation resource: V100 has 23.5% more tensor cores than RTX 2080 Ti; (2) training on V100 is able to run 10.4% more operations on TC than training on RTX 2080 Ti, because higher performance benefits of using TC on V100 offset casting cost in more operations.

Table 3: Model accuracy of NN models trained with FP32, TF_AMP and Campo, respectively.

NN models	Top-1 Accuracy (%)			Top-5 Accuracy (%)		
	FP32	TF_AMP	Campo	FP32	TF_AMP	Campo
AlexNet	63.39	64.41	64.38	81.24	81.21	81.19
ResNet50	78.77	78.74	78.75	94.86	94.82	94.85
Inception3	78.42	78.45	78.43	90.15	90.16	90.15
Vgg16	71.58	71.6	71.57	88.28	88.25	88.27
DCGAN	80.12	80.16	80.13	92.47	92.46	92.44
BERT-large	91.35	91.36	91.33	N/A		

7.4 Training Accuracy

Table 3 reports the model accuracy of six NN models trained with FP32, TF_AMP and Campo, respectively. We can see that across NN models, the model training with Campo leads to no loss in model accuracy compared to TF_AMP, which closely matches the FP32 training accuracy (the subtle differences across FP32, TF_AMP and Campo in accuracy are within typical bounds of run-to-run variations).

Campo preserves training accuracy, because of two reasons. (1) Those operations that are numerical unsafe still use FP32. (2) Campo uses the same effective loss-scaling optimizer as TF_AMP to preserve small gradients in FP16.

7.5 Prediction Accuracy of Performance Models

To evaluate the accuracy of the performance models, we use a metric denoted by M_A as follows.

$$M_A = 1 - \frac{1}{n} \sum_{i=1}^n \left| \frac{\hat{y}_i - y_i}{y_i} \right| \quad (3)$$

where n is the number of test cases, and \hat{y}_i and y_i are the predicted and measured execution time for the test case i .

We test 150 performance models for 143 operations respectively. For each model, we use 100 different input sizes as test cases. In total, there are 15000 tests. We report the modeling accuracy for five common operations, i.e., Cast, MatMul, Conv2DBackpropFilter, Conv2DBackpropInput and Conv2D in Figure 9.

In general, the average prediction errors for the five operations are less than 5%, which demonstrates high prediction accuracy. Overall, the prediction error for 143 operations is 5.8% on average (and less than 6%).

Handling mis-prediction of performance modeling. When a mis-prediction happens, there are two possible outcomes. (1) Based on performance modeling, the operation is not scheduled to run in FP16, although it should be for better performance. (2) Based on performance modeling, the operation is scheduled to run in FP16, although it should not, because of high casting cost.

For the case (1), mis-prediction does not cause any performance loss, compared with using full precision (i.e., the

Figure 8: Breakdown of the overall performance improvement from graph rewriting and improving TC utilization.

Figure 9: Performance prediction accuracy for five operations based on the operation-specific performance models

Table 4: Average system power consumption of NN models trained with FP32, TF_AMP and Campo on RTX 2080 Ti and V100, respectively.

NN Models	Average System Power (W)					
	RTX 2080 Ti			V100		
	FP32	TF_AMP	Campo	FP32	TF_AMP	Campo
AlexNet	274	268	267	325	319	316
ResNet50	272	265	263	324	313	311
Inception3	273	264	263	326	316	315
Vgg16	273	267	267	324	316	316
DCGAN	275	268	267	327	320	319
BERT-large	N/A	N/A	N/A	332	320	318

original execution). For the case (2), mis-prediction causes performance loss in that operation. But since the performance prediction accuracy is high, the performance loss is easily outweighed by the performance benefit of correctly using FP16 in other operations. In our evaluation, for each NN model, the case (2) happens at most 7 times, taking less than 1.5% of all prediction cases.

No matter whether the case (1) or (2) happens, neither of them causes any loss in training accuracy of the NN model, because the performance modeling is never applied to any numerical-unsafe operation and hence the mis-prediction never happens to any of them.

7.6 Power Consumption and Energy Efficiency

Power consumption. Table 4 summarizes system power consumption. Using TF_AMP and Campo, the system consumes less power than using FP32 across NN models by 6 - 13 Watts, because of the use of power-efficient TC in mixed precision training. Table 4 also shows that using Campo, the system consumes less power than using TF_AMP, due to better utilization of TC in Campo.

Energy efficiency. Figure 10 shows the energy efficiency

of NN models trained with FP32, TF_AMP and Campo. TF_AMP and Campo outperform FP32 by 109.5% and 154.6% on average, respectively, because of the use of reduced precision and power efficient TC. Compared to TF_AMP, Campo outperforms TF_AMP by 21.4% on average (up to 24.2%). This improvement comes from the fact that Campo leads to better performance (see Figure 5) without causing extra power consumption (see Table 4).

8 Related Work

Mixed precision for NN training. Many research efforts have been dedicated to achieve more efficient NN training with mixed precision. Mixed precision training was first introduced by Micikevicius et al [1]. Since then, Nvidia depicts how to use it with TC [3]. Jia et al. [2] use mixed precision to improve scalability of synchronized stochastic gradient descent (SGD) optimizers in NN models without losing model generability. Kuchaiev et al. [32] presents a TensorFlow-based toolkit for mixed precision training of sequence-to-sequence models, with an implementation of a wrapper around the standard TensorFlow performance optimization facility for mixed precision training. Besides the floating-point based mixed precision training, Das et al. [4] are the first to propose mixed precision training of convolutional neural networks using integer operations on ImageNet-1K dataset. Svyatkovskiy et al. [33] introduce a learning rate schedule for training distributed deep recurrent neural networks with mixed precision on GPU clusters. Their schedule facilitates neural network convergence at up to O(100) workers.

Different from the above efforts, our work reveals the overlooked performance issues related to casting cost in mixed precision graph optimization.

Mixed precision for other GPU applications. Mixed precision has been explored to speed up dense linear system solvers [34,35] and WZ factorization [36] in the context of HPC. Kotipalli et al. [37] present AMPT-GA, an automatic mixed precision optimization system that automatically selects the optimal data precision to maximize performance while meeting accuracy constraints for GPU Applications. However, its evaluation is only limited to an NVIDIA Tesla P100 GPU machine without TC. Haidar et al. [38] apply mixed-precision FP16-FP32/FP64 to a high-performance iterative refinement solvers and take advantage of TC. Gallo et al. [39] propose the concept of mixed-precision in-memory

Figure 10: Energy efficiency of NN models trained with FP32, TF_AMP and Campo.

computing with a combination of a von Neumann machine and a computational memory unit. Baboulin et al. [40] leverage mixed precision to accelerate computations in many dense and sparse linear algebra algorithms. Lam et al. [41] introduce a framework that employs binary instrumentation and modification to build mixed-precision configurations of existing binaries originally developed for the use of double precision. In contrast, our work focuses on applying mixed precision to NN training.

Investigation on the usage of TC. Nvidia TC follows the IEEE 754 standard [42] and utilizes mixed precision with matrix multiplication input in FP16 and accumulation in FP32. Motivated by the benefits of TC, Yan et al. [43] demystify how TC on Turing GPUs works and implement TC-based HGEMM on NVIDIA Turing GPUs. Markidis et al. [44] perform a performance evaluation of TC in mixed precision as well as three different approaches of programming matrix-multiply-and-accumulate on TC on V100. Brennan et al. [45] perform a thorough analysis of the effects of low precision operations and TC on graph convolutional neural networks. Abdelfattah et al. [46] explore leveraging TC to implement an optimized batched Matrix multiplication (HGEMM) in half-precision arithmetic. Our work is different from these efforts, as we explore the use of TC in NN training.

9 Conclusions

This paper introduces Campo, a cost-aware performance optimization tool for mixed-precision NN training that assigns the optimal precision (either FP32 or FP16) to training operations while minimizing the unnecessary casts to maximize the training performance. Campo is based on our unique observation that the casting cost to achieve mixed precision training may offset the performance benefit of using low precision in mixed precision training. This observation is ignored in the existing approaches of using mixed precision, which leads to smaller performance improvement or even performance loss. We build operation-specific performance models to predict and quantify the impact of casting cost on the performance of using low precision. With the performance models, at runtime Campo employs a cost-aware graph rewriting strategy to make decisions on which precision should be used for each operation without losing NN training accuracy. We evaluate Campo with six NN models on Nvidia Turing and Volta architecture-based GPUs, and show that Campo largely outperforms TensorFlow.

PRIMO: Practical Learning-Augmented Systems with Interpretable Models

Qinghao Hu^{1,2} Harsha Nori³ Peng Sun⁴ Yonggang Wen¹ Tianwei Zhang¹

¹Nanyang Technological University ²S-Lab, NTU ³Microsoft ⁴SenseTime Research

Abstract

While machine learning has demonstrated remarkable performance in various computer systems, some substantial flaws can prohibit its deployment in practice, including opaque decision processes, poor generalization and robustness, as well as exorbitant training and inference overhead. Motivated by these deficiencies, we introduce PRIMO, a unified framework for developers to design practical learning-augmented systems. Specifically, (1) PRIMO provides two interpretable models (PrAM and PrDT), as well as a *Distill Engine*, to support different system scenarios and deployment requirements. (2) It adopts *Bayes Optimization* to automatically identify the optimal model pruning strategy and hyperparameter configuration. (3) It also implements two tools, *Monotonic Constraint* and *Counterfactual Explanation*, to achieve transparent debugging and guided model adjustment. PRIMO can be applied to different types of learning-augmented systems. Evaluations on three state-of-the-art systems show that PRIMO can provide clear model interpretations, better system performance, and lower deployment costs.

1 Introduction

Over the years, machine learning (ML) has been widely adopted to optimize systems across many fields, e.g., storage [29, 82, 85], network [66, 77, 95], security [24, 28, 74], compiler optimization [8, 93, 94] and cluster scheduling [65, 89, 92]. These learning-augmented systems demonstrate marvelous performance compared with conventional heuristic or mathematical optimized systems.

However, most of these applied models are very complex and treated as black-boxes to developers, which brings significant gaps in deploying them in practice. **First, building a production-level learning-augmented system can incur huge costs.** From the experience at Microsoft [42], the model training process could take days to weeks with massive data. Some systems require frequent model updates to adapt to dynamic environment changes, whose cost often exceeds enterprise expectations. For some scenarios with limited data samples, developers have to use techniques to synthesize training samples [12, 45, 96], which inevitably introduce bias to the model and cause performance deterioration in practice [8, 10, 66]. Moreover, the inference process of these complicated models can pose heavy computational pressure to

systems which have high real-time requirements [43, 81, 82], which can significantly restrict parallel capabilities and affect scalability in practice.

Second, the prediction process of these black-box models are unintelligible to humans. Developers lack understanding and trust of the model's behavior [19, 53, 91], which makes it difficult for them to perform model adjustments and ad hoc debugging in practical scenarios. Some efforts have been made to improve system transparency through interpreting black-box models [26, 27, 55]. They typically build *surrogate* models to obtain explanations for individual predictions, thus validating model behaviors and diagnosing system mistakes. However, they cannot provide an interpretation fidelity guarantee, and therefore the corresponding explanations are unreliable and potentially misleading [58, 70]. In addition, they cannot address the aforementioned system cost issue.

In this paper, we aim to resolve the above challenges and facilitate *transparent, accurate* and *lightweight* system deployment in practice. We introduce PRIMO (**P**rior-based **I**nterpretable **M**odel **O**ptimization), the *first* unified framework that assists developers to design and optimize learning-augmented systems with interpretable models. The design of PRIMO is based on two key insights. First, *simple interpretable models have the capability of handling complex system problems*. Interpretable models do not sacrifice prediction accuracy [35, 62, 72], and simple model structures with low resource overhead are very suitable for real-time systems. Their effectiveness is often underestimated [70]. Second, *prior experience and domain knowledge can be leveraged by developers to further optimize the interpretable models* [20, 76], which is hard to achieve for black-box models.

PRIMO makes several innovations to enhance learning-augmented systems. First, to provide comprehensive support for different systems, PRIMO introduces two interpretable model algorithms: PrAM is designed for better prediction accuracy and PrDT applies to systems with strict latency or computation constraints. PRIMO can help developers select a suitable model *automatically* based on their system requirements, including latency, accuracy, and resource budget. In addition to training models directly, PRIMO also supports distilling existing complex models, which applies to exploration-based systems with reinforcement learning (RL) [23, 49, 56, 59].

Second, to fully exploit the potential of interpretable mod-

els, we design several built-in mechanisms to optimize model performance leveraging *prior* information. (1) PRIMO implements *Bayes Optimization* to find the optimal model pruning strategy and hyperparameter configurations for higher prediction accuracy and lower computation overhead. It fully takes advantage of prior search information to minimize the search space and training cost. (2) PRIMO also facilitates model post-processing for developers with their domain knowledge. Specifically, it provides two tools for model adjustment through adding *Monotonic Constraints* and transparent debugging with *Counterfactual Explanations*.

Based on these innovations, PRIMO provides not only precise and comprehensive interpretations for developers to understand and adjust models, but also better prediction accuracy and smaller overhead. To extensively evaluate these benefits in real scenarios, we apply PRIMO to three state-of-the-art learning-augmented systems, including two *online* systems (LinnOS for flash storage [29] and Pensieve for video steaming [51]), and an *offline* system (Clara for SmartNIC offloading [66]). For LinnOS, PRIMO provides a 2.8× system performance improvement, and reduces model training time by over 100×, as well as inference latency by over 20×. For Clara, PRIMO beats a series of black-box models in prediction accuracy and saves over 10× training cost. For Pensieve, PRIMO achieves better generalization ability and a 79× inference latency reduction. We believe PRIMO can bring similar benefits to other learning-augmented systems as well.

To summarize, we make the following contributions:

- To the best of our knowledge, PRIMO is the first framework to provide inherent interpretability for learning-augmented systems development.
- We design built-in mechanisms and adjustment tools for developers to achieve *transparent, accurate* and *lightweight* system deployment in practice.
- For the first time, we demonstrate that simple interpretable models can outperform complex black-box techniques in various real systems.

2 Background and Motivation

2.1 Learning-Augmented Systems

Learning-augmented systems apply machine learning techniques to optimize system performance [42]. They typically build various ML models to obtain preeminent system policies from historical execution data, such as Support Vector Machines (SVM) [65, 66], Random Forest (RF) [5, 86], Gradient Boosting Decision Tree (GBDT) [32, 92]. With the popularity of deep learning (DL) algorithms, they were also introduced to further enhance systems, e.g., Deep Neural Network (DNN) [29, 82], Convolutional Neural Network (CNN) [43, 53], Recurrent Neural Network (RNN) [66, 90] and Reinforcement Learning (RL) [41, 51]. We classify them into the following categories.

Taxonomy. Learning-augmented systems typically follow similar design workflows to integrate ML models into system operations. Based on the optimization type, they can be classified into two categories. (1) **Prediction-based** systems utilize the *supervised learning* paradigm (e.g., classification, regression) to optimize system problems. (2) **Exploration-based** systems usually adopt *reinforcement learning* to learn optimal policies in an explore-exploit way. Since there are relatively fewer unsupervised learning-based systems in practice, we consider them as our future work (§8).

Based on system requirements and application scenarios, learning-augmented systems can be divided into the following two types. (1) **Online** systems require the ML model to make prompt predictions for real-time data. Developers need to consider model inference latency and computation overhead, in addition to prediction accuracy. (2) **Offline** systems usually do not need to deploy ML models for real-time serving and have no latency or computation requirements. These systems are performance-critical and the objective of ML models is to improve prediction accuracy.

PRIMO is designed as a unified framework, providing respective optimization mechanisms for different types of learning-augmented systems.

2.2 Challenges and Motivation

While plenty of work has demonstrated the potential of ML techniques in improving system performance, there exist several challenges in the development and deployment of learning-augmented systems in practice.

Model development. First, building a qualified ML model for the target system has the following two challenges:

- **C1: high training and tuning cost.** As stated by Microsoft AutoSys [42], costs of ML model training often exceeds enterprise expectations. Real system environments are dynamically changing and stale models will cause performance deterioration. Therefore, frequent model fine-tuning or retraining is necessary, which could take days to weeks [42, 52] in order to outperform heuristic algorithms. If there are not enough GPU resources, the update time will become even more intolerable for DL models.
- **C2: susceptible to the quantity and quality of data.** A large amount of high-quality training data are essential to produce satisfactory ML models. However, in some cases, insufficient data [8, 10, 66] or excessive data collection cost [52, 88] hinder developers from training qualified models. Possible solutions include data augmentation and synthesis [12, 45, 96]. Nevertheless, owing to the sophisticated distribution of real-world data, the generated data inevitably introduce bias and shift to the learning model [66], which could compromise the system performance in practice.

Model deployment. Second, deploying ML models in practice has interpretability and inference overhead issues:

- **C3: opaque decision making process.** Developers mainly

Strategies	Interpretation Fidelity	Local Interpretation	Global Interpretation	Transparent Adjustment	Deployment Cost	Accuracy ↗	Roustness ↗	Latency ↘
Black-box models (e.g., <i>DNN, RL, GBDT</i>)	✗	✗	✗	✗	\$\$\$	★	★	★
Interpreting black-box models [26, 67]	✗	✓	✗	✗	\$\$\$	★	★	★
Building interpretable models (PRIMO)	✓	✓	✓	✓	\$	★☆	★☆	★☆

Table 1: Comparisons of different strategies for learning-augmented systems (☆: Performance improvement).

focus on improving key system metrics (e.g., I/O latency [29], user experience [51]) when designing and evaluating ML models, while ignoring their *interpretability*. As a result, most of these learning models are *black-boxes* whose prediction processes are unintelligible to humans [26, 40, 70]. Due to such opacity, system operators cannot guarantee model predictions are risk-free and have insufficient confidence to deploy them.

- **C4: difficulty in troubleshooting and adjustment.** In order to achieve expected performance in production environments, system operators typically need to adjust the learning models according to the actual scenarios [19, 53, 55], including input features alteration, model structure modification, data augmentation, etc. All these actions require the operators to have a profound understanding of the system and the corresponding ML technique [26, 42], which is difficult when the model is complex. In addition, ad hoc debugging is another substantial challenge to learning-augmented systems for black-box models. Improper modifications may cause severe performance degradation.
- **C5: exorbitant deployment overhead.** The model deployment overhead is another key factor for system operators' consideration [53]. The latency and computation requirements of some systems [43, 81, 82] are far more strict than conventional AI tasks. High inference overhead can cause side effects to production workloads and limit their parallelism capability [29], which can further restrict deployment scalability.

2.3 Model Interpretation as a Solution

One possible solution to address the above challenges is model interpretation. There are two primary directions to apply model interpretation for learning-augmented systems.

2.3.1 Interpreting Black-box Models.

The essential idea is to leverage existing interpretation methodologies to interpret the black-box models, making them more intelligible and transparent. A variety of interpretation tools (e.g., Lime [67], Captum [39], Shap [48]) were designed to explain the mechanisms of DNN models for CV and NLP tasks. Similar studies were also performed for other domains. For instance, Lemna [26] employs a mixture regression model [36] to interpret RNN models in DL-based security applications. Metis [55] proposes to interpret networking systems with the decision tree or hypergraph. However, we argue that the idea of interpreting black-box models is not sufficient

for learning-augmented systems for the following reasons.

(1) **No fidelity guarantee.** These tools typically interpret black-box models in a *post hoc* way, where another *local surrogate* model is created to explain the original model. They cannot have a fidelity guarantee with respect to the original model. Therefore, the corresponding explanations are often unreliable, and can be misleading [58, 70]. The fidelity of some widely applied interpretation methods (e.g., attention-based explain [84]) are still in dispute [34, 83]. Appendix B.1 presents an example of contradictory XGBoost explanations.

(2) **Limited interpretation.** Most existing tools (e.g., Lime, Lemna) focus on explaining individual predictions (local interpretation) instead of the entire model behavior (global interpretation). Thus, the interpretation results typically cannot yield enough information for system troubleshooting. Appendix B.2 shows their insufficiency for global understanding and model surrogate.

(3) **Requiring domain knowledge.** Different systems may employ different models and algorithms. There is no unified tool that can provide comprehensive support for interpreting arbitrary models. Consequently, domain knowledge and manual efforts are required to implement the tools and understand the explanation results. This poses a huge challenge for developers to design a learning-augmented system.

(4) **Incapability of handling other challenges.** Those tools only focus on model interpretation and understanding (C3 & C4), but ignore other challenges discussed in §2.2.

2.3.2 Building Interpretable Models

A more promising direction, which is adopted in PRIMO, is to train *interpretable models* directly for learning-augmented systems. Interpretable models refer to the models that are inherently intelligible, where their explanations provided by themselves are faithful to what the models actually compute [58, 70]. Common interpretable models include linear regression, logistic regression, decision tree, decision list, etc. They have great potential to enhance different types of learning-augmented systems.

According to our observation from recent state-of-the-art learning-augmented systems [1], the scale of models in these systems tend to be relatively smaller than popular production-level AI models (although they are still too complex for humans to understand). For instance, the number of neurons in a RL-based system is typically less than 10K [19]. This is because most data samples in learning-augmented systems are well structured, with good representations in terms of naturally meaningful features. In such scenarios, a much sim-

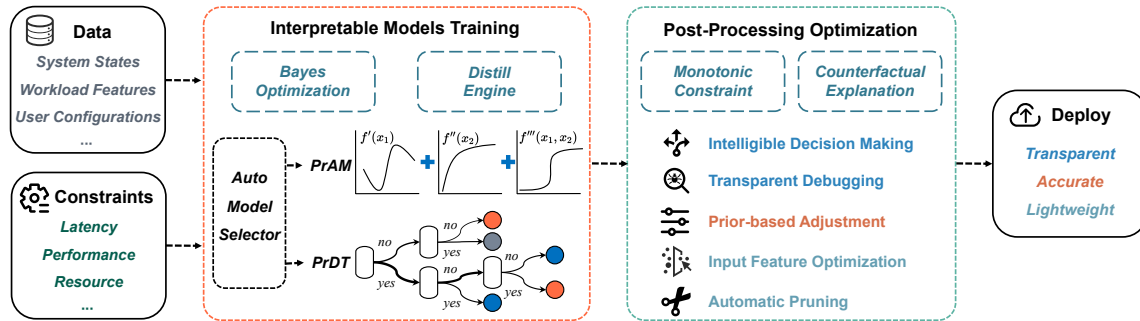

Figure 1: The workflow of learning-augmented system development using PRIMO.

pler interpretable model can give comparable performance to complex black-box models [70]. Therefore, developers can employ interpretable models for their systems, which require less data, training and tuning cost (C1 & C2). The models give more information for system operators to understand (C3), troubleshoot and adjust (C4), and the inference speed is much faster than the original black-box model (C5).

Summary. The benefits of PRIMO compared with other methods are summarized in Table 1. It can provide not only highly precise and comprehensive interpretations for developers to understand and adjust models, but also higher accuracy and robustness, and smaller training and inference overhead. These greatly facilitate model deployment in practice.

3 PRIMO Design

We introduce PRIMO, a unified framework that assists developers to design practical learning-augmented systems. Particularly, (1) we employ *transparent* and *deterministic* interpretable models to circumvent the uncertainty issues of black-box model inference. (2) We integrate new tools for developers to leverage prior knowledge to optimize interpretable models *automatically*. (3) We design a built-in mechanism to search optimal hyperparameters in a *fast* and *convenient* way, without extra effort from the developers. Based on these designs, PRIMO can address all the challenges in §2.2.

3.1 Framework Overview

PRIMO optimizes both the *training* and *post-processing* stages of building learning-augmented systems. Figure 1 illustrates the development workflow with PRIMO. In the model training stage, PRIMO provides two interpretable model algorithms (PrAM and PrDT) designed for different system scenarios¹. PRIMO helps developers automatically select suitable algorithms based on their system requirements including latency, accuracy, and resource budget. It supports training the interpretable model directly, or converting an existing complex black-box model into a simple interpretable model through the *Distill Engine*. We also leverage *Bayes Optimization* to find the optimal model pruning strategy and hyperparameter configurations for higher prediction accuracy and lower

¹Other interpretable models can also be conveniently integrated into this framework, which will be considered in our future work.

computation overhead. After the model is trained, PRIMO offers several optimization tools in the post-processing stage, e.g., prior-based model adjustment through adding *monotonic constraints*, transparent debugging with *counterfactual explanations*. Below we detail the mechanism of each component.

3.2 Interpretable Models

As introduced in §2.1, different system scenarios have different requirements for the learning models. To this end, PRIMO employs two types of interpretable model algorithms: PrAM is designed for better prediction accuracy and PrDT applies to systems with strict latency constraint or computation sensitivity. PRIMO supports automatic model selection based on the demands specified by the developers.

3.2.1 PrAM: Addictive Model based Method

Our first interpretable model, PrAM, is based on the Standard Generalized Additive Models (GAMs) [30]. GAMs consist of a series of *shape functions* $f_i(\cdot)$ and an intercept μ_0 (Equation 1). Since each shape function considers only one univariate term (the i th feature x^i) and their combination is additive, GAMs are interpretable: we can clearly understand the contribution of each single feature to the final prediction.

Compared with linear interpretable models (e.g., logistic regression), GAMs can cope with more complex prediction tasks because shape functions are typically nonlinear and have better fitting capability. To further increase model performance, we adopt the state-of-the-art GAM algorithm: GA²M [47], which additionally considers the interactions of two features and maintains the interpretability (more details are in Appendix A.1). GA²M has the following form:

$$g(E[y | \mathbf{x}]) = \underbrace{\mu_0 + \sum f_i(x^i)}_{\text{GAM}} + \underbrace{\sum f_{ij}(x^i, x^j)}_{\text{Interactions}} \quad (1)$$

where $g(\cdot)$ is a link function that adapts GA²M to different tasks, e.g., regression (identity), classification (logistic function); $f_{ij}(\cdot)$ represents the interaction effect of features i and j , which can be visualized as a two-dimensional heatmap.

In our implementation, PrAM extends the open-source library EBM [63] to obtain the optimal model with high compactness and accuracy. Compared to the complex DL models, PrAM can not only provide interpretability, but also takes less

training resources (without the need of GPUs) and training data samples, significantly reducing the training time and cost.

3.2.2 PrDT: Decision Tree based Method

Our second interpretable model PrDT is constructed from Decision Trees (DTs). DTs are binary tree-structured models where each *branch node* tests a condition and each *leaf node* makes a prediction [71]. Because DTs are non-parametric and can be essentially expressed as an equivalent rule list, they are transparent and simple to interpret how a prediction is obtained. Besides, the decision-making processes of DTs can be visualized so developers can easily adjust the trees according to the system requirements. They present powerful prediction capability for both classification and regression tasks, even compared with complex black-box models.

In addition to the excellent interpretability and accuracy, DTs have extremely low computation overhead and inference latency. Consequently, they are applicable to many scenarios with strict latency and resource constraints [29, 61]. Besides, DTs also exhibit other benefits, including robust performance under dynamic system environments, requiring less training data and no data preprocessing overhead during inference.

It is necessary to optimize the complexity of a DT to avoid the overfitting issue, which can affect the model generalization, accuracy and computation overhead. Instead of adding constraints (e.g., maximum depth, minimum number of samples for a leaf node) during DT training, PrDT trains a full decision tree without any limitation to capture more information from the training dataset. We adopt *minimal cost-complexity pruning* [14] to prune the full tree in the *post-processing* stage, which is elaborated in Appendix A.2.

3.3 Model Training

PRIMO supports two training modes. (1) *Direct*: the developer can train an interpretable model from scratch. This applies for most **prediction-based** systems. (2) *Distill*: the developer can generate an interpretable model from the original black-box model through the *Distill Engine*. This is mainly for **exploration-based** systems. To obtain high-quality models, both modes support the integration of *Bayes Optimization* for efficient model structure and hyperparameter search.

3.3.1 Bayes Optimization

There exists a trade-off between the model complexity and accuracy for both interpretable models. In order to find accurate and succinct models, PRIMO leverages Bayes Optimization (BO) [76], an iterative algorithm to automatically search for the optimal model configurations.

Objective function. For both PrAM and PrDT, we build a universal model scoring function $S(\theta)$ to quantify the model performance and complexity as the search objective:

$$S(\theta) = P(\theta) + \lambda \cdot C(\theta)^\gamma \quad (2)$$

where $P(\theta)$ represents the model performance (e.g., classification accuracy) under hyperparameters θ during validation;

Figure 2: Illustration for the counterfactual explanation.

λ is a knob that controls the model complexity according to users' preference; $C(\theta)$ is a metric for model complexity. For PrDT, $C(\theta^{\text{PrDT}}) = N_{\text{leaves}} \times N_{\text{depth}}$, where we consider both the number of tree leaves and tree depth since unbalanced-deeper trees typically cost longer condition inference time. For PrAM, $C(\theta^{\text{PrAM}}) = N_{\text{interactions}} \times N_{\text{maxbins}}$, where both the number of feature interaction terms and maximum number of bins in the feature histogram are included. Besides, the normalization factor γ regulates the effect of the model complexity.

Prior-based hyperparameter search. Specifically, PRIMO employs Gaussian Process (GP) as the probabilistic surrogate model of the objective function $S(\theta)$ in Equation 2. The prediction of GP follows a normal distribution: $p(S | \theta, \Theta) = \mathcal{N}(S | \hat{\mu}, \hat{\sigma}^2)$, where Θ indicates the hyperparameter search space. To determine which point should be evaluated next, PRIMO adopts expected improvement (EI) as the acquisition function to trade-off exploration and exploitation [20]. In each iteration, PRIMO generates a set of hyperparameters and evaluates them on the interpretable model to obtain new results which are used to update the surrogate model. Compared with Grid Search (GS) and Random Search (RS) [13], BO is more efficient since it fully utilizes the prior information to minimize the search space. For instance, as shown in Figure 17 in Appendix A.2, BO can rapidly reduce the search space to a smaller size ($10^{-5} \sim 10^{-2}$) for a better focus.

3.3.2 Distill Engine

In some scenarios, the learning models require special optimization. For instance, LinnOS [29] leverages *biased training* to reduce the false submit rate while causing the higher false revoke rate. PRIMO introduces the *Distill Engine*, which can build an interpretable surrogate model to approximate the behavior of the original black-box learning model using knowledge distillation [7, 31].

Another application of the *Distill Engine* is RL policy extraction. Both PrAM and PrDT work well for **prediction-based** systems using supervised learning, but are less supportive for **exploration-based** systems due to their incompatibility with RL. A series of works [11, 69, 75] have demonstrated the feasibility of converting NN-based learning policies to an interpretable models. PRIMO adopts Viper [11] to perform RL policy extraction. Specifically, we collect the trajectories of $\{\mathbf{s}_i, a_i\}$ pairs (i.e., system states \mathbf{s}_i and actions a_i of learned policy $\pi(\mathbf{s}_i, a_i)$) generated by the original RL model and perform supervised learning to build the interpretable models.

	System Scenario	ML Algorithm	Type	Primo
LinnOS [29]	Flash Storage I/O	DNN	Online	PrDT (Direct)
Clara [66]	SmartNIC Offloading	Mixture (LSTM, GBDT, SVM)	Offline	PrAM (Direct)
Pensieve [51]	Video Streaming	RL	Online	PrDT (Distill)

Table 2: Summary of case studies for PRIMO evaluation.

To obtain a robust policy, we augment the poor-performing pairs and train the model iteratively until it is converged.

3.4 Post-Processing Optimization

After the interpretable model is built, developers can use their prior knowledge to further optimize the model and enhance the system performance. PRIMO designs two tools to assist developers in model post-processing. Note that these operations are *optional* since generally the trained interpretable models already achieve satisfactory performance.

3.4.1 Monotonic Constraint

In many learning-augmented systems, the input features exhibit a monotonic relationship with the output values (e.g., higher video bitrate selection with better bandwidth). But the corresponding model often presents a non-monotonic pattern due to the sub-optimal construction strategy or noisy training data (e.g., outlier data points, biased synthetic data). This can lead to unstable performance and intelligibility degradation in practice. To this end, PRIMO leverages a method from DP-EBM [62], which adds monotonic constraints to boosted trees via post-processing. Specifically, we model this task as an isotonic regression problem [15] with respect to a complete order. The objective is to minimize $\sum_i w_i (y_i - \hat{y}_i)^2$ subject to $\hat{y}_i \leq \hat{y}_j$ and weights w_i are strictly positive. We adopt the Pool Adjacent Violators (PAV) [6] algorithm to obtain an optimal solution maintaining monotonicity, and use it to replace the original shape function of PrAM. Our tool only needs developers to provide the feature name or index and the subsequent model adjustment process is transparent and automatic.

3.4.2 Counterfactual Explanation

To make modifications to the models, developers need to answer some challenging questions, e.g., which feature related shape function should be adjusted? how to determine the modification degree? To help them make reasonable decisions, we design the Counterfactual Explanation tool in PRIMO to generate additional insights for model adjustment. As illustrated in Figure 2, this tool aims to find smaller change (green arrow) to the feature values that can alter the prediction to a predefined output within the dataset. It typically uses the k -nearest neighbors (kNN) algorithm to find k training instances with the minimum L_2 distances [80]. To address the inefficiency of the brute-force kNN approach, we propose to use Ball Tree [22] to partition data in a series of nesting hyper-spheres, thus the distance between a prediction point and the centroid is sufficient to determine a lower and upper bound on the distance to all points within the hyper-sphere node. This

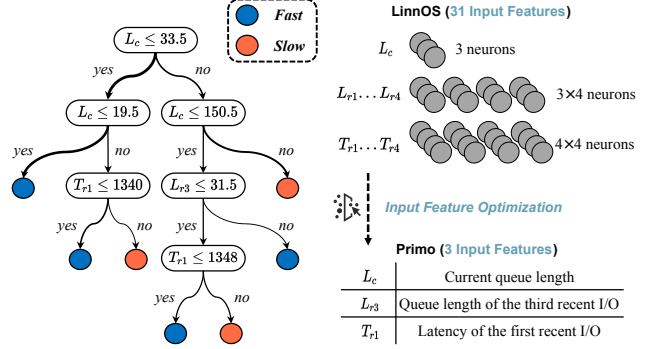

Figure 3: (Left) Learned PrDT model for an SSD. The thicker arrow line denotes the higher frequency. (Right) PRIMO optimizes the input features of LinnOS. Each feature represents a *digit* in LinnOS while a complete *number* in PRIMO.

approach considerably reduces the query time when dealing with large-scale and high-dimensional datasets. And developers could perform guided model adjustment easily.

PRIMO Experiments. In the following three sections, we will present three case studies to demonstrate how PRIMO can optimize state-of-the-art learning-augmented systems. Table 2 describes these three scenarios. The key observation for each case is summarized in Appendix C. We believe PRIMO can be applied to other learning-augmented systems as well.

4 Case Study 1: LinnOS

As the first case, we consider LinnOS [29], a learning-based operating system that accelerates storage applications. LinnOS adopts a 3-layer neural network (31-256-2, in total of 8706 parameters) for *each* SSD to precisely predict its performance. To achieve this, it collects the traces of real workloads running on the SSD and obtains fine-grained information (per I/O), including recent queue lengths and latency. Instead of predicting the concrete latency values, LinnOS simplifies it as a binary (fast / slow) classification task through setting an inflection point (*IP*). More details about LinnOS and our implementation can be found in Appendix D.1.

PRIMO automatically selects the PrDT model for LinnOS, since it has comparable accuracy and lower inference latency than PrAM. For comprehensive evaluation, we consider two models with different optimization objectives: *efficiency*-oriented (PRIMO-E) and *performance*-oriented (PRIMO-P). We compare PRIMO with two baselines. (1) Base: the vanilla Linux I/O mechanism. (2) LinnOS: we set the inflection point of LinnOS as a constant percentile (at p85 latency) and apply the biased loss to the model training (all keep the same).

4.1 System Interpretation

The primary goal of PRIMO is to provide interpretation for the target system. Figure 3 (left) presents the learned decision tree (PRIMO-E) for one SSD. The explanation of each notation can be found on the right side. From this tree, we can clearly understand how PRIMO makes decisions for each prediction

Figure 4: Overall performance comparisons. (a) CDF of I/O latency. (b) Average I/O latency.

Figure 5: Tail percentiles of I/O latency.

(*Local interpretation*). We can also obtain intuitive cognition of the overall model behavior (*Global interpretation*) through observing the thickness of each decision path (arrow lines).

Specifically, the top-2 layers of the DT show PRIMO first classifies I/O requests from the *current queue length* (L_c), indicating this feature can significantly affect the prediction results. Developers can perform adjustments to L_c thresholds to optimize system behavior. Because the 4-layer DT only contains 7 leaves (terminal nodes), each prediction needs to take at most 4 condition tests at the branch nodes and the majority of test instances only need to execute 2 condition tests. This inference overhead is much smaller than the original DNN model with 8706 parameters in LinnOS. Moreover, as shown in Figure 3 (right), PRIMO only takes 3 input features without any preprocessing, which further reduces the model complexity and deployment overhead. On the contrary, LinnOS needs to perform input data preprocessing for all 9 metrics to form a 31-dimensional input feature (e.g., $L_c = 15$ needs to be converted into a $\{0, 1, 5\}$ vector). This operation is necessary for *every* I/O read operation, remarkably exacerbating the inference overhead.

4.2 Performance Analysis

We evaluate the performance of PRIMO in the LinnOS flash storage I/O scenario from the following two perspectives:

Overall performance. Figure 4 shows the Cumulative Distribution Function (CDF) and average I/O latency (with the standard deviation) of each method over three independent experiments. It is obvious that both PRIMO-E and PRIMO-P significantly outperform LinnOS. Compared with the base I/O mechanism, LinnOS reduces 26.2% I/O latency on average, while PRIMO decreases the I/O latency by 70.0~73.6%. It indicates PRIMO can achieve an additional 2.5~2.8× (PRIMO-E

Figure 6: Model inference latency. Empty circles represent the minimum inference latency when the system is idle. Solid circles represent the inference latency of the median I/O operation when the system is busy. The vertical line indicates the basic SSD access latency (reading 4KB data in the idle state).

Figure 7: (a) Quantization impact. (b) Robustness test.

/ PRIMO-P) improvement over LinnOS.

Tail performance. The tail behavior is critical to system performance. Figure 5 presents the average I/O latency and the range at tail percentiles (from p90 to p99.99). We find LinnOS fails to reduce tail latency on the tail, and the curve almost overlaps with the Base case. On the contrary, PRIMO-P achieves 7.9×, 4.3× and 2.3× performance improvement over the vanilla I/O mechanism at p99, p99.9 and p99.99 respectively. Additionally, PRIMO-P also performs much better at p90 (2.2×) and p95 (7.5×) compared to LinnOS.

4.3 Effectiveness Analysis

We perform the effectiveness analysis from the following perspectives to investigate why PRIMO can outperform LinnOS.

Inference overhead. In Figure 6, we measure the extra inference latency of PRIMO and LinnOS. (1) When the system is idle, we measure the minimum inference latency. We observe that LinnOS takes 8μs, while the overhead of PRIMO-E is almost negligible ($\leq 1\mu s$), making the deployment more lightweight. (2) When the system is busy with heavy I/O operations, LinnOS requires a median inference latency of 33μs due to the high frequency of preprocessing and inference. This is even higher than the basic SSD access latency (25μs). In contrast, PRIMO remains relatively lower inference latency with smaller overhead.

Quantization. Since floating points are not well supported in the Linux kernel, the model weights of LinnOS and the thresholds of PRIMO are converted to integers by quantization. This can achieve smaller inference latency at the cost of accuracy degradation. Figure 7 (a) shows the quantization

Figure 8: Interpretation and visualization of the PrAM model in Clara-MS. **(Left)**: Global interpretation of overall feature importance. **(Middle)**: Local interpretation of each feature’s contribution to individual predictions. **(Right)**: Visualization of the learned shape function of R_{ec} (blue line), and with the monotonic constraint post-processing optimization (orange line).

Figure 9: Evaluation on Clara-MS. **(Left)**: Mean Absolute Error (MAE) of testset. **(Right)**: Prediction of 4 real NFs.

impact on the prediction accuracy. It is evident that the accuracy drop of LinnOS is over 2% and varies significantly among different SSD models. In comparison, PRIMO-E has negligible accuracy degradation, as the node threshold values are naturally integers or the decimal part is 0.5.

Robustness. A good model should exhibit high robustness against system state drifting. To measure the robustness of those methods, we synthesize some perturbed samples by adding Gaussian noise to the test dataset. The noise is added to all 4 recent I/O queue lengths ($\sigma = 5$) and I/O latency ($\sigma = 100$)². Figure 7 (b) illustrates the false submit and false revoke rates of LinnOS and PRIMO-E under the original and perturbed test datasets. Reducing the false submit rate is far more important since the *failover* overhead of false revoke is negligible. It is obvious that PRIMO keeps stable accuracy under perturbed input while LinnOS presents severe performance degradation. The robustness of the interpretable model in PRIMO derives from fewer input features and the inherent stability of the tree structure compared with the DNN model.

5 Case Study 2: Clara

Clara [66] is an offline tool that generates offloading insights for network functions (NFs) on SmartNICs. It can analyze a legacy NF in its unported form and suggest the optimal offloading strategies. The main challenge of adopting those ML techniques in Clara is that *insufficient* SmartNIC pro-

²Since the current queue length L_c is the most significant feature, we do not modify its value to avoid changing the real label.

Figure 10: Model precision and recall rates in Clara-AI.

grams can be served to produce training data. Clara has to utilize YarpGen [45] to generate abundant synthesized programs. Clara contains several components for the generation of different offloading insights. Each component adopts a ML algorithm as described below:

- **Multicore Scale-out analysis (Clara-MS).** SmartNICs use multicore parallelism to improve packet processing performance. Clara adopts *GBDT* [17] to predict the optimal number of cores for each NF.
- **Algorithm Identification (Clara-AI).** Certain packet processing algorithms in the host NF can benefit from ASIC accelerators in the SmartNIC. Clara adopts *SVM* [73] to identify such code blocks.
- **Cross-platform Prediction (Clara-CP).** Clara trains an *LSTM* network [9] to predict the number of compute and memory instructions that a NF can be compiled to.

We employ the PrAM model to replace all the three ML models in Clara, as it has better accuracy than PrDT. To analyze the effectiveness of transparent model adjustment in PRIMO, we also evaluate the model performance with post adjustment (denote as PRIMO+). We compare PRIMO with the original models in Clara (LSTM, GBDT and SVM), as well as some alternative baseline algorithms (CNN, DT, TPOT [64] (namely AutoML), K-Nearest Neighbor (kNN)). More details about Clara and our implementation can be found in Appendix D.2.

5.1 System Interpretation

As shown in Figure 8, PRIMO provides comprehensive interpretation for the Clara-MS task, including global and local

Figure 11: Weighted mean-absolute percentage error (WMAPE) over 8 types of NFs in Clara-CP.

interpretation, as well as transparent shape functions. We list the notation descriptions in Appendix D.2. From the left figure, we find R_i , R_{res} and R_{ic} are the most important features that contribute most to model prediction. Developers should pay more attention to shape function optimizations for these features. We also notice the impact of feature interactions is relatively less important, indicating that we can reduce their priority in model optimization. The middle figure presents the interpretation of the individual prediction for *UDPCount* NF. The final prediction equals the sum of every feature score and the intercept constant (Equation 1). Through the local interpretation, developers can clearly check the model behavior for each prediction to make the corresponding adjustment. Moreover, the right figure (blue line) illustrates the learned shape function for R_{ec} , which allows developers to dive deeper into fine-grained model adjustment (such as the orange line).

5.2 Performance Analysis

Since Clara is an offline system, for each task, we mainly evaluate the model accuracy rather than the inference cost.

Clara-MS. As shown in Figure 9 (left), our interpretable model in PRIMO achieves similar accuracy as the GBDT (XGBoost [17]) model in Clara, and outperforms other ML models over the synthesized test dataset. Figure 9 (right) further presents the accuracy of PRIMO for 4 real NFs. Compared to Clara, PRIMO achieves $1.4\times$ less prediction errors and at most 5% error to the optimal configurations.

Clara-AI. In Figure 10, PRIMO achieves the equivalent precision and recall rates as the SVM model in Clara, and beats other ML algorithms. Through successfully identifying CRC-based NFs, PRIMO could improve peak throughput by $1.6\times$ and decrease latency by 25% [66].

Clara-CP. Clara uses the LSTM model to predict the number of instructions for unported codes. Figure 11 shows the accuracy of the Clara-CP task over 8 representative real NFs and the Average column represents the WMAPE results across all the NFs. We observe PRIMO (14.4%) delivers better performance than Clara (15.1%). This demonstrates the capability of PRIMO to cope with complex program embeddings.

5.3 Model Adjustment

To overcome the training data insufficiency issue, Clara uses YarpGen [45] to generate synthesized programs. This inevitably introduces certain data distribution drifts from the

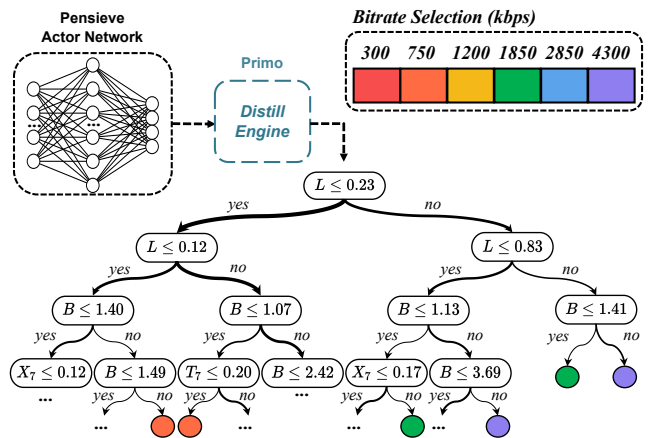

Figure 12: Visualization of the interpretable model distilled from the Pensieve policy. For simplicity, we only present the top 5 layers, and the ellipsis indicates subsequent nodes.

actual scenario. Specifically, there exist instruction distribution differences (0.0303 of Jensen-Shannon divergence and 0.0354 of Bhattacharyya distance) between real-world and synthesized click programs [66]. Such drifts could compromise the model performance. The transparency of the PRIMO model allows developers to discover and fix undesirable behaviors caused by the synthesized data. In addition, PRIMO designs two post-processing tools to help developers adjust the models based on their domain knowledge:

Monotonic Constraint. As introduced in §3.4.1, developers can leverage PRIMO to generate a new shape function with monotonic constraint and rectify the incorrect behaviors of the models automatically. For instance, in Figure 8 (right), the developers know the desired number of cores should be proportional to the memory/compute intensity, i.e., R_{ec} (EMEM/Compute Ratio). Then they can replace the original shape function (blue line) with the monotonic shape function (orange line). They can check each shape function and decide whether it is necessary to apply such adjustment based on their prior knowledge. To evaluate the effectiveness of this strategy, we apply the *Monotonic Constraint* tool to two shape functions (A_i & R_{ec}) and yield the adjusted model PRIMO+. As shown in Figures 9, PRIMO+ achieves better prediction accuracy. This shows the monotonicity of the PRIMO model can be achieved via simple post-processing and appropriate adjustment can bring better performance.

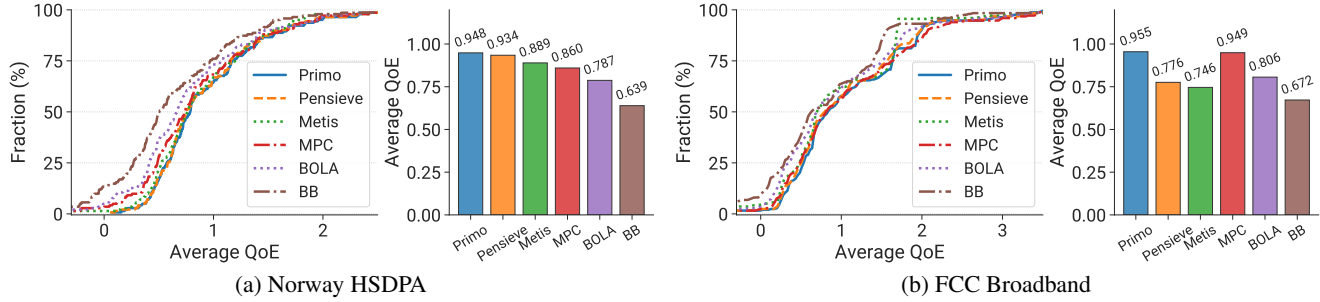

Figure 13: Overall performance of PRIMO compared with other methods on the Norway HSDPA and FCC Broadband traces.

Figure 14: Profiling the bitrate selections of ABR algorithms over one typical Norway HSDPA trace. Legend presents the average QoE of each algorithm.

Counterfactual Explanation. This tool aims to provide simple and intuitive explanations for model troubleshooting. More concretely, it helps developers to understand why this prediction is wrong and how to adjust the model to fix it. We use Clara-AI as an example to describe its usage and evaluation. Clara employs Sequential Pattern Extraction (SPE) [21] to extract code features as *boolean* sequences (each containing 102 features) to indicate whether the NF program contains code blocks for acceleration. Our PRIMO model allocates a contribution score for each feature. To fix False Negative (FN) predictions, we utilize this tool to find the closest k instances from the data set with the opposite label. Through the comparison of these instances, we can easily discover the feature with inadvisable learned scores and adjust the score. In this case, we increase the contribution weight of the 84th feature appropriately. We can also perform transparent debugging for False Positive (FP) predictions similarly. In Figure 10, PRIMO+ further enhances the F1 score from 89.6% to 92.5%.

6 Case Study 3: Pensieve

Our third case study is Pensieve [51], a system that uses RL for online video streaming. It learns the adaptive bitrate (ABR) algorithms automatically to optimize the user quality of experience (*QoE*) defined in Equation 4 in Appendix D.3.

We obtain an interpretable PrDT model through distilling from the original RL actor model. Then we implement the PrDT model into the ABRController of dash.js [2]. More details can be found in Appendix D.3. For baselines, we compare PRIMO with the following algorithms: (1) The RL model in Pensieve. (2) Buffer-Based (BB) [33]: selecting bitrates with the goal of keeping the buffer occupancy above 5 seconds.

Figure 15: Comparing three learning-based ABR methods.

(3) BOLA [78]: selecting bitrates with Lyapunov optimization on buffer occupancy observations. (4) MPC [87]: selecting bitrates with a control-theoretic model. We evaluate robustMPC variant which can better handle errors in throughput prediction. (5) Metis [55]: using a decision tree to explain the Pensieve RL model, which represents the handcrafted DT approach. Evaluations are performed on the simulator provided by Pensieve, except the deployment experiment (latency).

6.1 System Interpretation

Figure 12 illustrates the learning process with the Distill Engine, as well as the decision making process of the interpretable policy. Related notations are described in Appendix D.3. This DT contains 8 layers and 35 leaves in total, which is compact and simple enough for developers to understand its complete operation logic.

Similar to the PRIMO model in LinnOS (Figure 3), the first 2 layers divide decision flows based on the feature L (Last chunk bitrate) which is in line with our perception. In the third layer, PRIMO proceeds to classify environment states (inputs) according to the feature B (Current buffer size). These observations indicate both L and B are the key features that affect the final bitrate decision, inspiring developers to pay more attention to them when designing ABR algorithms.

6.2 Performance Analysis

Overall performance. Since the ABR algorithm could encounter unprecedented network conditions by different clients, it is important to evaluate its generalization ability. So in addition to the *Norway HSDPA* trace used for model training, we also evaluate another trace *FCC Broadband* that is never applied for training. Figure 13 presents the QoE distribution and average QoE of each method on the two traces. For Nor-

Figure 16: Model performance with less training data. **(Left)**: Recall rate in LinnOS (the higher the better). **(Right)**: WMAPE in Clara-CP (the lower the better).

way HSDPA, the CDF curve of PRIMO almost overlaps with Pensieve’s curve, and the average QoE is even 1.5% higher than Pensieve. This demonstrates PRIMO has successfully learned the Pensieve policy with a simple decision tree and outperforms other ABR algorithms. Furthermore, for FCC Broadband, PRIMO presents better generalization than other two learning-based algorithms. Such advantages are attributed to the adaptive pruning strategy in Bayes Optimization, and the imitation process in the Distill Engine. In contrast, although Metis also uses a decision tree to get a surrogate model from Pensieve, it has some performance degradation as its inflexible pruning strategy.

Example analysis. Figure 14 profiles the bitrate selection actions of different ABR algorithms over a single network trace. We find two heuristic algorithms (BB and MPC) keep fluctuating during the video streaming, which could cause a terrible user experience. The other three learning-based algorithms have more stable decisions. Pensieve decides to decrease the bitrate at 120s and Metis chooses to reduce the video resolution at 170s. This can cause an unsmooth experience (as the penalty term in Equation 4) even though they adjust back the bitrate quickly. In contrast, PRIMO gives a much more smooth experience.

Training and inference overhead. The PRIMO model is more compact and simpler. Figure 15 (left) compares the model complexity³ of different methods. We observe that PRIMO reduces the model scale by 1617× compared to the original Pensieve actor model. Even for Metis which also uses a decision tree, PRIMO can reduce the tree complexity by 7.9×. For inference, PRIMO only needs to perform 3~7 condition tests to make a bitrate decision. It can reduce 70× and 1.5× inference latency compared with Pensieve and Metis respectively, as shown in Figure 15 (middle). To generate a model, in Figure 15 (right), PRIMO only needs less than 4 minutes for model distillation, which is 21.3× faster than Metis (under the same setting). Compare with Pensieve 4 hours training time, less than 4 minutes distill time is ignorable. In summary, PRIMO can greatly reduce overall operating costs in the video streaming scenario.

³Model complexity refers to the number of parameters for Pensieve model, or number of nodes for PRIMO and Metis.

Task	DL Model	Origin	PRIMO	Improvement
LinnOS	3 × DNN (50 epoch)	564s	5s	112.8×
Clara-CP	LSTM (30 epoch)	1,081s	79s	13.7×

Table 3: Training time comparison with original DL models.

Task	Metric	PRIMO w/o BO	PRIMO w/ BO	Improvement
LinnOS	F1 Score	0.8089	0.8518	5.3%
Clara-CP	WMAPE	0.1728	0.1442	16.6%
Clara-MS	MAE	1.0155	0.8660	14.7%

Table 4: Ablation study for Bayes Optimization.

7 More Evaluation

We run some experiments to further evaluate the benefits of PRIMO more comprehensively.

Requiring less training data. Due to the simpler model structure and fewer parameters, PRIMO can have better performance in some scenarios without enough training data like Clara. In Figure 16, we compare the performance of two PRIMO models with the original DL models in LinnOS and Clara-CP using less training data. We use a smaller dataset (10%) in LinnOS as the baseline. Because LinnOS provides abundant data for DNN model training, 10% of original data can provide equivalent performance. It is clear that PRIMO models maintain better performance with limited training data, especially for the PrDT model. Conversely, the original DL models only work with abundant data. This shows PRIMO has broader applicability for various scenarios.

Short training time. Table 3 presents the training time of PRIMO and original DL models in LinnOS and Clara-CP, which adopt the default numbers of training epochs in their papers. PRIMO is able to reduce 2-3 orders of magnitude of training time. Even considering the hyperparameter search process, the significant time conservation could maintain since multiple trails can be executed concurrently. Note that GPUs can only provide very limited acceleration (<1.2×) for these two DL models. Additionally, LinnOS requires training a DNN model for *each* SSD and the prototype only considers three SSDs. In a production-level distributed storage system with thousands of SSDs, LinnOS could have a severe scalability issue. In contrast, PRIMO remarkably saves the training cost, making the deployment more feasible in practice.

Impact of BO. We further perform an ablation study on Bayes Optimization in PRIMO. Table 4 summaries the performance of the PRIMO model with and without BO in LinnOS and Clara. We observe 5.3%~16.6% accuracy improvement brought by BO. Besides, BO typically simplifies the model scale while obtaining better performance. For LinnOS, BO reduces over 15× tree nodes compared with PRIMO without BO. This verifies the importance of the BO component in making interpretable models more practical. For search time aspect, BO obtains over 1.2× acceleration compared with naive random search algorithm in Clara-MS task by reducing search trails to reach equivalent performance.

8 Discussion

Is the interpretation always correct? Yes. PRIMO provides the interpretation correctness guarantee for each generated model and each prediction. Existing interpretation tools [39, 48, 67] aim to offer explanations for understanding black-box models, whereas the generated interpretations are sometimes contradictory or even mislead users. In contrast, PRIMO models are inherently interpretable and developers can totally trust the interpretation.

Can PRIMO be applied to all systems? PRIMO has its limitations in some system scenarios. For instance, it does not yet support unsupervised learning scenarios (e.g., anomaly detection in security applications [16]). It cannot outperform black-box models in systems with extremely complex features, e.g., images, speeches. These will be our future work.

Is the post-processing step necessary? These operations are optional because the trained models without post-processing usually have excellent performance. In order to take full advantage of the interpretable models, the post-processing tools help developers leverage their expertise and domain knowledge to further optimize system performance. In a black-box model, it is hard to perform such optimization.

Can PRIMO work on a larger model? Yes. We have demonstrated PRIMO can outperform DNN models in various scenarios, including LinnOS (MLP with 8×10^3 parameters), Clara-CP (LSTM+FC with 4×10^4 parameters) and Pensieve (CNN+MLP with 1×10^5 parameters). They represent most model scale of learning augmented systems listed in [1]. For larger models, we evaluate Habitat [88] as an example. It leverages 8-layer MLP models, containing over 8×10^6 parameters, to prediction DL operation execution time on heterogeneous GPUs. PRIMO can provide comparable prediction accuracy as Habitat across conv2d, linear, lstm and bmm operations.

How to interpret high-dimensional data? Admittedly, when handling high-dimensional datasets, PRIMO models may become more complicated for users to understand the whole model. However, PRIMO provides ordered feature importance for interpretation. Generally, users can focus on the top several tree layers of PrDT or several significant shape functions according to the global interpretation of PrAM.

Future work. There are four possible directions as our future work. (1) We can extend PRIMO to support learning-augmented systems with unsupervised learning. (2) To obtain a more accurate interpretable model, we can optimize the model training algorithm. Currently, we use CART [14], the most popular and widely applied approach, for decision tree learning in PrDT. This is based on the heuristic greedy algorithm where locally optimal decisions are made in each node. In the future, we plan to employ novel decision tree training algorithms (e.g., GOSDT [44], based on dynamic programming method) to solve the sub-optimal problem. (3) For practical deployment, comprehensive programming language support is needed because different systems have their own coding

requirements. PrDT has a tool for converting Python-based models to other formats. But PrAM only supports the conversion to the ONNX [4] format currently. We aim to provide more model format conversion in the future. (4) Integration with existing RL-based system development frameworks (e.g., Park [50]) to facilitate more practical system deployment.

9 Related Work

Interpretability of learning-augmented systems. To our best knowledge, there is no prior work that develops a unified framework for providing inherent interpretability for systems like PRIMO. Besides, interpretability is often overlooked during the development of learning-augmented systems, and only a few works consider it. Bao [53] is a learning-based system that adopts TreeCNN [60] for query optimization and the decision process can be inspected by developers. Tang et al. [79] proposed an interpretable method that extracts a Finite State Machine from a RL policy for storage resource allocation in Huawei. Grüner et al. [25] generated concise and interpretable rule-sets for unknown proprietary streaming algorithms (e.g. ABR approaches in Youtube, Twitch), which is similar to the Pensieve case study with PRIMO (§6).

Some efforts were also made on building tools for interpreting black-box models [26, 27, 55], as discussed in §2.3.1. Different from these methods, PRIMO does not seek for interpreting black-box models but directly building transparent models, with higher fidelity and efficiency.

Machine learning and system co-design. It is non-trivial to apply ML techniques for system design and deployment in practice. Autosys [42] introduces a framework to address common design considerations (e.g., learning-induced system failures, extensibility), and reported years of experiences in designing and operating learning-augmented systems at Microsoft. WhiRL [19] facilitates the safe deployment of RL-based systems through verifying whether the learned policy meets the designer's requirements. Some components in PRIMO are inspired from these works.

10 Conclusion

This work introduces PRIMO, a unified framework that assists developers to design practical learning-augmented systems with interpretable models. For different scenarios, PRIMO provides respective models and optimization solutions to meet the system requirements. Based on our case studies, we demonstrate that PRIMO can achieve *transparent, accurate and lightweight* system deployment in practice.

A Supplementary Elaborations

In this section, we provide some supplementary elaborations about PRIMO algorithms, including algorithm detailed illustrations of PrAM and PrDT.

A.1 PrAM: Explainable Boosting Machine

Explainable Boosting Machine (EBM) [63] is a open-source implementation of Generalized Additive Models plus Interactions (GA²M) [47] written in C++ and Python. Similar to popular GBDT algorithms (e.g. LightGBM [37]), the EBM training procedure begins by bucketing data from continuous features into discrete bins of histogram [62], which can significantly accelerate model training. Then EBM starts to learn shape function $f_i(\cdot)$ for each feature. Common choices for shape functions are regression splines, step functions and binary trees. For better prediction accuracy, it chooses the boosted trees, where each successive tree tries to predict the overall residual from all the preceding trees [46]. Furthermore, EBM optimizes the traditional boosting (greedy search) approach by leveraging *cyclic gradient boosting*, which learns a shallow tree for each feature in a round-robin fashion [62]. PrAM is heavily based on the implementation of EBM.

For simplicity and accuracy, PrAM leverages BO to automatically adjust model configurations, including the number of histogram bins, the number of considered interactions, learning rate, etc. It helps developers easily obtain the optimal model which is compact and accurate.

A.2 PrDT: Minimal Cost-Complexity Pruning

We adopt Minimal Cost-Complexity Pruning (CCP) [14] to prune the full tree in the *post-processing* stage. This algorithm aims to minimize a cost-complexity metric $R_\alpha(T)$ which is defined as

$$R_\alpha(T) = R(T) + \alpha \cdot N(T) \quad (3)$$

where $R(T)$ and $N(T)$ denote the misclassification cost (error rate) and complexity penalty (the number of leaves) of the decision tree T respectively. The trade-off between accuracy and sparsity of the tree is controlled by the *complexity parameter* α : as α increases, more leaves are pruned and the total impurity increases.

Figure 17 presents the impact of the *complexity parameter* α on the model performance and complexity for the LinnOS system (§4). When α is too small (before the red dashed line), PrDT has poor performance because of the severe overfitting. With a bigger α , developers could trade-off the model accuracy and complexity based on their system requirements. The optimal pruning factor can differ by many orders of magnitude for different systems according to our experiments. It is hard for system developers to identify an appropriate value of α intuitively. To address this, PRIMO adopts bayes optimization to perform post pruning automatically (§3.3.1).

Figure 17: Performance (F1 Score) and complexity (Tree Depth) of the PrDT model under different α in LinnOS.

B Insufficiency of Existing Methods

To demonstrate the argument in §2.3, we provide some examples and perform analysis. These experiments reveal the insufficiency of both existing machine learning frameworks and interpretation tools.

B.1 Contradictory Interpretation

Clara adopts XGBoost to predict the optimal core counts for different NFs in Clara-MS. XGBoost contains a built-in api `get_score` to get the feature importance value of each feature and it can be regarded as the model interpretation. However, we argue that the interpretation has low fidelity. As evident from the Figure 18, interpretations based on different metrics present contrasting patterns, where both *gain* and *cover* are important intermediate metrics during model generation. For instance, R_{sum} is the second important feature according to *cover*-based explanation while seems ignorable from *gain*'s perspective. This makes developers feel confused which interpretation should trust. More seriously, this could mislead them to make wrong decisions, such as incorrectly omitting important input features while feature engineering.

B.2 Incapability for Global Surrogate

We have demonstrated the remarkable performance of PRIMO in this work. A common question is that *If using the existing interpretation tools for the model surrogate, can they also deliver equivalent effects?* Our answer is no. We evaluate two popular black-box interpretation methods: Lime [67] and Lemna [26]. Lime performs local interpretation through linear regression of data subset and Lemna adopts a mixture regression model to obtain interpretation in a similar way. Both of them are designed for local interpretation of several instances. However, we further explore whether they have the potential for the global model surrogate. Hence, we train the Lime and Lemna model on the LinnOS dataset, and compare the performance with PRIMO. As shown in Figure 19, Lime and Lemna cause much higher (7.3%~9.0%) false submit rates, which is the most significant metric for the system performance. As stated in §4, the overhead of failover (false revoke) is relatively negligible and all three methods perform well pertaining to this metric. Overall, existing interpretation tools are insufficient for the global model surrogate.

Figure 18: Interpretations of XGBoost model for Clara-MS task based on different metrics. Higher value indicates the feature is more important.

C Lessons Learned From the Case Studies

In order to draw high level conclusions from the three case studies discussed in §4, §5 and §6, we list the key observation of the PRIMO benefits for each system scenario as below. To summarize, in addition to model transparency, PRIMO provides higher prediction accuracy, smaller inference overhead and better model generalization ability. These greatly facilitate model deployment in practice.

1. LinnOS

Key Observation 1

The high inference overhead of the DNN model can hinder its deployment in practice, meanwhile seriously damaging the effect of system performance improvement. PRIMO successfully overcomes this bottleneck.

2. Clara

Key Observation 2

Instead of using various black-box models for different tasks, PRIMO uses a unified interpretable model achieving equivalent even better accuracy and endows capability of model adjustment to remedy the problem caused by drifted synthesis data.

3. Pensive

Key Observation 3

With PRIMO, we obtain an interpretable model that has better performance and generalization ability than the RL policy. Moreover, it achieves much less inference overhead and low distill cost for practical deployment.

D More Details about the Evaluated Systems

D.1 LinnOS

LinnOS infers the SSD speed using a lightweight neural network. The motivation behind LinnOS is that SSD read latency is unstable because some SSD internal operations (e.g., write-triggered garbage collection, buffer flushing) are contending with user read I/Os. In addition, there are the same replicas

Figure 19: Comparison of Primo global surrogate performance with Lime and Lemna in the LinnOS scenario.

in other SSDs within the storage array (e.g., flash RAID) and we can utilize the built-in *failover* logic to circumvent slow read I/Os. The overhead of switching the *read* operation to a redundant SSD (namely *failover*) is ignorable compared with I/O pending time.

Implementation. We implemented PrDT models into the Linux kernel v5.4.8 (same version with LinnOS) within the *block* layer (written in C). We use the same SSD I/O traces in LinnOS, which were collected from Microsoft Bing Index servers and have been preprocessed by the authors.

Although the LinnOS workflow files are open-sourced on the Chameleon Cloud [38], the experiment results are unreliable due to the unstable and random SSD I/O accesses (also argued by the authors). Consequently, we shift our implementation and evaluation on a bare-metal server from CloudLab [18]. It contains four homogeneous enterprise-level 1.6TB SSDs. One of them serves as the system drive and the rest three SSDs are used for performance evaluation. Additionally, due to the rapid development of the SSD technology in recent years, the Microsoft traces collected in 2016 cannot give sufficient load pressure for evaluation. So we execute a constant writing task in the background for each SSD (LinnOS only records read I/Os). According to our numerous tests, the additional load will not cause fluctuations in the evaluation results.

For the PrDT interpretation results, PRIMO can provide a more precise visualized file of the PrDT which covers the number of samples at each flow and the Gini impurity value of each node rather than Figure 3.

D.2 Clara

Clara is a system that generates the optimal offloading strategies for NFs in SmartNIC. Since the performance characteristics of offloaded programs are opaque prior to porting and offloading strategies are difficult to reason about, developers need to first cross-port NFs to the SmartNIC, perform workload-specific benchmarks, and then iteratively tune the ported programs to achieve higher performance. Clara can analyze a legacy NF in its unported form and suggest porting strategies for the given NF to achieve higher performance.

Implementation. We follow the author-provided data preprocessing pipeline to deal with synthesized and real traces for training and evaluation. We conduct Clara evaluation on a

Notation	Description
A_i	IMEM Access
A_e	EMEM Access
I_c	Compute Intensity
R_i	IMEM / Overall Intensity Ratio
R_e	EMEM / Overall Intensity Ratio
R_{ic}	IMEM / Compute Ratio
R_{ec}	EMEM / Compute Ratio
R_{sum}	(IMEM + EMEM) / Compute Ratio
R_{res}	(IMEM - EMEM) / Compute Ratio
R_{state}	Non-Stateful / Stateful Compute Ratio

Table 5: Notation descriptions of Clara-MS.

Ubuntu 20.04 server with one Intel Core i9-10900 CPU, 64 GB memory and an NVIDIA RTX 2080Ti GPU. Note that because it is an offline system and we focus on model accuracy, Netronome SmartNIC is not required in our experiment.

Notation. We clarify the notations used in system interpretations (Figure 8). Table 5 shows processed features used in Clara-MS, where IMEM indicates SRAM-based internal memory and EMEM indicates DRAM-based external memory on SmartNICs. Instructions can be classified into Stateful (e.g., loads and stores to global variables in memory) and Non-Stateful (e.g., compute instructions, or accesses to function-local variables). Moreover, Overall Intensity represents the sum of IMEM, EMEM and Compute Intensity.

D.3 Pensieve

Pensieve [51] is a system that learns adaptive bitrate (ABR) algorithms automatically using RL technique. The online videos are stored on servers as multiple chunks (a few seconds of the video) and each chunk is encoded at several discrete bitrates (resolutions). Specifically, Pensieve adopts A3C [57] to perform RL training. Both the actor and critic networks use the same NN structure which contains a 1D-CNN layer and a fully connected layer. The actor takes recent network observations as input and suggests the bitrate for the next video chunk as the output. Content providers employ ABR algorithms to optimize user quality of experiment (QoE) which is defined as:

$$QoE = \sum_{n=1}^N q(R_n) - \mu \sum_{n=1}^N T_n - \sum_{n=1}^{N-1} |q(R_{n+1}) - q(R_n)| \quad (4)$$

where R_n represents the bitrate of the n^{th} chunk and $q(R_n)$ maps that bitrate to the quality perceived by a user. T_n represents the rebuffering time and the last term penalizes changes in video quality to favor smoothness.

Implementation. We employ the same server used in Clara for the Pensieve experiment. The video server is based on Apache httpd (Version 2.4.41) and uses Google Chrome (Version 96) as the client video player. We use 142 Norway HSDPA [68] network traces (provided by the authors) for evaluation, in addition, we process another 249 FCC [3, 54] traces

Notation	Description
X_t	Past chunk throughput
T_t	Past chunk download time
N_k	Next chunk sizes
B	Current buffer size
C	Number of chunks left
L	Last chunk bitrate

Table 6: Notation descriptions of Pensieve.

(2018 version, follow the same preprocessing pipeline) for model generalization evaluation. Because the original FCC-18 network speed is much faster than HSDPA and we cannot distinguish the performance difference among algorithms, we scale down the network speed by 4 times to keep consistent with FCC-16 with regards to the median values.

We obtain PrDT model through distilling from the trained RL actor model (pre-trained model that Pensieve authors provided). After that, we implement PrDT (written in JavaScript) into *ABRController* of dash.js [2] (Version 2.4). For the test videos, we use the same video in Pensieve at bitrates in {300, 750, 1200, 1850, 2850, 4300} kbps (which pertain to video modes in {240, 360, 480, 720, 1080, 1440}p). This video is divided into 48 chunks and each chunk represented approximately 4 seconds. Furthermore, we adopt $q(R_n) = R_n$ in Equation 4 to set *linear QoE* as the our evaluation metric.

Notations. We clarify notations used in system interpretations (Figure 12). Table 6 shows environment state variables used in Pensieve to generate bitrate decision, where X_t and T_t denotes past sequences of throughput and download time respectively ($t = 1, \dots, 8$). Moreover, N_k represents sequence of next chunk sizes ($k = 1, \dots, 6$).

E Artifact

PRIMO and case study scripts are available as below. To reproduce the main results of this work, we also provide detailed documentation and instructions in the artifact repository.

Meces: Latency-efficient Rescaling via Prioritized State Migration for Stateful Distributed Stream Processing Systems

Rong Gu Han Yin Weichang Zhong Chunfeng Yuan Yihua Huang
State Key Laboratory for Novel Software Technology, Nanjing University, Nanjing 210023, China

Abstract

Stateful distributed stream processing engines (SPEs) usually call for dynamic rescaling due to varying workloads. However, existing state migration approaches suffer from latency spikes, or high resource usage, or major disruptions as they ignore the order of state migration during rescaling. This paper reveals the importance of state migration order to the latency performance in SPEs. Based on that, we propose Mecas, an on-the-fly state migration mechanism which prioritizes the state migration of hot keys (those being processed or about to be processed by downstream operator tasks) to achieve smooth rescaling. Mecas leverages a fetch-on-demand design which migrates operator states at record-granularity for state consistency. We further devise a hierarchical state data structure and gradual strategy for migration efficiency. Mecas is implemented on Apache Flink and evaluated with diversified benchmarks and scenarios. Compared to state-of-the-art approaches, Mecas improves stream processing performance in terms of latency and throughput during rescaling by orders of magnitude, with negligible overhead and no disruption to non-rescaling periods.

1 Introduction

In recent years, stateful Stream Processing Engines (SPEs) [16, 19, 33, 44, 53] have been widely adopted because of the increasing demands for complicated analytics over real-time data, e.g. fraud detection, log monitoring, sentiment analysis, and IoT applications [11, 13, 51, 60].

SPEs are expected to be long-running and always have low latency performance [21, 22]. It commonly requires SPEs to perform dynamic rescaling in the face of unpredictable circumstances (e.g. data rate fluctuations, machine failures, processing stragglers). However, as the processing operators in SPE are usually stateful and partitioned across workers, rescaling them calls for state migration, which means moving state data between workers, even across networks [26].

The problem of state migration in SPEs is fundamental and challenging. Prior major advances made in the last decades

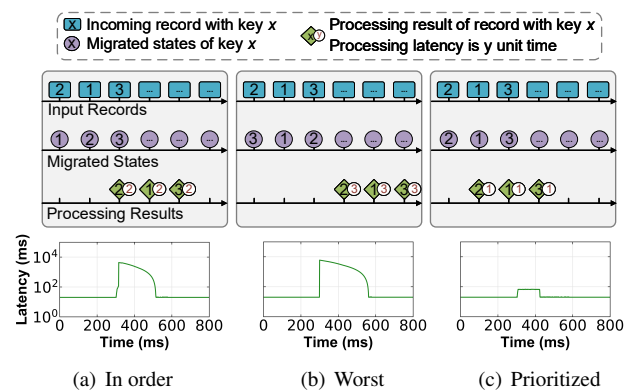

Figure 1: Impact of migration order on processing latency. The Y-axis indicates event-time latency, i.e., interval between a record’s event-time and its emission-time from the output operator [30]. Point (X, Y) means the average processing latency of the records generated at X ms is Y ms.

can be classified into four categories: (1) Full-Restart approach [16, 33, 53] pauses and resumes the whole task when redistributing states. (2) Partial-Pause approach [14, 52] restarts a subgraph instead of the whole job topology to reduce execution blocking. (3) Replicated-Dataflow approach [47, 61] executes a new dataflow in parallel with the old one until finishing the state migration. (4) Proactive approach [26, 43] adds extra behaviour to non-rescaling stream processing periods to relieve the pressure during state migration.

Unfortunately, prior approaches suffer from processing latency spikes, or high resource usage [26], or major disruption (see Section 5.6). Their common limitation lies in **order-unaware** state migration, i.e., not taking into account the order in which operator state migrates. Figure 1 illustrates how the migration order affects SPE latency performance during rescaling. We take a representative stateful stream processing job, key-count, as an example, where records with random keys come from upstream and are processed by the SPE in a FIFO manner. In this case, streaming operators store the

count value of each key as their corresponding states. During rescaling, an affected operator needs to receive the migrated state (the global count values of keys) before it can process the corresponding incoming records.

If the states are migrated in an order-unaware manner as in Figure 1(a), the first coming record may not be processed in time, because it needs to wait for the arrival of its corresponding state. This also blocks subsequent records in the queue due to FIFO processing, eventually accumulating the processing latency for all records over a period of time. In the worst case as shown in Figure 1(b), the state of the first record is the last one to be migrated, making all record processing blocked before the state migration is finished. Ideally, as shown in Figure 1(c), states are migrated in exactly the same order as the records arrive, therefore minimal time is spent in the waiting queue and the latency can be greatly reduced.

Based on this observation, we find that the state of hot keys (those being processed or about to be processed by downstream operator tasks) needs to be prioritized so that the stream processing proceeds without blocking. In this paper, we propose Mecas, an on-the-fly rescaling mechanism which enables **prioritized state migration** for SPEs. In fact, it is challenging to dynamically adjust the state migration order according to the incoming records during SPE rescaling. To achieve this, Mecas leverages a fetch-on-demand state accessing model, based on the fact that modern SPEs [16, 53] co-partition data records with stream operators to the same key space. During rescaling, the states can be actively *fetch*ed by the SPE operator instances when receiving a data record whose state is not local. In this way, the operators prioritize the transmission of those currently needed states to generate processing results with low latency.

Another challenge is to handle the state consistency during the prioritized state migration process. In Mecas, the state consistency in the above process is maintained by a control messaging based coordination protocol, inspired by [7, 40, 43]. In addition, as the fetch-on-demand model used in prioritized state migration calls for light-weight state accessing, we devise a hierarchical data organization and adopt a gradual migration strategy for finer-grained state transfer like [26]. Mecas is designed as a pluggable rescaling module without affecting non-rescaling periods. As far as we know, Mecas is the first stateful SPE rescaling approach that enables prioritized state migration, which can reduce the latency spikes without high resource usage or incurring major disruption.

To sum up, this paper makes the following contributions:

- We propose an on-the-fly rescaling mechanism, called Mecas, for stateful distributed stream processing engines. It prioritizes the migration of hot states to achieve low-latency and resource-efficient rescaling.
- In addition, we adopt a control messaging based coordination protocol to maintain state consistency during prioritized state migration. We further devise a hierarchical state data organization and a gradual state migration

Figure 2: A key-count job example in stream processing

- strategy, which lowers data transmission granularity.
- Mecas is implemented on the widely-used SPE Apache Flink, requiring minimal user code modification and no disruption to non-rescaling periods.
- We validate our design with various workloads. Compared with state-of-the-art approaches, Mecas reduces nearly 95% of processing latency peak during rescaling.

2 Background

In this section, we first introduce basic concepts and terminology of stateful stream processing in Section 2.1, and then review and analyze the design and shortcomings of existing rescaling approaches in Section 2.2.

2.1 Stateful Stream Processing

Stream Processing Topology: In scale-out distributed SPEs, the computation tasks are expressed as directed graphs (Figure 2(a)), where vertices represent stream processing operators. Each operator receives data from its upstream operators, processes data, and sends output to its downstream operators. Operators without upstream are called *source* operators, and those without downstream are called *sink* operators.

SPEs process input data in a data-parallel style by mapping the streaming *operators* to multiple parallel *instances*. The number of an operator’s instances is called its degree of *parallelism*. In Figure 2(b), the vertices represent parallel instances and the directed edges represent data channels.

Stateful Operator: In practice, many analysis tasks require operators to compute their output based on both current and previously received data. Examples of such tasks include data aggregation, window computation, ML models, etc. To realize this, *stateful* operators maintain internal and mutable states. Operator states remember information about past input and can be used for processing of future input [18]. For example, a counting operator of a WordCount job stores the current occurrences of each word as its states.

A stateful operator receives input data as a stream of keyed *records*. Each record can be denoted as a pair (k, v) representing the key and the payload value. Correspondingly, the stateful operator also holds its state S as a set of key-value pairs and divides the set into several disjoint partitions. During

processing, the partition S_l is assigned to an operator instance I . When I receives a record with key k , it processes the record by reading or updating the value v corresponding to k in S_l . In modern SPEs [16, 53], states of the stateful operators are co-partitioned with the parallel instances. For example, in Figure 2(b) the state of the keys mapped to C_1 operator instance is only stored in *part-1*.

Checkpoints: SPEs usually achieve fault-tolerance via checkpoints. A checkpoint marks the persistent state for each operator at a specific time point. SPEs can resume from failure by restoring the operator states with a recent checkpoint and replaying the records since the generation of the checkpoint.

A common way to realize consistent state snapshots of distributed streaming operators is Chandy-Lamport algorithm [10] or its variants. The checkpoint algorithm in Flink [7] works by injecting special streaming records called barriers into the pipeline. Each operator instance will persist its state when receiving a barrier. This workflow makes a globally consistent operator state snapshot on the basis of reliable FIFO data channels.

2.2 Prior Rescaling Mechanisms

The critical difficulty in on-the-fly rescaling distributed stream operators is efficiently migrating states among instances while keeping the exactly-once semantics. Prior approaches can mainly be categorized into the following strategies [6, 26].

Full-Restart: This approach halts the SPE execution, takes a state snapshot of all operators, redistributes the state among operator instances, and restarts the job execution until the state redistribution is complete. Since it is simple and naturally guarantees consistency using existing *checkpoint* mechanisms, it is adopted by many SPEs including Spark Streaming [53], Structured Streaming [5], Apache Flink [16], etc. However, this mechanism halts the whole pipeline and causes serious latency spikes during rescaling.

Partial-Pause: This approach only stalls the streaming operators that need state migration during rescaling. It mitigates the latency spikes by narrowing the interruption from the job-granularity to the operator-granularity. This mechanism is first introduced by Flux [52], and adopted by SEEP [14], FUGU [25], Chi [40], etc. However, if the affected operator is a critical component in the topology, this approach still pauses the entire pipeline during rescaling.

Replicated-Dataflow: This approach replicates the affected operators and executes the old and new configurations simultaneously until the migration completes. It minimizes processing latency and realizes on-the-fly state migration, but requires redundant computing resources for replication [26]. It also calls for additional de-duplication mechanisms as the concurrent execution generates duplicated data. This mechanism is adopted by ChronoStream [61], Gloss [47], etc.

Proactive: Proactive approach adds extra behaviour to non-rescaling periods to relieve the pressure when migrat-

ing states. Megaphone [26] works by splitting operators and embedding the migration flows into data flows. However, it introduces partitioning overhead inside the original processing operators during non-rescaling periods. Besides, in system design it calls for extra coordination and progress tracking mechanisms [26, 43] which are not directly supported by many modern SPEs [16, 53]. Rhino [43] periodically replicates operator states among all workers. It facilitates both fault-tolerance and state migration of extremely large states, but incurs extra network overhead to regular stream processing.

As far as we know, none of the existing approaches consider the state migration problem from the aspect of the state migration order. They rescale with latency spikes or high resource usage [26], or major disruption (see Section 5.6).

3 System Design

In this section, we first introduce the main idea of Meces in Section 3.1. Then, in Section 3.2 we describe the design in detail. Finally, we elaborate the optimization for finer-grained state transfer in Section 3.3 and Section 3.4.

3.1 Prioritized State Migration

If not introducing huge redundant resources [47, 61] or disrupting regular processing [26, 43], prior works [5, 14, 16, 25, 40, 52, 53] fail to achieve low latency when rescaling. They are mainly limited by "order-unaware" state migration. As Figure 1 in Section 1 shows, the migration for hot keys should be prioritized, so as to generate timely results and reduce queuing latency when rescaling.

In order to achieve prioritized state migration, we review the nature of states in streaming operators. We denote a record with key k as r_k , and a state value with key k as v_k . An important fact about recent scale-out stateful SPEs is that the operator states are partitioned across the operator instances in exactly the same way as data records according to their keys. That is to say, when an operator instance I processes a record r_k , the only state that it needs to access is v_k . It is also guaranteed that no common states need to be accessed when processing records with different data keys.

Given this property, we propose the prioritized state migration mechanism, which enables the system rescaling and data processing of SPEs to efficiently run at the same time. Specifically, when the SPE triggers an online state repartition, the previously responsible instances **send** states in batches to the newly responsible instances. In our design, as for the newly responsible instances, instead of only passively waiting for the arrival of migrated state batches, they can also actively **fetch** states from previously responsible instances, to get the individual states corresponding to the data records for timely processing. For example, as no more records with key in $\{k_1, k_2, k_3\}$ will be sent to I_a due to rescaling, the SPE decides to migrate a set of state values $S_m = \{v_{k_1}, v_{k_2}, v_{k_3}\}$

from operator instance I_a to I_b . Then S_m is sent by I_a . Before I_b receives the entire state set, if I_b encounters a record r_{k_2} , it immediately performs a single-value fetch for v_{k_2} . This lightweight operation helps I_b to generate processing results in time, instead of getting blocked until receiving the entire S_m from I_a .

In this way, we can keep the stream processing operators working during SPE rescaling. The batched "send" aims at quick state migration, while the active "fetch" ensures in-time processing for the records that requires a remote state. The processing latency performance will be affected only when an active "fetch" is triggered. In that case, only the processing of that single record is delayed a bit because of one extra state fetch operation, but the queuing cost of subsequent records can be greatly reduced. In other words, the performance interference caused by the state migration comes down to the record-granularity, so that we can keep the stream processing performance as high as possible during the rescaling period.

To achieve this, two obstacles need to be carefully dealt with: First, how to ensure state consistency when transferring states among operator instances in a dynamic order (Section 3.2). Second, how to minimize the performance impact brought by fetch operations (Section 3.3 and 3.4).

3.2 Fetch-on-demand State Accessing Protocol

To support prioritized state migration with dynamic order during rescaling, Mecas leverages a fetch-on-demand state accessing protocol. The state consistency of the fetch-on-demand model is based on a control messaging coordination protocol, inspired by [7, 40, 43]. In the following, we first briefly describe how the protocol works, then use an example to further explain its process.

Migration Process: We call the time period from the beginning to the end of a state redistribution as a *Migration* stage. The global controller of an SPE starts a *Migration* stage by injecting a special data record called *control message* into the source operators. The message then travels through the whole pipeline in the same way as a regular data record. Once an instance I receives a control message from its input data channels, it performs the following steps:

- (1) I sends the control message downstream.
- (2) If the downstream operator needs to migrate states, I updates its routing strategy.
- (3) If I itself needs to migrate states, according to whether it has received messages from all input channels, it successively goes through two phases: *Aligning* and *Aligned*.
- (4) I sends a confirming signal to the global controller. A *Migration* stage ends when the global controller receives confirming signals from all parallel instances.

Figure 3 and Figure 4 show the *Migration* stage during a scale-out operation of a streaming key-count job. The degree of parallelism of the count operator increases from 2 to 3, represented by A, B, C (see Figure 3(a)). The upstream source

Figure 3: Example of a rescaling stream processing job

operator has two parallel instances $S1, S2$. For simplicity, we assume the keys are between 1 and 12. Therefore, based on the uniform distribution, the distribution of the key space before and after the rescaling is as shown in Figure 3(b).

When $S1$ or $S2$ receives the control messages, it updates the routing strategy and outputs the subsequent data records in accordance with the new topology. As its downstream operator's degree of parallelism will increase by 1, its new strategy divides the key space into three parts equally. As shown in Figure 4(a), the records mapped to "9" were previously sent to B , but will be shipped to the new instance C from now on. Meanwhile, the records with key "6", which were consumed by A , should then be in the charge of B .

As for the count operator, in general, the states are sent from the previously responsible instances, but the newly responsible instances also actively fetch states in response to the incoming data records. We denote an instance's current key space before migration as C_k , and its future key space after migration as F_k . Specifically, the count operator successively goes through two phases. Taking B as an example:

1. **Aligning (Figure 4(b)):** When B first receives a control message, such as from $S2$, it can foresee the arrival of keys that did not belong to it before. After that, when B encounters a record whose key is not in its C_k , such as key "6", instead of considering it as an error, B first checks its F_k . If the key is found, B "borrows" the corresponding state of this key from other count operator instances to complete the processing. Note that in this phase, the message from $S1$ has not reached B , which means A may still have to deal with records with the "6" key. Because of that, B should also be prepared that its state of "6" can still be borrowed back by others.
2. **Aligned (Figure 4(c)):** The *Migration* for B is aligned once it receives control messages from all of its input channels. In this situation, it is guaranteed that all future records with the "5, 6" key are shipped only to B , and B will no longer receive records with keys from 9 to 12. Therefore, B can start its state migration. It checks C_k and F_k , sends the states between 9 and 12 to other instances, and fetches all the states in 5 and 6 asynchronously. When finishing sending and fetching, B sends the completion signal of its *Migration* stage.

Figure 4: *Migration* stage in a rescaling operation

In the above process, the stream processing operators keep functioning without explicitly blocking the input channels. The impact of state migration on the task is only perceived when an instance requires a remote state. The processing latency of this single record is then only increased by the fetching cost of a single state. For subsequent records, if the corresponding state has already been fetched, the processing of these records suffers from neither migration cost nor huge queuing cost. In this way, the influence of rescaling can be significantly reduced, therefore the system can avoid sudden and severe performance degradation in latency and throughput. For implementation details of the active state fetch process, please refer to Section 4.2.

State Consistency: In stream processing, the global state consistency usually refers to the exactly-once semantics. In Mecas, at a *Migration* stage where the state k is migrated from I_1 to I_2 , each incoming record affects the final results exactly once. Let t_1 be the timestamp when I_1 or I_2 receives the first control message of *Migration*, and t_2 be the timestamp when both of I_1 and I_2 have received control messages from all the input channels. Therefore, the *Aligning* phase begins at t_1 . In this phase, the data records of k can be sent to both I_1 and I_2 , but actually only one instance holds the state of k locally at a time. That is to say, only one instance can modify this state at a time. As the data record must be processed exactly once, and the state can only be flushed and "borrowed" after the processing of the current record is finished, the semantic is kept in $[t_1, t_2]$. After t_2 , subsequent data records are sent to I_2 only. I_2 only needs to borrow at most once to transfer the state to the local and process each data record exactly once until its *Aligned* phase is complete.

3.3 Hierarchical State Data Organization

This subsection proposes an adaptive state data organization, which keeps regular stream running at a coarse granularity to avoid extra overhead, and performs prioritized state migration at a fine granularity to reduce the impact on latency performance of streaming operators.

Since the states in SPEs are key-value data and it is

Figure 5: Split key-groups into sub-groups

common to have billions of keys in a real-world streaming dataflow services, managing each key individually can be unrealistic. Many existing SPEs divide the states into key-groups [17], which are disjoint subsets of the entire key space.

However, the shortcoming of this flat index structure is that the state migration is also conducted on the key-group granularity. As the number of the operator states accumulates, the size of one single key-group could grow large. This can make the active "fetch" become time-consuming, bringing long delays to the record processing at the *Migration* stage. A naive solution is to increase the number of key-groups, but this is not practical in many SPEs. A vast number of key-groups will bring a lot of additional metadata management overhead and fragmented read/write of checkpoints, thereby reducing the performance of non-rescaling stream processing.

To address this issue, we introduce the nested layer of state data organization in Mecas. Instead of using a single-layer map, we further divide each key-group into multiple sub-groups as illustrated in Figure 5. When encountering a record that requires a remote state, an instance tries to fetch the corresponding sub-group of the record key instead of the entire key-group. This reduces the time overhead used to obtain data that is not needed immediately.

Note that, key-groups are distributed among different operator instances and the metadata should be stored, indicating which instances are responsible for each key-group. When the number of key-groups increases, it incurs much more metadata management cost and record distribution cost. Differently, sub-groups of the same key-group must belong to the same operator instance when the system is not rescal-

Figure 6: An example of gradual state migration

ing. Therefore, increasing the number of sub-groups does not bring significant extra overhead to a steady dataflow. Users can choose an appropriate number of sub-groups to achieve smooth state migration. The appropriate settings are usually based on the maximum size of states and the expected maximum latency during rescaling.

3.4 Gradual State Migration

During a rescaling operation, a large part of the overall states may need transferring, even if the degree of parallelism does not change much. For example, to divide the states evenly across all operator instances in Figure 3, changing the degree of the parallelism from 2 to 3 causes half of the keys to be redistributed. For example, if we have an operator with 128 key-groups and change the degree of parallelism from 25 to 30, a nearly full state migration (115 out of 128 key-groups) has to be triggered. Migrating all of these states in a single batch can dramatically slow down the overall performance, because most of the records processed by the task in the next period may be affected by the fetch operations. As the data streams continue to flood in, lots of minor processing delays may accumulate into large latency spikes.

To resolve this issue, inspired by [26], we also achieve finer-grained migration via a gradual migration strategy in Mecas, which splits the update into several micro-batches of state migration as shown in Figure 6. The *Migration* stage in one rescaling operation is then composed of multiple *Gradual-Migration* steps. At each step, the global controller decides which states should be relocated based on the user-defined size of micro-batches (*batch_size*). For example, in Figure 6, *batch_size* is set to 1, which means that an instance can only dispose at most one key-group of states at a time. This splits the single *Migration* stage into four *Gradual-Fetch* steps.

At *Gradual-Fetch* steps, the information of migrated keys is included in the control messages and each upstream instance creates a temporary routing table indicating which downstream instance it should send records to. In this way, we affect only a tiny portion of the whole states at each *Gradual-Fetch* step, while most of the records can be processed normally. By changing *batch_size*, users can trade-off the lower latency spikes against higher migration throughput.

Note that during rescaling, the total number of migrated keys can be reduced by dividing the states differently. For example, in Figure 6, if the middle four keys are assigned to instance 3 and the last four keys are assigned to instance 2,

Figure 7: Mecas Architecture

only 4 of 12 keys need relocating. Mecas uses the uniform re-partition by default, but also supports custom partitioning, so that users can apply it to SPEs with sophisticated partitioning approaches [2, 29] such as consistent hashing. A brief evaluation of custom partitioning can be found in Section 5.3.

4 State Migration Implementation

This section describes the implementation of Mecas. We demonstrate the overall system architecture of Mecas in Section 4.1 and then introduce the details of state transition workflow among operator instances in Section 4.2. Finally, we discuss the fault tolerance mechanisms of Mecas in Section 4.3.

4.1 System Architecture and Usage

The overall system architecture of Mecas is shown in Figure 7, which consists of three layers:

1. Stream API: It provides basic operator functions for users to implement stream processing tasks.
2. State API: Mecas provides Apache Flink-compatible APIs for operator functions to access their states. This enables the users to easily migrate the existing stream tasks from Flink to Mecas.
3. SPE Runtime: This is where the system-level code is located. Mecas basically reuses Flink's state backend module to store the key-value pairs in memory/DFS. Additionally, Mecas implements the design in Section 3.

The underlying state management and migration in SPE Runtime are completely transparent to user codes. Therefore, it takes minimal effort to switch between Flink's and Mecas's state implementations.

4.2 State Transition

The state transition among operator instances is of great importance to the performance of SPEs during rescaling. However, if the transfer of states happens directly between parallel instances, a mesh communication network has to be established among the worker machines. This would significantly increase the runtime overhead and make the maintenance of

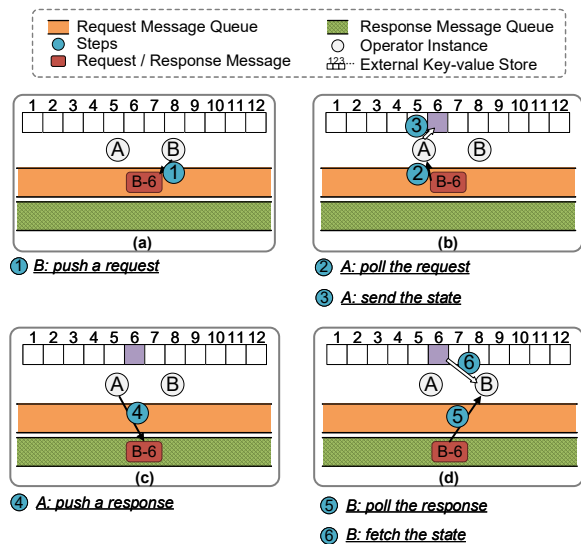

Figure 8: State transition process based on the pub-sub model

SPEs more complex. That is why SPEs like Flink [16] are designed to avoid direct inter-instance communication within an operator, i.e. adopting a shared-nothing architecture [17, 24] for low-cost, high-extensibility and high-availability.

To make it non-disruptive to SPEs, in implementation of Mecas, we design a pub-sub model based approach to transfer states between parallel instances during record processing. The model leverages two message queues (*RequestMQ* and *ResponseMQ*), and an external key-value store (EKS) to provide a state transition service at *Migration* stage. At *Migration* stage, each instance performs light-weighted operations to read from these two message queues continuously.

Figure 8 demonstrates the state transfer process from operator instance *A* to *B*. When *B* needs to fetch the state with key "6", it simply pushes a message "B-6" to the *RequestMQ*, meaning "*B* is requesting 6". Later, *A* gets the message, finds "6" in its C_k , and then pushes the state value into the EKS and considers its local "6" state as borrowed. After that, *A* pushes a message into the *ResponseMQ*, indicating the completion of the request. Eventually, the message will be consumed by *B*, making *B* fetch the corresponding data from EKS. Thus far, the workflow of the state transition is complete.

In the above process, when the request message comes to *A*, if *A* happens to be processing a record with a key of 6, *A* will not start pushing until it finishes processing the current record. Meanwhile, if "6" has already been pushed into EKS and then *A* receives a record requiring this state, *A* should trigger a similar process to fetch the state, as "6" is now considered not held by *A*. These two situations do not bring much degradation to the rescaling performance, because they only happen in the *Aligning* phase, which only lasts for a short time if the system is not running under severe load imbalance.

For decoupling the components, many scalable message queue techniques [27, 46, 49] can be utilized to implement the pub-sub model. These are common components in real-world stream processing tasks, because they suit the stream processing paradigm as data sources and sinks. For EKS, a high-speed key-value store with fault-tolerance guarantees can be integrated to ensure real-time computation.

4.3 Fault Tolerance

Mecas inherits fault-tolerance guarantees from the hosting SPEs, and relies on high-available message-queue/EKS service. Specifically, fault-tolerance is supported in both rescaling and non-rescaling scenarios.

During rescaling: If some of the message-queue/EKS nodes fail, the rescaling in Mecas can keep going without data corruption. This is because message-queue/EKS service adopted by Mecas is equipped with built-in fault-tolerance mechanisms [12, 48], such as replication. If the entire message-queue/EKS or any Flink node fails to respond (simple/cascading failures), Mecas considers this rescaling to have failed and invalidates the temporary data in message-queue/EKS. Then Flink's own failover mechanism is activated to recover the job from a checkpoint. Therefore, a failed rescaling does not break exactly-once semantics.

During non-rescaling: As Mecas is designed to be non-disruptive when rescaling is not executed, it introduces no extra fault-tolerance issues. Any exception is handled by the hosting SPEs' failover mechanism.

Finally, Mecas temporarily disables checkpoint generation only at *Migration* stages, and suspends new rescaling during an ongoing rescaling to avoid interference. Therefore, data consistency is kept throughout the job lifecycle.

5 Evaluation

This section presents an empirical evaluation of our prototype Mecas. We focus on the following three questions:

1. What is the performance of Mecas during rescaling with state migration? (Section 5.2 to 5.4)
2. How much overhead does Mecas incur? (Section 5.5)
3. How does Mecas compare to other state-of-the-art on-the-fly state migration approaches? (Section 5.6)

5.1 Experimental Setup

Hardware and Software: All experiments presented in this paper are conducted on a cluster of six computing nodes, each with two Intel Xeon E5-2620 v2 @2.10 GHz CPUs and 64 GB memory, running CentOS 7.9.2009.

The Mecas prototype is implemented based on Apache Flink 1.12.0. The same version of Apache Flink is used as a baseline in our evaluation, referred to as "Native Flink" in the following. Mecas and Native Flink run with Oracle JVM

11.0.10 to enable the low-latency garbage collector ZGC [63]. We pair Apache Kafka 2.7.0 with Apache ZooKeeper 3.6.0 as reliable message brokers with 25 partitions. Redis 3.2.0 is deployed to provide the external key-value store service globally. For persistent checkpoint storage, we deploy Apache Hadoop 2.9.2 to provide HDFS.

For SPE configurations, we configure Native Flink and Mecas to use at most 25 GB heap memory. Each computing node can host at most 5 parallel instances of an operator. The total number of key-groups is set to 128, as it is the default value in Flink and different settings of this value do not differ the performance much in our cases.

Workloads and Metrics: We choose the NEXMark benchmark suite [55] and the key-count job as workloads. Nexmark models an online auction system and provides real-world streaming queries. The key-count job takes a stream of randomly generated keys as input and accumulates the number of times each key has occurred.

To provide input data for stream processing jobs, we implement open-loop stream generators which continuously and concurrently push random records into Kafka topics. Unless otherwise specified, all these open-loop generators produce data at a steady rate of 800K records/s. This input rate is near the saturation point of processing and large enough to show the performance difference between the various approaches.

We focus on two metrics in measurement during rescaling:

Latency: To evaluate the end-to-end latency of SPEs, we configure the stream generators to periodically insert marker events into Kafka. We denote latency as the time difference between these markers entering and leaving the SPE. For windowed operators, the markers simply bypass them to exclude the time spent in window buffers. The latency still grows when the system’s processing rate cannot keep up with the production speed of upstream data, as the latency markers are queuing up. That is to say, the marker can still reflect the latency performance of the system with windowed operators.

Throughput: We define throughput of SPEs as the number of records output by the source operators per second. As the source operators are responsible for fetching records from Kafka, this reflects the capability of the system to read and process data from external data sources.

5.2 Latency Performance during Rescaling

We first evaluate the latency performance of the SPEs during rescaling. The SPEs are initially configured with global parallelism of 25. Each job runs steadily for 600 seconds and rescales by increasing the parallelism of critical operators (e.g., join or window operators in NEXMark queries, counting operator in the key-count job) to 30. This causes 115 out of 128 key-groups to be relocated during rescaling.

We compare Mecas with Native Flink (stopping the whole job when rescaling) and Order-Unaware (online block-based state migration without order prioritization). Figure 9~12

Figure 9: End-to-end latency of NEXMark Q1

Figure 10: End-to-end latency of NEXMark Q7

illustrate the end-to-end latency change of the representative queries in this process. For the performance evaluation results of all NEXMark queries, please refer to Appendix B.

NEXMark Q1 performs currency conversion on a bid stream. This simple task maintains no states and the behavior is demonstrated as a basic case for our evaluation. As shown in Figure 9, both Mecas and Order-Unaware reveal no latency peak but only system noise, because they incur no state migration cost during rescaling and operations can be done asynchronously. In contrast, Native Flink still needs to stop and restart the job even if there is no state to migrate.

NEXMark Q7 and Q8 tests window operators. They perform tumbling window join of two streams, to find out the items with the highest price and the new users who just registered in the last period of time. They can maintain large states when the window size grows. We set the window sizes to be 10 seconds and 100 seconds. The performance comparison is illustrated in Figure 10 and Figure 11, where the latency peak of Mecas during rescaling is an order of magnitude smaller than others. When the rescaling begins, Order-Unaware needs to block the currently processed records while migrating a considerable amount of states. As a result, Order-Unaware goes through a performance degradation near to Native Flink (Full-Restart), and reaches a latency peak of dozens of seconds. For comparison, Mecas can give state migration priority to the hot keys being processed and smoothen latency.

Key-count takes a stream of randomly generated keys as input and reports the cumulative counts of each key continu-

Figure 11: End-to-end latency of NEXMark Q8

Figure 12: End-to-end latency of key-count

ously. The state size of the counting operator can also grow large when the key range is big enough. Besides, this query requires reading and updating the states when processing every single record. We run the job with 10^8 unique keys. As reported in Figure 12, both Native Flink and Order-Unaware show a latency peak which is three orders of magnitude higher than usual. The latency decreases gradually after the restarting or migration completes. As for Mecas, it keeps the latency under 600 ms during the prioritized state migration stages.

In conclusion, during rescaling, Native Flink and SPEs with Order-Unaware can suddenly become out-of-service when migrating states, while Mecas significantly lowers the maximum latency. The impact of prioritized migration of Mecas is further evaluated in Section 5.3. Note that in some cases with a rather large size of states, Mecas also have increased latency. This is mainly caused by the Garbage Collection behaviour of JVM, which is further analyzed in Section 5.5.

5.3 Impact of State Migration on Latency Performance during Rescaling

In this subsection, we evaluate how state migration affects the processing latency of SPEs, especially how the prioritized migration improves the performance.

During a rescaling period involving state migration, the overall processing latency of SPEs can be generally divided into three parts: (1) Job-Cost: time to execute the processing logic. This is inevitable in both rescaling and non-rescaling periods; (2) Migration-Cost: when encountering a record whose state is not local, the task waits for the target states to arrive and then proceeds processing; (3) Queuing-Cost: If a record r is blocked due to migration cost, subsequent records may also be blocked in the queue as they cannot be processed until the processing of r is finished. Therefore the processing latency of these subsequent records is increased.

Figure 13 illustrates the various parts of the average processing latency of a certain operator instance per second during the rescaling of the key-count job. Note that in order to show the comparison between different parts, here we use linear axes instead of logarithmic axes and draw with different y-axis ranges in the upper two sub-figures.

As in Figure 13(a), Order-Unaware incurs high latency up to thousands of milliseconds, and the increased latency is composed of huge Migration-Cost and Queuing-Cost. Because Order-Unaware does not migrate the currently needed states

(a) Order-Unaware (b) Mecas

(c) Distribution of Migration-Cost for all operator instances

Figure 13: Latency composition of during rescaling

Figure 14: Rescaling performance of Mecas using different repartition strategies

with priority, some of records have to wait for a long time before the arrival of their corresponding states. The waiting time can be up to several seconds as indicated by the Migration-Cost bar in the figure. As for the subsequent records, their states have been previously transferred and they need not wait for data migration. However, they suffer from huge Queuing-Cost due to the previous records being blocked. When no further migration is required, the Queuing-Cost decreases to 0 almost linearly.

Figure 13(b) reports the latency breakdown of Mecas. Compared with Order-Unaware, the latency peak is greatly reduced to less than 400 ms. This is because when migrating states, Mecas uses its fetch-on-demand model to give priority to the records which are currently being processed. When a record calls for a remote state, the operator instance immediately fetches the single state for the key of this record. Since the amount of data in a single state is very small, a fetch request can be quickly responded to. Consequently, as shown in Figure 13(c), the several long-duration execution blocks caused by Migration-Cost are converted into thousands of short-duration fetch operations. Although the sum of Migration-Cost does not differ much for two strategies, each record does not wait long time for its state to be migrated in the prioritized migration of Mecas. More importantly, as the Migration-Cost of every single record is reduced, the Queuing-Cost for subsequent records is also significantly reduced. Eventually, the overall latency curve is flattened.

From another angle, Figure 14 compares the rescaling per-

formance of Mecas using different state repartition strategies: the default uniform repartition and consistent hashing, which have different migration cost during rescaling. For a total of 128 key-groups, consistent hashing decreases the number of migrated key-groups from 115 to 15. Eventually up to 70% rescaling duration and 90% max latency are reduced. This indicates that we can equip Mecas with existing re-balance technology to improve the rescaling performance. For a fair comparison, in all other experiments in this paper, we use the same repartition strategy in all SPEs including Mecas.

Note that the above experiments are all conducted without any node failure or connection loss. As for the unusual scenarios including failing nodes with different roles, we observe that: (1) If any Flink node or Kafka/Redis leader fails, the latency curve is similar to Native Flink, because Mecas restarts the job since the underlying service becomes unresponsive. (2) If Kafka/Redis loses some of the follower nodes but still provides timely service when job is rescaling, there is no observable fluctuation in the average latency of fetch operations, because of the relatively low traffic of messages sent by fetch operations. In both cases there is no data inconsistency in the stream processing results.

5.4 Performance under Backpressure

In practice, the rescaling of an SPE is usually triggered when it sends a backpressure signal, indicating that it cannot process data fast enough to keep up with the data generation rate. This happens when there is a sudden surge in data traffic or when the system is not configured properly with enough parallel instances. To validate our design in this situation, we evaluate the performance of Mecas under backpressure scenarios.

A costly version of key-count query is chosen as the workload. We first configure the counter operator parallelism to 15 and run input generators at a speed of 300K records/s for 600 seconds. After that the input rate is increased to 600K records/s for 150 seconds, and then gets back to 300K records/s. This simulates a temporary surge in data traffic. The rescaling operation takes place at the 620th second, which increases the counter operator to 30 parallel instances.

Figure 15(a) shows how quickly the SPE recovers its real-time performance from backpressure. As soon as the data traffic surge comes, the latency increases suddenly, because the input is beyond the capability of the system and the following records are queuing up. Then, after the scale-out operation is completed and all the queuing records have been fully consumed, the processing latency can go back to a normal low level. Here we record the time interval from the arrival of the data surge until the system latency drops below 100 ms. As can be seen, Mecas is the first one to get back to the previous processing rate, while it takes Native Flink and Order-Unaware much more time to consume the queuing data and recover because of the block of operator execution.

We then compare the system throughput within 2 min-

Figure 15: Rescaling performance under backpressure

Figure 16: Latency comparison with Native Flink

utes after triggering the rescaling operation, as shown in Figure 15(b). As Native Flink first triggers a global state snapshot and then restarts the job, its throughput immediately decreases to 0 and gradually increases after it restarts. As for Mecas and Order-Unaware, they both keep the throughput at a non-zero level, but as Order-Unaware incurs long-duration blocking periods, it first goes through a decrease in throughput. Meanwhile, as Mecas brings little degradation to the performance during the state migration, its throughput reaches the maximum much faster and higher than the others. This validates that the fetch-on-demand state migration mechanism of Mecas outperforms the other approaches under backpressure.

5.5 Overhead Analysis

This subsection discusses the overhead introduced by Mecas.

Latency Overhead: The latency performance is illustrated in Figure 16. On one hand, Mecas does not incur extra latency when not migrating states, as reported in the "Mecas (Normal)" bar. Under normal circumstances, the processing logic of Mecas and Native Flink is substantially the same. The only difference is that Native Flink uses a normal HashMap to manage operator states, while Mecas uses a nested HashMap with little overhead. Consequently, the difference in latency between the two SPEs is determined by system noise. This conclusion can also be drawn from Figure 9~12.

On the other hand, the processing latency increases when Mecas is performing a rescaling operation. In this experiment, each route table contains 128 keys and increases the latency by 35%. During these periods, when deciding which downstream operator to send records to, the simple modulo operation is replaced by a more costly map query operation. In Mecas, this mechanism is combined with the nested data structure, to reduce the migration granularity to an acceptable level without the need for an extremely high number of key groups. That means the route tables are kept in a reasonably small size, thus reducing the latency peak with negligible overhead.

Figure 17: Memory consumption of Mecos

Memory Overhead: Figure 17 demonstrates the memory consumption of one single machine. To clearly show the changes in memory usage, we configure the JVM to utilize `g1gc` as the garbage collector and do not trigger GC behavior for objects in old generation. The memory usage fluctuates up and down because JVM periodically reclaims the temporary objects in the continuously arriving data stream. In the meantime, the total memory usage shows an upward trend due to the gradual increase in the operator states.

When the state migration starts at 600 s, the curve rises rapidly, because the operator starts fetching states from others, allocating lots of new objects quickly. This can potentially decrease the processing performance if the system is implemented in programming languages like Java, as the garbage collector works under heavy pressure and can block the execution of user functions. To ensure the quick response of the system, we recommend a low-latency collector like ZGC [63], or a pre-allocated object pool to be utilized to reduce the overhead of Garbage Collection behavior.

5.6 Comparison with Other State Migration Approaches

In this subsection, we compare Mecos with two representative state-of-the-art work Rhino [43] and Megaphone [26]. We choose the key-count job due to its simplicity so that we can minimize interference from associated computation and highlight the differences between rescaling approaches.

5.6.1 Comparison with Rhino

Rhino [43] proposes a state management approach which handles large states very well by periodically replicating operator states among all worker machines. Because the source code of Rhino from the original authors is not publicly available, we implement the mechanism of Rhino based on Flink for a fair comparison. During a stateful rescaling, Rhino generally follows the Partial-Pause approach, but only reads/writes the incremental parts of states since the last global replication. The replication interval is set to 60 seconds.

As in Figure 18, Rhino on Flink shows a similar latency peak to Order-Unaware, whose peak is near 10,000 ms. As a comparison, the per-record latency of Mecos never reaches 1000 ms during the whole process. Rhino’s replication fails to improve the system performance for two reasons:

Figure 18: Latency comparison with Rhino during rescaling

Figure 19: Network overhead of Rhino

1. In such a scale-out scenario where new workers join the job, a global state migration is still necessary for these new workers because they lack the previous states.
2. Such read-modify-write jobs update the operator states very frequently. As lots of states are modified between two state replications, the incremental parts still occupy large proportions of the global state.

Eventually Rhino degrades to the Partial-Pause approach with latency spikes. In contrast, Mecos uses a fetch-on-demand state accessing model for efficient state sharing among operator instances and less processing latency.

In addition, we compare Rhino and Mecos in terms of the disruption to non-rescaling stream processing, by measuring the extra network bandwidth introduced by both systems compared to Native Flink. In Rhino, when replication interval decreases from 10 minutes to 1 minute, the extra network bandwidth ratio grows from 35% to 56% (Figure 19). This is consistent with the conclusion reported in the Rhino paper [43], where Rhino uses 30% network bandwidth during a replication. As Rhino periodically replicates operator states among all workers, it helps fault-tolerance in the face of very large states, but incurs extra communication across the network even if the system performs no state migration at all. In contrast, Mecos incurs no network overhead to non-rescaling stream processing, because it performs no additional operations during non-rescaling periods.

5.6.2 Comparison with Megaphone

Megaphone [26] is a state migration approach that splits the state load into batches and embeds the migration flows into data flows for lower latency. It relies on two specific SPE features [26]: (1) state extraction from upstream operators (2) dataflow frontiers. However, both are still not natively supported in many widely-used SPEs, including Flink [16], Heron [33], Spark Streaming [53], Samza [50], etc. Therefore, to run Megaphone in a widely-used SPE, we meet the above requirements of Megaphone in Flink with naive implementations for state extraction and splitting the data stream

Figure 20: Latency comparison with Megaphone

into micro batches underhook. Based on that, we implement Megaphone’s state migration mechanism on Flink.

We then run the key-count job in both Mecas and Megaphone with 10^8 unique keys. Megaphone is configured to use 2^{14} bins, according to the original suggestions [26]. The latency comparison is demonstrated in Figure 20.

When not rescaling, Megaphone on Flink shows an order of magnitude higher latency than Mecas. There are two reasons for this phenomenon: (1) Megaphone’s strong pre-requisite of SPE features calls for extra synchronization and communication techniques to fulfill the requirements, thus bringing dramatic overhead to the system performance [43]. (2) To prepare for state migration, Megaphone splits the original operators into two operators before the streaming job is submitted. However, this incurs extra partition overhead between the two new operators, resulting in increased processing latency for the regular execution of the job. As for Mecas, it can work without expensive system requirements or logic modification to a non-rescaling SPE, and thus brings no overhead when the system is not rescaling.

During rescaling, both systems show a limited amount of latency increase. However, the latency of Megaphone stays at the level of around 8000 ms, while Mecas never reaches the bar of 1000 ms. This verifies that compared with Megaphone, Mecas’s prioritized state migration can efficiently reduce the processing latency during rescaling with low overhead.

6 Related Work

Stateful stream processing has been an active research field in the past years, both in single-machine [1, 9, 44] and distributed settings [3, 8, 16, 50, 53, 62]. To meet diversified requirements of real-time computing in different scenarios, research works focus on various aspects of stream processing, including performance [32, 36, 37, 58, 59], reliability [45, 64], scalability [14, 15, 56], flexibility [23], programmability [5, 40], etc. In addition, some researchers propose SPEs with enriched semantics [38, 42, 57, 65, 66] to support more sophisticated analysis of streaming data.

Elasticity in batch processing systems has also been studied [34, 35], but they mainly deal with scenarios with rather higher processing latency. As for the field of elastic stream processing, the past decade also witnessed many advances [14–16, 25, 26, 33, 40, 43, 47, 52, 53, 61].

The most recent works related to ours are Megaphone [26] and Rhino [43]. Megaphone [26] provides efficient on-the-fly

state migration for SPEs. This is achieved by transferring the operator states in a small granularity upon dataflow reconfiguration. It also supports trading off low latency against high throughput of state migration. Rhino [43] periodically replicates operator states among all worker machines. It can speed up the process of state migration by asking the operator instances to read/write from an incremental checkpoint instead of a global state snapshot. They both reduce processing latency during state migration at the expense of SPE performance during non-rescaling periods, as neither of them considers the migration order of states. In contrast, Mecas uses a fetch-on-demand state accessing mechanism to enable prioritized state migration during rescaling, without extra resource usage in non-rescaling periods.

Another critical issue about the elasticity of stream processing is to decide when and how to rescale. Many SPE controllers [4, 19, 20, 28, 31, 39, 41, 54] have been proposed for adaptive rescaling to meet the QoS targets in various scenarios. These works are orthogonal to ours and can be combined with Mecas’s on-the-fly rescaling mechanism to provide self-regulating streaming systems.

7 Conclusion

This paper presents Mecas, a latency-efficient on-the-fly rescaling mechanism using prioritized state migration for stateful distributed SPEs. Mecas uses a fetch-on-demand model with hierarchical state data structure and gradual strategy, to achieve prioritized state migration with global consistency and high efficiency. This design puts all the operations in rescaling periods and requires no work during non-rescaling periods. We implement Mecas in Apache Flink and evaluate our design on diversified workloads. The experimental results show that compared to state-of-the-art approaches, Mecas improves the latency and throughput performance during rescaling by orders of magnitude without disrupting non-rescaling periods or using huge amounts of resources.

In the future, we plan to integrate Mecas with stream performance monitoring tools and further study more adaptive rescaling policies for diversified scenarios on Mecas.

A Artifact Appendix

Abstract

Meces is implemented on Apache Flink. It also relies on Kafka and Redis to function properly. We prepare the programs, assemble a workflow of Meces and package the artifact into a Docker image.

Scope

The artifact rescales a key-count job with different state migration mechanisms. It verifies the basic functions of Meces and validates the performance improvement brought by the prioritized state migration strategy proposed in this paper.

Contents

The artifact includes a compiled version of Meces, along with dependencies such as Kafka, Redis, Java and Python, etc. A "README.md" file can be also found in the image. It contains detailed description of the artifact and a step-by-step instruction for the rescaling workflow.

Hosting

The artifact is hosted on Docker Hub. It can be installed by downloading the pre-built Docker image from the public dockerhub repository and initiating a container from it:

- `docker pull njupalab/meces:latest`
- `docker run -it njupalab/meces:latest`

Artifact Check-list:

- Run-time Environment: Linux OS with Docker installed.
- Experiments: Workflow of rescaling a key-count job.
- Expected Experiment Running Time: About half an hour.
- Output: Data plots of latency comparison.

Expected Running Result

There are scripts that help pre-check the testing environment:

- `source scripts/install.sh`
- `scripts/start_background_environment.sh`
- `scripts/check_environment.sh`

Then, an experiment script evaluates the rescaling performance of Meces using the key-count job on your environment:

- `scripts/rescale_exp.sh`

It generally goes through three stages in series, namely *Meces*, *Order-Unaware*, *Native-Flink*. In each stage, the system submits the key-count job, runs for a while and then rescales the operator with its corresponding mechanism. For further details, please refer to "README.md" in the artifact.

After the process finishes, the experimental data is collected in the *data* folder. Each experiment should generate a plot of the latency curve, similar to what is reported in Section 5.2.

B Appendix: Latency Performance Evaluation on full NEXMark suite during Rescaling

We evaluate the latency performance of the SPEs during rescaling. The SPEs are initially configured with global operator parallelism of 25. Then, each job runs at a steady input rate of 800K records/s for 600 seconds. After that a rescaling operation is triggered. It increases the parallelism of critical operators (e.g., join or window operators in NEXMark queries, counting operator in the key-count job) to 30. This causes 115 out of 128 key-groups to be relocated during the scale-out.

Figure 21~28 illustrate the end-to-end latency change of each query in this process. We compare Mecas with Native Flink (stopping the whole job when rescaling) and Order-Unaware (online block-based state migration without order prioritization).

NEXMark Q1 and Q2 do currency conversion or filtering operations on a bid stream. These simple transformation tasks do not maintain states and the behavior is demonstrated as a basic case for our evaluation. As shown in Figure 21 and 22, both Mecas and Order-Unaware reveal no latency peak but only system noise, because they incur no state migration cost during rescaling and operations can be done asynchronously. In contrast, Native Flink still needs to stop and restart the job even if there is no state to migrate.

Figure 21: End-to-end latency of NEXMark Q1

Figure 22: End-to-end latency of NEXMark Q2

NEXMark Q3 and Q4 test join functionality. Q3 joins the stream of open auctions and the stream of people to local item suggestions for users. Q4 joins the stream of closed auctions and the stream of items to output the average deal price of items for a category. Both queries have to store information of records in the data stream as states of join operators. The per-record latency is demonstrated in Figure 23 and Figure 24. In our settings, Q3 maintains a rather small size of states. Meanwhile, operator states in Q4 grow large when millions of items have been sold. As a result, for Native Flink and

Order-Unaware, a sharp and short-lasting rise of latency can be seen in Figure 23, because the task executions are globally or partially blocked until the state migration is completely done. As a comparison, there is no obvious latency change in Mecas as it reduces the disturbance caused by state migration to a lower granularity. A similar conclusion can also be drawn from the results in Figure 24 for Q4. The degradation of real-time performance becomes more significant for Native Flink and Order-Unaware with a larger size of states, while Mecas only incurs a small range of latency fluctuations. The latency peak of Mecas is an order of magnitude smaller than the other two mechanisms, due to its fetch-on-demand accessing and gradual migration strategy.

Figure 23: End-to-end latency of NEXMark Q3

Figure 24: End-to-end latency of NEXMark Q4

NEXMark Q5 tests window operator with small states. It repeatedly selects the hottest item in the past period of time, which is the item with the most number of bids. The stateful operator maintains item counts in each time window. In our experiments, the job reports every second the hottest item over the last 60 seconds. As this query does not accumulate large states, it exposes similar behavior with Q1 and Q2, as shown in Figure 25. While the latency of Native Flink increases significantly due to a full restart, the record processing of Mecas and Order-Unaware is hardly affected because the state migration cost is minor.

Figure 25: End-to-end latency of NEXMark Q5

NEXMark Q6, Q7 and Q8 test window operator with bigger states. Q6 includes a sliding window over a single

stream to calculate the average of items recently sold by a seller. Q7 and Q8 perform tumbling window join of two streams, to find out the items with the highest price and the new users who just registered in the last period of time. These queries maintain large states when the window size grows. We set the window sizes to be 10 seconds, 10 seconds, and 100 seconds for the three queries respectively. The performance comparison is illustrated in Figure 26~28, where the latency peak of Mecas during rescaling is an order of magnitude smaller than the others. When the rescaling begins, Order-Unaware needs to block the currently processed records while migrating a considerable amount of states. As a result, Order-Unaware goes through a performance degradation near to Native Flink (Full-Restart), and reaches a latency peak of dozens of seconds. For comparison, Mecas can give priority to the hot keys being processed and smoothen the latency peaks.

Figure 26: End-to-end latency of NEXMark Q6

Figure 27: End-to-end latency of NEXMark Q7

Figure 28: End-to-end latency of NEXMark Q8

In conclusion, Mecas achieves better performance than existing approaches during rescaling. Native Flink and SPEs with Order-Unaware can suddenly become out-of-service when migrating states, while Mecas relieves the impact of rescaling to a lower granularity and reduces the maximum latency.

DepFast: Orchestrating Code of Quorum Systems

Xuhao Luo[†], Weihai Shen[‡], Shuai Mu[‡], Tianyin Xu[†]

[†]University of Illinois at Urbana-Champaign [‡]Stony Brook University

Abstract

Quorum systems (e.g., replicated state machines) are critical distributed systems. Building correct, high-performance quorum systems is known to be hard. A major reason is that the protocols in quorum systems lead to non-deterministic state changes and complex branching conditions based on different events (e.g., timeouts). Traditionally, these systems are built with an asynchronous coding style with event-driven callbacks, but often lead to “callback hell” that makes code hard to follow and maintain. Converting to synchronous coding styles (e.g., using coroutines) is challenging because of the complex branching conditions. In this paper, we present Dependably Fast (DepFast), an effective, expressive framework for developing quorum systems. DepFast provides a unique `QuorumEvent` abstraction to enable building quorum systems in a synchronous style. It also supports composition of multiple events, e.g., timeouts, different quorums. To evaluate DepFast, we use it to implement two quorum systems, Raft and Copilot. We show that complex quorum systems implemented by DepFast are easy to write and have high performance. Specifically, it takes 25%–35% fewer lines of code to implement Raft and Copilot using DepFast, and the DepFast-based implementations have comparable performance with the state-of-the-art systems.

1 Introduction

Quorum systems are critical distributed systems. In a quorum system, a node sends a request to a group of nodes, and proceeds on receiving a quorum of acknowledgements. The quorum size depends on the system design; it usually varies between a majority, a super-majority, or the whole group. The most common quorum systems are replicated state machines—a linearizable and fault-tolerant group of distributed nodes coordinating through a consensus protocol such as Paxos [39] and Raft [48]. Such quorum systems are widely deployed in practice, especially as critical infrastructures of large-scale cloud and Internet services [17, 20, 23, 34, 60].

Building a quorum system is hard. Quorum systems often have a complex consensus protocol. A node in these protocols have a complex state space. An event, e.g., a reply to a message, or a timeout, will trigger a state transition of the node. At each state, the node has multiple possible branches to go into based on the event and its current state. Though the state transition itself could be deterministic, the entire node behav-

ior is not. This is mainly because of: 1) non-determinism in some event types, e.g., timeout, 2) the inter- and intra-node parallelism, and 3) network asynchrony, e.g., message delays and out-of-order delivery.

The traditional way to code these complex state transition conditions is through an event-driven or asynchronous coding style. For each event, the developer defines an event handler, or a callback function, to drive the program to the next state. On the one hand, writing code in this style could have its benefits, mainly two-folded: 1) it could match the style of a more formal description, e.g., a TLA+ [38] specification; 2) it could have a high performance as even-driven programming is often considered to be fast in concurrent programs.

On the other hand, coding in an asynchronous style has drawbacks, mainly making the code harder to write and follow, more error-prone, and harder to debug. Since the main workflow of handling a request from begin to end is expressed in many (callback) functions as opposed to a single function, the developer needs to manually maintain the shared control, data, and debug variables across these functions. The developer also needs to manually map each function execution properly to the request’s lifetime, for example, dropping a reply if the system has moved with a quorum without the reply. Overall, this asynchronous code style could increase difficulty to develop and maintain the system. This problem is also known as stack ripping [15] or callback hell [28]).

A natural way of resolve the above issue is turning the asynchronous code into synchronous style, using lightweight solutions like coroutines. This is a well studied idea in systems research [15, 37, 52] and has been adopted widely in practice [13, 14]. However, the past study of using coroutines to inline callbacks mainly considers supporting a single asynchronous call [15, 52], e.g., inlining a single RPC callback. This is insufficient for a quorum system, which often has many concurrent callbacks and timeouts, and branches based on these concurrent event composition. Take the following behavior of a classic consensus system for example, a node sends requests to a group, then it needs to proceed to different branches based on the replies when it receives 1) a majority of acknowledgements, 2) a majority of rejects, 3) a majority of replies, mixed acknowledgements and rejects, and 4) fewer than a majority of replies. Each of these conditions have their own timeouts, and the program can only enter one branch. It is prohibitively difficult to express these conditions with a single coroutine. To make matters worse, the behavior could be even more complex with advanced protocols which have

multiple quorum sizes. For example, in fast-path enabled protocols such as Copilot [47], a super-majority quorum and a majority quorum apply at the same step in the protocol, which further complicates the situation.

In this paper, we present DepFast (Dependably Fast), a coroutine-based distributed programming framework to address the aforementioned challenges. Like prior works [15, 52], DepFast promotes synchronous code style with cooperative task scheduling and provides an Event abstraction to wrap the waiting points. The unique part of DepFast is that it provides a QuorumEvent abstraction that enables the construction of straightforward protocol descriptions, even for quorum systems with complicated timeout rules and multiple quorums (which was previously only expressible in bug-prone callback style). A QuorumEvent represents the system state of a quorum and any event that affects the state (e.g., arrival of a reply, a timeout) is funneled through the QuorumEvent. The program thus can synchronously express the conditions and branches using the QuorumEvent in a plain if-else style. Furthermore, the events are composable in DepFast, making it easier to deal with cases such as waiting for multiple quorums of different sizes at the same step.

Using DepFast to build quorum systems, the main control flow of the protocol can be written in a single function with an unripped stack. The code written in this style is easy to follow and to debug. As a case study, and as a motivation, we studied the fail-slow behavior of quorum systems, where a node in the system can be much slower than a non-faulty node but still functioning [55]. Debugging fail-slow behavior requires carefully identifying the line of code to add log statements for tracing the lifetime of a request. Writing code in the DepFast style simplifies debugging.

To evaluate DepFast, we use DepFast to implement two quorum systems based on Raft [48] and Copilot [47] respectively. We report our programming experience with DepFast. We demonstrate examples illustrating that DepFast leads to better implementations compared to the common practice of asynchronous, callback-style code; in particular, DepFast enables direct translation of the protocol algorithms and allows precise expressions of complex wait conditions, resulting in 25–35% fewer lines of code. We evaluate the performance of DepFast-based Raft and Copilot implementations against state-of-the-art versions to show our approach imposes no performance penalty. Moreover, the DepFast-based implementations have better tolerance against various types of fail-slow faults by construction, than the state-of-the-art versions.

The paper makes the following contributions:

- We design QuorumEvent to enable the construction of protocol descriptions even for quorum systems with complicated timeout rules and multiple quorum sizes.
- We develop DepFast, an effective, expressive framework that enables developers to implement complex quorum systems with a synchronous programming style.

- We show how DepFast benefits the implementation of quorum systems by illustrating DepFast-based Raft and Copilot implementations compared to state-of-the-art versions.
- We evaluate the performance of DepFast-based Raft and Copilot and show that the DepFast design for the ease of programming does not come with a performance penalty.

2 Background and Motivation

2.1 Quorum systems and async. programming

This paper uses quorum systems to refer to distributed systems with a communication pattern that requires replies from a quorum in a group of nodes. One typical type of quorum systems is a replicated state machine which uses consensus protocols (e.g., Paxos [39] and Raft [48]) to let nodes agree on the next state transition.

Consensus protocols are known to be hard to implement. Take the following behavior in Paxos and Raft for example, a node broadcasts a replication request (Accept in Paxos, or AppendEntries in Raft) to a group; then the node needs to react to events including replies and timeout. A reply can be either an acknowledgement or a reject. Based on different events, this node needs to enter different branches when it receives: 1) a majority of acknowledgements before the timeout, 2) a majority of rejects before the timeout, 3) a majority of replies, mixed acknowledgements and rejects at the timeout, and 4) fewer than a majority of replies at the timeout. After the node chooses a branch, any future event needs to be dropped. The inter- and intra-node concurrency and the non-deterministic event triggering lead to a very complex program state space.

Many formal and informal protocol descriptions of quorum systems are written in an *asynchronous* style: “upon receiving a (reply to a) message, the system acts as follows.” It is intuitive to construct the code in the same way (e.g., writing a message handler in the message loop, a callback in event-driven model, or an actor in the actor model to process a particular message). Coding in the asynchronous style has the benefit of matching a formal description of the protocol (e.g., a TLA+ [38] specification). However, it could cause the control flow to be shredded into many sub-functions like callbacks. This leads to spaghetti code, also known as stack ripping [15] or callback hell [28]. Take a Paxos system for example. For each request that goes through the 3 phases (Prepare/Accept/Commit), the main control flow will at least be shredded into 3 types of callbacks. If this is a 5-replica system, the callbacks will be executed 3×5 times. If we further count callbacks caused by disk logging (asynchronous I/O), there will be even more (at least doubled) callbacks.

It does not take long before a developer loses track of how callbacks affect each other. It also imposes significant challenges to manage the waiting process, especially in cases where the callbacks are written by different developers (which is often the case in practice). A natural way to address this

problem is to turn the code to a synchronous style by inlining the callback into the calling function. This could greatly improve understandability and maintainability. In fact, some papers describe the main control flow in this style. For example, in the Paxos paper [39], after a proposer sends out the proposal, “*if the proposer receives a response from a majority of acceptors...*” In practice, many projects started with the asynchronous callback style, but the growing size of codebase and the accompanying cognitive load of callbacks made the developers change to a synchronous code style [15, 18].

In the past, asynchronous versus synchronous programming styles (or event versus thread) have drawn many discussions [15, 19, 25, 26, 37, 44, 49]. The asynchronous or event-driven style is often preferred for performance reasons. For example, it can avoid the overhead of many OS threads, and the `epoll/kqueue` model of processing network interrupts can efficiently utilize the interrupt-based OSes and devices. Past works have proposed solutions to turn asynchronous code into synchronous and preserve its high performance, e.g., by using lightweight threads like stackful coroutines [15, 52]. However, existing solutions mainly consider inlining a single callback like a single RPC. It does not address the challenges of implementing quorum systems, where a broadcast request triggers a group of callbacks, and the system needs to proceed with a quorum.

2.2 Experience in debugging fail-slow behavior

We recently studied fail-slow behavior of real-world quorum systems [55]. Our journey started from observing that quorum systems of product-grade databases cannot meet fault-tolerance properties of the consensus protocols—a fail-slow follower affects system-wide performance. Such behavior contradicts the theory—a quorum system should proceed when there is a majority of non-faulty nodes. Specifically, a fail-slow follower should not have visible impact by design.

To reveal the root causes of the fail-slow behavior, we spent two person-years to analyze the three implementations. In our experience, debugging fail-slow fault tolerance is challenging and time-consuming. At a high level, the debugging process is a binary search for small fragments of code that caused the slowness using time stamping. The process sounds easy (as we imagined it to be), but is painful in practice. The asynchronous code often looks like spaghetti: the main control of a request is spread in different code fragments. Understanding where those code fragments are located and how they interact is non-trivial. In fact, working with developers of two of the databases, we find that even they have the same experience.

We also find that asynchronous code often lacks a clear abstraction between the quorum logic (e.g., the Raft protocol) and common, low-level utilities (e.g., RPC, disk I/O) in the spoken implementations. In addition to the challenge of expressing complex state transitions, lacking a clear abstraction has two more problems in implementation.

First, when a buggy fail-slow behavior occurs, it is hard to know whether the bug is caused by the protocol code or the utility code. A bug in the utility code is typically easier to identify and fix than a logic bug. It would be very helpful if the code can be constructed in a way that the logic code and utility code are isolated and separately profiled for debugging.

Second, a lack of abstractions also indicates lacking knowledge across the two parts. The utility code has to blindly execute the requests passed by the logic code and cannot perform optimizations to tolerate fail-slow behavior, but push the burden back to protocol logic. For example, the Raft logic broadcasts `AppendEntries` to all replicas and waits for a quorum of replies to proceed. In many existing implementations, the Raft logic sends the same message to each replica and the utility faithfully puts the message to the buffer of each replica. If one replica is slow, the connection would be slow and the buffer would keep increasing, leading to the backlog issue reported by recent work [27, 29]. If the utility is aware that this is a broadcast that can succeed with a quorum of replies, it can safely discard the messages for the slow connection.

2.3 Goal

Our experience in building and investigating complex quorum systems has driven us to rethink the programming practice and seek a more foundational solution that can make it easier to build and maintain quorum systems. We propose a synchronous programming framework for this purpose. In particular, we will propose abstractions that allow developers to implement complex quorum state transitions that can only be implemented with an asynchronous programming style before. We will show by our experiences that this framework can help programmers efficiently express complex quorum conditions in a way that is easy to follow and maintain.

3 The DepFast Framework

This section introduces the Dependably Fast (DepFast) framework. DepFast aims to provide an effective, expressive programming framework for building quorum systems. We first go through the interface of DepFast (§3.1), including an important abstraction we propose for quorum systems (§3.1.2). Then we go into internals of the framework, describing how it is implemented (§3.2).

3.1 DepFast from a programmer’s perspective

3.1.1 Coroutines and events

DepFast provides programmers with two main interfaces:

- a coroutine interface for launching tasks,
- an event interface which wraps the waiting points, or any potential fail-slow points, in the code.

The idea of using coroutine is to keep the code in one piece—avoiding callbacks, while maintaining the performance when dealing with an operation that needs to wait. For example, the code snippet below is triggering an RPC with a callback. Traditionally, it is considered the high-performance way of writing concurrent programs as it avoids the cost of creating and switching between threads. On the other hand, it comes with the cost of breaking the control flow, leading to many side effects besides increasing code complexity. For one, the programmer needs to manually maintain a shared stack from callbacks to callbacks, which is also known as *stack ripping* [15]. For a quorum-based system, the case could be more complex. For example, a reply is not always “valid”; an outdated reply needs to be ignored. The programmer needs to manually manage those, as exemplified in the code below:

```
void DoAppendEntries() {
    for (auto rpc_proxy : servers) {
        auto entries = ...;
        // the next line bears possible slowness
        auto rpc_event = rpc_proxy.AppendEntries(entries,
            AppendEntriesCallback);
    }
}
void AppendEntriesCallback(Id id, Result result) {
    // manually manage shared data
    auto reply_ok_cnt = reply_map_g[id];
    // manually manage lifetime
    auto status_ = status_map_g[id];
    if (status_ == undecided) {
        ... // only process when the log is still alive
    } // else ignore
}
```

Using coroutine, the above code can be expressed as:

```
Coroutine::Create([] () {
    vector<RpcEvent> events;
    for (auto rpc_proxy : servers) {
        auto entries = ...;
        // the rpc call is asynchronous and non-blocking
        auto rpc_event = rpc_proxy.AppendEntries(entries);
    }
    for (auto& rpc_event: events) {
        // block coroutine until the rpc returns
        rpc_event.Wait(); // possible slowness
        Process(rpc_event.Result());
    }
})
```

In the above code, what was split in callbacks is glued together in a single function, where the programmer can continue using the stack to share system states with a unified control flow. The code using coroutine can provide similar performance to the code with callbacks, because coroutines do not incur the heavy overhead of OS threads [15].

Note that the above code uses `RpcEvent::Wait()` on this object would suspend the current coroutine until the RPC has the return value ready. DepFast uses such event abstraction to wrap all the waiting conditions. With the events, a programmer can suspend/resume the coroutines. DepFast implements many built-in event types to support various operations (RPC, file I/O, etc.). With all waiting points moderated by the framework, DepFast naturally empowers more analysis (§A.2). DepFast also provides novel event types to better deal with distributed, quorum-based systems. We next introduce an important event in DepFast, `QuorumEvent`.

3.1.2 QuorumEvent

The coroutine-style code above is less efficient than the callback-style code. The coroutine-style code waits for the reply from each server sequentially with a fixed order, while in the callback-style code the callback for each server’s response can be triggered out of order. This gives the callback-style code a major benefit in performance, because it only needs to wait for the first quorum of messages to arrive. In particular, it is not affected by a fail-slow remote server. On the contrary, the coroutine-style code will be slower in performance and be affected by a fail-slow server.

To address this issue, DepFast has a special event type, termed `QuorumEvent`. The key idea is to prevent any individual fail-slow event from straggling a coroutine by combining many events together into a compound event. As the name suggests, `QuorumEvent` does not need all responses from each individual event. The usage of a `QuorumEvent` is demonstrated by the following example.

```
Coroutine::Create([] () {
    auto quorum_event = QuorumEvent();
    for (auto rpc_proxy : servers) {
        auto entries = ...;
        auto rpc_event = rpc_proxy.AppendEntries(entries);
        quorum_event.add(rpc_event);
        // no longer wait for any single event
    }
    quorum_event.Wait(MAJORITY); // wait for a majority
    ...
    // after 10s, release resources to avoid backlog
    quorum_event.Release(10000 /*ms*/);
})
```

Using the above `QuorumEvent` has two benefits. First, the replies can be received out of order and the program can proceed as soon as receiving a majority of replies. Second, the abstraction helps programmers avoid writing any code that would be blocked by any single-point fail-slow remote server. A key idea that DepFast deploys to help avoid fail-slow fault propagation is to encourage programmers to not wait on any event individually but always wait on a quorum of events when possible.

`QuorumEvent` also provides a better abstraction for resource management to help avoid the backlog issue constantly observed with fail-slow faults [27, 29]. In the code snippet above, calling `Release()` will tell DepFast to release all resources related to this event after a timeout. This is particular useful for a quorum system. It gives a deferment period for the slower response to arrive, after which the system will forcibly free all the resources related, e.g., the buffer in the RPC. Allowing a deferment period is very useful in implementing many protocols, because they often need to distinguish between the two cases: 1) the response is only a bit slow, or not at all slow but just ordered after other responses, but the host can still react to those responses which benefits the system liveness 2) the response is too slow, and the receiver should react differently (e.g., a failure recovery).

To see why using `QuorumEvent` is a better approach for resource management, consider the following alternative:

```

// Create a separate coroutine for each RPC
for (auto rpc_proxy : servers) {
    Coroutine::Create([]() {
        auto entries = ...;
        auto rpc_event = rpc_proxy.AppendEntries(entries);
        rpc_event.Wait();
        Process(rpc_event.Result());
    })
}

```

This alternative approach is both synchronous in programming style and avoids sequentially waiting on each RPC call. Actually, such a-coroutine-per-task approach is very popular in modern practices, especially in writing services with Go-lang [22]. However, in our experience this may cause problems under fail-slow behavior. If the target of the RPC is slow and cannot respond in time, the coroutine will hang in the system, waiting for the response. With new requests coming in, the hanging coroutines will accumulate, eventually exhausting system resources, as each coroutine consumes at least a memory space for its stack.

3.1.3 Other event types

In general, DepFast provides two types of events: basic events and compound events. Basic events are waiting on a task to finish, such as an RPC, a disk access, or a flag to be set, etc. A compound event is a combination of basic or other compound events. Table 1 summarizes common event types in DepFast and their trigger conditions.

Basic events. One common basic event is `ValueEvent`. This is a holder for a value to be set. If the value is set to match the target value, the event will be triggered. We find this event abstraction very useful because we often find statements in algorithms written like “wait for X to become Y.” For example, in Copilot [47], to decide the execution order of a command, the system needs to wait until the status of a selected group of commands to become “committed”. Traditionally, this could be hard to implement as it would involve complex callbacks or thread synchronization. With DepFast, statements of this type can be directly translated to one line of code.

Another basic event type is `IOEvent`. We use it to wrap all synchronous I/O operations, mainly disk-related operations. An `IOEvent` corresponds to a task executed in an I/O thread. For example, the program initiates a disk write through DepFast’s interface, the actual disk operations involving `fwrite` and `fsync` will be executed in the I/O thread. The program then waits on a `DiskEvent` returned by DepFast. When the disk operation finishes, the I/O thread will notify the scheduler that the event is ready. The synchronization between I/O threads and scheduler is the only part in a DepFast program that has multi-thread synchronization. We believe that this small footprint of multi-thread synchronization can minimize the possible fail-slow issues caused by multi-threading.

Compound events. For compound events, an example is `QuorumEvent` (§3.1.2). It takes many events (e.g., `RPcEvent`) as its subevents, and wait for at least a defined quorum of

Event	Trigger Condition
<code>ValueEvent</code>	If the value is set and matches the target (it supports customized comparators).
<code>DiskEvent</code>	If the disk access operation (e.g., <code>fread</code> , <code>fwrite</code> , and <code>fsync</code>) is finished.
<code>RPcEvent</code>	If the RPC call has returned.
<code>QuorumEvent</code>	If a quorum has reached (typically used together with <code>RPcEvent</code>).
<code>AndEvent</code>	If all subevents have been triggered.
<code>OrEvent</code>	If any subevent is triggered.

Table 1: The built-in events in DepFast

them to be triggered. Other compound events in DepFast includes `AndEvent` and `OrEvent`. As the name suggests, an `AndEvent` is triggered when all of its subevents are triggered; an `OrEvent` is triggered as soon as one of its subevents is triggered. Note that events can be nested: for instance, an `AndEvent` can contain many `QuorumEvents` as its subevents.

Nesting events can express complex waiting conditions. For example, one can use an `OrEvent` to combine these 3 events: 1) a `QuorumEvent` that waits for a majority of okays. 2) A `QuorumEvent` that waits for a minority-plus-one rejects. 3) A `TimeoutEvent`. This compound event can be used to effectively catch conditions in classic consensus protocols. In fact, as we find that the abstraction is very commonly used, we have merged these three conditions into `QuorumEvent` so it has three outcomes: `Ready()`, `Fail()`, `Timeout()`,

3.1.4 A showcase of DepFast’s expressiveness

DepFast can effectively express many complex behaviors of quorum systems, organize the main control flow in a clean way, and process the complex state transitions automatically in the background. We demonstrate the expressiveness of DepFast using the code snippet of our Copilot implementation built with DepFast in Figure 1. Copilot is one of the protocols that leverages a “fast-path quorum” [40, 45, 57]. In these protocols, after broadcasting a round of (`FastAccept`) messages, there are at least three concurrent conditions to decide how the system proceeds: 1) to a fast path if receiving a super-majority of acknowledgments with identical speculative information, 2) to a slow path if receiving a majority of acknowledgments, and 3) to failure recovery if neither the above is possible (e.g., when receiving a majority of rejects, or not enough messages after a timeout). Figures 1(a) and (b) show the code and control flow chart of Copilot built on top of DepFast. As demonstrated, the code implements the protocol in a clean manner. What DepFast handles in the background is shown in Figure 1(c). Upon every event (message arrival and timeout), DepFast processes the subtle state transitions and drives the main control flow forward to the proper next state. Without DepFast, one needs to carefully implement all state transitions and error handling manually, a complex and error-prone process. With DepFast, one can build the system cleanly, with code easy to follow.

Figure 1: Expressiveness of DepFast demonstrated by DepFast-based Copilot implementation: (a) code, (b) control flow, and (c) events and state transitions. The code logic is explained in Figure 3.

3.2 DepFast internals

3.2.1 Architecture

Figure 2 shows the architecture of DepFast. A DepFast process has two major types of threads: worker threads and system threads. The former run user code and the latter run background activities.

All user-defined tasks run in worker threads as stackful coroutines; we use Boost::coroutine2 [13] as a building block. A worker thread runs an `epoll` [6] (or `kqueue` [10] for BSD-based systems) loop that wakes up on network interrupts or timeouts. The system has a built-in high-performance RPC module that uses the `epoll` for incoming and outgoing messages similar to other high-performance networking library like `libev` [11]. The RPC module provides automatic client code and server handler header generation from an RPC declaration file (like `gRPC` [9]). The RPC works asynchronously and provides synchronous event binding (`RpcEvent`).

Having the RPC working asynchronously allows us to avoid launching a separate coroutine for each RPC (§3.1.2). Take the `QuorumEvent` for example. The system only has one global `epoll` loop that receives replies for all RPCs. Once the system receives a reply, it is matched to the belonged `QuorumEvent`, and a counter is updated in that `QuorumEvent`. Once that counter reaches the quorum number, the `QuorumEvent` is ready, and then the system resumes the coroutine waiting on it. There is no coroutine creation during handing a message that might contribute to a quorum.

In the same worker thread runs the scheduler functions. The scheduler is in charge of managing user coroutines. All coroutine lifetime related functions, including coroutine creation, deletion, pause, and resume, are provided by the scheduler. The scheduler performs a check at each `epoll` wakeup. It checks whether the event a coroutine is waiting on is triggered

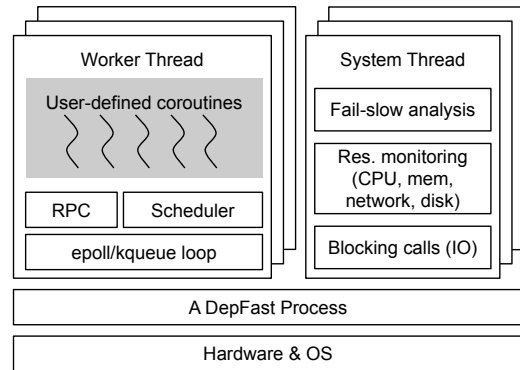

Figure 2: The architecture of DepFast

(or timed out), and then resume the paused coroutine.

While the worker threads handle most of the system functions on the critical path, the system threads deal with the additional features of the framework. Among these, a significant function is to support blocking calls. Examples include disk flush calls (`fsync`) and support for third-party libraries. DepFast supports these by wrapping them in system threads. Other features that run in system threads include the resources usage monitoring (CPU, memory, network, disk) and fail-slow analysis, which we will discuss later.

3.2.2 Lazy and cooperative scheduling

The base class of an `Event` is implemented as follows:

```
class Event {
    // timeout defines the maximum duration of waiting
    // on the event. -1 means waiting forever.
    void Wait(int timeout = -1) {
        if (IsReady()) return;
        if (timeout >= 0) {
            sched_s.sorted_timeouts.insert(now()+timeout);
        }
        // sched_s is a thread_local static variable
        sched_s.yield_current_coroutine(this);
    }
}
```

```

void Test() {
    if (IsReady()) {
        // the scheduler will put the suspended coroutine
        // back to the ready_coroutine queue.
        sched_s.notify_ready(this);
    }
}
// To implement by specific event type to define when
// this event is ready to resume suspended coroutine.
virtual bool IsReady();
}

```

The coroutine management operates in a lazy and cooperative approach. It does not preemptively suspend or resume a coroutine. When a coroutine is running, it fully occupies the worker thread. A key structure in the scheduler is a queue that records pending events and the corresponding suspended coroutines. When a coroutine runs, it may change the status of other events (e.g., changing the value of `ValueEvent`). When this happens, the scheduler will *not* yield the current running coroutine and switch to the resumable coroutine immediately, but mark the event ready and put it in a ready queue. Only when the running coroutine calls `Wait` on an event, the scheduler is triggered to do scheduling work.

The scheduler will first check if the event is ready (i.e., no wait is necessary). If so, the `Wait` call returns directly without yielding out the coroutine; the caller coroutine continues running. If not, the scheduler will put a reference of the event and the caller into a pending queue, and then looks for the next coroutine to run. The scheduler first checks the queue of ready events and resumes them one at a time. Note that the queue of ready events may grow during this process, as the resumed coroutine may turn more events ready. After the ready queue is empty, the scheduler searches the pending queue for events that are timed out, and resumes the suspended coroutines correspondingly. To make the search faster, the pending queue is sorted based on the timeout timestamps.

Reversed backlog. In our development of DepFast, we encountered an interesting issue termed “reversed backlog.” When a system has a slow node, RPCs to this slow node will be delayed. However, the delays are not necessarily uniform over time. The responses often arrive in a burst pattern—the RPC sender will not hear back from the slow node for a while, and then suddenly receive many responses from it. In our early implementation, the `epoll` loop would process everything available from a connection before moving on to the next. This caused the system to occasionally hang on processing the outdated RPC responses. To deal with this issue, the system is improved to process data from connections with a round-robin approach; it will pause processing a connection after reaching a threshold to avoid starving other connections.

3.2.3 Concurrency and multi-threading

Through the coroutine model, DepFast allows multi-task concurrency inside a single worker thread. Similar to many other asynchronous event or coroutine frameworks, DepFast encourages programmers to exploit concurrency in a single worker

thread before moving to multi-threading. The advantage of running tasks in a single thread is to avoid thread-safety issues. To DepFast, an extra benefit is to eliminate the possibility of fail-slow faults caused by thread locks, a known suspect of performance issues. In reality, running tasks concurrently with a single thread can give high enough performance in most cases, as shown in our evaluation (see §6.2 and §6.3).

Moving to multiple threads, to write thread-safe code the users need to either shard the system into different threads and regulate inter-thread communication, or write memory-sharing code and use mutexes for mutual exclusion. DepFast encourages the former as it minimizes the chances of performance issues caused by waiting on mutexes.

4 Discussion

We discuss the software engineering benefits of using DepFast to build quorum systems. We exemplify the challenges in implementing complex quorum conditions and discuss how DepFast can address the challenges. As an concrete example, the following code snippet processing a fast path is taken (and simplified) from the EPaxos implementation [3], a popular academic prototype of advanced consensus protocols.

```

func handlePreAcceptReply(reply) {
    inst := ... // find consensus instance
    ... // return if this is a delayed request
    if reply.OK {
        inst.preAcceptOKs++
    } else {
        inst.preAcceptRejects++
        if inst.preAcceptRejects >= r.N/2 {
            // TODO
        }
    }
    fastpathSatisfied = ... // test fastpath conditions
    if inst.preAcceptOKs >= N/2 && fastpathSatisfied {
        // proceed to fast path
    } else if inst.preAcceptOKs >= N/2 {
        // proceed to slow path
    }
    //TODO: take the slow path if msgs are slow to arrive
}

```

We can see two TODOs in the code. The first TODO is on counting rejects. If a node receives too many rejects to proceed, it should enter error handling to retry this request. In DepFast, this maps to the branch where `slowpath.Fail()` happens. The second TODO is when messages are slow to arrive, this case maps to DepFast’s branch where `fastpath.Timeout()` and/or `slowpath.Timeout()` happen.

Implementing the two TODOs would require heavy revisions on the code logic and change the control flow, as it cannot be done by naturally replacing the TODO comments with two function calls. In contrast, with DepFast, one can implement both TODOs in place. For the first TODO, a retry function can be synchronously called in the reject branch. For the second TODO, if messages are slow to arrive, a function calling the slow path can be put right in the timeout branch.

In fact, TODOs are not the only problem in the code. The fast-path condition is also simplified and suboptimal. The

condition is important, because it decides whether to enter a fast path or a slow path. In the code, once it sees a majority of OK replies, it makes the decision based on the current calculation of the conditions (`fastpathSatisfied`). However, this decision could be suboptimal, because the conditions could change if more replies arrive. As a consequence, a node loses the opportunity to enter a fast path if it waits a little longer, but directly enters the slow path. The simplification, despite being suboptimal, is understandable, because it is very hard to express the conditions accurately in the asynchronous code style. With DepFast, this can be expressed easily with the timeout scheme on a `QuorumEvent`.

Lastly, the conditions assume that the fast- and slow-path quorums have equal size, which indicates that it only works for at most 5 replicas. If the replication group size is bigger [4], the code needs heavy revisions. Simply replacing $N/2$ in the `if` branch with a larger super-majority value is incorrect: the code will always choose a slow path because the `else if` branch will always be taken.

Although this discussion is based on EPaxos, we find that the conditions are error-prone in other quorum system implementations, especially regarding timeout handling. For example, CockroachDB had a bug caused by having no timeout on lease acquisition [5], which may lead to system stalling. In DepFast, because timeout can be easily added to an event, such problems can be prevented. In fact, we often use this practice for debugging: for cases that cause the system to stall, we add a global default timeout to all events, and then we can easily find the stall point of the problematic code.

5 Building Quorum Systems with DepFast

To demonstrate the usefulness and effectiveness of DepFast, we use DepFast to build two quorum-based systems: Raft [48] and Copilot [47], named as DepFast-Raft and DepFast-Copilot respectively. In this section, we discuss our experiences in using DepFast to build these systems, with a focus on how to “translate” the protocol algorithms into system implementations effectively.

5.1 DepFast-Raft

Raft’s protocol largely consists of two parts: 1) *leader election*: a candidate broadcasts `RequestVote` RPCs to all the other servers; it becomes a leader once votes from a majority of servers are received. and 2) *data replication*: for each follower, the leader keeps a mark (`nextIndex`) of the next log position to send to that follower; if the follower is lagging (due to out-of-order messages, network issues, etc.), the leader repeatedly sends the log entries needed by the follower.

Leader election can be effectively expressed with DepFast’s `QuorumEvent` design: a server broadcasts requests to other servers and can proceed after it receives a quorum of acknowledgments. Data replication, though described in a different

style in the Raft paper [48]— from a follower’s view, not a quorum’s view—can also be expressed to the same pattern above. Our implementation uses one coroutine to initiate the broadcast of the `AppendEntries` requests and wait for a quorum of responses. As DepFast handles most of the complexity in the network, disk, and event processing, a Master student was able to translate Raft’s pseudocode directly into a stable C++ implementation (used in §6.2) in ten days. The implementation has $\sim 1,200$ lines of code. As a rough comparison, the Raft logic in etcd [8] is implemented in $\sim 1,600$ lines of code in Go; braft [2], an open-source Raft implementation in C++, has $\sim 3,500$ lines of code.

An interesting case we found in implementing DepFast-Raft relates to the way Raft describes its protocol. In the design of Raft’s data replication protocol (its `AppendEntries` RPC), if the follower is lagging, the leader repeatedly sends log entries that are missing on the follower. This design is optimized for lagging servers and for new servers trying to catch. However, the way the algorithm is described may naturally lead to an implementation with separate threads synchronizing with different followers. A natural implementation could split the code responsible for committing a request into different functions in different threads. This style of implementation works well when there are no failures, but could take more time to debug when there are unexpected fail-slow behaviors, because it requires more work to trace the progress of each request. Our implementation, instead, uses a single coroutine to initiate the broadcast of the `AppendEntries` requests and wait for a quorum of responses. In case of an occasional reject due to the follower being lagging, the leader will launch a background coroutine, which is off the critical path of client requests, to synchronize with the lagging follower with additional `AppendEntries`.

5.2 DepFast-Copilot

Copilot is a consensus protocol that tolerates any single fail-slow node including the leader. It has two leaders, a pilot and a copilot, each is the backup of the other in case one fails. Copilot’s complexities mainly rise from following designs:

- *Commands ordering*. Each leader maintains two separate logs, one for itself and one as the backup of the other leader. Copilot’s ordering protocol coordinates between pilot and copilot to determine the *dependencies* of log entries, which specifies the prefix of the other log that should be executed before a given log entry.
- *Commands execution*. Unlike Raft that uses an index to order command execution, Copilot’s execution order is more complex: (1) Copilot has a protocol that calculates the right order of a command based on its dependencies. The calculation process is restricted by the status of these dependencies, e.g., the execution must happen after all the dependencies satisfy a rule; (2) The execution of the command is also constrained by the dependencies, i.e., a command’s execution

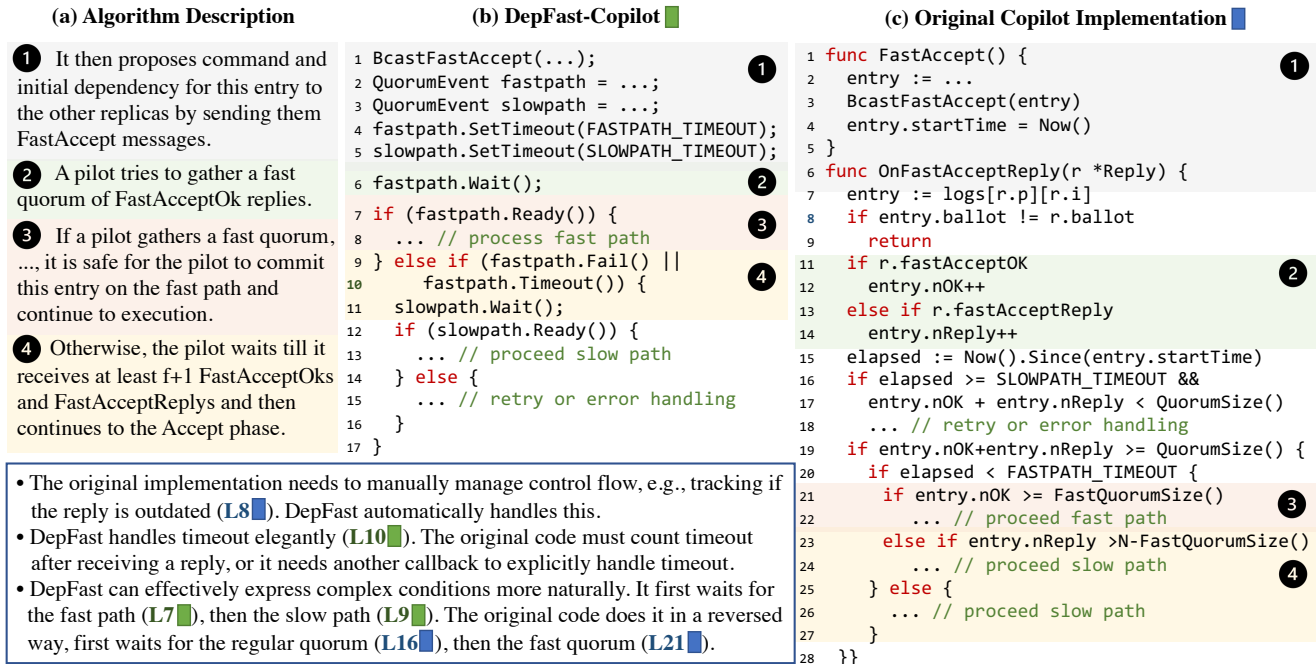

Figure 3: Comparison of the Copilot implementation using DepFast and the original implementation (both are simplified)

must wait until all the predecessors are executed.

- Fast takeover.* When one pilot becomes slow or fails, the other pilot needs to take over entries in the slow pilot’s log to prevent waiting for its commit for too long. It broadcasts Prepare to all other replicas to collect the entries and their status on other replicas at that position. Depending on the replies collected, Copilot distinguishes between many different cases to choose an entry properly, including whether there are committed entries, how many entries are fast-accepted, how many entries are accepted, etc.

As we have discussed in Section 3.1.4, DepFast can effectively express Copilot’s complex behaviors. Figure 3 shows a comparison of the DepFast version and the original version of Copilot. As shown, the DepFast version is closer to the algorithm in flow, and is easier to follow.

The commands execution algorithm contains statements like “waiting for the commit/execution of”, which is common in other protocols that use dependency for commands ordering (e.g., EPaxos [45]). However, such kind of behavior is not straightforward to express in an asynchronous programming style. In fact, the original Copilot implementation adopts this asynchronous programming style. It uses a separate Goroutine to keep scanning through the log and breaks the loop to start from the beginning when the above waiting condition is not satisfied. Instead, DepFast’s Wait API captures such behavior effectively. What we do is to represent the commit/execution of a log entry as an event and call Wait if there is a dependency on it as shown in Figure 4.

We find that the Copilot implementation using DepFast is more concise and readable than the original asynchronous,

callback-style implementation. To give a rough, unsolicited idea, the original implementation of the core protocol (excluding the utility code) has ~2,500 lines of Go code [12]. DepFast-Copilot only has ~1,600 lines of C++ code, despite that C++ is less expressive than Go.

Anecdotally, we started a Copilot implementation without DepFast, using an asynchronous callback style. In the process we ran into a bug that *sometimes* froze the system, which was caused by a wait condition being not triggered properly. We find bugs of this type are very hard to debug (we spent two weeks debugging it) because there is not a simple way to track each wait condition. We re-implemented the wait conditions using DepFast’s Wait API. The new implementation was done in roughly two days and we never encountered the same problem. Thanks to DepFast’s coroutine and event model, it is very easy to find out which event the system is waiting on, and print all the stack frames of the suspended coroutine.

6 Evaluation

We have shown the software engineering benefit of DepFast is its expressiveness and programmability (§3.1.4, §4 and §5). In evaluation, we mainly focus on answering two questions: 1) Does the expressiveness come at a cost of performance, or, can systems implemented in DepFast achieve the same level of performance as heavily optimized production and academic systems? 2) Can DepFast help system implementations guarantee their fault tolerance? This section answers the two questions by comparing Raft and Copilot implemented in DepFast to etcd and the original Copilot implementation. Specifically,

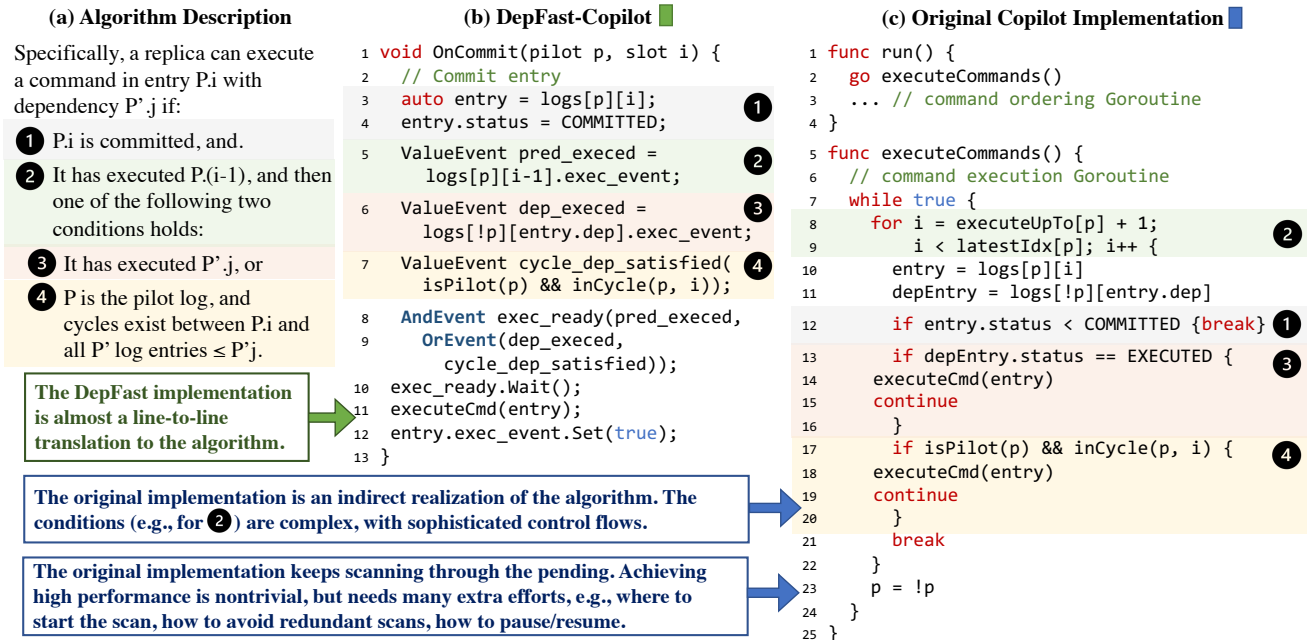

Figure 4: Comparison of the Copilot implementations using DepFast and the original impl. (both are simplified), cont'd

for fault tolerance, we evaluate DepFast-based systems on *fail-slow* fault tolerance using fail-slow faults [27, 31].

6.1 Experiment Methodology

We ran all the experiments on Azure Cloud. For each system, we evaluated it on a 3- and 5-replica cluster: each node runs on a Standard_D4s_v3 virtual machine (VM), with 4 vCPUs, 16GB RAM, and 64GB SSD. The server process is bind to one CPU core for all the systems evaluated. We ran the clients in a Standard_D16s_v3 VM, with 16 vCPUs and 64GB RAM.

Workloads and metrics. For all the evaluated systems, including our Raft and Copilot implementations, and the reference implementations (etcd [8] for Raft and the original Copilot implementation [12]), we use a single K-V, 100% write workload. We measure performance metrics, including throughput and latency distribution. Each trial runs for 120s and is repeated for 3 times. We display the results with the median throughput of the 3 trials, with the error bars showing the deviation.

Configurations. We use quorum reads and writes in our evaluation. We use the load that reaches the max CPU utilization on leader for the fault-injection experiments, marked with red stars in Figures 5(a) and 6(a). For DepFast-Raft, the server replies to the client after the log entry has been persisted on disk. For DepFast-Copilot, we set the fast-takeover timeout to 10ms and the command batching timeout to 1ms (same as the original Copilot implementation).

Fault Injection. We build a fail-slow fault injection testing tool to inject different types of fail-slow faults on system components (including CPU, memory, SSD, and network in-

terface) into the target systems and measure their impact in terms of the end-to-end performance. The fail-slow faults are simulated based on prior studies on fail-slow faults and represent common fail-slow modes [27, 31]. Table 2 describes those faults and the corresponding injection methods. For DepFast-Copilot, we do not inject faults on the disk, because the implementation is memory-based.

We inject fail-slow faults in the way that is expected to be tolerated without losing throughput by the consensus protocols of the target quorum systems. For DepFast-Raft, we inject faults to a minority of followers [55]. For DepFast-Copilot, we inject faults to a minority of nodes that can include one of the leaders [47].

6.2 DepFast-Raft

Figure 5(a) shows the latency and throughput of DepFast-Raft and etcd with both 3- and 5-replica setups. When binding the server process to one core, our DepFast-Raft achieves a maximum throughput of over 20K and 18K RPS (requests per second) with 3- and 5-replica setups, respectively; etcd has a peak throughput of 8K RPS. Claiming DepFast-Raft is better than etcd would be perhaps unfair as etcd is a production system with many features. However, this test at least proves that DepFast can be used to implement systems of production-level performance, with a class-project level of building difficulty.

Figures 5(b)–(d) show the fail-slow fault tolerance of DepFast-Raft in terms of throughput, median and P99 tail latency (in CDF) in both 3- and 5-replica setups. For the 3-replica setup, we inject fail-slow faults to one follower; for the 5-replica setup, we inject fail-slow faults to two followers (the

Fail-slow Type	Injection Method	Follower	Leader
Slow CPU	Use <code>cgroup</code> to limit DB process to utilize only p of CPU period	$p=5\%$	$p=50\%$
CPU Contention	Custom program (to consume cpu) assigned $t \times$ cpu share as the DB process	$t=15$	$t=1$
Slow Disk	Use <code>cgroup</code> to limit the disk I/O bandwidth available for DB to bw	$bw=128KB/s$	N/A
Disk Contention	Use program(<code>dd</code>) to do write operation on disk while DB is running	no parameter	N/A
Slow Network	Add a delay of d to the network interface using <code>tc</code>	$d=40ms$	$d=40ms$
Memory contention	Use <code>cgroup</code> to set the maximum amount of user memory for DB process to s	$s=50MB$	$s=250MB$

Table 2: Fail-slow faults used in the measurement study and our evaluation

Figure 5: Performance of DepFast-Raft with various fail-slow faults on follower(s) in the 3- and 5-replica deployments.

minority). We choose to only inject faults on the followers, because slow followers in Raft should not affect performance, while the slow leaders do.

We can see that DepFast-Raft consistently tolerates the injected fail-slow faults. The throughput differences are within 6% and 10% for 3- and 5-replica setup, respectively. The differences in both median and P99 latency are within 15% range. The results are comparable to etcd under the same test (see Figure 8, §B).

We attribute DepFast-Raft’s fault tolerance to the use of the DepFast framework to manage potential fail-slow points with the event interface. Specifically, we wrap every set of RPCs with `QuorumEvent` to avoid blocking on a single slow follower, preventing slowness propagation. Besides, blocking operations (e.g., disk I/O) are wrapped and put on a separate thread to avoid blocking the main worker thread.

Note that fail-slow followers inevitably have an impact, as the system is more susceptible to network and disk I/O spikes. In a 3-replica quorum, when one follower fails slow, the quorum reads and writes can be affected by the spikes of the other follower, affecting the tail latency.

6.3 DepFast-Copilot

Figure 6(a) shows the latency and throughput of DepFast-Copilot and the original Copilot implementation [12] in a 3-replica setup. (the 5-replica results can be found in B). The peak throughput of DepFast-Copilot is 33K RPS with a 3-replica setup. The performance is comparable to the original Copilot, which is just 9.3% higher at 36K RPS. The throughput is much higher than Raft, mainly because there is an optimization in Copilot called ping-pong batching that batches many requests into one command.

We inject fail-slow faults to both a leader and a follower, as Copilot is designed to tolerate any one of the fail-slow nodes.

Fail-slow follower. Figure 6(b) and 6(c) show the throughput and latency CDF of DepFast-Copilot with a fail-slow follower. Similar to the results of DepFast-Raft (§6.2), the faults do not have a significant impact on system-wide performance. The differences in throughput are within 10%, and the differences in median latency and P99 latency are within 9% and 30%, respectively. We observe that DepFast-Copilot’s tail latency is more susceptible to fail-slow faults than that of DepFast-Raft. Apart from the spikes discussed in §6.2, we attribute that to Copilot’s property of having two leaders. With a maximum number of minority followers being slow, a reply from another leader must be obtained to form a quorum, while with fewer slow followers a leader can form a quorum just with replies from non-slow followers. However, the load on a leader is much higher than a follower, causing the tail latency of replies from a leader node to be higher than replies from a follower node. That in turn results in longer tail latency to form a quorum, rendering the tail latency higher.

Fail-slow leader. Figure 6(b) and 6(d) shows the throughput and latency CDF of DepFast-Copilot with a fail-slow leader in a 3-replica setup. With Copilot’s multiple-leader design, there is no significant impact on throughput (the differences are within 25%) and the increase in median and P99 latency are within a reasonable range under the existence of one slow leader. For DepFast-Copilot, the CPU contention has the most significant impact on tail latency, in which case the P99 latency increased by 10ms.

The original Copilot implementation. We did the same fault-injection experiments on the original Copilot implementation (results are in Figure 9, §B). We can successfully duplicate the results in its paper that Copilot can tolerate a node slowdown in a slow network simulation. In some other cases (CPU, memory), we find that the original Copilot implementation cannot tolerate the failures as well as DepFast-Copilot. On one

Figure 6: Performance of DepFast-Copilot with various fail-slow faults on follower(s) and leader in the 3-replica deployment.

hand, this is justifiable as the original Copilot implementation is an academic prototype that focuses on verifying the design, rather than the implementation problems. On the other hand, it proves that fault tolerance is not only a design problem but also an implementation problem. It further proves the value of having another layer like DepFast in the system.

7 Related Work

Synchronous versus asynchronous programming. The discussion on synchronous and asynchronous programming styles started decades ago [41]. As common wisdom, synchronous programming (using threads instead of callbacks) is easy to follow, but tends to have unstable performance due to the overhead of OS threads [15, 25, 26, 37, 42, 43, 52, 53]. Prior work on synchronous programming focuses on reducing its overhead using cooperative task scheduling with lightweight user-space threads (e.g., coroutines or fibres) [15, 43, 52, 53]. Today, coroutines and cooperative task scheduling have been widely accepted, with built-in support in modern languages such as Go and C++. Our work follows the same principles, and extends the literature by considering distributed systems code (prior work focuses on I/O operations on a single node). An orthogonal direction is to improve the understandability of callback-style code, making it synchronous code alike [25, 37]. The approach needs compiler support and extra tooling.

Distributed programming patterns and frameworks. The actor model is a common model to construct distributed programs, e.g., Erlang/OTP [7] and Scala/Akka [1], Orleans [21] and ActOp [46]. Our target is not actor systems, as we focus on the imperative coding style with RPC for communication that is still a common practice in building C/C++ system software. But our results can be complimentary to the actor world, because the actor systems are mostly asynchronous, and may be subject to the same callback hell problem [56].

Rex [32], Eve [35], and Crane [24] target fault tolerance at the OS process level. Ambrosia [30] extends the actor model with built-in fault tolerance support. These frameworks are potential users of DepFast—they can use DepFast to build fault-tolerance mechanisms and services.

A few frameworks help programmers to match their implementations to the specifications rigorously and thoroughly.

Mace [36] translates specification into a C++ implementation and provides a model checker to verify correctness. Rules-based programming [50] promotes programming in an event-based state machine, which helps specify concurrent and non-deterministic conditions. Verdi [54] and Ironfleet [33] help build formally verified systems. DepFast has a different goal: making distributed system code easier to write, maintain, and debug. It also addresses different issues, e.g., fail-slow fault propagation and backlogs (reported in formally verified quorum implementations [29]). DepFast also imposes much fewer restrictions on how distributed systems are programmed.

8 Concluding Remarks

We have presented DepFast, a programming framework to build quorum systems. Our experience of using DepFast is encouraging. DepFast helped us to effectively develop high-performance, fault-tolerant quorum systems with complex consensus protocols. With DepFast, we can write quorum systems code that is easy to follow and maintain. Our future work includes using DepFast to build different types of distributed systems, such as sharded datastores with distributed transaction protocols which also have complicated waiting conditions. We will investigate adopting DepFast’s abstraction with other frameworks and interfaces, e.g., C++ 20’s coroutine interface, and the actor model in Erlang/Scala.

Acknowledgments

We would like to express our deep appreciation to our shepherd, Jon Howell, who was very responsive during our interactions with him and provided us with invaluable suggestions, which have fundamentally improved this paper and strengthened our work. We also thank the anonymous reviewers for their feedback. We thank the authors of Copilot, especially Khiem Ngo, for the discussions and reviews. We thank Dan Plyukhin for discussions that helped us understand the actor programming model deeper. We thank our industry collaborations for the discussions, especially Ye Ji (CockroachDB) and Siyuan Zhou (MongoDB). This work was supported in part by NSF CNS-2130590 and CNS-2130560, and Microsoft Azure credits.

A Appendix

A.1 Artifact evaluation

Abstract

A Docker image is provided which contains required dependencies and source code to run the system. Instructions are provided in the `README.md` to reproduce the major results.

Contents

The artifact evaluation includes experiments in Figures 5 and Figures 6. This artifact does not include (1) experiments for comparisons: etcd and ref-copilot, and (2) experiments in B.

Hosting

You can find the publicly available source code at https://github.com/stonysystems/depfast-ae/tree/atc_ae.

Requirements

At least one client plus five servers are used to reproduce the experimental results. Five servers must have an extra disk mounted for slowness experiments. We run all our code on Debian-10, which mainly depends on common Linux libraries (i.e., python, gcc and libyaml-cpp-dev). You can install all dependencies by `bash ./dep.sh`.

A.2 Empowered analysis

DepFast empowers a number of analysis to help programmers understand the fault-tolerance properties of their systems and to detect faults at the run time.

Monitoring with linked coroutines Through the event interface, the DepFast framework can link coroutines together and analyze fail-slow fault propagation. For example, the `RpcEvent` could link the caller and the callee coroutines. The framework will propagate the wait-for information and aggregate them at configured granularity. Figure 7 presents an example of a fail-slow fault propagation graph which shows the wait-for relationship at the node granularity in our DepFast-Raft implementation (§5.1). Each vertex represents a node in a quorum. Each edge is directed and weighted: the direction suggests the wait-for relationship; the weight is the count of the waiting. Each edge is colored. A wait on a potential fail-slow event (e.g., an `RpcEvent`) leads to a *red* edge. A wait on a `QuorumEvent` leads to a *green* edge. This graph is generated and refreshed periodically at runtime. It can be used with graph analysis to detect execution paths which are vulnerable to fail-slow fault, that is, the execution path that contains a red edge. Ideally, this graph should not contain any red edges except for those representing a client issuing requests to a server.

Figure 7: The fail-slow fault propagation graph of DepFast-Raft with three quorums (§5.1). The labels on the edge represents the quorum of the event. “2/3” refers to `QuorumEvent` where 2 responses are needed out of 3 RPCs; “1/1” refers to waiting on a single RPC (clients wait for the leader nodes).

Fault detection. DepFast has a few built-in fail-slow fault detection mechanisms. First, DepFast measures the CPU usage of the worker thread. When the worker thread is awake from `epoll` sleep, it should take up all the CPU core it is running on, because the worker thread does not have thread-blocking calls. The measurement excludes all the `epoll` sleep time and only measures the code executed in the worker thread. If it observes that the worker thread occupies less CPU time than it should, it alerts: either a fault occurs or other programs compete for CPU. Note that this is not perfect detection: the competition could be healthy if it is a shared host; a fail-slow fault could also make the `epoll` sleep longer rather than reducing the CPU utilization.

Second, DepFast measures the time of waiting on each event. If there is a spike for the same event, DepFast will report it. Or, if the wait time repeatedly breaks a user-configured threshold, DepFast will report fail-slow as well.

Third, DepFast exposes the runtime information of resource utilization by allowing applications to register a user-defined detector function. The user-defined detector will be called periodically (taking the monitoring information as inputs) and then make its own decision to notify the application.

B Supplemental evaluation

Figure 8 shows the results of etcd under various fail-slow faults. Our results show that etcd can tolerate these failures well as a production system.

Figure 9(b) and 9(d) shows the throughput and latency CDF of the original Copilot implementation with a fail-slow leader in a 3-replica setup. The experiment verifies that the original Copilot implementation can tolerate a fail-slow node in the cases tested in the Copilot paper. We find that largely due to its immature implementation, in some fail-slow follower cases that are not tested in the original paper, the performance is lower than expected. For example, our experiment of injecting CPU slowness to the original Copilot frequently fails. After some diagnosing, we found that when the follower fails

Figure 8: Performance of etcd with various fail-slow faults on follower(s) in the 3- and 5-replica deployments.

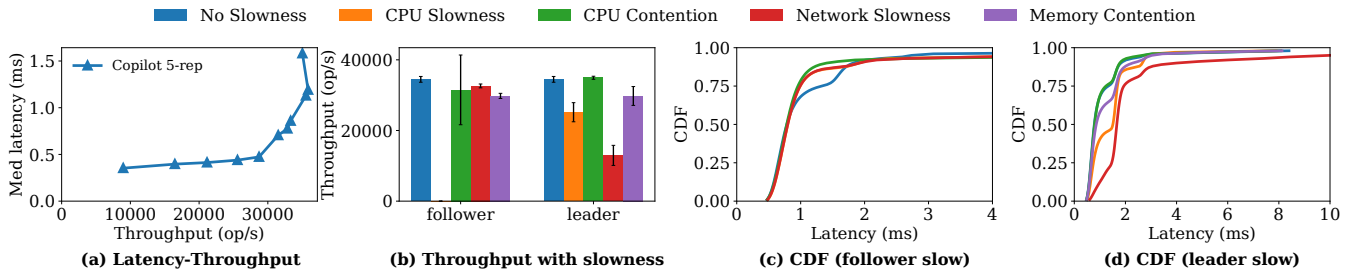

Figure 9: Performance of original Copilot with various fail-slow faults on follower(s) and leader in the 3-replica deployment.

Figure 10: Performance of DepFast-Copilot with various fail-slow faults on follower(s) and leader in a 5-replica setup

slow, it could detect the leader as dead as it cannot process the heartbeats from the leader in time and starts a view change. The leader then steps down and crashes due to what is suspected to be a memory bug. The fail-slow follower will next become the new leader. This results in two live nodes, with one of them failing slow, rendering the cluster into a slow or even stalled state.

Figure 10 shows the evaluation results of DepFast-Copilot in a 5-replica setup, in a similar vein as Figure 6. Figure 10(a) shows the latency-throughput of DepFast-Copilot and the original Copilot implementation. The peak throughput of DepFast-Copilot is 18% higher than the original Copilot.

Figure 10(b)-(d) show the throughput as well as latency CDF of DepFast-Copilot with fail-slow faults injected to follower and leader nodes. Recall from §6.1 that we inject faults on two followers (denoted as “*follower*” in Figure 10) and on one leader and one follow (denoted as “*leader*” in Figure 10). Similar to the results of 3-replica setup, there is no significant downgrade on throughput and latency in terms of both fail-slow follower and leader. For follower slowness, the

decrease in throughput is within 12%. The increase in median and P99 latency are within 10% and 35%, respectively. For leader slowness, the decrease in throughput is within 26%. The latency results are similar to those in a 3-replica setup.

Compared with the 3-replica setup (Figure 6), we find that the 5-replica setup is affected by network and disk I/O spikes more. We discussed the impact of the spikes in §6.2; we elaborate more here. Since we inject one fail-slow node in the 3-replica setup and two fail-slow nodes in the 5-replica setup, the probability of one of the remaining replicas experiencing network or I/O spike is higher in the 5-replica setup than in the 3-replica setup. As every request leads to a quorum read or write, the 5-replica setup is more susceptible to network or I/O spikes. The spikes, in our experience, are common in Azure Cloud (also reported by other studies [16, 51, 58, 59]). Note that Azure uses virtual hard drives that are accessed remotely over the network [59]. As a result, disk writes can also be impacted by network spikes.

High Throughput Replication with Integrated Membership Management^{*}

Pedro Fouto, Nuno Preguiça, João Leitão
NOVA LINCS & NOVA University Lisbon

Abstract

This paper introduces ChainPaxos, a new distributed consensus algorithm for high throughput replication. ChainPaxos organizes nodes in a chain, allowing for a pipeline communication pattern that maximizes throughput, by minimizing the number of messages transmitted. While other proposals have explored such patterns, ChainPaxos is the first that can execute linearizable reads in any replica with no communication overhead, relying only on information used to process updates. These techniques build on a fully specified integrated membership management solution, allowing ChainPaxos's fault-tolerance to be independent of an external coordination service, often used in other solutions, which can lead to possible safety violations in the presence of network partitions.

Our evaluation shows that, when compared with alternative Paxos variants, ChainPaxos exhibits significantly higher throughput and scalability with negligible latency impact. Compared to other solutions with similar communication patterns, besides avoiding the costs of an external coordination service, ChainPaxos's high throughput tends to increase with the ratio of read-only operations.

1 Introduction

Fault-tolerance is a key property for distributed systems, being fundamental to guarantee that they continue to operate despite failures of individual components. To achieve this, the state of the system needs to be replicated over multiple nodes.

A particularly interesting way of providing fault-tolerance is the state machine replication (SMR) [20, 30] approach, which allows to replicate any service providing strong consistency. SMR is achieved by executing the same sequence of deterministic operations on all replicas, making them transition through the same sequence of states.

^{*}This work was partially supported by Fundação para a Ciência e Tecnologia (FCT) under the projects NG-STORAGE (PTDC/CCI-INF/32038/2017) and NOVA LINCS (grant UIDB/04516/2020).

Experiments presented in this paper were carried out using the Grid'5000 testbed, supported by a scientific interest group hosted by Inria and including CNRS, RENATER and several Universities as well as other organizations (see <https://www.grid5000.fr/>).

The Paxos [15, 32] consensus protocol and its variants [6, 21, 24, 26–28] have been used as a fundamental building block for implementing SMR, by enabling replicas to agree on the order in which operations are executed. Many practical systems, such as coordination systems, scale-out, in-memory lock services and in-memory databases rely on the performance of their underlying SMR implementation, making it extremely relevant to improve the performance of consensus (or agreement) protocols.

This paper describes the design and implementation of ChainPaxos, a new consensus algorithm for high throughput replication of (deterministic) services. Our goal is to minimize the communication cost of the protocol to achieve the highest possible throughput, both for read and write operations. We achieve this by using a set of complementary techniques. For write performance, we rely on an efficient pipelined communication pattern between replicas, which has been explored and shown effective by previous approaches, notably ChainReplication [33]. This pattern allows to minimize and distribute the number of messages propagated (and therefore processed) by each node to achieve consensus, which highly contributes to maximizing the throughput of write operations. For read operations, we propose a novel scheme for linearizable reads served by a single replica, without incurring in additional communication cost (albeit at the cost of a small increase in latency), which further minimizes the communication overhead of ChainPaxos and increase its throughput.

Contrary to many recent proposals, ChainPaxos does not outsource membership management to an external coordination service (e.g., Zookeeper [12]). Instead, our system features its own integrated membership management solution that allows for the continuous execution of operations during reconfigurations, while uncoupling our system's fault-tolerance from that of an external service. As such, increasing the number of replicas in ChainPaxos effectively increases the maximum number of faults that are tolerated. On the other hand, when leveraging an external coordination service, the fault-tolerance of the replicated systems depends on the fault-tolerance of that coordination service. Additionally, as shown

recently [2], relying on an external coordination service is far from trivial as it makes a system more vulnerable to network partitions, requiring additional logic to ensure correctness.

Our design builds on the insight that it is possible to combine multiple Multi-Paxos messages and exploit a pipeline communication pattern. While this insight is not novel [19], ChainPaxos is, to the best of our knowledge, the first protocol that not only takes advantage of this insight, but also specifies an integrated membership management solution, allowing for lightweight linearizable reads to be served by any replica.

We conduct an extensive experimental evaluation of ChainPaxos where we evaluate its performance against several state-of-the-art variants of Paxos, in particular Multi-Paxos, Egalitarian Paxos, (U)-Ring Paxos, and Chain Replication. The results show that our algorithm provides higher throughput and scalability when compared with other Paxos variants, with even higher gains as both the number of the replicas of the system and the size of operations increase. When compared with other solutions that employ pipeline communication, ChainPaxos shows similar performance for writes, but improved scalability as the ratio of reads increases.

In summary, this paper makes the following main contributions: **i)** a new consensus algorithm that provides high throughput, with integrated membership management that makes it independent from external coordination services (Section 3); **ii)** a novel approach to provide linearizable read operations that distribute the load among all replicas without incurring additional communication costs (Section 4); and **iii)** an extensive experimental evaluation, showing that ChainPaxos provides better performance than state-of-the-art alternatives (Section 5).

2 Related Work

Paxos [15,32] and its variants [6,21,24,26–28] have been used in the design of replicated systems, employing diverse techniques to optimize performance aspects, such as *minimizing latency*, *reducing communication cost*, *distributing the load*, and supporting *linearizable reads*. We now discuss the most popular variants of Paxos, along with Chain Replication [33], an alternative SMR algorithm.

2.1 Minimizing latency

Multiple Paxos variants try to optimize latency. In FastPaxos [18], clients send Accept messages directly to acceptors, skipping the leader. Generalized Paxos [17] extends FastPaxos by allowing non-interfering requests to execute in different orders. In both cases, collisions in client requests result in additional round trips, hindering performance. Flexible Paxos [11] uses different quorum sizes for executing operations (akin to read-write quorum systems [34]), reducing the size of accept quorums and decreasing the latency of accepting operations in the fast path. While ChainPaxos only matches the fast path latency of these protocols when configured to tolerate a single fault, it requires each replica to

handle only one message per operation. In contrast, the $O(n)$ message complexity of Paxos leader and learners in these solutions results in lower throughput.

2.2 Communication cost

Some variants employ chain (or ring) topologies to decrease communication cost. Ring Paxos [28] sends *Accept* messages to all replicas using IP-multicast, with responses being propagated through a ring. IP-multicast limits the operation of the protocol across data centers and negatively impacts the performance under high load when messages are lost. Chain Replication [33] is an SMR algorithm, developed for synchronous systems, where replicas are organized in a *chain* and write operations are forwarded from the head to the tail, with acknowledge messages travelling the opposite way. This approach has the advantage that all replicas send and receive the same number of messages for executing an update. Similarly, U-Ring Paxos [13] propagates messages in a ring topology, with acknowledge messages being forwarded from the tail to the head. These solutions require an external coordination service (e.g., Zookeeper [12]) to reconfigure the system when faults occur, leading to higher operational cost, slower fault-handling, potentially lower fault-tolerance (dependent on that of the external service), and vulnerability to network partitions [2]. ChainPaxos, while having a similar communication pattern, further reduces the number of messages processed by each replica, while handling reconfigurations and faults in an integrated and efficient way.

2.3 Distributing the load

Other variants of Paxos try to distribute the load across replicas. Mencius [22] pre-assigns the leader of each instance to a different node. While providing better throughput, the overall availability suffers since the failure of *any* replica will cause the system to stop until another replica takes over. In Egalitarian Paxos (EPaxos) [26], any replica can commit operations and non-conflicting operations execute in different orders. When there is no conflict, operations commit in a single communication round. Multi-Ring Paxos [24] (based on Ring Paxos) uses a similar approach, while taking advantage of the ring topology to minimize communication. When concurrent operations conflict (which is often the case in SMR), these protocols require extra rounds of communication. Atlas [8] improves on this by allowing some conflicting operations to execute in a single round. Despite trying to distribute the load across all replicas, these protocols still require nodes to send and receive $O(n)$ messages. In contrast, ChainPaxos minimizes the overall load imposed by the protocol, having $O(1)$ message complexity, while also distributing the load across replicas.

2.4 Linearizable reads

In replicated systems, where reads are more frequent than writes, it is important to reduce the cost of read operations to improve overall performance.

Synchronous systems. Chain Replication [33] proposes to execute linearizable reads by contacting a single node: the tail of the chain. When the tail fails, as detected by an external coordination service, clients fallback to the previous node in the chain to continue reading the system state. This solution, however, was designed for a synchronous model where failures can be reliably detected. In an asynchronous system, linearizability can be violated, as the tail can become isolated and be excluded from the chain without knowing, while still serving (outdated) reads. To avoid this, for each read, either the tail or the client would need to contact the external coordination service to verify the current configuration of the chain, which is too expensive. In [33], the authors mention that the coordination mechanism needs to stop clients during reconfigurations, which is unfeasible under network partitions.

Asynchronous systems. Due to a similar reason, solutions based on Paxos cannot execute read operations by contacting only the leader, usually requiring to run a consensus instance for ordering read operations or, in special cases, to contact a quorum of replicas. However, some alternative read schemes to improve replication performance have been proposed. In Smarter [4], reads execute on a single replica, but require a special *whats_my_view* message to be sent to all replicas to gather a majority of replies confirming that no reconfiguration took place concurrently with the read operation. In [10], reads are executed on a single replica, however at the cost of requiring writes to execute in two phases. CRAQ [31] improves reads in Chain Replication by allowing to read from any replica in an asynchronous model, however it only provides per-object linearizability, and for SMR it would require all reads to contact the tail whenever there is a write executing.

In contrast with all these solutions, ChainPaxos includes a novel technique to execute linearizable reads on a single replica, in an asynchronous environment, without ever requiring any additional communication costs. Furthermore, it allows any replica to process reads, thus distributing the read load across all replicas.

3 ChainPaxos

We assume an asynchronous distributed system with n nodes, connected by a network that can lose, duplicate, and deliver messages out of order. Nodes communicate by exchanging messages over a network with a fair loss model that allows the creation of FIFO channels between any pair of nodes. Nodes can fail by crashing, where they stop sending messages.

We follow the SMR model [30], in which each replica holds a copy of the system state and there exists a set of deterministic operations that may output a reply. Replicas start in the same initial state and apply the same sequence of operations, thus guaranteeing that all replicas transition through the same sequence of states and output the same results. We defer the processing of read operations to Section 4.

ChainPaxos is used to order the execution of operations.

The system state includes the application state and the membership of the system, with `AddNode(n)` and `RemoveNode(n)` operations, respectively, adding and removing node n to the replica-set. These operations execute in the state machine, as other application operations, potentially impacting the quorum size of following operations. For correctness, a node can only decide a given instance strictly after knowing the decision of all previous instances (and the current membership).

3.1 Overview

This section introduces ChainPaxos, revisiting Multi-Paxos and Chain Replication to better contextualize our design.

In Multi-Paxos [15, 32], a distinguished proposer, known as *leader*, prepares multiple Paxos instances in a single step (Phase 1), followed by multiple sequential executions of Phase 2 of Paxos. In a fault-free run (Figure 1), the leader sends an *accept* message to all replicas, with each replying to all replicas with an *accept ack* message. Any replica that receives *accept ack* messages from a majority of replicas can decide and execute the request (with the replica that received the operation replying back to the client). With n replicas, the message complexity of the protocol is $O(n^2)$: each replica incurs in $O(n)$ message overhead (the leader sends/receives $2n$ messages). The reply to the client is produced after 2 communication steps between replicas. Alternatively, a replica could send the *accept ack* message only to the leader, which would then forward the decision to all replicas. In that case, the overhead of non-leader replicas decreases to $O(1)$ at the cost of an additional communication step.

Chain Replication [33] leverages a chain topology, forwarding operations from the head to the tail (Figure 2). The tail replies to clients after executing an operation, and sends *ack* messages backwards, to allow replicas to perform garbage collection. In a fault-free run, each replica incurs in $O(1)$ message overhead, with a reply being produced after $O(n)$ communication steps.

The main goals of ChainPaxos's design are: (i) minimize the number of messages each node processes in fault-free runs and make the load uniform, maximizing throughput; and (ii) integrate an efficient fault handling scheme into the algorithm, by taking advantage of Paxos messages, avoiding the need to rely on an external service. To achieve these goals, we leverage the chain topology to combine and forward multiple Multi-Paxos messages in a single ChainPaxos message. As ChainPaxos builds on Multi-Paxos, leader faults can be handled simply by falling back to the first phase of Paxos.

In ChainPaxos, in a fault-free run (Figure 3), the leader sends the *accept* message, including its *accept ack*, to the following replica in the chain. Upon receiving an *accept* message, a replica forwards the message modified to include its own *accept ack*. When the *accept* message reaches the tail of the chain, it sends a message directly to the head with the *accept ack* of all replicas, guaranteeing that the head learns about the decided value. Additionally, it is necessary to in-

Figure 1: Multi-Paxos message flow on a fault-free run.

Figure 2: Chain Replication message flow on a fault-free run.

Figure 3: ChainPaxos message flow on a fault-free run.

form the replicas that have not received enough *accept ack* messages to decide the value of the instance – ChainPaxos piggybacks this information in the next *accept* message.

When an *accept* reaches the replica at the middle of the chain, it includes *accept ack* from a majority quorum. Thus, the replica knows that the received request has been decided, and can execute the request and return the result to the client. In the example of Figure 3, with three replicas, the leader and replica 2 form a quorum, with replica 2 replying to the client.

The message flow for fault-free runs achieves the first goal of minimizing the number of messages handled by each replica and keeping the load uniform: a single message is sent and received by every replica. As ChainPaxos is just using a different communication pattern to convey the messages of Multi-Paxos, it can fall back to the regular two phases of Paxos to handle faults. This is the base for achieving the second goal of integrating fault handling in the protocol.

ChainPaxos builds on these ideas to provide high throughput replication by addressing the following challenges: *i*) optimize fault-handling and integrate membership management by leveraging information about the chain topology, thus avoiding the common vulnerabilities/complexity encountered in systems that rely on external coordination services in the presence of network partitions [2]; *ii*) support efficient garbage collection of the information about decided values, which is a common challenge in many variants of Paxos, rarely addressed in the specification of algorithms; and *iii*) integrate a novel mechanism that leverages the chain topology to enable efficient linearizable read operations handled by a single replica without additional communication.

Next, we detail the operation of ChainPaxos, describing the state maintained by each replica and the operation of the protocol in fault-free runs and during reconfigurations. We present correctness arguments for our solution in Annex A.

3.2 Protocol State

Algorithm 1 presents the state of each replica. The first variable group is related with the organization of the system and includes: the members and their order in the chain (*chain*); the identity of the local node (*self*); the next node in the chain that is not marked for removal (*c_{nextok}*); the currently supported leader (*c_{sleader}*); and the replicas for which a *RemoveNode* has been received but not yet decided (*marked*).

Algorithm 1 State of ChainPaxos nodes.

<i>chain</i> : array of nodes	
<i>self</i> : node	▷ local node identifier
<i>c_{nextok}</i> : node	▷ next (unmarked) node in the chain
<i>c_{sleader}</i> : node	▷ supported chain leader
<i>marked</i> : set of node	▷ nodes marked for removal (init : ∅)
<i>np_{leader}</i> : int	▷ special prepare number of the leader
<i>inst</i> : map int × PaxosInst	▷ PaxosInst : (n _a , val, n _{accepts} , decided)
<i>submitted</i> : set of requests	▷ requests submitted by the client
<i>pending</i> : set of requests	▷ requests waiting to execute (leader only)
<i>max_{ack}</i> : int	▷ highest instance acknowledged
<i>max_{accept}</i> : int	▷ highest leader initiated instance (leader only)
<i>amLeader</i> : bool	▷ true if current leader

The second group maintains the information to run Paxos instances. This includes the prepare number (*np_{leader}*) that the leader can use for bypassing the first phase of Paxos. Each replica also maintains a map (*inst*) with the information of Paxos instances including, for each instance, the highest prepare number (*n_a*) used by a leader to accept a value (*val*), the number of nodes that accepted *val* with *n_a* (*n_{accepts}*), and a boolean indicating if the instance was decided (*decided*).

The third group is used for managing client requests. It consists of two sets: *submitted* stores requests received from clients and not yet decided, and *pending* contains the requests received by the leader (redirected from itself or other replicas) but not yet submitted for ordering.

The final group of variables is used for clarity of presentation and stores information that could be derived from other variables, including the highest instance started by the leader (*max_{accept}*), and the highest instance known to have a decided value accepted by all nodes (*max_{ack}*). Each node also keeps track of whether it is the current leader in *amLeader*.

3.3 Fault-free execution

Algorithm 2 presents the ChainPaxos algorithm, with auxiliary functions detailed in Algorithm 3. The highlighted lines represent the logic used in faulty scenarios that require reconfiguration, which are detailed in the next section.

Requests from clients can be received by any replica, and are redirected to the leader (Alg. 2, line 1), which stores them in a set of pending requests (Alg. 2, line 5). The leader, upon receiving a new request, starts a new instance by increasing

Algorithm 2 ChainPaxos algorithm: message flow.

```
1: upon receive <NEW_REQUEST, req> from client do:
2:   submitted ← submitted ∪ {req}
3:   SEND(c_sleader, <REDIRECT_REQUEST, req>)
4:
5: upon receive <REDIRECT_REQUEST, req> from r do:
6:   if self = c_sleader then           ▷ Even if there is no quorum yet
7:     pending ← pending ∪ {req}
8:
9: function STARTINSTANCE
10:  max_apt ← max_apt + 1
11:  SEND(self, <ACCEPT, max_apt, self, np_leader, pending, 0, max_ack>)
12:  pending ← 0
13: upon receive <ACCEPT, n_i, ldr, n_a, val, n_apt_s, m_ack> from r do:
14:   if np_leader ≤ n_a then           ▷ Has not seen higher prepare
15:     UPDATELEADERINFO(ldr, n_a)     ▷ If a prepare was missed
16:     if ¬inst[n_i] ∨ inst[n_i].n_a < n_a then
17:       inst[n_i] ← (n_a, val, n_apt_s + 1, false)
18:     else                             ▷ Repeated accept
19:       inst[n_i].n_apt_s ← MAX(n_apt_s + 1, inst[n_i].n_apt_s)
20:     if inst[n_i].val = RemoveNode(node) then
21:       MARKFORREMOVAL(n_i, node)
22:     if ISQUORUM(n_apt_s) ∧ ¬inst[n_i].decided then
23:       DECIDE(n_i)
24:       DECIDEANDGCUPTo(m_ack)
25:       FORWARD(n_i)
26:
27: upon receive <ACCEPT_ACK, n_i> from r do:
28:   DECIDEANDGCUPTo(n_i)
29:
```

the instance number and generating a new *accept* message (Alg. 2, line 9). The *accept* message contains the following information: (i) the instance number, which the leader tracks in max_apt ; (ii) the id of the leader; (iii) the prepare number, np_leader , used by the leader in its previous prepare message; (iv) the client request (i.e., operation); (v) the number of nodes which have accepted the value (n_apt_s), initialized to 0; and (vi) the highest instance for which the decided value is known to have been accepted by all replicas (max_ack).

The leader is the first to handle the *accept* message of each instance, as it starts a new instance by sending the *accept* to itself (Alg. 2, line 11). Upon receiving an *accept* message for an instance (Alg. 2, line 13), a node stores the information for the instance, increasing the value of n_apt_s to indicate the node itself is accepting the value. If n_apt_s is greater than $n/2$, the message has already been accepted by a majority of nodes, and its value can be decided (Alg. 2, line 22). Otherwise, the value will be decided (and garbage-collected) when an *accept* message is received with m_ack greater or equal to its instance number. This is performed in function `DecideAndGCUPTo` (called in Alg. 2, line 24 and defined in Alg. 3, line 35). This function traverses every (non-garbage-collected) instance up to instance max_ack , marking them as decided (if they were not yet), and garbage-collecting the information about them after their execution. This is safe since all instances up to max_ack have been accepted by every node in the chain.

Finally, the node forwards the *accept* message (with the incremented n_apt_s) to the next node in the chain. If the replica

is the last node in the chain, it sends an *accept ack* message to the leader, signalling that every node in the chain has seen and accepted the instance. Upon receiving this message, the leader executes `DecideAndGCUPTo`, increasing its max_ack which leads subsequent *accept* messages to trigger `DecideAndGCUPTo` in every node across the chain.

The nodes in the second half of the chain (starting from the $n/2^{\text{th}}$ node) can decide instances as soon as they receive the *accept* message, while the first $n/2$ nodes only decide (and execute an operation) after receiving an acknowledgement (the leader via an *accept ack* message, and the other nodes via the max_ack value piggybacked in subsequent *accept* messages).

In a fault-free run, our protocol simply encodes the messages of Multi-Paxos in ChainPaxos messages. A ChainPaxos *accept* message sent by node n encodes the Multi-Paxos *accept* message and the *accept ack* messages of n and all nodes that precede it in the chain. It also encodes the *accept ack* messages of all nodes in the chain for all instances up to m_ack . A ChainPaxos *accept ack* message encodes the Multi-Paxos *accept ack* messages of all nodes in the chain.

3.4 Dealing With Faults and Reconfigurations

To describe how faults and membership reconfigurations are handled in ChainPaxos, we begin by describing the mechanisms used by replicas to suspect other nodes (i.e., fault detection) and then discuss the steps taken by ChainPaxos to reconfigure the system, either keeping the current leader or when the leader is suspected. The main challenge faced by ChainPaxos is that, when using a chain topology, the failure of a single node leads the chain to break, making it impossible for messages to keep flowing along the chain, resulting in a system halt.

Fault Detection: We have implemented two mechanisms for fault suspicion. To pinpoint faults in the chain, each replica expects to receive periodic keep-alive messages from the following node in the chain. If a node does not receive the keep-alive for a configurable period of time, it suspects the node, and requests the leader to remove it, triggering a *Reconfiguration not involving the leader*. In case the tail suspects the failure of the leader (which is its next node), it starts the process of taking leadership (Phase 1 of Paxos), and then starts the process of removing it. This effectively triggers a *Reconfiguration involving the leader*.

We note that, as we assume an asynchronous system, suspecting a node does not necessarily mean that it failed, but rather that there is a chance it might have, as it can just be temporarily slow [29]. However, since a single failed (or just slow) node can block progress in the whole chain, the keep-alive mechanism is important to allow quick removal of suspected nodes, minimizing their negative impact on the overall throughput of the chain. Incorrectly removed replicas can later rejoin the system.

The second mechanism is based on the continuous flow of *accept* messages. If a replica does not receive an *accept*

Algorithm 3 ChainPaxos algorithm: auxiliary functions.

39:      $inst \leftarrow inst \setminus \{i\}$ 
40:    $max_{ack} \leftarrow n_i$ 

```

for a configurable period of time, it assumes that the leader is faulty and attempts to take leadership. If, during this process, the new leader could not establish a connection to some other node (to send them the *prepare* message), it suspects and starts the process of removing them. To make sure this mechanism operates correctly even if the system is subjected to a low load, the leader issues periodic *accept* messages for a special *NoOP* operation if there are no client requests.

Reconfiguration not involving the leader: We now explain how ChainPaxos reconfigures the chain by removing a suspected node that is not the leader.

When the leader is notified that node n is suspected, it starts an instance with $RemoveNode(n)$ operation to remove node n from the chain. When the instance is decided, n is removed from the chain, updating the variables with the local configuration of the chain (*chain* and *marked*).

When a $RemoveNode$ operation is being propagated, two actions need to be taken to guarantee correctness and progress:

i) guarantee that all previous *accept* messages that might have been lost due to the failure of the node are forwarded to the next correct node (to reestablish the flow of those *accept* messages); and *ii)* guarantee that all subsequent *accept* messages are forwarded through the chain despite faulty nodes, until the $RemoveNode$ operation is decided, removing the faulty node, and repairing the chain.

The former is implemented in $MarkForRemoval$, executed when processing an *accept* message for a $RemoveNode$ operation (Alg. 2, line 21). The node to be removed is added to the set of marked nodes (Alg. 3, line 2). If the node to be removed is the next node that was not previously marked, it is possible that it failed to propagate previous messages through the chain. Thus, the node sends to the next non-marked node any *accept* messages (or *accept ack* for the leader) for instances that have not yet been garbage collected (i.e., instances from max_{ack} to $n_i - 1$) (Alg. 3, line 5). This guarantees that, when healing the chain by bypassing faulty nodes, all *accept* messages will be received by all nodes that will not be removed from the chain, somewhat falling back to the pattern of Multi-Paxos¹.

The latter guarantee is provided by the $Forward$ function (Alg. 3, line 7). This function forwards the *accept* message for a given instance to the next node. When one or more of the following nodes are marked to be removed (because a $RemoveNode$ operation has been received, but has not yet been decided), the function forwards the *accept* message to the next non-marked node. This guarantees that a node that is to be removed in instance n_i will not vote for instances $n > n_i$.

When a leader change occurs while a $RemoveNode$ operation for a node r is being propagated through the chain, it is possible that the operation, while observed by a minority of replicas (that add r to their marked set), is not decided. Following the regular behaviour of Multi-Paxos, the new leader might issue a different operation for that instance. Such operations should be sent to r to ensure correctness. To do so, when a replica learns about the new leader it removes all nodes from the *marked* set and updates the c_{nextok} variable, ensuring that messages flow across all nodes. (Alg. 3, line 12).

Reconfiguration involving the leader: ChainPaxos supports changing the leader by having a node become the leader at a given instance for that and all following instances by executing the first phase of Paxos.

This process is initiated in function $TryToBecomeLeader$ (Alg. 4, line 1). The node selects a prepare number higher than any prepare number already seen in any instance, and sends a *prepare* message for instance $max_{ack} + 1$ directly to all nodes. Although this prepare is for a given instance, it will make the node leader of all instances from that point onward – thus, the prepare number must be larger than any

¹Note that this might lead to nodes receiving multiple *accept* messages for the same instance with the same prepare number from different nodes. This is addressed by considering the highest observed number of acks reported in these messages. This is safe because the forward process employed during recovery never generates cycles.

Algorithm 4 ChainPaxos algorithm: leader election.

```
1: function TRYTOBECOMELEADER
2:    $n_p = \text{NEXTPREPARENUM}(n_{p_{\text{leader}}})$ 
3:    $\text{SEND}(\forall n \in \text{chain}, \langle \text{PREPARE}, \text{max}_{\text{ack}} + 1, n_p \rangle)$ 
4:   upon receive  $\langle \text{PREPARE}, n_i, n_p \rangle$  from  $r$  do:
5:     if  $n_{p_{\text{leader}}} \leq n_p$  then  $\triangleright$  Has not seen higher prepare
6:        $\text{UPDATELEADERINFO}(\text{leader}, n_a)$   $\triangleright$  New accepted leader
7:        $\text{insts}_{\text{accepted}} = \text{GETACCEPTEDINSTSFROM}(n_i)$ 
8:        $\text{SEND}(\text{node}, \langle \text{PREPARE\_OK}, n_i, n_p, \text{insts}_{\text{accepted}} \rangle)$ 
9:
10:  upon receive  $\langle \text{PREPARE\_OK}, n_i, n_p, \text{insts}_{\text{accepted}} \rangle$  from  $\text{rep}$  do:
11:    if  $n_{p_{\text{leader}}} \leq n_p$  then  $\triangleright$  Has not seen higher prepare
12:       $\text{REGISTERPREPAREOK}(n_i, n_p, \text{insts}_{\text{accepted}})$ 
13:      if  $\text{HASPREPAREOKQUORUM}(n_i)$  then  $\triangleright$  Became leader
14:         $\text{amLeader} \leftarrow \text{true}$   $\triangleright$  Can now start new instances
15:        for  $(a_{n_i}, a_{n_a}, a_{\text{val}}) \in \text{ACCEPTEDINSTSFROM}(n_i, n_p)$  do
16:           $\text{SEND}(\text{self}, \langle \text{ACCEPT}, a_{n_i}, \text{self}, n_p, \text{req}, 0, \text{max}_{\text{ack}} \rangle)$ 
17:           $\text{max}_{\text{acpt}} \leftarrow a_{n_i}$ 
18:
```

previously used by any replica. We use $\text{max}_{\text{ack}} + 1$, since it guarantees that previous instances have already been accepted by every node, and all messages regarding those instances can be discarded. As such, nodes only need to maintain the single highest prepare number $n_{p_{\text{leader}}}$ ever received (instead of keeping a prepare for each instance). Since *prepare* messages need to have unique prepare numbers, this number includes an identifier of the node which is used to make sure that no two *prepare* messages from different nodes have the same n_p .

A *prepare* message for a given instance is rejected if the node has already seen a higher prepare number for any instance (either on *prepare* or *accept* messages). Otherwise, the usual Paxos logic is executed for this and all higher instances, with the corresponding *prepare ok* message being returned, which includes all previously accepted values (and corresponding prepare numbers) for the instance indicated in the *prepare* message and all following instances (Alg. 4, line 8). This is necessary as a successful prepare also makes the node the leader of all future instances. From this point until a *prepare* with an higher prepare number is received, the sender of the *prepare* message will be set as the supported leader $c_{s_{\text{leader}}}$ and all pending and future client requests will be redirected to it (Alg. 3, line 12).

Upon reception of a quorum of *prepare ok* messages (Alg. 4, line 13), the node considers itself the new leader. It then executes the regular Paxos logic, but for multiple instances: for all instances for which accepted values exist, it uses the value with the highest associated prepare number as its proposal for that instance, and forwards the corresponding *accept* message over the chain. The regular protocol execution then resumes. In Annex A, we discuss in more detail the correctness of leader election and reconfigurations.

Adding a new replica: For adding a node n to the chain, n sends a request to a replica with $\text{AddNode}(n)$ operation as its value. The leader processes this request by starting an instance that is executed as any other instance of ChainPaxos.

When the instance is decided, the node is added to the

tail of the chain updating the local chain configuration (variables *chain* and c_{nextok}). Once the new node is added, it requests the current state (history of operations or snapshot) from another node at the instance in which the operation to add the node was decided. While this state transfers in the background, the new node can already participate in the following instances actively forwarding messages (although it can only locally execute and garbage collect operations after the completion of the state transfer).

4 Local Linearizable Read Operations

In this section, we discuss our proposal to execute read operations. As we mentioned previously, in Chain Replication, due to the use of an external coordination service, reading from the tail does not provide linearizable reads in the presence of network partitions, as the tail might become partitioned and not be aware that it was removed from the system. Guaranteeing linearizable reads requires contacting the external configuration service, which defeats the purpose of the low overhead achieved by only contacting the tail. Due to similar issues, most SMR protocols only support linearizable reads by executing them as normal consensus operations or, in some cases [5], by contacting a quorum of replicas (and falling back to executing the read as a normal operation when conflicts occur). We now discuss how we leverage on the chain topology and our integrated membership management to provide linearizable reads without any added communication cost.

To provide linearizable reads, it is necessary to guarantee that the result of a read reflects a state that, at the moment the read is received, is at least as recent as the most recent state for which any node has returned a result (either for a read or for a write). The base intuition of our proposal is that a node can guarantee this property by waiting for a message to loop around the entire chain, making sure that the local node is as up-to-date as any node was at the moment the message started looping around the chain.

Based on this intuition, our solution for linearizable reads works as follows. Clients issue read operations to any replica in the chain. Upon receiving the operation, the replica locally registers that the operation depends on the lowest unseen consensus instance (but no information is sent to other nodes). For instance, if the highest instance that the replica has seen so far is 6 (regardless of it being decided or not), the read operation will depend on instance 7. Upon receiving the *accept ack* message to the consensus instance for which the operation depends on, the read operation is performed locally in the local committed state and the reply is sent to the client.

This protocol implements linearizable reads by enforcing the following properties: **i)** a read r returns a value that is at least as recent as any value outputted by the protocol at the moment the read was received. By waiting that the following consensus instance is acknowledged and executing the read in the current local state, a replica is assured that the result of any read that was returned at any replica before the reception

of r cannot be more recent than the result that will be returned for r – this follows from the properties of ChainPaxos, which guarantee that as messages loop the chain they make the state of replicas advance, so that the following replica in the chain is in a state that is at least as recent as the previous replica. As such, if some replica has already returned a value for state s_i , by waiting that the following consensus message is acknowledged, which requires a full loop of an operation through the chain, the local replica state will be at least as recent as s_i . Due to the same reason, the result of a read will also reflect the result of any committed write operations, at the moment the read was received; **ii**), upon a reconfiguration, a node that is partitioned from the chain will not return stale values: when a replica loses connection to the others, either it is eventually removed from the chain, preventing it from ever replying to client read operations or it eventually reconnects to the other nodes, allowing it to continue responding to read requests. In the latter case, since the replica was not removed from the chain, no progress was made while it was partitioned, thus linearizability is not lost.

Our proposal trades a potentially higher latency (compared to executing a read as a normal operation) for the possibility of processing a read locally at any node, without additional consensus instances or communication steps. This leads to lower communication and processing overhead, and allows to balance the load of read operations across all replicas, leading to better overall performance. Under low load, write operations may be less frequent, which could delay read operations. We note however, that the head of the chain issues periodic *NoOP* operations if no write is received, as to show to the other replicas that the head is still correct, hence the maximum latency of reads in scenarios with a low load will be controlled by the frequency of these *NoOP* operations. Alternatively, to ensure faster read processing, a replica processing a read which has not received the message for the next consensus instance after some configurable timeout can forward the read to the leader to be executed as a normal operation (which in turn will allow other pending reads to complete).

5 Evaluation

This section reports the experimental evaluation of ChainPaxos in a broad range of scenarios. We start by assessing the performance and scalability in CPU-bound and network-bound settings (Section 5.2), and the impact of our novel read protocol (Section 5.3), using a replicated key-value store application under the YCSB workload [7], when compared with other consensus protocols. Then, we report the results of integrating ChainPaxos with ZooKeeper [12], by replacing the Zab [14] replication protocol (Section 5.4). Finally, we study how ChainPaxos behaves in a geo-replicated setting (Section 5.5) and the impact of reconfigurations in our integrated membership when compared to using an external coordination service (Section 5.6).

We have implemented a prototype of ChainPaxos in Java,

using a framework for building distributed protocols, Babel [9], which relies on the Netty [1] framework for the communications module. Similarly to other authors [8, 26], to guarantee fairness in our comparisons, the other consensus protocols were implemented using the same codebase as ChainPaxos. This guarantees that the results are not influenced by specific implementation aspects, such as the programming language, client communication patterns or differences in optimizations (such as batching). Each protocol was implemented following the description presented in their respective publications as well as available code bases for EPaxos [25] and Ring Paxos [23]. For the latter, as proposed by the authors, we limit the number of concurrent instances the leader can start as a form of flow control to mitigate the loss of multicast messages and include a mechanism for recovering from lost messages.

Each replica includes: an application (either the replicated key-value store or Zookeeper), which receives client requests, submits them for ordering, and replies to the client when the operation is executed; a proxy, serving as the intermediary between the application and the consensus protocol, also redirecting operations to the consensus leader when applicable and; the consensus solution itself, which receives operations from the proxy and notifies it once their ordering is decided.

5.1 Experimental Setup and Parameters

The experiments were conducted on the Grid5000 testbed [3], using a cluster of machines with an Intel Xeon Gold 5220 CPU with 18 cores and 96 GiB DDR4 RAM. Machines are connected through a 25 Gbps Ethernet switched network. Each replica executes in its own machine, and clients (running YCSB [7]) execute on 3 independent machines (with multiple client threads per machine). Each client thread connects to a replica for executing operations in a closed-loop.

Every protocol is executed in similar conditions, with the exception of Chain Replication that uses Zookeeper as the external management service (following [33]). For all protocols, the leader is elected at the start of the experiment and the protocols run multiple consensus instances in parallel. All results are the average of 5 independent runs, discarding the start and end periods of each experiment. In all results presented, the standard deviation between runs is always below 10%.

In addition to ChainPaxos, Chain Replication [33], and Ring Paxos [28], we report as: *EPaxos*, the execution of EPaxos [26] in a workload where all operations conflict (which is the same case of other baselines); and *EPaxos-NoDep*, the execution of EPaxos in a workload where no two operations conflict, which is equivalent to running multiple independent Paxos instance in parallel. We note that this is an unrealistic workload, as it would require all operations to be independent from each other, being presented only to provide the best (theoretical) results for a protocol following the strategy of EPaxos. *MultiPaxos* refers to the variant of Multi-Paxos [16] where acceptors forward their *accept ack*

Figure 4: Performance for operations with 128 bytes (CPU bottleneck).

messages to all replicas, whereas *Multi-1Learn* represents the variant where acceptors only send the *accept ack* to the leader that, upon collecting a quorum of replies, issues a *decided* to all replicas - this protocol has a message flow equal to Raft [27] in the normal case. *U-Ring Paxos* [13] is a variation of Ring Paxos, using unicast instead of multicast, with a message flow similar to our solution and Chain Replication.

5.2 Performance in a Single Data Center

This section reports the results obtained in a single data center, running the YCSB benchmark with a replicated key-value store application. We study scenarios that attempt to saturate the CPU and the available bandwidth, by varying the size of the data stored in the key-value store.

CPU Bound. Figure 4 shows the performance of each protocol in a CPU-bound scenario. For this experiment, clients execute small (128 bytes) operations and no batching is employed (i.e., each operation is executed in an individual consensus instance). Clients connect uniformly at random to a replica, and receive a reply after the operation is executed in that replica. While this does not provide optimal latency for some solutions, it maximizes throughput by distributing the load of handling client requests as much as possible.

These results show that, by pipelining a single message per each operation through all replicas, ChainPaxos minimizes CPU usage, achieving the best performance and scalability. Chain Replication and U-RingPaxos perform worse, as they propagate some extra messages: acknowledge messages in the former, and proposals being propagated to the leader through the chain in the latter. These messages could be batched or piggybacked with a small penalty to latency. We note that the throughput of ChainPaxos with 7 replicas, which tolerates 3

Figure 5: Performance with network bottleneck.

faults, is higher than that of Chain Replication with both 3 and 7 replicas, which tolerate 2 and 6 faults, respectively.

For both versions of MultiPaxos, the leader (and all replicas in regular MultiPaxos) transmits and receives messages from, at least, a majority of replicas, resulting in higher CPU usage and lower performance. The impact of this effect increases with the number of replicas. For EPaxos, when all operations need to be ordered, the algorithm requires two rounds of communication, leading to an higher number of messages and lower throughput. The execution of *EPaxos-NoDeps* is similar to executing multiple parallel MultiPaxos instances, distributing the load among replicas. This leads to an higher throughput than MultiPaxos and EPaxos that, unlike ChainPaxos, also decreases with the number of replicas, as more messages need to be processed. Furthermore, we note that *EPaxos-NoDeps* is not totally ordering all operations, as other protocols do. RingPaxos is tricky to tune, as a single lost multicast message can stall the entire system. Even for our best configuration (with 150 simultaneous consensus instances), RingPaxos performance is worse than U-RingPaxos.

Overall, these results show that lowering the number of messages processed by each replica allows to achieve higher throughput with a negligible latency overhead. Furthermore, the throughput of chain-based protocols degrades very slowly when increasing the number of replicas, while the throughput of other protocols degrades quickly, as the number of messages processed by each node depends on the number of replicas in the system. This is relevant for supporting critical systems with high availability requirements.

Network Bound. Figure 5 presents the performance in a network-bound scenario. For this experiment, the bandwidth of replicas is limited to 1Gbps, with clients issuing 2048 byte operations, saturating the bandwidth of the replicas without

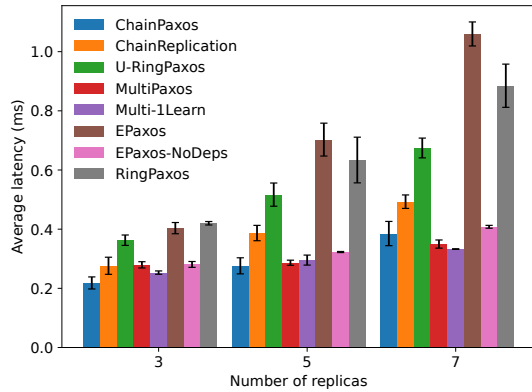

Figure 6: Latency under low load.

satürating their CPU. For saving the bandwidth consumed in redirects and maximizing the bandwidth available for the consensus protocol, all clients connect directly to the leader/head (uniformly distributed in both EPaxos variants).

Results show that ChainPaxos, ChainReplication, and U-RingPaxos, by only receiving and transmitting each operation once, achieve maximum use of available bandwidth. For these solutions, the replicas were consuming approximately 900 Mb/s of both inbound and outbound bandwidth. This allows the system to maintain its performance with an increasing number of replicas. For MultiPaxos, since the leader needs to transmit each operation to all other replicas, its bandwidth usage is disproportionately higher than that of other replicas, limiting their throughput. Furthermore, the throughput decreases with the number of replicas. EPaxos versions suffer from the same issue, but since EPaxos uses multiple leaders, it distributes the load of the leader across all nodes, leading to better scalability than MultiPaxos. *EPaxos-NoDeps* requires less communication steps, having higher throughput, but still far from ChainPaxos. For RingPaxos, the higher message size results in more frequent message losses. Even configuring the number of concurrent instances to 20 as to achieve the best results, the performance is substantially lower than that of ChainPaxos and Chain Replication.

Latency with a fixed throughput. Figure 6 shows the latency with a fixed load – clients execute 9000 operations per second, using payloads of 128 bytes. In this experiment, clients are setup to minimize latency: in RingPaxos and MultiPaxos clients connect directly to the leader; in EPaxos clients connect to all replicas uniformly; in Chain Replication and U-RingPaxos clients connect to the tail; and in ChainPaxos to the replica in the position $n/2 + 1$. Error bars present the standard deviation of the results.

The results show that, with 3 replicas, ChainPaxos and MultiPaxos variants exhibit the lowest latency, since they can respond to client requests after a single communication step. With increasing numbers of replicas, the latency of ChainPaxos increases, while the latency of both MultiPaxos variants remains mostly unaffected. Since both U-Ring Paxos and

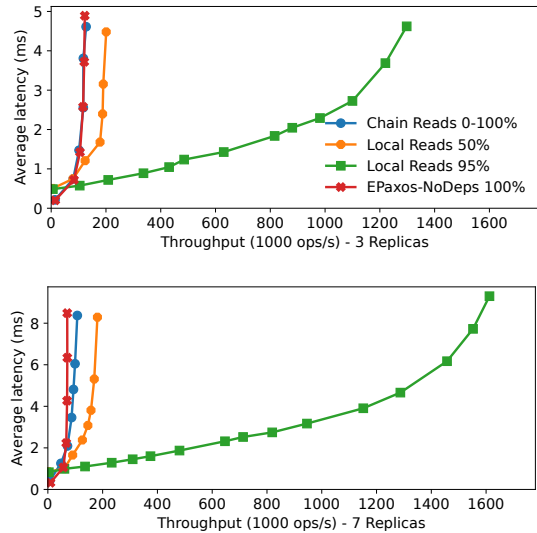

Figure 7: Performance with read operations.

Chain Replication require more communication steps until a reply is generated, their latency is always higher than ChainPaxos. We note that ChainPaxos with 5 replicas presents a similar latency to Chain Replication with 3 replicas, in which case both tolerate the failure of 2 replicas. In EPaxos, since conflicts lead to extra communication rounds, the variant where all operations conflict (*EPaxos*) naturally shows higher latency. For RingPaxos, multicast message drops (which happen even without saturation) and retransmissions lead to higher latency.

5.3 Performance of Read Operations

Figure 7 shows the impact of ChainPaxos’s novel linearizable read approach in workloads with different read ratios and payloads of 128 bytes. The throughput of executing reads as normal (consensus) operations (*Chain Reads*) is constant, regardless of the ratio of read operations. For our novel approach (*Local Read*), the throughput is much higher than executing reads as normal operations, and the throughput scales both with the ratio of read operations and with the number of replicas. This is explained by the fact that as reads impose no overhead to the consensus protocol and the load is distributed evenly among replicas, more replicas can process more reads. The high throughput of ChainPaxos’s local linearizable reads comes at the cost of a small additional latency under low load.

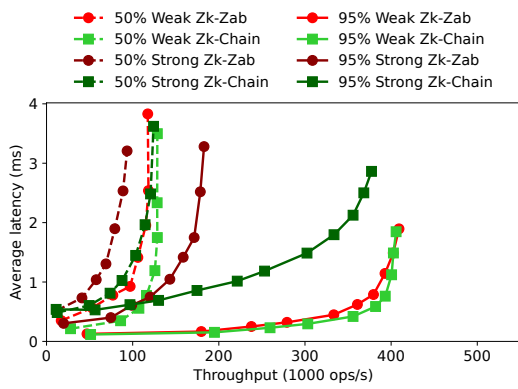

For comparison, we include the results of *EPaxos-NoDeps*, the Paxos-based protocol with best performance in the previous results. The results show that ChainPaxos achieves a significantly higher throughput than *EPaxos-NoDeps*.

5.4 Zookeeper case-study

To evaluate the performance of our protocol in a more realistic scenario, we adapted ZooKeeper [12] to use ChainPaxos as its consensus protocol, instead of Zab [14]. While some features were not implemented, such as ephemeral nodes, our implementation fully supports creating, updating, and retrieving

(a) Write-only workload

(b) Mixed workload with 3 replicas

(c) Mixed workload with 7 replicas

Figure 8: Performance of Chain-based Zookeeper vs original Zookeeper.

znodes. We evaluated the performance of our implementation (*ZK-Chain*) against the original ZooKeeper using Zab (*ZK-Zab*), in a setup similar to the CPU bound scenario of Section 5.2. The results are presented in Figure 8.

For a write-only workload (Fig. 8a), the results show that ChainPaxos achieves higher throughput than the original Zookeeper, with the difference increasing with the number of

replicas. This is due to the lower number of messages of our protocol (Zab’s message pattern is similar to *Multi-1Learn*).

Figures 8b and 8c present mixed workloads (50% and 95% of read operations), with both weak and strong reads. *Weak reads* represent the regular reads of ZooKeeper, where a replica replies with its current state, allowing for stale data to be served (e.g., with late replicas and under network partitions). *Strong reads*, in our solution, are executed using linearizable local reads. While ZooKeeper does not support linearizable reads, the authors suggest issuing a *sync* operation before a read as a close approximation of linearizability in most cases. The results show that, unlike with Zab, the strong reads with ChainPaxos scale to a throughput similar to executing weak reads. Overall, the throughput with ChainPaxos is higher than with Zab for the same setting, and the difference increases with the number of replicas.

5.5 Performance in a Geo-Replicated Setting

We evaluated our protocol in a geo-replicated setting by emulating an environment with 5 sites. Using the Linux `tc` command, we limited the bandwidth to 1Gbps, and increased latency to the following values, extracted from <https://cloudping.co>, related to AWS EC2 data centers.

Sites	A	B	C	D	E
North Virginia (A)	-	92	127	204	186
Frankfurt (B)	88	-	210	288	279
São Paulo (C)	122	207	-	338	359
Sydney (D)	211	292	325	-	161
Seoul (E)	188	287	309	156	-

In these experiments, we did not use Ring Paxos, since IP multicast is typically unavailable across data centers. The replica in site A is always the leader/head. Experiments with 3 replicas use sites A, B, and C. Clients connect to the replica that leads to the best performance: the leader for MultiPaxos; evenly distributed for EPaxos, and; the tail for chain-based solutions.

Figure 9 presents the throughput and latency when using all available bandwidth. As within a single data center, ChainPaxos, Chain Replication, and U-Ring Paxos are able to make optimal use of available bandwidth, providing higher throughput than other protocols that order all operations. The EPaxos variant without inter-operation dependencies is able to maintain its throughput with a varying number of replicas, since the cost of transmitting each operation to all nodes is divided among the multiple leaders. However, we remind the reader that this configuration of EPaxos provides weaker guarantees than the other alternatives. As for latency, the latency of the chain-based solutions degrades as the number of replicas increases, as it takes longer for the messages to traverse the chain. For a high number of replicas, MultiPaxos variants provide lower latency, as communication between the leader and other replicas proceeds in parallel, although with, at most, half the throughput of ChainPaxos.

(a) 3 Replicas

(b) 5 Replicas

Figure 9: Performance in geo-replicated setting.

5.6 Impact of Reconfiguration

In our final experiment we evaluate the impact of reconfiguration, comparing ChainPaxos that uses its own integrated management mechanism and Chain Replication that uses an external management scheme based on Zookeeper (executing on dedicated machines). We conduct these experiments in the geo-replicated scenario with independent Zookeeper instances at sites A, B, and D. This distribution minimizes latency for replicas without a local Zookeeper replica. We used 1s timeouts to suspect the failure of another node (both in ChainPaxos and in ZooKeeper).

Experiments run for 90 seconds. Every 10 seconds the following reconfiguration events occur (denoted by vertical red lines for replica failures and green lines for replica additions): 10s) the tail node fails; 30s) the middle node fails; 50s) the head/leader fails; 70s) the head and middle replicas fail simultaneously. Replicas are added at 20s, 40s, 60s, 80s, in sites where a replica had previously failed. Clients issue operations to a random active replica to distribute the load.

Figure 10 shows the throughput observed during the experiments. Despite Chain Replication using additional resources (3 extra machines executing Zookeeper), it takes more time to perform a reconfiguration than ChainPaxos, particularly when

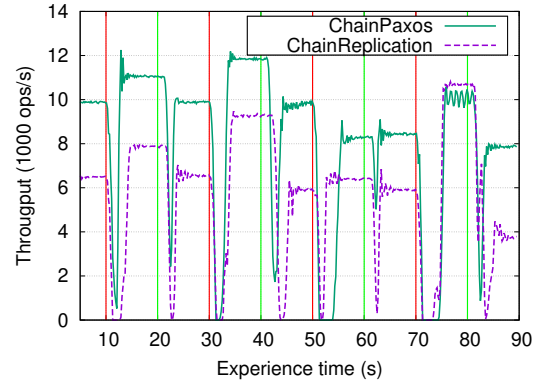

Figure 10: Reconfiguration

adding replicas to the set (green vertical lines). This happens because any reconfiguration has to be coordinated through Zookeeper. However, ChainPaxos takes longer to perform the reconfiguration when the leader fails because it resorts to the regular communication pattern of Paxos, whereas Chain Replication only fetches the new leader from Zookeeper. When the leader and middle nodes fail simultaneously (70s), both solutions take the same time to perform reconfiguration because ChainPaxos can handle both reconfigurations in parallel (albeit using two operations), whereas Chain Replication performs two sequential reconfiguration steps with Zookeeper. In general, ChainPaxos handles reconfiguration faster than Chain Replication without the cost of requiring additional machines to run the external management system, while avoiding the vulnerabilities to network partitions that can compromise the safety of the system [2].

6 Final Remarks

This paper presented ChainPaxos, a distributed consensus algorithm for high throughput replication of deterministic services. ChainPaxos exploits a pipeline communication pattern which allows to reduce the number of messages that each replica needs to send and process, while leveraging the foundations of Paxos to allow leader exchanges. Unlike previous solutions that exploit this communication pattern, ChainPaxos relies on a novel approach to execute linearizable read operations without incurring in any additional communication cost. Finally, ChainPaxos integrates membership management within the protocol. The fully specified algorithm fills an empty space in the literature and, unlike many recent proposals, decouples the fault-tolerance of ChainPaxos from that of the external coordination service. Our extensive evaluation shows that ChainPaxos achieves higher throughput and better scalability when compared to state-of-the-art solutions. Furthermore, our approach for executing linearizable reads has a huge impact on scalability. The results illustrate the benefits of our solution in the context of a key value store and the Zookeeper coordination services (where ChainPaxos leads to better performance than Zab).

A Correctness

In this section, we present the correctness argument for ChainPaxos, by showing that the execution of an instance of ChainPaxos is equivalent to an execution in Multi-Paxos. We consider the following cases: (i) an instance where all nodes agree on the leader; (ii) an instance that elects a new leader; (iii) instances following a new leader election; and (iv) instances where a replica is removed or added.

A.1 All nodes agree on the leader

This case is the one described in Section 3.3. In Multi-Paxos, an equivalent run would consist in: (i) the leader sending the *accept* message to all replicas; (ii) each node replying with an *accept ack* message to the leader that learns the decided value; (iii) the leader informing all other nodes of the learned value.

In ChainPaxos, the *accept* message is also sent to all nodes, but instead of being sent directly it is sent indirectly as the *accept* message is forwarded across all nodes of the chain.

The *accept* message also encodes the *accept ack* messages of the nodes through which it passes. When the leader receives the *accept ack* message from the tail of the chain, this message is equivalent to having all nodes sending the *accept ack* message to the leader in Multi-Paxos.

Piggybacked in the following *accept* messages (even for the NOOP request), the leader sends to all other nodes information that it has received the *accept ack* from all nodes of the chain (m_{ack} in *accept* message), which is equivalent to forwarding the learned value to all replicas in Multi-Paxos.

As messages are used to update the local state using the same logic in both ChainPaxos and Multi-Paxos, the execution of an instance in ChainPaxos is equivalent to the execution of an instance in Multi-Paxos.

A.2 Instance with a leader election (two-phases)

We start by considering the effects of an instance executed with the two phases of the Paxos protocol. In this case, the first phase of both protocols is identical – ChainPaxos uses the same message flow as Paxos, since *prepare* and *prepare ok* messages are sent directly between the node starting the prepare and all other replicas. The logic to process the *prepare* message in ChainPaxos differs from Multi-Paxos in the following aspect: ChainPaxos only acknowledges *prepare* messages for a given instance with prepare numbers higher than any prepare number used by any other leader in any other instance. The only implication of this is that the replica executing the prepare, might time-out several times. This is not different from Multi-Paxos, where the replica will complete the prepare in the current instance, and then, if any other following instance had already been executed by a different

leader (potentially using the special prepare number zero), it would have to repeat the prepare phase for each such instance. This is true because in ChainPaxos the prepare number is continually used by a leader in all subsequent instances after the one in which it complete the prepare phase successfully.

The second phase of ChainPaxos consists in sending the *accept* message to all nodes. As explained in the previous case, ChainPaxos flow of messages is equivalent to the Multi-Paxos flow of messages. As the logic employed to process the messages is the same as in Multi-Paxos, also in this case, the execution is equivalent to that of an instance of Multi-Paxos.

A.3 Instances following a new leader election

When a new leader is elected, by running the first phase of Multi-Paxos for instance n_i , it becomes the leader of all instances n_j such that $n_j \geq n_i$, for which it will subsequently issue *accept* messages through the chain (in order). To prove the correctness of ChainPaxos, we show that this execution is equivalent to running the two phases of the Paxos protocol for all instances n_j , such that $n_j \geq n_i$.

The processing of the *prepare* message ignores the prepare if the node has seen an higher prepare number employed by another leader (for any instance). If the prepare is not ignored, it runs the Paxos logic for all instances n_j , such that $n_j \geq n_i$, with the *prepare ok* message including the information relative to all these instances. This information includes any accepted value for each of those instances and the prepare number associated with that accepted value. The processing of the *prepare ok* message also executes the Paxos logic for all instance $n_j \geq n_i$, such that the new leader will send new *accept* messages for all those instances (in order) where, if there was already a value accepted by any replica for that instance, the new leader will propose that value and, similar to Multi-Paxos, if more than one value had been accepted by different replicas, the leader proposes the value with the highest associated prepare number. This ensures that for every instance $n_j \geq n_i$, if some value had already been accepted by a majority of replicas, then the new leader will propose that value with his current propose value.

Thus, executing the first phase of the Multi-Paxos in ChainPaxos for instance n_i and issuing the *accept* for all instances n_j , such that $n_j \geq n_i$ as described above is equivalent to executing the two phases of the Paxos protocol for all instances n_j , such that $n_j \geq n_i$, thus ensuring the correctness of ChainPaxos.

A.4 Leader Conflicts

As in Paxos, it is possible that two nodes receive a quorum of *prepare ok* messages for different prepare numbers concurrently. In this case, *accept* messages from the node with the lowest prepare number will be dropped during their propagation and will never be accepted by a majority of replicas.

The processing of *accept* messages also sets the leader and prepare number being used by the leader in all replicas. This is needed because a minority of replicas might have missed the *prepare* message.

If a previous leader is incorrectly suspected of being faulty, it might send *accept* messages for instances $n_i \geq n$ while a new node becomes leader in instance n . In this case, just like in regular Multi-Paxos, there are two possible scenarios for each instance n_i : **i)** the *accept* message of the previous leader reached a majority of nodes (i.e., has been decided) before the *prepare* message of the new leader, in which case at least one *prepareOk* message received by the new leader will contain the value proposed by that *accept* message, and the new leader will simply propose that same value; **ii)** the *accept* has been “cut-off” by the *prepare* message of the new leader (i.e., a node in the chain rejected the *accept* after receiving the *prepare* with an higher sequence number). In this case, the new leader may or may not receive the value proposed by that *accept* in a *prepareOk* message. Regardless, since the instance had not been decided, both alternatives are correct.

A.5 Removal and addition of a replica

We now discuss the correctness of ChainPaxos when reconfiguring the system to either remove or add a replica, which has been presented in Section 3.4. Such reconfigurations resort to special SMR operations which have to be ordered by ChainPaxos and executed by replicas. A challenge that is present in such reconfigurations is that the number of replicas that constitute a majority of the system might change due to the execution of these operations.

In ChainPaxos, we define a minimum quorum size, and then vary the size of the quorum required to decide operations to always be a majority quorum. For instance, assuming a configuration with 5 initial replicas (where a majority quorum is 3), and a minimum quorum size of 3, adding 2 replicas (to a total of 7), would increase the majority quorum to 4. If 2 replicas are then removed, the majority quorum will be back to 3. However, due to the minimum quorum size, removal of further replicas would not decrease the quorum size below 3, which also ensures that the number of replicas in the system can never be below 3. The minimum quorum size is independent from the initial configuration, serving as a threshold below which we do not wish the system to continue functioning.

Note that in ChainPaxos no replica considers an instance as decided before knowing the operations that have been ordered in all previous instances, hence a replica will never use the incorrect quorum size to decide (and execute) an operation.

We start with the addition of a replica. To ensure correctness we need to show that the replica that is added in an instance n_i will be considered towards forming the majority of *accept ack* messages necessary to decide any instance $n_j > n_i$. This derives from the agreement property of Chain-

Paxos, which ensures that all (correct) replicas will agree on the instance in which the new replica is added to the system. Since replicas only consider an operation as decided after learning the decided values for all previous instances, no replica will ignore the participation of the new replica when deciding the value of any instance n_j , since the replica has already been added on instance n_i (i.e., the instance where the new replica is added), affecting the size of the quorums.

Regarding removal of nodes, to ensure correctness we need to show that the removal of a replica in instance n_i , makes it impossible for that replica to affect the decided value in any instance $n_j > n_i$ (i.e., the *accept ack* messages of that replica are never considered to achieve a majority in such instances). As discussed previously, the *accept* message that is forwarded along the chain, in round n_i , to remove a replica r is forwarded by the node directly before r to both r and its successor replica in the chain. Any node that receives such a message, adds r to its `marked` set. This makes that any *accept* message for a subsequent instance is never sent to r , hence r is not able to increment the counter for *accept ack* within those messages.

This happens, even if nodes have not yet locally decided the outcome of instance n_i . This could be problematic if a new leader is meanwhile elected before the outcome of this instance is locally decided (and executed) by every node, since that node could be continuously skipped despite the fact that he was never removed from the system. However, if a leader change happens, the contents of the `marked` set of replicas are removed. This is performed either when the node replies to the *prepare* of the new leader, or when it receives an *accept* message from the new leader (which can be identified locally since the *accept* message will carry a prepare number higher than the last prepare number observed by that replica). This ensures that r receives subsequent *accept* messages for the re-executions of instances $n_j > n_i$ until the leader proposes the `removeNode(r)` in some instance (assuming r remains suspected).

Finally, in the case of concurrent addition or removal of replicas to the system, we note that ChainPaxos executes each addition or removal as an independent operation. We note that the fault detection mechanism may lead replicas to incorrectly suspect other replicas (e.g. due to temporary network failures). In this case, if a replica is incorrectly removed, it can ask to rejoin the system (note that ChainPaxos tries to propagate the remove operation to the node to be removed, as it is still part of the system in that instance). Finally, we note that it is easy to minimize scenarios where replicas ask for the removal of correct replicas by having the leader avoid to either remove replicas that he perceives as active, or removing replicas that were suspected by replicas being currently removed.

B Artifact Appendix

Abstract

The artifact includes the implementation of ChainPaxos, along with the other consensus algorithms that are studied in the evaluation, with instructions on how to launch and test them. These implementations include a simple replicated key-value store that was used to benchmark the algorithms. Additionally, we include our implementation of ChainPaxos in ZooKeeper, which replaces Zab.

For reproducibility, our artifact includes the client-side code that was used in the paper to measure the various performance metrics of the algorithms, along with instructions on how to run it and how to parse and interpret its results.

Scope

The artifact allows executing our consensus algorithm, ChainPaxos, which supports different read execution techniques. Our prototype fully supports the operations related with the integrated membership. The artifact includes everything that was used in the paper: source-code of all solutions; client source-code; scripts to execute the experiments; scripts to generate the plots from the experiment logs and; instructions on how to reproduce all plots.

Contents

The artifact is divided in four parts, which are distributed across four repositories:

ChainPaxos: This repository contains the code for our full implementation of ChainPaxos. Additionally, it includes the key-value store application and the different consensus algorithms that we used to compare against ChainPaxos (in the Figures 4 to 7, 9 and 10). The repository also includes information on how to compile and deploy ChainPaxos.

The source-code in the repository is divided in multiple Java packages, with the following structure: the package *chainpaxos* contains our implementation of ChainPaxos; the code for the key-value store application is on package *app*; packages *frontend* and *common* contain some generic interfaces and classes to uniformize the interaction between the application and all consensus algorithms and; all other packages are named after the consensus algorithms that we used to compare against our solution in the paper.

ZooKeeper with ChainPaxos: This part contains our modified version of ZooKeeper that replaces Zab by ChainPaxos, that was used for the results of Figure 8. The majority of code modifications are contained in the package *chain* that is on the *zookeeper-server* module.

Client-side benchmark: This part contains all the client code that was used in the entire experimental evaluation, both to benchmark the various algorithms using the key-value store, and to benchmark the original ZooKeeper against our version with ChainPaxos. The source-code itself consists of YCSB drivers, one for the key-value store and another for ZooKeeper. The repository also includes the scripts used to perform our experiments, and instructions on how to use them in order to reproduce the results in the paper.

Results parser: Finally, our artifact includes a series of Python scripts that were used to parse the results of each experiment and generate the plots presented in this paper. The *client-side benchmark* repository contains instructions on how to use these scripts.

Hosting

The artifacts can be found in the following locations:

- ChainPaxos
 - <https://github.com/pfouto/chain>
 - master branch
 - commit [72cebf2](#)
- ZooKeeper with ChainPaxos
 - <https://github.com/pfouto/chain-zoo>
 - master branch
 - commit [65a9690](#)
- Client-side benchmark
 - <https://github.com/pfouto/chain-client>
 - master branch
 - commit [ed28200](#)
- Results parser
 - <https://github.com/pfouto/chain-results>
 - master branch
 - commit [e716e4a](#)

Requirements

While the artifact does not have special hardware requirements, all experiments were conducted in the [Grid5000](#) testbed, using the [Gros](#) cluster. The client-side benchmark repository includes instructions on how to reproduce the experiments on this cluster. Furthermore, the same repository provides instructions on how to deploy and run the experiments in any other cluster platform (e.g. on a cloud infrastructure), which requires some additional setup, but should still allow to reproduce all the results in the paper.

CBMM: Financial Advice for Kernel Memory Managers

Abstract

First-party datacenter workloads present new challenges to kernel memory management (MM), which allocates and maps memory and must balance competing performance concerns in an increasingly complex environment. In a datacenter, performance must be both good *and* consistent to satisfy service-level objectives. Unfortunately, current MM designs often exhibit inconsistent, opaque behavior that is difficult to reproduce, decipher, or fix, stemming from (1) a lack of high-quality information for policymaking, (2) the cost-unawareness of many current MM policies, and (3) opaque and distributed policy implementations that are hard to debug. For example, the Linux huge page implementation is distributed across 8 files and can lead to page fault latencies in the 100s of ms.

In search of a MM design that has consistent behavior, we designed Cost-Benefit MM (CBMM), which uses empirically based cost-benefit models and pre-aggregated profiling information to make MM policy decisions. In CBMM, policy decisions follow the guiding principle that *userspace benefits must outweigh userspace costs*. This approach balances the performance benefits obtained by a kernel policy against the cost of applying it. CBMM has competitive performance with Linux and HawkEye, a recent research system, for all the workloads we ran, and in the presence of fragmentation, CBMM is 35% faster than Linux on average. Meanwhile, CBMM nearly always has better tail latency than Linux or HawkEye, particularly on fragmented systems. It reduces the cost of the most expensive soft page faults by 2-3 orders of magnitude for most of our workloads, and reduces the frequency of 10-1000 μ s-long faults by around 2 orders of magnitude for multiple workloads.

1 Introduction

Datacenter workloads present new challenges to kernel memory management (MM). MM encompasses a large collection of kernel mechanisms and policies to allocate and map physical memory. Cumulatively, they comprise a complex set of

tradeoffs that, when poorly navigated, lead to poor performance or unexpected behavior. For example, we found that for some workloads on Linux, a soft page fault lasting 25ms occurs every 100ms. This drastic tail latency is due to memory compaction or reclamation when attempting to allocate a huge page – a misnavigated tradeoff. Many applications would violate response latency objectives if one request per 100ms takes 25ms due to a page fault. As a result, Redis, MongoDB, and others advise users to disable Linux’s Transparent Huge Page (THP) feature [2, 3, 4, 7, 50]. Table 1 lists other examples of MM policies and their potential pathologies.

The hardware and software in modern datacenters differ vastly from those in use when MM techniques were first designed. Increased memory capacities allow more workloads to run but bring challenges too: huge page management becomes more critical due to increased reliance on TLB performance, but memory fragmentation and huge page management overheads also increase with memory capacity [36]. Datacenters also prioritize *tail* latency as a key service-level metric, in addition to median latency and throughput [19]. Datacenter behavior must be consistent, i.e., low variance, without compromising performance metrics to satisfy service-level objectives and efficiency goals.

Unfortunately, current MM designs often fall short of modern computing needs by exhibiting inconsistent, opaque behavior that is difficult to reproduce, decipher, or fix. These issues come from three key limitations.

First, kernel MM must predict workload behavior in an information-poor environment. Current MM designs rely on online measurements, particularly page table access/dirty bits and the frequency and location of page faults. Unfortunately, this information is expensive to collect and low bandwidth. For example, Google uses access bits to detect idle memory [15], but other work finds them insufficient to predict TLB miss overheads accurately [38], even though they can cost up to 11% of CPU cycles to collect [15]. Other data collection mechanisms induce additional page faults [16, 24]. Recent work uses performance counters in kernelspace [38], but currently available counters are hardware-thread-oriented

Policy	Goal	Pathology
Huge Page Allocation	Reduce TLB misses and page faults	Bloat memory usage if not all memory is used; increase page fault latency if compaction is required
Eager Paging [29]	Move page fault latency to allocation time, saving time later	Bloat memory usage if not all memory is used
Background Compaction	Reduce memory fragmentation and huge page fault latency	Increase CPU overhead
Background Zeroing	Reduce page fault latency	Increase CPU overhead
Idle Page Reclamation [32, 47]	Improve memory utilization	Increase overhead to fault reclaimed pages back in; increase CPU overhead to choose pages to reclaim

Table 1: Different MM policies and their goals and pathologies

and do not provide the detailed spatial information useful for most MM policies.

Second, current MM designs often ignore the cost of various MM operations, leading to inappropriate policy decisions. For example, Linux allocates a huge page when a memory region is first touched; however, we find that allocating and zeroing a huge page costs 10^6 cycles in the best case. Thus, promoting a page that averts $\leq 10^6$ cycles worth of TLB misses and page faults actually *regresses* performance, but the kernel does not account for this cost.

Third, current MM designs are implemented as disjointly acting policies distributed throughout the kernel that are hard to debug. For example, code implementing Linux’s huge page policies is scattered across more than eight files (and numerous functions), mixed with unrelated code. Users and developers observe erratic slowdowns without indication of what causes them or how to address them. They often resort to suboptimal coarse-grain solutions, such as disabling huge pages [2, 3, 4, 7, 50]. By distributing and obscuring policy-implementing code, current kernel MM implementations make it difficult for both kernel and userspace developers to decipher system behavior. This opaque system implementation and its consequent opaque behavior is a primary obstacle to improving kernel MM performance, consistency, and debuggability.

In search of a MM design that has consistent behavior, we designed Cost-Benefit MM (CBMM). CBMM reflects that all kernel MM operations have a cost and a benefit to userspace, and it estimates them using empirically based cost-benefit models to guide MM policy decisions. By explicitly modeling cost and benefit, CBMM is more cost-aware than current designs, so it makes fewer pathologically bad policy choices. Also, CBMM augments online statistics with offline-aggregated profiles to improve the quality of information available to the kernel. CBMM simplifies policy debugging and enables incremental performance improvement by centralizing models in a new kernel component: the *estimator*. To understand and fix anomalies, one must only understand the model inputs to determine the cause of a policy decision.

Our prototype implements models for huge page promotion, asynchronous page prezeroing, and eager paging [29], based on an in-depth analysis of huge page behavior and soft page faults. At runtime, they may make use of in-built em-

pirically based assumptions (e.g., about average TLB miss latency), online information (e.g., the current number of free pages), or offline-aggregated profile information (e.g., fine-grained information about huge page benefits). We focus on *first-party* datacenter workloads – software run by service providers in their own datacenters – as they are highly controlled and relatively stable over time, allowing better profiling and modeling [1, 6, 10, 12, 27, 42, 44, 45].

CBMM improves system consistency; it nearly always has better tail latency than Linux or HawkEye, particularly on fragmented systems. It reduces the cost of the most expensive soft page faults by 2-3 orders of magnitude for most of our workloads, and reduces the frequency of 10-1000 μ s-long faults by around 2 orders of magnitude for multiple workloads. Meanwhile, it has competitive performance with Linux and HawkEye, a recent research system [38], for all the workloads we ran, and in the presence of fragmentation, CBMM is up to 35% faster than Linux on average – all while using no more huge pages than Linux or HawkEye in most cases.

2 Motivation: Evaluating Current Behavior

To quantify the extent of these challenges and inform our design, we do an in-depth analysis of two important kernel MM code paths, huge page management and page fault handling. Our experimental setup is described in Section 5.1. Full results are available [in our artifact](#).

2.1 Measuring Huge Page Benefits

Huge pages speed up many workloads, but nobody has quantified the impact of workload behavior on the amount of speedup it receives from huge pages. Thus, we measure the fine-grained benefit of huge pages as described in Section 4.1. To avoid invasive instrumentation and a detailed survey of workload implementations, we measure huge page benefits from the perspective of the kernel: for each workload, we divide the address space into 100 equally sized ranges, excluding unmapped regions, and repeatedly run the workload backing one range at a time with huge pages.

Figure 1 shows the results. Each point on the x-axis represents one range, such that the x-axis represents the virtual

Figure 1: Runtime and usermode cycles spent in page walks for each address range, normalized to no huge pages (lower is better). Note the varying y-axes.

address space. The top y-axis shows the normalized performance compared to no huge pages. The bottom y-axis shows the normalized percentage of time spent in usermode page walks (i.e., TLB misses) for loads and stores.

The impact of huge pages varies extensively between workloads. *xz* and *canneal* primarily see improvements in *load* page walk cycles from backing particular regions of the address space corresponding to hot data structures. *memcached* and *mongodb* produce noisy results because of randomness in the workload. The magnitude of impact ranges from about 0.25% in *mongodb* to almost 7% in *canneal*.

Another benefit of huge page usage is fewer page faults. We found that they have only a minor contribution to performance (e.g., less than 1.2% of execution time for *canneal*).

Also, the relationship between runtime improvement and reduction in page walk cycles is not straightforward. For all workloads, runtime improvement is loosely correlated with either load or store page walk cycles. Strong effects on either load or store page walk cycles tended to be reflected in runtime, as seen in *xz* and *canneal*, but the magnitude of that effect varies. Small changes in page walk cycles often have no apparent effect on runtime.

Discussion Huge page impact varies greatly by workload, including the type and location of impacted memory accesses and the magnitude of impact. Additionally, the relationship between page walk cycles and runtime is complex, illustrating the challenge of huge page management given the limited, low-quality information available to the kernel at runtime such as CPU performance counters and page referenced bits. For example, *dc-mix* (not depicted) benefits from backing

Flag	Description
CLR	Memory was zeroed (usually during allocation).
CMPT	Allocator used memory compaction.
FLBK	Allocator used a fallback path during the page fault.
HAFAIL	Attempted to allocate a huge page and failed.
HUGE	A huge page was mapped.
PREZ	Allocator allocated a prezeroed page (CBMM only).
RCLM	Allocator used direct reclamation.
WP	Page fault due to write to a write-protected page.
ZERO	A (shared) zero page was mapped.

(e) Subset of bitflags for page fault tracing.

Figure 2: CDF of Linux soft page fault latency by type of page fault. Not all page fault types occur in all workloads.

individual regions with huge pages, but when THP is turned on, it sees a net regression in performance due to the overhead of compaction. CBMM aims to mitigate this problem by supplying the kernel with higher-quality information.

2.2 Soft Page Fault Latency Breakdown

We instrument Linux’s page fault handler to trace sources of page fault latency. Page fault tracing allows us to characterize system-wide costs, such as the cost of zeroing memory. We identified a set of events that occur during page faults and associate each with a bitflag (Figure 2e). Our instrumentation records the total time of the page fault, the time to allocate memory, and the time to clear/copy memory contents.

We record the flags and timing of all events longer than 10^4

cycles, and a count of shorter events, allowing us to compute the proportion of all page faults with each set of flags. We exclude hard page faults from our results, as they incorporate other kernel subsystems (e.g., block I/O, file systems). Our tracing records the total time to handle a page fault, but on x86 the handler can be interrupted in favor of another task, which inflates the latency of the page fault. This is rare in most workloads except `mongodb`, which uses a userspace asynchronous I/O framework and thread pool; even though a page fault handler may be descheduled for a while, userspace requests continue to make progress because of userspace threading.

Figure 2 shows the soft page fault latency breakdown for multiple workloads. For each distinct set of flags, the CDF of page faults with those flags is plotted. Note that the x-axis uses a log scale. The plot includes samples lower than the threshold by treating them as if they all took 10^4 cycles (in reality, most are faster than that). The figure shows results on a freshly booted, unfragmented system, which represents best-case performance; we also recorded results on fragmented system, and found them significantly worse for all workloads.

The results indicate three challenges current MM designs face. First, applications trigger a wide variety of kernel behaviors. Each of the 15 flag-sets of Figure 2 is a different combination of code paths. Second, different paths have very different latencies but are relatively consistent across workloads. For example, even in this best case, a huge page consistently takes hundreds of microseconds to be allocated (`HUGE` in the figure) due to zeroing overhead. Third, many pathological code paths execute that do not benefit applications. Most notably, a huge page allocation may invoke a fallback path (`FLBK`), which transitively invokes compaction (`CMPT`) or reclamation (`RCLM`). Worse, the fallback may fail (`HAFAIL`), resulting in a base page allocation after all. In `canneal` (Figure 2a) and `dc-mix` (Figure 2d), these fallback paths can take *dozens or hundreds of milliseconds*. In contrast, an Amazon search for “DRAM” completes in only 900ms from our office.

Discussion Linux’s fallback algorithms are severely cost-unaware and make system behavior inconsistent: invoking compaction or reclamation almost certainly outweighs any benefits of using a huge page. Also, the high cost of zeroing suggests that memory prezeroing (Section 4.2) may be a useful optimization to make huge pages more useful. Currently, if an average TLB miss costs around 30 cycles, then a huge page must avert over 33,000 TLB misses to pay for itself. These results highlight the need for cost-aware MM policies.

3 Cost-Benefit Memory Management

We created the Cost-Benefit Memory Manager (CBMM), which has several goals:

- Improve kernel MM behavioral consistency,
- Match existing systems’ performance,
- Improve the debuggability of policy decisions,

- Allow incremental improvement of individual policies.

Our key insight is that all MM decisions incur a cost against and provide a benefit to userspace. For example, huge page promotion averts TLB misses but may require zeroing or compacting memory. In CBMM, policy decisions follow the guiding principle that *userspace benefits must outweigh userspace costs*. By applying this principle uniformly, CBMM significantly improves consistency over Linux and HawkEye [38], while matching their performance. We design models for three important kernel MM policies: huge page promotion, asynchronous page prezeroing, and eager paging [29].

CBMM introduces a new component, the *estimator*, to the kernel. It estimates the cost and benefit of a given MM operation whenever a policy decision is needed. If $cost < benefit$, the kernel decides to execute the operation.

The estimator makes estimates based on empirically derived cost and benefit models. Models can optionally use live metrics and/or pre-aggregated profiling information. Such pre-aggregated information can mitigate the lack of high-quality online information. Meanwhile, CBMM explicitly estimates MM operation costs, improving cost-awareness.

In current MM implementations, policy decisions are scattered across the kernel, making it difficult to coordinate their actions and difficult to debug anomalous behavior. In contrast, CBMM invokes the estimator at decision points, which predicts the cost and benefit of taking an action. This centralizes decision making and explicitly marks policy decisions points. It also makes coordination between policies easier.

A key requirement of CBMM is that the system behavior can be modeled and/or profiled. This requirement holds for many first-party datacenter workloads, which often run with high redundancy for long amounts of time [1, 6, 10, 12, 27, 42, 44, 45], giving ample opportunity to observe and instrument a workload before applying policies to them.

3.1 The Estimator

In CBMM, the MM subsystem invokes the estimator at places in the code where policy decisions need to be made. We call these places in the code *decision points*. It uses models to estimate the cost and benefit of a particular MM operation and returns the estimates to the decision point, which executes the operation if $cost < benefit$.

When a decision point invokes the estimator, it passes information to the estimator about the type and parameters of the operations. For example, the decision point would pass the address to consider promoting or a number of pages to attempt to prezero. The estimator acts as a black box that returns a cost and benefit estimate for the given MM operation and parameters. In CBMM, costs and benefits are computed in units of time saved or lost by userspace, which usually corresponds closely to user objectives. In particular, CBMM uses the *rate* of time saving/loss over some horizon, as many datacenter workloads run continuously.

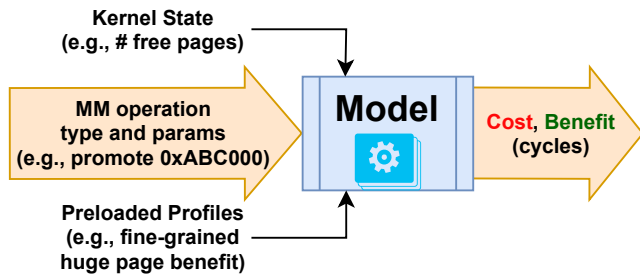

Figure 3: CBMM model inputs and outputs.

3.2 Cost and Benefit Models

Internally, the estimator comprises a collection of cost models and benefit models for different MM operations. Each model is built out of simpler submodels that estimate one cost and/or benefit well; the submodel results are added to produce the overall result. This allows reuse of submodels for different decision points, simplifying implementation and leading to more consistent behavior across decision points. For example, our huge page cost-benefit models were useful in both the page fault handler and `khugepaged`, the background promotion daemon, and our model for estimating the cost of running a daemon could be used for multiple daemons in the future.

Concretely, models manifest as C code in the estimator (in the kernel); in Listings 1 - 3 (discussed further in Section 4), we show the models in our prototype of CBMM. Each (sub)model is a self-contained black box that takes information from the decision point, combines it with information from the ambient kernel state and *preloaded profiles* – files loaded into the kernel that supply information about application-specific behavior – and outputs an estimate, as shown in Figure 3. The additional input from the kernel state and preloaded profiles allows the models to be more context-aware and to make use of higher-quality information about workload behavior.

Performance Debugging Unlike current heuristics, CBMM isolates policies to specific cost and benefit models; their inputs and outputs can be observed, and they can be improved in a single place, easing performance debugging in CBMM compared to Linux. A central idea behind CBMM’s debuggability is the ability to observe and control the inputs to models. Thus, while models can make use of any kernel or hardware state, they should use only state that has an intuitive interpretation, rather than internal implementation metrics. For example, our huge page promotion model takes into account whether any prezeroed huge pages are available and uses a profile to determine the worth of promoting a page. In contrast, internal implementation metrics give limited information about the origin of their values and how to cause them to change, making bug fixing difficult; for example, Linux’s page reclamation algorithm uses an obscure combination of page table bits, bit flags in the `struct page`, and what list a page happens to be on [9].

Model Development in CBMM can be done iteratively by beginning with a simple model and refining it as needed. For example, Listing 2 shows our asynchronous prezeroing model. Initially, we only accounted for the zeroing time of the daemon, but we found that this led to high lock contention on the allocator, so we refined the model to account for contention.

In designing our models, we found that benefits tend to be application-specific, whereas costs tend to be system-specific. For example, each application tends to benefit differently from huge pages, but the cost to allocate a huge page is application-independent and depends more on the state of the system allocator. As a result, our benefit models tend to use preloaded profiles, whereas our cost models tend to query kernel state.

Models necessarily make assumptions to simplify implementation and to make their execution cheaper than the actual MM operations. We based our assumptions on our empirical measurements, unlike many existing heuristics, which rely on intuitive simplicity or common-case optimization. For example, unlike Linux, CBMM does not blindly assume huge pages improve performance; rather, it incorporates the cost of promotion as measured by our experimental analysis and uses empirically derived profiles to estimate the benefit of promoting a particular memory region. Notably, CBMM improves system behavior even with imprecise profiles, as we will show in Section 5.5, making it practical to start with a simple model and refine it over time.

3.3 Preloaded Profiles

Different applications respond differently to MM policies, and kernels currently lack high-quality information with which to predict workload behavior. Preloaded profiles are files loaded into the kernel when starting a process (e.g., by a cluster manager) to provide models with information about a process’s behavior. They allow the estimator to benefit from offline processing for particular policy decisions. In contrast, prior methodologies resort to measuring inaccurate and expensive proxy statistics such as page fault counts or page access bits.

In CBMM, preloaded profiles specifically provide *spatial, per-process information*; that is, they provide information about regions of a single address space at arbitrary granularity as small as a 4KB page. For example, a profile may specify per-region reduction in page walk cycles from use of huge pages, or a bit indicating whether a page is likely to be touched or not. Models can query this information when making cost and benefit estimates. For example, to estimate the benefit of using a huge page, a model may incorporate the number of averted page walk cycles, or to determine whether to eagerly allocate memory or use copy-on-write, a model may incorporate information about the likelihood of memory accesses. This structure for preloaded profiles, while simple, is quite useful because many MM policies make *spatial* decisions, such as whether/how to map/unmap/remap a memory region. However, CBMM’s design is flexible enough to admit

future extensions to profiles. For example, it may be desirable to account for phases of workload activity or to apply profiles at different granularities, such as per-thread or system-wide.

Profile Management. While CBMM still has benefits even when profiles are imprecise (see Section 5.5), changes to data structures or algorithms could result in changing memory reference patterns. Thus, a natural future extension of CBMM is automating profile generation and management.

First-party datacenter workloads often run continuously and redundantly, so profiling could be automated and centralized at the cluster level. Recent work from industry suggests a trend of large-scale profiling and centralized planning [32, 35, 42] and demonstrates the feasibility of such an approach. We have done preliminary exploration and believe that the huge page methodology of Section 4.1 can be run in a distributed, automated manner by cluster managers.

3.4 System Management

We implemented models directly in the kernel source, but in principle, they could be implemented via another mechanism, such as kernel modules. Our models are application-agnostic (but can be customized if needed, like existing code), so application developers do not need kernel access. Many service providers have kernel teams that could maintain this code. Meanwhile, profiles are application-specific, and application developers can use existing configuration/deployment systems to schedule/manage/store/secure/deploy profiles without special privileges. The kernel memory overhead of profiles depends on profile resolution/detailedness. In Section 5, our largest profile is $\sim 170\text{KB}/\text{process}$ and most profiles are $< 50\text{KB}/\text{process}$.

Our implementation uses `procf`s files to load profiles, but any user-kernel communication mechanism could be used. Also, in principle one could load models through boot time configuration, similar to Facebook's SoftSKU system [42].

3.5 Discussion

CBMM addresses the (1) information-poverty, (2) cost-obliviousness, and (3) disjointed implementation of existing MM policy implementations, while other alternatives only partially address them. For example, interfaces such as `madvise` are coarse-grained, whereas workload memory access patterns can vary significantly within a region, as shown in Section 2.1. Merely disabling overly-aggressive policies, such as Linux's THP or defragmentation policies, harms workloads that require many huge pages, as we will see in Section 5. Additionally, it is difficult to modify existing policies to target different performance goals because their implementation is often distributed across many files, such as Linux's huge page policies. CBMM mitigates all three challenges by making costs and benefits explicit and centralizing policy decisions. Finally, more research is also needed to determine how

far CBMM's design can be generalized to other areas of the kernel, such as scheduling, filesystems, or I/O management.

4 Implementation

We implement CBMM based on Linux 5.5.8 for three kernel MM policies: huge page management, asynchronous prezeroing, and eager paging [29]. We implement the estimator and its models, along with related debugging interfaces, code for parsing profiles, and other infrastructure in 1159 lines of C in the kernel in a new and self-contained file. Additionally, we add 87 lines of instrumentation throughout the page fault handler and page allocator for page fault tracing (see Section 2.2). We add 10 calls to the estimator throughout the MM subsystem; each is self-contained and consists of about 10 lines of code to initialize a struct, make a function call, and respond to estimates. Asynchronous prezeroing is implemented in a kernel module from Hawk-Eye. We modify the module to run in a kernel thread and to query the estimator before running. Our version of the module is 196 lines of C. Our implementation is available at <https://github.com/multifacet/cbmm-artifact>.

4.1 Huge Page Management

Background Huge page support in current kernels can be either manual and automatic. A primary challenge is choosing memory regions to promote: the kernel must determine which memory regions would see enough benefit from huge pages.

Manual management allows applications to directly request huge pages for certain memory regions, but it requires modifying the applications, which is often impractical (e.g., Java does not expose a way to easily control memory allocation). Moreover, modern datacenter workloads are multi-programmed and diverse in behavior, requiring centralized coordination during resource allocation [31]. In contrast, automatic huge page management is a kernel feature that promotes application memory transparently to applications. This allows unmodified applications to benefit from huge pages but cannot make use of application-specific domain knowledge.

CBMM combines both the generality of automatic management and the application-specific knowledge of manual management. In contrast, current kernels either have only a manual system (e.g., Windows) or use simplistic heuristics to power an automatic system. For example, Linux's THP aggressively tries to promote on the first page fault to the huge page, potentially leading to memory bloat and increased page fault latency. FreeBSD waits for a specific percentage of the huge page to be touched before promoting. Various research systems use a mix of page access bits, performance counters, LRU lists, and trial-and-error [31, 38, 49] with mixed success.

Model Listing 1 shows CBMM's model for huge page promotion. It is used in both the page fault handler and `khugepaged` to decide whether to promote a page. We built

this model based on our analysis of huge page promotion overheads. It makes a number of simplifying assumptions when estimating both the cost and benefit, most notably that the cost is dominated by the allocation and zeroing time and that compaction and reclamation have a large fixed cost. We choose to ignore other costs in our model, such as caching, mapping changes, or potential memory bloat, but CBMM allows models to be iteratively improved over time.

```

void hpage_promo_model(u64 addr, mm_cost_delta *cost)
{
    // COST. Simplify using assumptions.
    // - Alloc is free if have free zeroed pages.
    // - Alloc cost is zeroing if have free unzeroed.
    // - Alloc cost is 2^32 if need to free mem.
    // - We don't care what node it is on.
    // - Constant prep costs (zeroing or copying), ~100us

    // `have_free_hpage` checks the allocator free list.
    const u64 EXPENSIVE = 1ul << 32; // cycles
    enum free_hpage_status fhps = have_free_hpage();
    u64 alloc_cost = fhps > fhps_none ? 0 : EXPENSIVE;
    u64 prep_cost = fhps > fhps_free ? 0 : 100*FREQ_MHZ;
    cost->cost = alloc_cost + prep_cost;

    // BENEFIT = averted TLB miss cycles from profile.
    cost->benefit = compute_hpage_benefit(addr);
}

```

Listing 1: CBMM huge page cost-benefit model.

Profiling Our methodology generates for each workload a mapping from virtual memory regions (i.e., ranges of virtual addresses) to the number of averted usermode page walk cycles when the region is backed by huge pages. We modify the Linux kernel to give precise control over promotions. We then repeatedly run a given workload varying the set of promoted pages. We additionally run the workload with no huge pages as a baseline. We use hardware performance counters to measure the number of TLB misses, the number of cycles spent in pages walks, and the overall cycle count for kernelspace and userspace execution. We then take the difference in overhead and overall runtime between any given set of pages and the baseline. The size of the sets of promoted pages can be varied to tradeoff profiling time with precision. Our prototype uses the offset into allocation zones instead of virtual addresses, so that profiles tolerate Address Space Layout Randomization.

Broadly, we found that our workloads could be categorized as *high-processing* or *low-processing*. *High-processing* workloads, such as `xz`, `canneal`, or `mcf`, heavily process their input data to produce internal data structures; their memory access patterns are driven by computation over these data structures. *Low-processing* workloads, such as `memcached`, `mongodb`, and `dc-mix` (see Section 5.1), often do little more than data storage and retrieval, so their access patterns are driven by client request patterns. We found that we can reliably distinguish between high- and low-processing workloads using the skewness¹ of the distribution of averted page walk cycles. High-processing workloads often have a small number of highly-impactful memory regions, so they have a high positive skew ($skew > 2$ seems to work empirically). When generating

¹skewness is a statistical measure of distribution asymmetry.

profiles for low-processing workloads, we assigned all regions a benefit equal to the mean benefit measured empirically. For high-processing workloads, we assigned each region the benefit it individually demonstrated.

At runtime, we can supply a profile to the kernel in the form of a CSV file that lists virtual address ranges and their benefit from huge pages. Our implementation aims to demonstrate the potential of our approach while remaining simple to implement. We do not attempt to account for phases in workload behavior, but our design is amenable to such an upgrade in the future by repeating the profiling process at multiple points during the workload’s execution. We assume the workload size is stable but can handle other input changes; in Section 5, we use randomized inputs for most workloads.

4.2 Asynchronous Prezeroing

Background We examine *asynchronous prezeroing* as a means of improving the latency of large physical memory allocations. Asynchronous prezeroing clears free pages using a background daemon to save time during a page fault when it would slow down userspace programs. Our analysis indicates that prezeroing would reduce the cost of a huge page by almost two orders of magnitude.

Prezeroing has fallen out of favor because the primary cost of zeroing 4KB pages is cache misses, but prezeroing pages leaves them cold when users access them, so latency is merely shifted to userspace [8, 46]. Recently, Panwar et al. find prezeroing is beneficial for huge pages and use non-temporal store instructions to avoid cache pollution [38]. However, their approach requires hand-tuning to avoid excessive CPU usage or lock contention on the page allocator. CBMM adapts their prezeroing implementation with a model to determine when and how long to run, eliminating the need for hand-tuning.

Model Listing 2 shows CBMM’s model for running the asynchronous prezeroing daemon. The model makes numerous assumptions; most importantly, it assumes that CPU time is free unless taken away from userspace (i.e., the system is not idle) and that the chief costs of prezeroing are the execution time of zeroing and contention on the allocator lock, rather than cache pollution. This matches our own analysis and observations while working on CBMM. The chief benefit of prezeroing is to move zeroing overhead out of the critical path of huge page promotion. For simplicity, we assume a constant processor frequency over short time windows, even though the frequency varies.

Also, this model exemplifies CBMM’s iterative approach to building models. We started with a model that only accounted for CPU time and potential huge page allocations. As we ran experiments, we discovered the lock contention and improved the model to account for it by adding the lines labeled as `COST` of lock contention in Listing 2, resolving the performance issue. The entire process took less than a day of debugging, measurement, and implementation.

```

void prezeroing_model(mm_action *action,
                    mm_cost_delta *cost)
{
    // COST of the runtime itself... Assume:
    // - Don't care about NUMA nodes.
    // - Zeroing costs ~10^6 cycles.
    __kernel_ulong_t cpu_load = get_avenrun();
    int ncpus = num_online_cpus();
    const u64 HPAGE_ZERO_COST = 1000000;

    // ncpus > cpu load average => idle cpu, free to run.
    if (ncpus > cpu_load) {
        cost->cost = 0;
    } else {
        cost->cost = HPAGE_ZERO_COST * action->prezero_n;
    }

    // COST of lock contention. Assume:
    // - Cost of lock acquisition = ~150cyc, do it 2x.
    // - Lock is unheld for ~1ms/horizon => free locking
    const u64 UNHELD = FREQ_MHZ * 1000; // cycles
    const u64 SINGLE_CS = 150; // cycles
    const u64 crit_sect_cost = SINGLE_CS * 2; // cycles
    const u64 nfree = UNHELD / crit_sect_cost;
    cost->cost += (action->prezero_n > nfree
        ? action->prezero_n - nfree : 0) *
        critical_section_cost;

    // BENEFIT. Assume past usage predicts future usage.
    u64 recent_used = mm_estimated_prezeroed_used();
    cost->benefit = min(action->prezero_n, recent_used)
        * HPAGE_ZERO_COST;
}

```

Listing 2: CBMM async prezeroing cost-benefit model

4.3 Eager paging

Background Eager paging allocates physical memory upon user request, rather than lazily on a page fault (the default) [29]. It enables large contiguous physical memory allocations, which are easier to back with huge pages and enable useful hardware optimizations [29, 37, 40, 43, 49]. However, a drawback to eager paging is memory bloat if the workload does not use all the allocated memory [29]. Preloaded profiles unlock this optimization while avoiding memory bloat.

Model Listing 3 shows CBMM’s model for eager paging, which is invoked by `mmap` or `brk` system calls. It uses a preloaded profile to determine which subregions will be touched and assumes that the model has perfect knowledge, allowing it to ignore the cost of potential bloat. If more than one page is being eagerly allocated, we create opportunity for contiguous allocation.

```

void eager_paging_model(vm_area_struct *mmap_region,
                      mm_cost_delta *cost)
{
    // ASSUME: past usage predicts future; use profile.
    // COST: time to create new page.
    const u64 PF_NEW_PAGE = FREQ_MHZ * 10; // cycles
    struct range *ranges = prev_touched(mmap_region);
    cost->cost = len(ranges) * PF_NEW_PAGE;

    // BENEFIT: time to create new page, coalesced faults
    const u64 PF_CS = 300; // cycles
    cost->benefit = len(ranges) * PF_NEW_PAGE
        + (len(ranges) - 1) * PF_CS;
}

```

Listing 3: CBMM eager paging cost-benefit model

Profiling We profile eager paging behavior by periodically reading the `/proc/<pid>/pagemap` file while the workload is

running. This file contains information about memory mappings for the given process and allows us to detect which virtual memory regions have been faulted in. Pages that were faulted in during the execution are noted in the profile, and the model assumes they will be faulted in again in the future.

5 Evaluation

CBMM seeks to improve consistency while matching or exceeding the performance and efficiency of existing systems. We evaluate CBMM along multiple axes. First, we evaluate the page fault latency of CBMM to understand its consistency compared to Linux and HawkEye. Second, we measure the end-to-end performance of CBMM. Third, we look at the efficiency of CBMM’s use of huge pages. Finally, we evaluate the generality of our approach by looking at the sensitivity of performance to profile changes.

5.1 Methodology

Table 2 describes our workloads. They represent a variety of software behaviors and exercise the kernel in different ways. `mongodb`, `memcached`, and `dc-mix` are memory-intensive workloads common in datacenters. `mongodb` and `memcached` are data stores, and `mongodb` is I/O heavy and makes use of the page cache. `dc-mix` induces memory pressure and tries to simulate a real system in which a server, device driver, and batch job are using system resources. We drive the data stores in these workloads using YCSB [17] with different read-write ratios to increase the variety of MM behavior. `mcf`, `xz`, and `canneal` are computational workloads. We scale up the inputs of `xz` and `canneal` to use more memory. In all experiments with server applications (e.g., `memcached`, `redis`, `mongodb`), we run the client program on the same machine as the server, so as not to measure network effects. We run each workload with its default number of threads and pin all workloads to one NUMA node to reduce variation caused by NUMA effects. To reduce noise, we run each experiment 5 times and report the median results. For all workloads except `mcf` and `xz`, the input is randomized and changes between executions of the workload. For `xz`, we use the native input to generate a profile and use a custom input when evaluating performance.

All experiments run on CloudLab [41] c220g5 machines with two Intel Xeon Silver 4114 (10C/20T, 2.2 GHz, Skylake 2017), 192GB 2666MHz DDR4 ECC DRAM, and a 480GB SAS SSD. We set the CPU scaling governor to `performance`. *Unless otherwise noted, we do not tune our systems at all*; the results represent CBMM’s “out of the box” behavior.

We replace the system allocator with `jemalloc`, which is better in a datacenter setting and is used by Facebook [23]. All experiments run on CentOS 7.8.2003 with the relevant kernel. We disable Meltdown and Spectre [30, 34] mitigations, which cause severe performance degradation. We use unmodified

Workload	Description	Input	Peak Mem
xz	data compression [5]	profiling: native input, eval: custom scaled up input	150GB
mcf	combinatorial optimization, scheduling [5]	native input	3GB
canneal	simulated annealing, chip routing [13]	custom input, randomly generated each time	150GB
mongodb	KV store	YCSB driver [17], 75%W-25%R	150GB
memcached	in-memory KV store	YCSB driver [17], 1%W-99%R	150GB
dc-mix	redis (KV store), memhog (microbench., creates fragmentation), metis (in-memory map-reduce) [28]	redis: YCSB driver [17], 50%W-50%R; memhog: N/A; metis: built-in	165GB

Table 2: Description of Workloads – their behavior, inputs, and peak memory usage.

Linux 5.5.8 with Transparent Huge Pages enabled as our baseline. We configure CBMM similarly to Linux but we preload a profile of huge page benefits and eager paging, as derived in Sections 4.1 and 4.3. We also compare against HawkEye [38], a state-of-the-art research huge page management system based on Linux 4.3. We configure HawkEye as in its paper, including its prezeroing daemon. We ran experiments against stock Linux 4.3 and found that it performs within 15% of Linux 5.5.8 on average (see Figure 5). To measure page fault latency in HawkEye, which runs on a different kernel without our instrumentation, we use eBPF to instrument the `handle_mm_fault` function, which represents the main portion of the page fault handler. We found that `canneal` crashes with a segfault on HawkEye when the system is unfragmented, so we omit that experiment from results.

Fragmentation We run each workload on a freshly rebooted system and on a preconditioned system. Preconditioning aims to simulate a long-running datacenter environment by inducing external fragmentation, which hinders large physical memory allocations, such as huge pages.

We had difficulty identifying a reproducible fragmentation methodology. We attempted to reuse techniques from prior work [38, 49, 51] and also made several attempts at our own methodologies with little success; on Linux, deferred freeing of physical memory and kernel daemons such as `kcompactd` and `kswapd` cause variable results. Also, each methodology preconditions machines in a different way, none of which is obviously more realistic than the others.

For our evaluation, we choose a simple methodology derived from prior work [18, 49, 51]. We enable `CONFIG_SLAB_FREELIST_RANDOM` and `CONFIG_SHUFFLE_PAGE_ALLOCATOR` when compiling the kernel and add a `sysfs` file that triggers shuffling of the kernel physical memory free lists. To precondition the system, we reboot and then trigger free list shuffling. Then we run a program that allocates all system memory (with `mmap(MAP_POPULATE)`) and frees all but the first page of each 2MB region before sleeping for the duration of the workload. This methodology is simple and yields comparable results to other methodologies. We measure the Free Memory Fragmentation Index [25, 31, 38, 51] after preconditioning but before the workload begins. On CBMM and HawkEye, preconditioning consistently leaves around 183GB of free memory with 99% fragmentation. On Linux, half of runs experience similar results, but in the other half, deferred page freeing causes < 2GB of memory to be considered free,

Figure 4: Soft page fault tail latency distribution on each system, weighted by page fault rate. A point (x, y) on the plot indicates that a fault of latency $\geq x$ happens at an interval of $\geq y$ on average.

making it difficult to measure fragmentation.

5.2 System Behavioral Consistency

Figure 4 shows tail latency on each kernel without fragmentation (when latency should be lowest); note the log x- and y-scales. To account for differences in the frequency of page faults due to differing MM decisions, we show the average in-

Figure 5: Runtime of workloads on each kernel, normalized to Linux with THP without fragmentation (lower is better).

terval between events, rather than the percentile on the y-axis.

Unlike Linux (Figure 2d), CBMM rarely attempts an expensive fallback path (e.g., compaction or reclamation) during huge page promotion, even under fragmentation; allocation failures usually result in the allocation of base pages. CBMM often experiences more page faults than Linux or HawkEye, but as Figure 4 shows, CBMM still sees a lower rate of long page faults than they do because its cost-awareness leads to fewer pathological cases, falling back to 4KB pages instead.

Even without fragmentation, CBMM always matches or improves on the tail latency of Linux and HawkEye, often by wide margins. In `xz`, `canneal`, and `memcached`, CBMM reduces the frequency of page faults taking 10-1000 μ s by two to three orders of magnitude compared to Linux or HawkEye. In `canneal` and `memcached`, CBMM reduces the frequency of (or eliminates) all page faults slower than 10 μ s by two or more orders of magnitude compared to Linux. In `memcached`, page faults taking over 1ms are nearly eliminated, while in `dc-mix`, they are reduced in frequency from nearly constant in Linux to every 10s or longer in CBMM. `mongodb` uses a userspace asynchronous I/O framework, as previously discussed, so its page fault latencies are dominated by context switches and other userspace threads; thus, our improvements are not visible in the figure. However, the figure does show that CBMM does not regress page fault latency, and as we will see in the next section, CBMM achieves significantly better performance than Linux or HawkEye for this workload.

Under fragmentation, CBMM usually achieves even larger tail latency improvements, particularly compared to Linux. For all workloads except `mongodb`, CBMM reduces the frequency of all page faults taking $\geq 50\mu$ s by 1-3 orders of magnitude compared to Linux and up to one order of magnitude compared to HawkEye. `mongodb` performs similarly to the unfragmented case, as discussed above.

Summary CBMM improves tail latency compared to Linux or HawkEye. For multiple workloads, CBMM reduces the frequency of slow page faults by one or more orders of magnitude, especially under fragmentation.

5.3 End-to-End Performance

CBMM’s major goal is to improve consistency and the debuggability of MM-related performance issues without degrading performance. Figure 5 shows the performance of each kernel with and without fragmentation. All results are normalized to Linux without fragmentation. Note that some of the performance difference of HawkEye compared to the other systems is due to Linux 4.3 (the black bar in the figure). On average, without fragmentation, CBMM has performance comparable to Linux and better than HawkEye. On average, with fragmentation, CBMM is 7% and 30% faster than HawkEye and Linux; in fact, it is only 12% slower than without fragmentation. With minimal tuning, on average, CBMM is 13% and 35% faster than HawkEye and Linux under fragmentation.

Without fragmentation, CBMM matches or exceeds the performance of Linux or HawkEye for all workloads except `canneal`. For `canneal`, CBMM is 15% slower than Linux because our profiles underestimate the benefit of huge pages. For `mongodb`, CBMM is 9% faster than Linux because it uses significantly more huge pages.

With fragmentation, CBMM outperforms Linux and/or HawkEye for all workloads except `mcf`. `mcf` uses too little memory to induce memory pressure; thus, CBMM overestimates the cost of huge pages and uses significantly fewer huge pages than Linux. In all other workloads, CBMM matches or outperforms at least one of Linux or HawkEye, often by wide margins. In `dc-mix`, `canneal`, and `memcached`, CBMM outperforms Linux by 34%, 34% and 81%, respectively, because its cost models allow it to adapt to a fragmented context, reflecting CBMM’s focus on consistent behavior. Notably, this includes all of our datacenter workloads.

To demonstrate CBMM’s benefit to performance debugging, we tune the performance of `mcf`, `canneal`, and `dc-mix` beyond the above results. In `mcf` and `dc-mix`, CBMM underestimates the benefit of huge pages, so we adjust the benefit upward in the respective profiles. We found that `canneal` exhibits a strong tradeoff between performance and page fault tail latency. As `canneal` is a non-interactive computational workload, we optimize for end-to-end performance by adjusting the profile to more aggressively allocate huge pages for the most important memory regions. After tuning, `dc-mix` without fragmentation runs 2% faster, and `mcf` with fragmentation runs 19% faster, than without tuning, but neither has a regression in tail latencies. `canneal` runs 18% faster than without tuning (46% faster than Linux) at the expense of some degradation in tail page fault latencies. In total, the tuning effort took less than a week, most of which was spent waiting for workloads to run.

Summary CBMM’s has competitive performance with Linux/THP and HawkEye and better tail latency and more interpretable behavior. In most cases, CBMM matches or exceeds Linux’s performance. Under fragmentation, CBMM often performs vastly better than Linux or HawkEye because of its

Figure 6: Runtime of CBMM workloads with generalized profiles, normalized to Linux with THP without fragmentations (lower is better).

focus on consistent behavior. Also, CBMM is easily debuggable and tunable by adjusting profiles and/or models.

5.4 Efficiency

Allocating huge pages to memory regions that do not need them wastes contiguous memory and promotion overheads and possibly bloats memory usage. Figure ?? shows the percentage of anonymous memory used by each workload that is backed by a huge page in CBMM, HawkEye, and Linux (with THP) with and without fragmentation preconditioning.

Generally, preloaded profiles drive CBMM’s huge page usage, while HawkEye and Linux are more indiscriminate with huge page promotion. Usually, Linux attempts to use more huge pages than CBMM or HawkEye, often backing almost all memory with huge pages. HawkEye uses huge pages more efficiently than Linux, often achieving similar performance with much fewer huge pages. For most workloads, Linux still attempts to use huge pages under fragmentation, whereas CBMM and HawkEye do not, leading to significantly better tail latencies, and often better performance.

For `xz`, CBMM’s profile allows it to promote only a small but important part of the address space, so it matches Linux’s performance (and outperforms HawkEye) while using almost 80% fewer huge pages. For `mongodb`, CBMM outperforms Linux and HawkEye by using more huge pages in the absence of fragmentation and fewer in its presence, exemplifying CBMM’s cost-awareness.

Summary Despite having the most consistent behavior and sometimes better performance, CBMM often uses significantly fewer huge pages than Linux or HawkEye. By being cost- and context-aware, CBMM is more targeted in its use of huge pages, though in some cases, our profiles underestimate the benefit of huge pages.

(a) mcf

(b) xz

Figure 7: Soft page fault tail latency distribution weighted by page fault rate for different profiles. Compare to Figure 4.

5.5 Generality

CBMM has benefits even when a profile is highly imprecise, primarily by avoiding the pathological behavior of Linux. We compare three versions of profiles: the standard CBMM profile is as in Section 4.1, `perapp` assigns a single value to all memory regions in the workload equal to the average benefit of enabling THP for the workload, and `shared` is shared between all workloads and assigns a single value to all memory regions equal to the mean benefit of the `perapp` profiles.

Figure 7 shows how the different profiles affect page fault tail latency in `mcf` and `xz`. The `perapp` and `shared` profiles have minor regressions in page fault tail latencies compared to the standard profiles but still improve over Linux.

Figure 6 shows how the different profiles affect performance. In most cases, *CBMM with the simpler profiles outperformed Linux* with fragmentation, and the performance differences between the three profiles are within 5%. The `perapp` and `shared` profiles outperform the standard profiles slightly in some workloads. One exception is `mcf` under fragmentation, where both the `perapp` and `shared` profiles outperform the standard profile by 20%, similar to the tuned profile in Section 5.3, by being more liberal with huge pages.

Summary More precise profiles improve CBMM’s performance and tail latency, but imprecise profiles still have good results. Furthermore, profiles can be used to trade off performance and page fault latency.

5.6 CBMM Models

We evaluate the contribution of each model in Section 4 via three configurations of CBMM: `huge` enables only the huge page model, `async` additionally enables prezeroing, and standard CBMM enables all three models. Figure 8 shows the performance of these configurations, while Figure 9 shows tail latency for `mcf` and `xz`.

Figure 8: Runtime of CBMM workloads when enabling more models, normalized to Linux with THP without fragmentations (lower is better).

Figure 9: Soft page fault tail latency impact of different models. Compare to Figure 4.

Each policy provides benefits in different settings. The huge page model alone (*huge*) captures most of the performance benefit of CBMM because it prevents costly huge page allocations. Asynchronous prezeroing (*async*) decreases page fault tail latency by making huge pages cheaper. It also reduces performance slightly on an unfragmented system, where free pages abound, because prezeroing is wasted work. With fragmentation, prezeroing has little effect on performance.

Eager paging does not directly benefit performance but enables larger contiguous allocations where hardware supports it [29, 37, 40, 43, 49]. To evaluate how well CBMM can make large allocations, we compare the number of eagerly allocated regions and peak memory usage of CBMM with eager paging against Linux with `MAP_POPULATE`, the `mmap` flag that eagerly maps memory. In all workloads, regardless of fragmentation, CBMM uses eager paging for nearly the entire working set of the workload. Thanks to profiles, CBMM has $< 1\%$ memory bloat – 3%-48% less memory than `MAP_POPULATE` would use.

Summary CBMM’s huge page model provides significant tail latency (and often performance) improvements. Asynchronous prezeroing enables more huge page usage under

fragmentation, but has a modest cost on unfragmented systems. Eager paging has a modest performance cost but enables more contiguous memory allocation.

6 Related Work

Performance consistency at scale is a well-known problem [19] afflicting, among other systems, cluster computations [20] and distributed caching [11]. Redundancy is a common workaround [20]. MittOS uses deadline-aware kernel APIs to improve tail latency [26]. Like MittOS, we seek to fix consistency issues rather than mitigate their impact.

Kwon et al. observe that current huge page support is “a hodge-podge of best-effort algorithms and spot fixes” [31]. They and others identify real concerns and improve performance but often at the expense of increasing kernel heuristic complexity [14, 31, 38, 39, 49]. CBMM tames the increasing complexity of MM policy decisions by consolidating it in one place and reducing anomalous behavior.

VMware ESX Server explores MM techniques based on economic models by quantifying the value of idle memory and “taxing” processes for it [47]. Google and Meta both track and reclaim cold memory from processes, too [15, 32, 48]. Google’s system centrally and empirically coordinates content migration to far-memory tiers (e.g., compressed memory) [32], while Meta’s system relies on better metrics and acts locally on each machine. Google also profiles the lifetime of allocations to decrease memory fragmentation [35]. These approaches inspired our work; they use empirical measurements and MM-wide guiding principles to make MM decisions. Our work extends and generalizes this idea. Sriraman et al. take a step in this direction by comprehensively profiling Meta’s workloads and using the profiles to guide coarse-grained boot-time system tuning [42].

There is much prior work on asynchronous prezeroing of pages [8, 21, 22, 33, 38, 46]. Recent work observes that larger page sizes and non-temporal store instructions make prezeroing useful again [38]. We demonstrate the usefulness of our approach by quantifying zeroing costs and the prezeroing implementation, and integrating them into our prototype.

7 Conclusion

Modern computing needs are placing new demands on kernel MM. To meet these demands, kernel MM must begin to prioritize behavioral consistency and debuggability. We propose CBMM, a MM system that uses cost-benefit analysis to make policy decisions. Despite using relatively simple models in its cost-benefit estimation, CBMM’s principled approach to MM allows matching the performance of existing systems while also improving system behavioral consistency. CBMM paves a way for kernel MM behavior to become less opaque, unlocking further performance and optimizations in the future.

A Artifact Appendix

Abstract

In order to aid future research and facilitate the reproduction of our work, we open-sourced our artifact, which is available at <https://github.com/multifacet/cbmm-artifact>. Our artifact includes both the CBMM kernel, which is a modification of the 5.5.8 Linux kernel, and our tooling for running the experiments discussed in the paper. The [README.md](#) file in the artifact contains detailed instructions for running each experiment in the paper and reproducing the results and plots therein.

Scope

Running the experiments as specified in the [README](#) on similar hardware to our own setup (described in Section 5.1) should allow the reviewer to generate comparable results to those in the accepted version of the paper.

Specifically, our paper's key claims are:

- CBMM improves page fault tail latency, our measure of MM system behavioral consistency, compared to Linux and HawkEye (Figures 2 and 4).
- CBMM does not regress application runtime, and under fragmentation can often significantly improve runtime compared to Linux and/or HawkEye (Figure 5).
- CBMM often uses huge pages more frugally than Linux or HawkEye despite getting better tail latency and comparable (or better) performance (Figure 6).
- CBMM has benefits even when profiles are imprecise (Section 5.5, 5.6).

Because running all experiments is time and resource intensive, we provide a screencast and intermediate results for the reviewers. This should allow generation of checkable partial results in a reasonable amount of time.

Contents

This artifact contains:

- [README.md](#): contains instructions for how to use the artifact.
- [paper.pdf](#): the accepted version of the paper, without any modifications responding to reviewer requests.
- [cbmm/](#): a git submodule containing our primary artifact, the CBMM kernel, which is a modified version of Linux 5.5.8.
- [cbmm-runner/](#): a git submodule of our runner tool, which runs our experiments.

- [profiles/](#): a set of profiles we used in our evaluation. More info is available in the [README](#).
- [scripts/](#):
 - Convenience scripts for running experiments (more in "Detailed Instructions"),
 - Scripts for processing experimental output into a consumable/plottable form,
 - Scripts for plotting experimental results to generate the figures from the paper.
- [figures/](#): copies of the figures from the paper.

Hosting

Our artifact is hosted on GitHub at <https://github.com/multifacet/cbmm-artifact>. Git tag [atc22ae](#) specifies the version submitted for review, but more recent versions of the [main branch](#) contain helpful additions, such as additional figures not included in the paper for lack of space.

Requirements

Reviewers will need a machine with specs similar to Section 5.1:

- 192GB DRAM
- Multiple cores
- \geq 50GB free disk space
- Running Centos 7
- Can install the CBMM kernel in place of the existing Linux kernel
- Internet connection

They will also need any other Linux machine that can connect to the first machine via passwordless SSH. This machine drives the experiments to run on the first machine.

They will also need access to SPEC 2017 ISO, which we cannot provide due to licensing constraints.

Full details are in the [README](#).

EPK: Scalable and Efficient Memory Protection Keys

Jinyu Gu, Hao Li, Wentai Li, Yubin Xia, Haibo Chen

Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China
Institute of Parallel and Distributed Systems (IPADS), SEIEE, Shanghai Jiao Tong University

Abstract

As a hardware mechanism for facilitating intra-process memory isolation, Intel Memory Protection Keys (MPK) has been leveraged to efficiently improve the isolation, security, or performance of the software. However, it can only support 16 isolated memory domains, which significantly limits its applicability in many scenarios.

In this paper, we present EPK which leverages off-the-shelf virtualization hardware features to extend the number of available protection domains in MPK. To demonstrate the effectiveness of EPK, we apply it in three scenarios, including better memory isolation for server applications as well as Non-Volatile Memory (NVM) applications, and a fast Inter-Process Communication (IPC) mechanism for microkernels. The evaluation results show that EPK can scale to provide hundreds of isolated domains. It can outperform the state-of-the-art (libmpk) by up to two orders of magnitude and usually achieve 95% of the performance of the system with no memory isolation.

1 Introduction

Intel MPK [7] has attracted many researchers since introduced in 2019 because it offers highly-efficient intra-process memory isolation by supporting memory domains inside one application. An application can switch between different domains with a new instruction, *WRPKRU*, which can execute in the user mode directly and takes only about 28 cycles. Compared with traditional software isolation or page table based isolation, MPK can achieve much lower performance overhead, and has been adopted in many scenarios, including: 1) enhancing the isolation between different threads of the same process by giving them different domain views [13, 55, 57]; 2) hardening the security of an application by separating different components, such as untrusted third-party libraries, into different domains [24, 40, 44, 46, 50]; and 3) improving the performance of software that uses multiple page tables for isolation by substituting domains for page tables [22, 29].

However, the small number (16) of isolated memory domains supported by MPK severely undermines its usability. First, typical server applications usually serve for more than 16 clients concurrently, and it is preferable to store clients' private data in isolated domains to prevent sensitive data leakage due to vulnerabilities like Heartbleed [5]. Second, there is a growing interest in protecting persistent memory [6] data from accidental or malicious accesses [56, 57]. Long-lived persistent data is usually directly mapped into processes and then accessed via load/store instructions. Isolating the data in more domains can reduce the data exposure time and benefit stray access protection. Third, both applications and system software may contain more than 16 components that need to be isolated. For example, popular applications use scores of third-party libraries [2]; an OS consists of tens or hundreds of modules like device drivers. Besides, prior studies also indicate the performance of NVM applications (which desire isolation) [57] and microkernel OSES [22] can boost by more than 10× with more MPK domains.

To scale MPK beyond 16 memory domains, recent researchers propose either software or hardware approaches to support more MPK domains [38, 41, 57]. However, the software approach suffers from a large overhead while the hardware approaches are infeasible on commodity machines.

In this paper, we propose EPK, which extends the maximum number of memory domains supported by MPK on commodity hardware efficiently. MPK's performance advantage stems from the decoupling of domain configuration (in privilege mode) and domain switching (in non-privilege mode). Our observation is that another hardware feature, named *fast EPT-switching* (Extended Page Table switching, with *VMFUNC*), has a similar pattern, which decouples EPT configuration (in host mode) from EPT switching (in guest mode). Thus, we propose *extended protection keys* by combining MPK with fast EPT-switching, i.e., reusing the same MPK protection keys in different extended page tables (EPT). Thus, with 512 EPTs, EPK can support up to 7,680 domains.

However, there are two major challenges to the new system. The first challenge is to provide a unified abstraction for appli-

cations although combing two orthogonal hardware features. EPK still retains the abstractions of memory domain and domain switching inherited from MPK while hiding the EPTs from applications, by elaborately managing domain mappings in multiple EPTs and developing a library to provide easy-to-use APIs. The second challenge is to enable one thread to simultaneously access memory domains across different EPTs, as the original MPK allows to access multiple domains together. To this end, EPK leverages another existing hardware feature named virtualization exception (VE) to switch the EPTs for the thread transparently when a domain access causes EPT violations.

We implement EPK prototype and apply it in the above scenarios. On the one hand, EPK can work like the original MPK for mitigating the memory errors and thus facilitates efficient intra-process memory isolation (Section 5). On the other hand, it can also isolate untrusted software components [46, 57] (Section 4 and Section 6) by further preventing illegal domain switching.

Experiments on server applications and persistent memory applications show that EPK’s overhead is usually around or below 5%. Compared with the state-of-the-art (libmpk) [38], the performance improvement can be up to two orders of magnitude. Furthermore, we incorporate EPK in a microkernel OS, a representative of large software. A microkernel OS runs system components like file systems and device drivers in user processes for embracing better isolation [20, 26, 30]. Nevertheless, costly inter-process communication (IPC) is required for the interaction between different OS components [22, 31, 37, 45]. EPK can provide enough isolated domains for running different OS components and the fast domain switch for IPCs. Thus, we propose a high-efficient IPC mechanism named HyBridge that can improve the performance of three well-known microkernels, seL4 [10], Google Zircon [4], and Fiasco.OC [3], and outperform two state-of-the-art IPC designs, SkyBridge [37] and UnderBridge [22].

In summary, this paper makes the following contributions: 1) a scalable and efficient intra-process memory isolation mechanism named EPK; 2) a real implementation and evaluation on Linux; 3) a new IPC design based on EPK for microkernel OSes with better performance.

2 Background and Motivation

2.1 Hardware Background

MPK. Intel MPK [7] can divide the virtual memory space of one process into 16 memory domains. By leveraging previously unused bits of the page table entry, each memory page is tagged with a four-bit protection key as the domain ID and exclusively belongs to one of the 16 domains. A new 32-bit register, *PKRU*, is introduced to specify the access permissions (read-only, read-write, none) on the 16 domains (two bits for one domain). Because the register is per-core, con-

current threads in the same process can have different access permissions on different domains. During runtime, MMU transparently checks the permissions. A non-privileged instruction called *WRPKRU* can update this register to change the access permissions.

MPK in the VM. The hardware feature of MPK is also usable in a VM. Protection keys are still tagged in the page tables of applications instead of EPTs. From the perspective of applications and the OS, the usage of MPK is just the same no matter in the VM or not.

Extended Page Table (EPT) and VMFUNC. Intel hardware virtualization technology employs EPT for memory virtualization. For a guest virtual machine (VM), the guest page table maps guest virtual addresses (GVA) to guest physical addresses (GPA) while the EPT maps GPAs to host physical addresses (HPA) and thus aids in the seamless translation of GVAs to HPAs. The guest VM’s OS (runs in non-root mode ring zero) controls the guest page table, while the hypervisor (runs in root mode) manages the VM’s EPT. *VMFUNC* is a hardware virtualization extension that provides VM functions for VMs. EPT pointer (EPTP) switching is currently the only VM function provided, allowing the guest VM (both Ring-0 and Ring-3) to directly load a new EPTP. The loadable EPTP can only be chosen from a list of EPTPs (up to 512) configured by the hypervisor. Note that TLB entries are tagged with the EPT base addresses to avoid flushing the TLB when switching the EPT.

Virtualization Exceptions (VE). EPT violations usually trigger VMExits, after which the hypervisor can fill the EPT mappings. Yet, Intel virtualization technology also supports converting EPT violations into VE without VMExits. With VE enabled, the hypervisor can configure bit 63 of certain EPT paging-structure entries to make EPT violations on some GPAs to cause VE and others to cause VMExits as before.

2.2 Motivation

Software fault isolation (SFI) can enhance memory isolation for applications [15, 19, 27, 36, 48, 58] by instrumenting and restricting memory accesses. Nonetheless, it may result in non-negligible runtime performance overhead and is inflexible (e.g., hard to be fine-grained). Many studies can avoid such disadvantages [25, 27, 32, 35, 39] using the MMU. They isolate different memory partitions of a process in different page tables or extended page tables and thus utilize MMU to check memory accesses at the page granularity.

Instruction	Cost (cycles)	Solution	Overhead
Write <i>CR3</i> (no TLB flush)	226	<i>LwC-simulate</i>	70%
<i>VMFUNC</i> (switch EPT)	146	<i>EPT-based</i>	12%
<i>WRPKRU</i>	28	<i>ERIM</i>	3%

(a)

(b)

Table 1: (a) Instruction cost. (b) The overhead of isolating session keys in one isolated domain.

However, constructing different memory domains with page tables is not free. Switching between different domains requires changing the page table through specialized hardware instructions. Table 1(a) presents the direct cost of the related instructions. We design an experiment to isolate each client’s session key in separate domains in the NGINX web server [9] to show the corresponding performance overhead. ApacheBench (ab) [1] generates the workload: 300 concurrent clients send requests to the server for a file. As presented in Table 1(b), light-weight contexts (lwC) [32], as a representative of page-table-based solutions, will lead to approximately 70% overhead if we isolate all the session keys in a separate context (i.e., a new page table) and switch to that context when accessing those keys. Similarly, for the EPT-based solution, we create a new EPT for isolating all the session keys and use *VMFUNC* instruction to switch to that EPT when accessing them. Although noticeably better than the page-table-based solution, such an EPT-based solution still introduces around 12% performance overhead. In contrast, ERIM [46] only adds about 3% overhead by utilizing MPK to construct an isolated memory domain for storing the session keys, which can demonstrate the efficiency of MPK.

Yet, MPK can only support at most 16 memory domains, limiting its usage. Take the web server for example: it is preferable to separate clients’ data in different memory domains, guaranteeing the isolation between multiple clients. Recent work [38, 41, 57] also identifies and addresses this limitation of MPK. Two studies [41, 57] propose non-trivial hardware extensions for efficiently supporting scalable domains, which are not achievable on current platforms.

libmpk [38] gives the illusion of multiple memory domains by exposing virtual keys to applications and maintaining the mapping between virtual keys and the 16 real keys (one key for one domain). When all 16 real keys are exhausted and a new virtual key is required, libmpk will evict a mapped real key and remap it to the new virtual key. But the key eviction may incur a large overhead. For instance, if we protect each client’s session key in a different memory domain (300 domains in total) provided by libmpk in the above NGINX experiment (rather than storing all keys in one domain), the overhead becomes about 20%. The overhead consists of both direct costs, i.e., the expensive key eviction procedure involving modifying page table entries, flushing TLBs, etc., and indirect costs, e.g., TLB misses due to flushing.

More seriously, libmpk’s domain switch cost increases as domain memory gets larger, as shown in Table 2. The micro-benchmark keeps switching to one domain randomly. When the domain number increases from 32 to 64, more key eviction occurs, resulting in higher overhead. As one domain contains more memory pages, the switch cost gets more expensive due to flushing more TLBs and updating more page table entries. The cost turning point (from 33 to 34) is because Linux flushes all TLBs together instead of one at a time when the number of TLBs to flush exceeds 33.

Domains \ Pages	16	33	34	64	1K	128K

32	6,576	11,173	4,090	5,270	42,912	5.1×10 ⁶
64	9,959	16,573	6,308	8,068	79,012	9.6×10 ⁶

Table 2: The CPU cycles of domain switches in libmpk. The page size is 4k.

	Memory Access Cost	Domain Switch	Memory Domain Number	Multi-domain Access	Multi-thread Support	Hardware Changes
SFI	High	Fast	Many	No	Yes	Zero
lwC	Low	Slow	Many	No	Yes	Zero
Donkey	Low	Fast	1,024	Yes	Yes	Heavy
libmpk	Low	Slow	Many	No	No	Zero
MPK	Low	Fast	16	Yes	Yes	Zero
EPK	Low	Fast	7,680	Yes	Yes	Zero

Table 3: Comparison of different approaches.

In brief, MPK-based intra-process memory isolation shows attractive performance advantages but can only support a limited number of isolated domains. Therefore, we intend to overcome this limitation while retaining MPK’s performance and flexibility advantages. As described in Table 3, SFI-based and page-table-based approaches (e.g., lwC) have performance issues and do not allow one thread to simultaneously access different domains. Existing hardware approaches (e.g., Donkey [41]) are hard to be implemented on commercial x86/ARM architectures due to intrusive hardware modifications. For example, to support 1024 domains, Donkey takes 10 bits in the page table entry as the domain ID, which is at least incompatible with the upcoming 5-level page table. libmpk makes several contributions like implementing fast *mprotect* by using MPK. But, its extension on the MPK domain number has both performance and flexibility issues. It cannot support multi-threading well, in particular, because it is difficult to maintain a consistent view of active domains across different threads.

3 The EPK Mechanism

According to prior studies on MPK-based intra-process isolation, the common usage model of MPK is as follows. An application (process) creates memory domains by binding different protection keys (pkey) to them as the domain IDs and separates the memory data into different domains. An application thread acquires/releases the access permission of one specific domain before/after accessing the data in it, which reduces the chances of the isolated memory being affected by vulnerabilities (e.g., leakage caused by buffer overflow) or faults (e.g., wild writes). Acquiring the domain access permis-

sion is efficiently achieved by executing *WRPKRU* instruction, which is referred to as switching to that domain. Releasing the permission is a reverse procedure that also makes use of *WRPKRU*. EPK still inherits such a usage model while supporting more memory domains.

Extended Protection Keys. The root cause of why MPK can only support 16 memory domains for one application is that each domain needs to exclusively take one pkey while the hardware only supports 16 pkeys. So, to extend the number of memory domains, the high-level idea of EPK is allowing multiple memory domains to use the same pkey at the same time. However, simply reusing the same pkey for different domains does not guarantee memory isolation. Therefore, EPK proposes *extended protection key*, which extends a pkey with different EPT indexes (get more keys), and then assigns different extended protection keys to different memory domains.

Figure 1: The memory mapping overview for an application.

As depicted in Figure 1, EPK allows an application to partition its virtual address space into different memory domains, with each domain containing discrete memory pages. A domain exclusively takes one *extended protection key* as its domain ID, which is composed of a pkey (1-15) and an EPT index (0-N, $0 \leq N < 512$)¹. EPK requires an application to run within a VM where cloud applications usually run in, and multiple EPTs need to be created for the VM. Each EPT can hold 15 domains for an application (domain-0 is used as the shared domain), and the 15 domain IDs (extended protection keys) have the same EPT index but different pkeys. For example, domain-1 and domain-2 are both in EPT-0 and use pkey-1 and pkey-2, respectively. The same pkey can be shared by domains in different EPTs concurrently, e.g., domain-1, domain-16, and domain-31 can all use pkey-1 because they will be mapped in EPT-0, EPT-1, and EPT-2, separately. Memory isolation between domains within the same EPT is achieved through the use of distinct pkeys. To achieve memory isolation between domains in different EPTs, EPK ensures that each domain's mappings only exist in one EPT. Specifically, the memory pages belonging to one isolated memory domain

¹ Domain-ID (extended protection key) = EPT-index \times 15 + pkey.

are tagged with the domain's pkey in the application's page table and are only mapped in the domain's EPT. Other memory pages, i.e., the global code and data of an application, are tagged with pkey-0 and mapped in all the EPTs (domain-0).

Although all the 512 EPTs are shared among different applications, it is worth mentioning that each application can construct 7,680 domains (15×512) since it has an individual guest page table.

Domain Switching. When an application thread needs to access some domain, it retrieves the permission by setting the PKRU value and choosing the corresponding EPT (switching to the domain). Switching between domains within the same EPT can be finished by executing one *WRPKRU* instruction. Switching between domains in different EPTs involves one additional *VMFUNC* instruction for EPT switching. Since both these two instructions are non-privileged, the domain switches are efficiently finished in user mode (one exception case will be explained in Section 3.2). From the perspective of programming, EPK provides easy-to-use interfaces (Section 3.3) through a user-level library for applications to create/delete domains, add/remove memory pages to/from domains, and switch domains. Applications can simply use the interfaces similar as programming on the original MPK.

Challenges. Although the idea sounds simple, there are two implementation challenges for combining the hardware features. First, how to make a VM seamlessly run with different EPTs, and how to differentiate a legal EPT violation caused by on-demand domain paging with an illegal one due to an unauthorized access? (Section 3.1). Second, given that MPK allows one thread to access multiple domains simultaneously, how to support such a flexible feature when multiple EPTs are in use (access domains mapped in different EPTs simultaneously)? (Section 3.2).

Threat Model. We assume the guest OS, hypervisor, and hardware are trusted, and EPK is correctly implemented. For the case of reducing the memory exposure time (Section 4), we assume the unreliable code may contain memory corruption bugs, which is similar to the existing work [38, 57]. For the case of isolating mutual-distrusted software components (Section 5 and (Section 6)), we assume the untrusted code or mutual-distrusted code may contain exploitable vulnerabilities like memory corruption and even use ROP to abuse *WRPKRU/VMFUNC* for illegal domain switches. So, EPK further integrates the mechanism of secure switching from previous systems [22, 46] (Section 6.1 explains how to avoid illegal domain switches). Other attacks, like side-channel attacks and rowhammer attacks, are not considered.

3.1 Extended Page Table Management

Traditionally, a VM has a single EPT that maps the GPAs of both the guest OS and applications to HPAs. Differently, EPK necessitates the creation of multiple EPTs for a VM based on two principles. *Principle-1:* GPAs that are not allocated for

memory domains should be mapped uniformly across EPTs. Thus, the VM can always run normally in any EPT. *Principle-2*: Each memory domain's GPAs should be mapped in only one EPT. As previously stated, this is for domain isolation.

GPA to Domain Association. Since the hypervisor is in charge of constructing EPTs, the first problem is how it can tell whether one GPA belongs to some memory domain or not. A straightforward solution is letting the guest OS, the GPA manager, share the information about which GPAs are allocated for memory domains with the hypervisor. Nevertheless, this entails non-trivial modifications to both the hypervisor and the guest OS. An alternative solution is to divide the whole GPA space into two halves and allocate GPAs for domain memory from one half, allowing the hypervisor to easily determine whether a GPA belongs to a domain. This solution still adds a significant amount of complexity to GPA allocation in the guest OS.

Figure 2: The EPT structures. PML4 is the top-level EPT page, and PDPT is the second top-level page.

To address this problem, EPK proposes the following design. Instead of partitioning the GPA space, EPK creates the illusion that there is a shadow address space (GPA) in the VM by simply adding a fixed offset (*SHADOW REGION OFFSET*) to the GPAs allocated to memory domains, as illustrated in the top half of Figure 2. As a result, the fixed offset becomes the boundary between the GPAs for memory domains and other GPAs. Based on this boundary, EPK constructs the EPTs, as shown in Figure 2. It sets the offset to 512 GB since an EPT PML4 entry can point to 512 GB GPA range. The entire GPA space is pointed by the first entry of each EPT PML4², and the shadow address space is pointed by the second entry of each EPT PML4. The first PML4 entry of different EPTs points to a shared PDPT, implying that the non-domain GPA mappings are always the same in different EPTs and thus satisfies *Principle-1*. By sharing this PDPT, the hypervisor can reduce the space overhead of multiple EPTs. More importantly, it does not need to explicitly synchronize an EPT update (e.g., adding a new mapping for the guest OS) across all EPTs, which is expensive. The second PML4 entry

²For simplicity, we assume the size of the GPA space is smaller than 512 GB. The fixed offset can be adjusted to support larger GPA space.

of different EPTs points to different PDPTs for adding the GPA mappings for memory domains, which is a prerequisite of *Principle-2*.

Illegal EPT Violations. The second problem is the hypervisor cannot determine if an EPT violation (EPT fault) within the shadow address space is legal or not. Assume an application thread executes in EPT-1 while accessing Domain-1 in EPT-0, resulting in an EPT violation. The hypervisor cannot decide whether to add the mapping because it does not know which domain the faulting address belongs to, i.e., whether the GPA should be mapped in the current EPT. Simply adding the mapping regardless of semantics will violate *Principle-2*. Instead, EPK chooses to avoid any legal EPT violation within the shadow address space (except accessing domains across EPTs which will be explained in Section 3.2). Specifically, the guest OS is required to invoke one new hypercall (a hypervisor interface provided to the VM) to fill the EPT mapping when a legal domain page fault happens, which eliminates the following EPT violation. The guest OS can check the legality of a domain page fault because applications tell it the semantics of domain mappings via the corresponding interfaces (explained in Section 3.3). As such, the hypervisor only needs to add a simple hypercall to add the EPT mapping, and EPT violations within the shadow address space must be illegal. Together with the carefully designed EPT structure, *Principle-2* can be met now. Furthermore, because it avoids original VMExits caused by EPT violations, this hypercall-based solution incurs no additional overhead.

EPT-ID Access. When a domain page fault occurs, the guest OS needs to check whether the faulting thread has the access permission according to the current PKRU value and EPT-ID. However, because the domain switches are performed in user mode, the guest OS is unaware of the changes of PKRU and EPT-ID. The guest OS can directly read the PKRU register but cannot get EPT-ID (the third problem). EPK enables the guest OS to efficiently retrieve the EPT-ID by subtly mapping one special guest physical page (named EPT-ID-Page) across different EPTs. During VM initialization, the guest OS allocates the EPT-ID-Page and passes its address to the hypervisor. The hypervisor maps the EPT-ID-Page to different host physical pages in different EPTs (in different PDPTs) and stores the corresponding EPT-ID in each physical page. Therefore, the guest OS can always obtain the current EPT-ID by simply reading the EPT-ID-Page (first four bytes).

3.2 Multi-Domain Access Support

MPK supports 16 domains and allows one thread to access any of them by configuring the PKRU register. Nevertheless, it is non-trivial to support this flexible feature in EPK since there are domains across different EPTs.

Accessing multiple domains in the same EPT can still be accomplished simply by configuring PKRU. To transparently support accessing multiple domains in different EPTs, EPK

further employs another hardware feature named VE (virtualization exception). The hypervisor converts EPT violations in the shadow address space into VEs which will be handled in the guest OS. The VE handler in the OS can switch the EPTs for one thread and thus help it to seamlessly access multiple EPTs. Specifically, when a thread needs to acquire the access permission of domains across multiple EPTs simultaneously, it needs to inform the kernel of the domain information. Suppose the thread needs to access domain-A in EPT-1 and domain-B in EPT-2 and first runs in EPT-1. As running in EPT-1, it can directly access domain-A but will trigger an EPT violation when attempting to access domain-B. Because domain-B is in the shadow address space, the corresponding EPT violation will be caught by the VE handler instead of causing expensive VMExits. Since the OS knows that the thread can access domain-B, the VE handler will switch to EPT-2 by using VMFUNC and setting PKRU to the required value. After that, the thread can be restored and continue to access domain-B. A similar procedure happens when it later accesses domain-A in EPT-2. Thereby, EPK gives an illusion that one thread can access domains in multiple EPTs at the same time.

Two points are worth mentioning. First, EPK only converts EPT violations to VEs within the shadow address space, which has no interference on the VM's original execution. Second, different from getting access to domains in the same EPT or a specific domain in other EPTs (fast path), getting access to multiple domains in different EPTs requires the kernel involvement (slow path).

3.3 System Components in Linux/KVM

EPK's prototype implementation on Linux/KVM mainly consists of three components: a user library, a kernel module in the guest OS (Linux), and a hypercall handler in the hypervisor (KVM).

Figure 3 lists the main library interfaces available to applications. The first two functions invoke the kernel module through *ioctl* to allocate and free domain IDs. *alloc_domains* can get multiple domain IDs, and the kernel module will try

```

/* Allocate domain IDs with affinity */
int alloc_domains(int num, int dom_ids[]);

/* Free domain IDs */
int free_domains(int num, int dom_ids[]);

/* Allocate a virtual memory range for a domain */
void *domain_mmap(int dom_id, void *addr, size_t len,
                 int prot, int flags);

/* Remove some mappings */
int domain_munmap(void *addr, size_t len);

/* Retrieve the access permission of a domain */
int domain_begin(int id, int prot);

/* Release the domain permission */
int domain_end(int id);

```

Figure 3: The APIs provided by the user library of EPK.

to return the domains that are located in the same EPT. This is because some domains may have affinities, i.e., they are likely to be traversed together. Properly utilizing affinity in the applications can benefit the performance. Although it is non-trivial in general, achieving locality is straight forward in some cases. For example, in Section 4.2, a simple locality-aware request dispatching scheme can make Memcached embrace the affinity benefits; in Section 5.2, simply letting one thread work on the warehouses within the same EPT is enough.

domain_mmap first invokes *mmap* and then informs the kernel module about the domain mapping information. The kernel module records the information by using Linux's *rbtree* and validates domain page faults based on it. Huge page mapping is also supported through setting the *flag* argument. The last two interfaces are responsible for switching memory domains and are purely implemented in user mode except for accessing multiple domains in different EPTs. It is also necessary to know the current EPT-ID in user mode. For example, switching domains in the same EPT requires no VMFUNC. EPK does this by reusing the EPT-ID-Page During its initialization, the library asks the kernel module to map the EPT-ID-Page as read-only into the application. Besides, a domain memory allocator based on [34] is also provided.

Since servicing invocations from applications and recording the domain-related information, the kernel module provides a routine that aids in handling domain page faults. We insert a hook in the Linux page fault handler for invoking this routine. When a page fault occurs, the page fault handler still executes as before (e.g., allocates a free page) but invokes this routine just before setting the GPA of the newly allocated page in the page table entry. The routine then checks whether the page fault occurred within the domain regions and whether it was legal. If it is a legal domain page fault, the routine updates the GPA by adding *SHADOW REGION OFFSET* to it and invokes the hypercall to fill the mapping for the updated GPA in the EPT (as described in Section 3.1). Finally, the routine returns and the page fault handler sets the updated GPA in the page table entry. Another simple hook is added to the OS schedule function (i.e., *__schedule*). It saves/restores the EPT-ID for threads of applications that use EPK. Specifically, it saves the current EPT-ID in the thread's *task_struct* when scheduling out such a thread and restores the EPT-ID with *VMFUNC* (if necessary) when scheduling in the thread. Moreover, we add the VE handler for transparently supporting flexible multi-domain access.

In KVM, besides enabling VE and VMFUNC, we extend the hypercall handler to provide two additional functions for the guest kernel module. The first is to map the EPT-ID-Page, and the second is to add the EPT mapping for the VM's shadow address space. Furthermore, to support reclaiming the pages mapped in the shadow address space, the hypervisor needs to first disable VE on the pages to reclaim and record the reclaim information. When swapping back the pages, the hypervisor needs to re-enable VE on the pages. Besides these,

the hypervisor can reclaim the pages as before. Yet, this reclaiming mechanism is not supported in the current implementation of EPK.

EPK only requires minor modifications on Linux/KVM. Our prototype only adds 250 lines of code (LOC) in KVM, 13 LOC in guest OS, and 600 LOC in guest kernel module.

4 Case Study: Protecting Server Applications

Experiment Setup. All the experiments in this paper are conducted on a Dell PowerEdge R640 server with Intel Xeon Gold 6138 CPU. Hyper-threading is disabled, and the CPU frequency is fixed to 2.0GHz. The L2 TLB has 1536 entries. In Section 4 and Section 5, we implement and evaluate EPK on Linux/KVM-4.19.88 (both the guest OS and the hypervisor). The experiments are conducted in a VM (20 CPUs and 80GB memory), and the loopback network is used. All experiments use 4k memory pages without explicit statements.

Comparison Systems. Besides the native performance (run benchmarks with no isolation), we compare the performance of EPK with libmpk [38], lwC [32], and a *VMFUNC*-only solution. We evaluate libmpk in single-thread experiments since it does not support multi-threading. Since lwC is implemented on FreeBSD, we simulate its performance on Linux. Specifically, we first measure its switch cost (around 6,000 cycles, which corresponds to the reported data in Table 2 in ERIM [46] and Table 2 in lwC [32]) and then add such switch cost in the benchmarks (i.e., waiting for 6,000 cycles when switching context is needed). Note that the simulated performance will be better than the actual performance because the indirect cost of switching address space is ignored. We also implement a *VMFUNC*-only solution that provides one memory domain in one EPT and leverages *VMFUNC* for domain switches. The experiment of libmpk is conducted in host, while all the other systems run in the VM.

4.1 Micro-benchmarks

Domain Num	3	4	8	15	16	32	64
libmpk(128 pages)	184	184	186	188	12,991	13,148	13,048
VMFUNC	350	831	830	836	834	849	830
EPK	97	97	100	101	111	115	162

Table 4: The average cost (in cycles) of domain switches.

We leverage different solutions to create multiple memory domains and evaluate the domain switching cost (shown in Table 4). The test program initially runs in domain-0 (not counted in the domain number) and switches between the created domains in order (sequential access). The number of iterations is 100,000 and we measure the average cost. libmpk’s switch cost gets much higher when the domain number is above 15 (domain-0 takes one protection key). Besides,

its switch cost is severely influenced by the size of protected memory. When each domain contains 128 pages, its switch cost becomes more than 10,000 cycles if the domain number exceeds 16, which is even 100× slower than EPK. With the domain size increasing, its switch cost will enlarge due to more page table updates during key eviction, as shown in Table 2. In contrast, the switch time of the other two approaches is immune to the domain size.

The *VMFUNC*-only solution uses one EPT for domain-0, and its switch cost is about 350 cycles which mainly comes from two *VMFUNC* instructions when the domain number is no more than 3 (the total EPT number is no more than 4). However, its cost increases to around 830 cycles when the domain number exceeds 3. This is because TLB entries are tagged with EPT base addresses, and the involvement of more EPTs may decrease the TLB hit rate. Specifically, accessing the same memory page in different EPTs generates different TLB entries and then may exceed the capacity of the corresponding TLB set. EPK shows the lowest average switch cost since most switches are based on *WRPKRU*. When the domain number is less than 16, it outperforms libmpk because the latter one involves virtual protection key management (although no key eviction). When the domain number exceeds 60, the average cost of EPK increases since there are more than 4 EPTs.

Yet, in the *worst case*, EPK needs both *WRPKRU* and *VMFUNC* for switching to one domain, and takes around 860 cycles for traversing domains like the above, which means the performance of EPK may converge with the *VMFUNC*-only solution with random switches.

4.2 Macro-benchmarks

NGINX. Introducing intra-process memory isolation to server applications brings the potential to achieve higher security or reliability. We first apply different solutions to a widely-used web server, NGINX [9] v1.12.1, to evaluate the performance overhead. We isolate SSL session keys as ERIM [46] does (including preventing the abuse of domain switching), except that we store per-client session keys in different domains rather than in one domain. We leverage ab [1] to generate the workload: 300 clients keep sending file requests one by one. The server thread is fully loaded. The total domain number is 300 and each domain contains 5 memory pages.

Figure 4a shows the evaluation results. The throughput is normalized because libmpk is implemented on Linux 4.14.2 and the native throughput differs on Linux 4.14.2 and 4.19.88 (EPK) (while KPTI is disabled on both, other mitigations on CPU vulnerabilities are key factors). EPK imposes overhead from 4.3% to 5.8% compared with native and outperforms other solutions. The overhead of the *VMFUNC*-only solution varies from 11.0% to 12.4%. Notice that the NGINX serving thread handles client requests in order. Thus, most domain

Figure 4: (a) shows the performance of protecting session keys in NGINX web server. (b) and (c) show the performance of isolating different users in Memcached (omit libmpk since it lacks the support of multi-threading).

switches in EPK need no EPT changing, making EPK outperform the *VMFUNC*-only solution. When storing each session key in an individual context in *lwC*, the overhead is 37.1% on average merely due to the explicit cost of domain switches. The overhead incurred by *libmpk* ranges from 14.5%-18.9% (23.4% to 33.2% if in the virtualization environment) due to the involvement of page table modifying and TLB flushing. In the cases of infrequent switching and small domain size (5 pages), *libmpk* will not lead to too much overhead.

Memcached. We evaluate Memcached [8] 1.6.9 and use *libMemcached* as the client library in this experiment. Memcached is a well-known key-value store and usually runs as a multi-thread server application. Arbiter [49] suggests that it is preferred to isolate data from different clients in Memcached for security-sensitive cases. Like Arbiter, we enable Simple Authentication and Security Layer (the SASL configuration) in Memcached and then isolate data stored by different clients. Besides, we slightly modify the request dispatching scheme of Memcached so that the requests from one client are always dispatched to the same worker thread for leveraging the domain affinity provided by EPK. The worker thread switches to the client’s corresponding domain before handling a request and exits that domain before sending back the reply. We create a different number of client threads, and each of them uses *libMemcached* for sending SET/GET requests. The sizes of key and value are 32 bytes and 256 bytes, separately. There are four worker threads (default configuration) on the server-side, and the clients will be evenly partitioned to them. In this experiment, the max domain number is 70 and each domain contains about 2,000 memory pages.

Figure 4b and 4c show the throughput of Memcached. As before, *lwC* leads to the highest overhead due to its expensive switch cost. When the client number is no more than 60, EPK incurs at most 0.7% overhead on the throughput of SET operations. The overhead on the throughput of GET operations is slightly higher (up to 2.9%) because the GET operations are lighter than the SET ones. The extremely low overhead is because no EPT switches happen on the critical path. EPK allows each worker thread to create 15 domains in one EPT, and thus four worker threads can handle 60 clients (60 domains)

without switching EPTs. When the number of clients exceeds 60, the overhead of EPK becomes larger because some worker threads need to handle requests from more than 15 clients, and then EPT switches happen.

In contrast, the *VMFUNC*-only solution incurs a much larger overhead, i.e., up to 17.9% and 34.0% overhead for the throughput of GET and SET operations, separately. The overhead mainly comes from TLB misses, as explained in Section 4.1. For validation, we further carry out two experiments marked as *VMFUNC-test-1* and *VMFUNC-test-2* in Table 5. The former one is that the worker thread switches to the target EPT and immediately switches back before handling a request. So, all the requests are handled in EPT-0. The latter one is that each worker thread always switches to EPT-1 for handling requests. So, all the requests are handled in EPT-1. Both of them show close-to-native performance, and the TLB miss number is not significantly enlarged. However, the *VMFUNC*-only solution causes many more TLB misses and then leads to the highest overhead. The overhead of TLB miss in NGINX is not obvious because the worker thread of NGINX only switches to other EPTs when accessing session keys while the worker thread of Memcached executes most logic in different EPTs.

	Throughput (×10K req/s)	dTLB/TLB misses
<i>Native</i>	24.5	1 / 1
<i>VMFUNC-test-1</i>	24.4	1.1 / 2.4
<i>VMFUNC-test-2</i>	24.0	1.2 / 2.4
<i>VMFUNC</i>	20.1	9.5 / 29.1

Table 5: The throughput and TLB misses (normalized) when evaluating Memcached SET operation with 60 clients.

Since *libmpk* does not support multi-thread, we evaluate *libmpk* in Memcached with a single worker thread. When there are 60 domains, the overhead of the above test exceeds 80%, which is significantly higher than that in NGINX because each domain contains about 2,000 pages.

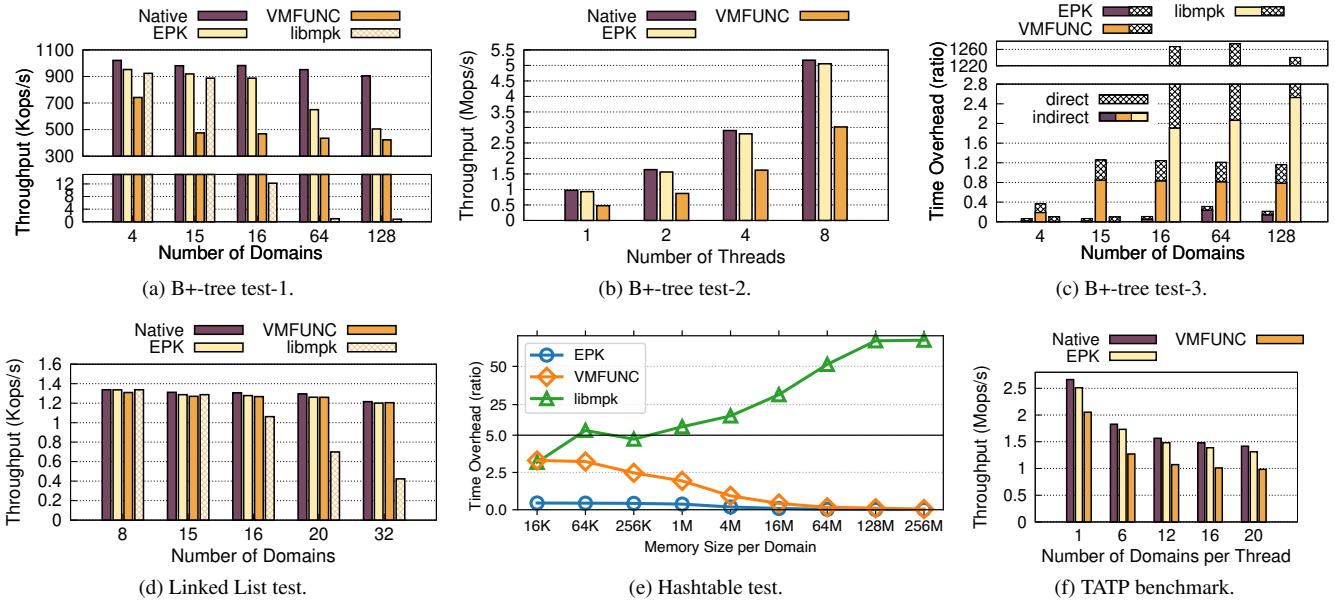

Figure 5: B+-tree (a) Single-thread and random access, (b) Multi-thread and each thread operates on 15 domains, (c) Time breakdown when single-thread and sequential access. (d) Linked List (low switch frequency). (e) Hashtable benchmark (different domain memory size). (f) TATP benchmark. Omit libmpk (single-thread support) in the multi-threaded cases.

5 Case Study: Isolating NVM Data

To embrace the low access latency of NVM, applications usually map NVM into the address space and access it through load/store instructions. Bringing intra-process memory isolation to protect NVM data (e.g., reducing the data exposure time) has also been investigated by recent work [56, 57]. In this section, we evaluate the benchmarks similar to existing NVM studies [23, 33, 56, 57], using DRAM as NVM.

5.1 Data Structure Benchmarks

We first experiment on B+-tree. We map each B+-tree in an individual domain and create different numbers of threads to do lookup or insert operations (the ratio is 1:1 and other ratios show similar performance trends). Domain switches occur before and after an operation. Each tree initially has 500,000 key-value pairs, and each tree node has up to 32 child nodes. In this experiment, the max domain number is 128 and the size of each domain is about 128MB.

The overhead of lwc in the above benchmarks is always around 80% because one B+-tree operation takes just about 2,100 cycles.

Figure 5a shows the throughput when a single thread operates on a randomly selected tree (i.e., randomly switching to a domain). If the domain number is less than 16, EPK and libmpk bring about 7% and 11% overhead, individually. When the domain number exceeds 15, libmpk introduces unacceptable overhead (throughput drops by 99.8%) due to the substantial cost of key eviction (as the domain size is not small), and EPK can outperform it by two orders of magni-

tude. Note that the kernel version has minor effects on the native performance since this benchmark rarely issues system calls. The *VMFUNC*-only solution incurs 27% overhead when the domain number is 4. Compared to EPK, its higher overhead comes from two sources: one is *VMFUNC* is slower than *WRPKRU*; the other is more TLB misses (its dTLB and iTLB misses are 1.34× and 3.34× of EPK’s, respectively). When the domain number increases to 64 and 128, EPK’s overhead also increases to 32% and 44% because more EPTs and EPT switches are required. Specifically, when there are 64 domains, 78% of domain switches in EPK involve EPT switches. If accessing different domains sequentially instead of randomly, EPK’s overhead is below 10% (3% for huge page) when the domain number is no over 60.

Figure 5b shows the performance when there are multiple threads on different cores and each thread accesses 15 different domains. EPK’s overhead remains below 5% as the thread number increases, which is significantly lower than that of the *VMFUNC*-only solution (41% to 51%).

We further analyze the overhead of the three approaches in terms of the time cost (the part that exceeds the native time): the switching time (direct cost) and the rest time overhead incurred by the pollution on CPU internal structures including TLBs and caches (indirect cost). The experiment is one thread operates on the tree in each domain sequentially to complete a fixed amount of operations. Figure 5c presents the breakdown. The *VMFUNC*-only solution brings about 1.2× time overhead when the domain number exceeds 8. Its indirect cost remains around 0.8× because the TLB miss rate is almost stable. The page table updating operations of libmpk leads to both high direct cost and indirect cost (not only incurs TLB misses

but also leads to intensive cacheline pollution). EPK causes $0.23 \times$ ($0.13 \times$ for huge page) indirect cost when there are 64 domains due to more than 4 EPTs, which is still better than others, and causes much lower cost for fewer domains.

Note that the domain switch frequency is proportional to the throughput in the presented benchmarks. We also conduct an experiment on Linked List (Figure 5d): each list is separated into one domain, and one thread performs 10 operations (search, insert, delete) in a random list for each time. The switch frequency is less than 1,400 times per second. libmpk still introduces 65.1% performance overhead when there are 32 domains and each domain is 256 MB. The other two approaches cause unnoticeable overhead.

Last, Figure 5e shows the overhead (in terms of the time cost) of different approaches as the domain size increases. In this experiment, each hash table resides in one domain (32 domains), and one thread keeps performing an operation (search or insert) in one random domain. We gradually increase the domain size by adding more buckets/key-value pairs in each hash table. The overhead of libmpk increases as the domain size grows, as expected, whereas the overhead of EPK and the VMFUNC-only solution decreases because the native performance decreases when more memory involves. Specifically, when each domain is 256 MB, the overhead of the latter two are 1.3% and 4.7%, respectively.

Virtualization Cost. Virtualization brings performance overhead to applications, especially when the working set is large and TLB misses are frequent. For example, when the domain size in hash table is configured as 16KB or 128MB, the virtualization overheads are 2.1% and 9.0%, respectively. When a VM application uses EPK, the virtualization cost is not accounted on EPK. Otherwise (in bare metal), the virtualization cost should be included in the overhead of EPK. Nevertheless, a thin virtualization layer instead of a full-fledged hypervisor can minimize the virtualization cost [22].

5.2 OLTP Benchmarks

TATP [43] is an online transaction processing (OLTP) benchmark. In the experiment, we use the above B+-tree as the data store and create four threads to execute transactions (three read-only and three read-write ones). We store a fixed amount of initial data in different domains, and each thread switches to the corresponding domain before executing one transaction. The max domain number is 80 and the size of each domain is 512MB. Figure 5f presents the throughput as the domain number for each thread increases from 1 to 20. The native throughput is in a decreasing trend along with the increase of domain number because more data weakens the cache locality. EPK's overhead is within 7%, while the VMFUNC-only solution incurs up to 32% overhead. We also run single-thread TATP with libmpk. Similar to B+-tree test-1, the overhead of libmpk is over 99% when the domain number exceeds 15.

TPC-C [18] is another OLTP benchmark in which there

are multiple warehouses. We isolate different warehouses as well as their associated data in different domains. The max domain number is 128 and the size of each domain is 400MB. According to its specification, 7.2% of the transactions update multiple warehouses simultaneously. There are also four threads executing the transactions. When each thread operates on less than 16 domains, EPK achieves almost the same throughput as the native (0.6% overhead). The overhead is lower than that in TATP because the transactions in TPC-C are more heavyweight. When each thread operates on 32 domains, the overhead of EPK becomes 3.2% as VEs are triggered for supporting transparent multi-domain access. The other approaches are infeasible in this experiment due to the lack of the support of multi-domain access.

6 Case Study: Boosting IPCs in Microkernels

6.1 HyBridge

Different from monolithic OSes which run all the OS modules in the kernel-level, microkernels leave minimal functionalities in the kernel while running all other OS modules (referred to as system servers below) such as file systems, network stacks, and device drivers into separated user-level processes. Inherently, microkernels embrace better security and fault isolation, but leads to non-negligible communication cost at runtime. Specifically, since system servers are user-level processes, the interactions between two servers or between an application and a server require inter-process communication (IPC). In contrast, on monolithic OSes (e.g., Linux), the interaction between two OS modules only requires function calls, and the interaction between applications and the OS can be as fast as about 150 cycles (*syscall* and *sysret*). So there has been a long line of research to reduce the cost of IPC to bridge the performance gap between microkernels and monolithic OSes.

Figure 6: Traditional IPC flow on microkernels is shown on the left, and IPC with UnderBridge is shown on the right.

A most recent IPC design called UnderBridge [22] retrofits Intel MPK to optimize (synchronous) IPC. For reducing the cost of IPC between an application and a server, it pulls system servers from user-level processes into the kernel address space as shown in Figure 6. Besides, it leverages Intel MPK to ensure the isolation between system servers in the kernel, and the IPCs between them are based on *WRPKRU* and thus greatly optimized. However, due to the limitation of MPK memory domains, it can only run limited system servers in the kernel and accelerate IPCs to them (issue-1). Also, although it can reduce the privilege switches during IPCs between ap-

applications and servers, the page table switches are still needed because it requires a separate kernel page table (issue-2).

Since EPK can construct even thousands of isolated memory domains efficiently and enable fast domain switch at user-level, we propose EPK-based HyBridge for boosting IPCs for microkernels, which is inspired by UnderBridge while fixing the two issues of UnderBridge. As shown in Figure 7, system servers run at user-level, and each one exclusively takes one or more memory domains for holding its own memory, including code, data, stack, and heap. Thus, one system server cannot access others' private memory, just like when they are isolated in different processes while IPCs are based on domain switches.

Cross-server IPC. The cross-server IPCs only happen between system servers that need to interact with each other. For example, a file system communicates with a disk driver while a network stack does not. This also matches the *domain affinity* in EPK. Therefore, the microkernel can run the related system servers in the same EPT. When two servers establish an IPC connection, the microkernel will map an IPC gate, i.e., a piece of code, for them. During an IPC invocation, the gate will transfer the control flow from the caller to the callee. Specifically, it saves the caller's execution states, then executes *WRPKRU* to switch to the callee's domain, and restores the callee's execution states. Similarly, it does the reverse procedure when the IPC returns. HyBridge also allows two servers to share memory for exchanging data by assigning a free memory domain to them, e.g., shared memory domain 4 in Figure 7.

Figure 7: The overview of HyBridge. The numbers after colons are domain IDs. Shared memory is short as shm.

Application-to-server IPC. Applications execute in different processes (in EPT-0) just like before while several system servers can run in one process (across one or more EPTs), which means each application has a unique guest CR3 (GPA) while multiple servers share one. Since an application and a server run in different EPTs, the IPCs between them need EPT switching. HyBridge attaches a trampoline in the EPTs for running servers and maps the trampoline into an application when it asks for establishing an IPC connection with some server. The trampoline plays the role of the IPC gate and uses *VMFUNC* to switch between the caller and the callee. Though *VMFUNC* can directly switch EPT, it does not change guest CR3. However, for an application-to-server IPC, the caller and callee use different CR3 (CR3-App and CR3-Server). So,

besides mapping the trampoline, HyBridge also maps CR3-App (GPA) to the HPA of CR3-Server in the server's EPT during the IPC establishment. In this way, the HPA mapping for the guest CR3 is transparently changed after executing *VMFUNC*, i.e., the guest page table is switched from the application to the server. When an application invokes an IPC, the trampoline saves the caller's execution states (executes in EPT-0), executes *VMFUNC* (switches the EPT), and restores the callee's execution states (executes in server's EPT).

Security Enforcement. Besides memory isolation, HyBridge employs additional security mechanisms to achieve the same security guarantee as original microkernels. Compared with original IPC designs, HyBridge makes an untrusted system server have two more potential attack vectors. One is that a server may bypass the memory isolation by maliciously executing *WRPKRU* or *VMFUNC* and then access others' memory. The other is that a server may issue arbitrary IPCs to other servers by maliciously executing the trampoline code without the corresponding capabilities.

HyBridge eliminates the two attack vectors as follows. First, it utilizes binary scanning and rewriting to ensure that each server contains no *WRPKRU* or *VMFUNC* instructions during binary loading. Meanwhile, it adds sanity checks in the IPC gates for ensuring the argument of *WRPKRU* is legal, which is similar as ERIM [46]. So, a compromised or malicious server cannot illegally execute these two instructions to retrieve unauthorized memory permissions even with return-oriented programming (ROP). Second, HyBridge uses a token-based mechanism to authenticate IPC invocations as SkyBridge [37] does. Considering control flow hijacking, trampolines can be executed arbitrarily or it is even possible to jump into the middle of the trampoline, i.e., using *VMFUNC* to switch to any EPT. Although they cannot be misused to break the memory isolation, an untrusted server may issue arbitrary IPCs by invoking them. To prevent this, HyBridge lets a server generate a random 64-bit token for a registered client (another server or an application) when building the IPC connection, and a client needs to pass the token during IPCs for authentication. The server only serves the IPC requests with legal tokens, so the problem of arbitrary IPCs can be avoided. Moreover, HyBridge also prevents the occurrence of *VMFUNC* in applications by scanning and rewriting the binary code. Thus, an application can only switch to system servers through the mapped trampoline.

6.2 Experiments

We implement HyBridge on three well-known microkernels, Zircon [4], seL4 [10], and Fiasco.OC [3], to assess its effectiveness. Besides, we also compare it with SkyBridge [37] which runs system servers in different EPTs and implements kernel-bypass IPCs based on *VMFUNC*, and UnderBridge [22]. We deploy the thin virtualization layer from SkyBridge while applying extensions needed by three IPC de-

Figure 8: Normalized throughput of SQLite3 on different microkernels. KPTI is short for kernel-page-table-isolation.

signs. We evaluate the performance of SQLite3 v3.23.0 [11], a database application, after applying different IPC mechanisms on different microkernels. For severing SQLite3, we run two system servers, a file system named xv6fs [16] and a RAMdisk. When SQLite3 operates a storage file, it will first invoke the xv6fs server by an application-to-server IPC; then, the xv6fs will access RAMdisk through cross-server IPCs. We also simulate the performance of a monolithic kernel by running system servers in the kernel and connecting them with function calls.

Figure 8a, 8b and 8c present the normalized throughput on the three microkernels. The native performance of each microkernel is set as the baseline. Because Zircon has the slowest native IPC among the three microkernels since it includes scheduling overhead in IPCs, HyBridge can provide the highest speedup for it, i.e., more than $9\times$ speedup for three database operations. The performance improvement of query operations is relatively small because SQLite3 has an internal cache of recent data and may handle the queries without issuing IPC requests. For seL4 which optimizes IPC performance extensively, HyBridge can also improve the throughput (except query) to more than $2.5\times$ of the native.

Besides, HyBridge can outperform SkyBridge by up to 66% because most IPCs issued from SQLite3 to xv6fs involve multiple cross-server IPCs between xv6fs and RAMdisk, whereas the cross-server IPCs are more lightweight in HyBridge. Specifically, a cross-server IPC takes 110 and 437 CPU cycles in HyBridge (*WRPKRU*-based) and SkyBridge (*VMFUNC*-based), respectively. In this benchmark, HyBridge only shows slightly higher performance than UnderBridge since cross-server IPCs dominate, while it has more advantage over UnderBridge in the application-to-server IPC (e.g., 527 vs. 723 CPU cycles when implemented on our research microkernel, ChCore [22]) owing to no CR3 changing.

7 Other Related Work

Many studies [15, 19, 27, 36, 42, 48, 58] leverage instruction instrumenting to achieve memory isolation, which may incur non-trivial overhead. Many other studies [25, 27, 32, 35, 39] utilize the memory management unit (MMU) to check memory accesses efficiently. Specifically, they divide a process into different compartments and assign each one an individual (extended) page table. However, switching between compart-

ments requires (extended) page table switching, which can be costly when the cross-boundary invocation is frequent. Twizzler [14] is a pioneer data-centric OS for NVM and uses EPT/VMFUNC to create different memory domains for NVM isolation. Differently, EPK focuses on solving the challenges of combining MPK and EPT/VMFUNC and outperforms a VMFUNC-only solution. Besides, recent work [28, 51] harnesses hardware features like Supervisor-Mode Access Prevention (SMAP) or underused intermediate privilege levels (Ring1 and Ring2 on x86) to achieve efficient intra-process memory isolation. Yet, they can only provide two isolated memory domains.

Prior work [21, 47, 52, 54] also proposes architecture designs to facilitate efficient intra-process memory isolation, which, however, is not achievable on commodity machines. PLB [53] proposes architecture changes which differs from Intel MPK for supporting scalable domains but requires virtually indexed cache which may cause performance issues. Besides Intel, both ARM (ARMv7) and AMD propose similar features of memory domains and face the same scalability problem of the domain number. The basic idea of EPK is feasible to be extended to them as they also support 2-stage address translation. Yet, for efficiency, hardware-assisted fast switching (currently commercially unavailable) of stage-2 page table is needed on the two architectures.

An orthogonal study [17] shows that some system calls can be used to break the MPK isolation, so the OS may need to be aware of MPK in the future or the applications needs to incorporate other mechanisms like system call filtering [12].

8 Summary

This paper presents EPK which first combines the usage of MPK and hardware virtualization features to achieve scalable and efficient intra-process memory isolation. The case studies demonstrate various potential usages of EPK.

Abstract

With the ever-growing demands for GPUs, most organizations allow users to share the multi-GPU servers. However, we observe that the memory space across GPUs is not effectively utilized enough when consolidating various workloads that exhibit highly varying resource demands. This is because the current memory management techniques were designed solely for individual GPUs rather than shared multi-GPU environments.

This study introduces a novel approach to provide an illusion of virtual memory space for GPUs, called hierarchical unified virtual memory (HUVVM), by incorporating the temporarily idle memory of neighbor GPUs. Since modern GPUs are connected to each other through a fast interconnect, it provides lower access latency to neighbor GPU's memory compared to the host memory via PCIe. On top of HUVVM, we design a new memory manager, called memHarvester, to effectively and efficiently harvest the temporarily available neighbor GPUs' memory. For diverse consolidation scenarios with DNN training and graph analytics workloads, our experimental result shows up to $2.71 \times$ performance improvement compared to the prior approach in multi-GPU environments.

1 Introduction

As the demand for GPUs explodes, it is now a common practice in both academia and industry to equip multiple GPUs in a single server and make them shareable. Many enterprises in the industry have built large GPU clusters comprised of a set of multi-GPU servers to satisfy the demand for a variety of workloads from deep learning [1, 13, 18, 26, 36] to graph applications [6, 10, 19, 31] while saving the infrastructure cost by sharing. However, as a downside, achieving high GPU resource efficiency in such multi-GPU servers remains a challenge. Figure 1 presents that the current memory management technique is not effective enough for shared multi-GPU

environments where multiple jobs are running across GPUs independently. Although a small amount of memory ranging from hundreds of MB to a few GB remains idle in one or a few GPUs, other GPUs under heavy memory pressure rely on the host memory as a swap device that is significantly slower than remote GPUs within the same server.

Meanwhile, GPU vendors have faced the challenge of scaling the memory capacity of single GPUs. To overcome the limited capacity of GPUs, a train of previous studies provides an illusion of infinite memory space with the host memory [11, 14, 17, 25, 28]. However, none of the work does utilize the idle memory of neighbor GPUs in commodity multi-GPU systems. As modern GPU servers are commonly equipped with 8~16 GPUs connected via high-speed interconnect such as NVLink, accessing the idle memory of neighbor GPUs is much faster than that of the host. For instance, NVIDIA DGX-2 has 16 GPUs with point-to-point connections through NVLink 3.0, yielding a large pool of 512GB GPU memory at 600GB/s bidirectional bandwidth [23]. On the other hand, swapping GPU memory to host DRAM via the latest PCIe 4.0 could utilize up to 32GB/s bandwidth only.

In this study, we introduce a new approach providing an illusion of virtual memory space for GPUs called *hierarchical unified virtual memory (HUVVM)* comprised of local GPU, spare memory of neighbor GPUs, and the host memory. HUVVM opens up a new opportunity for memory virtualization by increasing the effective memory space with minimal performance overhead. When the local GPU memory does not have free space, HUVVM leverages the spare¹ memory in neighbor GPUs *as a victim cache* between the GPU and host instead of directly swapping out data to the host memory.

However, it is challenging to effectively and efficiently harvest the spotty-available, small fraction of neighbor GPUs' memory because the amount of idle memory is highly variable and unknown a priori. Beyond the single GPU perspective, we redesign the memory management scheme for modern multi-GPU servers. HUVVM systems have to find the best

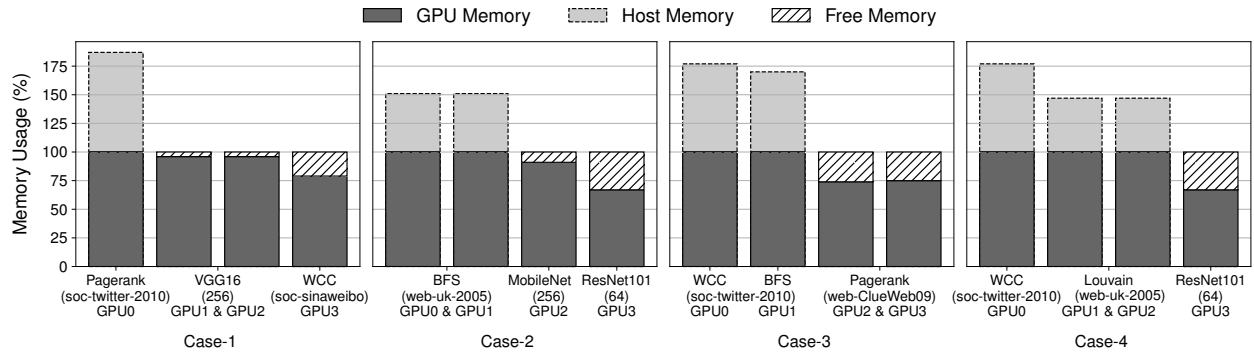

Figure 1: Memory usage snapshot in multi-GPUs hosting memory-intensive workloads (Section 6.1 and Table 2 present the detailed information for workloads and experimental environment)

way to utilize the small fraction of harvested memory while minimizing the performance impact on workloads running in the neighbor GPUs.

To that end, we propose a memory manager of HUVm, called *memHarvester*, implemented in the GPU driver layer. *memHarvester* functions as a centralized coordinator for data-path in HUVm. As an essential part of *memHarvester*, we propose a new multi-path parallel prefetcher, which exploits the path diversity of HUVm, comprised of PCIe and NVLink. Unlike many previous approaches [11, 14, 17, 25, 28] relying only on the host memory via PCIe, *memHarvester* first prefetches data from the spare memory to the local GPU through NVLink. Meanwhile, if the PCIe channel attached to the neighbor GPU is not contended, *memHarvester* allows for prefetching the data from the host memory to the spare memory of the neighbor GPU through the PCIe channel in parallel. Therefore, we can convert the latency of fetching data from the host memory to that of the spare memory effectively. *memHarvester* manages the space of harvested memory. Due to the limited space of spare memory, *memHarvester* is unable to keep all the evicted data in the harvested memory, leading to the host memory swap eventually. To reduce the performance overhead of data eviction from GPU to host, *memHarvester* supports eviction with 2MB large pages to host memory instead of 4KB base pages.

When HUVm and *memHarvester* host multiple workloads, it can improve memory utilization and overall server efficiency. However, on a downside, *memHarvester* may cause performance interference to the applications running on the GPU yielding idle memory. Thus, *memHarvester* immediately reclaims the spare memory to give it back to its original physical memory space with minimal latency whenever the application running on the yielding GPU needs additional memory, thereby minimizing performance interference.

We implement our prototype system on top of NVIDIA’s unified virtual memory (UVM) driver version 460.67, which is publicly accessible [29]. Without any modifications to applications or machine learning platforms, *memHarvester* transpar-

ently detects the availability of spare memory and dynamically constructs a new memory hierarchy. We quantify the effectiveness of *memHarvester* with HUVm for diverse consolidation scenarios on an AWS p3.8xlarge instance. The server has four NVIDIA V100 (16GB) GPUs connected through NVLink. Our experimental result shows that *memHarvester* can achieve significant throughput improvement for the large graph analytics workloads. For diverse consolidation scenarios with DNN training and graph analytics workloads, our experimental result shows up to $2.71\times$ performance improvement compared to the prior approach in multi-GPU environments with minimum interference of other workloads running on the same server.

2 Motivation and Background

This section characterizes memory usage behaviors of emerging workloads in shared multi-GPU environments and discusses opportunities to improve overall memory utilization by exploiting idle memory of neighbor GPUs.

2.1 Memory Usage in Shared Multi-GPUs

With the ever-growing demands of GPUs from development to deployment, most organizations allow semi-trusted users (e.g., employees in a company) to share the multi-GPU servers, reducing the cost of building the infrastructure [9, 13, 18, 35, 36]. Due to the shared nature, such GPU servers consolidate a wide range of workloads. In particular, many of the jobs running in the shared GPU servers are DNN training workloads for computer vision and natural language processing [11, 25, 28] that take a long time to complete. Thus, it leads to limited resource availability of certain GPUs at a time. Another widely witnessed application in multi-GPU servers is graph analytics [10, 19, 31], which figures out the relationships between objects in a given graph.

When looking at the memory consumption of such two emerging workloads, it is usually required for DNN training

jobs to tune the batch size to almost fit on GPUs to achieve maximum resource utilization [28]. On the other hand, the memory consumption of graph analytics jobs depends on the number of edges and vertices of a given graph. For a large dataset that does not fit in the given GPU memory, one can leverage a graph partitioning approach to make each partition fit on individual GPUs. However, the graph partitioning task introduces additional complexity in implementation [4] such that some of the graph algorithms are not supported to run on multi-GPUs (e.g., *Betweenness Centrality* in *cu-Graph* [6]). To overcome the memory space limitation, we can leverage host-side memory as a swap device to the GPUs through the unified virtual memory (UVM) technique that provides an illusion of infinite memory space [29]. Although this enables us to run analytics on large graphs or DNN training with large batches without out-of-memory errors, it significantly degrades performance.

In shared multi-GPU servers, we observe that a small amount of memory space across GPUs remains idle. Figure 1 shows memory snapshots of a 4-GPU (V100) server hosting multiple memory-intensive workloads. We profile four running scenarios each of which runs either graph analytics or DNN training jobs using one or multiple GPUs. The experimental environment is described in Section 6.1. The result shows that some GPU memory is not fully utilized, causing memory imbalance across workloads. In *Case-1*, *VGG16* and *WCC* leave a small amount of memory of GPU-1, 2, and 3, whereas *Pagerank* has to use the host memory for a swap device to run the large dataset. Another example is to run *Pagerank* with a relatively small dataset (*web-ClueWeb09*) with two GPUs in *Case-3*. In this case, the memory of GPU-2 and 3 is not fully utilized. Even though *Louvain* and *BFS* experience heavy memory pressure, the current memory management technique does not leverage the idle memory of the neighbor GPUs. These results confirm that the current memory management design is still not efficient in shared multi-GPU systems, wasting valuable GPU memory capacity. Considering that each workload has highly varying memory demands, achieving high global memory utilization in multi-GPU system is a challenging problem.

2.2 Exploiting Neighbor GPU Memory

Modern GPU servers provide useful primitives to facilitate memory harvesting, i.e., leveraging fast intra-server GPU interconnects without modifying applications or frameworks.

Fast interconnect. Modern GPU servers are commonly equipped with 8~16 GPUs connected via high-speed interconnect such as NVLink. For instance, NVIDIA DGX-2 has 16 GPUs with direct peer GPU access through fully connected NVLink topology, yielding a large pool of 512GB GPU memory at 600GB/s GPU-to-GPU bidirectional bandwidth [23]. With this HW specification, modern GPU servers can provide an attractive option for GPU-to-GPU communication to

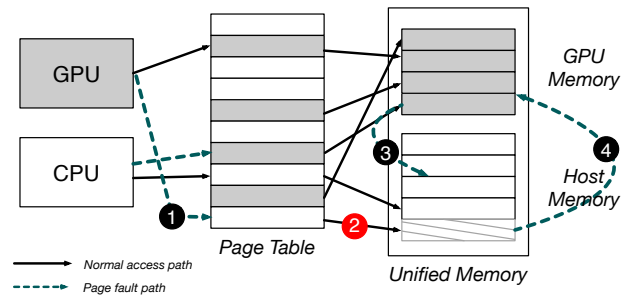

Figure 2: Unified address space in modern GPUs

transmit data without using the expensive PCIe interconnect.

Transparent control. Memory harvesting must address the cases that transfer data between GPUs running jobs across different applications. For example, in Figure 1, the graph analytics jobs and DL training jobs use their own frameworks. The unified virtual memory (UVM), introduced by NVIDIA and AMD, enables large-memory applications to seamlessly oversubscribe the limited GPU memory [29]. The technology is implemented as a GPU driver, so implementing memory harvesting in UVM requires no modification to the GPU applications or ML frameworks.

This section first explains how the current UVM driver works to leverage host memory for extending the limited GPU memory capacity. The UVM driver takes advantage of the host memory as a swap space for the GPU. Figure 2 presents how the UVM driver provides the unified address space across the GPU and host memory. The driver identifies whether the page being accessed by GPU is located on the GPU or the host memory through the page fault mechanism. With a single unified page table, UVM translates GPU virtual address into either GPU physical address or host physical address. If UVM identifies that the page accessed by the GPU kernel is mapped to the host by referring to the page table ①, a page fault exception is raised ② and the UVM driver brings the page into the GPU memory (typically via PCIe interconnect) ④. Meanwhile, when no free space is available in GPU, the driver needs to evict an old page from GPU memory before transferring the faulted page to GPU ③. Moving these pages requires page table entries to be properly updated to map new locations.

Opportunity. As observed in Figure 1, if one GPU needs more memory than its memory capacity, it can spill the fraction of oversubscription to one or more neighbor GPUs that still consume less than the total memory capacity with the fast interconnect. Moreover, by leveraging the unified address space supported by the UVM driver, we can serve diverse jobs ranging from graph analytics to DL training jobs without modifying applications or frameworks. Such *harvesting* of idle memory in neighbor GPUs opens up a unique opportunity to lower performance overhead under memory oversubscription by increasing the effective memory space. To work well

	PCIe	NVLink (speedup)
Throughput (GB/s)	12.3	40.1 (3.3×)
Latency (μ s)	16.7	5.1 (3.2×)

Table 1: Throughput and latency with PCIe and NVLink

with a very small fraction of idle memory, the mechanism for harvesting idle memory of neighbor GPUs should be timely and efficient. In Section 3.2, we address the design challenges in more detail.

3 Hierarchical Unified Virtual Memory

This section first measures the performance benefits of accessing the neighbor GPU’s memory connected through the high-speed interconnect (NVLink). Based on the measurements, we introduce a new unified memory, called *hierarchical unified virtual memory*, tailored for multi-layered memory systems comprised of local GPU, neighbor GPUs, and host memory. With the new memory organization, this section discusses how to incorporate the spare memory of neighbor GPUs into the memory hierarchy to bridge the performance gap between local GPU memory and host memory. Accessing neighbor GPUs is faster than accessing the host memory, but the spare memory space is dynamic and often limited, and may be shared by multiple harvesters. Therefore, utilizing a small amount of spare memory is crucial for effective harvesting. Finally, we discuss design challenges when leveraging the spare memory of neighbor GPUs with limited capacity.

3.1 Data Path with HUVM

To understand the performance benefit of harvesting the neighbor GPU memory, we conduct a performance analysis to measure the throughput migrating 2MB^2 data from a GPU memory to the host memory via PCIe and from a GPU memory to the other GPU memory via NVLink on an AWS `p3.8xlarge` instance. Two GPUs are connected through NVLink 2.0 with two lanes, providing up to uni-directional bandwidth of 50GB/s. Table 1 shows a comparison of bandwidth and latency between PCIe and NVLink. As expected, such NVLink provides more than $3\times$ better performance in terms of throughput and latency, indicating that data transfer time can be significantly reduced if we evict pages to neighbor GPUs. We anticipate that this performance gap will be higher in the next generation of high-speed interconnect.

Using the fast interconnect, i.e., NVLink, we build a new data path exploiting the spare memory of neighbor GPUs. Our approach brings two advantages in terms of performance. First, the new data path accelerates memory eviction. When evicting a memory chunk from the local GPU due to the

²Currently, the unit of memory eviction is a 2MB chunk in the UVM.

lack of memory space, if there is idle space in the neighbor GPU, our approach uses NVLink rather than PCIe to evict the memory chunk. Second, the new data path can reduce the latency of fetching. As the spare memory can act as a victim cache, we populate as many evicted chunks as possible on the spare memory. If these chunks are accessed again shortly, the chunks are fetched to the local GPU with the fast NVLink.

3.2 Design Challenges

Although our hierarchical unified virtual memory can reduce the performance penalty of GPU memory oversubscription, utilizing the spare memory poses several challenges.

- ① **Effective harvesting:** If the spare memory is not sufficient to serve all the evicted pages from the GPU applications, the effectiveness of memory harvesting would be limited to only buffering the evictions.
- ② **Minimal interference:** Harvesting may cause performance interference of the application running on the yielding GPU. Since we borrow the NVLink and PCIe bandwidth of the neighbor GPUs for the spare memory, our harvesting technique needs to minimize the performance interference.
- ③ **Low overhead:** Since UVM relies on the page fault mechanism, our approach inherits the same performance overhead, manipulating page table entries. Such overhead can prevent us from using full PCIe and NVLink bandwidth.
- ④ **Framework-agnostic:** All the GPU jobs do not rely on a specific framework. Our design and implementation need to be generalized to host a wide range of GPU workloads.

4 Memory Management for HUVM

This section presents a new memory manager, called *memHarvester*, for HUVM. *memHarvester* aims to hide the latency from the performance-critical path in accessing host memory with small but fast spare memory of neighbor GPUs. *memHarvester* opportunistically harvests the spare memory of neighbor GPUs while minimizing the performance penalty of memory-intensive applications that require more memory than available in one or more GPUs. To do so, *memHarvester* identifies the availability of spare memory in neighbor GPUs and plugs the spare memory into the memory hierarchy dynamically. To effectively harvest the spare memory, we explore a set of techniques: hierarchical and background eviction, fetching data in parallel, and prefetching in a neighbor GPU memory.

4.1 Overview

By harvesting spare memory in multi-GPU systems, *memHarvester* creates an illusion of GPU applications having a small cache between a GPU and host memory. Figure 3 presents the

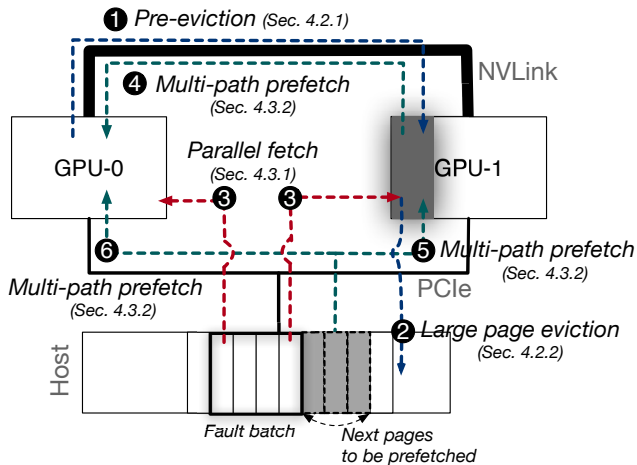

Figure 3: Exploiting spare memory with path diversity

overview of our proposed techniques. memHarvester allows GPU-0 to utilize the spare memory of GPU-1. ❶ Instead of evicting data to the host memory directly, memHarvester uses the spare memory connected through NVLink as a victim buffer to shorten the latency of memory evictions. To reduce the cost of memory evictions, memHarvester takes advantage of pre- eviction to the spare memory. With the spare memory, memHarvester reduces the number of evicting data to the host memory. However, it cannot eliminate accessing the host memory. ❷ To alleviate the penalty of populating pages on the host, we introduce a large page eviction scheme, amortizing the cost of evicting multiple base pages. ❸ If accessing data in the host memory is inevitable, we exploit the parallelism with path diversity in the multi-GPU systems when handling page fault batches. This approach utilizes the individual PCIe lanes attached to the harvested GPU and the local GPU at the same time.

To further hide the latency of migrating data to local GPU memory, we introduce a new *multi-path parallel prefetcher* exploiting the harvested memory and the path diversity in the multi-GPU systems. ❹ The data residing in the spare memory is prefetched into the local GPU through NVLink. Meanwhile, we prefetch the data belonging to the host memory to either the spare memory ❺ or local GPU memory ❻, depending on the PCIe congestion. Specifically, when there are multiple harvesters exercising the same spare memory, the harvested GPU can receive excessive prefetching requests, which saturate the PCIe bandwidth and adversely delay transfers of prefetch data. To address the problem, we have a facility dynamically enabling and disabling the use of spare memory in prefetching data from the host memory. Also, memHarvester prioritizes the memory eviction demands over prefetching on the harvested area because serving memory evictions is on the critical path of handling page faults.

Each GPU process has a separate page table. Even though evicted pages are located in the neighbor GPU yielding spare

memory, the process running in that neighbor GPU is not allowed to access the evicted pages. This is because the page table of the process in the neighbor GPU does not have the mapping information for the evicted pages, like the existing UVM driver [29]. Therefore, we do not violate the integrity and secrecy of evicted pages.

4.2 Hiding Eviction Latency to Host

Once the memory capacity is full, it is not allowed to bring data to the GPU before completing the memory eviction. The memory eviction is a part of the performance-critical path. Since migrating data to GPU memory is faster than to the host memory, our harvesting can reduce the latency of handling GPU page faults. After evicting the pages, memHarvester rapidly moves to the next step of fetching requested pages. While the harvesting GPU fetches the required pages, memHarvester invokes a background *writeback* thread to make a copy of the evicted page present in the harvested memory to the host memory. After copying pages, memHarvester marks the pages backed in host memory as *removable*. The purpose of the background copy is to immediately return the harvested space to the original GPU with negligible overhead. Once the application in the yielding GPU requires more memory than it currently has, it causes a GPU page fault. Then, memHarvester reclaims the harvested (*removable*) pages for the yielding GPU to use without the eviction. It picks the pages that come first into the yielding GPU. If there is no free or removable page, the yielding GPU may need to wait until the pages in the harvested region become removable. Although it can potentially incur the performance overhead, it rarely happens when evaluating our technique.

Therefore, our approach of using spare memory as a victim buffer allows that with a small fraction of memory, memHarvester turns the latency of host memory access into that of a neighbor GPU memory almost entirely, eliminating the host access latency from performance-critical eviction path.

4.2.1 Pre- eviction

When evicting pages to host memory, it is known that the pre- eviction scheme cannot hide the eviction latency entirely because the pre- eviction rate is limited to the PCIe bandwidth [25, 28]. In addition, pre- eviction requests contend with fetch requests occasionally, adding extra latency to critical fetch requests by stalling them. On the other hand, when evicting pages to harvested memory, it uses abundant NVLink bandwidth without contending the fetch requests from host memory. Once the memory consumption of harvesting GPU reaches a threshold of total physical memory (by default, if less than 50 free chunks are available), memHarvester invokes a pre- eviction thread. The pre- eviction has a good match with the background writeback technique because pre- eviction and writeback are pipelined. Ultimately, such pre- eviction allows

free memory available most of the time and effectively eliminates the eviction time from the GPU page fault latency. memHarvester uses the well-known LRU policy to select pages to be evicted. Pre-eviction with LRU policy works well with the memory access patterns of graphs and DNN workloads because most of them exhibit a cyclic memory access pattern with long reuse distances [2, 19, 35, 37, 38].

4.2.2 Large page eviction

The granularity for page faults is supposed to be the same size as the host architecture because the UVM driver relies on the demand paging scheme. On the other hand, the UVM driver uses a 2MB chunk as an eviction unit to simplify memory management. While evicting a 2MB chunk from the GPU to the host, the UVM driver splits the 2MB chunk into 512 4KB pages and performs the page population for the 512 pages because the driver is conservatively implemented to use the base page in the host architecture. To avoid such undesired inefficiency, memHarvester allocates 2MB of large pages in host memory by using the kernel's contiguous memory allocator [21]. Hence, memHarvester performs a single operation for populating a 2MB page between GPU and host memory instead of performing for individual 512 4KB pages. With or without our harvesting scheme, we can apply this large page eviction to all cases where a GPU has to interact with host memory.

4.2.3 Eviction policy

As multiple GPUs can leave a small amount of idle memory, as shown in Figure 1, memHarvester selects a target in a round-robin fashion to avoid hotspot contention and maximize the available GPU-to-GPU bandwidth in the system. Additionally, the round-robin policy enables each yielding GPU to make the removable pages in parallel through individual PCIe lanes. Eviction to the spare memory can incur performance interference to applications running on that yielding GPUs. We evaluate the negative performance impact of harvesting memory in Section 6.2.1.

When multiple harvesting requests are concentrated on a single spare memory, memHarvester handles the requests following their arrival orders. Note that the spare memory is used as a shared cache across harvesters.

4.3 Hiding Fetch Latency from Host

Evicting pages to the harvested memory reduces fetching latency if the local GPU accesses its evicted pages in a short period because memHarvester can fetch pages from the victim buffer in the neighbor GPU. In addition to that, memHarvester deploys two proactive schemes to hide fetch latency from the host memory with the limited space of harvested memory: fetching pages in parallel on page faults and pre-fetching pages with diverse paths.

4.3.1 Fetching pages in parallel

To reduce the cost of handling page faults, modern GPUs batch multiple page faults. The number of faults in a batch varies from time to time.³ The UVM driver handles requested pages corresponding to the page faults one by one. On the other hand, with the availability of harvested memory, memHarvester parallelizes handling multiple page faults in the same batch. memHarvester invokes page fault handling threads for each GPU (i.e., harvesting GPU and yielding GPUs), dividing tasks to each handling thread. As shown in Figure 3 (3), one thread for harvesting GPU takes faults from the head of the fault buffer, while the other thread for yielding GPU traverses the buffer from the tail and places the data corresponding to the fault on the harvested memory. memHarvester effectively reduces the latency of handling faults by fetching pages to local and the spare memory in parallel, so it utilizes the individual PCIe lanes attached to each GPU. Later, the fetched faults on the spare memory will be consumed through NVLink, reducing the fault latency further.

4.3.2 Multi-path parallel prefetcher

To hide the latency of accessing host and spare memory, we design a *multi-path parallel prefetcher* exploiting the path diversity in multi-GPU systems. When prefetching multiple memory chunks across the host and spare memory, there is no dependency between chunks. Our multi-path prefetcher can exploit the parallelism fetching the chunks with PCIe and NVLink. memHarvester first places the pages in the spare memory to the local GPU memory via NVLink (4 in Figure 3). For the pages in the host memory, memHarvester prefetches them on either the spare memory (5) or the local GPU memory through PCIe (6). The policy paragraph below explains how to select the target memory when prefetching from the host dynamically.

For selecting candidates to be prefetched, memHarvester uses a simple yet effective next line and stride prefetchers, which are good enough for graph analytics [2, 19, 38] and DNN training workloads [7, 32, 33, 35, 37]. By extracting the memory access pattern from the page fault history, memHarvester prefetches the next couple of chunks from either the host memory or the harvested memory, depending on where the chunks are located. We empirically select the amount of prefetch as 32MB and will show the sensitivity study in Section 6.2.1.

4.3.3 Prefetch policy

Unless the PCIe lane attached to the spare memory is crowded, we observe that prefetching to the spare memory can further reduce the fetch latency compared to the prefetch directly from the host to the local GPU. This is because leveraging

³The stock UVM driver handles up to 128 faults in a batch.

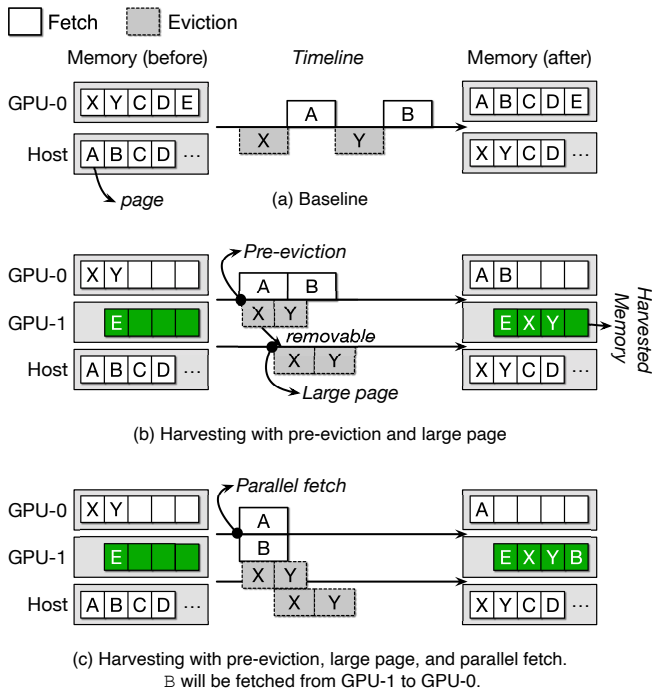

Figure 4: Timeline comparison for pre-emption, large page, and parallel fetch (Suppose that GPU-0 is harvesting the idle memory of GPU-1)

spare memory can reduce both 1) the number of page faults by proactively fetching pages and 2) the page fault latency by placing the pages highly likely to be accessed on the spare memory. On the other hand, as the number of active harvesters increases, the PCIe lane attached to the spare memory can be congested. Then, it slows down supplying the pages to the spare memory due to the limited PCIe bandwidth, increasing the fault latency.

To deal with diverse harvesting scenarios in multi-GPU servers, we have a policy in prefetching to dynamically select where the data in the host memory to be prefetched to either the spare memory (5) or the local GPU memory (6) based on the number of active harvesters.

4.4 Putting It All Together

Suppose the application running on the GPU-0 is accessing page A and B on the host memory. The GPU-0 memory is fully occupied except for the small number of reserved pages that hide memory eviction time in handling page faults. Figure 4a and Figure 4b compare how memHarvester eliminates the memory eviction latency from the critical path. While handling the page faults, if the number of the reserved chunks falls below the threshold (set as 50 chunks), memHarvester triggers the pre-emption task to secure the free space for upcoming page faults without the memory eviction. In this example, the oldest page X and Y in the GPU-0 are evicted

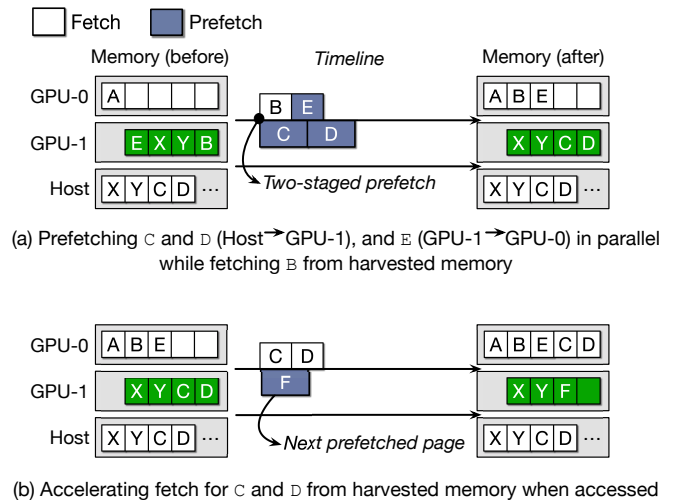

Figure 5: Timeline for our multi-path parallel prefetcher

to the harvested memory of the GPU-1 as background. Once it is completed, memHarvester makes a copy of that pages to the host and marks them as removable.

While handling the fault for page A, memHarvester looks up the faulted pages belonging to the same batch group. Figure 4c presents that page A and B are in the same batch. Thus, the fault batch can be processed to the local and harvested memory in parallel. While fetching page A to the local GPU memory, memHarvester places page B on the harvested memory. Since each GPU has its PCIe lane, we can fetch page A and B in parallel. Although it cannot reduce the number of page faults, we can hide the latency for fetching page B. Eventually, it does reduce the fault latency by fetching page B from the harvested memory connected through NVLink, rather than the host via PCIe.

Since the page A and B are faulted in order, memHarvester prefetches the next page C, D, and E. Assume that the number of pages to be prefetched is three in this example. Figure 5a depicts how the multi-path parallel prefetcher works. As page C and D are in the host memory, those can be prefetched into either the harvested memory or the local GPU memory through the PCIe lane. In this example, we assume that the PCIe lane is not contended so that memHarvester selects the harvested memory as the target. On the other hand, page E, which is in the harvested memory, is prefetched to the local GPU memory in parallel via NVLink. It can eliminate the fault if page E is accessed from the application. Figure 5b presents that we can potentially reduce the fault latency for page C and D by fetching such pages from the harvested memory when they are accessed.

5 Implementation

We implement our prototype, memHarvester, in the NVIDIA UVM driver version 460.67. The modification of the UVM

driver is 1,838 lines of C code measured by SLOCCount. We do not require any modifications to runtime and frameworks.

5.1 Managing Spare Memory

As UVM, memHarvester manages GPU physical memory as 2MB chunks. Each chunk has metadata, which describes the states and physical address of the 2MB chunk. For each GPU, memHarvester maintains a linked list of the metadata for free 2MB chunks. By referencing the free list of GPUs, memHarvester can easily extract available spare memory in the system. Once a GPU harvests a neighbor GPU's memory, memHarvester marks the metadata to indicate that a 2MB chunk is harvested from the neighbor GPU.

5.2 Managing GPU Memory Eviction

To evict a chunk, memHarvester selects the oldest chunk from per-GPU LRU⁴ lists as the stock UVM. The pre-eviction path diverges depending on the availability of harvested memory. If memHarvester has harvested memory, the background thread evicts chunks to the harvested memory. Otherwise, it evicts chunks to host memory. When memHarvester evicts a chunk to the harvested memory, memHarvester moves the chunk metadata from the LRU list to the evicted list. Since the evicted chunk resides only on the harvested memory, memHarvester does not allow the chunk to be reclaimed by the harvester. Once the eviction to the harvested memory is completed, memHarvester invokes a writeback thread to duplicate the chunk in the harvested memory to host memory. After that, memHarvester marks the chunk as removable and moves the chunk to the removable list. When the harvested memory has to be returned to the original GPU, memHarvester reclaims the removable chunks first. Before completing the writeback task, we are not able to reclaim the harvested space for serving the other request. Thus, the throughput of the writeback thread is critical. memHarvester increases the eviction size with large page to accelerate writeback thread and eviction.

5.3 Managing Fetch Requests

When a page fault exception occurs, the fault exception handler supplies faults from the head of the fault batch as usual. At the same time, memHarvester wakes up another kernel thread to serve fault entries from the tail of the fault batch to the harvested memory in parallel. As a result, we spend less time completing the fault batch with harvested memory. To coordinate consuming the fault batch shared between two threads, we use the mutex lock to handle a fault entry from the buffer synchronously.

After handling the demand fault batch, memHarvester triggers our multi-path prefetcher utilizing both the PCIe and NVLink bandwidth. memHarvester employs a simple but

⁴The LRU term presents the least recently swapped-in page.

effective next-line prefetcher for capturing the memory access pattern observed in graph analytics and DNN training. It keeps track of the addresses for the faulted pages to identify the direction of previous page fault addresses. Once the direction is determined, memHarvester prefetches the next 32MB as default. For the selected chunks, we examine the metadata to filter out the chunks already in the local GPU. We separate the selected chunks into two different queues according to their origin, either the host or the harvested memory, and then conduct the multi-path prefetch. While prefetching the chunks in the host to the harvested memory through PCIe, we use a kernel thread to prefetch the other chunks in the harvested memory to the local GPU via NVLink. We mark prefetched chunks as removable so that it can be immediately reclaimed when needed. If we encounter on-demand faults while prefetching, we abandon the ongoing prefetches to serve the demand faults first.

6 Evaluation

6.1 Experimental Setup

To evaluate the effectiveness of memHarvester, we conduct performance comparisons with the stock version of the unified virtual memory (Base) and the prior approach employing the pre-eviction and prefetch techniques for the host memory [11, 14, 17, 25, 28] (Pre-ef-host). As the implementation of prior studies is not publicly available, we imitate the behavior of pre-eviction and prefetch on top of the stock UVM driver. The evaluation is performed on an AWS p3.8xlarge which has four NVIDIA V100 GPUs, each with 16GB of memory. These four GPU cards are connected to each other through NVSwitch and NVLink 2.0 [16] and 240GB of host memory is attached through PCIe 3.0.

6.2 Experimental Results

6.2.1 Inter-job Harvesting

First, we evaluate our scheme in a shared multi GPU server hosting multiple DNN training and graph analytics workloads. We show how the idle memory of GPUs can be harvested by memory-intensive workloads running on other GPUs with inter-job harvesting. In this evaluation, all training workloads run with PyTorch (version 1.10.1), and all graph analytics workloads run with cuGraph (version 21.12).

Performance improvement. We evaluate the execution time of multiple workloads in four scenarios by varying the type of jobs and the number of harvesters to mimic a shared multi-GPU server environment. Table 2 presents the scenarios and the memory usage ratio for each job according to the given graph dataset or batch size. Figure 6 shows the speedup of the execution time to Base and also measures the performance

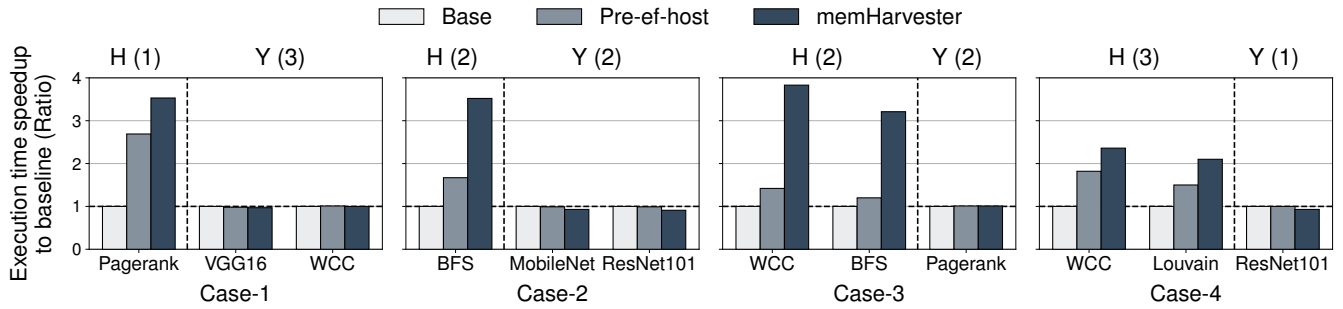

Figure 6: Execution time speedup of memory intensive workloads with memHarvester on four different harvesting scenarios (H: Harvesting GPU, Y: Yielding GPU, and the numbers in parentheses indicate the number of participating GPUs)

	GPU-0	GPU-1	GPU-2	GPU-3
Case-1 (ratio)	Pagerank (1.87x) soc-twitter-2010	VGG16 256 (0.96x)	WCC (0.79x) soc-sinaweibo	
Case-2 (ratio)	BFS (1.51x) web-uk-2005	MobileNet 256 (0.91x)	ResNet101 64 (0.67x)	
Case-3 (ratio)	WCC (1.77x) soc-twitter-2010	BFS (1.70x) soc-twitter-2010	Pagerank (0.74x) web-Clue09-50m	
Case-4 (ratio)	WCC (1.77x) soc-twitter-2010	Louvain (1.47x) web-uk-2005	ResNet101 64 (0.74x)	

Table 2: Multi-job scenarios with memory usage ratio in parentheses, input graph, and batch size (Gray cell: harvester)

of Pre-ef-host (i.e., the prior approach [17, 28]) for performance comparison. For all the cases, the execution time of harvesters, which do not fit on one or more V100 GPU memory (16GB), can be significantly improved by harvesting the idle memory of neighbor GPUs connected through NVLink.

In Case-1, Pagerank running on GPU-0 benefits from the spare memory of GPU-1 and 2 where VGG16 is running in data-parallelism and spare memory of GPU-3 where WCC is running, leading to 3.53 \times and 1.31 \times improvement over Base and Pre-ef-host, respectively. The amount of total spare memory of GPU-1, 2, and 3 is around 4.64GB, which is much smaller than the overcommitted memory of 13.92GB by Pagerank. Although the spare memory is unable to serve all the evictions from Pagerank, our memHarvester effectively harvests the spare memory to hide the latency of accessing the host. In addition, the negative performance impact to the applications running on the yielding GPUs is negligible.

We also evaluate the performance changes by varying the number of harvesting and yielding GPUs. In Case-2, BFS running on GPU-0 and 1 harvests the spare memory of GPU-2 and 3 where MobileNet and ResNet101 are running in each of the GPUs. memHarvester considers that the separated spare memory is logically unified like a shared cache across the harvesters. Our memHarvester can increase the performance of BFS by 3.52 \times and 2.1 \times compared to Base and Pre-ef-host, respectively. While harvesting, the perfor-

Figure 7: Effectiveness of individual techniques

mance impact of yielding GPUs is around 7~9%.

We show a different scenario in Case-3 where two applications each of which runs on a single GPU contend for the idle memory of neighbor GPUs. WCC running on GPU-0 and BFS running on GPU-1 harvests the spare memory of GPU-2 and 3 where Pagerank is running with its graph partitioned across two GPUs. Our memHarvester can increase the performance of WCC by 3.83 \times and 2.71 \times , and that of BFS by 3.21 \times and 2.67 \times compared to Base and Pre-ef-host, respectively. There is no performance degradation in Pagerank running on the yielding GPU.

In Case-4, we evaluate the effectiveness of our approach when two workloads share a limited spare memory contributed by a single GPU. ResNet101 yields 4.16GB idle memory that is shared by WCC running on GPU-0, and Louvain running on GPU-1 and 2. Although the throughput improvement is not much compared to other cases, it still outperforms pre-ef-host by 30~40%. Compared to Base, the harvesters show around 2.1~2.36 \times improvement while the performance impact of yielding GPU is around 7%.

Analysis of performance improvement. We decompose the contribution of the performance improvement to individual schemes constituting memHarvester. To this end, Figure 7 shows performance changes for each workload (from the left to the right) while we enable spare memory harvesting (H), pre-eviction (PE), large page support (LP), parallel fetch (PLF), local prefetcher (LPF) and multi-path parallel prefetcher (MPF) in order. Note that local prefetcher (LPF) is not a scheme of

Figure 8: Sensitivity to the amount of prefetch

memHarvester and it is evaluated as a baseline to compare the performance gain of our multi-path parallel prefetcher (MPF).

In general, we observe higher performance gain while we enable each scheme one by one. This is because each scheme has its complementary benefit to memHarvester: i) spare memory harvesting (H) utilizes the spare memory as an eviction buffer and a victim cache to reduce the latency of migrating chunks by using NVLink rather than PCIe; ii) pre-eviction (PE) eliminates the eviction latency from the critical path by reducing on-demand page faults; iii) large page support (LP) reduces the time of making removable pages by writing back the chunks to host in batch; and iv) parallel fetch (PLF) reduces the latency of handling on-demand page faults by fetching the pages in the fault batch in parallel with both PCIe and NVLink. While the first three schemes (H, PE, LP) focus on optimizing the eviction penalty, parallel fetch (PLF) focuses on reducing the latency when handling page faults.

Finally, we investigate our multi-path parallel prefetcher (MPF) which drastically improves performance compared with local prefetcher (LPF). For Case-1, 2, and 3, some of the evicted data reside in the host memory due to the lack of aggregated idle GPU memory in the system. Our multi-path parallel prefetcher utilizes the PCIe of the yielding GPU to prefetch data in host to the harvested memory. For Case-4, however, our multi-path parallel prefetcher (MPF) selects to prefetch data in the host memory to the local GPU memory rather than the harvested memory to avoid contention in the PCIe lane attached to the yielding GPU. Because there is more than one harvester per one spare memory, multi-path parallel prefetcher (MPF) changes the policy to directly fetch data from the host to local GPU memory. Thus, multi-path parallel prefetcher (MPF) has no performance gain compared to local prefetcher (LPF) in Case-4.

Sensitivity study. In this subparagraph, we present the sensitivity study of memHarvester to examine three aspects.

① **Prefetch size and stride:** We evaluate the sensitivity study for our next line and stride prefetches used in multi-path parallel prefetcher. Figure 8 depicts the execution time improvement by varying the amount of prefetches from 2MB to 32MB with a 2MB stride. Since both graph analytics and DNN training workloads exhibit sequential access patterns during the execution [2, 19, 35, 37, 38], our prefetcher extracts the direction of accessing the memory address and issues the

Figure 9: Sensitivity to the size of spare memory (The numbers in parentheses indicate the overcommitment ratio)

prefetch requests for the next chunks to either the host memory or the spare memory depending on where the selected chunk is located (host to spare and spare to local). While evaluating our prefetcher, we observe that the 2MB stride shows better throughput than the next line (0MB stride). For all four cases, increasing the amount of prefetch steadily improves the performance. We select 32MB as our default prefetch size with a stride of 2MB. We will further investigate how the amount of prefetch can be dynamically adjusted for maximizing the prefetch effects in our future study.

② **Available spare memory:** In a shared multi-GPU server, we expect that the available memory for harvesting fluctuates. We evaluate the execution time of four graph analytics workloads by manually varying the amount of spare memory from 5% to 60%. We imitate a scenario with 2 GPUs with one GPU running a memory-intensive graph analytics workload and the other GPU yielding spare memory with an appropriate size of `cudaMalloc`. Figure 9 exhibits that the performance can be improved by harvesting more idle memory of neighbor GPUs. Interestingly, even with 5% (800MB) of spare memory, we can achieve more than $2\times$ improvement for all four workloads. By effectively managing the small amount of idle memory of a neighbor GPU, the performance improvement is significant. However, when a certain amount of spare memory is harvested to accommodate all the active working sets to fit in the local GPU with the harvested memory, maximum performance is achieved and there is no additional improvement even if we increase the amount of spare memory. We observed that the amount of overcommitment size is larger than the active working set. For Louvain with an overcommitment ratio of $1.83\times$, the maximum performance is achieved when the spare memory size is 40% and even if the spare memory size is increased, there is no additional performance gain. We found a discrepancy between the size of the active memory working set and the size of memory `malloc'`d by the user-level and will further investigate whether we can also harvest the unused memory space that is not included in the active working set in our future study.

③ **Performance interference:** While harvesting spare memory, our approach can cause performance interference to the applications running on GPUs that yield the spare memory. This is because the harvesters piggyback the

	ResNet101			
	Base	H	H+PE+LP	memHarvester
VectorAdd (1)	1	0.99	0.99	0.97
VectorAdd (3)	1	0.91	0.88	0.87

Table 3: Normalized execution time of ResNet101 by increasing the number of VectorAdd harvesters

memory and PCIe bandwidth of yielding GPUs. Table 3 presents the impact of performance interference through a VectorAdd microbenchmark designed to generate a significant memory harvesting traffic. By increasing the number of VectorAdd harvesters, we measure the performance of ResNet101, which yields idle memory on one GPU. To investigate the interference incurred by individual schemes, we decompose our schemes into harvesting only (H), with pre-emption and large page (H+PE+LP), and with all the prefetchers (memHarvester). When running with a single harvester, the impact of performance interference for ResNet101 is negligible, up to 3% compared to the baseline. The maximum pressure to the GPU yielding idle memory is bounded by the network bandwidth of two GPUs through NVLink.

Meanwhile, three harvesters reduce performance by 13%. Even with harvesting only (H), it shows 9% performance degradation. As the number of harvesters increases, the amount of memory traffic to the idle memory can also increase, leading to the memory bandwidth contention. When enabling pre-emption and large page (H+PE+LP) schemes, it can utilize the idle memory more effectively, but it poses an additional 3% overhead. When all the proposed schemes are applied (memHarvester), the performance interference is not much different. Since our multi-path parallel prefetcher (MPF) selects to prefetch data in the host memory to the local GPU memory rather than the harvested memory to avoid contention in the PCIe lane attached to the yielding GPU. We anticipate that throttling the harvesting traffic can reduce the performance interference though it decreases the benefits to the harvesters. We leave this optimization to future work.

6.2.2 Intra-job Harvesting.

Our memory harvesting technique can be applied to multi-GPU applications where the memory consumption of individual GPUs is not even. The representative example is multi-GPU DNN training exploiting pipeline parallelism [20]. Such memory usage imbalance is primarily due to non-identical model partitions placed across the GPUs to balance the computation of each partition, leading to different memory demands (e.g., some of the GPUs need to have multiple weight and activation versions in pipeline parallelism). We evaluate the effectiveness of HUVm with memHarvester for single DNN training jobs. For this evaluation, we select GNMT16, GNMT8, ResNet50, and VGG16 with PyTorch. For the baseline,

Figure 10: Throughput improvement for single training workloads (H: # harvesting GPU and Y: # yielding GPU)

Figure 11: Memory usage for single training workloads (H: # harvesting GPU and Y: # yielding GPU)

the PyTorch framework is modified to support the memory oversubscription with NVIDIA UVM.

Performance improvement. Figure 10 shows the results of throughput comparison among memHarvester, Pre-ef-host, and Base. To initiate memory oversubscription, the batch size in each model is chosen such that at least one of the four GPUs goes beyond the local memory capacity. The figure shows that for all the models, memHarvester outperforms Pre-ef-host. In particular, for GNMT16 and ResNet50, memHarvester can effectively eliminate the host memory accesses in the increased batch size by harvesting only idle memory of neighbor GPUs. This leads to the throughput in memHarvester 1.5~1.6 \times higher than that in Pre-ef-host for the two models.

Figure 11 shows the memory profiles of the four models across the individual GPUs. It is worth noting that model training under memHarvester achieves throughput gains via diverse memory harvesting paths. For GNMT16, GPU-1 is the only GPU harvesting the spare memory of GPU-0, 2, and 3. On the contrary, for ResNet50, GPU-0 and 1 are the two harvesting GPUs that utilize the spare memory of the other two yielding GPUs, i.e., GPU-2 and 3.

More interestingly, for GNMT8 and VGG16, the aggregated idle memory across the yielding GPUs is not sufficient to serve the data evicted from the harvesting GPUs. In VGG16 with batch size 128, GPU-0, 1, and 2 use up all the idle memory of GPU-3 and then require using the host memory additionally. In spite of exercising the host memory, memHarvester shows meaningful throughput gains for both workloads. memHarvester improves throughput over Pre-ef-host by 2.16 \times and 1.24 \times for GNMT8 and VGG16, respectively.

7 Related Work

To the best of our knowledge, memHarvester is the first to propose a framework that allows GPU applications to utilize neighbor GPU's memory connected through the high-speed interconnect (NVLink). There have been significant efforts in both the architecture and systems community to support GPU memory oversubscription while minimizing the performance degradation of applications. Demand paging on GPUs [3, 22, 24] allows the GPUs to move pages from the GPU's memory to/from the CPU's memory automatically. We survey recent techniques that provide mechanisms to allow applications with a large working set to run on GPUs.

Framework-guided approach. For deep learning (DL) training workloads, prior studies proposed to have the framework insert the pre- eviction and pre- fetch operations by analyzing the dataflow graph [11, 17, 28]. Peng et al. introduced a sophisticated technique employing the pre- fetch and recomputation opportunistically without relying on the dataflow graph [25], these also require the intensive framework modification in terms of tensor allocation. Besides the pre- fetch technique, Animesh et al. proposed to compress the data, which shows the long reuse distance to save memory while the data is not being actively used [12]. Although this design approach can be effective, it requires the framework modification and understanding of the target applications, incurring the engineering overhead. Unlike such previous studies, we design and implement our solution in the GPU driver which can coordinate all the GPU memory in a centralized way.

Architectural approach. The architecture community also explored hardware techniques to minimize the overhead of GPU memory virtualization. Recently, Choukse et al. explored the advantage of leveraging the neighbor GPU memory which is connected through the high-bandwidth interconnect (NVLink). Unlike our approach, they studied a HW-based compression scheme to squeeze the limited neighbor GPU memory [5]. Ganguly et al. studied the prefetch technique used in the NVIDIA UVM driver in the overcommitted environment and proposed a HW-based pre- eviction and pre- fetch techniques [8]. Kim et al. exploited that modern GPUs handle the page faults in a batch and co- designed the GPU runtime and hardware to overlap the page eviction and migration effectively [14]. Li et al. proposed a framework for memory over- commitment [17] to efficiently virtualize GPU memory, but the disadvantage of those studies requires significant changes to the GPU runtime and hardware. Although such hardware approaches can further improve the performance as well as the efficiency, it requires new hardware structures.

Memory compression. Many previous studies [5, 15, 17, 27, 30, 34] proposed techniques to perform memory compression. While these techniques allow more data on the GPU memory, they are orthogonal to HUVm and can be used in conjunction to further improve the effectiveness of our proposal.

8 Conclusion

In this study, we propose a new approach of virtualizing multi-GPU memory, hierarchical unified virtual memory, by dynamically incorporating the spare memory of neighbor GPUs in multi-GPU systems. This can alleviate the memory fragmentation problem by creating the illusion of GPU applications having an increased effective memory space. To effectively utilize the small fraction of neighbor GPUs' memory, we introduced a memory manager for multi-GPU systems that has a set of techniques, including large page support, parallel fetch, and multi-path parallel prefetcher. Since our techniques can effectively reduce the latency of accessing host memory, for memory-intensive workloads, throughput performance is significantly improved compared to baseline and prior studies based on pre- eviction and prefetch techniques.

Abstract

Cloud services have recently undergone a major shift from monolithic designs to microservices running on the cloud-native infrastructure, where monitoring systems are widely deployed to ensure the service level agreement (SLA). Nevertheless, the traditional monitoring system no longer fulfills the demands of cloud-native monitoring, which is observed from the practical experience in Alibaba cloud. Specifically, the monitor occupies resources (*e.g.*, CPU) of the monitored infrastructure, disturbing services running on it. For example, enabling monitor causes jitters/declines of online services in Alibaba’s “double eleven” shopping festival with high loads. On the other hand, the quality of service (QoS) of monitoring itself, which is vital to track and ensure SLA, is not guaranteed with the high loaded system.

In this paper, we design and implement a novel monitoring system, named ZERO, for cloud-native monitoring. First, ZERO achieves zero overhead to collect raw metrics from the monitored hosts using *one-sided* remote direct memory access (RDMA) operations, thus avoiding any interferences to cloud services. Second, ZERO adopts receiver-driven model to collect monitoring metrics with high QoS, where credit-based flow control and hybrid I/O model are proposed to mitigate network congestion/interference and CPU bottlenecks. ZERO has been deployed and evaluated in Alibaba cloud. Deployment results show that ZERO achieves no CPU occupation at the monitored host and supports 1 ~ 10k hosts with 0.1 ~ 1s sampling interval using single thread for network I/O.

1 Introduction

Recent shifts in the production cloud environment from monolithic designs to microservice-based architecture [33, 34] have made cloud-native infrastructure the cornerstone of cloud computing services. The cloud-native applications consist of thousands of single-concern, loosely-coupled microservices running on containerized platforms [76]. The underlying systems are treated as disposable and immutable, finally enabling highly available, flexible and scalable cloud services.

In order to ensure the service level agreement (SLA) [52], the whole infrastructure is monitored with not only the upper-layer application metrics, but also the fundamental system metrics [84]. The novel cloud-native infrastructure, however, brings new challenges/demands to cloud-native monitoring, along with two major issues in commercial deployments.

First, traditional monitoring systems [10, 11, 65] occupies host (physical/virtual machine, PM/VM) resources to collect, process and upload metrics (Figure 1), which inevitably causes resource contentions with cloud services — enabling monitors causes jitters/declines of online services in Alibaba “double eleven” shopping festival (Figure 3). To ensure service SLA with resource constraints, the deployed monitor at the host should have no resource occupation.

Second, the quality of service (QoS) of monitoring itself is not guaranteed, which fails to support massive metrics with rapid variations in cloud-native monitoring. The latency/throughput of monitoring jitters severely due to the high system loads or small CPU quota set by the cloud provider (Figure 4). However, monitoring system with high QoS is vital to track and ensure SLA of monitored services [80, 84].

To resolve the limitations of traditional monitoring system and fulfill the demands of cloud-native monitoring, we design and implement a novel ZERO monitoring system in this paper. ZERO proposes a receiver-driven model, which collects raw metrics from the monitored host via *one-sided* RDMA operations, *i.e.*, RDMA read. Based on the ZERO framework, the monitoring system is expected to achieve no CPU occupation at the monitored host, low latency and high throughput, finally avoiding any interferences to services and fulfilling the QoS requirements of large-scale distributed monitoring.

However, there still exist several challenges to achieve the above goals. As shown in Figure 1, traditional monitor collects and processes raw metrics from the monitored processes, then upload metrics to the remote host, which inevitably causes CPU occupations. How to manage memory regions of system/application metrics and expose them to the remote host, finally achieving zero-overhead monitoring via RDMA read, is challenging. On the other hand, the remote

Figure 1: Traditional monitoring System.

monitoring host becomes bottlenecks in the receiver-driven model, as a tradeoff of offloading local monitoring overhead to the remote host. The remote host performs RDMA read on many monitored hosts, resulting in incast problem [85]¹. The remote host not only collects metrics, but also processes raw metric for further operations, all of which are CPU intensive. How to enable large-scale monitoring with network/CPU bottlenecks is challenging as well.

To access raw metrics with no CPU occupation, ZERO proposes the novel control plane and data plane. For the ease of clarity, we separate ZERO into local agent and remote controller (Figure 2). To achieve high scalability in reliable connection (RC) mode [26, 82], system/application metrics are managed by one agent and share one queue pair (QP) connection. In the control plane, ZERO agent provides universal interfaces for systems/applications to register the memory regions of their metrics at the RDMA NIC (RNIC). The metadata of these metrics are recorded at the control region. ZERO controller can thus acquire metadata of metrics from the control region as the prerequisite to access raw metrics. All metrics only need to register once if the metadata is not updated, after which ZERO agent enters blocking mode. In the data plane, the memory regions of metrics (data region) are exposed to the agent process via shared memory, finally to the remote controller. The ZERO controller can thus perform RDMA read on the data region directly without involving memory copies and CPU usages at the monitored host. As a result, ZERO achieves disposable overhead in the control plane and zero overhead in the data plane.

To deal with the network/CPU bottlenecks at the controller, ZERO proposes credit-based flow control (Credit-FC) and hybrid I/O model. We observe that the receiver-driven model is

¹Incast problem happens when multiple senders transfer data to one receiver simultaneously.

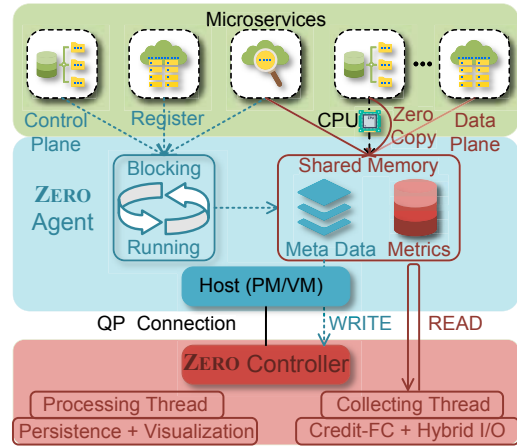

Figure 2: ZERO monitoring system.

superior to the traditional sender-driven model (*i.e.*, agent actively uploads metrics as per heartbeat): i) collecting metrics on demand to ensure the QoS of monitoring on latency; ii) limiting the total in-flight data of concurrent flows to avoid network congestion/interference. Accordingly, ZERO proposes Credit-FC to mitigate the incast problem while fulfilling the latency/throughput requirements of monitoring. On the other hand, ZERO introduces hybrid I/O model (a combination of event driven and busy polling mechanisms) and adopts thread dispatching to remedy the CPU bottlenecks of collecting and processing metrics, respectively.

As case studies, we integrate application (Redis [12]) metrics, system (kernel/containers [27, 76]) metrics and eBPF [3] metrics into the ZERO framework to demonstrate its generality and flexibility. We also share our experience about building large-scale monitoring system using RDMA.

The major contributions of this paper are summarized as follows:

- We propose the first zero-overhead monitoring system, ZERO, to resolve limitations of traditional monitoring system in cloud-native monitoring.
- We tackle several challenges of zero-overhead monitoring, including data plane with no CPU involvement, network congestion/interference caused by monitoring traffics, and CPU bottlenecks at the controller.
- We have deployed and evaluated ZERO in Alibaba cloud. ZERO achieves no CPU occupation at the monitored host and supports 1 ~ 10k hosts with 0.1 ~ 1s sampling intervals. We also share our experience with ZERO.

The paper is organized as following. Section 2 introduces the background and motivation. Section 3 proposes zero-overhead monitoring. Section 4 designs and implements ZERO framework. Section 5 presents case studies. Section 6 evaluates the proposed design. Section 7 introduces the experience and future work. Section 8 discusses related works and Section 9 concludes this paper.

Figure 3: Monitor interfering with services.

2 Background and Motivation

In this section, we further elaborate cloud native monitoring and the inherent limitations of traditional monitoring system.

2.1 Cloud-Native Monitoring

Monitoring system deployed at the cloud-native infrastructure, namely, cloud-native monitoring, is indispensable to ensure the SLA of cloud services. Monitor collects the bottom-layer system metrics, such as the utilization of physical resources (CPU, memory, *etc.*). Based on system metrics, monitoring system performs health checks on the underlying system, makes early alert and provides suggestions to administrators [18]. Furthermore, by analyzing the historical resource consumption and performance variations, cloud providers improve system utilization and lower operational expenses (OpEx) [27, 28, 41]. On the other hand, the upper-layer application metrics, *e.g.*, requests per second of key-value service [12, 45], directly reflect user activities and functional state of applications. The monolithic applications are decoupled to thousands of microservices [33], all of which are monitored to track and ensure the SLA.

The novel cloud-native applications together with the essential infrastructure bring new challenges/demands to cloud-native monitoring, along with two major issues in commercial deployment.

How to avoid monitor interfering with services? Microservices have much stricter requirements of QoS compared with typical applications [33]. However, the cloud-native environment is highly resource constrained. For example, Alibaba cloud adopts mixed deployment of CPU-intensive online service [42] and I/O-intensive batch jobs [93] at the same host, to maximize resource utilization [43, 78] and reduce long-term capital expenses (CapEx). Microsoft Azure also reports that 80% of VMs only have 1 ~ 2 vCPU cores [27]. The monitor

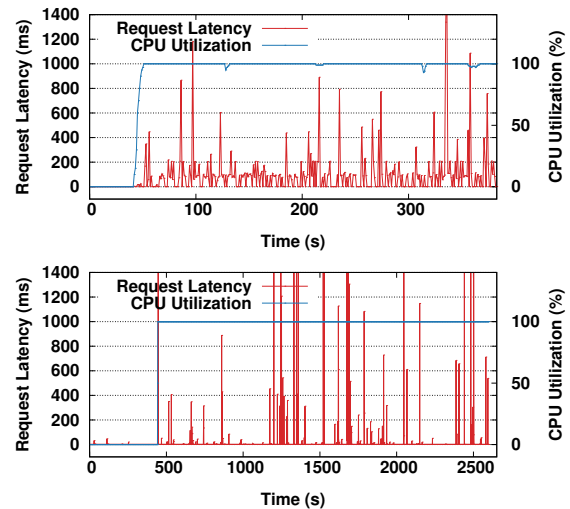

Figure 4: Monitoring jitters with high system loads in Netdata (upper) and Prometheus (bottom).

should have no CPU occupation to avoid contentions with cloud services.

How to ensure QoS of monitoring? Cloud-native monitoring needs to support massive metrics with rapid variations. Cloud providers, such as Alibaba, Netflix and Uber, need to monitor millions of metrics with hundreds to thousands of microservices [80]. Besides, these application metrics (financial transactions, social network and e-commerce [67, 94]) and system metrics (CPU, memory, network [6, 54]) have rapid variations with a time scale of seconds/milliseconds. To track and ensure SLA of services, monitoring requires high QoS from the perspective of latency and throughput.

2.2 Traditional Monitoring System

We next introduce traditional distributed monitoring systems [10, 51, 65] and elaborate their limitations as the motivation of ZERO. As shown in Figure 1, multiple collectors acquire application/system metrics via specific interfaces, meanwhile raw metrics are processed as the final outcomes (Section 5). After that, the collected metrics are uploaded to the remote controller for further analysis and visualization. Each step occupies host CPUs for memory copy, calculation, network transmission, *etc.*, which inevitably interfering with services running on the host. On the other hand, traditional monitor massively relies on the kernel's TCP/IP network stack to transmit metrics. However, kernel data processing overhead has become the main bottleneck of end-to-end latency/throughput [90]. State-of-the-art works thus offload network functionality from kernel to user-space network stack [39, 53, 64] or hardware [35, 44, 70].

We next elaborate the limitations of traditional monitors in our real deployment. We consider two representative open-

sourced monitors, i.e., Netdata [10] and Prometheus [11]. We observed that enabling monitors causes jitters of online service in Alibaba “double eleven” shopping festival with high loads. We use Netdata to monitor a high-loaded host running Redis services with 1s sampling interval. As shown in Figure 3, monitor process causes jitters of Redis service, i.e., the throughput declines by 6.25% while tail latency increases by $2\times$ periodically, due to the CPU occupation in each monitoring cycle. We analyze that reasons for such “interference spikes” are two folds. First, the deployment of service and monitor processes may adopt default CPU scheduling or specific CPU bonding [48], where contentions happen when service/monitor processes are scheduled/bonded to the same CPU core. Second, the CPU utilization keeps on high water level and exhibits burst natures, especially during sales promotion with high loads. Thus, the duty-cycled monitoring process with slight CPU occupation ($1 \sim 5\%$) already causes severe interference (Figure 3). The CPU breakup of monitor shows that the uploading phase occupies $5 \sim 10\%$ of the total CPU utilization while the collecting phase occupies the majority. On the other hand, the QoS of monitoring is highly affected by the system load or CPU quota set by the cloud operator. The latency of monitoring increases by more than $10\times$, when host CPU is saturated or CPU quota is reached (Figure 4). Assigning dedicated cores for monitoring may avoid these problems, however, causes large wastes of resources and high CapEx. Besides, the monitoring process may be blocked to request metrics via service interface (Section 5).

3 Zero-overhead Monitoring

To avoid resource contentions with services and ensure QoS of monitoring, we propose the zero-overhead monitoring system, namely ZERO, for cloud-native monitoring. ZERO exploits features of monitoring metrics and RDMA capability in modern data center. The basic idea is that most of raw metrics are counters updated at fix memory regions — the remote controller can thus obtain these metrics by performing RDMA read on these memory regions — without any CPU involvement at the monitored side. We next elaborate possibilities and challenges of realizing ZERO.

Metric features. ZERO is based on two features of monitoring metrics. First, most of the monitoring metrics are counters. Systems/applications update these metrics at fixed memory region after initialization. For instance, the number of stored/evicted key-value pairs in Redis and the number of sent/received packets recorded by kernel stack are all counters. Second, processing of raw metrics is simple algebraic calculation and can be offloaded to the controller. For example, Redis exports statistic data on the raw metrics and per-CPU counters are summed to get the final kernel metrics. These features are general to system/application metrics and ZERO can thus support various metrics as an universal framework (Section 5).

RDMA support. ZERO then leverages *one-sided* RDMA operation to read raw metrics/counters, to achieve no CPU/kernel involvements at the monitored host. RDMA has been widely used in data centers and provides new characteristics of low latency (as low as $1 \mu s$), high bandwidth (more than 100Gbps) and kernel/CPU bypass. RDMA supports both *one-sided* and *two-sided* operations. The one-sided operations directly operate on the remote memory via *read* and *write* without involving the remote server’s CPU. To perform one-sided RDMA operations, one needs to register the *memory region* (MR) at the RNIC of remote host and acquire the generated *remote protection key* (rkey). The two-sided operations, i.e., *send* and *recv*, communicate via an interface similar to socket. In the following paper, we refer to RDMA read, write, send and recv as READ, WRITE, SEND and RECV, respectively. RDMA hosts create queue pairs (QP) consisting of a send queue and a receive queue, then post RDMA operations on send/receive queue to communicate with the remote host. RDMA transport supports reliable or unreliable connection (RC/UC) and unreliable datagram (UD). One-to-one connections between QPs are required in RC/UC mode, whereas one-to-many communication is supported in UD mode. Different transport types support different subsets of RDMA operations, and READ operation is only supported in RC mode.

Challenges. While ZERO is expected to achieve zero-overhead monitoring, there still exist two challenges to make the idea practical. First, we observe that most CPU time of traditional monitor are spent on collecting metrics from system/application processes (Section 2.2). ZERO also needs to eliminate such overheads in its data plane, besides the transmission overheads offloaded to RNIC. Second, controller is bottlenecked on both network and CPU with large number of monitored hosts, as all monitoring overheads are offloaded to the remote controller. With all these challenges, the key innovation of Zero lies in effectively exploiting one-sided RDMA and designing the separate control/data plane to realize zero-overhead monitoring. Zero further incorporates several designs to resolve practical issues (network congestion/interference, scalability) in distributed monitoring.

4 Design and Implementation

In this section, we present the overview of the ZERO framework. We then introduce the design and implementation of ZERO in details.

4.1 Overview

As shown in Figure 2, ZERO proposes the novel control plane and data plane to collect raw metrics without CPU involvements at the monitored host. ZERO adopts receiver-driven model to collect metrics from large number of hosts, and deals with the network and CPU bottlenecks at the controller.

Figure 5: READ w/o (left) or w/ (right) memory management.

The scalability of RDMA-based system is constrained by the on-chip memory (SRAM) of RNIC [26, 82]. To achieve high scalability at the controller, all metrics at the host are managed by one agent and share one QP connection. In the control plane, ZERO agent provides interface for systems and applications to register the memory region of their metrics (data region) at the RNIC. The metadata of metrics (*e.g.*, address, rkey) are written into the control region. ZERO controller can thus obtain metadata by reading the control region and access to raw metrics via reading the data region. The agent process is blocked unless systems/applications need to register/update metrics. In the data plane, the memory region of metrics are exposed to the agent process via shared memory, finally to the remote controller. The controller performing READ on the data region to acquires metrics, which achieves zero copy and no CPU involvement at the monitored host. In the real deployment, the control-plane overhead is usually disposable — the metrics only need to register once — then keeps in use or updates after a long time. The data plane has no CPU occupation as expected.

ZERO supports large-scale monitoring via single controller. ZERO adopts thread dispatching, where only $1 \sim 2$ threads are used to collect metrics and the rest cores are used to process metrics in parallel for further operations, *e.g.*, visualization and persistence. ZERO controller uses receiver-driven model, *i.e.*, issuing READ requests on the monitored hosts to collect raw metrics, which is superior to the traditional sender-driven model. ZERO achieves high monitoring QoS by posting READ requests on demand and avoids network congestion/interference by controlling the total in-flight data. Accordingly, credit-based flow control (Credit-FC) and hybrid I/O model are proposed to remedy the incast problem and CPU bottleneck, respectively.

4.2 ZERO Control Plane and Data plane

We introduce the ZERO control plane and data plane, together with ZERO framework usage and interface in this subsection.

Control plane. ZERO agent deals with registration requests from systems/applications, which uses UNIX domain socket for inter-process communications (IPC). To handle the request, the MRs of monitoring metrics are registered at the

RNIC and the metadata of MRs (*e.g.*, address, type, size, rkey) are recorded at the control region (Figure 5a). Note that the MR is pinned after metrics are registered and will be released only after metrics expire. ZERO agent registers the control region at the RNIC and builds a QP connection with the remote controller in advance. The controller can thus acquire the metadata of metrics by reading and parsing the control region, then access raw metrics.

The control plane has disposable overhead. ZERO agent inevitably occupies host resources to deal with registration requests. However, we observe that the control-plane overhead is disposable for most of metrics. We divided metrics into three types according to the practice in Alibaba cloud. First, metrics of the underlying systems and persistent services, *e.g.*, database and storage services [56, 91], are usually immobile once registered. Second, some services may be dynamically created/destroyed. For example, e-commerce services are periodically expanded/shrunk according to the number of users shopping online [60]. Third, some user requests are served by ephemeral serverless *functions* to mitigate the cost of long-lived services with intermittent activities [25, 33].

Generally, ZERO agent enters into blocking mode with no CPU occupation (Figure 2). When services change, ZERO agent resumes to (de)register metrics and update the corresponding control region. For the first two cases, ZERO agent handles registration requests and updates control regions infrequently with negligible overhead. ZERO controller also only reads control regions once in a long period. In the serverless case, ZERO agent may frequently (de)register metrics of serverless *functions*. ZERO agent further uses WRITE to write the updated metadata into the remote control region (Figure 2). ZERO controller can thus obtain raw metrics by only reading the data region with one RTT. Note that the overhead of ZERO using WRITE or SEND/RECV is still much lower than that of the traditional monitor (Section 6.2).

Data plane. To eliminate the overhead of collecting metrics from multiple processes and avoid frequent memory copies, ZERO exclusively adopts shared memory in its data plane. Specifically, ZERO agent uses `mmap` operations, which are invoked when registering metrics, to expose MRs of metrics (data region) to the agent process, finally to the remote controller. The `mmap` operation takes 4KB page as the basic unit. However, metrics are not necessarily locating at the page header (Figure 5). ZERO agent calculates the page header of metrics to `mmap` their pages. As shown in Figure 5, ZERO agent records the page address and page offset in the control region. To protect data region from being modified by local agent or malicious remote host, ZERO sets read-only access to the data region via `mmap` flags and uses the rkey mechanism inherently supported by RDMA. ZERO controller obtains raw metrics by performing READ on the data region.

The data plane has zero overhead. The data plane achieves zero CPU occupation, zero copy, and no extra memory footprint at the monitored host, via the shared memory design.

```

// type one, specifying attributes of variables
struct disk my_disk{
    .disk      = "sda",
    .hash      = 0x000f3456, ...
} __attribute__((section(".zero_init")));
//type two, using allocator
struct disk *my_disk = zero_malloc(sizeof(struct disk));

```

Figure 6: Management interface for two types of metrics.

An alternative solution of copying metrics when updating causes frequent CPU occupations for memory copies, and extra memory footprints. Besides, ZERO data plane ensures the read-write consistency between remote and local memory. Most of application/system metrics are defined as atomic variables, which are updated atomically in the shared memory. The atomic update only needs $1\sim 3ns$ in Intel Haswell architecture [74] — three orders of magnitude lower than that of RDMA operations ($1\mu s$) — the memory consistency is guaranteed between update and READ. For non-atomic variables, ZERO uses bit flags to indicate the states of updating. FaRM [31] and Pilaf [68] use a similar method to ensure data consistency with READ. ZERO controller will check whether metrics are read correctly via bit flags and retry in the next cycle. We eliminate all synchronous locks for zero overhead, which may cause inconsistency under rare race conditions while ensuring accuracy for most cases.

Memory management is indispensable. While local host achieves zero overhead in ZERO data plane, we observe that simply performing READ on massive metrics cannot achieve desirable performance. Because metrics are distributed across the process/kernel space with discrete memory addresses, ZERO controller needs to read large number of entries in control region as well as metrics in data region (Figure 5a). However, the bandwidth of READ falls rapidly and the latency is nearly doubled when the number of MRs increases from 100 to 10k, due to evictions in the RNIC SRAM [26, 82]. ZERO introduces memory management to reduce the number of MRs and READ requests required to collect massive metrics. Specifically, ZERO proposes two memory-management mechanisms for two types of metrics (Figure 6). First, many metrics are global variables or data structures. One can mark these metrics by specifying attributes of variables [13]. The compiler will distribute these metrics to the same data segment. Second, metrics are defined as pointers to variables. ZERO provides a memory allocator for these metrics. Specifically, the MRs of metrics are allocated with continuous space via the allocation API. The core idea of both methods is concatenating metrics to the same MR to support massive metrics. Besides, data region is aligned as `struct` and recorded at the control region for the ease of memory parsing at the controller. As shown in Figure 5b, ZERO controller only needs to post one READ request on the same MR to get a list of metrics.

Framework usage and interface. ZERO can be easily deployed at hosts (PM/VM) with RDMA support. ZERO agent and controller need to be initiated at the local and remote host respectively. Systems/applications then invoke agent API to manage and (de)register their metrics. The agent accomplishes all control-plane operations, e.g., `mmap`, updates of control region, when handling (de)register requests.

4.3 Scaling-out Monitoring

We next present how to support large-scale monitoring with single ZERO controller. ZERO proposes credit-based flow control (Credit-FC) and hybrid I/O model, to avoid network congestion/interference and remedy CPU bottlenecks respectively. ZERO controller needs to collect and process metrics from large number of hosts, while fulfilling the monitoring QoS in latency and throughput. To achieve this goal, the controller adopts thread dispatching to collect and process metrics in parallel with individual threads.

Collecting metrics. The controller only assigns $1\sim 2$ threads to collect metrics. ZERO achieves high efficient network I/O with single thread by posting READ requests then polling completions on multiple QPs in batch. This is feasible because both `post_send` and `poll_cq` are fast non-block operations. According to our experiment, the batch operations only add negligible latency (tens of μs).

Receiver-driven model is superior to send-driven model. Issuing READ on data region turns out a receiver-driven model to collect metrics from multiple hosts. The receiver-driven model has two benefits compared with the traditional sender-driven model. The controller posts READ requests on demand to meet the target latency or updating frequency in monitoring. Besides, it also facilitates to avoid network congestion/interference by limiting the total in-flight data of concurrent flows. We next intuitively formulate the scale-out ability of such receiver-driven model. The monitored hosts have different requirements in terms of updating interval U and data size S , i.e., controller needs to collect S bytes in every U seconds for a specific host. Assuming the bandwidth B of the receiver is fully utilized, the maximum number of supported hosts $n = B \times U / S$. Our deployment shows that ZERO supports at least 1k hosts with 128KB metrics and 100ms sampling interval.

Credit-based flow control. Concurrent READ requests generate burst network traffics, which are transmitted from multiple hosts to the controller simultaneously, resulting in severe incast problems. ZERO introduces Credit-FC to remedy the incast problem, which works as follows.

Large-sized READ requests are segmented into fix-sized fragments with 4KB page size. ZERO chooses such moderate size due to three considerations: i) page is the basic unit of shared memory, which can accommodate 1k 32-bit metrics and fulfill the demands of most services; ii) the number of READ requests is bounded as the total size of metrics in

single host is general hundreds of KBs; iii) the small size facilitates congestion control in severe incast.

Subsequently, credits are used to limit the total in-flight data of concurrent flows (identified by a QP). Posting READ requests or polling completion events will consume or regain credits for the target flow. The state-of-the-art works [44, 70] adopt bandwidth-delay product based flow control (BDP-FC), which bounds the in-flight data per flow by the BDP of the network. However, BDP is large enough to cause congestion and trigger explicit congestion notification (ECN) packets or priority-based flow control (PFC) pause frames [95], with large number of concurrent flows (Figure 11c). ZERO proposes Credit-FC to limit the total in-flight data. Specifically, the credit of each flow C_f is set to T/n , where T is the total credit and n is the number of concurrent flows. Finally, Credit-FC effectively avoids triggering ECN/PFC (Section 6.3) and network interference with service traffics (Section 7).

Hybrid I/O model. To avoid the thread performing network I/O being saturated, ZERO proposes the hybrid I/O model incorporating event driven and polling mechanisms, which is similar to NAPI in Linux [73]. The event-driven I/O can effectively avoid CPU occupation for busy polling. Each QP is associated with an event channel to notify a new (first) completion event. The I/O multiplexing interface, *e.g.*, `epoll`, is used to listen the `fds` of multiple event channels. The collecting thread blocks until completion events are notified from one or multiple QPs, then polling the in-flight requests of the corresponding QPs. We observe that the event-driven model effectively reduces CPU utilization with large number of in-flight requests (Figure 12b). However, when the monitored data size is too small with only several requests after segmentation, the `epoll` syscall and thread blocking incur high variations in READ latency (Figure 12a). The controller thus uses busy polling for hosts with small number of requests. In the hybrid I/O model, ZERO assigns two threads to perform event-driven polling and busy polling, respectively. Note that both threads share Credit-FC.

Processing metrics. The controller dispatches multiple threads to processing raw metrics in parallel. Specifically, the MRs of the collected metrics are placed into the appropriate queue where each MR can be handled by one of multiple processing threads. Each MR concatenated by a list of metrics is parsed as `struct` directly according to the metadata recorded at the control region. The parsed metrics are then processed by reproducing the same calculations which are originally performed by the monitored host. Finally, the controller imports processed metrics into InfluxDB [7] for persistence and uses Grafana [5] for visualization.

5 Case Study

In this section, we present how to integrate application/system metrics into the ZERO framework using three typical cases of

Redis [12], Linux kernel [81] and eBPF [3].

Redis Case. Redis [14] has been widely deployed in Alibaba cloud as database, cache, and message broker, providing low-latency in-memory data structure storage services. Traditional monitor acquires Redis metrics by requesting `INFO` interface of Redis server. Traditional monitor thus occupies the resource of Redis server and the host to obtain metrics. As a comparison, ZERO only needs to register metrics and requires no resource occupation for collecting metrics. There exist more than two hundred metrics in each Redis service instance. The naive implementation is performing READ on these metrics one-by-one (see Figure 5a), resulting in high latency and CPU utilization. To resolve this problem, we use allocation API (type two) to allocate and structuralize Redis metrics with continuous memory. As shown in Figure 5b, ZERO only needs to register and perform READ once for each Redis instance in our implementation. ZERO controller then parses metrics as `struct` according to the memory structure.

Linux Kernel Case. Linux kernel exports system metrics to user space via `proc` interface, which creates files under `/proc` directory and bonds corresponding kernel functions. Traditional monitor usually needs to read hundreds of `proc` files to get all system metrics, which incurs extra overhead for user/kernel-space processing. With ZERO framework, kernel metrics are registered at the ZERO agent then exported to the ZERO controller directly. We use ZERO to monitor metrics managed by container namespace for the container-based services [1]. Kernel metrics are usually implemented as lock-free per-CPU counters to avoid locking overhead. ZERO controller needs to READ all replications of metrics in each CPU core, locating at separate pages. Production cloud environment adopts fine-grained resource assignment and isolation, in which more than 90% hosts only have 1 ~ 4 CPU cores [27]. ZERO only needs 1 ~ 4 requests to obtain kernel metrics.

eBPF Case. The extend Berkeley Packet Filter (eBPF) [3, 66] is an evolving technology, which can dynamically attach program to running kernel for tracing, instructing, and even controlling the kernel code path. eBPF has been widely used in cloud computing for monitoring [6, 54], networking [38, 83], virtualization [21, 22] and security [29, 30]. We use eBPF to monitor traffics and retransmissions of large number of TCP connections in MaxCompute [32, 93] service. eBPF provides in-kernel data structure, called `map`, to enable control and data messages delivery within kernel or between kernel and user space. eBPF attaches probes to kernel/application functions at runtime and exports metrics, events and histograms to eBPF `map`. User process reads the entry of eBPF `map` via syscall. However, reading large number of entries incurs large overhead due to frequent syscalls. To integrate eBPF into ZERO framework, eBPF `array map` is adopted, which supports `mmap` operations (from Linux kernel 5.5+) and can thus export its memory to ZERO agent directly.

Name	Nodes	Hosts	OS kernel	Intel Xeon CPU code	Mellanox NIC	Protocol	ECN	PFC

Table 1: Deployment environment.

6 Evaluation

6.1 Evaluation Setup

In our evaluation, we adopt a multi-phase deployment with two typical clusters, as summarized in Table 1. Initially, we deploy Zero in a test environment (Cluster1) with a rational scale that mimics the production environment for demonstration. We next deployed ZERO in a public-cloud environment (Cluster2), which covers common cloud services in production. The deployment scale has continued to grow according to the feedback of canary testing and the actual demands of services. In Cluster1, services operates in guest VMs with 4 vCPU cores. The RNICs are virtualized and assigned to VMs via passthrough [87]. In Cluster2, services are deployed in containers running on bare-metal servers [92]. Each VM/container is monitored independently to evaluate the scalability of ZERO. Note that both configurations are typical in Alibaba cloud-native platform [15]. We use ZERO to monitor typical services, *e.g.*, Redis [14], container [1] and MaxCompute [32, 93].

We evaluate ZERO performance from three aspects:

- *CPU Utilization*: The CPU utilization is defined as occupied CPU time per second. We use `perf` tool to measure the CPU utilization of both ZERO agent and controller. We verify the CPU involvement of monitor in control plane and data plane. We also need to concern about the CPU utilization of ZERO controller for scalability.
- *Latency*: The latency of ZERO is the time used to READ all metrics from the monitored host. For traditional monitor, the latency consists of time used to collect/process all metrics and time used to upload all metrics. We verify whether monitor can meet up the updating frequency of metrics by latency.
- *Throughput*: The throughput is the collected bytes per second during each monitoring period. We verify whether monitor can support massive metrics by throughput.

We test the impact of the following parameters on monitoring performance:

- *Sampling Interval*: The required sampling interval is determined by the updating frequency of metrics. We evaluate ZERO with 10 ~ 1000ms sampling intervals and use 1000ms by default.
- *Number of Instances/Connections/Requests*: All of three parameters impact the CPU utilization and data size of monitoring. The number of service/container instances varies from 10 to 40, with a default value of 10. The number

Metric	Monitor	Redis	Kernel	eBPF
Total Latency (ms)	Baseline	0.7 ~ 19.3	0.5 ~ 1.6	0.8 ~ 12.5
	ZERO RPC	0.08 ~ 0.18	0.14 ~ 0.36	0.10 ~ 1.02
	ZERO	0.05 ~ 0.14	0.07 ~ 0.23	0.08 ~ 0.87
Agent CPU Utilization (%)	Baseline	0.5 ~ 45	0.01 ~ 4	0.08 ~ 6
	ZERO RPC	0.01 ~ 0.55	0.08 ~ 0.9	0.05 ~ 0.68
	Control plane	0.05 ~ 0.07	0.8 ~ 1.5	0.04 ~ 0.05
	Data plane	0	0	0

Table 2: Summary of ZERO overhead.

of TCP connections varies from 1k to 16k, with a default value of 1k. The number of work requests varies from 8 to 128 for a host, with a default value of 32.

- *Number of Hosts*: One ZERO controller is deployed to monitor multiple hosts running ZERO agent. We increase the number of hosts (from 64 to 1024) to evaluate the scalability of ZERO framework.

We use the state-of-the-art monitoring system named Netdata [10], existing *NX* monitor in Alibaba cloud, and ZERO RPC as comparison benchmarks:

- *Netdata*: Netdata is widely used by cloud providers, *e.g.*, Amazon Web Services (AWS) and Microsoft Azure [8]. Netdata integrates application/system metrics in one agent by requesting application interface or reading `proc` files respectively. The agent uploads metrics to the controller as per heartbeat or the controller acquires metrics via sending RPC requests to the agent.
- *NX*: *NX* is a network monitoring tool deployed in Alibaba cloud. *NX* exports network metrics as logs, *e.g.*, info of TCP connections, then uploads the collected metrics via log service. We have integrated ZERO framework into the *NX* monitor to improve its performance.
- *ZERO RPC*: ZERO RPC adopts the same data plane to access raw metrics. However, ZERO RPC is implemented via SEND/RECV instead of READ. The controller issues RPC requests to the agent, after which agent returns metrics as response. We explore design alternations of two-sided RDMA via ZERO RPC.

6.2 ZERO Overhead

We evaluate the CPU utilization and latency of ZERO in monitoring Redis, container and MaxCompute services. We present overall performance and summarize two key observations, followed by detailed micro-benchmarks for each case.

Figure 7: Monitor performance with 10 – 40 Redis instances and 10 – 1000ms sampling interval.

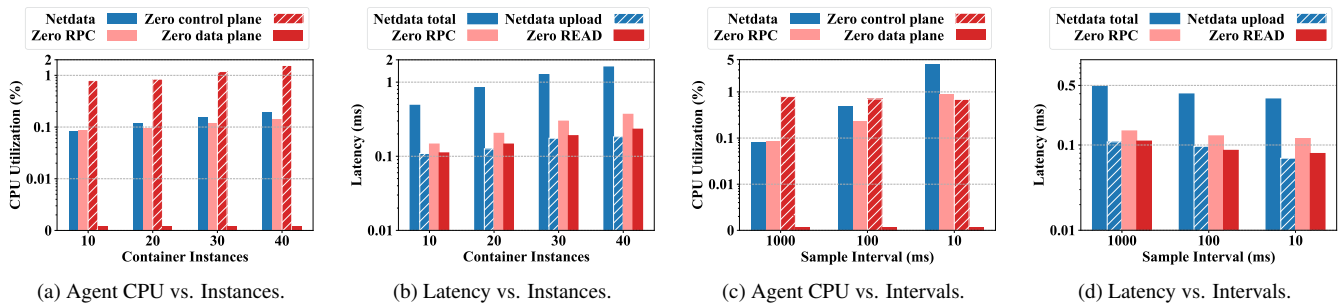

Figure 8: Monitor performance with 10 – 40 container instances and 10 – 1000ms sampling interval.

Figure 9: Monitor performance with 1 – 16k TCP connections and 10 – 1000ms sampling interval.

Overall. Table 2 summarizes the overhead of ZERO monitor. We focus on the monitoring latency and the CPU utilization of ZERO agent. Both Netdata or NX are referred as baselines. First, ZERO monitor reduces latency by one/two order of magnitudes compared with baselines. Our following breakdown of total latency reveals that baseline methods spend most of time to collect metrics from system/application processes. The TCP-based baselines actively upload metrics and achieve similar latency in uploading phase as ZERO READ. ZERO RPC has higher latency than ZERO READ because each RPC requires at least two RTTs [45, 68]. Second, ZERO agent achieves disposable overhead in control plane and zero overhead in data plane. The CPU utilization of ZERO control plane only increases slightly when registering more MRs, which is not affected by the sampling interval. The CPU utilization of ZERO data plane is always zero as expected. On the contrast,

the CPU utilization of baselines reaches very high values with lower sampling intervals. ZERO RPC eliminates the overhead of collecting metrics, however, the CPU utilization for posting SEND/RCV requests and polling completions still increases with lower sampling intervals. In summary, the benefit of ZERO to cloud services is enabling higher SLA of infrastructure, which effectively avoids performance jitters caused by CPU interference. Zero also improves monitoring performance, which reduces latency by 1~2 orders of magnitude and increases throughput by 3~6 \times (Section 6.3).

Redis Case. The monitoring performance of Redis case is shown in Figure 7. Netdata uses single or multiple threads to collect metrics from multiple Redis instances. With the increment of service instances, the CPU utilization of single- and multi-thread Netdata increase from 0.4 ~ 0.5% to 1.5 ~ 2%, which already severely interferes Redis services (Figure 3).

Figure 10: Monitor performance with 64 – 1024 hosts × 128KB data in Cluster1.

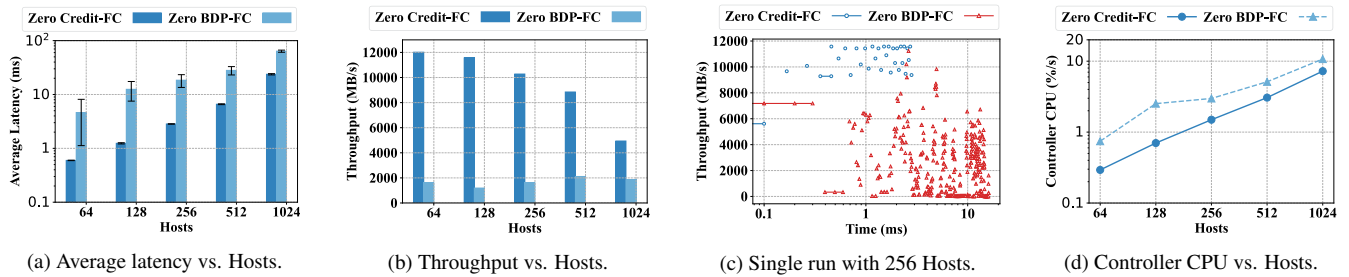

Figure 11: Monitor performance with 64 – 1024 hosts × 128KB data in Cluster2.

With $10\times$ lower sampling interval, the Netdata CPU increases $10\times$, while the gap of CPU utilization between single- and multi-thread becomes larger. However, the multi-thread Netdata achieves $0.7 \sim 1ms$ latency (Figures 7b and 7d). Netdata thus trades off CPU utilization with latency. On the contrary, ZERO has negligible CPU utilization ($< 0.1\%$) in its control plane, which is a one-off expense independent of sampling intervals as shown in Figure 7c. ZERO data plane has zero CPU overhead denoted by the tiny pillar in Figures 7a and 7c. ZERO reduces latency by one/two order of magnitudes compared with Netdata, as shown in Figures 7b and 7d.

Linux kernel case. Figure 8 illustrates the performance of Linux kernel case, where ZERO monitors multiple container instances. As shown in Figures 8a and 8c, the CPU utilization of the ZERO data plane is zero. The CPU utilization of ZERO control plane is high, because of the frequent invocations of `mmap` when registering per-CPU kernel metrics. However, the total CPU time of ZERO control plane is fixed, *i.e.*, $3.4 \sim 14.7$ ms to register $10 \sim 40$ instances. As shown in Fig 8c, the overhead of ZERO control plane is only 0.8% independent of sampling intervals, while the Netdata CPU increase to 4% with $10ms$ sampling interval. ZERO achieves $0.07 \sim 0.1ms$ latency, which is an order of magnitude lower than that of Netdata ($0.5 \sim 1.6ms$). ZERO may have higher READ latency than the uploading latency of Netdata. Because kernel metrics are per-CPU counters, ZERO controller needs n requests to obtain n copies of counters in each CPU.

eBPF case. Figure 9 shows the performance of monitoring TCP connections of with NX, NX-eBPF and ZERO. NX monitor has the highest CPU utilization ($1.6 \sim 59\%$) and latency

($16 \sim 250ms$), due to its outdated implementation, which traverses all TCP connections using the kernel `tcp_diag` interface. NX-eBPF introduces eBPF to low the overhead of getting TCP info, while ZERO further eliminates the syscall and memory copy overhead of reading eBPF map. As shown in Figures 9b and 9d, ZERO performs $40\% \sim 80\%$ lower latency than that of NX. Similar with Redis and Linux kernel case, the CPU utilization of ZERO data plane is still zero.

6.3 ZERO Scalability

We then evaluate the scalability of ZERO. The controller adopts receiver-driven model to obtain raw metrics, which issues TCP-based RPC or READ requests to the agent. The collecting phase at the monitored host is omitted to compare the raw performance. The controller adopts busy polling by default. The ideal result is obtained via `ib_read_bw` [16]. Our three key observations are summarized as follows.

READ achieves better performance. The TCP-based baseline achieves much higher average latency compared with ZERO (Figure 10). The total elapsed time of collecting metrics from all hosts is usually $2 \sim 3\times$ the average latency in TCP, resulting in low throughput. We analyze that TCP suffers from low efficient congestion control (CC) [20, 37] and the processing overhead of kernel stack [24]. Both factors incur large delay to concurrent RPC requests, resulting in variations of starting/ending time. On the contrary, ZERO eliminates the overhead of kernel stack via RDMA. The average latency and elapsed time of ZERO are nearly equivalent (Figures 10a and 10b). ZERO also achieves lower CPU compared with the baseline as shown in Figure 10d.

Figure 12: Monitor performance with 8 – 128 WRs × 4KB.

Credit-FC avoids triggering ECN/PFC. In Cluster1, we evaluate the ZERO performance w/ Credit-FC and BDP-FC, and w/o any flow control (FC). For tests w/o FC, the controller posts all requests in the beginning. The BDP-FC adopts a fixed credit of BDP (16KB with 25GbE bandwidth and $5 \sim 6\mu s$ RTT). Interestingly, PFC pause is not triggered until 256 QPs for ZERO w/o FC, due to the large dynamic buffer of switches [17] and the high threshold of PFC pause action (XOFF) [95]. Besides, the RNIC limits the maximum of outstanding READ requests to 16. Accordingly, the total credit is set to $8MB = 128 \times 64KB$. As shown in Figure 10a, both Credit-FC and BDP-FC effectively avoid PFC. The gap between ZERO and ideal is origin from the extra overhead in monitoring (Figure 10c), *e.g.*, virtualization, initializing and posting work requests (WRs) for each VM. The 25GbE bandwidth is still saturated with the $C_f \geq BDP$.

In Cluster2, the network has much higher BDP (96KB with 200GbE bandwidth and $4\mu s$ RTT) and the ECN is enabled by default. We observe a large fraction of ECN marked packets and high latency in BDP-FC (Figure 11a), because the ECN minimum threshold [95] is set to $\sim 1000KB$. Credit-FC still works with 512/1024 QPs due to the posting and arrival delay of READ requests with single thread (Section 4.3), where the build-up buffer should reach $2/4MB$ with the smallest quota of 4KB. We observe similar phenomenon with 1024 QPs in Cluster1. As shown in Figure 11b, Credit-FC only utilizes half of the 200 GbE bandwidth — because the credit is much smaller than the BDP of network to avoid congestion/ECN ($4 \sim 16KB$ vs. 96KB) — the bottleneck lies in the switch buffer/threshold instead of end host. The throughput also degrades rapidly because large number of QPs share RNICs at both agent and controller.

We next zoom into the difference between Cluster1 and Cluster2. Cluster1 set much higher PFC threshold than the ECN threshold in Cluster2, resulting in larger credit to saturate the bandwidth. However, the tradeoff is that the pause duration occupies $\sim 99\%$ (Figure 10b) when PFC is triggered. As a comparison, ECN reacts to congestion and recovers traffic rapidly (Figure 11c). Another benefit of Credit-FC is reducing the CPU utilization for busy polling via avoiding network congestion as shown in Figures 10d and 11d.

Hybrid-I/O model is highly CPU efficient. We then evaluate the hybrid-I/O model in Cluster1. We post all requests in the beginning as the maximum outstanding READ requests is bounded to 16 by RNIC. As shown in Figure 12b, the CPU utilization of both epoll and polling increases with large data size, while epoll achieves lower CPU utilization. To highlight the gap, we set lower sampling interval to monitor 128 hosts with 256KB data. Results show that the CPU utilization of epoll and polling are 13.5/40.9% and 20.2/72.6 respectively with 100/10ms interval. However, the event-driven polling has high performance variations with small number of requests (Figure 12a), due to *epoll* syscall and thread blocking. With large-sized data, such overhead is averaged across many in-flight requests. We thus adopt epoll for general cases ($32 \sim 128$ requests) and polling for hosts with small-sized data (< 32 requests).

7 Experience and Future Work

In this section, we share our experience of building large-scale monitoring system using RDMA.

Achieving high scalability and availability. The scalability of RDMA-based distributed systems is limited by the number of QPs [26, 62, 82], which are cached in the limited SRAM of RNIC. Even several works [46, 47] adopt UD to reduce the number of QPs, ZERO uses READ to bypass the monitored host, which is only supported in RC mode. ZERO adopts QP sharing and grouping to remedy the QP constraints. First, ZERO agent manages all system/application metrics in a host sharing one QP connection. Second, ZERO controller monitors a group of QPs/hosts in each period, *e.g.*, 64 hosts with $1 \sim 10ms$ period, then switches to another group of QPs/hosts to avoid frequent QP evictions. To achieve high availability, each agent will build QP connections with at least three controllers in the practical deployment. Similar to most distributed systems, all these controllers run a consensus-based coordination service [40] to detect failures, and ZERO can switch to a standby controller seamlessly when the active controller is down.

Avoiding network interference. In the practical deployment, monitoring traffics co-exist with service traffics and inevitably impacts the network performance of services, due to the contentions at both agent and switches. Note that the controller has no such concerns with dedicated server for monitoring. Before ZERO, existing deployment adopts several mechanisms for traffic isolation, which inevitably brings other side effects. For example, a thorough solution is physically isolating traffics of services and monitoring with independent NICs and links [2]. However, physical isolation incurs large CapEx and is only suitable to high-priority services necessitating high SLA. Another solution is assigning a separate and lower-priority queue for monitoring traffics [35]. The persistent high loads of services may cause starvation of mon-

itoring traffics and losses of data in consecutive monitoring periods. Besides, ZERO built on RDMA is sensitive to such timeouts, which may cause QP state machine errors [72]. We thus abandon the traditional method of traffic isolation and resort to receiver-driven CC to avoid network interference.

ZERO provides a new perspective to mitigate network interference, *i.e.*, limiting the credit of monitoring traffics when co-existing. Specifically, the controller adopts group switching with 64 QPs/hosts in each group. The QPs of next group will be pre-fetched to RNIC SRAM for warming up. The total credit T in Credit-FC is set to 256KB, which maximally adds $\sim 20/10\mu s$ queuing delay with 100/200GbE bandwidth. Note that the maximum build-up queue is much less than 256KB due to the posting and arrival delay (Section 6.3). As a comparison, the traditional send-driven model easily causes network jitters with burst traffics. Besides, such settings have a negligible impact on monitoring QoS and single controller supports $1 \sim 10k$ hosts with $0.1 \sim 1s$ intervals. The agent only occupies $0.01 \sim 0.1\%$ bandwidth of the monitored host.

Receiver-driven CC. Compared with existing sender-driven CC, the receiver-driven CC achieves several benefits in monitoring. Existing CC mechanisms, *e.g.*, DCQCN [95] and TIMELY [69], react to congestion after switch buffer/queue reach threshold. Besides, they aim to achieve equal bandwidth sharing across multiple flows, and cannot avoid interference between service traffics and monitoring traffics. As a comparison, the receiver-driven CC avoids network congestion and interference in advance by limiting the total in-flight data of monitoring. On the other hand, existing CC mechanisms, *e.g.*, DCQCN and HPCC [57], are complex in deployment and requires ECN or in-network telemetry (INT) supports from switches. However, ECN or INT capability are not always supported, *e.g.*, in Cluster1. The Credit-FC in our deployment is simple and effective to avoid triggering PFC/ECN.

We also observe several limitations of current Credit-FC. It only adopts credit without pacing [50] and cannot support massive concurrent flows with a 4KB transmission fragment. Besides, it is not a universal CC mechanism for data-center traffics, which dedicates to avoid network congestion and interference caused by monitoring traffics in the ZERO framework. In our future work, we will try to resolve these limitations from two aspects. First, we will consider both host bandwidth and ECN threshold [88] with a combination of credit- and pacing-based CC, to achieve full bandwidth utilization while avoiding network congestion. Second, we will explore the universal receiver-driven model in cloud networks, which has the benefits of CPU offloading via RDMA and more convenient CC [77].

8 Related Work

One-sided RDMA. In the system area, it is a trend to leverage one-sided RDMA operations to bypass the server CPUs.

As pioneering works, Pilaf [68] enables the clients to directly read data from the server memory via RDMA read. Clients use CRC64 to search for the inconsistency of data caused by the possible read-write races on the server. RFP [79, 86] explores one-sided RDMA to provide another alternative solution for RPC, which uses RDMA read to fetch the response result. On the other hand, several works [46, 61, 86] explore how to optimize the raw performance of one-sided RDMA. To the best of our knowledge, ZERO is the first work to leverage one-sided RDMA for distributed monitoring.

Monitoring system. There are plenty of works targeting for the design of monitoring system [65]. Yet, all these works focus on data analytic [51, 80], tracing bugs [59, 63] and visualization [71]. Distinct from these works, where monitors are tightly coupled with the monitored applications and hosts, ZERO decouples the monitor from the monitored infrastructure and eliminates the monitoring overhead completely.

Cloud-native monitoring. Netdata [10] enables users to quickly identify and troubleshoot issues, and make data-driven decisions according to the pre-built visible dashboards. Prometheus [11] is an open-sourced monitoring system with complete ecosystem to extract time series data from the cloud-native applications, and it focuses on collecting metrics via a powerful query language called PromQL. Stackdriver [4] is the logging and monitoring solution of Google, which is integrated tightly into Google Cloud. Likewise, ZERO is deeply used in the cloud-native ecosystem of Alibaba cloud.

9 Conclusion

We propose the ZERO monitoring system framework, exploiting one-sided RDMA read for remote monitoring. ZERO achieves zero-overhead monitoring via the novel control plane and data plane. ZERO supports large-scale distributed monitoring via credit-based FC and hybrid I/O model. ZERO thus paves the way for integrating RDMA into the monitoring systems, which desires to benefit from the high performance of RDMA while avoiding poor scalability. We deploy ZERO in Alibaba cloud-native platform to evaluate its performance. The deployment results show that ZERO resolves interference problem of traditional monitor and easily fulfills both latency and throughput requirements in cloud-native monitoring.

Abstract

Microservice architectures have become the lifeblood of modern service-oriented software systems. Remote Procedure Calls (RPCs) among microservices are deeply nested, asynchronous, and large in number, thus making it very hard to identify the underlying service(s) that contribute to the overall end-to-end latency experienced by a top-level request. State-of-the-art RPC tracing tools collect a deluge of data but provide little insight. We need sophisticated tools to bubble-up signals from a myriad of RPC traces to assist developers in identifying optimization opportunities, pinpointing common bottlenecks, setting appropriate time outs, diagnosing error conditions, and planning and managing compute capacity, to name a few.

In this paper, we present CRISP — a tool to perform critical path analysis (CPA) over a large number of traces collected from RPCs in microservices environments. CRISP provides three critical performance analysis capabilities: a) a *top-down* CPA of any specific endpoint, which is tailored for service owners to drill down the root causes of latency issues, b) a *bottom-up* CPA over all endpoints in the system — tailored for infrastructure and performance engineers — to bubble up those (interior) APIs that have a high impact across many endpoints, and c) an on-the-fly anomaly detection to alert potential problems.

We have applied CRISP’s capabilities on Uber’s entire backend system composed of $\sim 40\text{K}$ endpoints that cater to real-time requests from more than 100 million active daily users worldwide. Using the critical path as the basis of performance analysis has a) helped us identify five performance issues and optimization opportunities across two business-critical microservices, b) guided us in our future hardware choice that reduces end-to-end latencies, and c) reduced the false positives in anomaly detection by up to 50% while speeding up the training and inference by up to $28\times$ and up to $67\times$, respectively, over the state of the art.

1 Introduction

Microservice architectures [23, 27, 28, 36, 43, 45, 56] have become the lifeblood of modern service-oriented software sys-

Figure 1: Complex microservice RPC call graph at Uber collected via Jaeger tracing.

tems. As opposed to monolithic software development and deployment, in a microservice environment, the business logic is broken into individually deployable programs, which allow fast development and scalable deployment. Individual microservice *instances* interact with one another via remote procedure calls (RPCs). As microservices evolve with the business, they grow in number and their interactions become complex.

Uber’s backend is an exemplar of microservice architecture. Uber has $\sim 4,000$ microservices interacting with each other via RPCs. Each microservice hosts a handful of APIs, leading to a total of about 40,000 unique RPC endpoints that can call one another in complex ways, as depicted in Figure 1. Hereafter, we use the terms *endpoint* and *API* interchangeably to mean a uniquely named functionality provided by a service. We use the terms *operation* and *RPC* interchangeably to mean an instance of invocation of such an API.

A service request arriving at an entry point API to the Uber backend systems undergoes multiple “hops” through numerous microservice RPCs before being fully serviced. The life of a request results in intricate microservice interactions. These interactions are deeply nested, asynchronous, and invoke numerous other downstream APIs. As a result of this complexity, it is very hard to identify which underlying service(s) contribute to the overall end-to-end latency [21, 32, 38, 44, 52, 53, 63] experienced by a top-level request. Answering this question is critical in many situations. For example:

- Identifying optimization opportunities for a top-level

- microservice (e.g., reducing tail latency)
- Identifying bottleneck APIs that affect numerous endpoints
- Setting appropriate time-to-live values for RPCs
- Diagnosing outages and error conditions
- Planning for computing and other capacity management

The critical path [59] is the longest chain of dependent tasks in a microservice dependency graph. Reducing the critical path length is necessary to reduce the end-to-end latency of a request. Hence, latency optimization efforts benefit from prioritizing the services that are on the critical path.

We have developed a tool, CRISP¹, to pinpoint and quantify performance problems in microservice architectures. CRISP uses the RPC tracing facility provided by Jaeger [6] and constructs the critical path through a request's graph of dependencies. The critical path may vary among requests; hence, CRISP computes the critical path per request. It then aggregates and summarizes critical paths from millions of requests. Finally, it presents them as digestible and actionable insights via rich heat maps [5] and flame graphs [31]. CRISP provides knobs to dissect the details with different percentile values that help in performance diagnoses.

As a full-fledged performance analysis tool, CRISP caters to various use cases via the following rich set of capabilities that scale to work on millions of traces:

- **Top-down analysis:** A top-down analysis of any specific endpoint of interest. This capability allows service owners to deep dive into their specific endpoint and pinpoints and quantifies bottlenecks encountered in the RPC dependency graph. Improving these bottlenecks should be the first-order priority to reduce the latency of the endpoint.
- **Bottom-up analysis:** A bottom-up analysis over all endpoints, which bubbles up and ranks by the impact of those interior APIs that cause the most latency across most endpoints. Optimizing these interior APIs reduces latency across numerous endpoints.
- **Neural network-based anomaly detection:** An automated anomaly detection system, which detects whether a request is exhibiting abnormal behavior compared with the past history of the endpoint. The system is trained per endpoint using an autoencoder-decoder machine learning technique [39]. This system is set up to expedite problem detection and alert developers. Basing the abnormality detection on the divergence in the critical path as opposed to the full call graph [39] not only makes the training and inference faster but also reduces false alerts.

Practical deployment of CRISP at Uber over a three-month period working on 40K endpoints while processing $\sim 200GB$ of traces with ~ 18 million spans in ~ 256 hours of CPU time per day has resulted in the following impact:

- Detection and narrowing down the causes of five latency impacting bugs in two business-critical services
- Identification of a $1.5\times$ tail latency lengthening due to

hardware choice and the resulting guidance for future hardware selection

- Up to $27.77\times$ speedup in training, up to $66.85\times$ speed up in inference, and 50% reduction in false alerts in identifying abnormality of service behaviors over the state of the art [39]

The rest of this paper is organized as follows: Section 2 motivates CRISP with a use case at Uber, Section 3 describes the Jaeger tracing framework, Section 4-6 describe the methodology, internals, and features of CRISP, Section 7 evaluates CRISP at Uber, Section 8 discusses the related work, and Section 9 offers our conclusions.

2 Motivating Example for CRISP

Fulfillment [8] at Uber is a platform to orchestrate and manage the lifecycle of orders and user sessions with millions of active participants. The Fulfillment platform is a foundational Uber capability that enables the rapid scaling of new verticals. The platform handles more than a million concurrent users and billions of trips per year that span over ten thousand cities. The platform handles billions of database transactions a day. Hundreds of Uber microservices rely on the platform as the source of truth for the accurate state of the trips and driver or delivery sessions. Events generated by the platform are used to build hundreds of offline datasets to make critical business decisions. Over 500 developers extend the platform using APIs, events, and code to build more than 120 unique fulfillment flows.

The `createOrder` endpoint allows capturing the requester's intent in the Uber backend. Intent can be to request a ride from one of the ridesharing lines of products, food booked and dispatched by one of the courier partners, or a package be delivered to a customer. This endpoint has a complex task dependency graph necessary for: a) determining order risk such as user fraud, sufficient user balance via authentication hold, b) ensuring the fare presented to the requester in the shopping phase is still valid, c) determining the benefits the requester is eligible for, d) enriching data with location information, and e) creating an order in the backend to start the matching process.

The tasks in this endpoint have grown organically as requirements evolved. This has led to an increase in p95 latency to 6 seconds, affecting user experience. The service itself is written in Java, and highly (both macro and micro) optimized using periodic profiling. However, the profiling offered no insights into downstream calls, where most time is spent. Quantitative insight into the causes of the latency was hard to analyze by looking at individual traces because each trace contains thousands of nested and overlapping RPCs.

There are numerous sampling- and instrumentation-based profilers [10, 11, 13, 29] for intra-service profiling. However, they do not collect metrics at the individual request level. The Fulfillment microservice (as most other microservices) is highly threaded; the work of an individual request may be partitioned among multiple threads within a process as well

¹named taking letters from `critical` and `span`

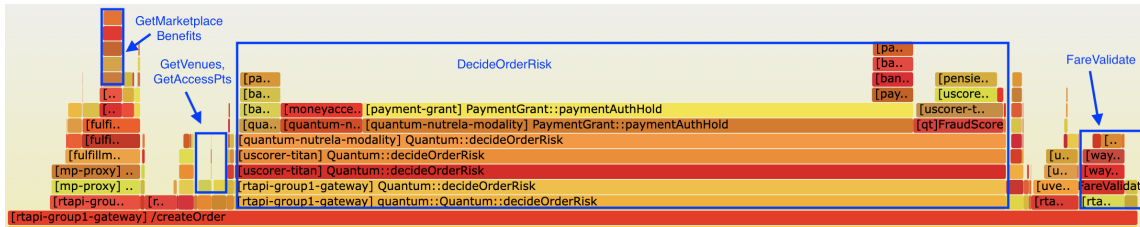

Figure 2: Critical path(s) of createOrder endpoint shown as a flame graph via CRISP after processing 100K Jaeger traces.

as multiple threads may be handling independent requests simultaneously. In such a setup, traditional profilers fail to highlight the causes of latencies incurred at an individual request level. Also, traditional profilers fail to capture IO waiting, task dependencies, and serialization patterns.

With CRISP, the development team performed a top-down critical path analysis of this endpoint over 100K traces (~200GB of traces) and visualized the results as a flame graph as shown in Figure 2. Navigating the “hot” critical paths via the flame graph not only corroborated an existing hunch while offering quantitative guidance but also shed light on new optimization opportunities lurking in the wild. Below, we enumerate a few defects and optimization opportunities that became evident by inspecting CRISP-provided insights.

Async flow optimization: `decideOrderRisk` contributes to about 68% of the end-to-end P50 latency, revealing the following optimizations: a) aggressively use cache in `FraudScore` to reduce its latency and b) parallelize the calls beneath this big endpoint (e.g., `PaymentAuthHold` and `FraudScore`). In the long term, the team envisions using an asynchronous invocation of `paymentAuthHold` and using notification to the requester when a provider is assigned.

Unnecessary API serialization: There was an unnecessary serialization between `GetVenues` and `GetAccessPts`. These two RPCs can be done in parallel.

Avoidable server roundtrip for validation: `FareValidate` contributes to about 5% of the end-to-end P50 latency. This is a call that need not be performed every time. Trusted edge devices (e.g., company mobile app) can validate at the edge improving performance for trusted users and falling back to server validation if the fare has expired based on fare expiry TTL; untrusted apps will use the full server validation.

Caching over DB fetch: `GetMarketplaceBenefits` contributes to about 5% of the P50 latency. This can be served via a cache rather than a database read to fetch requester benefits.

3 Background

In this section, we first describe the microservice tracing infrastructure at Uber and then enumerate its shortcomings.

3.1 Distributed Tracing at Uber

Microservices run over several physical hosts, usually owned by multiple teams, and written in multiple languages. It is impossible to use traditional profilers [7, 13, 29] to gain insight into the events involved in processing a request. Because each physical host can have a separate clock, it is intractable to infer causality using time alone. Distributed tracing [47] encodes causality information in a distributed context, which is propagated across process boundaries. It provides a way to infer states across various services for the lifetime of a request.

At Uber, Jaeger [6] is used as the distributed tracing system. Jaeger provides clients for generating trace data and components for storage and retrieval of traces. Microservices instrumented with Jaeger clients produce OpenTracing [6]-compliant spans when receiving new requests and attach distributed context information (trace ID, span ID, custom key-value pairs). The “span” [46] is the primary building block of a distributed trace, which represents a serial unit of work done in a distributed system. Each span contains the following information:

- API name
- Start and finish timestamps
- Custom key-value pairs
- Span context and references (described below)

Each span may reference other spans with a causal relationship by span context. A span may reference a parent with the `ChildOf` relationship, indicating that the parent span waits for the child to finish a certain task. Multiple child spans can be referenced by the same parent and run concurrently.

While the source code is always instrumented, the overhead is controlled by a dynamic sampling rate, which is adjusted based on the traffic received by Internet-facing endpoints. No data is collected for traces that are not sampled. Specifically, adaptive sampling sets a target QPS for traces on a per root service-endpoint basis, which ensures that the number of samples on the external API request remains roughly constant. Jaeger does not support tail-based sampling [12].

Figure 3 depicts the Jaeger deployment at Uber. Jaeger is deployed as multiple components, with a `jaeger-agent` running on every host. All applications running on this host send spans to `jaeger-agent` over UDP [9]. `jaeger-agent` then forwards these spans to a `jaeger-collector`, which then buffers spans onto the Kafka [37] distributed event

Figure 3: Jaeger deployment at Uber.

streaming platform. The spans buffered in Kafka have multiple consumers: `jaeger-ingester`, which inserts them into Docstore [3], a distributed SQL database, and allows for retrieving full traces; `jaeger-indexer`, which inserts them into Sawmill [4], a schema-agnostic logging platform that allows user-friendly search on spans fields. Additionally, spans are consumed by Apache Flink [15] jobs to produce multi-hop dependency graphs. Depending on the sampling configuration in effect, the backend processes around 400K-1M spans per second, which is approximately 20TB each day. Variance is common due to diurnal patterns.

3.2 Difficulties with Large-Scale Jaeger Traces

Despite their power, Jaeger traces are highly complicated. Jaeger provides a UI to filter traces by time ranges and also provides a UI to view the trace as a callgraph, as well as an expandable tree over a timeline. In spite of these facilities, the users of this manual workflow often complained about the following limitations to analyze endpoint latencies:

- Only first-level insights are possible from drilling down into microservice latencies and errors.
- Using a few Jaeger traces is insufficient to reach a reliable conclusion. Users can visualize and navigate only one Jaeger trace at a time. There is no aggregate summary of traces.
- A single Jaeger trace can be so complex that it is not humanly possible to browse and understand the details. Endpoints commonly have thousands of nodes in the RPC graph with 25-deep call chains and up to 40 spans overlapping in time. It is cumbersome to manually understand the critical path due to the asynchronous nature of calls.
- There is a lack of regular, performance-driven feedback tooling to optimize the workflow or downstream systems.

These challenges introduce a barrier to our developers in effectively using Jaeger to either detect anomalous situations or identify optimization opportunities.

4 CRISP Methodology

The fundamental difficulty in making sense out of a Jaeger trace is due to the complexity of the graph. Our premise is that while the whole graph is interesting in terms of data richness, it brings a lot of noise. There are many RPCs and call paths that are insignificant for a high-level analysis and optimization task. With this understanding, we shrink the graph to its quintessential element—the *critical path*—and aggregate many traces into a single summary that is still rich with call path information.

Critical Path Analysis [25, 59] (CPA) is a well-studied concept over directed acyclic graphs (DAG) formed out of computing graphs in parallel computing. The nodes in the DAG represent tasks (units of serial execution) and the edges represent dependencies between tasks. A node with an out-degree greater than one “spawns” children’s tasks and a node with an in-degree greater than one waits (“syncs”) for the children to finish. Total work is the sum of weights of all nodes and the critical path is the longest weighted path in the DAG.

Definition 1 (Critical Path). In a task graph $G = (V, E)$ made of task vertices V and their dependency edges E , with two special vertices S (start node) and F (finish node), the critical path is a maximal-weight path from S to F . G may contain more than one critical path.

The critical path identifies the sequence of dependent computations that consume the most time. To speed up the service, it is strictly necessary to boost the components on the critical path.

RPCs among microservice operations have a parent-child hierarchical relationship and can be construed as a parallel computation DAG. The deriving critical path from Jaeger traces, however, has the following challenges:

- Unlike a traditional parallel computing DAG seen in the academic literature, the Jaeger traces do not provide clear “spawn” and “sync” events in the DAG.
- The parent spans in Jaeger traces carry no dependence information and so the information of the last “sync” child span is not directly available.
- In order to obtain the last “sync” child span, clock information is needed. However, the clocks on different machines where spans are collected are not time-synchronized.
- The critical path across all requests may not be unique. Services have diurnal patterns and different traces may exhibit different critical paths, which need to be aggregated, and yet “hot” critical paths need to be bubbled up.
- Since the service codes keep evolving, the critical path keeps changing.

We address these challenges in the next section.

We also mention in passing that the CPA is not a performance analysis panacea. Once the exposed latency on the critical path is eliminated, a new critical path may emerge which necessitates the need for an iterative profiling and optimization approach.

5 Critical Path Analysis

In this section, we detail how we compute, aggregate, and represent critical paths from many Jaeger traces for a given endpoint.

5.1 Deriving Critical Path from a Single Trace

CRISP’s trace analysis exploits a map-reduce paradigm to process millions of traces belonging to each endpoint. To this end, each process loads an input Jaeger trace file (JSON format) and builds an n-ary tree, where each parent node is the RPC caller and the children nodes are the immediate downstream callees.

In order to compute the critical path through the trace, we need a computational DAG. To accomplish this under Jaeger/Opentrace trace format, we make use of the start and end times of children’s spans. The start time in every immediate child creates a “spawn” event in the parent and splits its span at that point in time. Similarly, the end time in every immediate child creates a “sync” event in the parent and splits its span at the point in time. Thus, we transform the tree into a logical DAG for critical path construction.

Figure 4 shows an example DAG constructed from Jaeger traces by looking at span start and end times. In Figure 4, the span *A* is the root span, which invokes spans *B*, *X*, and *D*. The span *B* in turn invokes span *C*. The start time T_1 and its end-time T_6 of *B* create a spawn and sync points on *A*, respectively. Similarly, the spans *X* and *D*, create further segments in *A*. Similarly, *B*’s child *C*, creates the spawn and sync points on *B* at T_3 and T_4 , respectively.

Limitations of Jaeger/Opentrace format: One key limitation of the Jaeger is that the parent spans (a.k.a., caller) do not contain dependence information. Specifically, they lack the information of both start and end of callee RPC. Instead, it is the callee that stores both the ID of its parent and callee’s start and end time (per callee’s local clock) in its own span. The implication of the constraint is that the dependency relationship needs to be inferred via clock information recorded in the callee span.

In addition, the inference can be inaccurate because of the clock skew that will be discussed in Section 5.2. Traditionally, the computation of the critical path depends on the last returned child of the parent spans [24]. In Jaeger traces, the last arriving child information is not directly recorded in the parent span. Instead, the last arriver needs to be inferred using the span end time for each child, which will be based on each child’s local clock. Without correctly handling the clock skew, the critical path analysis can go wrong.

One may extend Jaeger tracing by making the callee return additional data to the caller. Unfortunately, ensuring that these changes are adopted universally across thousands of services is an engineering hurdle. Such changes also require support from different RPC libraries used by our system. Our solution, in contrast, does not require such large-scale system-wide

Figure 4: Trace with root span *A*, its children *B*, *X*, and *D*. *B* further calls *C*. CRISP further segments each parent traces based on the start and end time of its children. The red-colored blocks represent the critical path through the trace.

```
def CP(root):
    path = [root]
    if len(root.child) == 0:
        return path
    children = sortDescendingByEndTime(root.children)
    lfc = children[0]
    path.extend(CP(lfc))
    for c in children[1:]:
        if happensBefore(c, lfc):
            path.extend(CP(c))
            lfc = c
    return path
```

Listing 1: Pseudocode to compute critical path.

changes but yet produces high quality results as we describe in the rest of this section.

5.1.1 Critical Path Algorithm

We, first, describe how we compute the critical path in a trace assuming perfectly synchronized clocks in this subsection. We expand to handle unsynchronized clocks in Section 5.2.

The process of computing the critical path (*CP* shown in Listing 1) on the logical DAG starts at the root node *R*—the endpoint under study. We sort all its children by their span *end time* and pick the last finishing child (LFC). The entirety of LFC is on the critical path. Let LFC_s be the start time of the LFC; we ignore all children spans of *R* that may start or end in the time intervening between the start and the end of LFC. We now look for the next child of *R* whose end time immediately precedes LFC_s and perform the same procedure iteratively until no child is left to process. Time not attributed to any child of *R* is attributed to the root span itself.

The process is also recursive. Once an LFC is identified, it recursively calls *CP* on its own children to distribute its time under its children. The result of the *CP* algorithm is a sequence of graph nodes with time associated with each one of them. Applying this algorithm to the trace shown in Figure 4, the critical path is represented by the fragments $A_1B_1C_1B_3A_5D_1A_7$.

There are two types of metrics associated with each node of the critical path — inclusive time and exclusive time. The “exclusive” time does not include the time spent in a node’s callees. The “inclusive” time is the total wall clock time from the start to the end of the RPC on the specific node.

Figure 5: From trace to DAG to critical path (CCCT) to aggregate critical calling context tree. In the trace DAGs (left of the diagram) the x-axis is the flow of time. Horizontal lines are Jaeger spans and vertical lines are caller-callee relationships. Red-colored horizontal spans are on the critical path.

Since every node on the critical path encodes the information on how it was called, and since all call paths originate from a common root — the endpoint under investigation — it enables us to merge all call paths into a calling context tree (CCT) [14] by looking at their common prefixes. Consider the critical path $A_1B_1C_1B_3A_5D_1A_7$ for the trace in Figure 4. This path encodes the following call and return information: A calls B calls C returns to B returns to A calls D returns to A . With this, we can infer that there are the following call chains involved on the critical path: A , $A \rightarrow B$, $A \rightarrow B \rightarrow C$, $A \rightarrow B$, A , $A \rightarrow D$, and A . We can merge all these call paths into a CCT and call it a Critical Calling Context Tree (CCCT). This process is presented in the center section of Figure 5.

The calling context information makes it not only rich but also helps in aggregating critical paths from multiple traces described later in Section 5.3. A level of aggregation happens immediately within each trace processing: if the same endpoint appears multiple times on the critical path, we sum them as long as their call chains are exactly the same. For example, in the previous $A_1B_1C_1B_3A_5D_1A_7$ critical path example, we merge the multiple occurrences of call paths A_* and $A_* \rightarrow B_*$. This merger discards the ordering relationship between events, which we do not need for further analysis.

5.2 Challenges with the Clock Drift

The span start and end times recorded in Jaeger traces are both callee’s local-machine time stamps converted to the standard UTC time. Machine clocks on two different physical machines drift [17, 49, 58] despite their periodic NTP-based synchronization. As a consequence of using local clocks, our critical path algorithm (if not corrected) can go wrong and sometimes lead to significant misattribution.

Span overlap problem: Figure 6 shows an ideal trace where the three spans A , B , and C are invoked one after another by the parent P . Most of the time should be attributed to the children. Figure 7 shows the trace for this example from our production, where the time recorded for the children spans have a small overlap; there is an overlap between the end of A and the start of B and the end of B and the start of C . In this case, the critical path

Figure 6: Ideal traces for a parent with three serialized children executions. Red lines show the corresponding critical path.

Figure 7: Actual traces due to clock drift. Red lines show the corresponding critical path.

Figure 8: Distribution of time overlap recorded in Jaeger for two sequentially invoked RPCs. A positive value shows an overlap. The mean is $204.21\mu s$ and the max is $1696.00\mu s$.

is not attributed to span B and instead attributed to the parent. Due to the clock drift, more than 50% of our traces recorded this type of span overlaps causing misattribution in critical paths.

We conducted a detailed study on the impact of such clock drift. Figure 8 plots the time overlap recorded in Jaeger traces of two sequentially invoked RPCs sampled over 118K traces. A positive value shows overlap and a negative value shows non-overlap. More than 50% of samples show an overlap. The P50 overlap is $204\mu s$ and the maximum overlap is $1696\mu s$.

Based on this empirical observation, we tuned the happensBefore (A , B) part of our CP algorithm with the following relaxation:

- $A_{end} - threshold < B_{start}$, and
- No other children of the parent of P of A can start or end in the overlapped time range

The first condition allows a small `threshold` amount of overlap between the end of the previous span with the start of the next span. The second condition ensures that in the region of the allowed overlap, there is no other spawn and sync event, which ensures the parent-child serialization. The threshold is set to $1ms$.

Span overflow and underflow problems: In addition to the overlap, there can be overflow and underflow of child spans due to the clock drift. We enumerate these problems along with our pragmatic solutions below:

- A child span C may start before the start of the parent span P . In such cases, we truncate the start time of C till the start time of P . This may involve the recursive truncation of C ’s descendants.
- A child span C may end after the end of the parent span P . In such cases, we truncate the end time of C to the end time of P .

This may involve the recursive truncation of C 's descendant.

- Although rare, a child span C may end before the start time of parent span P . Similarly, a child span C may start after the end time of the parent span P . In these cases, we completely drop the subtree formed by C for CPA.

This tailoring fixed our CP algorithm. The total time truncation over millions of traces was under 5% giving us the confidence that a significant part of the data was retained.

5.3 Aggregating Critical Paths

While one trace can be compressed into its essential critical path and represented as a CCCT, it may not be representative. Hence, we need to inspect numerous traces to derive a “typical” shape of the critical path. Distinct traces may exhibit different critical paths based on many things, such as calling parameters, scheduling decisions, system load, time of the day, and network delays, to name a few. Hence, a *summary* of *typical* components on the critical path is desired.

To this end, we merge all critical paths (represented as CCCTs) into a weighted, *aggregate CCCT*. We follow the tree merging process done in HPCToolkit [13]. The aggregate CCCT succinctly summarizes all call paths leading to critical path nodes in all traces; it captures the quantitative aspect by associating higher weights to those call paths that are often on the critical path. The weights of the nodes in such a tree would be the summation of the weights of the constituent call paths. Specifically, we provide different percentiles (e.g., P50, P95, P99) of the latency values, which are widely used for QoS purposes. Figure 5 exemplifies this process.

5.4 Workflow for Continuous CPA

Figure 9 depicts the workflow followed by CRISP for performing critical path analysis of microservice traces for all endpoints. The components belonging to CRISP are marked by the outermost rectangular box.

All services are instrumented to produce Jaeger traces during their RPCs. The instrumentation is enabled across languages such as Go, Java, Node.JS, and Python. The RPCs emit Jaeger spans into a common data store, which can be queried via SQL-style queries.

The CRISP workflow runs as a daily job. The workflow begins by collecting a list of endpoints. Each endpoint can be handled in parallel. Hence, we dedicate a handful of machines that shard the list of endpoints among them.

For each endpoint, CRISP queries the Jaeger data store (via `sawmill-query`) service to fetch a list of traceIDs. This query is set up to obtain the last two weeks' worth of traces. We then use these traceIDs to fetch the actual JSON traces (`jaeger-query`) service. We exploit IO parallelism here to fetch many traces concurrently.

We compute the critical path over each trace in parallel using the map-reduce paradigm. The set of critical paths obtained is

fed into an aggregating process that summarizes and produces the daily critical path report for each endpoint (top-down analysis) and also produces overall metrics aggregated over all endpoints (bottom-up analysis). The results are injected into blob storage that can be easily navigated by a varied set of users, including service owners, performance engineers, and capacity managers. An offline anomaly detection model is also trained per endpoint result.

6 CRISP Features

We have developed tools to inspect critical paths for top-down performance analysis of specific endpoints, bottom-up analysis over all endpoints, and automatic anomaly detection over traces. We describe these features in this section.

6.1 Top-Down Analysis

We store the results of our CPA for each endpoint into profiles for investigation by service owners. CRISP provides the following means of visualization of CPA over each endpoint.

Flame graph: Flame graph [31] is a powerful way to visualize hierarchical call paths arising from profiling. The interactive visualization is easier to digest and investigate. Since we maintain the summarized critical paths as aggregate CCCTs, which are formed of many weighted call paths, it naturally avails itself to be represented as a flame graph.

If we chose all traces to represent a single flame graph, the critical path found in P99 latencies may dominate the flame graph and mask the other common cases. For that reason, we show three different flame graphs for different percentiles of latency values (e.g., P50, P95, and P99). We also produce differential flame graphs [30] that show how the critical paths change between two percentile values.

Heat map: Flame graphs are useful for navigating call chains but developers sometimes need access to an actual Jaeger trace that represents a given data so that they can inspect it in further detail. For this reason, CRISP provides the heat map view (see Figure 10), where the rows are the endpoints and the columns represent individual traces. Each cell in the heat map represents the exclusive time on the critical path and each cell is gradient colored based on its contribution (exclusive time) to the total latency. In this view, we collapse the call paths and accumulate the metrics from all call paths, reaching the same endpoint in a single row. However, for exploration, the developers have access to the top 5 call chains (not shown) for each endpoint, which is available by hovering over any row. In this view, the user can also choose percentile values and inclusive or exclusive metrics to sort the rows. Each column is also sorted by a high to low contribution for a given chosen metric. Selecting any trace takes the user to the Jaeger-UI to inspect the trace.

Figure 9: Schematic diagram of CPA over Jaeger traces.

Figure 10: Example heat map from 1000 traces. The result is sorted by the P50 percentile value of the exclusive time of each operation. Each cell is the accumulated time in μ s.

6.2 Bottom-Up Analysis

The objective of the bottom-up analysis is to derive insights from *all* endpoints and to bubble up those interior APIs improving which will improve many endpoints. The bottom-up analysis is a data-intensive process and needs access to critical paths from all endpoints. For this reason, we retain the aggregate CCCT computed for each endpoint from the top-down process, along with some additional statistics related to the overall graph structure. Once all endpoints are processed, the bottom-up analysis runs; it aggregates the statistics from each endpoint and quantifies the impact of each API over all other endpoints. The output of the bottom-up analysis is a descending priority list of top APIs that are often in many endpoints. Additionally, the bottom-up analysis produces various histograms over all traces taken together, which include the total number of times any API appears in any graph, the total number of times an API appears on the critical path, the number of unique APIs on the critical path, the critical path length, and the maximum degree of concurrency in a trace, among others. These graphs are intended to inform infrastructure and hardware engineers to better understand the current needs of our systems and aid capacity planning for the future.

6.3 Anomaly Detection

We also employ CRISP to pinpoint whether a new incoming trace (for a given endpoint) deviates from the normal execution behavior. For this purpose, we have trained a machine learning model and used it for inference.

During the offline training, we encode the critical path (CCCT) for each trace of an endpoint into feature vectors,

Figure 11: An example CCCT (left), the letters indicate name and the numbers indicate the exclusive time on the span. The corresponding SCPV (right).

which we call service critical path vectors (SCPV). We feed several SCPVs into an autoencoder to learn the normal execution pattern of the given service. During the online inference, the learned model will infer whether the given new trace is abnormal or not based on an anomaly score.

The architecture design, training, and inference of the autoencoder are derived from TraceAnomaly [39], which is the state-of-the-art framework for anomaly detection in microservices trace. The neural architectural details are described in Appendix B. The key difference between CRISP and TraceAnomaly is in the data encoding. TraceAnomaly uses a service trace vector (STV) which encodes every path in the trace and, in contrast, CRISP encodes only on the call paths for those spans that are on the critical path spans.

SCPV encoding: Figure 11 exemplifies encoding the critical path present as a CCCT into an SCPV. For each node in CCCT, it assigns weights based on its exclusive execution time. Notice that endpoint *C* occurs twice on the critical path, thus it is also encoded twice in the SCPV, given the call chain is different. The training set is a 2D matrix where each column is a feature (call path) and each row is the feature values of a given trace.

Using the call paths of spans only on the critical path, compared with the prior work that used all call paths in the entire graph, offers significant benefits. It reduces the feature dimensions; it reduces the training and inference time; and, most importantly, it improves the model accuracy. The impact of the CCCT-based encoding is substantial and evaluated in Section 7.3.

7 Experience and Evaluation

In Section 7.1, we describe one of our findings by applying the top-down analysis of CRISP at Uber, in Section 7.2 we

Figure 12: Differential flame graph for the `getDriverTask` endpoint. Red colors indicate the growth from P50 critical paths to P95 critical paths.

show valuable characteristics of microservices at Uber by applying the bottom-up analysis of CRISP. In Section 7.3, we empirically evaluate the anomaly detection capability of CRISP and in Section 7.4 we describe how we employed CRISP in guiding future hardware selection to reduce tail latency in our services.

7.1 Tail Latency Investigation via Top-Down Analysis

`getDriverTasks` is a business-critical endpoint in the `driver-presentation` service responsible for returning the task plan that a driver needs to perform. A sample task plan could be: passenger mask check, pickup passenger, pickup food, drop off passenger, and drop off food. This endpoint assembles the task plan and enriches it by calling numerous other microservices such as `courier-task-platform`.

Figure 12 shows the *differential* flame graph for the `getDriverTask` endpoint. The graph plots a difference between the critical paths seen in the traces with the P50 latency vs. P95 latency for the `getDriverTask` endpoint. The red-colored boxes show the growth in percentage time spent in P95 with regards to P50. The `getTaskCompletionStatus` API was absent in the P50 traces, whereas it occupies 47% of the total execution in P95 traces, contributing to the same amount of addition to the tail latency. This endpoint dependency makes a call to Cassandra—an expensive database read. Based on this insight from CRISP’s differential flame graph views, we identified the root cause of performance variance and high tail latency. We recommend caching with timestamp filtering optimization as opposed to a database read to reduce the tail latency.

Trace processing overheads: Table 1 shows the overhead of analyzing the `getDriverTasks` endpoint discussed in this section running on 16 cores of an Intel Xeon Skylake machine clocked at 2.4 GHz.

Table 1: Overhead of top-down analysis of `getDriverTasks`.

Num Traces	Trace size	Processing time	Memory usage
10k	6.8 GB	48 sec	2.1 GB
20k	14 GB	109 sec	4.2 GB
40K	28 GB	232 sec	8.5 GB
80K	56 GB	553 sec	17.6 GB

Sparse sampling vs. quality of CPA: We observed that the sampling rate does not qualitatively affect the aggregate critical path results. We conducted an experiment where we first produced an aggregate critical path from 1 million traces.

We also produced critical paths from randomly sampled 100K and 10K traces from the same data set. We noticed that the attribution of the top 20 services on the critical path, whether for 10K or 100K samples, was essentially the same as the one produced from 1M traces.

7.2 Systemic Insights via Bottom-Up Analysis

In this section, we show the result of running CRISP with bottom-up analysis on the collected trace dataset and some insight associated with the data. The dataset includes more than 1 million traces, ~4k services, and ~40k endpoints. It takes around 4 hours on 32-cores of a Intel Xeon Skylake machine clocked at 2.4 GHz.

Total RPCs per request: Figure 13 is a histogram of the total number of RPCs made per request, which is same as the total number of spans in a trace. On average there are 112 spans in a trace. However, there exist several large ones with a maximum of 275K spans. Such scale brings significant challenges for the developer to debug without proper reduction of the graph size.

Total endpoints in a trace: Figure 14 is a histogram of the total number of unique endpoints found in each trace. At most each trace has 1400 unique endpoints.

Latency distribution: Figure 15 plots the histogram of latencies observed in each of ~1M traces. The tail is several orders of magnitudes longer than the mean or median.

RPC depth: Figure 16 is a histogram of the longest call chain found in each trace. The depth of the call chain is another measure of the complexity of traces. The average RPC depth is 8.5. The maximum observed depth is 36.

Unique caller: Figure 17 is a histogram of the number of the unique callers for each endpoint across one million traces. The number differs wildly as the mean value is just above 2 but the maximum value is 620.

Degree of concurrency: Figure 18 is a histogram of the maximum number of spans that overlap in time in each trace. This number gives the degree of concurrency (and hence a measure of the complexity) in our traces. Overall, the microservices show a high degree of concurrency. On average, the degree of concurrency is 21. The degree of concurrency often grows to 100s for more complicated services. The maximum degree of concurrency we observed in ~1M traces was 3076.

Total RPCs on the critical path: Figure 19 is a histogram of the number of spans on the critical paths, which counts the number of RPCs made on the critical path. Besides a few outliers, the length of the critical path is short. On average, there are 33

Figure 13: Histogram of the number of spans per trace.

Figure 14: Histogram of number of unique endpoints per trace.

Figure 15: Distribution of latency among all traces.

Figure 16: Histogram of longest call chain per trace.

Figure 17: Histogram of the number of unique caller for each endpoint.

Figure 18: Histogram of the degree of the concurrency (max no. of overlapping spans) per trace.

Figure 19: Histogram of the number of spans on the critical path per trace.

Figure 20: Histogram of the number unique endpoints on the critical path per trace.

RPCs on the critical path (in contrast, the entire graph in Figure 13 shows 112-275K RPCs in traces). The short critical path length allows the developer to investigate and debug easily.

Endpoints on the critical path: Figure 20 is a histogram of the unique endpoints on each critical path. Compared with the number of endpoints in the entire trace (Figure 14), the number of the endpoints on the critical path is an order of magnitude smaller (the maximums are 1400 vs. 140). The 10x size-reduction matches our observation of the 6 services we test for anomaly detection.

7.3 Empirical Analysis of Anomaly Detection

Here, we will evaluate CRISP’s anomaly detection on six critical endpoints.

Methodology: We collect traces for six microservices in real production over a 14-day period. The training data for each case includes 20,000 traces and the testing data has 500 unseen traces for normal and abnormal data. To generate abnormal inference data, we drop 20% of the nodes in the graph and randomly shuffle the duration of the nodes as described in [26,39,48]. We did not use real anomalous traces for evaluation since we do not have a large number of labelled anomalous traces (i.e., we have a lot of false negatives). Also, the labeled data contains false positives and coordinating with hundreds of developers to verify the veracity of labeling is non-trivial.

We use TraceAnomaly [39] as the baseline against which we compare our results. We adopt the same architecture of the autoencoder and reuse their code. The main difference is that we use CRISP to preprocess the trace before feeding it into the autoencoder so that only paths appearing on the critical path information are included. A fundamental assumption is that any

noticeable difference in the trace must impact the critical path.

Hardware: We use two machines in our evaluation: a CPU-only machine with 256 GB memory and a CPU+GPU machine with 128 GB memory. Most of the experiment is done on a machine with GPUs. It has 2 Quadro RTX 5000 GPUs and 2 socket Intel Xeon Gold 5218 CPU at 2.30GHz. The CPU machine has 2 sockets with Intel Xeon Silver 4214 CPU at 2.20GHz. Both machines run on Linux 4.14. The reason to use two machines is that for some experiments, the training data for TraceAnomaly cannot fit the GPU memory, whereas CRISP’s training data always fits on GPU memory. In such cases, for a fair comparison, we also run the experiment on the 256 GB CPU-only.

Table 2 shows the empirical evaluation results of anomaly detection on 6 large online services at Uber. It captures the essential features such as the number of RPCs, unique endpoints, and call path diversity in these services. It also shows the training and inference time with both STV (prior art from TraceAnomaly) and SCPV (our work) data. Finally, the last 4 columns present the model accuracy in terms of precision and recall. In summary, using critical path via CRISP reduces the training time and inference time and improves the recall performance on top of the state of the art.

Training speedup: From the table, we can observe that CRISP offers up to 22× speedup for training compared with TraceAnomaly. Even the smallest speedup is more than 50%.

The reason for the speedup is that the training data from CRISP (SCPV) is one magnitude smaller than TraceAnomaly (STV) up to 25× for Service 6. The number of unique call paths on the critical path is significantly smaller than the total number of call paths in the entire graph (also see Figures 13-20). Furthermore, when the number of the trace and the dimension

Table 2: Evaluation results for large online services. Inference time is measured with 1000 traces. (TA*=TraceAnomaly.)

	No. of Unique endpoints	Max no. of spans	No. of callpaths/features		Training Time		CRISP training speedup	Inference Time		CRISP inference speedup	Precision		Recall	
			STV	SCPV	TA*	CRISP		TA*	CRISP		TA*	CRISP	TA*	CRISP
Service 1	214	1429	5117	1186	70m (GPU)	46m (GPU)	1.52X	2.24s (GPU)	1.21s (GPU)	1.85X	1.0	0.998	0.986	0.992
Service 2	969	1724	9725	1860	100m (GPU)	50m (GPU)	2.00X	3.54s (GPU)	1.40s (GPU)	2.54X	1.0	1.0	0.958	0.984

Service 4	912	20001	25347	2715	1184m (CPU)	56m (GPU) 219m (CPU)	21.14X (GPU) 5.41X (CPU)	56.67s (CPU)	1.56s (GPU) 9.26s (CPU)	36.33X (GPU) 6.12X (CPU)	1.0	1.0	0.928	0.978
Service 5	768	6562	26404	2336	811m (CPU)	51m (GPU) 177m (CPU)	15.90X (GPU) 4.58X (CPU)	42.90s (CPU)	1.36s (GPU) 5.81s (CPU)	31.54X (GPU) 7.38X (CPU)	1.0	0.998	0.5	0.982
Service 6	1477	10992	28968	1151	1305m (CPU)	46m (GPU) 148m (CPU)	27.77X (GPU) 8.82X (CPU)	78.88s (CPU)	1.18s (GPU) 4.48s (CPU)	66.85X (GPU) 17.61X (CPU)	1.0	1.0	0.912	0.977

of the feature vector is large, the size of the training data of TraceAnomaly can easily exceed the memory of the GPU, which makes it unable to train. For such cases (Service 4, 5, and 6), we can still see more than $4\times$ speedup even if we train both TraceAnomaly and CRISP on CPU machines. When CRISP is trained on the GPU machine, the speedup can easily exceed $15\times$. The faster training allows for more practical deployment.

Inference speedup: Similar to training speedup, the reduction in inference data size leads to a faster inference of CRISP. The smallest speedup is more than $1.85\times$ whereas the largest speedup is over $66\times$. This lower latency allows us to batch many inferences together to exploit GPU throughput.

Precision: From Table 2, we can see that both TraceAnomaly and CRISP are capable of detecting the abnormal trace accurately. Autoencoders are capable of capturing the complex pattern of the graph. TraceAnomaly works slightly better than CRISP on 2 services, but overall accuracy is very high for both methods.

Recall: The recall is the part that differentiates the quality of results between TraceAnomaly and CRISP. Recall measures how many of the actual positives the model captures through labeling it as positive, (i.e., $\frac{True_Positive}{True_Positive+False_Positive}$). When the recall is closer to 1, it indicates that the model makes fewer false-positive predictions (an anomaly in this case). From Table 2, it is clear that CRISP outperforms TraceAnomaly by a noticeable margin. Particularly for Service 3 and 5, half of the positive prediction of the anomaly is false, meaning all normal traces for inference are labeled abnormal by TraceAnomaly. To make sure the prediction is actually incorrect, we asked the service owners and verified that the normal inference testing traces are not showing any abnormal behaviors. On the contrary, CRISP’s recall is close to 1. For Service 1 and 2, the performance of CRISP is slightly better than TraceAnomaly, as both models make relatively accurate predictions. CRISP shows more than 5% improvement for Service 4 and 6.

CRISP produces superior results on services with a large number of call paths. For instance, there are 912 endpoints in Service 4 but the total call paths is 25,347. Since there is more diversity among the shapes of the call chains on the entire graph, the SCPV encoding fails to capture its full variety; consequently, unseen call paths easily trigger a false positive in TraceAnomaly. In contrast, the critical path remains

fairly stable when trained over a large corpus of traces, and consequently CRISP has fewer false positives.

7.4 CPA in Hardware Selection

In addition to the parent-child transitive relationships and times, Jaeger traces also contain additional information, such as the hostname on which the span was executed. Uber’s data center consists of diverse hardware CPU SKUs. Services can be installed on different hardware versions. Hence, an API may run on different hardware on different requests.

We collected the critical path for one of our important services using CRISP and identified that a downstream operation was on the critical path. We further clustered the samples from the profiles by the CPU versions on which they were running. The violin plot in Figure 21 in Appendix A shows how the latencies vary on 2 prominent CPU SKUs: Intel Xeon Silver 4212 running at 2.2 GHz (SKU-A) and Intel Xeon Silver 4212R running at 2.4 GHz (SKU-B). The two SKUs are identical (same vendor, microarchitecture, cache size, etc.) with the only exception being that their CPU clock speeds are different. This mild (9%) difference in the clock speed has a profound impact on the behavior of the plotted service. The P50 value for SKU-A is 15% higher than that on SKU-B. Moreover, the tail latency on SKU-A is 1.5x higher than the one on SKU-B.

To summarize, a slightly faster CPU clock proves to have a significant impact on reducing the tail latency and overall latency. This difference has a significant impact on the overall capacity allocation since tail latency (e.g., P95) is often used in capacity allocation. This observation demands further, systematic investigation into classifying critical path components as CPU SKU sensitive vs. insensitive; also, such categorization helps data center-wide microservice schedulers to favor SKU-sensitive services on the critical path onto the SKUs where they exhibit superior performance.

8 Related Work

Critical Path Analysis (CPA) has been extensively explored in the shared-memory parallel programming paradigm [13, 20, 25, 40, 50, 54, 55, 59, 62] but less explored in distributed parallel systems. Unlike shared-memory and struc-

tered parallel programs, microservices use distributed parallel computing environments and are unstructured in nature.

Barford and Crovella [16] utilize critical path analysis for profiling and understanding TCP transactions and improve data transfer latency in web applications; however their scale is significantly smaller than the 4K services deployed over millions of CPU cores that we handle. Bohem et al. [18] employ tracing and CPA for MPI programs in HPC environments; this approach has not been employed in microservice environments. Kaldor et al. [33] develop an end-to-end tracing system (Canopy) for tracking requests from web-browsers/mobile to backend services; it handles billions of traces. A distinguishing feature of CRISP compared with Canopy is the use of CPA, which significantly reduces the data needed for analysis.

Qiu et al. [48] propose a fine-grained resource management framework based on microservice traces using CPA. They employ the insights for scheduling and other resource management to reduce CPU utilization. However, their work does not cover industry-scale deployment; they also do not facilitate performance bug or anomaly detection and cannot provide bottom-up system-wide performance insights.

Fields et al. [24] explore a hardware predictor to analyze the criticality of instructions by using CPA and use it to guide dynamic instruction scheduling. Venkataramani et al. [55] propose Global Critical Path (GCP) to predict system-level performance and optimize the performance of highly concurrent self-timed circuits. These approaches rely on the precise last arriver information, which is readily available in these cases. Our critical path computation in microservices also depends on knowing the last arriver. Unlike the aforementioned approaches, we do not have direct access to the last arriver in our distributed system. As a result, we need to use clock information from different hosts and adjust for clock skew to heuristically infer the last arriver.

Multiple tools have been developed to profile and debug large distributed and parallel systems. `lprof` [64] constructs request flow from logs and it is as good as the quality of logs; it has not been evaluated on microservices; it also does not provide CPA and hence suffers from a voluminous noisy data. Mace et al. [41] developed Pivot as a dynamic, extensible tracing system for inter-operating applications. Pivot employs a happen-before relationship between events to establish causality. Pivot does not build a critical path and hence pays equal attention to any causal relationship unlike CRISP. Chow et al. [19] build a system that utilizes a large number of request traces to validate hypotheses about causal relationships. Edgar [2] provides a summarized view of request traces, logs, and metadata in distributed systems. It does not employ sophisticated analyses or automated anomaly detection.

Several works have focused on microarchitectural aspects of microservices [34, 42, 52, 60, 61]. Most of these works are focused on how microservices utilize microarchitectural features, but ignore the end-to-end user request; in contrast, CRISP takes a higher-level approach and looks at the entire

flow of requests through a chain of services.

Multiple works have studied anomaly detection in distributed systems. Liu et al. [39] use Deep Bayesian Network to detect the performance anomaly in an unsupervised manner. They utilize machine learning to learn the normal behavior pattern of the given dependency graph and try to detect the anomaly online. Gan et al. [26] propose a root cause analysis system for large-scale microservices using machine learning. The system uses Conditional Variational Autoencoders (CVAE) [51] to automatically generate the counterfactual training data. These approaches have used the entire call graph, leading to significant training and inference time. In contrast, CRISP uses only the critical path(s), leading to dramatic speedups while producing higher quality results.

9 Conclusions and Future Work

Microservices are the preferred architecture choice in modern service-oriented software systems. Large-scale microservices have tens of thousands of endpoints with complex, nested, and asynchronous. Prior work in profiling microservices has either focused on tracing techniques, which produce a lot of data, but lack in delivering insights, or on micro-architectural optimization within a service, ignoring the full picture of the life of a request through myriad services. This paper develops a tool, CRISP, which uses critical path analysis (CPA) over RPC traces to bubble-up interesting activities and discard noisy events. CRISP provides rich developer insights both for service owners and infrastructure engineers. In a short three-month deployment period, CRISP's analyses have sifted over 4,000+ services, 40,000+ endpoints, hundred of millions of traces, and tens of terabytes of data at Uber; as a result, CRISP has bubbled-up profiling results that helped developers understand and optimize important services. Employing the critical path, as opposed to the whole RPC trace, speeds up the training of models and on-the-fly inference for anomaly detection while also producing noticeably higher quality results.

Our future work involves enhancing CRISP to address other use cases such as setting the TTL values for downstream calls and bubbling up those downstream services that often return errors. We plan to expand our anomaly detection to include developers in the loop and improve traces with labelled data.

A Violin Plot for Hardware Selection

Figure 21: Violin plots of the exclusive execution time of a critical path operation with two different CPUs. The latency is in μs .

B Autoencoder Model Architecture

We choose the Deep Bayesian Network for anomaly detection given it is capable of learning complex patterns from the trace. We adopt the model from TraceAnomaly [39], which is the state-of-the-art framework for microservice trace based anomaly detection. Specifically, we adopt Variational Auto-Encoder (VAE) [35] to model the distribution pattern from the normal execution. VAE is an unsupervised learning that does not require a label, which can be expensive to obtain in our setting due to the volume of traces. Figure 22 depicts the architecture of VAE. It has three components: encoder, posterior flow, and decoder.

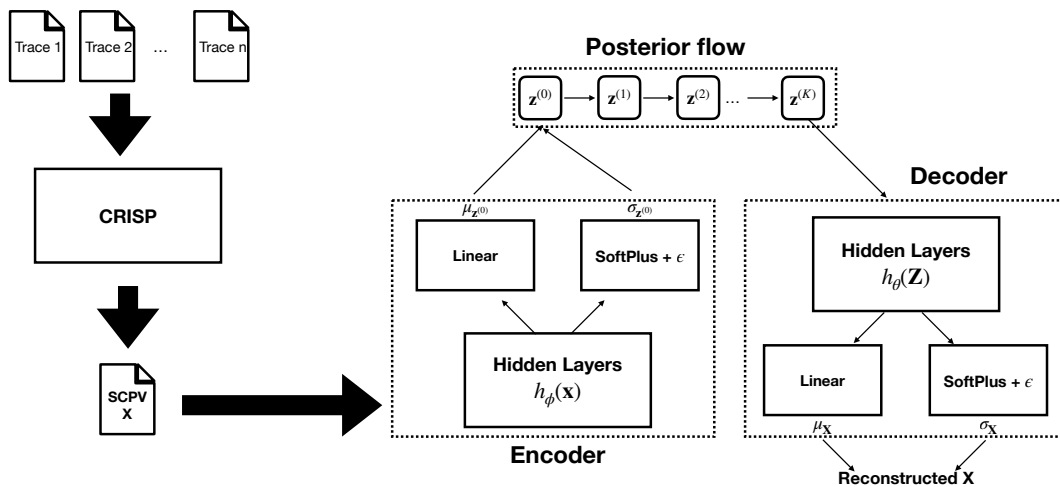

Figure 22: Architecture of neural network for anomaly detection.

The encoder contains 1 hidden layer ($h_\phi(\mathbf{x})$) to learn the hidden features of SCPV. The goal is to learn the mean $\mu_{\mathbf{z}^{(0)}}$ and the standard deviation $\sigma_{\mathbf{z}^{(0)}}$ of the SCPV. $\mathbf{z}^{(0)}$ is sampled from diagonal Gaussian $\mathcal{N}(\mu_{\mathbf{z}^{(0)}}, \sigma_{\mathbf{z}^{(0)}} \mathbf{I})$ and served as the latent variable to fit the distribution. ϵ is a small constant vector that has been introduced to avoid numerical issues during the training [39]. SoftPlus is defined as $\text{SoftPlus}(\mathbf{x}) = \log(1 + \exp(\mathbf{x}))$.

For the next step, posterior flow allows the network to learn more complex patterns of the trace. The input is $\mathbf{z}^{(0)}$ and after passing length of K flow it will become as $\mathbf{z}^{(K)}$.

Then, $\mathbf{z}^{(K)}$ will be passed into the decoder network to extract hidden features. Similarly, the purpose of those hidden features is to derive the mean $\mu_{\mathbf{x}}$ and standard deviation $\sigma_{\mathbf{x}}$ of the input trace vector. After that, the reconstructed \mathbf{x} will be sampled from $\mathcal{N}(\mu_{\mathbf{x}}, \sigma_{\mathbf{x}}^2 \mathbf{I})$

C Inference

When a new trace is given, the log-likelihood value will be computed against the model to detect whether the trace is abnormal or not. If the trace \mathbf{x} is significantly different than the normal trace, the value of a trace $\log p_\theta(\mathbf{x})$ is noticeably smaller than the value of the normal traces. Instead of manually setting the threshold of anomaly, we follow the work from Liu et al. [39] and use Kernel Density Estimation (KDE) [22] to learn the distribution of the normal traces log-likelihood. Specifically, we adopt the p-value [57] approach and set the value as 0.001 to check if the probability of the log-likelihood value not following the learned distribution.

If the trace contains any unseen *call chain*, it will be regarded as abnormal. Training is a continuous process since the code evolves and the call paths keep changing over time. We use a sliding window of last 14 days of trace to keep our model up-to-date.

Artifact Appendix

Abstract

This artifact includes the script to utilize CRISP as we presented in the paper.

Scope

The artifact allows: top-down analysis, bottom-up analysis, and preprocessing for anomaly detection. It does not come with any traces to analyze and those traces need to be provided by the user.

Contents

It contains the implementation of CRISP with corresponding script to run the analysis.

Hosting

The artifact is available at <https://github.com/uber-research/CRISP> under **atc-2022** branch.

Requirements

- Python3.6 is recommended to run the anomaly detection. Otherwise, any python3 version should be fine.
- Git is also needed.
- "git clone https://github.com/NetManAIOps/TraceAnomaly.git" is required under the root directory in order to run anomaly detection.

Setup

- "python3.6 -m pip install -r requirements.txt" to install the dependency for CRISP.
- "python3.6 -m pip install -r TraceAnomaly/requirements.txt" to install the dependencies for TraceAnomaly.
- You may need to install protobuf if the requirements.txt doesn't work in TraceAnomaly by "python3.6 -m pip install protobuf==3.12.4".
- specify "TRACE_DIR" in "bottom-up.sh", "top-down.sh", and "preprocess.sh".

Top-down Analysis

Before running, you need to specify the input, output, serviceName, operationName, and processor number in `top-down.sh`. Make sure the output directory already existed. To run the analysis, simpling typing

```
mkdir top-down-result
bash top-down.sh
```

By default, the script will use all processors to run. You can change the processor number with `--parallelism` knob in `top-down.sh` script.

The result will be in `top-down-result` folder. It will represent Figure 2, Figure 11, and Figure 13 in the original paper. The number and shape won't be exactly the same given the trace and endpoints are different from the paper.

Specifically, flamegraph like Figure 2 is generated as `flame-graph-P50.cct.svg`, `flame-graph-P95.cct.svg`, and `flame-graph-P99.cct.svg`. `criticalPaths.html` is like the heatmap in Figure 11 and please open it in browser. The differential flamegraph like Figure 13 can be viewed in `flame-graph-P50vsP95.cct.svg`

Bottom-up Analysis

To use the artifact, run

```
bash bottom-up.sh
```

The figure will be generated under `result-bottom-up/` folder, which looks like Figure 13 ~ Figure 20 from the paper.

Anomaly Detection

Data Preprocessing run `bash preprocess.sh` to run generate the data for anomaly detection. Note each training, normal, and abnormal data needs to be parsed twice as it is shown in `preprocess.sh`. The reasons is that we need to know the total number of call path to generate the data.

Training Please refer to <https://github.com/NetManAIops/TraceAnomaly>.

Result Parsing Please go back to root directory when parsing the results. The trained model and the predicted results will be in `TraceAnomaly/webankdata/`.

To parse the results, run `python3.6 parse-rnvp.py -i path_to_rnvp_file`.

Whale: Efficient Giant Model Training over Heterogeneous GPUs

Xianyan Jia¹, Le Jiang¹, Ang Wang¹, Wencong Xiao¹, Ziji Shi^{1,2}, Jie Zhang¹, Xinyuan Li¹, Langshi Chen¹, Yong Li¹, Zhen Zheng¹, Xiaoyong Liu¹, Wei Lin¹

¹Alibaba Group ²National University of Singapore

Abstract

The scaling up of deep neural networks has been demonstrated to be effective in improving model quality, but also encompasses several training challenges in terms of training efficiency, programmability, and resource adaptability. We present Whale, a general and efficient distributed training framework for giant models. To support various parallel strategies and their hybrids, Whale generalizes the programming interface by defining two new primitives in the form of model annotations, allowing for incorporating user hints. The Whale runtime utilizes those annotations and performs graph optimizations to transform a local deep learning DAG graph for distributed multi-GPU execution. Whale further introduces a novel hardware-aware parallel strategy, which improves the performance of model training on heterogeneous GPUs in a balanced manner. Deployed in a production cluster with 512 GPUs, Whale successfully trains an industry-scale multimodal model with over ten trillion model parameters, named M6, demonstrating great scalability and efficiency.

1 Introduction

The training of large-scale deep learning (DL) models has been extensively adopted in various fields, including computer vision [15, 30], natural language understanding [8, 35, 43, 44], machine translation [17, 26], and others. The scale of the model parameters has increased from millions to trillions, significantly improving model quality [8, 24], but this has come at the cost of considerable efforts to efficiently distribute the model across GPUs. The commonly used data parallelism (DP) strategy is a poor fit, since it requires the model replicas in GPUs perform gradient synchronization proportional to the model parameter size for every mini-batch, thus easily becoming a bottleneck for giant models. Moreover, training trillions of model parameters requires terabytes of GPU memory at the minimum, which is far beyond the capacity of a single GPU.

To address the aforementioned challenges, a series of new parallel strategies in training DL models have been pro-

posed, including model parallelism (MP) [25], pipeline parallelism [20, 32], etc. For example, differing from the DP approach where each GPU maintains a model replica, MP partitions model parameters into multiple GPUs, avoiding gradient synchronization but instead letting tensors flow across GPUs.

Despite such advancements, new parallel strategies also introduce additional challenges. First, different components of a model might require different parallel strategies. Consider a large-scale image classification task with 100K classes, where the model is composed of *ResNet50* [19] for feature extraction and Fully-Connected (FC) layer for classification. The parameter size of *ResNet50* is 90 MB, and the parameter size of FC is 782 MB. If DP is applied to the whole model, the gradient synchronization of FC will become the bottleneck. One better solution is to apply DP to *ResNet50* and apply MP to FC (Section 2.3). As a result, the synchronization overhead can be reduced by 89.7%, thereby achieving better performance [25].

Additionally, using those advanced parallel strategies increases user efforts significantly. To apply DP in distributed model training, model developers only need to program the model for one GPU and annotate a few lines, and DL frameworks can replicate the execution plan among multiple GPUs automatically [27]. However, adopting advanced parallelism strategies might make different GPUs process different partitions of the model execution plan, which is difficult to achieve automatically and efficiently [23, 46]. Therefore, significant efforts are required for users to manually place computation operators, coordinate pipeline among mini-batches, implement equivalent distributed operators, and control computation-communication overlapping, etc. [26, 38, 41, 43]. Such an approach exposes low-level system abstractions and requires users to understand system implementation details when programming the models, which greatly increases the amount of user effort.

Further, the training of giant models requires huge computing resources. In industry, the scheduling of hundreds of homogeneous high-end GPUs usually requires a long queuing

time. Meanwhile, heterogeneous GPUs can be obtained much easier (e.g., a mixture of P100 [2] and V100 [3]) [21, 47]. But training with heterogeneous GPUs efficiently is even more difficult, since both the computing units and the memory capacity of GPUs need to be considered when building the model. In addition, due to the dynamic scheduling of GPUs, users are unaware of the hardware specification when building their models, which brings a gap between model development and the hardware environment.

We propose Whale, a deep learning framework designed for training giant models. Unlike the aforementioned approaches in which the efficient model partitions are searched automatically or low-level system abstractions and implementation details are exposed to users, we argue that deep learning frameworks should offer high-level abstractions properly to support complicated parallel strategies by utilizing user hints, especially when considering the usage of heterogeneous GPU resources. Guided by this principle, Whale strikes a balance by extending two necessary primitives on top of TensorFlow [7]. Through annotating a local DL model with those primitives, Whale supports all existing parallel strategies and their combinations, which is achieved by automatically rewriting the deep learning execution graph. This design choice decouples the parallel strategies from model code, and lowers them into dataflow graphs, which not only reduces user efforts but also enables graph optimizations and resources-aware optimizations for efficiency and scalability. In this way, Whale eases users from the complicated execution details of giant model training, such as scheduling parallel executions on multiple devices, and balancing computation workload among heterogeneous GPUs. Moreover, Whale introduces a hardware-aware load balancing algorithm when generating a distributed execution plan, which bridges the gap between model development and the heterogeneous runtime environment.

We summarize the key contributions of Whale as follows:

1. For carefully balancing user efforts and distributed graph optimization requirements, Whale introduces two new high-level primitives to express all existing parallel strategies as well as their hybrids.
2. By utilizing the annotations for graph optimization, Whale can transform local models into distributed models, and train them on multiple GPUs efficiently and automatically.
3. Whale proposes a hardware-aware load balancing algorithm, which is seamlessly integrated with parallel strategies to accelerate training on heterogeneous GPUs.
4. Whale demonstrates its capabilities by setting a new milestone in training the largest multi-modality pre-trained model M6 [28] with ten trillion model parameters, which requires only four lines of code change to scale the model and run on 512 NVIDIA V100M32 GPUs (Section 5.3.2).

Whale has been deployed as a production system for large-scale deep learning training at Alibaba. Using heterogeneous GPUs, further speedup of Bert-Large [13], Resnet50 [19], and GNMT [48] from 1.2x to 1.4x can be achieved owing to the hardware-aware load balancing algorithm in Whale. Whale also demonstrates its capabilities in the training of industry-scale models. With only four-line changes to a local model, Whale can train a Multi-Modality to Multi-Modality Multitask Mega-transformer model with 10 billion parameters (M6-10B) on 256 NVIDIA V100 GPUs (32GB), achieving 91% throughput in scalability. What's more, Whale scales to ten trillion parameters in model training of M6-10T using tensor model parallelism on 512 V100 GPUs (32GB), setting a new milestone in large-scale deep learning model training.

2 Background and Motivation

In this section, we first recap the background of distributed DL model training, especially the parallel strategies for large model training. We then present the importance and the challenges of utilizing heterogeneous GPU resources. Finally, we discuss the gaps and opportunities among existing approaches to motivate the design of a new training framework.

2.1 Parallel Strategies

Deep learning training often consists of millions of iterations, referred to as *mini-batches*. A typical mini-batch includes several phases to process data for model updating. Firstly, the training data is fed into the model layer-by-layer to calculate a set of scores, known as a *forward* pass. Secondly, a training loss is calculated between the produced scores and desired scores, which is then utilized to compute gradients for model parameters, referred to as a *backward* pass. Finally, the gradients scaled by a learning rate are used to update the model parameters and optimizer states.

Data parallelism. Scaling to multiple GPUs, data parallelism is a commonly adopted strategy where each worker holds a full model replica to process different training data independently. During the backward pass of every mini-batch, the gradients are averaged through worker synchronization. Therefore, the amount of communication is proportional to the model parameter size.

Pipeline Parallelism. As shown in Figure 1, a DL model is partitioned into two modules, *i.e.*, M0 and M1 (which are also named pipeline stages), which are placed on 2 GPUs respectively. The training data of a mini-batch is split into two smaller *micro-batches*. In particular, GPU0 starts with the forward of the 1st micro-batch on M0, and then it switches to process the forward of the 2nd micro-batch while sending

Figure 1: Pipeline parallelism of 2 micro-batches on 2 GPUs. Figure 2: Tensor model parallelism for *matmul* on 2 GPUs.

the output of the 1st micro-batch to GPU1. After GPU1 finishes processing forward and backward of the 1st micro-batch on M1, GPU0 continues to calculate the backward pass for M0 after receiving the backward output of M1 from GPU1. Therefore, micro-batches are pipelined among GPUs, which requires the runtime system to balance the load and overlap computation and communication carefully [16, 20, 32, 54]. The model parallelism [11, 12] can be treated as a special case of pipeline parallelism with only one micro-batch.

Tensor Model Parallelism. With the growing model size, to process DL operators beyond the memory capacity of the GPU, or to avoid significant communication overhead across model replicas, an operator (or several operators) might be split over multiple GPUs. The tensor model parallelism strategy partitions the input/output tensors and requires an equivalent distributed implementation for the corresponding operator. For example, Figure 2 illustrates the tensor model parallelism strategy for a *matmul* operator (*i.e.*, matrix multiplication) using 2 GPUs. A *matmul* operator can be replaced by two *matmul* operators, wherein each operator is responsible for half of the original computation. An extra all-gather operation is required to merge the distributed results.

In selecting a proper parallel strategy for model training, both model properties and resources need to be considered. For example, transformer [44] is an important model in natural language understanding, which can be trained efficiently using pipeline parallelism on a few GPUs (*e.g.*, 8 V100 GPUs with NVLINK [4]). However, pipeline parallelism does not scale well with more GPUs (*e.g.*, 64 V100 GPUs). Given more GPUs, each training worker is allocated with fewer operators, of which the GPU computation is not sufficient enough to overlap with the inter-worker communication cost, resulting in poor performance. Therefore, a better solution is to apply hybrid parallelism, where model partitions can be applied with different parallel strategies in combination, and parallel strategies can be nested. Particularly, for the training of a transformer model on 64 GPUs, the model parameters can be partitioned into 8 GPUs using a pipeline strategy, and apply model replica synchronization among 8 pipelined groups using nested data parallelism. Moreover, different parallel strategies can also apply to different model partitions for a hybrid.

Figure 3: Hybrid parallelism for image classification. Figure 4: Data parallelism on heterogeneous GPUs

As an example, a large-scale image classification model (*i.e.*, 100K categories) consists of the image feature extraction partition and the classification partition. The image feature extraction partition requires a significant amount of computation on fewer model parameters. Conversely, the classification partition includes low-computation *fully-connected* and *softmax* layers, which are often 10x larger in model size compared to that of image feature extraction. Therefore, adopting a homogeneous parallel strategy will hinder the performance of either partitions. Figure 3 illustrates a better hybrid parallelism approach, in which data parallelism is applied for features extraction partition, tensor model parallelism is adopted for classification partition, and the two are connected.

2.2 Heterogeneity in GPU Clusters

Training a giant model is considerably resource-intensive [17, 33]. Moreover, distributed model training often requires resources to arrive at the same time (*i.e.*, gang schedule [21, 50]). In industry, the shared cluster for giant model training is usually mixed with various types of GPUs (*e.g.*, V100, P100, and T4) for both model training and inference [47]. Training giant models over heterogeneous GPUs lowers the difficulty of collecting all required GPUs (*e.g.*, hundreds or thousands of GPUs) simultaneously, therefore speeding up the model exploration and experiments. However, deep learning frameworks encounter challenges in efficiently utilizing heterogeneous resources. Different types of GPUs are different in terms of GPU memory capacity (*e.g.*, 16GB for P100 and 32GB for V100) and GPU computing capability, which natively introduces an imbalance in computational graph partition and deep learning operator allocation. Figure 4 illustrates training a model using data parallelism on two heterogeneous GPUs, *i.e.*, V100 and T4. The V100 training worker completes forward and backward faster when training samples are allocated evenly, thereby leaving idle GPU cycles before gradient synchronization at the end of every mini-batch. Through the awareness of hardware when dynamically generating an execution plan, Whale allocates more training samples (*i.e.*, batch-size=4) for V100 and the rest of 2 samples for T4 to eliminate the idle waiting time. Combined with advanced parallel strategies and the hybrids over heterogeneous GPUs, different GPU memory capacities and capabilities need to

be further considered when partitioning the model for efficient overlapping, which is a complex process (Section 3.3). Model developers can hardly consider all resources issues when programming, and we argue that developers should not have to. A better approach for a general deep learning framework would be automatically generating the execution plan for heterogeneous resources adaptively.

2.3 Gaps and Opportunities

Recent approaches [20, 26, 38, 41, 43] have been proposed for giant model training, however, with limitations as a general DL framework. Firstly, they only support a small number of parallel strategies, which lack a unified abstraction to support all of the parallel strategies and the hybrids thereof. Secondly, significant efforts are required in code modifications to utilize the advanced parallel strategies, compared with local model training and *DP* approach. Mesh-tensorflow [41] requires the re-implementation of DL operators in a distributed manner. Megatron [43], GPipe [20], DeepSpeed [38], and GShard [26] require user code refactoring using the exposed low-level system primitives or a deep understanding for the implementation of parallel strategies. Thirdly, automatically parallel strategy searching is time-consuming for giant models. Although Tofu [46] and SOAP [23] accomplish model partitioning and replication automatically through computational graph analysis, the search-based graph optimization approach has high computational complexity, which is further positively associated with the number of model operators (*e.g.*, hundreds of thousands of operators for GPT3 [8]) and allocated GPUs (*e.g.*, hundreds or thousands), making such an approach impractical when applying to giant model training. Finally, due to the heterogeneity in both GPU computing capability and memory, parallel strategies should be used adaptively and dynamically.

There are significant gaps in supporting giant model training using existing DL frameworks. Exposing low-level interfaces dramatically increases user burden and limits system optimization opportunities. Users need to understand the implementation details of distributed operators and handle the overlapping of computation with communication, which is hard for model developers. Using a low-level approach tightly couples model code to a specific parallel strategy, which requires code rewriting completely when switching between parallel strategies (*i.e.*, from pipeline parallelism to tensor model parallelism). More constraints are introduced to model algorithm innovations, because the efforts of implementing a new module correctly in hybrid strategies are not trivial, let alone consider the performance factors such as load balancing and overlapping. From the system aspect, seeking a better parallel strategy or a combination using existing ones also requires rewriting user code, demanding a deep understanding of the DL model.

To address the aforementioned challenges, Whale explores

a new approach that supports various parallel strategies while minimizing user code modifications. By introducing new unified primitives, users can focus on implementing the model algorithm itself, while switching among various parallel strategies by simply changing the annotations. Whale runtime utilizes the user annotations as hints to select parallel strategies at best effort with automatic graph optimization under a limited search scope. Whale further considers heterogeneous hardware capabilities using a balanced algorithm, making resource heterogeneity transparent to users.

3 Design

In this section, we first introduce key abstractions and parallel primitives which can express flexible parallelism strategies with easy programming API (Section 3.1). Then, we describe our parallel planner that transforms a local model with parallel primitives into a distributed model, through partitioning *TaskGraphs*, inserting bridge layers to connect hybrid strategies, and placing *TaskGraphs* on distributed devices (Section 3.2). In the end, we propose a hardware-aware load balance algorithm to speed up the training with heterogeneous GPU clusters (Section 3.3).

3.1 Abstraction

3.1.1 Internal Key Concepts

Deep learning frameworks such as TensorFlow [7] provide low-level APIs for distributed computing, but is short of abstractions to represent advanced parallel strategies such as pipeline. The lack of proper abstractions makes it challenging in the understanding and implementation of complicated strategies in a unified way. Additionally, placing model operations to physical devices properly is challenging for complicated hybrid parallel strategies, especially in heterogeneous GPU clusters. Whale introduces two internal key concepts, *i.e.*, *TaskGraph* and *VirtualDevice*. *TaskGraph* is used to modularize operations for applying a parallel strategy. *VirtualDevice* hides the complexity of mapping operations to physical devices. The two concepts are abstractions of internal system design and are not exposed to users.

TaskGraph(*TG*) is a subset of the model for parallel transformation and execution. One model can have one or more non-overlapping *TaskGraphs*. We can apply parallel strategies to each *TaskGraph*. By modularizing model operations into *TaskGraphs*, Whale can apply different strategies to different model parts, as well as scheduling the execution of *TaskGraphs* in a pipeline. A *TaskGraph* can be further replicated or partitioned. For example, in data parallelism, the whole model is a *TaskGraph*, which can be replicated to multiple devices. In pipeline parallelism, one pipeline stage is a *TaskGraph*. In tensor model parallelism, we can shard the *TaskGraph* into multiple submodules for parallelism.

```
import whale as wh
wh.init(wh.Config({
    "num_micro_batch": 8}))
with wh.replicate(1):
    model_stage1()
with wh.replicate(1):
    model_stage2()
```

Example 1: Pipeline with 2 TaskGraphs

```
import whale as wh
wh.init()
with wh.replicate(total_gpu):
    features = ResNet50(inputs)
with wh.split(total_gpu):
    logits = FC(features)
predictions = Softmax(logits)
```

Example 2: Hybrid of replicate and split

VirtualDevice (VD) is the logical representation of computing resources, with one *VirtualDevice* having one or more physical devices. *VirtualDevice* hides the complexity of device topology, computing capacity as well as device placement from users. One *VirtualDevice* is assigned to one *TaskGraph*. Different *VirtualDevices* are allowed to have different or the same physical devices. For example, VD0 contains physical devices GPU0 and GPU1, VD1 contains physical devices GPU2 and GPU3 (different from VD0), and VD2 contains physical devices GPU0 and GPU1 (the same as VD0).

3.1.2 Parallel Primitives

The parallel primitive is a Python context manager, where operations defined under it are modularized as one *TaskGraph*. Each parallel primitive has to be configured with a parameter *device_count*, which is used to generate a *VirtualDevice* by mapping the *device_count* number of physical devices. Whale allows users to suggest parallel strategies with two unified primitives, i.e., *replicate* and *split*. The two primitives can express all existing parallel strategies, as well as a hybrid of them [20, 25, 26, 32, 43].

replicate(device_count) annotates a *TaskGraph* to be replicated. *device_count* is the number of devices used to compute the *TaskGraph* replicas. If *device_count* is not set, Whale allocates a *TaskGraph* replica per device. If a *TaskGraph* is annotated with *replicate(2)*, it is replicated to 2 devices, with each *TaskGraph* replica consuming half of the mini-batch. Thus the mini-batch size for one model replica is kept unchanged.

split(device_count) annotates a *TaskGraph* to apply intra-tensor sharding. The *device_count* denotes the number of partitions to be sharded. Each sharded partition is placed on one device. For example, *split(2)* shards the *TaskGraph* into 2 partitions and placed on 2 devices respectively.

The parallel primitives can be used in combination to apply different parallel strategies to different partitions of the model. Additionally, Whale also provides JSON Config API to enable system optimizations. The config *auto_parallel* is used to enable automatic *TaskGraph* partitioning given a provided partition number *num_task_graph*, which further eases the programming for users and is necessary for hardware-aware optimization when resource allocation is dynamic (Section 3.3). In Whale, pipeline parallelism is viewed as an efficient inter-*TaskGraph* execution strategy. Whale uses the

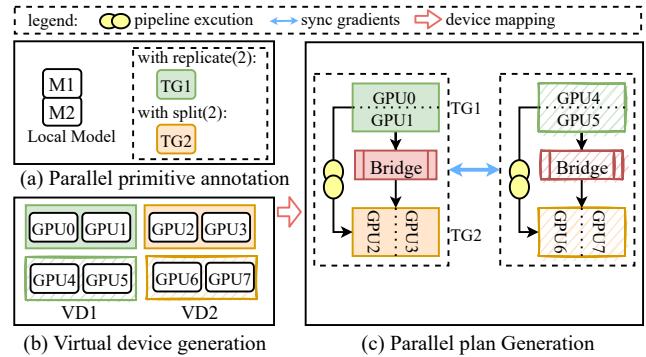

Figure 5: Whale Overview

config *num_micro_batch* to enable efficient pipeline parallelism among *TaskGraphs* when the value is greater than 1. In this way, Whale decouples the generation of *TaskGraph* from the choice of pipeline parallelism strategies [16, 20, 32]. The system can easily extend to incorporate more pipeline strategies (e.g., swap the execution order of *B0* and *F1* for *M1* in Figure 1).

Besides the combination of parallel strategies or pipeline parallelism, Whale further supports nested data parallelism to the whole parallelized model. Nested data parallelism is enabled automatically when the number of available devices is times of total devices requested by *TaskGraphs*.

Example 1 shows an example of pipeline parallelism with two *TaskGraphs*, with each *TaskGraph* being configured with 1 device. The pipeline parallelism is enabled by configuring the *pipeline.num_micro_batch* to 8. The total device number of the two *TaskGraphs* is summed to 2. If the available device number is 8, which is 4 times of total device number, Whale will apply a nested 4-degree data parallelism beyond the pipeline. In contrast, when using two available devices, it is a pure pipeline. Example 2 shows a hybrid strategy that replicates *ResNet50* feature part while splitting the *classification* model part for the example in Figure 3.

```
wh.init(wh.Config({"num_task_graph": 2,
    "num_micro_batch": 4, "auto_parallel": True}))
model_def()
```

Example 3: Auto pipeline

Example 3 shows an automatic pipeline example with two *TaskGraphs*. When *auto_parallel* is enabled, Whale will partition the model into *TaskGraphs* automatically according to the computing resource capacity and the model structure. (Section 3.3)

3.2 Parallel Planner

The parallel planner is responsible for producing an efficient parallel execution plan, which is the core of Whale runtime. Figure 5 shows an overview of the parallel planner. The workflow can be described as follows: (a) The parallel planner takes a local model with optional user annotations, computing

resources, and optional configs as inputs. The model hyperparameters (e.g., batch size and learning rate), and computing resources (e.g., #GPU and #worker) are decided by the users manually, while the parallel primitive annotations and configs (e.g., `num_task_graph` and `num_micro_batch`) could be either be manual or decided by Whale automatically; (b) the *VirtualDevices* are generated given computing resources and optional annotations automatically (Section 3.2.1); and (c) the model is partitioned into *TaskGraphs*, and the *TaskGraph* is further partitioned internally if `split` is annotated. Since we allow applying different strategies to different *TaskGraphs*, there may exist an input/output mismatch among *TaskGraphs*. In such case, the planner will insert the corresponding bridge layer automatically between two *TaskGraphs* (Section 3.2.3).

3.2.1 Virtual Device Generation

VirtualDevices are generated given the number of devices required by each *TaskGraph*. Given K requested physical devices $GPU_0, GPU_1, \dots, GPU_K$ and a model with N *TaskGraphs*, with corresponding device number d_1, d_2, \dots, d_N . For the i^{th} *TaskGraph*, Whale will generate a *VirtualDevice* with d_i number of physical devices. The physical devices are taken sequentially for each *VirtualDevice*. As mentioned in Section 3.1.2, when the available device number K is divisible by the total number of devices requested by all *TaskGraphs* $\sum_i^N d_i$, Whale will apply a nested *DP* of $\frac{K}{\sum_i^N d_i}$ -degree to the whole model. In such case, we also replicate the corresponding *VirtualDevice* for *TaskGraph* replica. By default, devices are not shared among *TaskGraphs*. Sharing can be enabled to improve training performance in certain model sharding cases by setting cluster configuration¹. Whale prefers to place one model replica (with one or more *TaskGraphs*) within a node, and replicates the model replicas across nodes. Advanced behaviors such as placing *TaskGraph* replicas within a node to utilize NVLINK for AllReduce communication can be achieved by setting the aforementioned configuration. For example, as shown in Figure 5, there are two *TaskGraphs*, and each *TaskGraph* requests 2 GPUs. Two *VirtualDevices* VD1 and VD2 are generated for two *TaskGraphs*. VD1 contains GPU_0 and GPU_1 , and VD2 contains GPU_2 and GPU_3 . As the number of available GPUs is 8, which is divisible by the total GPU number of *TaskGraphs* 4, a replica of *VirtualDevices* can be generated but with different physical devices.

3.2.2 TaskGraph Partitioning

Whale first partitions a model into *TaskGraphs*, either by using explicit annotations or automatic system partitioning. If a user annotation is given, operations defined within certain parallel primitive annotation compose a *TaskGraph*. Otherwise, the system generates *TaskGraphs* based on the given config

¹<https://easyparallellibrary.readthedocs.io/en/latest/api/config.html#clusterconfiguration>

Figure 6: Sharding pattern example for MatMul. One ShardingUnit can map to multiple sharding patterns.

parameter `num_task_graph` and hardware information. The details of the hardware-aware model partitioning is described in Section 3.3.

If a *TaskGraph* is annotated with `split(k)`, Whale will automatically partition it by matching and replacing sharding patterns with a distributed implementation. Before describing the sharding pattern, we introduce two terminologies for tensor model parallelism: 1) *ShardingUnit* is a basic unit for sharding, and can be an operation or a layer with multiple operations; and 2) *ShardingInfo* is the tensor sharding information, and is represented as a list $[s_0, s_1, \dots, s_n]$ given a tensor with n dimensions, where s_i represents whether to split the i^{th} dimension, 1 means true and 0 means false. For example, given a tensor with shape $[6, 4]$, the *ShardingInfo* $[0, 1]$ indicates splitting in the second tensor dimension, whereas $[1, 1]$ indicates splitting in both dimensions. A sharding pattern (SP) is a mapping from a *ShardingUnit* and input *ShardingInfo* to its distributed implementations. For example, Figure 6 shows two sharding patterns SP1 and SP2 with different input *ShardingInfo* for *ShardingUnit* MatMul.

To partition the *TaskGraph*, Whale first groups the operations in the split *TaskGraph* into multiple *ShardingUnits* by hooking TensorFlow ops API². The *TaskGraph* sharding process starts by matching *ShardingUnits* to the predefined sharding patterns in a topology order. A pattern is matched by a *ShardingUnit* and input *ShardingInfos*. If multiple patterns are matched, the pattern with a smaller communication cost is selected. Whale replaces the matched pattern of the original *ShardingUnit* with its distributed implementation.

3.2.3 Bridge Layer

When applying different parallel strategies to different *TaskGraphs*, the input/output tensor number and shape may change due to different parallelism degrees or different parallel strategies, thereby resulting in a mismatch of input/output tensor shapes among *TaskGraphs*. To address the mismatch, Whale proposes a *bridge layer* to gather the distributed tensors and feed them to the next *TaskGraph*.

²TensorFlow Ops: <https://github.com/tensorflow/tensorflow/tree/r1.15/tensorflow/python/ops>

Figure 7: Bridge patterns.

Whale designs two *bridge patterns* for *replicate* and *split* respectively, as shown in Figure 7. For *replicate*, the *TaskGraph* is replicated to N devices, with different input batches. The *bridge layer* gathers the outputs from different batches for concatenation in batch dimension $batch_dim$. For *split*, the outputs of *TaskGraph* are partitioned in split dimension $split_dim$. The *bridge layer* gathers *TaskGraph* outputs for concatenation in $split_dim$. By using the *bridge layer*, each *TaskGraph* can obtain a complete input tensor. If the gather dimension of the *bridge layer* is the same as the successor *TaskGraph* input partition dimension, Whale will optimize by fusing the aforementioned two operations to reduce the communication overhead. As an example, if the outputs of the *TaskGraph* are gathered in the first dimension, and the inputs of the successor *TaskGraph* are partitioned in the same dimension, then Whale will remove the above *gather* and *partition* operations.

3.3 Hardware-aware Load Balance

In this section, we describe how we utilize the hardware information to balance the workloads among *TaskGraphs*, which achieves high performance even in heterogeneous GPU clusters. The Whale parallel planner obtains the hardware information from the cluster scheduler when the training job is launched, and is responsible for both intra-*TaskGraph* and inter-*TaskGraph* load balancing.

3.3.1 Intra-TaskGraph Load Balance

When the allocated devices are homogeneous, by default Whale distributes the workloads within a *TaskGraph* to multiple devices evenly. However, when allocated with heterogeneous GPUs with different computing capacities (e.g., V100 and P100), the aforementioned identical distribution effectuates suboptimal performance. Such performance can be attributed to a synchronization barrier at the end of *TaskGraph* execution, which leads to long idle GPU time for the faster GPU, as shown in Figure 4(a). To improve the overall utilization of heterogeneous GPUs, we need to balance the computing according to the device’s computing capacity. The intra-*TaskGraph* load balance attempts to minimize the idle time within a *TaskGraph*, which is achieved by balancing the workloads proportional to device computing capacity while being subject to memory constraints. For a *TaskGraph* annotated with *replicate*, Whale balances the workload by adjusting the batch size for each *TaskGraph* replica. The local batch size on heterogeneous devices might differ due to the load balancing strategy (Whale keeps the global batch size

unchanged). If batch-sensitive operators such as *BatchNorm* exist, the local batch differences might have statistical effects. Yet, no users suffered convergence issues in our experiments or in our production deployment, which is probably due to the robustness of *DL*. Besides, techniques like SyncBatch-Normalization³ might help. For a *TaskGraph* annotated with *split*, Whale balances the FLOP of a partitioned operation through uneven sharding in splitting dimension among multiple devices.

We profile the *TaskGraph TG* on single-precision floating-point operations(FLOP) as TG_{flop} and peak memory consumption as TG_{mem} . Given N GPUs, we collect the information for device i including the single-precision FLOP per second as DF_i and memory capacity as DM_i . Assuming the partitioned load ratio on the device i is L_i , we need to find a solution that minimizes the overall GPU waste, which is formulated in Formula 1. We try to minimize the ratio of the computational load of the actual model for each device L_i and the ratio of the computing capacity of the device over the total cluster computing capacity $DF_i / \sum_{i=0}^N DF_i$, the maximum workload being bounded by the device memory capacity DM_i .

$$\min \sum_i^N \left\| L_i - \frac{DF_i}{\sum_{i=0}^N DF_i} \right\| \quad (1)$$

$$\text{s.t. } \sum_{i=0}^N L_i = 1; L_i * TG_{mem} \leq DM_i, (i = 1, 2, \dots, N)$$

The load ratio L_i in each device is initialized in proportional to the device’s computing capacity, which ideally results in a most balanced partition. However, when the memory constraint is not satisfied, we need to adjust the load allocation to avoid out-of-memory (OOM) errors, while still trying to achieve good performance. Whale proposes a memory-constraint balancing algorithm to balance the workloads among devices. The main idea of the algorithm is to shift the workload from the memory-overload device to a memory-free device with the lowest computation load. The details of the algorithm are illustrated in Algorithm 1. It takes a *TaskGraph TG* and *VirtualDevice* with N physical devices as inputs. The algorithm first initializes (line 3-10) the profiling results including 1) *load_ratios* as the workload ratios of devices; 2) *mem_utils* as the memory utilization of devices; 3) *flop_utils* as the FLOP utilization of devices; 4) *oom_devices* records out of memory devices whose value in *mem_utils* is greater than 1; and 5) *free_devices* records devices that have free memory space. The algorithm then iteratively shifts the load from a memory-overload device to a memory-available device (line 11-18). It first finds a *peak_device* with maximum memory utilization from *oom_devices*, then it finds a *valley_device* with available memory space and the lowest

Algorithm 1: Memory-Constraint Load Balancing

Input: $TaskGraph\ TG, VirtualDevice(N)$

```
1 load_ratios = 0; mem_utils = 0; flop_utils = 0
2 oom_devices = 0; free_devices = 0
3 foreach  $i \in 0..N$  do
4   load_ratios[i] =  $\frac{DF_i}{\sum_{i=0}^N DF_i}$ 
5   mem_utils[i] =  $\frac{load\_ratios[i]*TG_{mem}}{DM_i}$ 
6   flop_utils[i] =  $\frac{load\_ratios[i]*TG_{flop}}{DF_i}$ 
7   if mem_utils[i] > 1 then
8     oom_devices.append(i)
9   else
10    free_devices.append(i)
11 while oom_devices  $\neq$  0 & free_devices  $\neq$  0 do
12   peak_device = argmax(oom_devices, key = mem_utils)
13   valley_device = argmin(free_devices, key =
14     (flop_utils, mem_utils))
15   if shift_load(peak_device, valley_device) == success
16     then
17     update_profile(mem_utils, flop_utils)
18     oom_devices.pop(peak_device)
19   else
20     free_devices.pop(valley_device)
```

Figure 8: Pipeline *TaskGraphs* on heterogeneous GPUs

FLOP utilization. The *shift_load* function attempts to shift the workload from a *peak_device* to a *valley_device*. For data parallelism, the batch size in the *peak_device* is decreased by b , and the batch size in the *valley_device* is increased by b . b is the maximum number that the *valley_device* will not go OOM after getting the load from the *peak_device*. The profiling information for each device is updated after a successful workload shift is found. The aforementioned process iterates until the *oom_devices* are empty or the *free_devices* are empty.

3.3.2 Inter-TaskGraph Load Balance

When multiple *TaskGraphs* are executed in a pipeline, we need to balance the inter-*TaskGraph* workloads on heterogeneous GPUs. As we introduced in Section 2.1, pipeline parallelism achieves efficient execution by interleaving forward/backward execution among multiple micro-batches. For a model with N *TaskGraphs*, the i^{th} *TaskGraph* needs to cache $N - i$ forward activations [32]. Notably, i^{th} *TaskGraph* has to

cache one more micro-batch forward activation than the previous *TaskGraph*. Since activation memory is proportional to batch size and often takes a large proportion of the peak memory, e.g., the activation memory VGG16 model with batch size 256 takes up around 74% of the peak memory [18], resulting in uneven memory consumption among different *TaskGraphs*. The different memory requirements of *TaskGraphs* motivate us to place earlier *TaskGraphs* on devices with higher memory capacity. This can be achieved by sorting and reordering the devices in the corresponding *VirtualDevice* by memory capacity, from higher to lower. Figure 8 shows the memory breakdown of the pipeline example (Figure 1) with two *TaskGraphs* over heterogeneous GPUs V100 (32GB) and P100 (16GB), we prefer putting *TaskGraph0* to V100, which has a higher memory config. The *TaskGraph* placement heuristic is efficient for common Transformer-based models (i.e., BertLarge and T5 in Figure 18). There might be cases where later stages contain large layers (i.e., large sparse embedding), which can be addressed in Algorithm 1 on handling OOM errors. After reordering the virtual device according to memory requirement, we partition the model operations to *TaskGraphs* in a topological sort and apply Algorithm 1 to balance the computing FLOP among operations, subject to the memory bound of the memory capacity of each device.

4 Implementation

Whale is implemented as a standalone library without modification of the deep learning framework, which is compatible with TensorFlow 1.12 and TensorFlow 1.15 [7]. The source code of Whale includes 13179 lines of Python code and 1037 lines of C++ code. We have open-sourced⁴ the Whale framework to help giant model training accessible to more users.

Whale enriches the local model with augmented information such as phase information, parallelism annotation, etc., which is crucial to parallelism implementation. To assist the analysis of the user model without modifying the user code, Whale inspects and overwrites TensorFlow build-in functions to capture augmented information. For example, operations are marked as backward when *tf.gradients* or *compute_gradients* functions are called.

The parallel strategy is implemented by rewriting the computation graph. We implement a general graph editor module for ease of graph rewriting, which includes functions such as subgraph clone, node replacement, dependency control, and so on. To implement data parallelism, Whale first clones all operations and tensors defined in a local *TaskGraph* and replaces the device for model replicas. Then it inserts NCCL [6] AllReduce [40] operation to synchronize gradients for each *TaskGraph* replica. To implement tensor model parallelism, Whale shards the *TaskGraph* by matching a series of predefined patterns, replacing them with corresponding distributed

⁴<https://github.com/alibaba/EasyParallelLibrary>

Figure 9: Whale DP vs TF DP on ResNet.

implementation, and inserting communication operations as needed. To implement pipeline parallelism, Whale builds a pipeline strategy module that supports state-of-the-art strategies [16, 20, 32]. By default, Whale adopts a backward-first strategy which is similar to PipeDream [32]. The pipeline strategy is implemented by first partitioning the minibatch into micro-batches. The interleaving of forward-backward micro-batch execution is achieved by inserting control dependency operations among entrance and exit operations of different *TaskGraphs*.

To assist hardware-aware optimizations, Whale implements profiling tools that profile the model FLOPS and peak memory consumption. The parallel planner gets the hardware information from our internal GPU cluster, which is used to generate an efficient parallel plan by balancing the computing workloads over heterogeneous GPUs.

Besides, Whale is highly optimized in both computing efficiency and memory utilization by integrating with a series of optimization technologies such as ZERO [36], recomputation [10], CPU offload [39], automatic mixed precision [31], communication optimization [40], XLA [7], etc.

5 Experiment

In this section, we first demonstrate the efficiency of the parallelism strategy by evaluating micro-benchmarks. We then evaluate the training with heterogeneous GPUs to show the advantages of the hardware-aware load balance algorithm. We end by showing the effectiveness and efficiency of Whale by two industry-scale multimodal model training cases. All the experiments are conducted on a shared cloud GPU cluster. Every cluster node is equipped with a 96-core Intel Xeon Platinum 8163 (Skylake) @2.50GHz with 736GB RAM, running CentOS 7.7. Each node consists of 2/4/8 GPUs, with NVIDIA 32-GB V100 GPUs [3] or NVIDIA 16-GB P100 GPUs [2], powered by NVIDIA driver 418.87, CUDA 10.0, and cuDNN 7. Nodes are connected by 50Gb/s ethernet. All the models are implemented based on TensorFlow 1.12.

Figure 10: Whale DP vs TF DP on BertLarge.

Figure 11: Whale Pipeline vs GPipe.

Figure 12: Hybrid pipeline parallelism on BertLarge.

5.1 Micro-benchmark

In this section, we evaluate Whale with a series of micro-benchmarks. We first demonstrate that Whale is efficient in single parallel strategy by comparing with TensorFlow Estimator [14] DP and GPipe [20] pipeline. We then show the advantages of Whale hybrid strategies over single parallel strategy. Next, we measure the overhead of the bridge layer for hybrid strategies. Finally, we evaluate the effect of sharding patterns in automatic *TaskGraph* partitioning.

5.1.1 Performance of Single Parallel Strategy

We evaluate Whale DP by comparing it with TensorFlow Estimator DP, using the BertLarge [13] and ResNet50 [19] on different number of V100 GPUs. Figure 9 and Figure 10 show the training throughput speedup on ResNet50 and BertLarge respectively. The throughput speedup is calculated by dividing the training throughput on N devices by the throughput on one device. Whale DP consistently obtained better speedup and higher GPU utilization than TensorFlow Estimator DP. Such findings could be attributed to Whale's communication optimization technologies such as hierarchical and grouped AllReduce, which is similar to Horovod [40].

We then evaluate the efficiency of Whale pipeline parallelism by comparing with GPipe [20]. The pipeline scheduling strategy in Whale is similar to PipeDream [32]. The experiments are conducted using the BertLarge model with 4/8 pipeline stages on the different numbers of V100 GPUs. As shown in Figure 11, the training throughput speedup of Whale outperforms GPipe in both 4 stages and 8 stages by 1.45X and 1.14X respectively. We attribute the performance gain to the use of the alternating forward-backward scheduling policy [32], which improves GPU utilization. We also find that the pipeline performance is sensitive to the *num_task_graph*, thus exposing it as a configurable parameter can help achieve a better performance when models and computing resources change.

5.1.2 Performance of Hybrid Strategy

We evaluate hybrid strategies by comparing them with the single parallel strategy. We also compare the performances of

Figure 13: DP vs Hybrid on ResNet50 w/ 100K classes.

Figure 14: Hybrid strategy on ResNet50 w/ 1M classes.

Figure 15: Effect of Sharding Pattern.

Figure 16: Overhead of Bridge Layer.

hybrid strategies on different numbers of devices. We select two typical types of hybrid strategies: 1) Nested pipeline with DP; and 2) Combination of DP and tensor model parallelism.

We first apply a nested pipeline with DP to the BertLarge model on V100 GPUs. The model is partitioned into 2/4/8 number of *TaskGraphs*, and we measure the training performance of each model on 8/16/32 GPUs. Figure 12 shows that pipelines with 2 *TaskGraphs* and 4 *TaskGraphs* get similar training speedups and GPU utilization. However, we observe a performance drop on 8 *TaskGraphs* and lower GPU utilization compared to 2/4 *TaskGraphs*. This is because 8 *TaskGraphs* lead to relatively fewer model operations in each *TaskGraph*, and the GPU computation is not enough to overlap the inter-*TaskGraph* communication, resulting in poor performance.

Next, we evaluate the combination hybrid strategy on a large-scale image classification model, as we have discussed in Section 2.1 and illustrated in Figure 3. We perform experiments on classification numbers 100K and 1M on different numbers of V100 GPUs. To reduce the communication overhead of hybrid parallelism, we collocate the *ResNet50* replicas with *FC* partitions. We compare the hybrid results of 100K classes with DP, as shown in Figure 13, hybrid parallelism outperforms data parallelism by 1.13X, 1.66X, and 2.43X training throughput speedup with 8, 16, and 32 GPUs respectively, with the line plot corresponding to GPU utilization. When the number of workers increases, hybrid parallelism maintains a near-linear speedup, while the DP strategy fails drastically beyond 16 workers. This is because the heavy *FC* layer (the parameter size of ResNet50 backbone is 90 MB, while the parameter size of *FC* layer is 782MB) incurs a huge gradient synchronization overhead. For the task of 1M classes, DP fails due to OOM. With hybrid parallelism, Whale allows for the training of image classification task with one million classes. Figure 14 shows the performance of hybrid parallelism over 8/16/32 GPUs. The training throughputs from 8 GPUs to 32 GPUs achieve 95% scaling efficiency, which highlights the need for using a hybrid strategy.

5.1.3 Overhead of Bridge Layer

To demonstrate the efficiency of the hybrid strategy, We measure the overhead of the bridge layer by profiling the bridge layer time with 100K classes on 8/16/32 GPUs. We then compare the overhead of gradient AllReduce time in DP with the

Figure 17: Hardware-Aware Data Parallelism.

Figure 18: Hardware-Aware Pipeline Parallelism.

bridge overhead to understand the performance gain from hybrids. As shown in Figure 16, the overhead of the bridge layer takes around 6% in overall training time in 8 GPUs and 10% in 32 GPUs. The overhead of the hybrid is reduced by 6X on 32 GPUs compared to gradient synchronization overhead of pure DP.

5.1.4 Effect of Sharding Pattern

As Whale automatically chooses a sharding pattern with minimum communication cost (Section 3.2.2), to demonstrate the effect of exploring the sharding patterns, we force the framework to use a specific pattern in this experiment. We evaluate two types of sharding patterns as illustrated in Figure 6 on large scale image task with 100K classes. *SP1* shards the second input tensor in the second tensor dimension, and *SP2* shards the two input tensors and aggregates the results with *AllReduce*. The comparison results of the two sharding patterns are shown in Figure 15, where *SP1* outperforms *SP2* by 1.6X to 3.75X as the number of requested GPUs increases from 8 to 32, as *SP1* has a lower communication cost than *SP2*. The exploration of sharding patterns allows for the possibility of system optimization in distributed model implementation.

5.2 Performance of Load Balance

We show the benefits of the hardware-aware load balancing algorithm by evaluating data parallelism and pipeline parallelism.

For data parallelism, we evaluate three typical models, including ResNet50, BertLarge, and GNMT [48]. The experiments are conducted on heterogeneous GPUs that consist of 8 32GB V100 GPUs and 8 16GB P100 GPUs. We set the same batch size for all model replicas as the baseline. We

```

import whale as wh
wh.init(wh.Config({
    "num_micro_batch": 35,
    "num_task_graph": 8}))
# Define M6 model.
m6_model_def()

```

Example 4: M6-10B model with pipeline

Figure 19: M6-10B with Pipeline and DP.

then apply the hardware-aware algorithm to each model and get the speedup compared with the baseline performance, as shown in Figure 17. Whale outperforms the baseline in all three models by a factor from 1.3X to 1.4X. We also measure GPU utilization and report the average metric for each GPU type. The hardware-aware policy significantly improves the GPU utilization of V100 by 1.39X to 1.96X for the three models, which improves the overall training performance.

For pipeline parallelism, we evaluate two models, including BertLarge and T5-Large [52]. The training is performed on heterogeneous GPUs that consist of 4 32GB V100 GPUs and 4 16GB P100 GPUs. Both BertLarge and T5-Large are partitioned into 4 stages. We further apply a nested DP to *pipeline*. We set the evenly partitioned model as the baseline. We conducted training with the hardware-aware policy and got about 20% speedup on both models, as shown in Figure 18. The GPU utilization of hardware-aware load balancing strategy improved the GPU utilization of V100 by around 40%, which shows the efficiency of the hardware-aware load balancing algorithm.

5.3 Industry-Scale Giant Model Training

5.3.1 Training M6-10B Model

The M6-10B [28] model is a Chinese multimodal model with 10 billion parameters. The model consists of 24 encoder layers and 24 decoder layers. We use Adafactor [42] as the training optimizer. We parallelize the training of M6-10B model with a hybrid parallel strategy, by nesting pipeline parallelism and data parallelism. Whale can easily scale a local M6 model to a distributed one by only adding a few lines on top of the model definition as shown in Example 4. We set the number of pipeline stages to 8 and the number of micro-batches to 35. We enable recomputation [10] to save activation memory during training. The training performance is evaluated on 32-GB V100 GPUs. Each node contains 8 GPUs. When scaling the computing nodes from 8 to 32, Whale achieved 91% scalability, as shown in Figure 19.

5.3.2 Training M6-MoE Model to Trillions

We scale the model parameters to 10 trillion (10T) by switching to hybrids of *DP* and tensor model parallelism with only a small number of lines of code change. The computation cost of training dense models is proportional to the model parameters. If we scale the dense 10B model to the dense

10T model linearly without considering overhead, we need at least 256,000 NVIDIA V100 GPUs. Instead of scaling the M6 model with dense structure, we adopt M6-MoE [53] model with sparse expert solution [17, 26]. The sample code of the MoE structure is implemented with Whale by adding four lines, as shown in Example 5. Line 3 sets the default parallel primitive as *replicate*, i.e., data parallelism is applied for the operations if not explicitly annotated. Line 5 partitions the computation defined under *split* scope across devices.

```

1 import whale as wh
2 wh.init()
3 wh.set_default_strategy(wh.replicate(total_gpus))
4 combined_weights, dispatch_inputs=gating_dispatch()
5 with wh.split(total_gpus):
6     outputs = MoE(combined_weights, dispatch_inputs)

```

Example 5: Distributed MoE model

We evaluate M6-MoE model with 100 billion, 1 trillion and 10 trillion parameters respectively, the detailed configurations can be found in [29, 53]. We enable built-in technologies of Whale to optimize the training process, such as recomputation [10], AMP (auto mixed precision) [1], XLA [5], CPU offloading [39], etc. We can train the M6-MoE-100B model with 100 million samples on 128 V100 in 1.5 days. We advance the model scale to 1 trillion parameters on solely 480 NVIDIA V100 GPUs, in comparison with the recent SOTA on 2048 TPU cores [17]. We further scale the model to 10 trillion parameters by adopting optimized tensor offloading strategies [29] with 512 NVIDIA V100 GPUs. Whale can scale models from 100 billion to 10 trillion without code changes, which makes giant model training accessible to most users.

6 Related Work

Giant model training. TensorFlow [7] and PyTorch [34] provide well-supported data parallelism and vanilla model parallelism by explicitly assigning operations to specific devices. However, they are not efficient enough for giant model training. Megatron [43], GPipe [20], and Dapple [16] have proposed new parallel training strategies to scale the training of large-scale models. DeepSpeed [38] lacks general support for tensor model parallelism, besides, model layers are required to rewrite in sequential for pipeline parallelism. GShard [26] supports operator splitting by introducing model weight annotations and tensor dimension specifications. The high performance of those works is achieved by exposing low-level system abstractions to users (e.g., device placement, equivalent distributed implementation for operators), or enforcing model or tensor partition manually, which results in significant user efforts. As a parallel work to Whale, GSPMD [51] extends GShard by annotating tensor dimensions mapping for both automatic and manual operator partitioning. As a general giant model training framework, Whale adopts a unified abstraction to express different parallel strategies and their hy-

brid nests and combinations, utilizing high-level annotations and pattern matching for operator splitting. Whale further scales to M6-10T through automatically distributed graph optimizations with the awareness of heterogeneous resources.

Zero [36, 37, 39] optimizes memory usage by removing redundant GPU memory, offloading computation to the CPU host, and utilizing non-volatile memory respectively. Recomputation [10] trades computation for memory by recomputing tensors from checkpoints. Such memory optimization approaches are orthogonal to Whale, which can be further combined for giant model training efficiently.

Graph optimization. Deep learning is powered by dataflow graphs with optimizations to rewrite the graph for better performance, such as TensorFlow XLA [7], TVM [9], Ansor [55], AStitish [56], *etc.* TASO [22] and PET [45] adopt a graph substitution approach to optimize the computation graph automatically. Those works mainly focus on the performance of a single GPU, while Whale utilizes the graph optimization approach for achieving efficient performance in distributed training. Tofu [46] and SOAP [23] also use graph partition to produce distributed execution plans, but with a high search cost. Whale utilizes the introduced annotations to shrink the search space, thus making graph optimization practical for giant model training at a trillion scale. Besides, Whale extends the graph optimization approach to complicated parallel strategies in a unified abstraction, capable of pipeline parallelism, tensor model parallelism, and hybrid parallelism.

Resource heterogeneity. Philly [21] reports the trace study in multi-tenant GPU clusters of Microsoft and shows the effect of gang scheduling on job queuing. MLaaS [47] studies a two-month trace of a heterogeneous GPU cluster in Alibaba PAI. Gandiva [49] shows jobs are different in sensitivity to allocated resources. Whale is capable of adapting to resource heterogeneity, which can reduce the queuing delay of giant model training with hundreds of GPUs. The design of Whale advocates the approach of decoupling model programming and distributed execution. It dynamically generates an efficient execution plan by considering the properties of both model and heterogeneous resources.

7 Conclusion

Whale demonstrates the possibility of achieving efficiency, programmability, and adaptability in a scalable deep learning framework for training trillion-parameter models. Whale supports various parallel strategies using a unified abstraction, hides distributed execution details through new primitive annotations, and adapts to heterogeneous GPUs with automatic graph optimizations. Going forward, we hope that Whale can become a large-scale deep learning training foundation to further engage model algorithm innovations and system optimizations in parallel, making giant model training technology to be adopted easily and efficiently at scale.

Abstract

Processing input data plays a vital role in ML training, impacting accuracy, throughput, and cost. The input pipeline, which is responsible for feeding data-hungry GPUs/TPUs with training examples, is a common bottleneck. Alleviating data stalls is critical yet challenging for users. While today’s frameworks provide mechanisms to maximize input pipeline throughput (e.g., distributing data processing on remote CPU workers and/or reusing cached data transformations), leveraging these mechanisms to jointly optimize training time and cost is non-trivial. Users face two key challenges. First, ML schedulers focus on GPU/TPU resources, leaving users on their own to optimize multi-dimensional resource allocations for data processing. Second, input pipelines often consume excessive compute power to repeatedly transform the same data. Deciding which source or transformed data to cache is non-trivial: large datasets are expensive to store, the compute time saved by caching is not always the bottleneck for end-to-end training, and transformations may not be deterministic, hence reusing transformed data can impact accuracy.

We propose Cachew, a fully-managed service for ML data processing. Cachew dynamically scales distributed resources for data processing to avoid stalls in training jobs. The service also automatically applies caching when and where it is performance/cost-effective to reuse preprocessed data within and across jobs. Our key contributions are autoscaling and autocaching policies, which leverage domain-specific metrics collected at data workers and training clients (rather than generic resource utilization metrics) to minimize training time and cost. Compared to scaling workers with Kubernetes, Cachew’s policies reduce training time by up to $4.1\times$ and training cost by $1.1\times$ to $3.8\times$.

1 Introduction

Input data processing is an essential part of machine learning (ML) training. Transformations applied to input data before it is fed to a model for training – such as extracting features, sampling data from imbalanced classes, and randomly augmenting data – are key to achieving high accuracy [19,57,63]. Furthermore, the speed at which the input pipeline can ingest data from storage, apply transformations on-the-fly, and load

Figure 1: Training jobs benefit differently when given more CPU resources for input data processing per accelerator core.

transformed data to training nodes greatly impacts the time to accuracy and the overall cost of model training.

While GPUs and TPUs used for training computations continue to provide more FLOPS, CPUs – which are responsible for input data processing – are not keeping up. Hence, the input pipeline is a common bottleneck in ML training [38].

Removing bottlenecks in the input pipeline can improve end-to-end training time by over an order of magnitude and greatly reduce costs [47,48]. However, optimizing ML data processing is non-trivial. Users face several key challenges.

First, allocating the right amount of CPU, memory, and storage for input data processing, to optimize training time and cost, is difficult. Users should allocate *just enough* resources for the input pipeline to produce batches of data at the throughput that the model can ingest data, which depends on the model’s computational intensity and the hardware (# of GPUs) allocated for training. As shown in Figure 1, each model requires a different ratio of CPUs for data processing and GPUs or TPUs for training. Hence, although ML frameworks traditionally couple input data processing and training such that the two stages execute on the same node, it is becoming increasingly common to disaggregate data processing, with systems like `tf.data` service [25] and Meta’s Data PrePreprocessing (DPP) Service [69]. Disaggregation enables customizing resource allocations per job. However, today’s ML resource management systems focus on GPU allocations [28,44,65], leaving users on their own to decide input

pipeline resource allocations that maximize performance and minimize cost of training jobs. This is notoriously challenging in the multi-dimensional resource setting of ML training [64].

Another major challenge is the significant amount of compute and memory resources required for input data processing. For example, when training deep recommender models with petabytes of data, data ingestion can consume more power than model training itself [69]. A promising approach to reduce data processing compute requirements is to memoize the outputs of commonly executed data pipelines, since ML training often involves redundant data accesses and transformations, both within and across jobs [34, 47, 48, 66]. Within a job, it is common to iterate multiple times (i.e., epochs) over a dataset. Across jobs, ML engineers typically experiment with variations of models (e.g., hyperparameter tuning and model search) while re-executing the same data pipeline.

ML data processing frameworks provide mechanisms for reusing memoized data transformations, such as `tf.data`'s `cache` and `snapshot` operators [22, 61, 62]. However, determining which (transformed) datasets are optimal to cache in fast storage is non-trivial. Transformed datasets are costly to store and slow to read if they are significantly larger in volume than source data, which can occur after decompression and data augmentations. Figure 2 shows that reusing memoized results stored on local SSDs of a training node does not always improve epoch time, since local SSD bandwidth may saturate when reading the larger transformed dataset. Even caching source data on local SSDs does not always improve epoch time compared to reading from cloud data lakes (e.g., we use GCS [27]) since model training may be the bottleneck. If an input pipeline applies random transformations to data each epoch, the caching decision is further complicated as reusing the transformed dataset from a single epoch can negatively impact model training dynamics [16, 40].

In summary, ML data processing frameworks provide useful *mechanisms* to alleviate data bottlenecks, such as distributing data processing on remote CPU workers and reusing cached data transformations. However, today's systems lack *policies* that efficiently leverage these mechanisms to optimize the overall performance and cost of ML training.

We propose Cachew, a fully-managed service for ML input data processing. Inspired by the serverless computing paradigm, which relieves developers from the burden of managing virtual machines in the cloud [13, 55], Cachew relieves ML users from the burden of managing compute, memory, and storage infrastructure for ML input data processing. Cachew consists of a centralized dispatcher, distributed input data workers, and a disaggregated storage cluster that stores cached datasets. We build Cachew on top of the `tf.data` framework [48], extending its distributed service [25] to support multi-tenancy, autoscaling, and autocaching. Cachew is open source¹ and compatible with the existing `tf.data` API.

¹Cachew is available at: <https://github.com/eth-eas/cachew>

Figure 2: Caching source data or materializing data in local storage does not always improve training throughput.

Our key contributions are the design and implementation of autoscaling and autocaching policies for ML input data processing. We show that traditional resource autoscaling approaches (e.g., in Kubernetes [1]), which are based on CPU and memory utilization, are not sufficient to optimize training time and cost. Instead, we base our policies on application-specific metrics collected at input data workers and clients while a job is running. The Cachew dispatcher leverages the stateless nature of ML input data processing to adjust the number of workers per job during runtime. By monitoring batch time reported by clients, the dispatcher dynamically finds the minimum number of workers (i.e., minimum cost) that minimizes batch time (i.e., maximizes performance). By monitoring per-worker throughput and the volume of data produced by the input pipeline, the dispatcher also decides on whether reading data from Cachew's cluster cache is likely to improve performance compared to reading and transforming data from cloud data lakes on-the-fly. Cachew extends the `tf.data` API with an `autocache` operator, which allows users to specify up to which point in their input pipeline it is acceptable to cache and reuse data from a training dynamics perspective (e.g., before any random transformations).

We evaluate Cachew with microbenchmarks and three popular ML models and data pipelines from the TensorFlow Model Garden. We show that while the Kubernetes autoscaler under-provisions or over-provisions input data workers, Cachew is able to identify the optimal number of data workers to allocate for each job as well as the optimal caching strategy at each `autocache` operator location in the input pipeline to minimize training time and cost. We show that compared to scaling workers with Kubernetes, Cachew's policies reduce training cost by $1.1\times$ to $3.8\times$.

2 ML Input Data Processing

We summarize the key characteristics of ML input data pipelines (§ 2.1) and discuss why it is increasingly common to disaggregate data processing from model training (§ 2.2). § 2.3 provides an overview of existing mechanisms for fast, efficient input data pipeline execution.

2.1 ML Input Data Pipeline Characteristics

Reading input data from storage: The first step in ML input data processing is reading source data. Deep learning input pipelines typically read datasets that range from gigabytes to petabytes in size, stored in low-cost distributed storage systems, such as cloud data lakes [48, 68, 69]. To avoid I/O bottlenecks during training, it is common to cache input datasets in more expensive, higher bandwidth storage systems [39, 47].

Transforming data: Before raw input data can be consumed by a model, it must be preprocessed into elements that the model can learn from. Common transformations include decompressing data, parsing file formats, extracting features, and batching elements. It is also common to add randomness to input data (e.g., randomly sampling, augmenting, and shuffling elements) to improve model generalization [12]. Random data augmentations are critical for achieving state-of-the-art accuracy in image classification [14, 15, 18, 21, 58], object detection [19, 67], and speech recognition [49, 50].

Data transformations are generally executed on CPUs rather than specialized hardware to better support user-defined functions [48]. While some transformations can be applied in offline batch processing jobs [6], many transformations are applied *on-the-fly* during training for greater flexibility. For instance, it is common to experiment with feature extraction, tune the batch size for a given GPU configuration, or randomly augment data using different seeds across epochs.

While some transformations (e.g., decompression and augmentation) expand the volume of data read from storage, other transformations (e.g., filtering and sampling) decrease the volume of data fed to a model. A study of ML input pipelines at Google found that the ratio of data fed to a model versus the data read from storage varies widely across jobs. For 75% of jobs, data transformations reduced data volume [48].

Loading data to training nodes: The final step is to load data to GPUs/TPUs for model training. To avoid data stalls, the input pipeline must produce data at a throughput greater than or equal to the rate at which the model can consume data. The model's data ingestion rate depends on the algorithmic intensity of the training computations and the hardware FLOPS. Feeding data-hungry accelerators requires high software parallelism and pipelining for data processing [38, 48].

Re-executing input pipelines: In large-scale production and research deployments, ML input data pipelines are commonly re-executed. Within a job, each training epoch reads and transforms the same input dataset. Across jobs, common ML training workflows, such as neural architecture search and hyperparameter tuning, involve feeding the same pre-processed data to different variations of a model [34, 70]. At Google, the top 10% most commonly executed input pipelines accounted for 77% of all input pipeline executions and 72% of CPU cycles used for ML input data processing [48]. Others have also observed a sizeable opportunity to reuse data processing within and across ML jobs [47, 66].

2.2 Why disaggregate input data processing?

ML input data processing and training consist of fundamentally different types of computation (user-defined data transformations vs. gradient updates) that primarily use different resources (CPUs vs. GPUs/TPUs). Yet ML frameworks have typically coupled these two stages, such that they run on the same nodes. Tight coupling has two major drawbacks. First, CPU/memory-intensive input pipelines can easily saturate host resources and limit training throughput. Zhao et al. [69] showed that loading data over the network from distributed storage – even without performing data transformations on the CPU – consumes significant CPU cycles and memory bandwidth in production deployments, leaving scarce resources available for transforming data on training nodes. Second, the ratio of resources required for input data processing vs. model training varies across jobs (as seen in Figure 1, where we varied the CPU cores available using the Linux `taskset` command). However, cloud providers typically limit the CPU cores and memory capacity that can be provisioned per accelerator on a virtual machine [9, 26]. The fixed ratio of CPU cores and memory attached to accelerators often leads to imbalanced usage (i.e., either idle accelerators or idle CPUs).

To improve resource utilization and avoid input data stalls, it is increasingly common to disaggregate data processing from model training [25, 69]. Disaggregation is a well-known approach for improving resource allocation flexibility [23, 36]. This flexibility can save cost, since users can distribute input data processing across as many or as few CPU worker nodes as needed to avoid data stalls, without provisioning additional expensive GPUs/TPUs.

2.3 Existing Mechanisms

We describe key mechanisms in existing frameworks for efficient input data processing. Users can define and execute ML input data pipelines with a variety of data loading frameworks, such as `tf.data` [48], PyTorch DataLoader [17], NVIDIA DALI [29], and CoordDL [47]. We highlight the `tf.data` framework, as its combination of state-of-the-art mechanisms serve as a foundation for our work. `tf.data`'s programming model allows users to build input pipelines by composing and customizing operators. The framework runtime executes input pipelines as dataflow graphs, applying static and dynamic optimizations to improve performance.

Disaggregation: `tf.data` service supports executing input pipelines in a distributed manner [11]. The service consists of a centralized dispatcher and a number of remote input data workers. Clients (i.e., training nodes) register input pipelines defined in the `tf.data` API with the dispatcher, which shards data processing across all workers in the service. Clients fetch data directly from workers. The Data PreProcessing Service at Meta is another example of a framework that disaggregates input data processing [69]. In both frameworks, users are

responsible for managing the number of input data workers and deciding per-job resource allocations.

Dataset Caching: The `tf.data.snapshot` operator allows users to cache the output of their input pipeline to disk, and materialize the transformed data on a subsequent training run [22]. This trades off I/O capacity and bandwidth to free up CPU resources. Inserting the `snapshot` operator at the appropriate point in an input pipeline to optimize overall training time and cost remains the user’s responsibility. The current `snapshot` implementation does not coordinate between asynchronous reads and writes from multiple nodes, making it incompatible with `tf.data` service (hence, we implement our own `put` and `get` operators, described in §5.1).

CoorDL [47] and OneAccess [34] reuse input pipeline outputs when jobs are scheduled in a coordinated manner (e.g., hyperparameter tuning). However, these frameworks do not reuse data transformations across arbitrary ML jobs that can be submitted asynchronously to a service over time. Revamper [40] allows users to partially reuse the outputs of random transformations in input pipelines while minimizing the impact on training dynamics. Quiver [39] implements distributed caching for DNN training, but it is designed exclusively for managing source data rather than transformed datasets.

Autotuning: `tf.data`’s runtime and Plumber [38], a tool for diagnosing input data bottlenecks, can dynamically tune software parallelism and memory buffer sizes to maximize performance on a given training node [48]. However, this tuning does not scale resources beyond a single node.

GPU Offloading: NVIDIA DALI supports offloading certain input data processing, such as image data augmentations, to GPUs [29]. This is a viable option to alleviate CPU bottlenecks but may lead to GPU resource contention among input data transformation tasks and model training tasks. Users therefore need to decide which input data transformations should run on CPUs vs. GPUs.

3 ML Input Data Service Challenges

While many useful mechanisms for ML input data processing exist, it remains challenging for users to leverage these mechanisms to minimize end-to-end ML training time and cost. We focus on two key challenges: scaling resources for data processing (§ 3.1) and saving compute resources by selectively caching (transformed) datasets (§ 3.2).

3.1 Autoscaling Challenges

Selecting the right amount of compute, memory, and storage resources to provision for ML input data processing is critical yet challenging for ML users. Under-provisioning resources for data processing leads to data stalls, which leave expensive hardware accelerators idle, increasing end-to-end training time and cost. Over-provisioning resources for data

processing leads to extra costs without improving end-to-end performance. The optimal resource allocation for data processing depends on the compute intensity of data transformations in the input pipeline, the volume of data that must be read for each training batch, and the rate at which the pipeline must produce data to match model ingestion throughput.

Determining the right resource allocation for ML input data processing is non-trivial as each model and input data pipeline combination have unique requirements [69]. For example, in Figure 1, we vary the amount of CPU cores allocated for input data processing to show how many cores are needed to meet model training throughput requirements in various jobs. To process the COCO dataset [43] and train the RetinaNet [42] model, 4 CPU cores per TPU accelerator core are sufficient, whereas to process the ImageNet [21] dataset and train the EfficientNetv2 [59] model, the user should provision 12 CPU cores per TPU accelerator core to avoid input data stalls during training. We also observe that scaling memory capacity and bandwidth greatly impacts performance. Furthermore, we find that training throughput does not scale linearly with CPU and memory resources, making it difficult to model how resource allocation affects performance.

3.2 Autocaching Challenges

Deciding which input data transformations to materialize and reuse versus which transformations to execute online during training is complex. At Google, where `tf.data` is heavily used in research and production ML training jobs, only 19% of jobs use any kind of caching operator [48]. Meanwhile, the same study found that many jobs would benefit from caching.

Making caching decisions requires users to reason about the cost of storing preprocessed data to save CPU cycles. This trade-off depends on the compute intensity of the input pipeline, the size of the materialized dataset, and the relative cost of CPU and storage resources. Transformed datasets may be slow to read and costly to store if they are significantly larger in volume than source data, which can occur with decompression and data augmentations. Caching does not always improve epoch time, in particular if reading source data from cloud storage and transforming it on-the-fly is sufficiently fast to saturate model ingestion throughput. Another challenge is that caching and reusing the results of transformations which randomly permute data from one epoch will remove this randomness across epochs. Reusing this transformed data within a job can significantly impact training dynamics. Prior work has shown that reusing random augmentations across epochs in a job is plausible, but must be done sparingly to avoid degrading model accuracy [16, 40]. For example, Revamper proposes caching partially augmented data elements and mixing them with freshly-computed, fully-augmented elements [40].

An over-arching challenge is to jointly optimize autocaching and autoscaling. Regardless of whether input data

workers are reading and transforming source data on-the-fly from data lakes or reading transformed data from a cache, we need to determine the right number of input data workers and storage bandwidth to provision to maximize training throughput while keeping costs low.

4 Cachew Design

We introduce Cachew, a multi-tenant service for ML input data processing. To minimize end-to-end training time and cost, Cachew jointly optimizes: 1) elastic, distributed resource allocation for input data processing and 2) materialization of data processing computations within and across jobs. Cachew can be operated by an organization with multiple users that asynchronously submit ML training jobs or by a public cloud provider. With minimal extensions to the `tf.data` user API, Cachew transparently manages resource allocation for data processing, data caching, and network communication between Cachew clients and workers.

4.1 Service Architecture

Cachew consists of a centralized dispatcher, a dynamic number of input data workers, and a disaggregated storage cluster for data caching, as shown in Figure 3.

Users register training nodes (i.e., clients) of ML training jobs with the Cachew dispatcher. Clients provide a dataflow graph representation of their input pipeline and a path to the input data (§ 4.2). We assume input data resides in durable, low-cost cloud storage, i.e., data lakes [68] such as S3 [56].

Input data workers are stateless components responsible for producing batches of preprocessed data for clients. The dispatcher dynamically adjusts the number of input data workers for each job and divides each job’s input dataset (e.g., a list of filenames) into independent partitions, called *splits*. Workers pull new splits (e.g., indexes of the file list) from the dispatcher when they are done processing previous splits. Workers may read splits that correspond to source data which they must transform on-the-fly by executing the job’s input pipeline dataflow graph. Alternatively, splits may correspond to files that contain already transformed (or partially transformed) data in Cachew’s cache from previous executions of the input pipeline.

The dispatcher maintains metadata about input pipeline executions across jobs to make worker allocation and data caching decisions. The scaling and caching policies (described in § 4.3) and § 4.4) rely on the metrics listed in Table 1, which the dispatcher aggregates in its *metrics metadata store*, indexed by job ids, input pipeline hashes and job names. Since there may be multiple workers and clients per job, metrics are averaged across clients and workers of the same job. The dispatcher also tracks which source and transformed datasets are cached. The *cache metadata store* maintains the location of cached datasets in Cachew’s cluster cache and is indexed

Figure 3: Cachew system architecture. Solid lines depict control logic and metadata communication. Dotted lines show the flow of training data. Communication occurs via RPCs.

```

1 dataset = tf.data.TFRecordDataset(["file1", ...])
2 dataset = dataset.map(parse).filter(filter_func)
3                 .autocache()
4                 .map(rand_augment)
5                 .shuffle().batch()
6 dataset = dataset.apply(distribute(dispatcherIP))
7 for element in dataset:
8     train_step(element)

```

Figure 4: User API to distribute `tf.data` input pipeline execution with Cachew. Users insert `autocache` to hint which data is acceptable to cache/memoize and reuse within a job.

by various hashes of the input pipeline dataflow graph, which we call fingerprints.

Clients fetch data from the workers that are assigned to them by the dispatcher. Clients and workers periodically send heartbeats to the dispatcher (by default every five seconds) to maintain membership in the service and provide metrics.

Cachew’s cache cluster consists of high-bandwidth NVMe SSD storage nodes, which are disaggregated from input data workers. Hence, Cachew can scale storage independently, based on data caching capacity and bandwidth requirements. In addition to caching transformed datasets of frequently executed input pipelines, Cachew can also cache source datasets, to avoid I/O bottlenecks from cloud data lakes during training.

4.2 Cachew API

Cachew leverages the existing `tf.data` API for defining ML input data pipelines [48]. Users define a pipeline by chaining dataflow operators that can be parameterized with user-defined functions (UDFs). Figure 4 shows an example `tf.data` pipeline that reads input data from files, applies `map` and `filter` operators with UDFs for parsing, filtering, and randomly augmenting data, then shuffles and batches data.

Applying `distribute` in line 6 serializes the dataflow graph and sends it to the service dispatcher to register the job. If there are multiple training nodes in a job (i.e., for dis-

Source	Name	Description
Client	batch_time	Time taken to get and process the last 100 batches
	result_queue_size	Avg. number of batches located in the prefetch buffer over the last 100 batches
Worker	active_time	Avg. time per element spent in computation in the subtree rooted in the node
	bytes_produced	Total number of bytes produced by the node so far
	num_elements	Total number of elements produced by the node so far

Table 1: The set of metrics that are submitted by the workers and clients to the dispatcher via heartbeats.

tributed ML training), each node registers as a separate client with the dispatcher and specifies an additional `job_name` parameter that is common across all clients of the same job. The communication between clients and workers is abstracted away from the python API. As shown in line 7, clients simply iterate over the `dataset` to access a sequence of elements, as if executing the input pipeline locally on the client.

Cachew introduces a new operator, `autocache`, which allows users to specify point(s) in an input pipeline where model training dynamics safely permit memoizing and reusing data within a job. To avoid any impact on training accuracy, users should apply `autocache` before any random data transformations in their pipeline (e.g., see line 3 of Figure 4). Users may apply `autocache` in multiple locations in a pipeline. Cachew will not always apply caching at an `autocache` operator; § 4.4 describes Cachew’s decision strategy. When `autocache` is placed after a read operator (e.g., line 1), Cachew decides whether caching source data in fast cluster storage improves performance compared to reading source data from a low-cost data lake. In §6, we evaluate Cachew with up to two `autocache` operators per pipeline.

4.3 Autoscaling Policy

We describe how Cachew leverages the per-job client metrics described in Table 1 to make worker scaling decisions.

Allocating workers for new jobs: The dispatcher starts by executing each new job with a single worker. After the client reports metrics from a configurable number of training batches, the dispatcher allocates a second worker for the job and monitors the change in `batch_time`. We observe that averaging metrics over 100 batches generally provides a satisfactory level of noise smoothing. If `batch_time` decreases by more than a threshold (which we empirically set to 3%) with the second worker, the dispatcher adds an additional worker. The dispatcher continues adding workers until a new worker improves `batch_time` by less than 3%, in which case the scaling decision converges. The epoch time (and hence batch time) plateaus when the workers can provide data at sufficient throughput to saturate the model ingestion rate (e.g., the red dotted line in Figure 6). The true plateau occurs when the addition of a new worker leads to 0% change in `batch_time`. However, we choose a slightly higher threshold due to the noisy nature of metrics gathered at runtime.

This makes Cachew’s autoscaling policy more stable. We observed that a 0% threshold would lead to unstable scaling decisions, as the slightest noise could trigger the addition of superfluous workers or the removal of essential workers from the cluster. In order to reduce noise, it is possible to gather the metrics over more batches, however this slows down the scaling process. §6.2 shows a sensitivity study.

Re-scaling over time: Since metrics can be noisy, Cachew periodically revisits the scaling decision each 10 new metrics received from the client (i.e., every 1000 batches). Cachew adds a worker if the current `batch_time` is significantly higher than the value recorded at scaling convergence. To detect if we are on the batch time plateau and can afford to scale down, our intuition is that although batch time will be the same, the result queue will build up if workers are able to provide data faster than the model can ingest it. Hence, Cachew removes a worker if the current `result_queue_size` is significantly (e.g., > 40%) higher than the size recorded at convergence. Cachew continues removing workers as long as the increase in `batch_time` is below the threshold. Clients temporarily pause metric collection (e.g. 150 batches) when they are notified that a worker has been added or removed for their job. When the dispatcher de-allocates a worker from a job, the worker processes any remaining splits, which clients consume before the worker is removed. Hence, the model sees all data in an epoch, regardless of scaling events.

We observed that in some cases, when the input dataset consists of few files (e.g., the COCO dataset), the scaling policy may not converge within an epoch because workers may prefetch all dataset splits, leaving no splits for newly added workers to process until the next epoch. Cachew detects these scenarios and inserts an artificial epoch, which allows workers to fetch data from the next epoch while other workers process data from the current epoch. We do not introduce artificial epochs if workers are writing to cache.

4.4 Autocaching Policy

When a new job is sent to Cachew, a hash of the entire input pipeline is generated, which is then used to check if the given pipeline has ever had some of its data cached. If yes, the dispatcher extracts a hash for each `autocache` op. This is done by traversing and hashing the input pipeline from its source nodes up until the `autocache` node. Cachew checks its

Figure 5: Cachew autocaching policy calculation.

cache store against these hashes to find potential hits. Cachew will choose to introduce caching at the `autocache` location with the highest throughput. It should be noted that in such cases, compute is not considered, as caching only occurs if it was deemed better in terms of throughput than compute. If the given pipeline has not got any of its data in cache, the job enters profiling mode. This stage is equivalent to full input pipeline computation, with the exception that scaling is blocked to not skew any metrics relevant to the autocaching decision. The relevant metrics are presented in the Worker section of Table 1. Once the input pipeline has produced a sufficient amount of batches (we observe 300 batches to be enough) Cachew’s dispatcher produces the autocaching decision.

To carry out the autocaching decision, for each `autocache` operator, the dispatcher estimates the time it takes the pipeline to produce N elements if caching were to be introduced at the `autocache` location. The dispatcher compares these N -element-times with the compute mode N -element-time (i.e., how long it takes to produce N elements if no caching is applied to the pipeline) and selects the option with the minimum time. If caching is chosen, Cachew introduces caching at the relevant `autocache op` location. Figure 5 shows the main values inferred by the dispatcher for the autocaching decision. It should be noted that due to operations such as `batch`, `filter`, or `repeat`, an `autocache op` sees M elements being produced, where $M \neq N$ can be true.

Let the `LastOp`’s `active_time` be `active_timeL`, an `autocache`’s `active_time` be `active_timeA` and the bytes per element at an `autocache op` be b_A . Cachew employs a throughput model of GlusterFS, formally defined as $g_{GFS} : \mathbb{R}_{>0} \rightarrow \mathbb{R}_{>0}$, which can infer the read time of b bytes from cache. Cachew initially computes the `TotalComputeTime` = $N \times \text{active_time}_L$. For each `autocache op`, Cachew computes the `PreAutocacheTime` = $M \times \text{active_time}_A$, and then obtains the `PostAutocacheTime` = `TotalComputeTime` - `PreAutocacheTime`. Next, Cachew computes `ProjectedCacheReadTime` = $M \times g_{GFS}(b_A)$. Finally, the `ProjectedTotalCacheTime` = `ProjectedCacheReadTime` + `PostAutocacheTime` is computed. The `ProjectedTotalCacheTime` of each `autocache op` and the initial `TotalComputeTime` are compared, and the

option with the lowest value is selected.

Once the decision is made, scaling is re-enabled. Scaling is triggered when the execution policy of the input pipeline changes (e.g. from putting to getting data from cache). When this happens, the worker count of a job is set to 1, and the autoscaling policy is applied by initially scaling up.

4.5 Multi-tenancy

Cachew supports multi-tenancy. Jobs submitted by different clients are accepted by Cachew, whose dispatcher applies the autoscale and autocache policies on each job. The jobs are self contained, and the autoscale and autocache decisions are independent of other jobs running in Cachew. To ensure such decisions are correct, metrics from different jobs with identical input pipelines are stored in the metadata store separately from one another using the job names. Moreover, to avoid performance interference, Cachew assigns each workers to at most one job at a time.

Our current prototype of Cachew assumes that tenants are mutually trusted and have permission to access each other’s data. Hence, Cachew shares cached datasets across jobs from different tenants. In §7, we discuss how the implementation can be extended to implement data access control.

4.6 Fault tolerance

Dispatcher: The dispatcher stores metadata in memory for fast look-ups. To avoid being a single point of failure, the dispatcher can journal its state to a durable directory, such that no state is lost when the dispatcher is restarted. Journaling is also supported in the vanilla `tf.data` service [25].

Workers: Our implementation builds on top of existing single-node `tf.data` checkpointing mechanisms, extending them to work in the distributed setting. Workers communicate with the dispatcher via heartbeats. If a parametrizable number of heartbeats are missed (we set this parameter to 2), the dispatcher considers the worker failed and initiates a failover. The dispatcher reassigns pending tasks to a free worker in the pool. The new worker recovers any progress the failed worker had made on the pending tasks by reading the latest checkpoint committed in remote storage. The new worker recomputes batches between the latest checkpoint and the time of failure, to make the new worker’s iterator state match the old worker’s iterator state at the time of failure. The client includes an incrementing index in its request which the new worker uses as time of failure to fast forward to. However, the new worker does not transmit the recomputed batches to the client since repeating data elements in training epochs can harm model accuracy. For instance, Mohan et al. observed a double-digit drop in Top-1 accuracy when training a ResNet18 for 70 epochs on ImageNet-1k without exactly-once semantics [46]. In contrast, Cachew guarantees that clients see each batch of input data exactly once during

training, even in the face of failures. Furthermore, our fault-tolerance mechanisms make it viable to run Cachew workers on transient cloud resources (i.e., spot VMs) to reduce the cost of using remote workers for data processing.

Storage nodes: Cachew’s distributed cache applies erasure coding with configurable redundancy. By default, we configure the storage layer to store data with sufficient redundancy to handle up to 25% of nodes in the storage cluster failing at a given time. If a storage node fails, the distributed file system uses parity blocks to recover data.

5 Implementation

We implement Cachew on top of the `tf.data` ML data processing framework [48], leveraging its familiar API and mechanisms for distributed data processing and dataflow graph rewriting. We also add a scalable cluster cache to the vanilla `tf.data` service and expose the `autocache` operator to users in the API. We extend the `tf.data` service dispatcher with metadata stores that manage client/worker metrics and locations of cached datasets to implement our scaling and caching policies. Our implementation consists of approximately 9000 lines of C++ code and 500 lines of Python on top of the open-source `tf.data` code base. Cachew is open-source.

We run the Cachew dispatcher and workers inside Docker containers and use Kubernetes to elastically scale the deployment. All communication between clients, workers, and the dispatcher is done over gRPC [24]. We use GlusterFS [53], deployed on high-bandwidth NVMe SSD storage nodes, as our distributed caching storage system. GlusterFS is highly scalable, offers sufficient throughput to saturate NVMe SSD bandwidth, and its consistent hashing data distribution policy supports dynamically adding and removing storage nodes. We configure GlusterFS with distributed dispersed volumes, which use erasure coding for fault-tolerance [54].

5.1 Autocache Mechanisms

Graph rewrites: When a user registers a new job, Cachew’s dispatcher inspects the input pipeline’s dataflow graph. Whenever the pipeline contains an `autocache` op, Cachew generates two versions of the pipeline, in which the `autocache` is replaced by a `put` op and a `get` op, respectively. The dispatcher transparently replaces `autocache` with graph rewrites using the TensorFlow Grappler [60] optimization framework. The dispatcher sends workers the correct version of the input pipeline graph, which depends on the execution mode selected by Cachew’s autocaching policy for the job.

The put and get ops: Cachew introduces `put` and `get` ops which store and retrieve data to and from the cache. These ops build on underlying mechanisms in the `tf.data` `snapshot` op implementation, but are designed for multi-worker scenarios, where several different worker nodes can concurrently write and/or read to the same cache location

without conflicts. To support asynchronous behaviour, the `put` and `get` op implementations both leverage queues and multi-threading. For the `put` op, data to be written to cache is placed in a queue. Multiple threads greedily dequeue elements and write them to cache. Each thread writes in its own file, which is closed when the size exceeds 250MiB and a new file is opened. The `get` op functions in the opposite manner, where threads read from cache and place elements in the queue. When downstream operations require data from the `get` op, they dequeue elements. Each thread requests the file paths to read from the dispatcher. Operations before the `get` op are not executed since the output is read from cache.

Since the ops are asynchronous, reads and writes will be performed out of order. Hence, cache reads and writes behave as a sliding-window shuffle of size $w_s = s \times n$, where w_s is the window size, s is the number of elements per cache file and n is the number of readers or writers.

Dealing with limited cache capacity: Our current prototype assumes that Cachew’s cache capacity is unbounded (i.e., there is always space in the cache for a `put` op to succeed). To operate Cachew with a limited cache size, we plan to extend the dispatcher implementation to periodically evict cached datasets that provide the least performance improvement across jobs, as in prior caching systems like Nectar [30].

6 Evaluation

6.1 Methodology

Workloads: We evaluate Cachew with three popular ML models and their corresponding input data pipelines in TensorFlow Model Garden [3]. ResNet-50 [31] is an image classification model whose input pipeline consists of parsing raw TFRecord files, converting images to float16 format, and applying a random crop and horizontal flip [4]. We use ImageNet [21] and observe that the data transformations increase the source dataset by 2.6×. RetinaNet [42] is an object detection model whose input pipeline consists of parsing TFRecords, converting images to float16, applying a random horizontal flip, and a series of computationally-intensive operations that create candidate anchors at five different scale levels [5]. We train RetinaNet on the COCO [43] dataset and the data transformations increase the data volume by 32.6×. Finally, SimCLRv2 [15] is a semi-supervised learning framework used for visual representation learning model. Given a randomly sampled mini-batch of images, each image is augmented twice with a random crop, color distortion, and Gaussian blur, creating two views of the same example. The model learns representations by maximizing agreement between differently augmented views of the same data example [2]. We use SimCLR for semi-supervised image classification on ImageNet. The data transformations increase the data volume by 10.7×.

Baselines: We compare Cachew’s resource scaling policy with the Kubernetes Horizontal Pod Autoscaler (HPA)

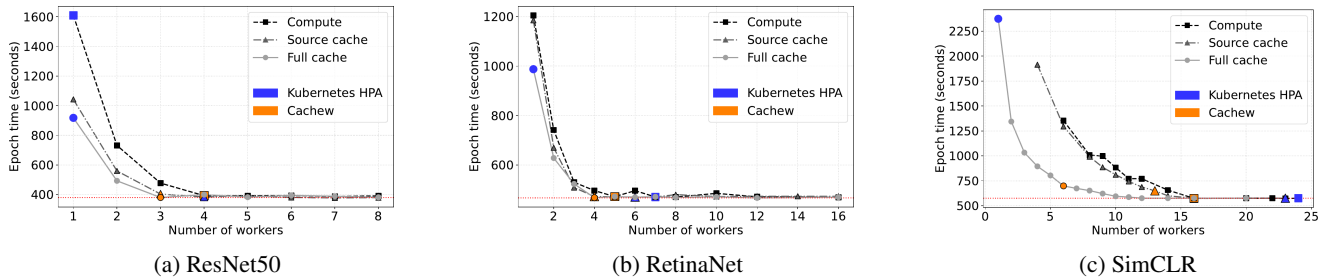

Figure 6: Scaling policy. Cachew selects the right number of workers to minimize epoch time and cost (orange markers). Kubernetes Horizontal Pod Autoscaler does not select the optimal number of workers (blue markers), since it only scales based on CPU usage and does not account for other potential input pipeline bottlenecks, e.g., memory and I/O bandwidth.

policy, which scales input data workers in the service based on a 80% CPU resource utilization target per node [1]. We measure the best-case epoch time for each model (i.e., model ingestion rate) by running an infinitely fast input pipeline that feeds synthetic data. Finally, we report the overhead of running `tf.data` pipelines on remote workers versus on training nodes.

Execution modes: We consider two different placements of the `autocache` operator in our input pipelines. We assume the user inserts `autocache` near the beginning of the input pipeline, immediately after a data read operator and before any data transformation operators. We call this placement *source cache mode* since it causes data workers to read source data from Cachew’s cluster cache if the dispatcher decides to apply caching at this point in the pipeline. We also assume the user inserts `autocache` at the end of the input pipeline, after all data transformations. We refer to this placement as *full cache mode*, since input data workers will read fully transformed data from the Cachew cluster cache if the dispatcher decides to apply caching at this point in the pipeline. We compare the performance of the source cache and full cache execution modes with a *compute mode*, in which no data is reused in the input pipeline, i.e., Cachew reads source data from cloud storage and transforms data on-the-fly.

Metrics: We measure epoch time, i.e. the time it takes to train the model on a complete iteration of the dataset, for each model while varying the number of input data workers and execution modes. We also report total training time and cost for the compute and source cache execution modes. For cost, we consider the Cachew input data worker node costs, storage resources, and the cost of training nodes used for the duration of the job. We assume the cost of the dispatcher is amortized across multiple users and jobs. Note that in our workloads, we observed full caching decreases training accuracy due to the presence of random transformations in the input pipelines. In our evaluation, we focus on demonstrating that Cachew can select the right execution mode to maximize throughput, assuming the user has placed the `autocache` operator in a location that is acceptable for their use-case. Prior studies

Figure 7: Cachew’s first scaling decisions in compute mode relative to the value of the improvement threshold.

have explored the impact on training dynamics when reusing randomly transformed data across epochs [16, 40].

Cluster hardware setup: We run our experiments on Google Cloud. The dispatcher runs on a n2-standard-16 VM. We train ResNet-50 on n1-standard-32 VMs with four Tesla V100 GPUs. We train SimCLRv2 and RetinaNet models on v3-8 TPU VMs since the reference implementations are designed for training on TPUs. We use n2-standard-2 VMs with two 375GB NVMe SSDs for the GlusterFS storage cluster. The network bandwidth between the storage cluster, workers, and clients is at least 16 Gb/s.

6.2 Cachew Autoscaling

We sweep the number of input data workers for the compute, source cache, and full cache execution modes for each model. Figure 6 plots epoch time as a function of the number of data workers and shows the number of workers selected by Cachew’s scaling policy in orange and Kubernetes’s scaling policy in blue markers. The dotted red line shows the minimum epoch time achievable with an infinitely fast input pipeline. In all execution modes, Cachew finds the minimum (or near minimum) number of data workers to avoid data stalls

Figure 8: Cachew’s autocaching policy selects the execution mode that minimizes batch time.

in model training. In contrast, the Kubernetes Horizontal Pod Autoscaler noticeably under or over-provisions data workers. Kubernetes HPA performs poorly as it does not detect bottlenecks besides CPU and memory capacity, such as memory bandwidth bottlenecks and I/O bottlenecks that can limit input pipeline throughput. For SimCLRv2, the input pipeline is highly compute intensive, hence Kubernetes scales up to 24 data workers to maintain per-node CPU utilization at the 80% target. In contrast, Cachew’s scaling policy checks the relative improvement in batch time and determines there are diminishing returns to scaling beyond 16 workers in compute mode and 13 workers in source cache mode.

Figure 7 shows Cachew’s scaling decision sensitivity to the `batch_time` improvement threshold value, which we sweep from 1% to 11%. We include decisions that are suboptimal, which Cachew may later correct in the training process. Both ResNet50 and RetinaNet are robust to this threshold, as the addition of a worker yields clear epoch time benefits (see Figures 6a and 6b), thus the value of the threshold can be quite large. For SimCLR, the addition of a new worker does not always yield significant benefits to the epoch time (see Figure 6c). Consequently, for such a model, lower thresholds are more suitable. The downside of a lower threshold is that the autoscaling policy becomes more susceptible to noise in the metrics. This is visible in Figure 7, as the variance of the decision increases, and outlier decisions become more common. Cachew triggers rescaling in such cases, and eventually converges to the right decision. Gathering metrics over multiple batches can help alleviate noise.

6.3 Cachew Autocaching

To evaluate Cachew’s caching policy, we run the service with an input pipeline in which we carefully control and simulate compute intensity. The input pipeline consists of reading input data from storage (56GB), increasing the size of data elements by 2.5×, and sleeping for a controlled duration of time to simulate applying a time-consuming data processing

Figure 9: RetinaNet training timeline for the first 4 epochs. Cachew picks the right caching mode and number of workers.

operation. Figure 8 plots the time it takes to process a batch of elements as a function of the injected processing time, for the three different execution modes we consider. The experiment is designed such that the compute, source cache, and full cache execution modes are each optimal in a particular regime and verify that Cachew makes the optimal choice.

At low data processing intensity, reading data from the cloud data lake (GCS) is an I/O bottleneck and Cachew recognizes the service should store and read source data from the cluster cache. When sleep exceeds 350ms, Cachew recognizes that data processing intensity is high enough that GCS I/O is no longer the bottleneck. Reading and transforming data on-the-fly from GCS (i.e., compute mode) becomes optimal until 400ms. When source cache mode reaches a similar throughput as compute mode (as in the 350-400ms regime), Cachew prefers compute mode as it saves storage costs. When sleep time exceeds 400ms, storing and reading the transformed dataset from cache minimizes batch time compared to other modes. Cachew chooses full caching in this regime.

6.4 Autocaching & Autoscaling over Time

We demonstrate how Cachew jointly optimizes elastic scaling and caching to maximize epoch time and cost. Figure 9 plots the scaling and caching decisions that Cachew makes over time. As an example, we show the first four epochs of RetinaNet training, where we place two `autocache` ops: one after the reading ops, and one at the end of the input pipeline. The red curve shows the number of workers used for the job and orange vertical lines show when Cachew makes a scaling decision. Cachew starts by processing the pipeline in compute mode with a single worker (highlighted in yellow), first blocking scaling and profiling the worker. During the single-worker profiling phase, Cachew collects metrics to make a caching policy decision and decides on caching at the end of the input pipeline. This decision takes place at the time marked by the green vertical dashed line. The caching decision is applied at the end of the first epoch, when we enter the `put` epoch

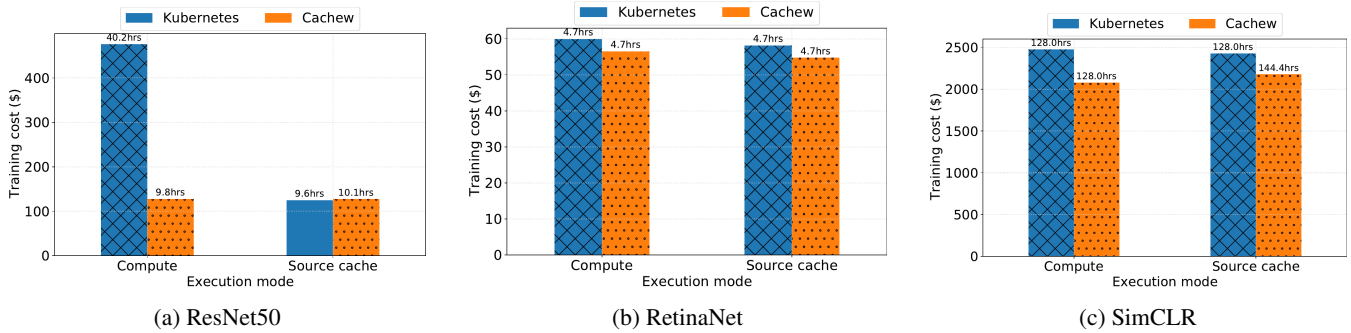

Figure 10: Total training cost (and training time) for Cachew vs. Kubernetes HPA worker scaling policy decisions.

(highlighted in blue) which writes the dataset to the cluster cache and takes longer as a result. Due to prefetching, splits are exhausted in the first two epochs before the autoscale completes. The other two epochs presented are in cache *get* mode (highlighted in green). In the third epoch, Cachew scales the number of workers up to 5, where no more improvements are observed. At this point Cachew removes the superfluous worker and converges to 4 workers. Cachew will continue to run the pipeline in *get* mode with 4 workers for the remaining epochs, and only adjust this number if input pipeline characteristics evolve, requiring less or more workers.

6.5 End-to-end performance and cost

6.5.1 Time to Accuracy and Training Cost

Figure 10 shows the total training cost (bars on y-axis) and total training time (annotations) for the input data worker configurations that Kubernetes and Cachew select in the compute and source cache execution modes. As we saw in Figure 6, Kubernetes under-provisions input data workers for ResNet50 compute mode, while Cachew picks the optimal worker count, allowing it to reduce training time by $4.1\times$ and cost by $3.8\times$. For SimCLR, Kubernetes over-provisions workers, slightly reducing training time but Cachew still saves overall cost by 12-20% by optimizing the number of workers based on its relative improvement threshold in the scaling policy.

6.5.2 Service Overhead

We compare the performance and resource overhead of running *tf.data* pipelines with the service versus locally on training nodes. The service requires additional CPU resources to achieve the same input pipeline throughput, due to the extra network hop (i.e., gRPCs) between data workers and training nodes. Since local *tf.data* workers fetch source data over the network and transform data on the training node, whereas Cachew clients fetch transformed data over the network, the service overhead also depends on the difference between the source and transformed dataset sizes. In our experiments, we find that the service should provision 30% to 50% more CPU

Figure 11: Multi-tenancy: Cachew detects cache hits across jobs while scaling workers for each job separately.

cores compared to the CPU cores we observe being heavily utilized when running the same input pipeline locally on training nodes. Note that this overhead is not an artifact of Cachew’s scaling or caching policies, but rather a measurement of the overhead Cachew inherits from the distributed data processing mechanisms in *tf.data* service [25]. Data marshaling is known to consume significant cycles in datacenters [35]. Networking overheads can be reduced (e.g., by using RDMA), though this is not the focus of our work. The cost of using extra CPUs for data processing is justified as it allows keeping expensive GPUs/TPUs highly utilized and reducing end-to-end training time (see Figure 10).

6.6 Multi-tenancy

We show that Cachew can optimize input data processing across jobs. We run two jobs with the ResNet input data pipeline but different model ingestion rates (simulated with different sleep times in the dataset iteration loop on the clients). The second job has double the ingestion rate of the first. We again place *autocache* ops after reading the data and at the end of the input pipeline. Figure 11 shows how the batch processing time varies over time for each job as Cachew makes its scaling and execution mode decisions. The red

curve shows the first job’s number of workers over time. The epoch boundaries are highlighted by the red dotted vertical lines. This job progresses through a compute epoch (yellow highlight) with profiling, a put epoch (blue highlight), where it caches the data of the `autocache` at the end of the input pipeline and a get stage (green highlight), which consists of two get epochs. The job ultimately converges to two workers.

We show that the dispatcher detects a cache hit after the first job has written to cache and selects the cache `get` execution mode for the second job in all of its four epochs. The epochs are separated by blue dotted vertical lines. The blue curve shows the number of workers for the second job over time. As this job has double the ingestion rate requirements of the first job, it converges to four workers.

7 Discussion

Data access control: Our current prototype of Cachew assumes that clients have permission to access each other’s data (e.g., tenants are all members of the same organization). The implementation can be extended with Access Control Lists (ACLs) to prevent unauthorized access to the data. Workers can check/set permissions before reading/writing datasets. If a job attempts to read from a dataset for which the client does not have read permission, the worker’s request will fail and the client will get a permission error.

Model training dynamics: Though reusing the output of random data augmentations can negatively impact model accuracy, prior works have found that negative impacts can be mitigated by tuning the extent to which caching is applied in an input pipeline. Choi et al. showed that reusing data after random transformations has a small negative impact on the final accuracy trained models, reaching highly competitive out-of-sample error rates with fewer non-cached data instances than a model with no echoing [16]. Revamper [40] demonstrated that partially caching random transformations, while leaving some to be applied after reading from cache, has negligible accuracy penalties, as long as the downstream random transformations provide sufficient sample diversity. Hence, a good rule of thumb is to cache expensive random transformations, while applying highly diverse and inexpensive random transformations after the cache. For instance, in tasks such as image classification, inexpensive random transformations, such as random crop and flip, generally provide sufficient sample diversity [40].

Leveraging local resources on training nodes: Although our autoscaling policy has focused on leveraging remote CPU workers for data processing, `tf.data` service also supports running data processing on local workers, which execute on client training nodes. Adapting Cachew’s autoscaling policy to leverage a mix of local and remote workers would ensure that the extra cost of remote workers is only incurred if the CPU/memory resources for data processing on client training nodes are not sufficient to avoid data stalls.

8 Related Work

§ 2.3 discussed existing mechanisms in input data frameworks, which serve as the foundation for Cachew’s autoscaling and autocaching policies. We discuss other related work below.

Automated resource provisioning: Cluster management systems aim to automate resource allocation decisions, which are notoriously difficult for users [8, 20, 37, 45]. Generic cluster managers treat workloads as black boxes, making them unsuitable for jointly optimizing data caching and resource scaling decisions. Cachew is able to jointly optimize caching and scaling by using metrics that are tailored to the ML input data processing domain. Several resource management systems have been developed specifically for deep learning jobs [28, 44, 65]. However, they assume GPUs are the dominant resource for ML training, whereas recent work has shown that allocating resources for input data processing is equally important yet not well addressed by existing systems [64].

Caching vs. recomputing intermediate data: Caching data and memoizing data transformations is a common technique [10, 41, 52]. Trade-offs of caching vs. recomputing data arise in various contexts [7, 32, 33, 51]. We draw particular inspiration from Nectar [30], a datacenter-scale caching system that treats computations and their intermediate results as interchangeable. We address ML-specific challenges, where estimating the benefit of caching on training time is non-trivial since the model may be the bottleneck or the (transformed) dataset may be prohibitively large to cache. We also jointly optimize caching and resource scaling.

9 Conclusion

We proposed Cachew, a system architecture, to enable input data processing *as a service* for machine learning. To avoid input data stalls while minimizing cost, Cachew dynamically scales distributed data processing resources to match the rate at which each job’s training nodes can ingest data, while avoiding over-provisioning. Cachew leverages its centralized view of data processing pipelines across mutually trusted jobs to reduce the overall compute power required for data processing, by transparently reusing (transformed) datasets within and across jobs when performance and cost efficient.

A Artifact Evaluation README

A.1 Abstract

The artifact consists of the source code of Cachew², the Cachew client binaries³, as well as scripts for building wheel files and Docker images. We also provide reference scripts for deploying GCE VMs for evaluation and for running the some representative experiments⁴. Do note that these scripts might not work as they depend on resources that might not be public. In these cases, experiment VMs will have to be manually set up.

The evaluation focuses on reproducing key experiments and their respective results which demonstrate how the main contributions of Cachew work:

- **Autoscaling** (*Figure 6a, compute curve*): show how input pipeline resources affect training time, how Cachew's autoscaling policy finds the right number of workers automatically, and how the Kubernetes Horizontal Pod Autoscaler fails to find the right scale.
- **Autocaching** (*Figure 8*): Show how Cachew's autocaching policy behaves under various execution scenarios, and how the most efficient execution mode is selected by Cachew.
- **Multi-tenancy with autoscaling and autocaching** (*Figure 11*): Show how Cachew behaves in multi-worker scenarios, selecting the most efficient execution mode, as well as the right scale for each job. Furthermore this experiment should also show how caching can be used in cross-job settings.

A.2 Artifact check-list

The artifact with the components listed below is available at: https://github.com/eth-easl/cachew_experiments.

- System to deploy: Cachew service (dispatcher, input data workers, remote cache cluster)
- Algorithms to evaluate: Cachew's autoscaling and autocaching policies
- Workloads to run:
 - *Figure 6a*: ResNet50 model and its open-source canonical input pipeline.
 - *Figure 8*: Synthetic input pipeline
 - *Figure 11*: Canonical ResNet50 input pipeline
- Binary: Cachew Docker image for workers and dispatcher, Cachew wheel file for client, GCE VM image.

²<https://github.com/eth-easl/cachew>

³gs://cachew-builds/tensorflow-2.8.0-cp39-cp39-linux_x86_64.whl

⁴https://github.com/eth-easl/cachew_experiments

- Model: ResNet50 and its canonical input pipeline
- Data Sets: ImageNet 2012 (stored in GCS bucket)
- Output: CSV files with metrics, text-based logs, and plots to compare with figures in the paper.
- Experiments: Experiments and deployment are fully scripted. See §A.4.
- Publicly available?: yes
- Code licenses: Apache 2.0
- Data licenses: ImageNet 3-Clause License
- Archived (provide DOI)? 10.5281/zenodo.6543943

A.3 Prerequisites

Hardware dependencies: The experiments require a cluster of x86 CPU servers with hardware virtualization support, with 4 Nvidia V100 GPUs on one of the servers. We recommend (and our scripts assume that you are) conducting experiments on Google Cloud. Some of the VM deployment scripts might not work out of the box as they can require access to resources which are no longer private. In this case, the scripts will either have to be modified or the deployment will have to be done manually.

Software dependencies: Our scripts make extensive use of the gcloud CLI tool. As a consequence, this tool is a prerequisite for setting up VMs and running experiments. Please follow [this tutorial](#) to install it. We additionally make use of the gsutil tool. To install it, please follow [this tutorial](#). We also suggest to use Python 3.9 with [PyEnv](#) as a means to install and manage multiple python versions and virtual environments. The [software requirements](#) for the Google Cloud service deployment are installed on the VM images we provide.

Estimated time and cost: The estimated time needed to prepare the workflow is 30 minutes. The estimated execution time of experiments is approx. 15 hours in total. We provide an estimated breakdown of the time and cost for each experiment⁵.

A.4 Instructions

Detailed instructions are provided in the [artifact repository README](#). The evaluator will need to `git clone https://github.com/eth-easl/cachew_experiments.git` locally, then use the scripts provided in the `deploy` folder to spin up a VM, and later tear it down. Once the VM is spun up, one needs to `ssh` into the VM and use the scripts in the relevant experiment directory. Once the experiment is finished, the VM can be torn down. Note that as mentioned before, some of the scripts might not work due to private dependencies. In such cases, use the scripts as reference.

⁵Time and cost estimate sheet: <https://tinyurl.com/52mwtccn>

A.4.1 Getting Started

Please see the artifact repository [Getting Started section of the README](#) for instructions on how to write a simple Cachew input data pipeline and execute it locally.

A.4.2 Reproducing Experiment Results

We provide scripts to automate the deployment, execution, and result plotting for the three key experiments listed in §A.1. See the [Artifact Evaluation section of the README](#) for instructions to run the scripts. Please follow the following steps for each experiment:

1. Deploy a VM for artifact evaluation using `deploy/deploy.sh <vm-name> <gpu-count>`
2. Use the `gcloud compute ssh <vm-name>` command to ssh into the VM
3. Use `cd ${HOME}/cachew_experiments/experiments/<ename>` where `<ename>` is the experiment name, and follow the README there and the associated scripts to run the experiments.
4. Use `gcloud compute scp` to collect whatever resource you find relevant after the experiment is done.
5. Exit the ssh session, and tear down the VM using the `deploy/terminate.sh` script.

For Figure 6a (compute curve) experiment, which required 4 GPUs, see the `experiments/autoscaling` directory. For Figure 8, see the `experiments/autocaching` directory. For Figure 11, see the `experiments/multi-tenancy` directory.

A.5 Evaluation and Expected Results

Each of the three experiments produces a plot which should be comparable with the associated plot in the paper.

A.5.1 Experiment Metrics

- *Figure 6a*: Epoch time in seconds, number of workers chosen by Cachew’s autoscale policy and number of workers chosen by Kubernetes HPA
- *Figure 8*: Batch time, Cachew’s autocache policy decisions
- *Figure 11*: Epoch time, autocache policy decision, autoscale policy decision

A.5.2 Expected Results and Possible Variations

- *Figure 6a*: Epoch time can vary depending on cloud conditions. Decay may or may not be more or less aggressive due to this. Consequently, autoscale decision might vary around 4 workers (at most ± 1 worker). While it is rare, it can happen that the Kubernetes HPA scaling also changes from one worker to two.
- *Figure 8*: Epoch times might vary due to cloud conditions. Shape of curves should still be the same (although *compute* might change as it depends heavily on GCS). Note that the points on the curves, and Cachew’s decisions are recorded separately (i.e. in different runs). Consequently, conditions might change, and metrics could potentially vary leading Cachew to make a seemingly ‘wrong’ decision at points where the three options have similar throughput. Otherwise, Cachew decision expected to follow lowest batch time option.
- *Figure 11*: Job 1’s first two epochs are not always expected to converge during autoscale phase (as Cachew prefers to move to next epoch in those compute modes), but it could happen at 3 workers (both epochs). Job 1’s third epoch expected to converge around 2 workers. Job 2 is expected to converge around 4 workers. Epoch times for Job 1 should be around [366s, 363s, 266s, 253s] while for Job 2 around 158s initially then around 129s in the later epochs. The expected sequence of execution modes for Job 1 is [PROFILE, PUT, GET] and for Job 2 is only GET. Both jobs can have epoch extensions towards the end of a run. A reasonable amount of variability in the worker count (± 1 worker) and epoch times is expected. This experiment is expected to be the relatively volatile, and emphasis should be placed on epoch time convergence and the autocache decisions. On rare occasions the autoscaling decisions can converge to a wrong scale due to the short and synthetic nature of the experiment and the implicit noise this causes on the scaling metrics. As this is a short job, Cachew cannot correct the scale in good time. We have also recently identified a bug caused by the merge with the recent TensorFlow 2.8 codebase which affects our cache store. More detailed information regarding this experiment’s expected outcome and variability can be found in its README.

A.5.3 Experiment customization

It should be possible to modify some of the parameters pertaining to each experiment. For instance, for the Figure 6a experiment, it is possible to change the number of workers across which clusters are deployed. These parameters can be changed in the experiment scripts themselves or for some as command line parameters. Please see the experiment scripts for further details.

CoVA: Exploiting Compressed-Domain Analysis to Accelerate Video Analytics

Abstract

Modern retrospective analytics systems leverage cascade architecture to mitigate bottleneck for computing deep neural networks (DNNs). However, the existing cascades suffer from two limitations: (1) decoding bottleneck is either neglected or circumvented, paying significant compute and storage cost for pre-processing; and (2) the systems are specialized for temporal queries and lack spatial query support. This paper presents CoVA, a novel cascade architecture that splits the cascade computation between compressed domain and pixel domain to address the decoding bottleneck, supporting both temporal and spatial queries. CoVA cascades analysis into three major stages where the first two stages are performed in compressed domain, while the last one in pixel domain. First, CoVA detects occurrences of moving objects (called *blobs*) over a set of compressed frames (called *tracks*). Then, using the track results, CoVA prudently selects a minimal set of frames to obtain the label information and only decode them to compute the full DNNs, alleviating the decoding bottleneck. Lastly, CoVA associates tracks with labels to produce the final analysis results on which users can process both temporal and spatial queries. Our experiments demonstrate that CoVA offers $4.8\times$ throughput improvement over modern cascade systems, while imposing modest accuracy loss.

1 Introduction

Every day, a massive corpus of video data is produced, which is only growing (9.4 exabytes per day, as of 2021 [1]). Extracting insights and actionable semantics from the captured video can enable a variety of applications in healthcare, smart cities, security, customer behavior analysis, etc. Prior works [2–7] have built *retrospective analytics systems* that allow analysts to interactively query over a large corpus of accumulated video data stored in disk.

Modern retrospective analytics heavily rely on deep neural networks (DNNs). Although DNNs are effective, they come

Figure 1: (a) Existing state-of-the-art cascade systems [2, 3], excluding video decoding from the end-to-end setting with two costly assumptions; (b) the proposed cascade architecture that addresses the decoding bottleneck and supports spatial queries, exploiting the compressed domain analysis.

at the cost of significant compute complexity, even for an image. Evidently, passing all the frames of a video through DNN inferencing is computationally prohibitive. To address this challenge, recent works [2–4, 6–13] have focused on *cascade* architectures. They stage processing as (relatively) inexpensive predicates to filter the incoming frames of video by trading analysis accuracy for higher throughput. As such, only a handful of frames arrive at the last stage that performs the full DNN inferencing.

While effectively resolving the DNN throughput bottleneck, the existing cascade systems have two limitations. First, as shown in Figure 1(a), these systems either ignore or sidestep a new bottleneck stage, *video decoding*, by making one of the two costly assumptions: (1) input video is decoded a priori and the raw frames are stored in storage [2, 3, 5, 7], or (2) input video is pre-transcoded and stored in multiple lower resolutions at ingest time to facilitate the query time decoding [4, 6]. However, in practice, decoding (or transcoding) the entire video corpus and storing the uncompressed (or

duplicate) data in disk is often infeasible due to the significant compute and storage cost.

Second, to achieve otherwise-unachievable throughput, the existing cascade systems often exclusively support *temporal* queries. More specifically, many cascade systems [2, 3, 5, 11] only support binary predicate query, which is to get timestamps of frames that contain the queried object. However, recent studies in video analytics [7, 15] propose *spatial* queries (e.g., car in upper right region) and demonstrate their usefulness, which cannot be supported by the current cascades.

To tackle the two limitations, this paper sets out to devise CoVA¹, an alternate cascade architecture. As illustrated in Figure 1(b), the key contribution of CoVA is to split cascade computation between compressed domain and uncompressed pixel domain, which collaboratively alleviate the decoding bottleneck at query time without requiring any pre-processing and support both temporal and spatial queries. To design this cascade architecture, we leverage the following two insights:

- (1) A small set of encoding metadata, commonly used by modern video codecs, provides noisy, yet rich, information to accurately locate potential objects and track them across frames in compressed video, while decoded pixel data is only necessary to classify objects.
- (2) Video analytics queries can be fulfilled by answering the following three questions: (1) where and when are interesting objects present in the video (i.e., spatiotemporal information); (2) what are the object classes (i.e., label information); and (3) what specific information do queries ask about these objects?

With these insights, CoVA divides video analytics over compressed footage into three major stages. The first stage (**Track Detection**) detects occurrences of moving objects (called *blobs*) over a collection of consecutive compressed frames (called *tracks*). To realize this objective, we devise a novel compressed-domain blob tracking technique, refitting a neural network based segmentation algorithm and a multiple object tracking algorithm, both of which are originally designed for pixel domain. Our second stage (**Frame Selection**) avoids decoding the whole track and selects a minimal set of frames that are representative and yet minimize the decoding load. CoVA passes only this subset through the full DNN object detection. The third stage (**Label Propagation**) takes the labels and the coordinates of the detected objects in the subset and uses spatiotemporal information from the first stage to propagate labels across all the frames of the track. Altogether, these approaches offer a novel cascade architecture that performs its first and second stages in the compressed domain, while the third stage is in the pixel domain.

Finally, the three stages produce a collection of analysis results for each frame, which include a list of present objects,

¹CoVA: Compressed Video Analytics.

their pixel coordinates, their labels (e.g., car), and all other properties associated with the objects (e.g., color). Note that the results are query-agnostic and not specific to a certain query. Therefore, CoVA runs the three stages only for the initial query and stores the analysis results along with the video in database. When other queries are requested over the same video in a future, CoVA simply retrieves the results and process the queries without reprocessing the video.

We prototype a CoVA system² on NVIDIA's streaming analytics framework, DeepStream [16]. We evaluate the effectiveness of CoVA using five video streams and four queries. Compared to existing cascade systems for query time retrospective analytics, CoVA offers 4.8× throughput improvement, while compromising only modest accuracy loss. We also show that CoVA is capable of serving spatial queries without having significant accuracy loss, compared to the full DNN analytics baseline.

Contributions. Our key contributions are as follows:

- We show that encoding metadata is sufficiently rich to identify objects of interest along with their spatiotemporal information for retrospective video analytics.
- To extract the spatiotemporal information, we devise a novel compressed-domain blob tracking technique, refitting the pixel-domain video segmentation and object tracking algorithms.
- We present the design of CoVA, a mixed-domain retrospective analytics system that leverages the track information to alleviate the decoding bottleneck, and support both temporal and spatial queries.
- Our experiment shows that CoVA offers significant throughput improvement over conventional cascade systems, while compromising modest accuracy loss.

2 Background and Motivation

CoVA aims to tackle limitations of existing retrospective analytics systems. Below, we first provide background on state-of-the-art retrospective analytics and discuss their limitations. We also discuss common compression mechanisms of modern video codecs, which drive the design of proposed techniques.

2.1 Retrospective Analytics

Modern retrospective analytics systems [2–8, 10–14] share two common properties: (1) heavy reliance on DNNs, and (2) cascade architecture to resolve the DNN compute bottleneck.

²Our prototype is available at <https://github.com/casys-kaist/CoVA>.

Figure 2: Throughput comparison among various system environments of cascade video analytics.

While they have these common properties, there are two different dimensions that categorize the instances of retrospective analytics systems.

Time of analysis – query time vs. ingest time. Retrospective analytics systems are categorized into two groups, depending on whether the analysis occurs at *query time* [2, 3, 11] or *ingest time* [4, 6, 8, 13]. While ingest time analysis leverages offline pre-processing to facilitate and expedite the query time analysis, it requires to scan the entire video data corpus and consume compute resources on it, even though a significant portion of the data is not queried. This approach is not only cost-inefficient but also environmentally suboptimal since it would consume a massive amount of energy for mostly unnecessary computations. In contrast, query time analysis performs the full analysis at query time without having any pre-processing. Therefore, it does not touch raw video data unless it is queried, which allows analysts to prevent the waste of resources. To this end, this work focuses on the query time analysis and aims to address its limitations.

Supported query – temporal vs. both temporal and spatial. Most, if not all, of query time cascade systems [2, 3, 11] limit the types of supported queries to be only the *temporal* ones and specialize the cascade stages for a specific temporal query to achieve high throughput. However, recent work [7] points out that *spatial* information can enable richer capabilities for video analytics. CoVA is a novel cascade architecture that leverages compressed-domain analysis to address both spatial and temporal queries.

2.2 Video Decoding: the New Bottleneck

Decoding for end-to-end cascade. With the volume of video data growing at an explosive rate, the use of compression is imperative to keep storage costs in check. Video codecs such as H.264 strike a balance between quality and storage size, being used as the de facto way of storing large corpus of video data. As such, the first step in an end-to-end system for processing video queries is to decode the video data before further processing. However, even with hardware-

acceleration for standard codecs baked-in to modern CPUs and GPUs, video decoding can be up to orders-of-magnitude slower than the capabilities of cascade systems to process raw video frames.

Bottleneck analysis. To quantify this bottleneck, we examine the performance impact of video decoding for an existing state-of-the-art cascade system, Tahoma [3], using NVIDIA RTX 3090 GPU, and present the results in Figure 2. The detailed methodology is provided in Section 8.1. The cascade system is effective in addressing the DNN-execution bottleneck and offers up to $327\times$ improvement in performance compared to a native DNN-only solution. However, even with decoding accelerator hardware NVDEC [17], the decoding throughput is significantly lower than the throughput of cascade system, which curtails most performance gains.

Further, as video resolution increases, the decoding throughput almost linearly decreases, exacerbating the decoding bottleneck. Considering the trend that even IoT devices such as surveillance cameras produce HD (1080p) or higher resolution video, we believe that this decoding bottleneck will become increasingly severe and significantly hinder the usefulness of video analytics in interactive applications. Motivated by these insights, the objective of CoVA cascade is to address the decoding bottleneck in query time retrospective analytics.

2.3 Block-based Video Coding

To alleviate the decoding bottleneck, CoVA leverages the unique characteristics of *block-based* compression, used in many modern video codecs. Below, we provide background on block-based compression and discuss opportunities that it opens for compressed-domain analysis.

Video codecs. Many video codecs, such as H.264, HEVC, VP8, VP9, and AV1, use block-based compression algorithm. In this paper, we primarily focus on the H.264 format since it is one of the most widely used codecs in various applications as of publication date [18]. However, CoVA is compatible with other block-based codecs since all of them compress video, generating the same set of metadata we use for compressed-domain analysis in CoVA.

Block-based compression. Block-based codecs compress (or encode) video frames by splitting each frame into a two-dimensional array of fixed sized blocks, called *macroblocks* (e.g., 16x16 pixels). There are three *macroblock types* – I, P, and B – depending on the way how the macroblocks are compressed. An I-macroblock is independently compressed, while P- and B-macroblocks are compressed referring to one and two other macroblocks, respectively. To maximize compression ratio, the codecs select dependent macroblocks for P and B-macroblocks with the highest similarity and store the spatial offsets as metadata called *motion vectors*. Depending

Figure 3: Overview of CoVA.

on the composition of macroblocks, frames are again categorized into three types, I, P, and B. An I-frame, also known as a keyframe, is only composed of I-macroblocks, while a P-frame contains I/P-macroblocks and a B-frame has all of the I/P/B-macroblocks.

To maximize the compression rate, codecs can *partition* macroblocks (e.g., 16x16) into smaller sub-macroblocks (e.g., 4x4). This optimization allows codecs to achieve a higher compression rate but at the expense of storing larger metadata. Modern codecs employ multiple *macroblock partitioning modes*. For instance, H.264 uses six modes from no partitioning (i.e., 1 macroblock of size 16x16) to 16-way partitioning (i.e., 16 sub-macroblocks of size 4x4).

CoVA leverages the insight that the encoding metadata – (1) macroblock types, (2) motion vectors, and (3) macroblock partitioning modes – in the compressed video is sufficiently rich to detect potential objects and track them across frames.

Compression rate optimization. Due to the higher compressibility, codecs tend to prefer P/B-macroblocks over I-macroblock. However, the preference for P/B macroblocks ends up creating long dependency chains among the macroblocks, which cause compression errors to propagate across the chains and hinder random access to frames in the video. To resolve the problems, the codecs insert I-frames at regular intervals, typically every 250 frames, to create independent sets of consecutive video frames, called Groups of Pictures (GoP). Within a GoP, the number of dependent frames that need to be decoded grows linearly, with zero for the first I-frame and maximum for the last frame.

CoVA exploits the inter-frame dependencies and object track information extracted from compressed-domain analysis to prudently select the frames with the least number of dependencies in each GoP that enable to identify all the objects present and minimize decoding effort.

3 Overview of CoVA

CoVA divides video analytics over compressed footage into three major stages, as illustrated in Figure 3.

1 First Stage: Track Detection. First, CoVA detects occurrences of moving objects over a collection of consecutive compressed frames, which we call tracks. The track detection stage further breaks down into two steps: (1) *blob detection*: CoVA *spatially* detects whether and where moving objects (called blobs) are present in each compressed frame; and (2) *blob tracking*: CoVA *temporally* associates the blobs across frames to identify unique blob tracks. For the blob detection, we devise a novel compressed-domain blob detection model, refitting a neural network architecture originally designed for pixel-domain video segmentation. The neural network only takes as input three encoding metadata commonly used by modern codecs, recognizes movements as masks, and spatially associates the masks clustered in a region as blobs. While the neural network architecture is fixed, CoVA trains the model individually for each video to learn the data-specific patterns of blobs and specialize for the target video. Finally, the found blobs are fed into the blob tracking step that employs an object tracking algorithm, SORT [19], which was also originally developed for pixel domain. Note that the blob track results still lack the object class labels.

2 Second Stage: Frame Selection. To attain the object labels for the detected blobs, CoVA needs to perform DNN-based object detection for the frames where tracks appear, which ordinarily require decoding all the frames. However, as frames on a track most likely contain the same object, it is enough to perform the object detection on a subset of the frames in the track, which we call *anchor frames*. Thus, CoVA only decodes frames required to decode the anchor frames, which improves the effective decoding throughput. The challenge is how to prudently select the anchor frames so as to minimize the decoding cost and at the same time acquire the accurate label information. We develop a frame selection algorithm that leverages a common property of video codecs where compressed frames are encoded in dependency chains. Thus, anchor frames are the ones that are located on the max-

imal number of tracks and at the same time have the short dependency chain with respect to the decoding algorithm. Note that while the anchor frames are the only ones that are inferred upon for object detection, all the frames in the track need to be labeled to handle various video analytics queries.

③ Third Stage: Label Propagation. In the third stage, CoVA takes the approximate positions of potential objects (or blobs) from the first stage and labels for the anchor frames from the second stage to temporally propagate the labels across all the frames of the tracks. To merge the spatial and temporal results, CoVA first spatially correlates blobs with objects on anchor frames using the intersection ratios of their bounding boxes. Then, CoVA uses the tracking information to identify the same objects across the frames and propagates the labels, while populating bounding boxes around the corresponding blobs in the temporally consecutive frames.

Finally, when a video passes through the three stages, CoVA produces a collection of analysis results for each frame, the examples of which are a list of present objects, their pixel coordinates, their labels (e.g., car), and all other properties associated with the objects (e.g., color). Note that the results are created only once when CoVA receives the initial query over a video and they are permanently associated with the video in the database. After then, analysts can use the same results to process various future queries without reprocessing the video.

4 Compressed Domain Blob Tracking

In this section, we describe the track detection mechanism that is the first stage of CoVA’s cascade architecture. Figure 4 depicts the overall workflow.

4.1 Learning to Detect Blobs

Limitations of existing compressed domain video processing techniques. Detecting objects or blobs from compressed video is a traditional research problem in the computer vision community [20–25]. However, the following two limitations prevent the simple adoption of these techniques. First, the techniques often require human-crafted parameters that need to be tuned for each input video, which makes automated analytics impossible. Secondly, the techniques are not sufficiently robust to be applied to arbitrary video data, producing inadequately accurate tracking results for video analytics. To overcome such limitations, recent works [26, 27] explored to use neural networks for vision tasks over compressed video. Unfortunately, we could not employ the neural networks for CoVA since they not only still require pixel-domain data for a subset of frames, but also offer insufficient throughput that is significantly lower than the decoder.

Figure 4: Track detection.

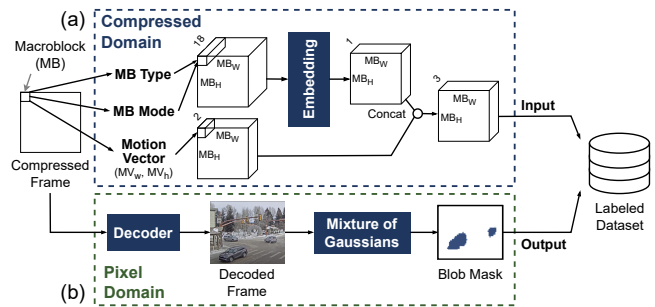

Figure 5: (a) Feature engineering that transforms three compression metadata into a tensor of input features; (b) labeled data collection using the Mixture of Gaussians (MoG) model.

Leveraging the similarity between video segmentation and blob detection. To address these limitations, we exploit an observation that blob detection using compression metadata is akin to the problem of the semantic image segmentation using pixel data. *Blob detection* task aims to find potential objects and their approximate position within video frames. *Image (or video) segmentation* task, on the other hand, aims to semantically split an image (or frames of a video) and classify each segment into one of the predetermined labels. When there are only two classes – blob and non-blob – the image segmentation task can be reduced to the approximate blob detection task. This observation allows us to tap into the vast range of techniques, including Deep Neural Network (DNN) based image and video segmentation, that can be geared towards compressed domain blob detection.

4.2 BlobNet

To this end, we devise a lightweight DNN-based blob detection model, called BlobNet, building upon the state-of-the-art Temp-UNet [28] model for video segmentation. Unlike the Temp-UNet model, which operates on pixel frames, BlobNet operates on compression metadata.

Feature engineering. Figure 5(a) depicts the feature engineering, which converts the three metadata into a tensor of input features. BlobNet takes the three types of metadata as input – macroblock types, macroblock partitioning modes, and motion vectors. To obtain the metadata, CoVA performs

only a few early stages of the decoding process required to extract metadata, called *partial decoding*. CoVA encodes the first two metadata, macroblock types and partitioning modes, by mapping each of their combinations into a one-hot vector (e.g., total 12 combinations for H.264). These one-hot vectors are fed into an embedding layer, which converts each one-hot vector into a scalar weight value. This weight value is concatenated to the motion vector (MV_w, MV_h) for each macroblock, which finally results in a 3D tensor ($MB_W \times MB_H \times 3$). CoVA temporally stacks these tensors from consecutive frames and constructs a 4D tensor, which is the input for BlobNet.

BlobNet architecture. Similar to the architecture of TempUNet³, BlobNet has three major components: (1) **encoder** that extracts the presence and approximate location of blobs from noisy metadata; (2) **decoder** that reconstructs the shapes of blobs from the blob presences; (3) **skip connections** that offer spatial information to the decoder for assisting the shape reconstruction process. While this overall composition is the same as that of TempUNet architecture, we maximally reduce the depth of encoder and decoder modules such that the resulting model still offers high accuracy while maximizing the inference throughput.

Video-specialized model training. Pixel video segmentation models typically train once during a training phase, followed by inference on unseen video data. However, CoVA trains BlobNet at query time for every video data to specialize the model for the specific data. This design choice is derived from our empirical observation that without such model specialization, the model cannot capture the variations of data-specific encoding parameters and fails to reach sufficient accuracy. Note that once training is completed for a video data, no further training is required for additional video if the video is recorded from the same angle of view with the trained one. We empirically observe that $\approx 3\%$ of the video is sufficient to train the model for the evaluated video (see Table 2). The training process, including data collection and training, takes only a few minutes, which can be amortized for multiple queries on the same video data. Such training cost amortization is inspired by existing query-time cascade systems [2, 3, 6, 8] that train specialized neural networks for each video.

Labeled data collection for supervised learning. As CoVA aims for large-scale video analytics, manually labeling the video data is infeasible. As such, CoVA needs a method to automatically label the video data. Similar to prior works [2, 3, 8, 29], using pixel domain object detection is a possible option. However, object detection models are not only computationally expensive but also produces labels for non-moving objects, which should not be used to train BlobNet, designed to detect only moving objects. Instead, we exploit the conventional Mixture of Gaussians (MoG) based background

³We omit the detailed architecture and refer to the paper [28].

Figure 6: Example scenario of track-aware frame selection.

subtraction technique since it is lightweight and only looks for the moving objects.

4.3 Tracking Blobs

Blob detection results. The output of BlobNet is merely a collection of 1’s on the resulting bitmap, which lacks the notion of objects. CoVA uses connected-component labeling algorithm to uniquely identify the interesting regions in compressed frames as potential objects, called *blobs*. Once the blob identification process is completed, CoVA obtains the spatial information of blobs on each frame. However, the blobs existing across consecutive frames are not yet temporally associated with each other, which necessitates the next stage of CoVA, blob tracking.

SORT-based blob tracking. The end objective of blob tracking in compressed domain is to minimize the number of frames to be decoded to mitigate the decoding bottleneck. Hence, the tracking algorithm must (1) offer high throughput that significantly outperforms the decoder throughput, (2) while accurately tracking the inter-frame blobs to minimize the accuracy loss at the label propagation stage. We extensively explore existing object tracking techniques in pixel domain [19, 30–36], and choose the SORT object tracking algorithm [19], which satisfies the above two requirements. SORT offers the near-best tracking accuracy among the state-of-the-art tracking techniques and keeps the computation lightweight by exploiting conventional optimization algorithms, Kalman filter and Hungarian assignment.

5 Track-aware Frame Selection

Leveraging the track information, CoVA prudently select a small subset of frames to decode, called *anchor frames*, so as to maximize the decoding throughput. The key idea behind the anchor frame selection algorithm is to pick the ones that require to decode the least number of frames and thus maximize the *effective* decoding throughput.

Dependency between compressed frames. As described in Section 2.3, block-based compression uses a combination of (1) independent frames that are self-contained (i.e., I-frame), and (2) dependent frames (i.e., P/B-frames) that depend on

Input : efs: compressed frames in a GoP_{*t*}
tracks: blob tracks that maintain across GoPs

Output : dfs: compressed frames chosen to be decoded
afs: anchor frames

```

1 cur_tracks = tracks that terminate in GoPt
2   with no anchor frames assigned
3 dfs = afs = ∅
4 if cur_tracks ≠ ∅ then
5   start_timestamps = sorted(cur_tracks.starts())
6   end_timestamps = sorted(cur_tracks.ends())
7   sidx = eidx = 0
8   for ef in efs do
9     while start_timestamps[sidx] == ef.timestamp do
10      candidate_af = ef
11      sidx = sidx + 1
12    end
13    while end_timestamps[eidx] == ef.timestamp do
14      afs.add(candidate_af)
15      dfs.add_dependants(candidate_af, efs)
16      eidx = eidx + 1
17    end
18  end
19 end
20 dfs.output()
21 afs.output()

```

Algorithm 1: Track-aware frame selection algorithm.

either preceding frames, subsequent frames, or both. Due to the presence of P-frame and B-frame within a GoP, the number of dependent frames that need to be decoded to fully decode a frame follows a saw-tooth structure, as depicted in Figure 6. The number of dependent frames is zero for I-frame at a GoP boundary and grows linearly until it resets to zero at the end of GoP⁴.

Selecting anchor frames for decoding. To minimize the decoding load, we leverage two insights: (1) CoVA can find the consecutive frames where an object keeps appearing in the video, and (2) the computations load to decode a frame is proportional to its number of dependent frames. Within each GoP, CoVA identifies a set of anchor frames, which can identify all objects present in the GoP and perform the least computation for decoding, by minimizing the number of dependent frames. The selected anchor frames are the only ones that are passed to the DNN object detector to produce the label information.

Example. Figure 6 presents an example where CoVA identifies three unique objects, (a), (b), and (c), as well as the range of frames where each object stays in the video. In this example, the best choice of anchor frame would be Frame ② since (1) all the objects are present in Frame ②, and (2) Frame ② has the least number of dependent frames among frames where all the objects are present.

⁴For brevity, we simplify Figure 6 by only visualizing dependency chains for P-frames since the number of dependent frames for B-frames is similar to that of the nearby P-frames.

Figure 7: Label propagation.

Algorithm. Algorithm 1 describes the frame selection algorithm in detail. *Line 1*: When a GoP arrives at the frame filtering, to select the anchor frames, CoVA only considers tracks that (1) terminate in that particular GoP and (2) do not have any anchor frames yet (e.g., object (a)/(b) at time *t*). *Line 9*: Then, as CoVA visits frames in order, it first checks if a track starts appearing in the visiting frame. *Line 10*: If it does, the visiting frame is marked as “candidate” anchor frame (e.g., Frame ① at *t*). Later on, if a new track starts appearing in a successive frame, the frame becomes the new candidate (e.g., Frame ② at *t*+1). *Line 14–15*: When a track ends, CoVA adds the current candidate frame into the anchor frame list (e.g., Frame ②) and inserts all the dependent frames into the dependent frame list (e.g., all frames between Frame ① and Frame ②). The intuition behind this algorithm is that, if a track started but did not terminate, any frame in between can be an anchor frame. However, when a track ends, an anchor frame for the track must be selected, because otherwise, we may not have any anchor frame for the terminating track.

6 Label Propagation

In the last stage, CoVA takes the blob tracks and labels for the anchor frames to temporally propagate the labels across all the frames on the tracks. Figure 7 illustrates the example workflow of label propagation. When the selected anchor frames and their dependent frames are decoded, CoVA takes only anchor frames to perform the DNN object detection and obtain the labels (e.g., “car”) as well as their spatial information. To associate the labels with blobs, CoVA first spatially correlates blobs with the detected objects using the intersection over union (IoU) between their bounding boxes (e.g., bounding boxes of blobs and detected objects are denoted using green and blue boxes, respectively). When the IoU is larger than a threshold, CoVA associates the detected objects with blobs and propagates the labels to all frames in the tracks.

Multiple-objects overlapping problem. One challenge with the label propagation mechanism is that when BlobNet fails to separately identify multiple objects clustered together and creates a large single blob, CoVA cannot correctly propagate the multiple labels. To overcome the challenge, we prepend

an additional step to the label propagation. When a multitude of detected objects are spatially overlapped with a single blob, CoVA splits the blob into multiple blobs, proportionally projecting the locations of objects in the anchor frame to the blob. The proportional projection is also applied to other frames in the same track, populating multiple tracks from a single track. This way, CoVA is able to propagate the multiple labels to the separated tracks, instead of giving a single erroneous label to the clustered objects.

Static object handling mechanism. As CoVA relies on the compressed domain analysis to detect blobs, it is impossible to detect static objects from the compression metadata. Therefore, our BlobNet focuses on detecting moving objects, intentionally excluding the static object information from the training data through the use of MoG. However, CoVA still performs full-fledged object detections on anchor frames. Therefore, the static objects can be detected at least on the anchor frames. As the static objects stay still at the same location across subsequent anchor frames, CoVA is able to associate them as the same object and produce the corresponding track.

7 Implementation

System architecture and constituent software modules. We prototype a CoVA system using DeepStream, which is built upon GStreamer, for constructing the skeleton pipeline of video analytics. As described in Section 4, the initial stage of CoVA is the partial decoding, which extracts the metadata. Hardware-accelerated decoder (e.g., NVDEC) does not support partial decoding and only generates the fully decoded frames. Thus, we modify an open-source video codec, libavcodec, such that it only produces the three types of metadata. In addition, CoVA performs two neural network inferences, one for the blob detection and the other for the full DNN inference (YOLOv4). We use on a TensorRT-based DNN inference plugin on DeepStream, nvinfer [37].

Parallelization in CoVA. Our prototype system distributes the computations of pipeline stages over CPU and GPU, while exploiting their parallelism. Initially, CoVA scans the entire video and splits it into chunks at the I-frame boundaries to parallelize the computation on CPU threads. This scanning takes just a few seconds even for hours of video data, which imposes negligible overhead. Such parallelization results in cutting tracks at the chunk boundaries, but its impact on accuracy is negligible since there are only a few dozens of chunks. For a chunk, the first two stages, track detection and frame selection, should be pipelined in the same thread since these algorithms rely on the temporal dependencies of frames. For object detection, anchor frames are independently computed, which can be fully parallelized. Therefore, CoVA maintains only a single thread for object detection and anchor frames from different chunks are batched together for inference.

Table 1: Descriptions of example video analytics queries.

Query	Abbr.	Description	Metric
Binary Predicate	BP	Return frames where querying object appears	Accuracy
Count	CNT	Return the average count of querying object in frames	Absolute Error
Local Binary Predicate	LBP	Return frames where querying object appears in a certain region of frames	Accuracy
Local Count	LCNT	Return the average count of querying object in a certain region of frames	Absolute Error

8 Evaluation

8.1 Methodology

Queries. To demonstrate the effectiveness of CoVA, we evaluate four example queries, two queries widely used in prior work [2, 3, 8], and their spatial variants supported by CoVA. Table 1 reports the list of evaluated queries with their descriptions and accuracy metrics:

- (1) Binary Predicate.** Binary predicate (BP) query finds frames where queried objects appear. Collecting frames with queried objects is an initial step of advanced analysis, which makes BP an important query for evaluation despite the simplicity. Many retrospective analytics systems evaluate their solutions only using the BP query [2, 3].
- (2) Count.** The count (CNT) query is introduced by a prior work, BlazeIt [8], which is an aggregate query that counts the number of queried objects appearing in the whole video. As the aggregated count is largely dependent on the length of each dataset, the number is normalized by dividing it by the number of frame counts.
- (3) Local Binary Predicate and Local Count.** The local binary predicate (LBP) and local count (LCNT) queries are spatial variants of BP and CNT queries, respectively; however, the only difference is that they exclusively look for objects located in a certain region of interest. For instance, users can query northbound traffic in highway monitoring video by annotating the corresponding region of video as “northbound”. Serving these queries not only requires the temporal query results, but also needs spatial information to determine the object locations.

Metrics. Table 1 also reports metrics used for each query. We use the same metrics that prior works use to evaluate their

Table 2: Descriptions of video datasets, queried objects, ground truth results, and region of interest used for spatial queries. Note that we use the Yolov4 DNN model applied frame-by-frame to the original video to get ground truth.

Video Name	Num of Frames	Length	Object in Interest	Object Occupancy	Object Count	Local Occupancy	Local Count	Region of Interest
amsterdam [38]	3,580K	33H	Car	70.07%	1.40	29.05%	0.44	Lower Right
archie [8]	3,567K	33H	Bus	10.48%	0.17	6.63%	0.11	Upper Left
jackson [39]	2,921K	27H	Car	31.91%	0.56	18.28%	0.29	Lower Left
shinjuku [40]	1,782K	16H	Car	82.29%	2.19	19.91%	0.38	Lower Left
taipei [41]	3,564K	33H	Car	84.48%	5.03	22.16%	0.64	Lower Right

solutions. For BP and LBP, as in prior works [2, 3], we use *accuracy*, which is a traditional metric for binary classification that evaluates how many observations, both positive and negative, are correctly classified. Similarly, for CNT and LCNT, we use *absolute error* as used in Blazelt [8].

Datasets. Table 2 reports the video datasets used for the evaluation. Taking a similar approach with prior works [2, 3, 6–9, 42], we collect the video datasets from YouTube live streams [38–41]. They are recorded from statically installed cameras, which is a widely used setup in various applications domains such as traffic monitoring [43–45], security [46, 47], surveillance [48], and healthcare [49]. Video contents involve various kinds of scenarios, which include traffic circle, highway, harbor, city streets, and park. As the datasets have different resolutions ranged from 720p to 2160p, we transcode them to 720p and evaluate the throughput and accuracy for ease of comparison. Note that higher resolutions (e.g., 2160p) create more severe decoding bottleneck, so using them would be favorable to CoVA, producing higher throughput gains and therefore, to be conservative, we choose to use 720p for all video datasets. The rightmost five columns report the ground truth results for the four queries and the region of interest that spatial queries focus on. Getting the ground truth results by manually labeling the hours of video data is infeasible, so we apply a full DNN model (YOLOv4) to the entirety of video in a frame-by-frame manner.

Hardware specifications. Our CoVA prototype is built on a server with two 16-core Intel Xeon Gold 6226R CPU (2.9 GHz), 192 GB of DRAM, and an NVIDIA RTX 3090 GPU (24 GB GDDR6 DRAM). We turn off hyperthreading to avoid interference among threads.

Decoder. For all experiments, we use NVIDIA’s hardware accelerated decoder, NVDEC, for both baseline and CoVA systems to make a fair comparison. We choose not to use the CPU decoder, libavcodec, since it shows lower throughput than NVDEC even with 32-core parallelization.

Baseline cascade system. As the baseline, we use existing cascade systems for query time retrospective analytics. As discussed in Section 2, cascade systems such as Tahoma [3]

Figure 8: End-to-end system throughput of the baseline decode-bound cascade and CoVA. The throughput of decode-bound cascade is equivalent to the throughput of NVDEC (i.e., 1,431 FPS), which is marked with a red line.

are significantly bottlenecked by video decoding. Therefore, for a conservative comparison with these decode-bound cascade systems, we assume that the cascade systems are only bottlenecked by the decoder, not by any other stages. With this assumption, the throughput of cascade systems is equivalent to the decoder throughput. We refer to this baseline as *decode-bound cascade* in this paper.

8.2 Performance Implication of CoVA

Throughput improvement. Figure 8 compares the end-to-end system throughput of the baseline decode-bound cascade system and CoVA across five video datasets. CoVA achieves on average 4.8× throughput improvement, which ranges from 3.7× for archie to 7.1× for jackson. The significant speedup shows that CoVA effectively pushes a large proportion of analysis to the compressed domain, unclogging the decoding bottleneck that prevents the existing cascades to achieve beyond the constant NVDEC throughput. The results also suggest that depending on the datasets, CoVA sees different speedups. The datasets, jackson and amsterdam, see relatively larger gains, while archie and taipei datasets show lower benefits. These gaps can be attributed to the unique content properties of each evaluated video dataset that deliver varying throughput for the

Table 3: (1) Filtration rate at decoder stage (decode filtration rate) and (2) filtration rate at DNN inference stage (inference filtration rate).

Dataset	Decode Filtration Rate (%)	Inference Filtration Rate (%)
amsterdam	87.16	99.60
archie	72.94	99.15
jackson	94.81	99.79
shinjuku	77.18	99.26
taipei	74.03	99.81

Figure 9: Effective throughput of CoVA stages. The lowest bar represents the bottleneck of CoVA pipeline, which is marked with hatching lines.

CoVA pipeline stages, which eventually engenders a different bottleneck point. To better understand the throughput implication of these stages, we delve into the interplay of algorithms and system in the CoVA pipeline below.

Effectiveness of frame selection. Frame selection is the key to alleviate the decoding bottleneck since it determines the computational load for decoder. Table 3 reports the filtration rates at decoding stage (decode filtration rate) and DNN inference stage (inference filtration rate). The decode filtration rate is calculated based on the number of decoded frames that include both anchor frames and their dependent frames, while the inference filtration rate only considers the anchor frames that are passed to the DNN object detection stage. Intuitively, various semantics of datasets cause different filtration rates. If video contains many objects having lots of motions, blob tracking would produce numerous tracks, which would require many anchor and dependent frames to proceed to the decoder. For crowded video streams such as archie, CoVA sees lower decode filtration rate of 72.94%, while the uncongested ones like jackson capture less activity and provide higher decode filtration rate of 94.81%. Across all datasets, CoVA filters out over 73% to deliver over $3.7\times$ ($=100/(100-73)$) throughput boost for decoder. At the same time, the inference filtration rate closely reaches 100%, which addresses the DNN bottleneck since the object detector only sees a handful of frames.

Bottleneck analysis. To understand the throughput variation

Table 4: Accuracy results of the four evaluated queries for the video datasets. The acronyms for accuracy metric are specified below.

Dataset	Object	BP (ACC)	CNT (AE)	LBP (ACC)	LCNT (AE)
amsterdam	Car	85.79	0.15	81.61	0.09
archie	Bus	86.96	0.04	90.06	0.01
jackson	Car	86.13	0.10	92.01	0.05
shinjuku	Car	90.15	0.30	91.31	0.05
taipei	Car	87.74	1.10	83.98	0.37
average	-	87.34	N/A	87.69	N/A

* ACC: Accuracy (%), AE: Absolute Error

of CoVA stages across different datasets, we measure the performance of individual stages. Figure 9 reports the effective throughput of each stage by starting from the first partial decoding stage and adding successive stages one by one to the system. The *effective* throughput is defined as the product of the absolute throughput of stage and the accumulated filtration rates. Note that since we measure the throughput from the pipelined system, the effective throughput of a stage cannot be larger than that of the previous stage. The results suggest that different datasets experience bottleneck at different stages. The datasets that attain lower decode filtration rate than the others (i.e., archie, shinjuku, and taipei) are still bottlenecked at the decoder, while the other two datasets are bounded by the DNN object detector. We observe that the inference of BlobNet never becomes a bottleneck and always matches the throughput of the preceding partial decoding stage.

8.3 Accuracy Implication of CoVA

Table 4 reports the accuracy results of evaluated queries. For the BP query, CoVA achieves on average 87.3% accuracy. For the CNT query, CoVA experiences absolute errors from 0.04 (archie) to 1.10 (taipei), respectively. For spatial queries (LBP and LCNT), we do not observe a noticeable difference in accuracy with the temporal queries. The lack of difference is intuitive since CoVA processes the spatial queries by simply restricting the focus of analysis to a certain region of frames. Therefore, the results of spatial variants are merely a subset of temporal query results.

The results show that the approximate nature of compressed domain analysis introduces accuracy loss. However, we argue that such modest level of accuracy degradation (10~20%) is tolerable to retrospective video analytics, which aims to process large corpus of video data interactively at query time. The video analytics also inherently produce approximate results due to the nature of noisy analog video data and predictive object detection models. Moreover, our accuracy results are conservatively calculated by treating the YOLOv4 detection results as ground truth and marking the CoVA results as error

Table 5: Raw throughput of four different video codecs on the libavcodec and NVDEC decoders.

Codec	Full Decoding (FPS)		Partial Decoding
	NVDEC	libavcodec	(FPS)
VP8	1,590	1,802	32,774
H.264	1,431	1,230	16,761
VP9	3,249	1,179	35,349
H.265	3,888	2,026	25,862

if they do not match. However, we empirically observe that there are many cases where YOLOv4 misses small objects when the objects are faraway from the shooting point, while CoVA can correctly detect them by successfully tracking blobs even for the small objects and propagating the correct labels to the tracks. In this case, the correct results of CoVA would be marked as false positives due to the erroneous ground truth.

Discussion. As discussed above, approximation is fundamentally inevitable for video analytics, because even the best effort results are still imperfect. Thus, our goal in designing CoVA is to achieve *acceptable* approximation accuracy loss for video analytics. According to a study [50], the level of acceptable approximation accuracy loss is higher when the users consider contexts such as application purpose and cost. We believe that CoVA could be a useful tool where analysts can quickly and cost-efficiently extract high-level insights from a large corpus of videos. For instance, consider an application that monitors traffic in a harbor in Amsterdam (see Table 2). For binary predicate query, it suffers from 15% accuracy loss. However, CoVA does not miss the cars completely from the video in most cases since the cars stay in the video for at least several tens of frames (only 2% of cars are eventually missed). Hence, if analysts merely wanted to estimate traffic, CoVA would be able to offer sufficiently precise results. We also believe that if an application requires more accurate results, CoVA could serve as an initial scanning tool that quickly identifies “worth-to-be-further-analyzed” video clips.

8.4 Sensitivity Study

Implication of video codecs. We implement the CoVA system based on H.264, one of the most widely used video codecs. However, to demonstrate applicability of CoVA to other block-based compression standards, we take three alternatives, VP8, VP9, and HEVC (i.e., H.265), and develop metadata extraction in their partial decoding implementations. Table 5 reports throughput results when using the four different codecs with 720p videos and 32 cores. The throughput of NVDEC for the four codecs ranges from 1,431 FPS to 3,888 FPS, which is significantly lower than the effective throughput of existing cascade systems and thus our problem statement regarding decoding bottleneck still holds true. In addition, we observe

Figure 10: Throughput of partial and full video decoding (libavcodec) on CPU, as the number of cores changes from 4 to 32. For comparison, we also report the throughput of BlobNet and NVDEC, while they have constant throughput since they run on GPU.

that for all codecs, the full decoding throughput in both software and hardware significantly falls short of throughput of the partial decoding. This throughput gap allows CoVA to construct a cascade architecture that enables blob tracking to run at a higher throughput than the vanilla decoder and effectively lowers the full decode workload.

Implication of CPU parallelism. To further analyze the scalability of our parallelization scheme, Figure 10 compares the throughput of partial and full decoding as we parallelize them using the varied number of cores from 4 to 32. We also show the throughput of BlobNet and NVDEC for comparison. Note that these results are averaged across the datasets. The results show that the parallelized partial decoder not only scales significantly better than the full decoder when using the same number of cores (i.e., $1.5\times$ vs. $5.9\times$), but also largely outperforms the throughput of NVDEC. Currently, we use all the available cores (32) for partial decoding to optimize for throughput. However, one may be able to revise the objective function such that it also takes into account resource utilization and energy efficiency, which we leave as a future work.

9 Related Work

A growing body of literature [2–9, 14, 15, 29, 51–57] aims to address the computational challenges in video analytics. CoVA differentiates itself by addressing video decoding bottleneck, exploiting compressed-domain analysis. Further, CoVA does not require pre-processing, transcoding, or profiling to obtain the benefits.

Cascade architectures for binary predicate queries. No-Scope [2] and Lu et al. [5] use a series of approximate pixel-domain filtering stages to build their cascade. Tahoma [3] and Shen et al. [29] use multiple pipelined neural networks to build their cascade architecture. BlazeIt [8] builds on top

of NoScope to support Aggregate and Limit Queries. All five works aim to increase the effective throughput of the system for raw video frames by filtering a majority of the frames using pixel-domain operators. Alternatively, Thia [51] splits up the DNN-inference model using exit points for early termination, similar to the stages of cascade architecture. In contrast, CoVA splits the cascade computation between compressed domain and pixel domain to alleviate the decoding bottleneck.

Spatial queries for video analytics. An emerging class of video analytics systems aim to enable queries based on spatial relationship between labeled objects. Koudas et al. [7] accelerate spatial queries using separate stages for inexpensive DNN-based classification followed by expensive DNN-based object detection. TASM [15] dynamically adapts the layout of tiles, which partition compressed video frames, based on the spatial location of objects to improve performance. Unlike the above works, CoVA uses compressed domain blob tracking to accelerate spatial queries. Unlike TASM, CoVA does not need to update the compression to gain performance benefits.

Storage-accuracy trade-off for decoding bottleneck. VStore [4] uses a search space of fidelity and encoding/decoding knobs (frame sampling rate, resolution, etc) to optimize for query performance and storage cost. SMOL [6] jointly optimizes complexity of the reference DNN for inference and the resolution of data (360p, 720p, etc), for accuracy-performance trade-off. VSS [52] proposes optimizations for video storage to yield higher read rates and compression ratios. CoVA takes an orthogonal approach of performing approximate blob tracking using compression metadata at *query time*. Nevertheless, CoVA is complementary to the above approaches.

Ingest time analysis. Focus [9] generates approximate labels using an inexpensive DNN and Boggart [53] tracks objects at ingest time to generate additional metadata. At query time, both Focus and Boggart use the stored metadata to yield improved performance. Scanner [54] identifies sampling frames offline for pixel domain analysis and skips decoding for all other frames. In contrast, CoVA does not require additional metadata and can operate on standard video compression formats. VideoStorm [55] uses offline profiling data for dynamic load balancing and Chameleon [14] uses inexpensive online profiling to improve accuracy-resource tradeoff at query time. These two profiling approaches are orthogonal and complementary to compressed-domain query processing in CoVA.

Compressed domain object detection. Many prior works [23, 25, 58, 59] have proposed object detection from compression metadata using classical approaches such as pre-defined kernels [24] and statistical models [20, 60, 61]. Further, the prior works impose restrictions on the compression-time parameters (e.g., 4 frames per GoP), which limit their applicability [20, 23–25]. Liu et al. [62], Wang et al. [27], and Wu et al. [26] employ DNNs to detect moving objects using *both* pixel and compressed domain data, training a single

model for all datasets. BlobNet differs from prior works in the following aspects: (1) BlobNet does not require any pixel data; (2) BlobNet does not impose restrictions on the compression parameters; and (3) BlobNet is trained for given video to compensate the accuracy.

10 Conclusion

Existing cascade systems for video analytics assume to pay significant compute and storage cost for addressing the decoding bottleneck. Further, the systems are specialized for temporal query to achieve otherwise-unachievable throughput. To tackle the two limitations, this paper proposes CoVA, which splits cascade computation between compressed and uncompressed pixel domain. Leveraging the unique characteristics of video analytics and video compression algorithm, CoVA effectively unclogs the decoding bottleneck while additionally supporting spatial queries. Our experiments demonstrate that CoVA reduces the decoding workload by 83.6% and offers $4.8\times$ system speedup compared to state-of-the-art query-time retrospective video analytics systems, while compromising modest accuracy.

Abstract

The prosperity of AI and edge computing has pushed more and more well-trained DNN models to be deployed on third-party edge devices to compose mission-critical applications. This necessitates protecting model confidentiality at untrusted devices, and using a co-located accelerator (e.g., GPU) to speed up model inference locally. Recently, the community has sought to improve the security with CPU trusted execution environments (TEE). However, existing solutions either run an entire model in TEE, suffering from extremely high inference latency, or take a partition-based approach to handcraft partial model via parameter obfuscation techniques to run on an untrusted GPU, achieving lower inference latency at the expense of both the integrity of partitioned computations outside TEE and accuracy of obfuscated parameters.

We propose SOTER, the first system that can achieve model confidentiality, integrity, low inference latency and high accuracy in the partition-based approach. Our key observation is that there is often an *associativity* property among many inference operators in DNN models. Therefore, SOTER automatically transforms a major fraction of associative operators into *parameter-morphed*, thus *confidentiality-preserved* operators to execute on untrusted GPU, and fully restores the execution results to accurate results with associativity in TEE. Based on these steps, SOTER further designs an *oblivious fingerprinting* technique to safely detect integrity breaches of morphed operators outside TEE to ensure correct executions of inferences. Experimental results on six prevalent models in the three most popular categories show that, even with stronger model protection, SOTER achieves comparable performance with partition-based baselines while retaining the same high accuracy as insecure inference.

1 Introduction

Driven by the remarkable success of AI [25] and edge computing [11, 17], giant companies are increasingly shifting their well-trained Deep Neural Network (DNN) models from the cloud to enormous edge devices, to compose mission-critical applications such as autopilot navigation [8, 15], home monitoring [20] and visual assistance [49]. By employing accelerators (e.g., GPU), clients of edge devices can conduct low-latency inferences without connecting with a remote server

with high latency and network instability, and clients do not have to transfer their sensitive data to the cloud.

Since obtaining accurate models requires model providers to pay substantial resources to train parameters with private datasets [10, 45], in order to preserve their competitive advantages, model providers usually require their offloaded models to keep black-box (confidential) with traditional *semantic security* guarantee [7]: a client can query the local model for results, but will learn nothing about the parameters' *plaintexts*.

To preserve model confidentiality, a pragmatic approach is to use the publicly available Trusted Execution Environments (TEE), in particular Intel SGX [14], a pervasively used CPU TEE product. SGX provides both code integrity and data confidentiality for enclaves [5, 33], and avoids severe performance downgrading caused by using traditional cryptographic tools (e.g., Homomorphic Encryption [36, 44]), making it attractive for model providers to protect their offloaded models while retaining high inference service quality.

Much prior work has explored using SGX for secure model inference, and these approaches can be summarized into two categories. First, the *TEE-shielding* approach, which runs the entire unmodified model in enclaves, achieves both model confidentiality and high accuracy same as the original model, but suffers from extremely high latency due to the limited computing resources on CPU's enclave and the lack of publicly available secure GPU devices [3, 65]. As a typical TEE-shielding work, MLCapsule [27] incurs dramatically higher latency (up to 36.1X) than insecure GPU inference for diverse workloads (§6.1).

In order to mitigate the high latency issue, the second category of work, including eNNClave [56] and AegisDNN [68], takes a *partition-based* approach to manually select a portion of sensitive model layers to run in an enclave, and partition the rest of the layers to run on an untrusted GPU for acceleration, achieving lower inference latency than TEE-shielding approaches by utilizing the strong GPU computing power.

Unfortunately, existing partition-based approaches face a fundamental *confidentiality-accuracy* dilemma: some of the approaches replace the partitioned layers' parameters with public parameters from other models composed by the same layers, which effectively protects model confidentiality but trades off the accuracy. This is because the original parameters are usually trained by model provider's private datasets tailored for a specific task [10, 45]; hence the parameters are

[†]Tianxiang Shen and Ji Qi contribute equally.

*Jianyu Jiang is the corresponding author.

exclusive to achieve the original high accuracy. In contrast, some partition-based approaches preserve the original high accuracy by holding plaintexts of partitioned operators' parameters on an untrusted GPU, which partially compromises the confidentiality by revealing a fraction of parameters' plaintexts to the adversary outside an enclave.

Our key observation to resolve this dilemma is the *associativity* property of many inference operators. *Associativity* means that the way that factors are grouped in an operator's computation does not change the final result [43]. With associativity, we can securely transform an associative operator into *parameter-morphed*, thus *confidentiality-preserved* operator by scaling its parameters with a hidden scalar in an enclave, run that morphed operator on the GPU and fully restore the execution result of that operator with the scalar hidden in an enclave. Since associative operators (e.g., *Convolution*, *Fully-connected*) widely exist in general DNN models, and these operators represent a major fraction of computation in a DNN model (e.g., 93.5% of the computation on VGG19 [61] is spent on convolution), we can achieve dramatically increased performance by partitioning morphed, computationally expensive operators to run on a GPU.

Based on this observation, we present SOTER¹, the first partition-based approach that achieves model confidentiality, low latency and high accuracy simultaneously. SOTER carries a *Morph Then Restore* (MTR) protocol for cooperative executions between kernels (enclave and GPU). Specifically, SOTER randomly selects a major fraction of associative operators, morphs their parameters with randomly generated *blinding coins* (scalars) in the enclave, and partitions these parameter-morphed operators to run on a GPU. For each client's input, SOTER executes each operator (either in an enclave or GPU) in order, transfers intermediate execution results (IR) across kernels when needed, and restores the final execution result with reciprocal coins in the enclave. A subtle case is that, under special partition cases, an adversary who observes IRs transmitted across kernels can reveal the value of coins hidden in an enclave (§4.1). Hence, SOTER additionally morphs the value of IRs before they are transmitted across kernels to hide the blinding coins, thus protecting the model confidentiality.

However, even with these steps, SOTER still faces an inherent integrity hazard in the presence of an adversary at the edge side, who can observe and manipulate any components (e.g., morphed parameters on GPU) outside the enclave to mislead the offloaded model to produce wrong output, ruining the model provider's inference service quality.

To tackle the integrity hazard, SOTER's MTR protocol generates *oblivious fingerprints* at runtime to detect integrity breaches outside the enclave in a *challenge-proof* manner [71]. Our key idea is that the associativity property can be used to efficiently generate integrity challenges at run-

Table 1: Comparison of SOTER and related systems. "*" / "•" means that the system uses either a TEE-shielding approach (*), or a partition-based approach (•).

time. Specifically, before running inferences, SOTER collects *fingerprints* of partitioned operators in enclave, which hold the ground-truth of these operators' execution results; during the inference, SOTER challenges partitioned operators with fingerprint input to ask them for execution proofs. By comparing the returned proofs with expected fingerprint output in enclave, SOTER learns whether integrity breaches occur.

To prevent an adversary from distinguishing fixed fingerprint challenges thus bypassing the detection, inspired by traditional steganography techniques [34, 52], SOTER dynamically derives new fingerprints by using existing fingerprints in enclave based on the associativity property. The new fingerprints statistically share the same distribution as client's normal input (§4.2), making fingerprints oblivious to the attacker. Therefore, by leveraging the same key observation of associativity, SOTER achieves both model confidentiality and integrity in a unified manner.

We implemented SOTER with Graphene-SGX [63], a mature framework that supports developing neural network applications with Intel SGX. We evaluated SOTER with six popular DNN models covering three popular categories, including Multi-layer Perception (MLP) [40], Convolution Neural Network (CNN) [24] and Transformer [64]. We compared SOTER to three notable TEE-based secure inference systems, covering both the TEE-shielding approach and partition-based approach. Our evaluation shows that:

- SOTER is secure. For confidentiality, SOTER effectively hid parameters' plaintexts, and achieved comparable model protection as TEE-shielding baseline under powerful model stealing attacks (§6.3); for integrity, SOTER detected any integrity breaches within ten fingerprint challenges with an overwhelmingly high probability of 99.9% (§6.4).
- SOTER is efficient. SOTER achieved up to 72.6% lower latency than the TEE-shielding baseline, and had moderate latency (up to 1.2X) compared to partition-based baselines, while the baselines do not have integrity protections (§6.1).
- SOTER is accurate. SOTER retained the same high accuracy as insecure inference, while the most efficient partition-based baseline caused 1.1%~5.5% accuracy drops.

Our major contribution is the MTR protocol, the first work that achieves model confidentiality, low latency and high ac-

¹SOTER is an ancient Greek god, guards safety against cosmic chaos.

curacy with integrity protection for secure model inference. Compared to existing relevant baselines, SOTER achieved comparable strong confidentiality as the TEE-shielding approach, comparable low-latency as the partition-based approach, high accuracy same as insecure inference, and overwhelming high probability of detecting integrity breaches outside an enclave. This makes SOTER unique to greatly promote the prosperity of AI on edge devices, encouraging enormous model providers to develop powerful models and deploy them on third-party edge devices. Also, our MTR protocol can generally protect model inference on the cloud when the model provider does not trust the owner of cloud servers that host the model. SOTER’s source code is released on github.com/hku-systems/SOTER.

In the rest of this paper: §2 introduces background; §3 gives an overview of SOTER; §4 describes SOTER’s design; §5 covers SOTER’s implementation; §6 shows our evaluation; §7 discusses related work and §8 concludes.

2 Background

2.1 Deep Neural Network

A DNN model (in short, model) can be represented as a sequence of connected *layers* with each layer assigned a set of *operators*, as shown in Figure 1. An operator is either a *linear operator* or a *nonlinear operator* where a linear operator is weighted by *parameter matrices* (in short, parameters).

Inference workflow. Figure 1 shows the inference workflow. A model M passes an input X (e.g., an image) through layers of operators to compute *logits* [30], normalizes logits with *softmax* function to produce a probability vector, and assigns a class with the highest probability to input X as the class label. Without losing generality, we use image classification as an example to illustrate model composition in the following discussions.

Associativity of DNN operators. Operators are the basic building blocks of a DNN model, among which linear operators have been proven to take up the majority of computation resources in general model inferences [1, 70].

Many DNN models deployed at the edge are built on top of *associative* operators. Suppose we have an input X and a scalar μ , a DNN operator F is associative if

$$(\mu^{-1} * \mu) \cdot F(X) = \mu^{-1} \cdot F(\mu * X) \quad (1)$$

Linear operators, including computationally expensive *convolution* and *fully-connected*, have the associativity property as they conduct linear transformation on input data. For instance, take the convolution operator as an example: as shown in Figure 1, if we multiply each element in the convolution kernel by 2^{-1} (i.e., $\mu = 2^{-1}$), we will get the output $2^{-1}R$, while it always holds $(2 * 2^{-1}) * R = 2 * (2^{-1}R)$ in Equation 1. This property applies to other linear operators as well.

For nonlinear operators that conduct nonlinear transformation on data, most of them do not have an associativity property (e.g., *Sigmoid*). However, interestingly, under specific

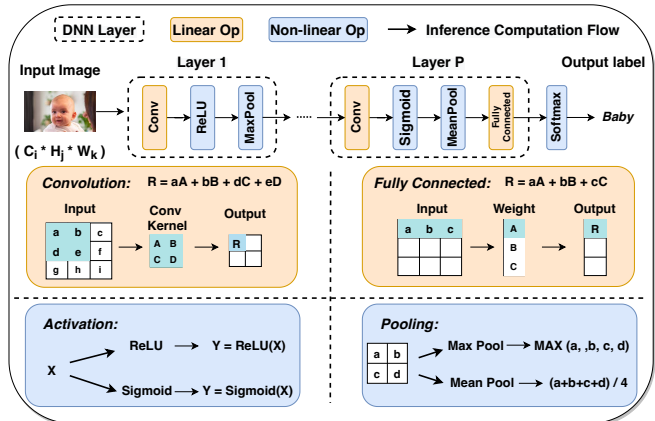

Figure 1: An overview of the DNN model.

constraints, some nonlinear operators can also be associative. Take the most commonly used *ReLU* as an example: the *ReLU* function, $F(x) = \text{Max}\{0, X\}$, is *scale-invariant* when $\mu > 0$, i.e., $F(\mu x) = \text{Max}\{0, \mu X\} = \mu F(X)$. Hence, given a scalar μ , Equation 1 applies to *ReLU*. Similar to *ReLU*, the *pooling* function is associative as well.

Operators that satisfy Equation 1 also meet a variant of the associativity property. Given that

$$F(X_1) = y_1, F(X_2) = y_2, \dots, F(X_n) = y_n$$

it always holds

$$F\left(\sum_{i=1}^n \mu_i * X_i\right) = \sum_{i=1}^n \mu_i * y_i \quad (2)$$

SOTER leverages Equation 1 as the key weapon to produce parameter-morphed, thus confidentiality-preserved operators to run on GPU for acceleration, and restore accurate results in enclave. SOTER uses Equation 2 to efficiently generate oblivious fingerprints for integrity checking at runtime. We illustrate our detailed designs in §4.

2.2 Intel SGX and Related Work

Intel Software Guard eXtension (SGX) [14] is a pervasively used hardware feature on commodity CPUs. SGX provides a secure execution environment called enclave, where data and code execution cannot be seen or tampered with from outside.

As shown in Table 1, there are two categories of SGX-based work that provides secure inference service. The first category is the TEE-shielding approach that runs all inference computations within enclave (e.g., MLCapsule [27], Privado [26], Occlumency [41]). Such an approach shields the entire model in enclave to hide parameters’ plaintexts, but fails to achieve low inference latency owing to the computational bottleneck of CPU and the lack of publicly available trusted GPU [3, 65].

The second category is the partition-based approach that runs a portion of model layers in enclave and runs the rest of the layers on a GPU for acceleration. AegisDNN [68] only shields partial critical model layers in enclave and accelerates other plaintext layers on GPU. To decide which layers should

be partitioned, AegisDNN takes a user-specified argument (i.e., deadline for an inference task), uses silent data corruption mechanism [23] to learn each layer’s criticality, and partitions uncritical (plaintext) layers to GPU to meet the stringent deadline. eNNclave [56] argues that the feature extraction operators (e.g., convolution) of different models are generally transferable, hence it replaces partitioned operators’ parameters with pre-trained parameters of other models, which sacrifices inference accuracy. This is because, model providers usually train their models with private datasets tailored for a specific task, thus each parameter in the trained model is exclusive to achieve high accuracy [10, 45, 72]. Also, such an approach is only applicable to specific models where public parameters are available. Serdab [21] and Darknight [28] assume the model is deployed on a trusted cloud. Instead of protecting model confidentiality, they have an orthogonal goal of protecting users’ data privacy on the cloud.

3 Overview

3.1 System setup

We consider a client-side inference scenario shown in Figure 2. Different from a cloud-side inference scenario (e.g., Delphi [44], Gazelle [36]) where the model is hosted on the trusted cloud server, we consider the model provider offloads its model to the client’s untrusted edge device to run model inferences. The device constantly takes sensitive queries from the client and sends inference results back to the client.

3.2 Security model

We consider an honest model provider that provides the correct model requested by the client, and the model is offloaded to run on an SGX-equipped third-party edge device. We trust the hardware and firmware of Intel SGX, which ensure that code and data in enclave can not be seen or tampered with from outside. However, any components outside the enclave are untrusted.

We consider a malicious edge-side attacker outside the enclave that aims to (1) steal the parameters of the offloaded model, and (2) perturb any components outside the SGX to modify the inference results. An edge-side attacker could be a business competitor who wants to steal the model for competitive advantages and ruin the inference service to screw up the model provider’s reputation [12, 13, 54]. Even worse, the integrity attack against edge-side model inference could pose severe threats to edge users. For instance, an attacker may hack into a self-driving system running with an obstacle detection model, and perturb the model parameters to produce incorrect navigation instructions to the car [9].

Semantic security. Similar to prior secure inference systems, namely the MLcapsule [27] and eNNclave [56], SOTER aims to achieve model confidentiality with the semantic security guarantee: knowing only ciphertexts, it must be infeasible for a computationally-bounded adversary to derive significant information about the plaintexts [7]. In the secure infer-

Figure 2: The client-side inference scenario.

ence scenario, it captures the requirement that the parameters’ plaintexts cannot be derived from any data observed by the adversary.

Note that, we do not hide information that is revealed by the results of inference queries, and we focus just on protecting the parameters’ plaintexts. Protecting against attacks that exploit the leakage of inference results is a complementary problem to that solved by SOTER. We give a detailed illustration of these attacks and potential mitigations in §7.

3.3 System overview

SOTER’s two-phase design. SOTER’s protocol consists of an offline *preprocessing phase*, and an online *inference phase*. Specifically, the preprocessing phase is independent of the client’s query input which changes regularly. We assume the offloaded model from the server is static, if the model changes, then both parties should re-run SOTER’s preprocessing phase. After preprocessing, during the inference phase, the client sends query input to get the eventual result. Note that, SOTER is best suited for applications whose inference is latency-sensitive, but is usually not performed frequently enough to take up all computational resources needed for preprocessing. **SOTER’s workflow.** In Figure 3, we show how SOTER leverages the general associativity property of DNN operators to automatically partition a DNN model.

In the preprocessing phase: during **P1~P3**, a SOTER client conducts standard SGX attestation to the server for obtaining the model M and decryption keys KEY_M , and then loads the encrypted model M in a layer-wise manner by decrypting with KEY_M locally. In **P4** and **P5**, SOTER extracts the model architecture, statically filters out all *associative* operators that meet Equation 1, and then invokes SOTER’s MTR protocol for model partitioning.

Specifically, in **P5**, SOTER’s MTR protocol runs as follows: With a given partition ratio θ , SOTER randomly selects $\theta\%$ associative operators, and generates (1) *fingerprints* of the selected operators for integrity checking (used in the inference phase), and (2) random scalars for all operators. These scalars serve as the *blinding coins* to hide the parameters [44] and are always kept secret in enclave. With the associativity property (Equation 1), SOTER morphs every selected associative operator by multiplying each element in the operator’s parameter matrices with a blinding coin (the computation result can be restored by using the reciprocal coin), and then partitions the selected operators with morphed parameters to GPU. In Figure 3, the selected operators (in green) are morphed with

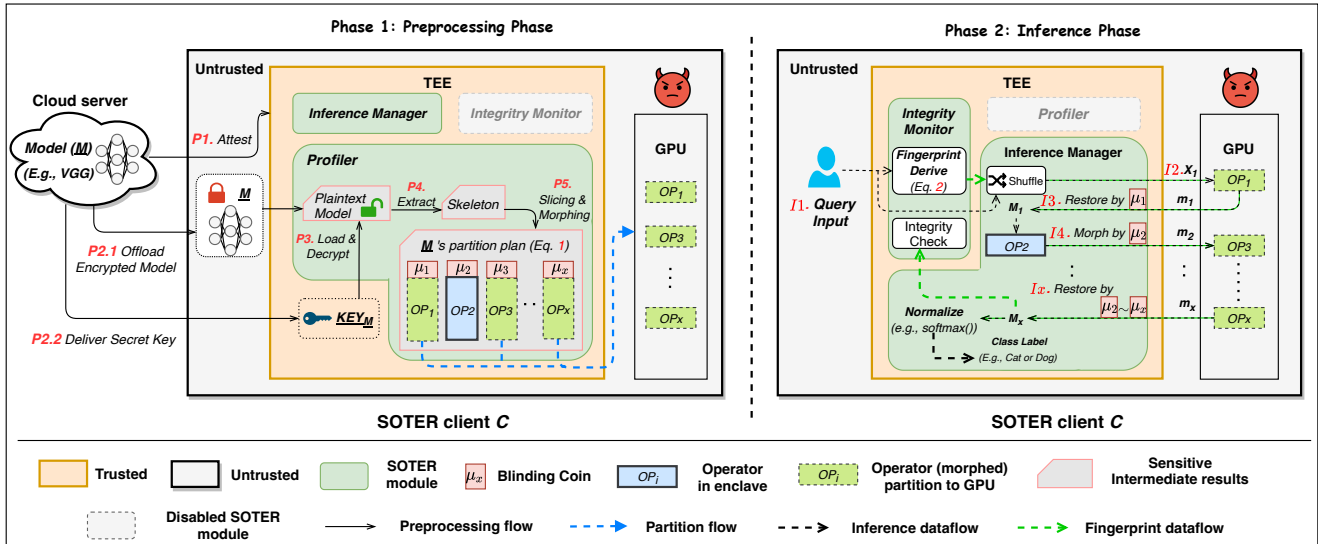

Figure 3: The architecture of SOTER in a modular manner. SOTER’s secure inference protocol has three modules (shielded in green) running in an enclave. An adversary can observe and manipulate any components outside the enclave.

corresponding coins, e.g., the parameters of the third operator OP_3 are morphed with its coin μ_3 and partitioned to GPU, while the second operator (in blue) is kept within an enclave.

Note that, we choose to run the preprocessing procedures (P1~P5) at the client-side because client C might select his θ according to his GPU capability, e.g., choose a smaller θ if the GPU has limited usable memory.

In the inference phase, there are two types of data flows: the inference flow (black dotted line) and the fingerprint data flow (green dotted line). The life-cycle for the inference data flow is: (I1) The client C sends a query input (i.e., data for inference) to the trusted inference manager module and shuffles with the fingerprint input (introduced below). (I2) The inference manager forwards C ’s input X_1 to the GPU, and the first *morphed* operator OP_1 takes X_1 as input and computes the output m_1 . (I3) Since the next operator OP_2 is expected to run within enclave according to the plan made in the preprocessing phase, the inference manager takes the computation result of previous partitioned operators (i.e., m_1) as the input, restores m_1 with all previous partitioned operators’ blinding coins since the last kernel switch (in Figure 3’s circumstance, SOTER restores with only OP_1 ’s blinding coin μ_1), and gets the restored result M_1 . (I4) After that, the second operator OP_2 computes with M_1 and gets an intermediate result (IR), then morphs IR with the OP_2 ’s blinding coin μ_2 and forwards the result m_2 to the partitioned operator OP_3 in GPU.

The above procedures (I2~I4) repeat until all partitioned operators in GPU are computed. In (Ix), with the last computation result m_x from OP_x , SOTER restores the real result with all partitioned operators’ coins since the last kernel switch (same as I3). In this case, SOTER restores with $\mu_2 \sim \mu_x$ and gets the real inference result M_x . Last, SOTER runs a standard normalization to get the class label for client C .

The fingerprint data flow is used to detect integrity breaches of partitioned operators outside an enclave. Specifically, with a set of fingerprints produced in the preprocessing phase (P5), SOTER dynamically derives new fingerprints by utilizing the general associativity of Equation 2, injects these fingerprints into the inference data flow to check whether the partitioned parameters have been maliciously modified by an adversary outside the enclave.

SOTER’s generality. SOTER supports general neural networks. SOTER’s key insight into partitioning neural networks lies in the broad associativity of common inference operators (§2.1), including all linear operators (e.g., *convolution* and *fully-connected*) and typical nonlinear operators (e.g., *ReLU*, *Max-pool*, and *Mean-pool*). Hence, SOTER theoretically supports all neural networks (including recurrent neural networks [69]), but exhibits varying performance gains (compared with running the entire neural network in TEE) depending on the ratio of associative operators in neural networks (§6.1). SOTER also supports general TEEs (e.g., ARM TrustZone [53] and AMD SEV [58]) as long as the TEE provides data confidentiality and code integrity guarantees that SOTER’s MTR protocol requires.

4 Protocol Description

This section describes SOTER’s MTR protocol. At a high level, MTR utilizes the general associativity property of DNN operators to automatically profile a model (with Equation 1), randomly selects a portion of associative operators, and then morphs these operators’ parameters with hidden *blinding coins* in enclave to hide parameters’ plaintexts (§4.1). Besides, to tackle the integrity threat (described in §3.2), stemming from the same observation of the general associativity property, MTR dynamically derives *oblivious fingerprints* (with

Table 2: SOTER’s protocol variables.

Variable	Description
$\Theta(\text{default} = 0.8)$	Portion of associative operators partitioned to GPU.
$O_g \mid O_e$	Partitioned operators in GPU / maintained in TEE.
$O(O_g \cup O_e)$	The whole set of model M ’s operators.
$Para(O_i)$	Parameters of operator O_i .
FP_{O_i}	Fingerprint of operator O_i .
μ_i	Blinding coin of operator O_i .

Equation 2) and uses fingerprints to check the integrity of partitioned operators in a *challenge-proof* manner (§4.2). Table 2 shows the variables used in the MTR protocol.

4.1 Morph Then Restore (MTR) protocol

The MTR protocol is divided into two stages: a *morphing* stage and a *restore* stage. In the morphing stage, SOTER first makes *blinding coins* for every operator (including both associative and non-associative operators), and then makes a partition plan with a given partition ratio θ . Then, in the restore stage, SOTER runs inference across GPU and enclave, and restores inference results in enclave when needed. Algorithm 1 and 2 show the MTR protocol.

Stage 1-1: Morphing with blinding coins. SOTER assigns every operator with a randomly generated scalar, which serves as the blinding coin to hide the plaintext value of parameters. Given an operator O_i (the partition plan is described in **Stage 1-2**), SOTER morphs $Para(O_i)$ by multiplying each element in $Para(O_i)$ with the corresponding coin μ_i . Note that, SOTER requires periodically updating of the coins to avoid potential chosen plaintext attacks [6, 37], as the morphing is completely linear. According to the hill cipher theory [48], each coin can tolerate up to n^2 attacks (i.e., n^2 inferences) where n is the parameter matrix’s size of the operator that the coin applies to. Hence, SOTER updates a morphed operator with matrix size n every n^2 inferences. Notably, this updating can be done off the critical path when the inference tasks are not busy (§5).

- **Protect coins during kernel switches.** One subtle case is that, SOTER assigns random coins to every operator (rather than selected operators for partitioning) to avoid potential information leakage during kernel switches, i.e., when intermediate results (IRs) are transmitted between the enclave and GPU. We illustrate our design by giving a running example.

- **Running example.** We demonstrate our idea with the example in Figure 4, which is a common architecture in typical DNN models. SOTER selects a portion of model operators to run in the TEE enclave (green portion), and partitions the remaining operators to run on the untrusted GPU (red portion). An adversary outside the enclave is attempting to deduce the blinding coins used to morph the GPU operators according to the attacker-visible IRs (Y_1 and Y_2).

We begin with the **Before** case, in which only the partitioned GPU operators are protected by SOTER’s blinding coins. OP_1 (on the GPU) is a linear operator and OP_2 (in

Algorithm 1: MTR protocol at client c (offline) (§4.1).

```

1 Function partition( $O$ ) do
2   foreach operator  $op$  in  $O$  do
3      $op.partition \leftarrow \text{False}; op.index \leftarrow O.index(op);$ 
4     if  $op.index > W$  then
5       if  $0 < \text{normalize}(\text{sgx\_read\_rand}()) < \Theta$  then
6          $op.partition \leftarrow \text{True};$ 
7       if  $op$  is associative &  $op.partition$  then
8         foreach element  $e$  in  $para(op)$  do
9            $e \leftarrow \mu_{index} \times e;$  // Morph
10           $O_g.add(op);$  // GPU operators
11        else
12           $O_e.add(op);$  // TEE operators
13       $O_g.copyTo("cuda");$  // Partition to GPU

```

enclave) is a non-linear *ReLU* operator. If we only morph OP_1 with μ_1 and do not assign a coin to OP_2 , then, with a client input X , OP_1 outputs $y_1 = X(\mu_1 * OP_1)$ and OP_2 outputs $y_2 = ReLU(y_1/\mu_1) = ReLU(X * OP_1)$. However, since the *ReLU* operator only filters out negative values in parameter matrices and does not transform a scalar, an adversary who observes both y_1 and y_2 will directly infer the value of coin μ_1 , violating the confidentiality of the partitioned OP_1 (concretely, $Para(O_i)$). To tackle this problem, we assign coins to all operators rather than partitioned GPU operators only. As demonstrated in the **After** case of Figure 4, by assigning coin μ_2 to OP_2 , OP_2 will output $y_2 = \mu_2 * ReLU(X * OP_1)$. An adversary observes $\mu_1 * \mu_2$ but has no way of inferring either μ_1 or μ_2 .

Overall, by morphing both the enclave and the partitioned GPU operators with blinding coins stored in TEE enclave, an attacker cannot deduce the blinding coins from the IRs, ensuring the confidentiality of the model parameter’s plaintexts. **Stage 1-2: Partitioning model with hidden operators.** With all coins prepared, given a partition ratio θ , we automatically partition a portion of associative operators (that are morphed) to GPU for inference acceleration. The *partition* function in line 1~13 of Algorithm 1 shows the pseudo-code.

Specifically, in the preprocessing phase, SOTER iterates every operator in model M and randomly selects a portion of associative operators and adds them to the partition set O_g . For instance, with $\theta = 0.8$, an associative operator would have an 80% chance to be partitioned to GPU. After all operators are iterated, all operators in O_g are partitioned to GPU for inference acceleration.

Note that, SOTER always keeps top- W ($W=2$ by default) operators in enclave even if these operators are associative (Line 4). This design choice is made to ensure the input to the first several partitioned operators on GPU (e.g., X_1 in Figure 3) are always unknown to the adversary, such that we can stealthily check the integrity of all partitioned operators by injecting fingerprint challenges (more details in §4.2).

Stage 2: Guarded black-box inference. Next, we present the

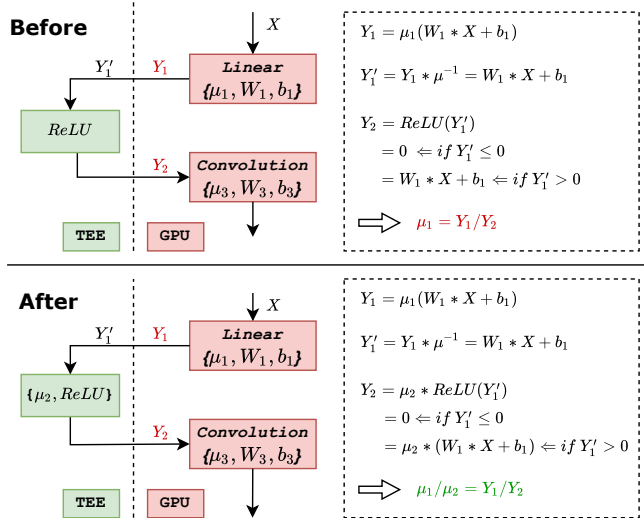

Figure 4: Morphing only partitioned operators' parameters can leak the blinding coins in some partition cases.

end-to-end black-box inference process given that we have prepared coins and partitioned a portion of operators to GPU.

As shown in Algorithm 2, SOTER first computes the reserved top- W operators in enclave, and then iterate **I2**~**I4** as follows. **I2**: SOTER finds the longest length of consecutively partitioned operators in O_g and computes the inference result by forwarding the input through these operators (line 6~11). **I3**: Then SOTER copies the result back to enclave, restores the real inference result by multiplying the reciprocal coins of all operators in the last step (line 13), and then forwards the result to operators maintained in enclave (before the next copy to GPU). **I4**: SOTER morphs the forwarding result with all coins of enclave operators in the last step (line 18), and then copies back to GPU. This procedure terminates when all partitioned operators on GPU are iterated. Then SOTER normalizes the final result and returns the result to the client.

4.2 Integrity checking with fingerprints

Obliviousness requirement. To detect integrity breaches outside an enclave (as described in §3.2), a straw man approach could be using a fingerprint (with ground-truth input/output pair) to *challenge* the partitioned operator on GPU to recompute the fingerprint input to provide *proof*, and report a crime if the proof is different from the expected output.

However, such an approach needs to be oblivious. Since the adversary can continuously monitor the inference process and observe every intermediate result (IR) transmitted from enclave to GPU, if using only a fixed set of fingerprints, the adversary can easily distinguish those fixed challenges among all IRs, and bypass our detection by returning correct proofs. **The timeliness-obliviousness dilemma.** Unfortunately, trivially using different fingerprints for integrity checking brings a *timeliness-obliviousness* dilemma.

Specifically, generating new fingerprint input and pre-

Algorithm 2: MTR protocol at client c (online) (§4.1).

```

1 Function secure_inference() do
2    $\nabla$  I1.
3    $X \leftarrow \text{copyTo}(\text{"enclave"})$ ;
4   foreach index  $i \in \text{normalize}(W)$  do
5      $X \leftarrow O_i(X)$ ; // Top-W Inference
6   start  $\leftarrow$  next op in  $O_g$ ; end  $\leftarrow$  next op in  $O_e$ ;
7   while start < | $O$ | do
8      $\nabla$  I2.
9      $X \leftarrow \text{copyTo}(\text{"cuda"})$ ;
10    foreach index  $i \in \text{range}(\text{start}, \text{end})$  do
11       $X \leftarrow O_i(X)$ ; // GPU Inference
12     $\nabla$  I3.
13     $X \leftarrow \prod_{\text{start}}^{\text{end}-1} \mu_i^{-1} \times X$ ; // Restore
14    start  $\leftarrow$  end;
15    end  $\leftarrow$  start from  $O_{\text{end}}$  find the next op in  $O_g$ ;
16    foreach index  $i \in \text{range}(\text{start}, \text{end}-1)$  do
17       $X \leftarrow O_i(X)$ ; // TEE Inference
18     $\nabla$  I4.
19     $X \leftarrow \prod_{\text{start}}^{\text{end}-1} \mu_i \times X$ ; // Morph
20   $X \leftarrow \text{normalize}(X)$ ;
21  return Top $_1(X)$ ; // Final result

```

computing expected output in CPU would cause late detection, because CPU computation for an operator is extremely slow (up to 30x slower inference speed for linear operation); on the other hand, if we use a fixed set of fingerprints for challenging the integrity, we could timely detect breaches. However, the detection would be easily bypassed by the adversary because all fingerprints are now distinguishable.

SOTER's insight and approach. Stemming from the same observation of parameter morphing (§2.1), we tackle this challenge by efficiently generating new fingerprints in CPU without re-computing operators. At a high level, we take two steps by first making a set of *cornerstone fingerprints* for each partitioned operator, and then encapsulating new fingerprints from these cornerstone fingerprints with a constant cost at runtime based on the associativity property.

Step 1: Preparing cornerstone fingerprints. During the pre-processing phase, SOTER prepares K (by default $K=10$) cornerstone fingerprints for each partitioned operator. A fingerprint is a two-element tuple: $\{\text{input}, \text{output}\}$, where the input is a randomly generated matrix and the output is pre-computed by forwarding the input through a ready-to-partition operator. The whole preparing procedure is running within enclave, such that the correctness of each cornerstone fingerprint can be guaranteed.

Step 2: Efficiently deriving new fingerprints in TEE. Now with K cornerstone fingerprints for each partitioned operator, SOTER efficiently derives oblivious fingerprints at runtime by leveraging the general associativity property. Specifically, with a fixed set of cornerstone fingerprints $FP_O[K]$ for each

partitioned operator O , we randomly select T fingerprints and generate T random coefficients with SGX’s trustworthy random number generator. Then, by applying the associativity property (Equation 2), we generate a new fingerprint FP_{New} as follows: the input for FP_{New} is $\sum_{i=1}^T T_i * FP_O[i].input$, i.e., we multiply each selected cornerstone fingerprint’s input with a corresponding coefficient and add them all as the new input; For the output, since the associativity property implies that the corresponding output for a group of associated operators has the same transformation as the input, thus we can directly get the expected output as $\sum_{i=1}^T T_i * FP_O[i].output$ without conducting slow CPU inference for a given new input.

Step 3: Challenge-proof fingerprint issuing. For fast detection of integrity breaches, rather than submitting fingerprint challenges for random user inference tasks, SOTER submits fingerprint challenges for every user inference task. By doing so, SOTER can detect any integrity breaches within only ten fingerprints with an overwhelmingly high probability of 99.9% according to our theoretical analysis and evaluation results (§6.4).

In detail, SOTER issues a *challenge* whenever a kernel switch (an IR transmitted from enclave to GPU) happens. When an IR (produced by client’s query) is sent to a partitioned operator O , we challenge the integrity of O by sending the IR to O together with a new $FP_O.input$ (produced in Step 2), and compare the returned *proof* with the expected $FP_O.output$. Any mismatch reveals an integrity breach of partitioned operator O .

Whenever integrity breaches are detected, SOTER can simply abort the inference process and restart the preprocessing phase to prepare new blinding coins and re-morph the GPU operators with the procedures described in §3.3.

5 Implementation

We built SOTER on top of PyTorch C++ [51] with 5.3K LoC. We chose PyTorch C++ as it incurs less memory footprint compared to PyTorch, and previous work [63] has shown that running programs with a high memory footprint within SGX could incur prohibited overhead due to SGX’s small memory capacity. SOTER uses Graphene-SGX to run SOTER’s components within an SGX enclave (denoted as SOTER-Graphene), because Graphene-SGX provides a library OS for running applications within the enclave without any modifications.

Due to SGX’s limitation (§2.2), Graphene-SGX cannot directly access GPU within the enclave. SOTER tackles this problem by spawning an extra PyTorch process (SOTER-GPU) outside the enclave for offloading computations to GPU. SOTER-Graphene and SOTER-GPU communicate through shared memory (untrusted and not protected by SGX). We did not choose to modify Graphene-SGX to forward GPU computations at the syscall-level (e.g., by modifying `ioctl`), because doing so results in frequent enclave transitions for each GPU task. This is because launching one GPU task requires multiple system calls (e.g., `ioctl` and `mmap`).

Runtime Construction. SOTER builds the runtime according to the two-phase design (§3). In the *preprocessing* phase, SOTER bootstraps the enclave with the standard SGX attestation library [14], and decrypts the model (in ONNX format [42]) sent from the server in the client enclave. The enclave bootstrapping takes 1.84~2.92 seconds. Then, the decrypted model is processed by `enclave_model_dispatcher`, which randomly selects a major fraction of associative operators and morphs these operators’ parameters with random scalars produced by the SGX trustworthy source (`sgx_read_rand`).

In the *inference* phase, SOTER-Graphene runs inferences on DNN layers stored within TEE. When an inference computation needs to be offloaded outside the enclave, SOTER-Graphene serializes the activation using `pickle`, pushes the data to the shared memory and hands over to SOTER-GPU; SOTER-GPU deserializes the data and the morphed model, computes the results, and pushes the result to the shared memory; SOTER-Graphene retrieves the results and continues execution.

Optimization. First, SOTER reduces the memory footprint by reusing a single `paraheap` buffer to store operators’ parameters, and gradually loading and decrypting parameters from disk when they are required for computations in CPU. Second, SOTER enables SGX paging [14] to support the execution of large DNN models. Note that all baseline systems we evaluated were also enabled with these two optimizations. Third, SOTER takes unused CPU cycles to provision new coins and produce newly morphed operators in TEE (§4.1), to replace staled partitioned operators on GPU in a nonstop manner.

6 Evaluation

Testbed. Our evaluation was conducted on a server with 2.60GHZ Intel E3-1280 V6 CPU, 64GB memory, and SGX support. The partitioned computations were performed on a co-located Nvidia 2080TI GPU with 11 GB physical memory.

Baseline systems. To evaluate the performance of SOTER, we compared SOTER with three notable TEE-based secure inference systems, namely MLCapsule [27], AegisDNN [68] and eNNclave [56]. MLCapsule is a popular TEE-shielding open-source project, which shields the entire model within the CPU enclave without any modification to parameters, thus achieving model confidentiality, integrity (no partitioned operators outside enclave) and retaining high accuracy as the original trained model.

AegisDNN and eNNclave are two state-of-the-art partition-based systems that empower accelerator-assisted low-latency inference same as SOTER (Table 1). AegisDNN only shields partial critical model layers in enclave and accelerates other plaintext layers on a GPU. To decide which layers should be partitioned, AegisDNN takes a user-specified argument (i.e., deadline for an inference task) and uses a silent data corruption mechanism [23] to learn each layer’s criticality. AegisDNN is not open-source so we implemented all its protocols. eNNclave handcrafts a partition plan by manually replacing

Figure 5: Normalized latency of all systems running six prevalent models. All systems’ latency results are normalized to **insecure GPU** inference latency (red dotted line). The value on each red bar indicates SOTER’s averaged inference latency.

some layers’ parameters with public insensitive parameters, and running these parameter-precision downgraded layers on a GPU. Hence, eNNclave achieves model confidentiality at the expense of accuracy, and is only suitable for specific models with publicly available parameters of known layers. We ran eNNclave based on its open-source implementation.

Note that, both AegisDNN and eNNclave do not provide integrity protection for a partitioned model. While some approaches (e.g., Darknight [28]) have integrity protection for computations on untrusted accelerators, they are not designed to protect model confidentiality at the untrusted edge; hence they are orthogonal to the goals of SOTER.

Models and datasets. We evaluated all baseline systems with six well-studied DNN models in the three most popular categories that are widely used in the deep learning community, including a Multi-layer Perception (MLP) model, four Convolution Neural Network models including Alexnet (AN) [38], Densenet121 (DN) [31], VGG19 (VGG) [61], Resnet152 (RN) [29], and a Transformer (TF) [64]. We used the open-source release of each model.

We conducted our study on two representative datasets, ImageNet [16], and WNMT [57], targeting both computer vision (CV) and natural language processing (NLP) tasks. ImageNet is a full-scale image dataset that contains 600k images from 1k classes for CV studies; WNMT is the major translation dataset that has been used in recent NLP studies.

Default setting. By default, we ran all experiments by sequen-

SOTER’s inference results (in milliseconds)

Table 4: End-to-end latency breakdown of AegisDNN.

tially feeding the inference data (i.e., *input_batch_size=1*). Unless conducting sensitivity studies, we ran SOTER with 80% probability of partitioning an associative operator to run on a GPU (i.e., *selective partition ratio=0.8* in §4.1).

Our evaluation focuses on the following questions:

§6.1 How efficient is SOTER compared to baselines?

§6.2 How sensitive is SOTER’s performance to different partition ratio?

§6.3 What could be leaked with and without SOTER?

§6.4 How robust is SOTER under integrity breaches?

6.1 End-to-end inference performance

We first investigated the end-to-end inference latency of SOTER and three baseline systems with six prevalent models. All reported measurements are the averaged inference latency of 10k independent inference input.

Figure 5 shows the comparison of normalized inference latency, where all systems are normalized to the insecure GPU inference, which was measured by directly running model inference on GPU without protection. SOTER’s end-to-end latency (in milliseconds) is reported on its bar. N/A means a system cannot handle such a case because eNNclave only reports its method on partitioning VGG-series models. Overall, SOTER’s latency was $1.21X \sim 4.29X$ lower than MLCapsule when running inferences on the same model. This is because MLCapsule shields the entire model in the CPU enclave without involving GPU, and CPU is at least one order of magnitude less efficient than GPU in executing inference tasks [62].

Meanwhile, SOTER incurred $1.03X \sim 1.27X$ higher latency compared to AegisDNN for two reasons. First, SOTER additionally enforces integrity protection of partitioned operators on GPU (§4.2) while AegisDNN does not support integrity check. Second, AegisDNN partitions models in a coarse-grained manner: by packing consecutive layers into blocks and partitioning these blocks to run on a GPU, AegisDNN reduces the number of kernel switches (memory copy) between enclave and GPU. In contrast, SOTER partitions model in a fine-grained operator granularity, thus may incur more kernel switches on some models. Next, we evaluate this moderate performance downgrading with a detailed latency breakdown.

Figure 6: Running SOTER on (a) VGG19 with different input shapes (*batch_size, channels, height, weight*), and (b) Transformer with different token size.

Latency breakdown. To understand SOTER’s low latency and moderate overhead, we recorded the time taken for each step of the workflows in SOTER and AegisDNN, as shown in Table 3 and Table 4.

In addition to the integrity check and kernel switch overhead, we observed that SOTER took more time for enclave computations by comparing **P1** in both tables. This is because SOTER provides confidentiality for all model operators by either shielding plaintext operators in enclave, or selectively morphing associative operators to run on a GPU and reverting concealed execution results to accurate results in enclave with preserved blinding coins (§4.1). In contrast, AegisDNN only protects confidentiality for partial operators in enclave, and leaves other operators’ plaintext parameters to the untrusted GPU. Therefore, SOTER paid additional overhead for parameter morphing and restoration in enclave.

Besides, when running models with complex dependencies among operators (Resnet, Transformer), SOTER’s operator-level partition protocol incurred more frequent kernel switches than AegisDNN (**P3**), but such design protects the entire model architecture from being leaked. As recent work on AI demonstrates that model architecture has a significant impact on achieving high inference accuracy [2, 22], a complex, thus potentially well-designed architecture is urgent to get protected. In contrast, AegisDNN partitions a bunch of consecutive layers to GPU thus leaking architecture information to the adversary outside enclave. We will further investigate the information leakage in all systems in §6.3.

Overall, compared to the TEE-shielding baseline (MLCapsule [27]), SOTER achieves lower inference latency by securely partitioning most associative operators to run on an untrusted GPU, and the performance gain brought by GPU computations on associative operators dominates the overhead for TEE paging and TEE-GPU interaction (Table 3). Typical associative operators (e.g., convolution and fully connected) are proven to be the major computational bottleneck in neural networks. For example, 93.5% of the computation on the classic VGG19 model is spent on convolution [61]. However, compared with the partition-based baselines (eNnclave [56] and AegisDNN [68]), SOTER incurs slightly higher (up to 1.27X) latency for using fingerprints to detect integrity breaches (latency breakdown in Table 3 and Table 4).

No accuracy loss. SOTER retained high inference accuracy provided by original models, because SOTER ran either unmodified operators in enclave or morphed associative operators in GPU, while concealed execution results of morphed operators can be reverted with the associativity property (§2.1). MLcapsule directly shields the entire model in enclave without modification so it retained high original accuracy; AegisDNN partitions plaintext model layers to run on a GPU so it incurred no accuracy downgradation as well; eNnclave obfuscates partitioned operators’ parameters by replacing them with public parameters. Since public parameters are not tailored for a given task, eNnclave incurred 1% ~ 5.5% accuracy drops on the evaluated VGG19 model.

In summary, SOTER achieves much lower inference latency than MLcapsule, but SOTER incurs slightly higher latency than AegisDNN and eNnclave because SOTER pays additional effort to provide stronger model confidentiality and integrity, and retains high accuracy same as original models.

6.2 Sensitivity

We tested different partition ratios (denoted as θ) to look into the performance sensitivity of SOTER. The experiments were conducted on VGG19 with different input shapes, and we ran different values of θ for each input shape; each experiment was conducted ten times, as shown in Figure 6a.

The shading next to each line is the performance jitter caused by different computation volumes of randomly selected associative operators partitioned to GPU. With an increased θ , SOTER’s inference latency dropped accordingly because more associative operators were selected and partitioned to a co-located GPU for acceleration. Interestingly, we observed that when θ is small (0.1 ~ 0.2), the latency of $\theta = 0.2$ could be even larger than $\theta = 0.1$. This instability is because, with a small partition ratio, the partitioned operators were fragmented, and GPU’s performance gain could be amortized by the frequent kernel switches between enclave and GPU. When θ increases, the latency gain became more stable because the partitioned operators became less fragmented, thus fewer kernel switches would occur.

Comparing figure 6a with figure 6b, we observed that SOTER achieved more stable performance on Transformer. This is because, the number of operators in VGG19 is relatively limited (only 41 associative operators with 18 linear operators), while the Transformer has a rich set of operators (360 associative operators with 311 linear operators). Hence, the randomness of selecting associative operators with different computation volumes was downgraded, leading to a more stable performance. This implies that SOTER is more suitable for big complex models with a rich set of operators.

6.3 Security analysis

As mentioned in §3.2, SOTER provides *semantic security* guarantee for protecting model confidentiality: knowing only ciphertexts of parameter-morphed operators, it is infeasible

Figure 7: The model stealing experiments of all baseline systems running (a) VGG19 and (b) Transformer. The red dotted line marks the ground-truth accuracy/ BLEU score of VGG19 and Transformer respectively.

for a computationally-bounded adversary to learn about operators’ *exact* blinding coins hidden in enclave. It is notable that increasing the number of partitioned morphed operators (with a larger θ) does not degrade the confidentiality because (1) SOTER generates coins for each operator independently in enclave, and (2) an execution result of a morphed operator is concealed to ensure that it reveals neither the coin of that operator, nor the coins of all previous operators (§4.1).

Quantifying information leakage. To evaluate whether our confidentiality analysis given above has a meaningful effect in practice, we applied model stealing attacks [35, 47] on all baseline systems to quantify how much information could leak with that system. A model stealing attack feeds synthetic data to a *victim model* to get an output, and trains a *substitute model* (depicted as Sub_M) with these new samples to mimic the inference behavior of the *victim model*.

- *Setup.* We targeted two popular models, VGG19 and Transformer, running on all baseline systems. We did not run Transformer on eNNclave because eNNclave does not support such a case. We conducted the state-of-the-art Wang’s attack [67] for model stealing. Concretely, for the training dataset, with the bounded computational capability assumption [35], we generated synthetic data which composes 10% of total training samples; for the backbone of the substitute model, we adopted VGG13 as the architecture for VGG19 and the standard encoder/decoder architecture for Transformer. We initialized all unknown parameters using a truncated normal distribution with std of 0.02 and learning rate of 0.0001. By training on one Nvidia 2080TI GPU, Sub_{VGG} converged within 150 epochs and Sub_{TF} converged within 13 epochs.

- *Results.* Figure 7 depicts the inference results of the trained substitute model on all baselines. MLCapsule, which shields the entire model within enclave (i.e., $\theta = 0$), achieved the minimum accuracy through the stealing attack. The accuracy results of AegisDNN grew as θ increased, because AegisDNN only runs partial model layers in enclave and exposes other layers with plaintexts to the adversary. With more plaintext revealed in AegisDNN, the accuracy of Sub_{VGG} and BLEU of Sub_{TF} increased dramatically. SOTER, however, achieved comparable results as eNNclave, which directly replaces partitioned operators’ parameters with insensitive public parame-

Figure 8: The l_2 distance distribution of randomly sampled fingerprints with or without oblivious fingerprinting technique.

ters. Notably, this implied that SOTER’s MTR protocol with semantic security guarantee is effective to provide sufficient model confidentiality.

6.4 Robustness to integrity breaches

In this subsection, we begin by investigating the obliviousness of SOTER-generated fingerprints for obfuscating the adversary. Then we evaluated SOTER’s robustness to integrity breaches of partitioned operators outside enclave.

Figure 8 shows that, when running with SOTER’s oblivious fingerprinting technique, the l_2 distance between randomly sampled fingerprints shares the same form of normal distribution as normal query input (Figure 8a). Hence the fingerprints are oblivious to the adversary. Whereas, when running with fixed fingerprints (Figure 8b), the distribution dramatically changed, hence those fixed fingerprints are observable to the adversary. We evaluated the robustness of SOTER under 10K random perturbation attacks, which randomly perturbs the parameters of partitioned operators. All attacks were successfully detected, and 99.9% attacks were detected with less than ten fingerprints while we incurred zero false positives.

7 Discussion

Model leakage from black-box attacks. Modern black-box attacks [4, 35, 47, 50] use inference APIs of an inference service to learn private information of an offloaded model or even the training dataset, by using the inference results of perturbed input queries. These attacks widely exist in either cloud-side or client-side inference systems [27, 36, 44, 56], as inference systems inevitably open access to arbitrary queries.

Currently, there is no general defense against black-box attacks other than query authentication and rate limiting [35, 47]. But fortunately, defenses against specific attacks are emerging. For instance, Prada [35] uses query distance auditing to mitigate model extraction attacks with adversarial examples; Shokroi et al. [60] use differential privacy to train DNNs that do not leak model owner’s sensitive training datasets.

The guarantees of SOTER, like all prior secure inference systems targeting at protecting the model at the edge or the cloud, are complementary to those provided by any defenses. With sufficient engineering effort, these mitigations can be integrated into SOTER to provide even stronger privacy guarantees, and we leave it to future work.

Computation overflow. Multiplying the model parameter with SOTER’s blinding coin (§4.1) may, in rare cases, causes

potential computation overflows (we did not find any computation overflow in our experiments in §6). However, even if an overflow occasionally happens, SOTER can immediately detect such overflow by checking if the computed result is INF or -INF [39]. Then, SOTER can simply re-morph the overflowed GPU operator by replacing the blinding coin with a smaller new coin, which can be prepared offline (§4.1).

Trusted GPU. Although there are some promising trusted GPU research systems [3, 32, 46, 65] that can protect model confidentiality and accelerate inference with the strong GPU computing power, these systems are not publicly available as they either require extensive hardware modifications [65] or support only hardware simulators [3, 32, 46]. Thus, in this paper, we consider only publicly available (untrusted) GPU deployments.

Limitation. SOTER requires clients at the edge to be equipped with TEE (e.g., Intel SGX) due to the lack of commonly available trusted GPUs [3, 65]. SGX has been pervasively used in existing secure inference systems [27, 56] and is commonly available in modern Intel CPUs. While the inherited SGX vulnerabilities of sophisticated side-channel attacks based on timing or cache access patterns still exist [18, 59, 66], we do not consider these attacks currently, and we believe these attacks can be mitigated by integrating with state-of-the-art defenses [18, 19, 55].

8 Conclusion

We present SOTER, the first secure inference system that ensures model confidentiality, low latency, high accuracy with integrity protection for general DNN models. SOTER's MTR protocol carries out cooperative executions between the TEE and GPU. Specifically, SOTER morphs a fraction of associative operators' parameters to run on a GPU, SOTER conceals the execution results on GPU and then restores the real execution results in TEE. SOTER efficiently generates fingerprints to check the integrity of partitioned operators. Evaluation on notable client-side secure inference systems and all prevalent types of DNN models shows that, compared to existing relevant baselines, SOTER achieved comparable strong confidentiality as the TEE-shielding approach, comparable low-latency as the partition-based approach, high accuracy same as insecure inference, and overwhelming high probability of detecting integrity breaches of any partitioned operators. These features make SOTER unique in encouraging enormous model providers to develop powerful models and deploy them on third-party edge devices.

IPLFS: Log-Structured File System without Garbage Collection

Juwon Kim Minsu Jang Muhammad Danish Tehseen Joontaek Oh Youjip Won
Department of Electrical Engineering, KAIST

Abstract

In this work, we develop the log-structured filesystem that is free from garbage collection. There are two key technical ingredients: *IPLFS*, a log-structured filesystem for infinite partition, and *Interval Mapping*, a space-efficient LBA-to-PBA mapping for infinite filesystem partition. In IPLFS, we separate the filesystem partition size from the physical storage size and set the size of the logical partition large enough so that there is no lack of free segments in the logical partition during SSD's lifespan. This allows the filesystem to write the updates in append-only fashion without reclaiming the invalid filesystem blocks. We revise the metadata structure of the baseline filesystem, F2FS, so that it can efficiently handle the storage partition with 2^{64} sectors. We develop Interval Mapping to minimize the memory requirement for the LBA-to-PBA translation in FTL. Interval Mapping is a three level mapping tree. It maintains mapping only for actively used filesystem region. With Interval Mapping, the FTL can maintain the mapping for the 2^{64} sector range with almost identical memory requirement with the page mapping whose LBA range is limited by the size of the storage capacity. We implement the IPLFS on Linux kernel 5.11.0 and prototype the Interval Mapping in OpenSSD. By eliminating the filesystem level garbage collection, IPLFS outperforms F2FS by up to $12.8\times$ (FIO) and $3.73\times$ (MySQL YCSB A), respectively.

1 Introduction

Log-structured filesystem [49] has become a popular storage management system due to its unique append-only nature. This append-only nature brings significant performance advantage against the journaling-based counterparts in practically all types of storage devices including hard disk [49, 50], flash storage [35], shingled magnetic recording (SMR) drive [44] and even persistent memory [55].

The append-only nature of the log-structured filesystem brings another dimension of complexity to the filesystem: the *garbage collection*. As the log-structured filesystem ages, the filesystem runs out of free segments and needs to reclaim the obsolete filesystem blocks to make

more free segments. The activity of reclaiming the invalid blocks is called *garbage collection*. When the filesystem performs the garbage collection in the foreground, it freezes the entire filesystem till it completes [2]. The garbage collection exposes the underlying log-structured filesystem under excessive tail latency and lowers the throughput of the filesystem. The garbage collection also generates extra write traffics that increase flash wears.

A fair amount of works have been dedicated to mitigate the overhead of garbage collection in the log-structured filesystem. They include performing the garbage collection in the idle period [10, 43, 47], performing the garbage collection in a preemptive way [37], selecting the right victim segment to maximize the garbage collection efficiency, e.g. greedy, cost-benefit, age, etc [27, 41]. Some works proposed to cluster the file blocks with a similar lifespan together to improve the efficiency of the garbage collection [31, 35, 48]. The overhead of device-level garbage collection is also of serious concern. A large body of works are dedicated to mitigate the overhead of the device-level garbage collection [12, 36, 61]. When the log-structured filesystem is used with flash storage, the overhead of garbage collection may compound due to the garbage collection activities at the filesystem as well as at the device [58]. A number of works proposed to enable the host filesystem to directly manage the flash pages in the storage and eliminate the device-level garbage collection [39, 59, 60]. Recently proposed ZNS (zoned name space) treats the storage device as append-only log so that address mapping and device-level garbage collection become much simpler [5, 20]. Despite all these efforts, the root cause of garbage collection still remains neglected; the filesystem needs to reclaim the invalid filesystem blocks to make the free segments.

For several decades, the operating systems have been separating the logical entity from the associated physical entity for various types of physical resources. The typical examples include virtualizing the CPU [13], virtualizing the memory [15] or virtualizing the entire computer system [11, 17]. Unlike the other physical resources, modern operating system still tightly couples the logical storage partition from the physical storage and the size of the logical partition is bounded by the capacity of the

physical storage.

In this work, we design the log-structured filesystem without garbage collection. We separate the logical partition from the physical storage and allow the filesystem to define very large logical partition independent of the capacity of the physical storage. We make the size of the logical partition large enough so that the filesystem never runs out of free segments during the lifespan of the flash storage. With very large logical partition, the filesystem does not have to reclaim the invalid filesystem blocks and therefore can eliminate the critical drawbacks of the log-structured filesystem, the garbage collection. In the absence of the garbage collection, we can greatly simplify the log-structured filesystem design.

Our work consists of two key ingredients. First is Log-structured filesystem for Infinite Partition, *IPLFS*. The second is the space-efficient LBA-to-PBA mapping, *Interval Mapping*. For IPLFS, we use F2FS as the baseline filesystem. Modern IO subsystem uses 64 bit **unsigned long** to represent the sector number. IPLFS allows that the logical storage partition for the log-structured filesystem can grow as large as 2^{64} sectors. When the filesystem writes the disk block in an append-only manner, the lifespan of flash storage is going to expire long before it reaches the end of the filesystem partition. IPLFS ensures that the number of valid blocks does not exceed the physical storage partition. IPLFS eliminates the allocation bitmap and the reverse mapping information from the log-structured filesystem. We develop *Discard Bitmap* and *Discard Logging* to discard the invalid filesystem blocks. To support prohibitively large LBA space, we develop a space efficient LBA-to-PBA mapping, Interval Mapping FTL. Interval Mapping maintains the LBA-to-PBA mapping information only for the actively used filesystem regions. The contribution of our work can be summarized as follows.

- We successfully eliminate the key complication, garbage collection, from the log-structured filesystem. We analyze the metadata structures of the log-structured filesystem and redesign the log-structured filesystem to handle very large filesystem partition.
- In the absence of garbage collection, we greatly simplify the log-structured filesystem design. We eliminate the block allocation bitmap and reverse mapping from the log-structured filesystem. We develop space-efficient and crash-safe data structures to represent the invalidated filesystem blocks that need to be discarded at the storage, *Discard Bitmap* and *Discard Log*.
- We develop space efficient mapping scheme, *Interval Mapping*. With tree-based structure, Interval Mapping maintains the mapping only for the actively used filesystem region and can handle the LBA-to-PBA mapping for 8 ZByte logical storage partition.

- We develop *fixed-region mapping* and *map node compaction* to reduce the size of the mapping tree. With map node compaction, the fixed-region mapping periodically reorganizes the structure of the map node in the Interval Mapping tree to exclude the invalidated filesystem blocks from the map node.

Via eliminating the garbage collection overhead from the log-structured filesystem, IPLFS increases the benchmark performance by up to $12.8\times$ (FIO) and $3.7\times$ (MySQL YCSB-A) against F2FS, respectively. With fixed-region mapping, the memory overhead of Interval Mapping is limited by the size of the physical storage, not by the logical partition size. The memory overhead of Interval Mapping is similar to that of page mapping.

2 Background

2.1 Flash Translation Layer

Flash Translation Layer is mainly responsible for three tasks: LBA-to-PBA mapping, the garbage collection, and the wear-leveling. All these three features are for hiding the physical characteristics of the flash storage media: inability to overwrite, asymmetry between the read latency and write latency and limited erase/write cycles. FTL maintains a table that holds the physical locations of the individual logical blocks in the storage device. This data structure is called *mapping table*. The size of the mapping table is proportional to the number of LBA's which it needs to map and again it is linearly proportional to the capacity of the storage device visible to the host. Page mapping maintains mapping information in page granularity [7]. While it exhibits superior random write performance [34], it suffers from excessive memory pressure for the mapping table. Block mapping maintains a mapping in the granularity of the flash block, e.g. 2 MByte. It reduces the memory pressure for the mapping table but it leaves the SSD under block thrashing [28, 34, 38]. Hybrid mapping applies block mapping for data blocks and page mapping for log blocks to reduce the mapping table size and to avoid block thrashing in the block mapping [18, 28, 29, 42, 45].

DISCARD (or TRIM) command [52] informs the SSD that a given set of blocks in the storage are no longer needed by the filesystem. It is proposed to prohibit the garbage collection module of FTL from blindly migrating the flash pages whose contents are invalid [25].

2.2 Lifespan of the Flash Storage

Flash storage can be erased and programmed only a limited number of times [23]. Table 1 illustrates the TBW (TeraBytes Written) of flash storage products released between 2019 to 2020. TBW is the amount of data that

Manufacturer	Model	Release	TBW
Adata	XPG Gammix S50	2019	3,600
Samsung	970 EVO Plus	2019	1,200
Patriot	Viper VPR100	2019	3,115
Sabrent	Rocket Q	2019	1,800
Samsung	S980 PRO	2020	600
Samsung	870 QVO	2020	2,880
T-Force	Cardea Zero Z340	2020	1,665
WD	Black SN850	2020	1,200
SK hynix	Gold P31	2020	750

Table 1: TBW(terabytes written) of the SSD products

Dataset	Write volume (GB/day)	Time to exhaust address space (M year)
YCSB SSD [56]	1,159	20
Systor [51]	57	422
Nexus 5 [21]	13	1,853

Table 2: Daily write volume and estimated SSD lifespan, traces are from SNIA open dataset [4]

can be written to the SSD over the lifespan of the drive. In Table 1, the largest TBW corresponds to 3.6 PByte.

The actual amount of data that is written to the storage device is much smaller than what the storage device can sustain. We compute the per-day write volume from the real IO traces [4](Table 2). They correspond to IO traces in the Key-value storage [56], SYSTOR [51], and smartphone [21]. Key-value storage engine generates the largest amount of write among the three traces; it writes 1.13 TByte per day to the storage.

The modern OS uses 64 bit, **unsigned long** type, variable to represent the sector number (LBA). With **unsigned long** type variable, the host can create the logical partition of 2^{64} sectors. The size of the logical partition corresponds to 8 ZByte. With 8 ZByte logical storage partition, the log-structured filesystem can keep appending the updated blocks at the end of the active filesystem region without reclaiming the invalid filesystem blocks. The lifespan of the underlying SSD will expire long before the filesystem reaches the end of the logical partition of 8 ZByte. For YCSB-A workload in Table 2, it will take 20 million years to exhaust the 8 ZByte filesystem partition.

2.3 F2FS, a log-structured file system

F2FS is the log-structured filesystem specifically developed for the flash storage. Despite the promising characteristics, the preceding log-structured filesystems [49, 50] have failed to be widely deployed in the commodity hardware with the prime cause for the failure being the overhead of reclaiming the invalid blocks. F2FS is the first log-structured filesystem that has gained the publicity successfully. It is the default filesystem for wide variety of Android devices ranging from smartphone to

automotive [1].

F2FS divides the filesystem partition into two areas: metadata area and data area. F2FS updates the contents in the metadata area in an in-place manner and writes the data area in an append-only manner. The metadata area contains the filesystem metadata such as a superblock, a checkpoint pack, a block allocation bitmap for each segment (a segment information table, SIT), and reverse mapping information (the file id and the file offset) for each segment (segment summary area, SSA). To avoid the wandering tree problem of the out-of-place update associated with the log-structured filesystem [8], F2FS clusters the file index blocks for all files in the filesystem together in the metadata area (a node address table, NAT) and updates it in an in-place manner. F2FS organizes the data area as a set of zones. A zone consists of a set of sections and a section consists of a set of segments. The segment is the unit of disk write and the section is the unit of garbage collection. In most (if not all) deployment of F2FS, a zone and a section consist of a single segment.

F2FS defines two block types (node and data) and three hotness levels (hot, warm, and cold) to represent the update frequency of a filesystem block. The node block corresponds to the inode or the index block of the file. There are total six combinations of block type and hotness level pair. F2FS maintains the six active segments in memory for each combination. F2FS places the blocks of the same type and temperature at the same active segment. When the active segment is full, it is flushed to the storage device. F2FS clusters the filesystem blocks with the same type and hotness level together at the flash storage. This is to reduce write-amplification caused by the device level garbage collection.

F2FS reclaims the invalid filesystem blocks either when the filesystem is idle (background garbage collection) or when there runs out of free segments (foreground garbage collection). In background and foreground garbage collection, F2FS uses cost-benefit policy [41] and greedy policy [27], respectively, in selecting the victim section.

For crash recovery, F2FS reads the most recent checkpoint pack from the disk and recovers the filesystem state with respect to the time of the most recent checkpoint. Then, F2FS scans the node area of the filesystem, and identifies the files that have been made durable via `fsync()` after the most recent checkpoint. For each such file, F2FS compares the node block at the time of checkpoint and the node block synchronized to the disk via `fsync()` and identifies the newly allocated blocks and the invalidated blocks in the file. For the newly allocated blocks, F2FS updates the associated filemap. For invalidated blocks, F2FS invalidates the block allocation bitmap in the segment information table in memory. After reconstructing the allocation bitmap, the recovery

Figure 1: Active Region w in the logical partition

module creates the discard commands for the invalidated blocks.

When a filesystem operation invalidates one or more blocks, e.g. `truncate()`, or `unlink()`, F2FS updates the associated bitmap in the segment information table. F2FS checkpoints the filesystem state either periodically or when the garbage collection is triggered. In checkpoint, F2FS constructs the discard commands for the invalidated filesystem blocks. When the checkpoint finishes, F2FS wakes up the discard thread. The discard thread dispatches the discard commands in a regular interval (default = 50 msec). It limits the number of dispatch commands that are sent at a time (default = 8). It dispatches the discard command only when the system is idle.

3 Design Overview

3.1 Design Philosophy

The fundamental design philosophy behind IPLFS is the *separation of the logical storage partition from the physical storage*. The log-structured filesystem [49] offers natural ground to separate the logical partition from the physical partition due to its level of indirection inherent in the out-place update filesystem. In the legacy in-place update filesystems, a file block is bound to the fixed location in the physical storage when the file block is allocated. It is non-trivial to separate the logical partition size from the physical partition size [24]. On the other hand, the log-structured filesystem dynamically updates the file mapping information to keep track of the location of the most recent version of the file block.

The existing log-structured filesystem [32, 35] limits the size of the logical partition to the size of the associated storage device and reclaims the invalid filesystem blocks when it runs out of free blocks in the logical partition. In this work, we set the size of the logical partition large enough so that there is no lack of free LBAs during SSD’s lifespan. Fig. 1 visualizes the usage pattern of the log-structured filesystem in the very large logical partition. X and Y axes denote time and LBA, respectively. As the filesystem ages, file blocks get invalidated. The window of actively used filesystem region, w , moves towards the higher end of its filesystem partition. Actively

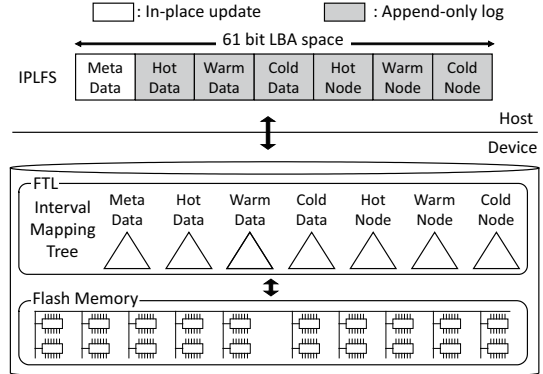

Figure 2: Concept: Log-structured filesystem for Infinite Partition, IPLFS, and Interval Mapping

used filesystem region starts at the lowest valid LBA and ends at the highest valid (allocated) LBA. Within the actively used filesystem region, w , some blocks are invalid and discarded at the storage device. When the size of the logical partition is very large, only a small fraction of the logical partition, w , is being accessed by the filesystem. The storage controller needs to maintain LBA-to-PBA mapping only for the actively used filesystem region, w .

3.2 Organization

Fig. 2 illustrates the main components of our system. Eliminating the garbage collection in the log-structured filesystem is achieved by two ingredients: Log-structured filesystem for Infinite Partition, *IPLFS* and FTL for very large logical partition, *Interval Mapping*. The first component is IPLFS. IPLFS uses F2FS as a baseline filesystem. The in-memory and on-disk structures of F2FS are carefully trimmed and modified so that it can handle the logical partition of 2^{61} blocks and that it can dispense with filesystem level garbage collection.

The second component is a space-efficient FTL, *Interval Mapping*. In most existing LBA-to-PBA mapping techniques, the number of entries in the mapping table corresponds to the number of blocks in the logical storage partition. These techniques become practically infeasible due to its prohibitive mapping table size when it needs to map 2^{61} blocks. Interval Mapping maintains an LBA-to-PBA mapping only for the actively used region in the logical storage partition. Interval Mapping is multi-level tree based mapping. By using the multi-level mapping, Interval Mapping tries to avoid allocating the mapping table entries for the invalid filesystem blocks.

4 IPLFS

IPLFS never recycles the blocks in the filesystem partition. This very nature enables IPLFS to dispense with garbage collection at the filesystem layer and yet can

Figure 3: Multi-area Partition of IPLFS

maintain its append-only update nature. IPLFS consists of three key design ingredients: (i) multi-area partition layout, (ii) garbage collection-less metadata design, and (iii) discard map and discard logging.

4.1 Multi-area Partition Layout

We partition the entire filesystem partition of IPLFS into seven areas of the same size (Fig. 3). One area (the first one) is used for hosting the metadata of IPLFS. It holds the filesystem metadata information such as superblock and the node address table. Existing log-structured filesystems treat the filesystem partition as a single log [49, 50] or two logs [35]. IPLFS has six logs each of which accommodates the filesystem blocks of the same type and hotness level. Via clustering the filesystem blocks with similar update frequency together, IPLFS maintains the size of the actively used filesystem region small. We use MSB 3 bits of the LBA address as the area identifier. The size of each area is 2^{58} blocks, 1 ZByte.

4.2 Metadata Design

We carefully design the metadata structure of IPLFS so that it can handle the very large filesystem partition. Particular care has been taken to minimize any changes in the on-disk layout of its baseline filesystem, F2FS. Log-structured filesystem provides two essential metadata: reverse mapping and block allocation bitmap. These data structures have two main usages: the filesystem level garbage collection and the block discard. These two data structures are no longer used for the filesystem-level garbage collection because IPLFS does not perform garbage collection. IPLFS cannot use the reverse mapping and block allocation bitmap for block discard purpose, either, due to the prohibitively large logical partition. The size of the block allocation bitmap and the size of the reverse mapping information are linearly proportional to the size of the filesystem partition. Given the filesystem partition of 2^{64} sectors, 8 ZByte, the size of the block allocation bitmap and the reverse mapping corresponds to 512 PByte and 8 EByte, respectively. IPLFS cannot afford the storage space for block allocation bitmap and reverse mapping.

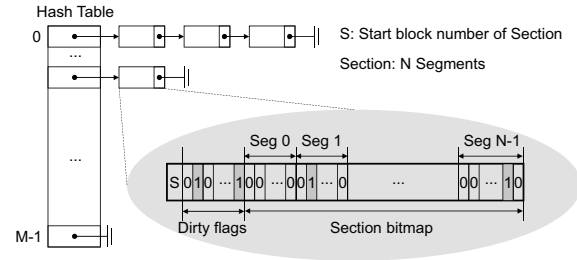

Figure 4: Discard Bitmap

IPLFS retains the node address table (NAT) in F2FS as is. The number of entries of the node address table corresponds to the maximum number of inodes in the filesystem partition. The number of inodes in the filesystem is limited by the capacity of the physical storage, not by the size of the logical filesystem partition. The size of node address table does not increase even though the size of the logical partition is very large.

In IPLFS, we remove the block allocation bitmap (Segment Information Table) and reverse mapping information (Segment Summary Area) from its baseline filesystem, F2FS and develop a new metadata structure for discarding the filesystem blocks, *Discard Bitmap* and *Discard Log*.

4.3 Discarding the Invalid Blocks

The log-structured filesystem maintains the block allocation bitmap for two reasons: to represent the space utilization of the individual segments and to keep track of the newly invalidated filesystem blocks. Former is for the filesystem-level garbage collection purpose and the latter is for discarding the filesystem blocks. In IPLFS, the former reason for maintaining the allocation bitmap disappears but the latter reason remains outstanding.

Eliminating the block allocation bitmap, we develop a new data structure, *discard bitmap*, that represents the newly invalidated filesystem blocks since the last checkpoint. IPLFS maintains the discard bitmap in per-section basis. In IPLFS, a section consists of more than one segments. A discard bitmap consists of two components: the start LBA of the section and the bitmap itself. When the filesystem invalidates the block, it sets the associated discard bit at the discard bitmap. IPLFS organizes a set of the discard bitmaps using the hash table. Fig. 4 illustrates the structure of the set of discard bitmaps. M and N correspond to the number of hash buckets in the hash table and the number of segments in a section. The hash table uses the section number as a hash key.

When a filesystem block is invalidated, IPLFS searches the hash table for the associated discard bitmap. If the discard bitmap is found, IPLFS updates the discard

bitmap with the newly invalidated block. If the associated discard bitmap does not exist, IPLFS allocates the discard bitmap for the section which the newly invalid block belongs to, and sets the associated bit of the block that needs to be invalidated. Then, IPLFS inserts the newly created discard bitmap at the hash table.

There is a trade-off between the section size and the filesystem performance. With a larger section size, the hash table for the discard bitmaps becomes larger. With a smaller section size, there exists more discard bitmaps in the hash table and the latency for searching the hash table becomes longer. Through experiment, we find that the section size of 1 GByte renders the reasonable balance between the filesystem performance and the memory pressure. In the later part of this paper, the section size is set as 1 GByte, i.e. 512 segments.

In each checkpoint, IPLFS scans the hash table and constructs the discard commands for each discard bitmap. After constructing the discard commands, it removes the discard bitmap from the hash table. IPLFS issues the discard commands periodically, e.g. in 50 msec interval. As in F2FS, IPLFS allocates a separate thread for dispatching the discard commands. IPLFS issues the discard commands in a more aggressive fashion than F2FS does. IPLFS dispatches the discard commands no matter whether there is a pending I/O or not. In F2FS, the dispatch thread issues the discard commands only when there is no pending I/O. In IPLFS, the dispatch thread issues up to sixteen discard commands each time when it wakes up. F2FS takes particular care to prohibit the discard command from interfering with the foreground IO requests [3]. We find in our platform (OpenSSD), the aggressive discard policy renders better benchmark performance since it makes the SSD garbage collection more efficient and reduces the write amplification.

4.4 Discard Logging

In the absence of the block allocation bitmap, IPLFS is subject to the *Storage Leak*. Storage Leak denotes the situation where the flash page contains invalid filesystem block and the filesystem never reclaims the associated flash page. Assume that the system crashes while there are outstanding discard commands. As a result of the system crash, the outstanding discard commands are lost. In F2FS, the recovery routine creates the discard commands based upon the recovered allocation bitmap.

Figure 5: Checkpoint Pack with Discard Logs

Figure 6: Roll-forward Recovery in IPLFS

Unlike F2FS, IPLFS does not have allocation bitmap and cannot reconstruct the discard commands that are lost due to crash. The flash pages associated with the lost discard commands will remain valid permanently even though they will no longer be used.

To save IPLFS from Storage Leak, we develop a mechanism called *Discard Logging*. In Discard Logging, IPLFS checkpoints the information associated with the discard commands prior to issuing the discard commands to the storage. With discard logging, IPLFS guarantees that discard command is made durable at the storage before it is issued to the storage. With Discard logging, IPLFS can recover the outstanding discard commands when the system crashes unexpectedly.

IPLFS allocates a certain region, *Discard Log Area* at the checkpoint pack (Fig. 5). At each checkpoint, IPLFS scans the discard bitmap and creates the discard commands. After it finishes creating the discard commands, IPLFS logs the information associated with the discard commands, [startLBA, Length], at the discard log area of the in-memory checkpoint pack. After it finishes preparing the checkpoint pack, it synchronizes the checkpoint pack to the disk. After the checkpoint, IPLFS wakes up the discard thread for issuing the discard commands.

When the system crashes, IPLFS recovers the discard commands in two phases. In roll-backward recovery, the recovery module reads the most recent checkpoint pack and reconstructs the discard commands with respect to the discard logs. In roll-forward recovery, IPLFS identifies the fsynced files after the most recent checkpoint. IPLFS compares the node block that is found at the roll-forward recovery phase and the node block at the time of the checkpoint. IPLFS then identifies the changes in the block allocation and updates the filemap with respect to the newly allocated node blocks. Based upon the difference on the block allocation, IPLFS identifies the invalidated filesystem blocks and constructs the discard commands for the invalidated blocks. Fig. 6 illustrates how IPLFS reconstructs the discard commands. At the time of the checkpoint, the node block of file B consists of three file blocks, a, b and c. After the checkpoint, the file block b is updated to b' and file block c is truncated in file B. Then, file B is synchronized to disk through

Figure 7: active region of the filesystem, I_j : active region at time t_j

`fsync()`. After `fsync()`, node block of file B refers to two blocks, a and b'. Block b' is newly allocated and block b and block c are invalidated. In roll-forward recovery, IPLFS updates the filemap of file B to refer to a and b' and creates the discard command for discarding b and c.

5 Interval Mapping

5.1 Design

We develop a space-efficient LBA-to-PBA mapping, called *Interval Mapping*. It is similar to interval tree [16] in that each leaf node has an interval of LBA's associated with it. Unlike interval tree, the height of the interval mapping tree is fixed to three. Limiting the height of the tree, the interval mapping increases the fan-out degree of the root node to accommodate the new leaf nodes. In designing the LBA-to-PBA mapping, we exploit the fact that in IPLFS, the actively used filesystem region moves towards the higher end of the logical storage partition as the filesystem ages. Fig. 7 illustrates how the active region moves with time. At t_1 , the active region corresponds to I_1 . At t_2 , the active region corresponds to I_2 .

In IPLFS, there are 2^{61} blocks in the logical storage partition. With 16 KByte flash page size, the page mapping table size for this storage partition corresponds to 4EByte. None of the existing mapping techniques such as block mapping [18], hybrid mapping [29, 34, 38, 40, 46], or superblock-based mapping [26] can reduce the mapping table size for LBA space of 2^{61} blocks to a manageable one. Interval Mapping addresses the prohibitive mapping table size requirement in IPLFS. Flash storage for IPLFS uses the page mapping for the metadata area and Interval Mapping for each of six data areas. Storage controller identifies the interval mapping tree for the incoming LBA using the most significant three bits of LBA.

Interval Mapping is organized as three level tree (Fig. 8). We limit the height of the mapping tree to three to reduce the number of memory accesses associated with the address translation. Interval Mapping organizes a storage area as an array of *zones*. The zone is an array of *mapping segments*. The size of the zone and the size of mapping segment correspond to 16 GByte and 16 MByte, respectively.

Figure 8: Structure of Interval Mapping Tree

A root node has a number of *zone nodes* as children. The sub-tree rooted at each zone node maintains a mapping for a single zone. When the interval tree is first created, the fan-out degree of the root node is set to 32. We increase the root node size to accommodate more child nodes when it is necessary. The maximum size of the root node is currently set to 1 MByte. With 1 MByte root node, the root node can have 2^{18} child nodes and can map up to 4 PByte of logical storage partition. It can be increased if the root node needs to map larger LBA region.

A single Zone node has 1024 *Map Nodes* as its child nodes. A map node maintains the LBA-to-PBA mapping for a single mapping segment. In map node, we avoid using plain table based mapping structure. Instead, for the compact mapping organization of the map node, we develop a new technique, *fixed-region mapping*, for the LBA-to-PBA mapping.

5.2 Mapping Interval and Active Interval

Interval Mapping defines two important concepts associated with mapping: the *Mapping Interval* and the *Active Interval*. Mapping Interval is a region of the logical partition that the interval mapping tree needs to map. Mapping interval is represented by the start LBA of the first zone and the start LBA of the last zone in the mapping interval, respectively. When the storage partition is created, Interval mapping creates six interval mapping trees for individual data areas of the IPLFS filesystem partition. Mapping interval is initialized when the mapping tree is first created. The start LBA of each mapping interval corresponds to the first LBA of associated filesystem area. Initially, each mapping interval consists of thirty-two zones, 512 GByte.

Active Interval is a window of actively used zones within the associated mapping interval. Active interval

Figure 9: Updating the Mapping Interval

is similar to the active region in Fig. 7. The active interval starts at the first valid zone of the mapping interval and ends at the last valid zone of the associated mapping interval. If all filesystem blocks in a zone become invalid, the zone becomes invalid. The start of the active interval is updated to the following valid zone in the active interval when the first zone of the active interval becomes invalid. The end of the active interval is extended to the newly allocated zone if the new zone is appended to the active interval to accommodate more blocks.

As the filesystem ages, active interval moves towards the higher end of the logical partition. When the end of active interval nearly reaches the end of the mapping interval and there is little room to grow, Interval Mapping creates the new root node with the new mapping interval which can better accommodate the current active interval. The details of updating the mapping interval are as follows. First, we compute the mapping interval for the newly created root node. If the length of the current active interval is less than 1024 zones, the length of the new mapping interval is set as twice the length of the current active interval. Otherwise, it is initialized as the length of the current active interval plus sixteen zones. Second, we allocate the new root node with updated mapping interval. Third, we copy the child pointers of the old root node to the new root node.

The start of the mapping interval of the newly created root node is initialized to the start of the current active interval. The active interval of the new root node inherits the current active interval. Fig. 9 illustrates an example of creating the new root node with updated mapping interval. σ is the minimum number of free zones which the interval mapping tree needs to maintain. If the number of free zones in the mapping interval becomes less than σ , Interval Mapping updates the mapping interval creating the new root node. For an interval mapping tree, the mapping interval can be updated multiple times. When the mapping interval is updated, IPLFS allocates the new root node each time. Let i be the number of times when the mapping interval is updated for the associated mapping tree. z_m^i and z_a^i denote the number of zones in the mapping interval and the number of zones at the active interval of the i^{th} version of the root node, respectively. The new mapping interval starts at the same zone as the start of the current active interval. The length of the new mapping interval is twice the length of the current active interval, $z_m^{i+1} = 2z_a^i$. The length of the new active interval is the same as the length of the

current active interval, $z_a^{i+1} = z_a^i$.

FTL creates the new root node and updates the mapping interval in non-blocking way so that it can minimize the interference with the foreground IO request for address translation or for allocating the new zone. When a new zone node needs to be inserted at the root node while the new root node is being created, the newly created zone node is appended at the new root node and the active interval of the new root node is updated accordingly. For address translation, FTL uses the old root node if the incoming LBA belongs to the active interval of the old root node. Otherwise, it uses the new root node for address translation.

5.3 Fixed-Region Mapping

A Map Node maintains the mapping for single mapping segment, 16 MByte by default. The total size of the map nodes accounts for 99.9% of the entire mapping tree. It is critical that map node data structure is carefully designed to minimize the memory requirement as well as the mapping latency in Interval Mapping. To address the two objectives, we develop a new mapping technique called *fixed-region mapping*. Fixed-region mapping partitions a mapping segment into the same size *regions* with a given *region size*. Map node maintains the LBA-to-PBA mapping in per-region basis. Fixed-region mapping allocates the mapping table only for the valid regions, i.e. the region that has one or more valid blocks. Map node maintains a region directory which has the location of the per-region mapping tables. If the region is invalid, the associated entry in the region directory is NULL. To reduce the size of mapping table, each mapping table specifies the start LBA of the active region and excludes the mapping for invalid blocks at the beginning of the associated region.

The *region size* plays a key role in the mapping efficiency of the map node. Mapping efficiency is the ratio of the number of the valid mapping entries against the total number of mapping entries. As the region size gets smaller, the mapping segment is partitioned into smaller regions and the number of invalid regions is likely to increase. As the region size becomes smaller, the mapping efficiency improves but the region directory becomes larger. As the region size becomes larger, the mapping segment consists of smaller number of regions. With larger size region, the region directory becomes smaller but the mapping efficiency becomes worse. We need to find the right region size that can maximize the mapping efficiency and minimizes the map node size. Interval Mapping sets the region size as *the size of the smallest hole in the mapping segment*. To avoid that the region size becomes too small, we set the minimum region size, 256 KByte. When the region size corresponds to the size of the smallest hole, it is guaranteed that there can be

Figure 10: Mapping Segment and Map Node

only one active region in the associated region. Active region is a consecutive array of valid blocks in a region.

A map node consists of the three components: the range of the mapping segment, the region directory, and the array of mappings for individual regions. The number of entries in the region directory corresponds to the number of regions of the map node. The mapping information for each region consists of the start address of the active region and associated LBA-to-PBA mapping. Fig. 10 illustrates the mapping segment and the organization of the associated map node. There are 32 blocks in the mapping segment. There are two holes with 10 blocks and 6 blocks, respectively. The region size of this map node is set to 6. Map node partitions the mapping segment into six regions. In Region 0, there are four valid blocks. Region 1 does not have any valid blocks. The directory entry for region 1 is NULL since it does not have any valid blocks. There are three active regions in the mapping segment. The second active region spans across region 2 and region 3. The map node allocates a single region map for the active region that spans region 2 and region 3.

Interval Mapping periodically reorganizes the map node. We call it *map node compaction*. It updates the region size for the mapping segment and reconstructs the per-region mapping tables with respect to the updated regions. This is to reduce the map node size by eliminating the mappings for the invalid flash pages. When the map node is first created, the region size is set to size of the mapping segment. When the FTL invalidates the mapping table entry at the map node, it examines the mapping efficiency. If the mapping efficiency becomes smaller than a certain threshold, (50%), the FTL inserts the map node to the compaction candidate list. The compaction thread periodically scans the compaction candidate list (default 30s), and estimates the size of the reorganized map node with the updated region size. If the map node can become smaller by more than 30% after compaction, FTL reorganizes the map node. Fig. 11 illustrates the map node compaction. Before the compaction, the original map node has a single region that has 16 mapping entries and three active regions. There are two holes of four blocks and five blocks. For compaction, the region size is updated to four (the minimum

Figure 11: Reorganizing the Map Node

hole size). The mapping region is partitioned into four regions based upon the new region size, four. After compaction, the map node has three region mappings, each of which includes two, two and three mapping entries, respectively. As a result of map node compaction, the map node size decreases by approximately half.

The memory overhead of Interval mapping is almost the same as the memory overhead for page mapping. Assume that the storage size is 512 GByte and flash page size is 16 KByte. The page mapping consists of a 4 KByte block bitmap (for subpage mapping [30]) and a mapping table. The page mapping requires 144 MByte (16 MByte for bitmap and 128 MByte for mapping table). The interval mapping consists of a root node, 32 zone nodes, and 2^{15} map nodes with sizes 128Byte, 4096Byte, and 4624Byte, respectively. The size of Interval Mapping corresponds to 144.6 MByte.

6 Evaluation

We implement IPLFS on F2FS (Linux 5.11.0) and Interval Mapping on OpenSSD (230GByte, 8 channels) [33], respectively. A default FTL in OpenSSD uses page mapping and maps LBA to PBA of different channels in a round-robin way. So does Interval Mapping FTL. We use a PC server with Intel CPU i7-4770K (3.50GHz, 4 cores), and 8 GByte DRAM for the experiment.

6.1 Eliminating the Garbage Collection

FIG 1. We examine the performance benefit of eliminating the filesystem-level garbage collection. We use FIO [6]. The logical storage partition is 30 GByte. In this experiment, four threads perform random write on 28GByte file. We measure the throughput in every 2 sec. Since the F2FS partition is almost full at the beginning of the experiment, it quickly runs out of free segment. On the other hand, the logical partition size is set to be much smaller than the physical storage size. This is to prohibit the storage device from running FTL garbage collection. The effect of eliminating the filesystem level garbage collection is substantial. In Fig. 12a, the performance of F2FS drops to 1/10 when it starts to perform garbage collection. IPLFS performance remains steady at its full speed till the experiment finishes.

(a) Only with F2FS garbage collection. Time: 600s, file size: 28GByte, partition size: 30GByte

(b) F2FS garbage collection and FTL garbage collection. Time: 1200s, file size: 210GByte, partition size: 230GByte.

Figure 12: FIO (random write) Throughput: IPLFS vs. F2FS. The number indicates the total write volume.

FIO 2. We examine the performance impact of filesystem-level garbage collection as well as device-level garbage collection. Fig. 12b illustrates the result. We set the size of the logical partition to 230 GByte, which is the physical storage capacity of OpenSSD. We perform the random write on 210 GByte file. When F2FS starts garbage collection, the throughput decreases to nearly 1/10. While IPLFS is free from filesystem level garbage collection, the underlying flash storage is not. When OpenSSD starts device-level garbage collection, the FIO performance of IPLFS decreases to 60%. The filesystem-level garbage collection bears more significant impact on the benchmark performance than the device-level garbage collection does.

MySQL. We run YCSB-A workload with MySQL and examine how database operations are interfered by the filesystem garbage collection. YCSB A workload [14] consists of the same amount of reads and updates. To

Figure 13: MySQL latency and throughput: YCSB-A, record size: 1KB, record count: 5M, operation count: 1M (read:update=1:1), threads: 50, partition size: 18GB.

Figure 14: IPLFS vs. F2FS: filesystem benchmarks under varying disk utilization, file size: 2 MByte, partition size: 230GByte

quickly trigger the filesystem level garbage collection, the filesystem is 90% full at the beginning of the experiment. Fig. 13a illustrates the average read and update latencies of IPLFS and F2FS, respectively. The average read latency and the average update latency of IPLFS are 1/2 and 1/3 of those of F2FS, respectively. The absence of garbage collection improves the tail latency of the filesystem significantly. The tail latencies of update at 95% and at 99% in IPLFS are $5.2\times$ and $5\times$ lower than those of F2FS. Fig. 13b illustrates the throughput. IPLFS's throughput remains steady throughout the experiment. F2FS renders the similar performance to IPLFS at the beginning but the performance decreases substantially when it starts running the garbage collection.

6.2 Discard Policy of IPLFS

We examine how the more aggressive discard policy affects the FTL garbage collection and the application performance. We use filesystem workload in Filebench [53], where 50 threads create, update and delete 2 MByte files. Fig. 14a shows the write amplifications in IPLFS and F2FS. IPLFS exhibits lower write amplification than F2FS in all disk utilizations. Fig. 14b depicts the throughput under varying disk utilization. IPLFS improves the

Figure 15: Block trace: Filebench filesystem workload, Partition size: 30GB

throughput by as much as 24% against F2FS. Aggressive discard policy of IPLFS saves the FTL garbage collection from migrating the invalid filesystem blocks. As a result, IPLFS renders substantial improvement in write amplification and the benchmark performance.

We examine the IO traces in IPLFS and F2FS, respectively. In IPLFS and F2FS, the logical partition sizes correspond to 1 ZByte and 30 GByte, respectively. Fig. 15a and 15b illustrate the results. IPLFS never recycles the filesystem blocks and keeps appending the blocks throughout the experiment. On the other hand, F2FS recycles the invalid filesystem blocks in round-robin manner. We observe that IPLFS issues the discard command a lot more frequently than F2FS does. This is because F2FS issues discard command only when there is no pending IO. In this experiment, F2FS rarely finds that there is no pending IO.

6.3 Address Translation Overhead

Address Translation Latency. We examine the overhead of address translation in Interval Mapping and page mapping (Fig. 16a). We run FIO with four threads. They perform random write on 10 GByte file. Interval Mapping yields 88% longer mapping latency than the page mapping. This is because Interval Mapping performs multiple index lookups for address translation. When creating a new mapping entry, Interval Mapping exhibits 3.3× longer latency than the page mapping.

End-to-end Latency. We measure the micro-benchmark performance under Interval mapping and the page mapping. Fig. 16b shows the latencies of read and write (direct IO) in FIO benchmark. The read latency and the write latency of Interval Mapping and page mapping are almost identical. This result shows that the overhead of accessing the NAND flash and the overhead of transferring the data blocks between the host and storage device account for dominant fraction of IO latency and FTL overhead is not significant.

6.4 Map Node Size

We examine the memory overhead of fixed-region mapping. We run fileserver workload with 50 threads. Each thread creates, updates and deletes 2 MByte files.

Figure 16: FTL Overhead: Interval Mapping vs. page mapping

Figure 17: CDF of region size

Figure 18: Mapping Tree size under varying region sizes

Region Size. We examine the IO volume associated with write and discard. We also examine the size of holes for each filesystem area (Table 3). The median hole size varies widely subject to the area type. Median hole size of the warm data area is 2860 KByte while that of the hot data area is 8 KByte. IO's for warm data area (write and discard) account for dominant fraction of all IO's (99% of write, 99% of discard).

We examine the region size distribution (Fig. 17). Region size is set as the size of the smallest hole in the associated mapping segment. For the warm data area, 3/4 of the region sizes are greater than 1 MByte. Subsequently, most of the map nodes have sixteen or less number of regions. Recall that the size of mapping segment is 16 MByte. The size of region directory accounts for approximately 1% of the map node size. In map node design, the size of the region directory is negligible.

Minimum Hole Size for region size. We compare the sizes of the mapping trees when the region size is fixed and when the region size is chosen dynamically to the size of the smallest hole in mapping segment. Fig. 18 shows results. The mapping tree becomes the smallest when we use the the minimum hole size as the region size. For small region size (64 KByte), the tree size is 13% larger than the tree size when we use the minimum hole size as region size. This is due to the increase in the region directory size. In a map node with 64 KByte region size, the region directory accounts for 13% of the total size of the mapping tables. The mapping tree size becomes larger when we use large fixed region size

Log type	W/D volume (GB)	Median (KB)	75% (KB)	90% (KB)
Warm Node	1.99 / 1.69	32	32	80
Warm Data	305.9 / 170.4	2860	6352	11764
Hot node	0.4 / 0.38	48	232	816
Hot Data	0.87 / 0.36	8	24	40

Table 3: Statistics on the hole size, Filebench fileserver workload. Average file size: 2MByte, runtime: 1600s, W/D volume: total volume of Write/Discard

Figure 19: Mapping Tree size

(1 MB or larger) than when we use the minimum hole size as a region size. This is because with the larger region size, the fixed-region mapping fails to exclude the mappings for invalid flash pages and the mapping efficiency becomes worse.

Reorganizing the Map Node. We examine the effectiveness of map node compaction. We configure the compaction period to 30s and a compaction ratio threshold to 0.7. Total size of the files is 160GByte. When the benchmark finishes, the active interval in the filesystem partition corresponds 305GByte. Fig. 19 illustrates the sizes of mapping trees in two cases: when the Interval Mapping periodically reorganizes the map node and when it does not. Without compaction, the mapping tree size increases as the filesystem ages and reaches over 80 MByte. This is because the active interval becomes larger and the Interval Mapping allocates new map nodes as the active interval expands. With map node compaction, the mapping tree size stays at around 40 MByte. Mapping table size remains almost the same as the mapping table size for 160 GByte even though the active interval expands to 305 GByte.

7 Related Works

IO stack largely consists of two layers: the host (filesystem and block device layer) and the device (SSD). A body of works try to migrate the FTL overhead from the storage device to the host. They include DFS [24], ParaFS [60], Application Managed Flash [39], and Or-cFS [59]. In these works, the software overhead at the host side increases; the host side software directly manages the flash pages and performs essential managerial activities such as garbage collection and wear-leveling. Nameless Write eliminates the address translation layer from the IO stack [62]. Migrating the device’s functionality to the host has its cost. Flash storage needs expose its physical nature, e.g. physical flash page location, page size or block size, to the host. ZNS saves the device from the FTL overhead [9, 20]. On the contrary to these works, IPLFS aims at reducing the host side overhead, the filesystem level garbage collection with reasonable increase in the device firmware complexity.

IPLFS shares the same idea with DFS [24] in that IPLFS separates the logical filesystem partition from the physical storage capacity and fully exploits 2^{64} logical partition size. Despite of the similarity, the underlying

philosophies and the approaches of the two lie at the other ends of spectrum. DFS migrates the garbage collection from the device to the host whereas IPLFS migrates the garbage collection from the host to the device. DFS introduces new indirection layer to separate the logical partition from the physical storage. Host side’s IO stack becomes heavier to handle LBA-to-PBA mapping, garbage collection, and etc. It requires the flash device to expose physical details to the host. IPLFS does not require new layer nor any physical information of the flash storage. Separating the logical partition from the physical storage, IPLFS becomes simpler and lighter-weight than its original counter part, F2FS.

A number of works proposed to make the garbage collection more efficient. Kim et al. [31] proposed to distinguish the hot data and the cold data according to the program context. Wu et al. [54] proposed to optimize background segment cleaning scheduler based on Q-learning algorithm. Gwak et al. [19] optimized a foreground segment cleaning. A few works proposed to trigger background segment cleaning during system idle time. [10, 22, 47] Lee et al. [37] proposed preemptive garbage collection. Yan et al. [57] proposed copying valid pages in victim block to another block so that the copies handle IO operations to victim block.

To reduce the mapping table size, Kang et al. proposed to use larger granularity mapping [26]. Zhou et al. [63] increased the cache hit ratio of the page-level mapping information by employing a two-level LRU list. Liu et al. [42] proposed the FTL, which enables partial erase operation in 3D NAND flash storage.

8 Conclusion

In this work, we propose IPLFS, a log-structured filesystem for infinite partition. Separating the logical filesystem partition size from the physical storage size and making the logical filesystem partition size virtually infinite, we free the log-structured filesystem from recycling the invalid filesystem blocks. To maintain the mapping information for the prohibitively large logical filesystem partition, we develop Interval-Mapping which maintains the LBA to PBA mapping only for the actively used filesystem region. With IPLFS and Interval mapping combined together, we relieve the log-structured filesystem from the overhead of reclaiming the invalid blocks, the garbage collection.

A Artifact Appendix

Abstract

Our artifact consists of two parts: IPLFS and Interval Mapping FTL. IPLFS is a log-structured filesystem with Infinite logical partition. Interval Mapping FTL is flash translation layer that maintains mapping for Infinite logical partition.

Scope

This artifact can be used to validate all experiments that measure throughput, latency and block trace in the paper.

Contents

IPLFS artifact is implemented on the top of F2FS in Ubuntu 5.11.0. The IPLFS artifact does not conduct garbage collection, and does not have metadata for garbage collection, such as a block allocation bitmap (a segment information table) and reverse mapping information (segment summary area). To replace the block allocation bitmap, discard bitmap is implemented in the IPLFS artifact. The IPLFS artifact also conducts discard logging to prevent storage leak. As specified in the paper, the IPLFS artifact partitions infinite logical space into seven areas.

Interval Mapping artifact is implemented on the top of OpenSSD. The design of the Interval Mapping artifact is three level tree, as written in the paper. The root node, zone node, and map node are all implemented in the artifact. We implement Expansion of root node and Compaction of map node in the artifact. In the artifact, there are total seven Interval Mapping trees to support for multi-area partition layout of IPLFS.

Hosting

The IPLFS artifact is uploaded in Github repository, <https://github.com/ESOS-Lab/IPLFS>. A branch named 'IPLFS-stable' contains IPLFS source code, and IPLFS format utility (f2fs-tools). A branch named 'original_kernel' is vanilla kernel which is compared with IPLFS for experiment in the paper.

The Interval Mapping artifact is uploaded in Github repository, https://github.com/ESOS-Lab/Interval_Mapping. A branch named 'main' is the artifact mainly used for the experiments in the paper. If you try measuring 'get' and 'set' latencies of Interval Mapping FTL, please use branches named 'exp-getlatency' and 'exp-setlatency', which print out the latencies of 'get' operation and 'set' operation, respectively. A branch named 'expansion+compaction'

is Interval Mapping that conducts root node expansion and map node compaction in the foreground.

Requirements

Interval Mapping FTL is built on Cosmos+ OpenSSD, the PCIe-based SSD platform on which open source SSD firmware can be developed. To operate the Interval Mapping artifact, OpenSSD is required.

Vigil-KV: Hardware-Software Co-Design to Integrate Strong Latency Determinism into Log-Structured Merge Key-Value Stores

Abstract

We propose *Vigil-KV*, a hardware and software co-designed framework that eliminates long-tail latency almost perfectly by introducing strong latency determinism. To make Get latency deterministic, Vigil-KV first enables a predictable latency mode (PLM) interface on a real datacenter-scale NVMe SSD, having knowledge about the nature of the underlying flash technologies. Vigil-KV at the system-level then hides the non-deterministic time window (associated with SSD's internal tasks and/or write services) by internally scheduling the different device states of PLM across multiple physical functions. Vigil-KV further schedules compaction/flush operations and client requests being aware of PLM's restrictions thereby integrating strong latency determinism into LSM KVs. We implement Vigil-KV upon a 1.92TB NVMe SSD prototype and Linux 4.19.91, but other LSM KVs can adopt its concept. We evaluate diverse Facebook and Yahoo scenarios with Vigil-KV, and the results show that Vigil-KV can reduce the tail latency of a baseline KV system by $3.19\times$ while reducing the average latency by 34%, on average.

1 Introduction

Log-structured Merge Key-Value stores (LSM KVs) such as RocksDB [1] and LevelDB [2] are widely adopted in diverse computing domains to handle large-scale data thanks to their simplicity, scalability, and high-performance [3–10]. LSM KVs are also used in many production environments to offer large-scale storage whose capacity is beyond main memory subsystems to latency-sensitive applications. For example, Facebook uses RocksDB as the storage engine of an SQL database, which is used for social graph processing [11–14]. This type of application considers the query latency (e.g., Get) of each social action (e.g., view profile, list friends, etc.) as a first-class citizen. In particular, managing long-tail latency of reads (and latency consistency) is a matter of meeting diverse user demands and service-level agreements (SLA) [15–17].

However, we observe that the long-tail read latency of the Facebook scenario is $10.4\times$ worse than normal read oper-

ations, making the user experience inconsistent. The main contributor to this long-tail latency is device-level SSD latency, not software or operating system (OS); the execution times of all the software, including storage stack and user application, account for only 13% of the long-tail latency (99.9th percentile). We will give a detailed analysis of this in Section 3.1. The long-tail latency mainly comes from I/O interferences caused by two different levels of internal tasks: i) *LSM KV's internal tasks* and ii) *SSD's internal tasks*. LSM KVs periodically perform internal tasks such as compaction and flushing for their persistence and effectiveness [18–21]. The compaction merges data from the lower to a higher level of their LSM tree, whereas the flush writes the in-memory buffer back to the underlying storage in securing more space to buffer and making the buffered data persistent. Since the write operations of these internal tasks exhibit long latency and often stall all incoming requests, many prior studies (e.g., TRIAD [22], PebblesDB [23], and SILK [24]) reschedule additional writes of the internal tasks and serve them at future idle times. These LSM KVs would reduce the latency inconsistency imposed by the internal tasks to some extent, but we observe that they lead to serious side-effects, which deteriorate read services and increase memory footprints significantly (cf. Section 3.2).

Even with an ideal case of abolishing all the LSM KV's internal tasks, the long-tail read latency cannot be eliminated because of SSD's internal tasks such as DRAM caching/flushing [25–30], garbage collections [31–39], and read-reclaiming [40–44]. For example, even in cases where LSM KV solely reads the underlying SSD at a certain period, it exhibits long latency on the reads since the SSD internally flushes the buffered/cached data to its backend storage. Similarly, at any given time, a garbage collection or read-reclaiming can introduce a set of reads and writes, which also prevent the incoming requests from being serviced. Note that these internal tasks are scheduled by the underlying SSD firmware, which makes the read latency behaviors non-deterministic at the user-level and increases the latency significantly (cf. Section 2.2).

In this work, we propose *Vigil-KV*, a hardware and soft-

ware co-design to eliminate the long-tail latency of LSM KVs and make their read services consistently deterministic. Vigil-KV hardware offers a scheduling interface to remove SSD's internal tasks, whereas its software is designed toward eliminating the overhead imposed by LSM KV's internal tasks without delaying compaction or flushing in-memory buffer at idle times. To this end, we advocate a *predictable latency mode* (PLM) interface, which is recently added to the standard NVMe protocol [45]. We enable the brand-new interface on a high-performance NVMe SSD and enforce the read latency deterministic on a specific time window. Obviously, PLM cannot deliver the latency consistency indefinitely since SSD's internal tasks are essential to managing the reliability and persistence of the backend's storage media. For the host's finer PLM scheduling, Vigil-KV hardware also implements NVMe's NVM set features by internally partitioning the storage volume into multiple functions.

While PLM has great potential to eliminate the long-tail latency of LSM KVs by having a closer collaboration between a host and storage, there are several constraints that have not been analyzed in the literature yet. Specifically, PLM relies two essential scheduling components, *deterministic window* (DTWIN) and *non-deterministic window* (NDWIN). DTWIN is the time window to offer predictable latency, whereas NDWIN is not. This work reveals three important characteristics of PLM, which should be considered when the host communicates with the underlying SSD to achieve the latency consistency: i) *write-free on DTWIN* ii) *fair-scheduling for PLM windows*, iii) *device lockdown constraint*. First, DTWIN can be guaranteed only if there is no write request in a DTWIN period. The reason behind this DTWIN's write-free constraint is that, even though PLM supports the latency consistency by removing SSD's internal tasks at DTWIN, it cannot completely eliminate the stalls caused by online write requests coming from clients. Second, as SSD's internal tasks should be performed at some point, the longest-serving time of DTWIN is determined at design time, and NDWIN should be preserved and appropriately scheduled before jumping in DTWIN. Lastly, the host curbs I/O requests when the underlying SSD transits from NDWIN to DTWIN. This is because the transition requires a make-ready time, which must not be interrupted by any other I/O activities (i.e., device lockdown).

Based on the restrictions that we observe, the software part of Vigil-KV classifies the requests of LSM KVs at runtime and carefully assigns them to appropriate PLM time windows through our device state scheduling. This device state and request scheduling can make the latency of client-side I/O requests deterministic and have no long-tail all the time. To this end, we introduce a PLM driver atop Vigil-KV hardware, which manages all the device states across different NVM sets but makes them visible as a single storage volume. This driver makes sure that there are always $n - 1$ NVM sets having DTWIN (where n is the total number of data NVM sets) while allowing an NVM set to schedule SSD's internal task via ND-

WIN. During the device state management, it also takes into account the fair-scheduling and lockdown constraints such that a kernel-level scheduler can focus on assigning the I/O requests based on the condition of given PLM time windows. Specifically, Vigil-KV's kernel-level scheduler packs all I/O activities coming from LSM KV's internal tasks into NDWIN (scheduled by the PLM driver), which takes the overhead of all the internal tasks off the critical path in I/O services. In addition, it makes all the incoming read requests (heading to the NDWIN-scheduled set) non-blocking, inspired by a novel memory/storage array-level technique [46–49]. The kernel-level scheduler detects the read requests targeting an NVM set (configured with NDWIN) and directly serves the corresponding data without touching it at all. Since there are $n - 1$ NVM sets with DTWIN at an any given time (invisible to the host clients), the scheduler can collect data from them within the deterministic time window and reconstruct the requested data (with the help of the PLM driver) thereby making the target SSD latency consistent constantly.

Even though the Vigil-KV driver and thread can put all the internal tasks into NDWIN and isolate them from the client reads, they unfortunately fail to meet the write-free constraint. This is because of additional writes for providing atomicity and durability at the system-level (e.g., journaling). Since these writes can interfere with the reads on DTWIN, we dedicate an NVM set for the metadata management dealing with the write-ahead log (WAL) and file system journaling. To this end, we have a minor modification of RocksDB (but other LSM KVs can adopt its concept) to give a different priority to each process based on their nature of I/O activities. This technique can address the write-free constraint and make the target SSD be in all DTWIN for client requests consistently.

We prototype Vigil-KV hardware on a 1.92TB Datacenter-scale NVMe SSD, while implementing Vigil-KV software using Linux 4.19.91 and RocksDB 6.23.0. To the best of our knowledge, this is the first paper that implements the PLM interface in a real SSD and makes the read latency of LSM KVs deterministic in a hardware-software co-design manner. We evaluate six Facebook and Yahoo scenarios, and the results show that Vigil-KV can reduce the tail latency of a baseline KV system by $3.19\times$ while reducing the average latency on Get services by 34%, on average.

2 Preliminaries

We will explain RocksDB as representative of LSM KVs in this section. We will also explain the internal tasks of LSM KV and SSD in detail and analyze the challenges imposed by those two different levels of internal tasks.

2.1 Log-Structured Merge KV Stores

Figure 1a explains the major data structure and corresponding operations of RocksDB. RocksDB maintains all information

Figure 1: Log-Structured Merge KV Stores.

in the log-structured merge (LSM) tree consisting of two separate structures, each of which is optimized to volatile memory and block storage. The in-memory data structure, called *Memtable*, holds data before turning their state into persistent in an unsorted manner. Memtables allow users/clients to quickly update by serving the requests from the memory (rather than storage). The storage data structure manages key and value (KV) pairs, which are managed in an immutable form of *sorted string table* files (SSTFiles). SSTFiles are maintained in hierarchical levels, each being denoted by L0 (level-0), L1 (level-1), ..., LK (level-K).

Client operations. RocksDB supports various query services such as Put (writes), Get (reads), Delete, and Scan. Since the majority of the queries are *Put* and *Get*, this work focuses on those two operations. Users' Put requests are inserted to a Memtable as a KV pair by RocksDB if the Memtable is mutable, meaning that it has available room to update. In default, RocksDB maintains two Memtables, each taking 64MB spaces, which are the same as the size of logfiles; we will explain this in detail with LSM KV's internal tasks (i.e., flush and compaction) shortly. If there is no available space in a Memtable, RocksDB locks down and changes its state from mutable to immutable, which does not allow further updates. RocksDB then places another Memtable for the next Put requests while writing the data of the immutable Memtable to L0 by converting the Memtable to an SSTFile in the background. Since it is important to secure Memtable(s) in memory as soon as possible, turning a Memtable into L0 is performed in an unsorted and out-of-order manner. Thus, L0 can contain multiple SSTFiles associated with the same key. Later, the SSTFiles at L0 are migrated into a lower level of storage space (L1) by LSM KV's internal tasks.

On the other hand, Get requests accompany a series of reads the value associated with a given key. RocksDB first searches the key in Memtables and serves the value if there is. In cases where it fails to find the key in the Memtables, RocksDB scans all the SSTFiles residing in L0 and searches for the key. This is because the files are stored in an unsorted way, and it can be possible for L0 to have multiple SSTFiles corresponding to the given key. If RocksDB cannot find the key at L0, it goes L1 and searches again. Since L1's SSTFiles are compacted from L0, each file contains a unique key, making RocksDB faster to search the target KV pair. Note that the unsorted data structure of L0 allows RocksDB to quickly secure in-memory

Figure 2: SSD internal tasks.

buffers, thereby preventing Put against stalls, but it introduces many storage accesses (reads) on Get services.

Internal tasks. Figure 1b illustrates the detailed procedure of LSM KV's internal tasks and major software components associated with the tasks. While Memtables are well designed toward taking performance advantage of volatile memory media, their data can be lost when there is a power failure. To make the KV pairs in the buffer persistent and durable, RocksDB writes the KV pair as a form of logfiles to a designated area in the underlying storage, called *write-ahead log* (WAL) before its Memtable update. Writing WAL (per request) is performed as a synchronous operation bypassing the page cache of the underlying file system for crash consistency control. Since it is a time-consuming task, RocksDB employs another internal buffer, called *write group* existing in front of Memtables. In the meantime, it checks the space utilization of Memtables and L0, and if there is no available space, RocksDB enqueues *flush* and/or *compaction* tasks item to reclaim a Memtable and an L0 SSTFile, respectively. These items include an appropriate pointer for the space reclaiming, which is all performed by RocksDB's background threads. For a Memtable flush, the internal task checks all the keys in a Memtable, builds an SSTFile, and flushes the SSTFile to L0. In cases of an L0 compaction, its internal task selects a target SSTFile. Consider Figure 1c as an example, the SSTFile's key ranges from 60 to 120. The task also picks L1's SSTFiles whose keys are associated with the compaction target's keys (e.g., two L1 SSTFiles, each having 80~90 and 100~140, in the figure). It then performs a merge sort by checking up all entries of three SSTFiles and letting only the latest information remain, which generates a new L1's SSTFile. Lastly, RocksDB synchronously writes the new SSTFile and removes the three old SSTFiles from the underlying SSD.

2.2 SSD Internal Tasks and Challenges

Internal DRAM flush. Since flash writes are slower than its reads by order of magnitude, high-performance SSDs employ a large size of internal DRAM, and their firmware buffers the writes [25–27, 50]. For example, our baseline NVMe hardware has 3GB DRAM buffering/caching data. These buffered writes are periodically flushed to the storage backend with a specific access pattern in favor of increasing bandwidth. Thus, even though there is no write at all for a certain period,

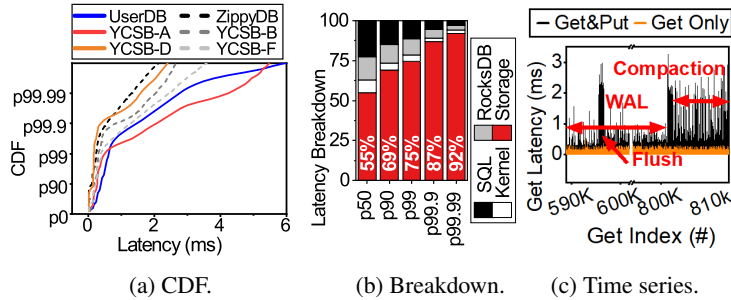

Figure 3: Long tail analysis.

draining the data (buffered previously) can interfere with incoming read operations. Figure 2a shows the read latency interfered by SSD’s internal flush; we write a block (64MB) to SSD before the test and only issue 4KB-sized read requests (in sequential) without any writes for the test period. As shown in the figure, the baseline NVMe hardware suffers from massive latency spikes, which are higher than the typical latency by $7.75\times$ at most, and its latency significantly fluctuates during the read-only time. This is because the writes introduced by the internal flush stall the reads until their service completes.

Note that, since the internal flushes are solely managed by the firmware, host software components cannot unfortunately control the latency consistency of reads. To remove the latency fluctuation analyzed above, it requires a tight collaboration between the host and firmware.

Garbage collection. Flash also has unique device-level characteristics such as erase-before-write and asymmetric I/O granularity for read/write and erase [51–54]. Because of this nature, SSD’s firmware writes incoming data into a free block (erased in advance) instead of its actual location. While this address remapping (translation) for out-of-updates makes flash compatible with the existing block devices, it needs to perform a *garbage collection* (GC) if there is no free block [31, 38, 55, 56]. Since GCs are performed on the basis of a flash block containing hundreds of pages, the valid data residing in the target block(s) should be safely migrated into a new location of a block. This internal task introduces block erase operations even longer than the flash writes and many read/writes for the migration. It exhibits long latency and stalls many incoming requests before completing the task. Figure 2b shows the read latency while performing GCs (from 195 sec). In this test, reads exhibit sustainable latency (16.2 μ s), but their latency sharply increases and reaches as high as 9.8 ms once GCs begin.

While these internal tasks significantly hamper the read performance, all their activities are essential to secure more available rooms for further requests and manage the reliability of the storage backend, which cannot be simply removed or scheduled by host-side software modules.

Read-reclaiming. Flash is very well optimized for read services at the low-level [57–60], but a read-only scenario can also introduce additional data migration and block erase operations in certain circumstances. Specifically, when one keeps

Figure 4: Limitations internal tasks.

reading out a set of pages in a block without an erase, it stresses the block even without any writes and affects all data residing in the block together. This *read disturbance* unfortunately increases error rates often beyond the coverage that parity-check codes (e.g., ECC [61–64] and LDPC [65–68]) can correct [69–72]. To address the read disturbance issue, the underlying firmware needs to periodically reset (erase) the block(s) being intensively touched over the past period. Once the firmware erases the block, its internal state returns back to the nominal state, such that the block can endure the stress imposed by subsequent reads again. To erase the block, it requires reading the existing data on the target and copying all of them to a new block. As shown in Figure 2c, this internal task, called *read reclaiming* [69], can deteriorate the read performance seriously. In this test, we intensively read a set of specific blocks four times as a precondition and read them again in a random I/O pattern. One can observe from the figure that the read latency affected by the read reclaiming reaches as high as 2.5 ms, which is $32\times$ longer than the typical cases.

Even with the ideal situation that only utilizes the underlying SSDs as read-dedicated storage, this long-tail latency imposed by the read reclaiming are inevitable, and thus, it is necessary to devise new interface and firmware assistance to get them off the critical path in LSM KV’s read services.

3 Motivation and Related Work

3.1 Long-tail Latency on Reads

Figure 3a shows the cumulative distribution function (CDF) of Get latency for diverse RocksDB usage scenarios of Facebook [12, 73] and Yahoo [74]. In this evaluation, we use RocksDB 6.23 [1] on a baseline 1.92TB NVMe hardware that we will modify in Section 4.1 and use for all the remaining tests. This baseline employs 3GB internal DRAM and includes 64 TLC NAND flash (64 layers), which are connected to eight different channels. The detailed environment descriptions are the same as what we used for Section 7.

Significance of long-tail latency. Thanks to the low device-level latency of flash, the nominal performance trend of them is similar to each other; all their Get latencies are under 200 μ s. However, the Get latencies reach a few ms from three nine

(P99, 99.9th percental), and all their latencies increase compared to the normal Get latency as high as $15.7\times$. The main reason why this long-tail latency is observed across all the RocksDB usage scenarios that we test does not stem from database or kernel computation but heavy storage accesses. To be precise, we also decompose the execution time of UserDB, Facebook’s social graph data processing workload [12, 73], into Get’s storage latency (*Storage*), client computation times (*App*), database latency (*RocksDB*), and kernel latencies (*Kernel*). As shown in Figure 3b, the computation of LSM KV’s software stack does not sit on a critical path in the Get long-tail latency, but *Storage* takes 87% of the total execution time thereby dominating Get service times at the tails. While the computation of latency of software stack is well balanced with *Storage* (taking half of the total execution time), LSM KV’s heavy I/O requests sharply increase the fraction of *Storage* when it should reclaim Memtables and/or SSTFiles.

Internal tasks’ performance impacts. Figure 3c shows a time series analysis for the UserDB workload and compares its read characteristic with an ideal Get-only workload, which exhibits I/O patterns the same as UserDB but removes all Put queries from its execution. One can observe from this analysis that, when RocksDB flushes Memtable (at 596K index), the baseline read latency increases from $147\mu s$ to $2.97ms$, and the read latency does not return for a while. Similarly, once RocksDB begins to compact SSTFiles, it introduces many reads and writes to merge KV pairs, which unfortunately block incoming Get requests thereby exhibiting $30\times$ longer latency than the normal cases. Note that the latency of reads being performed in parallel with WAL is not that significant (compared to flush and compaction), but WAL also makes the Get latency $10.6\times$ worse than the usual cases.

3.2 Scheduling Internal Tasks

Challenges of system-level approaches. There are many studies [4, 5, 7–10, 15, 16, 18–20, 22–24] that try to address the performance degradation imposed by RocksDB’s internal tasks, such as TRIAD [22], PebblesDB [23], and SILK [24]. There are variant optimization points across these approaches, but their proposals in general reschedule or delay flush and compaction into idle or other available times, thereby removing the long-tail latency. While these system-level approaches can hide the read/write overhead imposed by LSM KV’s internal tasks to some extent, they cannot remove the long-tail latency on Get services because of unavailability to handle SSD’s internal tasks and side-effects raised by their scheduling. Specifically, postponing the compaction removes the suspending time for incoming Put services, but it enforces LSM KV’s L0 accumulatively accommodate SSTFiles without a data migration to L1, thereby increasing the Get latency. Figure 4a compares two tail latency trends on Gets, each being served with and without compaction rescheduling. The

Get tail latency is sustainably managed when RocksDB compacts SSTFiles at the right time (lower than $1ms$), but its tail latency served with the delayed compaction keeps increasing and reaches $3.1ms$, which is $3.6\times$ longer than the no-scheduling case of RocksDB compactions. This is because Get services require searching the appropriate values (paired with input keys) from the beginning to the end of RocksDB’s L0. Since the SSTFiles on L0 are not sorted, the KV searching introduces many outstanding reads thereby increasing the tail latency.

On the other hand, as shown in Figure 4b, the delayed flush of RocksDB also increases the Get tail latency as high as $27.4\times$. The reason why the Get tail latency looks more severe than the rescheduled compaction is that delaying Memtable flush gobbles up all the in-memory spaces, allocated to Memtable management. Thus, the writes of RocksDB are all stalled until it secures a Memtable, which in turn makes the read service suspended seriously.

Device-level latency determinism and limits. The aforementioned SSD’s internal tasks are well-known challenges to exhibit serious performance drop and long latency [31–44, 75–77]. Since the internal tasks are invoked in an arbitrary time period, they render many productions in diverse computing domains difficult to deploy latency-critical applications in the environment. Recently, the standard NVMe protocol introduces the *predictable latency mode* (PLM) interface in an attempt to make the latency predictable and deterministic. PLM proposes that SSDs operate in either a deterministic performance window (*DTWIN*) or a non-deterministic performance window (*NDWIN*). Based on the NVMe specification [45], *NDWIN* is the time period to prepare the next *DTWIN*.

Note that PLM interface is simply a part of interface protocol, which does not enforce specific requirements or design details for the guarantee of deterministic latency. While this young interface presents blueprints on how to handle the unpredictable SSD behaviors in a well-managed manner, *PLM is in practice a just best-effort contract, which only supports soft latency determinism*. For example, we cannot make the underlying SSD always appropriately work with *DTWIN* because SSD’s internal tasks for hiding the flash characteristics are inevitable to invoke. Even in the ideal case where the underlying hardware hides all the SSD’s internal tasks with its maximum efforts, the latency determinism can be easily broken according to how the host-side LSM KV behaves at anytime. To support strong latency determinism, it is necessary to have a close collaboration between the host-side LSM KVs and the underlying storage.

4 High-level View of Vigil-KV

The main goal of this work is to secure an LSM KV system that has no long-tail latency on Get services to make their read performance deterministic and consistent. As this strong latency determinism is infeasible to achieve by scheduling

either only LSM KV's or SSD's internal tasks alone, Vigil-KV takes a hardware and software co-design approach. Specifically, Vigil-KV hardware is designed towards offering basic scheduling blocks that allow the host to integrate strong latency determinism into the LSM KV. On the other hand, the software part of Vigil-KV classifies the requests of LSM KV's at runtime and carefully assigns them to appropriate by fully utilizing the scheduling blocks that the underlying hardware provides. This hardware and software co-design approach can make the latency of client-side Get queries consistently deterministic and have no long-tail all the time.

4.1 Hardware Support for Fine-Granular Performance Windows

PLM interfaces. As shown in Table 1, Vigil-KV hardware implements and provides a set of PLM interfaces that allow the host-side Vigil-KV software to precisely schedule the device states. The functionalities that our PLM interfaces offer are largely classified into three: i) PLM setup (`PLMConfig()`), ii) NDWIN and DTWIN configuration (`PLMWindow()`), and iii) device log queries (`GetLogPage()`). The table also includes how the host-side kernel driver can implement those three semantics using NVMe feature commands. For example, a LSM KV system's kernel driver can turn on or off the target storage's PLM mode by configuring a feature ID (PLM configuration) and enable flag (on/off) through NVMe's `set-feature` [45]. In similar way, it can simply configure the performance window of Vigil-KV hardware using `PLMWindow()`. To query the device state/condition information (that we will reveal in Section 5.2), the LSM KV system can communicate with Vigil-KV hardware through `GetLogPage()` simply returning the results into 512B data package, called a *log page*. Based on a given performance window information, Vigil-KV hardware prioritizes NDWIN to perform SSD's internal tasks as much as possible, and it guarantees that the internal tasks are not scheduled in DTWIN. As discussed in Section 3.2, SSD's internal tasks cannot permanently be postponed, we regulate the longest-serving time of DTWIN and reports it to the host through `GetLogPage`. In addition, Vigil-KV hardware defines the minimum time of NDWIN that should be secured to handle SSD's internal tasks and exposes the configuration time to the host via the log page. Thus, Vigil-KV software can utilize this information by referring into the log page to schedule performance windows appropriately.

NVM multi-set architecture. To offer a variety of performance scheduling options to the host, our hardware also introduces *NVM multi-set*, which splits the backend storage into multiple volumes, each being exposed to the host as a separate PCIe physical function. Vigil-KV hardware then enables the PLM interface to each physical function, called *NVM set* and makes them work independently by allocating different internal logic/cores across the sets. This NVM multi-set archi-

PLM semantics	NVMe cmd	Field name		
		OP CODE	Feature ID (CDW10)	NVM Set ID (CDW11) Feature Enable (CDW12)
<code>PLMConfig()</code>	Set	PLM Config	SetID	Enable (0: Off, 1: On)
Arg1: SetID	Features			
Arg2: Enable				
<code>PLMWindow()</code>	Set	PLM Window	SetID	Enable (0: NDWIN, 1: DTWIN)
Arg1: SetID	Features

Table 1: Vigil-KV hardware.

Figure 5: Vigil-KV software.

ture can grant maximum flexibility to the host-side LSM KV's software components, such that they schedule the underlying device states (DTWIN and NDWIN) in a finer granular manner. For example, the LSM KV system can configure different performance windows within a single NVMe device by configuring the NVM Set ID of NVMe's `set-feature` (i.e., the codeword 11 of NVMe's command) differently.

4.2 Software-Defined Strong Latency Determinism for Get services.

Figure 5 shows how Vigil-KV software achieves strong latency determinism by utilizing the finer-granular performance windows that Vigil-KV hardware provides. It consists of three major logical components: i) *metadata separation*, ii) *device state scheduling*, and iii) *request scheduling*.

Managing data, devices, and requests. Vigil-KV software excludes a physical function from the storage volume and internally allocates it for metadata management, called *meta-set*. PLM of this meta-set is disabled by `PLMConfig()`, and Vigil-KV software isolates all WAL and journaling activities from LSM KV's regular queries by forwarding the metadata-related requests to the meta-set. This metadata separation allows the kv-sets not to be interfered with by the heavy internal writes for crash consistency management, such that our device state and request scheduling mechanisms can mainly focus on offering strong latency determinisms for Get services.

On the other hand, the remaining physical functions that Vigil-KV hardware exposes are allocated to handle incoming LSM KV's query requests at the kernel-level, which is referred to as *kv-sets*. Vigil-KV software then schedules all the kv-sets device states (i.e., performance windows) to make $n - 1$ kv-sets be in DTWIN at any given time (using `PLMWindow()`) while allowing NDWIN to be granted to the underlying kv-sets in a fairly scheduled aspect (round-robin). n is the total number of physical functions that Vigil-KV can assign to the SSTFile management. Vigil-KV software classifies LSM KV's internal tasks and client requests at runtime and schedules them differently by knowing the underlying device's configured performance windows. Specifically, all the client requests are scheduled to be served from the $n - 1$ kv-sets, configured with DTWIN. In contrast, Vigil-KV software

Figure 6: Vigil-KV hardware prototype.

schedules all the requests coming from LSM KV’s internal tasks with a kv-set, scheduled by NDWIN (if there is), but regulates the number of the internal tasks’ requests not to make NDWIN be too much long, thereby having always $n - 1$ kv-sets configured with DTWIN. We will explain the details of this device state and request scheduling in Section 6.2.

Data reconstruction for NDWIN. Vigil-KV pushes all the LSM KV’s and SSD’s internal tasks into NDWIN, which are scheduled across different kv-sets in a round-robin manner. While handling requests over NDWIN is essential for both the LSM KV and SSD, the client requests, particularly Get services, targeting the kv-set scheduled with NDWIN can be blocked, thereby exhibiting the long-tail latency. To address this, Vigil-KV encodes parity bits and writes them with internal tasks at NDWIN. Specifically, when Vigil-KV stores an SSTFile, it splits the file into multiple chunks and stripes those chunks across kv-sets at NDWIN. Since we ensure that there are $n - 1$ kv-sets configured DTWIN at any given moment, Vigil-KV reads out the data from other kv-sets, reconstructs the original data, and serves them without touching the NDWIN kv-set. This data reconstruction inspired by emerging “array-level” memory and storage techniques [48, 78–81] can obviously remove the long tail latency on Get services, but its reconstruction time can increase the average latency compared to ideal storage making all kv-sets DTWIN consistently. Thus, Vigil-KV also minimizes NDWIN to avoid unnecessary data reconstruction at the physical function level. Note that, as the parity bits are generated per chunk (not per SSTFile) in our scheme, it does not need to recalculate the parities after compaction. The details of this technique and implementation will be described in Section 6.2.

5 Hardware Prototype and Characterizations

5.1 Enabling PLM with NVM Multi-Sets

Partitioning an SSD. Modern SSDs employ many flash packages, which are connected to multiple embedded cores through multiple memory buses, called *channels*. All flash packages per channel are managed by a specific micro-coded controller, called flash memory controller (*FMC*). For example, our baseline hardware (SSD) contains eight flash packages, each containing eight flash memory banks, and all of them are connected to four cores through eight channels and FMCs. Since each FMC manages the underlying flash pack-

Figure 7: PLM and its constraint.

ages in a self-governing manner, we modify the baseline hardware to partition the single storage space into multiple spaces. Specifically, as shown in Figure 6a, we allocate each core to every two FMCs and make all the cores work independently as a (separate) physical function. As each physical function should not interfere with each other, we also evenly split the internal DRAM space into multiple spaces, each being allocated to a different physical function. Figure 6b shows our prototype of Vigil-KV hardware. There are four physical functions, each being able to be indicated by a different identifier from the host (cf. Table 1’s NVMSet ID). Flash firmware is instantiated per core, such that a physical function performance is not interfered with by other physical functions.

Integrating PLM. To implement DTWIN, each firmware of Vigil-KV hardware employs multiple queues, each being associated with the host command control and internal task management (Figure 7a). Specifically, the internal job queue (*IJQ*) is dedicated to a firmware module that manages address translation while legacy *I/O* queues (*LIQ*) are allocated to the firmware part that manages the host (NVMe) interface. The requests in Vigil-KV hardware can be therefore classified into legacy and internal tasks and served differently using *IJQ* and *LIQ*. Specifically, if a physical function is configured with DTWIN (using `PLMWindow()`), our firmware only handles the requests coming from *LIQ* and suspends all the requests of *IJQ* in both foreground and background. This device can immediately serve the incoming (client) read requests without an interruption of SSD’s internal tasks. However, the firmware cannot suspend the requests of *IJQ* if there is no room, which enforces the host schedule DTWIN appropriately. We will explain this constraint in detail shortly.

5.2 PLM Constraint and Behavior Analysis

DTWIN/NDWIN conditions. While resource partitioning and queue isolation (*IJQ/LIQ*) can remove the read latency spikes imposed by SSD’s internal tasks, unfortunately, making deterministic latency consistent is not that simple; it needs a strong collaboration with the host. First, read services on DTWIN suffer interference from a write, which was buffered in a previous NDWIN state. To eliminate this interference, Vigil-KV’s firmware explicitly flushes the internal buffer before jumping into DTWIN and disables the buffer for further writes in DTWIN. Note that offering DTWIN with fewer restrictions is the mission that our hardware targets to

Figure 8: Performance characterization of prototype.

achieve, but it should not lose any data during I/O services with DTWIN. Thus, it is necessary to clear the internal buffer and bypass it before DTWIN and in the middle of DTWIN, respectively. During the internal buffer flush, the host should not further write data in order to clearly wipe it out, which is called *device lockdown* condition. Figure 7b analyzes the device lockdown times varying based on how much data were written in the previous NDWIN. All the workloads that we tested [12, 74] write tens of MB during NDWIN. it is sufficient for the host to hold the data (if there is) by under 20 ms. Similarly, when there is a write on DTWIN, our hardware returns the performance window from DTWIN to NDWIN in order to guarantee strong durability and consistency of the written data. The host therefore makes sure that there is no write on DTWIN, called DTWIN’s *write-free* condition.

DTWIN must also not hurt the current level of reliability management that the existing flash firmware provides. Specifically, the underlying flash media can be stressed only with reads even though there is no write or internal task because of the read disturbance issue (Section 2.2). Thus, Vigil-KV hardware regulates the most extended time window for DTWIN, called *maxDTWIN*, by considering the worst case where the heavy reads on a specific block can corrupt all the page data therein. Similarly, NDWIN should be continued for a certain level of the time duration, called *minNDWIN*, which is the shortest time to complete SSD’s internal tasks (data migration and block erases) and the accumulated requests in IJQ during *maxDTWIN*. Obviously, these *maxDTWIN* and *minNDWIN* periods are strongly correlated because IJQ is limited to queue SSD’s internal tasks. By considering this, the host should schedule DTWIN and NDWIN fairly, called *fair-scheduling* condition. Based on preliminary profiles, we configure *maxDTWIN* and *minNDWIN* as 60 and 4 seconds, respectively.

Note that all these information such as the device lockdown time, *maxDTWIN*, and *minNDWIN* are exposed to the host through `GetLogPage()` (cf. Table 1).

Performance characterization and validation. Figure 8a compares the read latency trends between the baseline device and our Vigil-KV hardware prototype. While the baseline device exhibits multiple latency spikes ($\sim 402us$), the reads with Vigil-KV hardware are all served by $74us$, on average, and it is guaranteed for the latency to be under $200us$. Note that, when we change DTWIN to NDWIN by calling `PLMwindow()` at 128 seconds, the read latency reaches as high as 736

Figure 9: Implementation of Vigil-KV software stack.

us as SSD’s internal tasks are scheduled in that performance window correctly. When we schedule DTWIN and NDWIN one by one (by satisfying the fair-scheduling), as shown in Figure 8b, the performance behaviors mentioned above are all guaranteed across multiple DTWINs. At the same time, the hardware is busy handling the accumulated internal tasks in NDWIN. Lastly, Figure 8c compares the baseline device that collocates reads and writes within a single storage space and Vigil-KV hardware isolating the interference across multiple physical functions. One can observe from this figure that the read latency of the baseline device severely fluctuates and reaches as high as 2 ms. In contrast, the read latency on a physical function of Vigil-KV hardware is not interfered with by the writes heading to other physical functions even though we turned off the PLM interface for the physical function. This is because we partition each physical function with completely different resources. Note that Vigil-KV software utilizes this performance isolation for metadata management, which can make kv-sets free from managing the write-free condition in cases of writing WAL and journaling to the underlying storage.

6 Details of Vigil-KV Software

While there are constraints for PLM management, Vigil-KV hardware opens the opportunity to schedule performance windows across different physical functions being mapped to NVM sets in a finer granule manner. Vigil-KV software separates LSM KV’s internal tasks, including metadata management from client Get services, and schedules them with NDWIN having SSD’s internal tasks together. In addition, the software part of Vigil-KV reconstructs data in cases where it cannot serve the data because NDWIN services, which can in turn allow LSM KVs to have DTWIN consistently, providing strong latency determinism.

6.1 Vigil-KV Stack Implementation

Figure 9 shows the implementation of our Vigil-KV software stack. RocksDB connects Vigil-KV hardware through existing file system interfaces and performs SSTFile-related services on `/dev/kv`. Underneath the file systems, we locate our Vigil-KV driver operating with two kernel threads, `reqd` and `devd`, each scheduling block I/O (`bio`) requests and our hardware’s device states, respectively. Vigil-KV driver maps

Figure 10: Performance window management.

multiple physical functions that Vigil-KV hardware exposes to different NVM sets (meta-set and kv-sets) at the system’s initialization. `reqd` is similar to Linux existing multiple device `md` driver for striping data chunks and bios across different kv-sets, but it schedules them being aware of underlying device states. Specifically, `reqd` ensures the scheduled bio requests satisfy the write-free condition on DTWIN. In addition, it makes sure that the client’s read requests are not stalled due to LSM KV’s internal tasks by performing the data reconstruction on-the-fly. On the other hand, `devd` schedules the device states for kv-sets by considering the fair-scheduling condition and device lockdown time. More details of this device state scheduling will be explained shortly.

To make read latency predictable, the Vigil-KV driver also bypasses Linux page cache and block layer, which can make the read latency fluctuate and/or be difficult to manage to some extent. For example, Since kv-sets are only managed internally, the bio structures for kv-sets (e.g., logical block address and offsets) are different from the bio requests that the page cache manages. Instead, the Vigil-KV driver employs an internal buffer, called `plm_cache`, which buffers bio requests of kv-sets in a form of Linux `stripe` list. The `plm_cache` size can be configured by the user as a kernel parameter at the boot time. When `reqd` schedules the including bio requests to underlying kv-sets, it thus uses `stripe` requests. Since the Vigil-KV driver bypasses the page cache, it also offers `plm_sync` system call (a variant of file system’s `fsync`) to RocksDB. This `plm_sync` makes sure that the Vigil-KV driver completely flushes `plm_cache` before Memtables, WAL, and SSTFiles are deleted because of LSM KV’s internal tasks. The reason why our Vigil-KV driver bypasses the block layer and directly communicates with the `nvme` driver is that the block layer’s bio merging and ordering can break determinism. For example, the requests of LSM KV’s internal tasks are scheduled for NDWIN, but they can be issued at DTWIN by the block layer. Note that as `reqd` schedules LSM KV’s internal tasks and client requests differently, it is required to deliver the priority information from LSM KV to the Vigil-KV driver. To this end, we have a minor modification on RocksDB and journaling block device daemon (`jbd2`), which can be easily applied to other LSM KVs. When RocksDB creates background threads, it calls a system call, `ioprio_set` that configures I/O priority as ‘internal task’. `ioprio_set` delivers the priority by storing its information into `io_context` of process control block,

`task_struct`. Since Get queries and WAL are managed by all the same thread of RocksDB, we modify `WriteImpl()` such that it configures I/O priority as ‘WAL’ by calling `ioprio_set` before performing `WriteToWAL()`. Journaling is also classified by `ioprio_set` before committing a transaction (e.g., `jbd2_log_do_checkpoint()`).

6.2 Performance Window Management

Device state scheduling. As shown in Figure 10a, `devd` schedules DTWIN and NDWIN to make sure that there are always $n - 1$ kv-sets, configured with DTWIN. Therefore, all the client requests are served from DTWIN or `reqd`’s data reconstruction. When `devd` schedules performance windows to meet the fair-scheduling and device downtime constraints, there are two more technical challenges. Even though `reqd` reads the data from kv-sets configured with DTWIN, the read request can be delayed because of the outstanding reads issued previously and not yet completed. These delayed reads can be served at NDWIN, which cannot in turn offer the strong latency determinism. Similarly, the writes issued to NDWIN can be practically served at DTWIN because of the outstanding writes as well as the time delay caused by SSD’s internal tasks to some extent. This situation is less desirable than the former as it can break the write-free condition on DTWIN.

We classify DTWIN and NDWIN more specifically by considering those two unavailabilities further. DTWIN is split into *ADT* (available DTWIN) and *UDT* (unavailable DTWIN), and similarly, NDWIN is also separate into available/unavailable NDWIN (*AND/UND*). Since UDT and UND can have such outstanding operations on `reqd`, `devd` schedules NDWIN and DTWIN with a time unit as long as *nonDTWIN*. *nonDTWIN* includes UDT, AND, UND, and the device lockdown time windows (*Lockdown*), and each of the windows should satisfy the condition described by Equations 10b. `devd` profiles kv-sets’ bandwidth and then estimates UDT and UND by dividing the total amount of data volume for the outstanding requests with the read and write bandwidth of kv-sets, respectively. Note that, in contrast to the read bandwidth, the write bandwidth on DTWIN can vary. We thus use the worst-case bandwidth of writes for the UND estimation.

Dynamic adjustment for NDWIN. When `devd` controls performance windows of the underlying kv-sets per *nonDTWIN*

(=ADT), there are two challenges that it needs to address as shown in Figure 10c: NDWIN *underflow* and *overflow*. In cases where the amount of internal tasks of LSM KV and/or SSD at NDWIN, reqd wastes computation for data reconstruction and can increase the read latency when there is heavy read traffic; we observed that, when one increases QPS (queries per second) from 60K to 150K, the read latency increases by 26%, on average. While minimizing the data reconstruction involvement (NDWIN) is the matter, NDWIN can break determinism if too many the internal tasks are issued. We also preliminary evaluated all our workloads and observed that 48.3% of compaction scheduled at NDWIN (excluding UDT, UND, and Lockdown) are executed at DTWIN.

As shown in Figure 10d, devd adjusts NDWIN at runtime to address the underflow and overflow situation. Specifically, devd begins scheduling NDWIN (per ADT) by setting it as long as minNDWIN to minimize the involvement of reqd’s data reconstruction and spreads buffered bio requests (stored on plm_cache) across different minNDWIN. If the outstanding requests are accumulated more than a threshold, it maximizes NDWIN to serve LSM KV internal tasks’ I/O as fast as possible. For example, as shown in Figure 10e, devd examines reqd’ queues containing outstanding bio requests at the time epoch 1 ($t1$). In this case, all the outstanding requests are served/completed before $t2$. However, since the requests associated with LSM KV internal tasks at $t3$ are not resolved by $t4$, devd maximizes NDWIN. Note that, Vigil-KV applies dynamic NDWIN adjustment for plm_cache by using the user-defined memory limits as adjustment threshold.

7 Evaluation

7.1 Experimental Setup

Prototype and environments. We implement a prototype of Vigil-KV hardware on a 1.92TB datacenter-scale NVMe SSD for research purposes. Vigil-KV hardware employs four physical functions, and they equally divide the hardware resources such as 3GB LPDDR4 DRAM, eight channels, and 64 TLC NAND flash dies into four. Note that the baseline hardware is not that different from the Vigil-KV hardware. It has hardware resources the same as Vigil-KV hardware, but

	Short description.	Get (%)	Put (%)	Get \$ hit (%)	Flush write (GB)	Compaction write (GB)
FB	UserDB All social graph actions	54	46	25	2.4	8.8
	ZippyDB Read ObjStorage meta	42	58	86	8.9	17.5
YCSB	A Log user action	66	34	17	3.6	19.2
	B Update/read photo tag	95	5	23	0.2	1.3
	D Read latest record	95	5	83	0.5	1.8
	F Update user record	74	26	45	3.1	15.6

Table 2: Important characteristics of evaluated workloads.

it only employs a single physical function. We perform the evaluation on a 12-core AMD Ryzen 9 5900X, 96GB DRAM, and Vigil-KV hardware by running Vigil-KV software implemented on RocksDB 6.23.0 and Linux 4.19.91. For the evaluation, we set the size of plm_cache as 2GB.

Workloads. We evaluate six workloads that use an LSM KV as their backend storage engine. (two from Facebook [12] and four from Yahoo [74]) For social network services, Facebook uses UserDB and ZippyDB workloads that serve social graph data and object (e.g., image or video) storage metadata as a form of key-value, respectively. The key-value cache hit ratio of UserDB is only 25% due to its irregular key access pattern, whereas that of ZippyDB is 86% because of its read-latest characteristics of social contents. Yahoo also provides representative LSM KV access patterns of various cloud services, such as write-intensive (YCSB-A), read-intensive (YCSB-B), read-latest (YCSB-D), and read-modify-write intensive (YCSB-F). In the table, also analyze the amount of writes caused by internal tasks (compaction) during our evaluations.

Configurations. We evaluate six different LSM KV hardware and software combinations.

- Base [1]: the representative conventional LVM KV (e.g., RocksDB) with the baseline hardware.
- SILK [24]: the state-of-the-art software supports of LSM KV with the baseline hardware.
- PLM: Vigil-KV hardware with a simple driver, which utilizes the PLM interfaces (cf. Section 4.1).
- I-PLM: based on PLM, we add the metadata isolation support (cf. Section 6.1).
- R-Vigil: based on I-PLM, we add the device state scheduling support (cf. Section 6.2).
- O-Vigil: based on R-Vigil, we add the dynamic non-determinism scheduling support (cf. Section 6.2).

(b) PLM and I-PLM.

(c) R-Vigil.

(d) O-Vigil.

Figure 12: Time series analysis of representative workload (UserDB).

Figure 13: CDF graphs.

Since Vigil-KV adopts the concept of array-level memory and storage techniques making three NVM sets as a single storage volume, we use conventional multiple device (md) driver for Base and SILK as well to satisfy the fair performance comparison among the configurations that we tested.

7.2 Long-tail Latency Analysis

We analyze the long-tail latency on Get services by executing all the Facebook and Yahoo workloads atop the six configurations. As shown in Figure 11, UserDB, YCSB-A, and YCSB-F show longer p99.9 tail latency than others due to their high Put service ratio, which increases the LSM KV and SSD internal tasks. Meanwhile, ZippyDB and YCSB-D further exhibit shorter tail latency than YCSB-B thanks to their high key-value cache hit ratio, which can reduce the number of reads interfered with by internal tasks. To understand how six different configurations impact long-tail latency, Figure 12 analyzes time series by selecting UserDB as a representative workload. It shows both storage read latency (left axis with black line) and write throughput (right axis with red line), which allow us to infer how much LSM KV and SSD internal tasks interfere with Get queries and when the internal tasks occur.

Base vs. SILK. As shown in Figure 11, SILK only reduces 5% of the tail compared to Base, on average. Even though UserDB can capture the user idle behaviors while YCSB workloads cannot, still there was not an enough idle time to schedule LSM KV internal tasks as shown in Figure 12a. Thus, the delayed compaction starts to interfere with Get services from 2600 seconds in SILK, and the storage read latency spikes.

SILK vs. PLM. PLM experiences the tail similar to Base (5.4% longer than SILK), which indicates that Vigil-KV hardware cannot guarantee latency determinism without Vigil-KV software. As shown in the top of Figure 12b, Vigil-KV hardware is in NDWIN most of the time (red background) since WAL or journaling breaks the DTWIN’s write-free condition.

PLM vs. I-PLM. Therefore, I-PLM isolates WAL and journaling to dedicated meta-set and securing NDWIN (white background) as shown in the bottom of Figure 12b. Since UserDB has a higher Put service ratio than others, it experiences 24.4% shorter long-tail latency compared to PLM, while others achieve 12% shorter long-tail latency, on average.

I-PLM vs. R-Vigil. As shown in Figure 12c, R-Vigil

Figure 14: Normal cases.

schedules NDWIN across three kv-sets and guarantees latency determinism as much as possible by reconstructing reads with DTWIN kv-sets. Thus, it can reduce long-tail latency by 48.2% compared to I-PLM, on average. As shown in Figure 11, especially for high Put service workloads (YCSB-A and YCSB-C), they exhibit 70% shorter long-tail latency than I-PLM. However, R-Vigil still exhibits long-tail latency due to NDWIN overflow (cf. 736 ~ 809 seconds in Figure 12c).

R-Vigil vs. O-Vigil. Therefore, O-Vigil strongly guarantees the latency determinism with out dynamic NDWIN adjustment. O-Vigil reduces long-tail latency by 33.5% than R-Vigil, on average, while high Put service workloads (UserDB, YCSB-A and YCSB-F) can achieve shorter long-tail latency 59%. As shown in Figure 12d, O-Vigil dynamically schedules LSM KV’s internal tasks.

Note that O-Vigil not only reduces the long-tail latency of the Base by 3.19 \times , on average, but also guarantees under 500us Get service latency across all the workloads.

7.3 Analysis of Different-level Latency

Tail latency distribution. To understand the impact of Vigil-KV for the different levels of tail-latency, we analyze the CDF of Get latency for three representative workloads, such as UserDB, YCSB-A, and YCSB-D. Since UserDB and YCSB-A are high Put service ratio workloads, the long-tail of Get latency start from p99 as shown in Figures 13a and 13b. On the other hand, as YCSB-D has higher Get service ratio workloads and most of the Get is serviced from the key-value cache, the long-tail of Get latency start from p99.9 as shown in Figure 13c. Thus, for the YCSB-D workload, O-Vigil achieves 78% shorter p99.99 long-tail latency than Base, while only 11% of the long-tail is reduced at p99.9 latency. Not only for YCSB-D, O-Vigil can further mitigates the p99.99 long-tail latency of UserDB and YCSB-A by 69% and 94%, respectively.

Note that Vigil-KV can also guarantee the strong latency determinism (us-scale latency of Get service) more than four nines long-tail latency (p99.99) as shown in Figure 13.

Normal cases. Since Vigil-KV adds more software supports than conventional LSM KV, it is important to analyze the Get service latency of normal cases to check whether Vigil-KV slows down the average Get latency or not. Figure 14 shows the average latency of Get services for all the workloads and

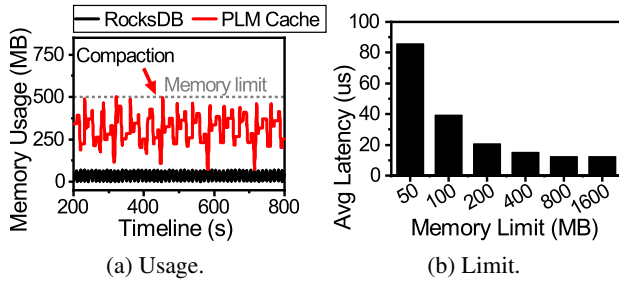

Figure 15: Memory consumption.

configurations, and we observed that Vigil-KV (O-Vigil) reduces the average Get latency by 34% compared to Base (not increases the average Get latency). This is because of two reasons: 1) Vigil-KV isolates the write I/O traffic of metadata (e.g., WAL and filesystem journaling) from the read I/O traffic of Get service, and 2) Vigil-KV minimizes the data reconstruction as much as possible. Note that, the reason why ZippyDB and YCSB-D show shorter average Get latency compared to other workloads is that they have a high key-value cache hit ratio (which is not related to Vigil-KV solutions).

7.4 Memory Consumption and Scan Service

Time series analysis. Figure 15a shows memory consumption of application-level (e.g., RocksDB’s Memtable) and kernel-level (e.g., Vigil-KV driver’s `plm_cache`) during workload execution. We select ZippyDB as a representative workload since there is a large amount of storage writes by compaction internal tasks (cf. Table 2). While RocksDB periodically flushes Memtables to the underlying storage to maintain a certain threshold (e.g., 64MB) of the application-level write buffer, Vigil-KV has to cache/buffer write requests until the target kv-set reaches NDWIN. Thus, the memory usage of `plm_cache` increases when LSM KV internal tasks (e.g., Memtable flush and compaction) occur. However, Vigil-KV supports dynamic adjustment for NDWIN being aware of the memory limits of `plm_cache` which can regulate the maximum memory consumption.

Sensitivity test. To understand the impact of `plm_cache`’s memory limits to the average latency of Get services, we perform sensitivity tests by increasing the memory limits from 50MB to 1.6GB as shown in Figure 15b. While extremely low memory limit (e.g., 50MB) exhibits long normal latency of more than 80 μ s, a few hundreds of MB `plm_cache` is enough to serve normal Get latency without performance degradation.

Note that, although Vigil-KV delays LSM KV internal tasks until target kv-sets reach NDWIN, it does not increase memory footprints or degrade the Get latency, unlike prior studies (e.g., TRIAD [22], PebblesDB [23], and SILK [24]).

Performance with Scan. Vigil-KV mainly considers improving the performance of Get queries as a first-class citizen. This is because Get of most large-scale workloads (Facebook [12] and Yahoo [74]) account for 78% of the total queries in the workloads that we tested. While Scan in contrast accounts

Figure 16: Performance analysis of Scan queries.

for 3% of the total queries, its query latency may also be important for a specific workload such as scanning many posts in parallel (e.g., YCSB-E).

In this subsection, we compare the latency behaviors of Vigil-KV (O-Vigil) with those of SILK by evaluating YCSB-E as the representative of Scan-sensitive workloads (95% and 5% for Scan and Put, respectively). Figure 16a shows the comparison for the average (p50) and p99.9 latency. Since RocksDB performs readahead and prefetch in default, the sequentially of Scan exhibits many cache hits. Similar to YCSB-D, this in turn benefits the average latency marginal as Scan operations of both O-Vigil and SILK from memory than devices in most cases. However, such readahead and prefetch techniques cannot avoid every I/O request and hide all the read latency that the underlying SSD exposes. Vigil-KV can support deterministic latency for such cases, thereby offering 1.6 \times shorter p99.9 latency of SILK. This performance benefit becomes more promising as the degree of the long-tail latency gets higher. As shown in Figure 16b, even though there are few Put operations, they lead LSM KV internal tasks, which can make p99.9~p99.999 tail-latency much longer. Vigil-KV can remove such long-tail latency with hardware/software co-designed strong latency determinism, thereby improving the tail latency by 1.6 \times ~ 4 \times .

8 Conclusion

In this paper, we propose Vigil-KV, a hardware and software co-designed framework that eliminates long-tail latency by introducing strong latency determinism into LSM KVs. We evaluate diverse Facebook and Yahoo scenarios with Vigil-KV, and our empirical evaluation shows that Vigil-KV can reduce the tail latency of the baseline KV system by 3.19 \times while reducing the average latency by 34% as well.

Abstract

Recent persistent memory (PM) key-value (KV) stores adopt the log-structured approach to reap PM's full potential. However, they fail to sustain high performance at high capacity utilization due to inefficient compaction. The inefficiency results from the unawareness of PM's characteristics. This paper proposes PACMAN, an *efficient PM-aware compaction approach* for log-structured KV stores on PM. PACMAN (1) offloads reference search during compaction to service threads, so as to mitigate the onerous index traversal overhead, (2) leverages tagged pointer and DRAM-resident compaction information to avoid excessive PM accesses introduced by garbage collection, (3) redesigns the compaction pipeline based on the PM peculiarities to lower the persistence overhead, and (4) separates hot and cold objects in a lightweight manner to reduce PM data copying in compaction. We apply PACMAN to state-of-the-art PM-based log-structured KV stores and evaluate PACMAN using various benchmarks. Our evaluations show that PACMAN curtails the performance degradation at high capacity utilization, increases the compaction bandwidth by 2-4 \times , and boosts the performance of the state-of-the-art systems by 1.5-1.8 \times under write-intensive workloads.

1 Introduction

The log-structured approach has been adopted in key-value (KV) stores on PM [8, 12, 30, 44] for benefits like high capacity utilization (low fragmentation), small device-level write amplification on PM, and low failure atomicity overhead. Despite having these benefits, the log-structured approach needs to reclaim free space (i.e., garbage collection or compaction) by dedicated background threads (called *cleaners*), which contributes to the major bottleneck, especially under a high capacity utilization [39].

Over-provisioning can alleviate this problem but is not cost-efficient. Datacenters place more emphasis on space utilization in recent years [15] and try hard to fully utilize their storage to reduce the total cost of ownership (TCO) [40]. Thus,

it is important for storage systems to keep high performance under high space utilization, especially for PM that has a much higher cost than traditional storage devices.

The compaction overhead is already severe in DRAM-based log-structured KV stores. For example, RAMCloud's throughput could drop by up to 50% at high capacity utilization [39]. Nibble, a concurrent log-structured KV store, enables 8 compaction threads to carry out the compaction work per socket which has only 15 cores; even so, its throughput drops to nearly a quarter in dynamic workloads [35].

Worse still, we observe that PM's idiosyncrasies exacerbate the bottleneck of compaction. Our evaluation on state-of-the-art PM-based log-structured KV stores¹ (including FlatStore [12] and Viper [8]) shows that their performance drops significantly at high capacity utilization. With abundant CPU resources for compaction (foreground thread count to background cleaner thread count is 3:1), when the capacity utilization increases from 50% to 80%, the system throughput drops by up to 75% under write-intensive workloads. Unfortunately, simply adding more CPU resources for compaction is inefficient, because the performance of PM does not scale well with high thread count [46]; in our experiment, the decline is still up to 60% even with doubling cleaner threads.

We analyze that there are four deficiencies in the conventional compaction approaches of these KV stores accounting for the performance degradation. First, after copying valid objects from the log segment being reclaimed, cleaners need to update object references in the index, which incurs a huge overhead, especially when the index resides on PM due to PM's high access latency (3 \times of DRAM in terms of random read [46]). Second, service threads (i.e., threads performing user requests, such as Get and Put) generate quantities of small random PM accesses for compaction (e.g., marking deleted flags). These small random accesses result in I/O amplification of PM, wasting PM's limited bandwidth (1/3 and 1/6 of DRAM in terms of read and write, respectively [46]). Third, cleaners need to perform many expensive persistence

¹Note that this paper targets PM-based log-structured KV stores but not LSM-tree-based KV stores.

*Jiwu Shu is the corresponding author (shujw@tsinghua.edu.cn).

instructions to guarantee crash consistency. Fourth, excessive data copying in compaction contends limited PM bandwidth with service threads. All these deficiencies boil down to *unawareness of PM's characteristics*.

To solve the problems above, this work proposes PACMAN, an efficient PM-aware compaction approach for log-structured KV stores on PM. PACMAN comprises a series of techniques to improve the compaction efficiency of log-structured KV stores on PM. ① PACMAN introduces a technique called *short-cut*, which offloads reference search operations during compaction to service threads. Therefore cleaners can locate and update references without traversing the index. ② PACMAN reduces excessive PM random accesses. Specifically, PACMAN leverages *tagged pointer* to reduce high-latency PM reads, and stores frequently-accessed metadata in DRAM to avoid small random PM writes. ③ PACMAN redesigns the compaction pipeline in a batch pattern and leverages several optimizations according to the characteristics of PM, which accelerates the compaction and reduces the persistence overhead. ④ PACMAN adopts a lightweight hot-cold separation method to reduce the amount of valid data copying on PM and corresponding reference updates. Consequently, PACMAN boosts compaction efficiency, decreases CPU resources for compaction, and enhances system performance at high capacity utilization.

We apply PACMAN to state-of-the-art PM-based log-structured KV stores, FlatStore [12] with different indexes and Viper [8], and evaluate PACMAN using a variety of benchmarks. Our evaluation shows PACMAN enhances the compaction bandwidth by up to 4× and system performance by 2.4-4.6× under write workloads at high capacity utilization. Besides, PACMAN has nearly no side-effects under read-intensive workloads and has little overhead on recovery.

In summary, this paper makes the following contributions:

- We analyze the deficiencies of existing compaction approaches for log-structured KV stores on PM.
- We propose PACMAN, an efficient PM-aware compaction approach for PM-based log-structured KV stores, which enables them to achieve high performance even at high capacity utilization.
- We apply PACMAN to state-of-the-art PM-based log-structured KV stores and conduct a series of experiments to show the efficiency of PACMAN.

2 Background and Motivation

2.1 Log-Structured KV Stores on PM

Benefits of the log-structured approach on PM. The log-structured approach has been adopted by state-of-the-art KV stores on PM [8, 12, 30, 44] for the following benefits. First, a log-structured approach to memory management supports high capacity utilization (i.e., the percentage of space used by alive data) of 80-90%, which is unfeasible for non-copying allocators having great memory fragmentation [39]. Second,

Figure 1: Overview of a log-structured KV store.

due to the mismatch of access granularities between cache lines and PM media (64 bytes vs. 256 bytes of Optane DIMM, the only available PM production for now), small random writes would cause write amplification. The log-structured approach adopts a sequential write pattern, thus alleviating the write amplification and improving the write throughput. Third, in comparison with update-in-place approaches which need expensive logging operations, the log-structured approach makes it easy to commit an arbitrarily-sized persistent write.

Storage structure. Figure 1 shows the basic structure of log-structured KV stores on PM. The whole log space locates on PM and is divided into small-sized (e.g., 4 MB) pieces called *segments*. Each service thread maintains a thread-local segment to append KV objects. Compared to writing to a global log tail, using per-thread segments not only avoids contention but also limits the number of concurrent threads accessing an Optane DIMM [8, 46]. Once a service thread has run out of its local segment, it requests a new free segment from the free segments pool. A global index stores *references* which point to the actual address of KV objects in the log. The index is put in DRAM or PM for different requirements. A volatile index in DRAM delivers better performance but needs more time to restore after a restart. On the contrary, a persistent index in PM provides instant usability after a restart but relatively lower performance.

Garbage collection. Despite having numerous benefits, log-structured systems are obliged to tackle garbage collection by compaction, the main culprit of performance degradation. Update or delete operations make prior objects stale in the log. These stale objects occupy the memory space until being reclaimed. When there is no free space left, service threads stall and wait for new free space produced by compaction. In other words, the system's throughput at high capacity utilization is nearly limited to the compaction throughput.

A qualified compaction process is described as follows. When the fraction of free space is low, the compaction is triggered, and candidate segments are selected to compact through a certain strategy such as cost-benefit score². During

² $score = \frac{(1-u) \times age}{u}$, where u is the segment's utilization (fraction of data alive), and age is the time since the segment running out [39].

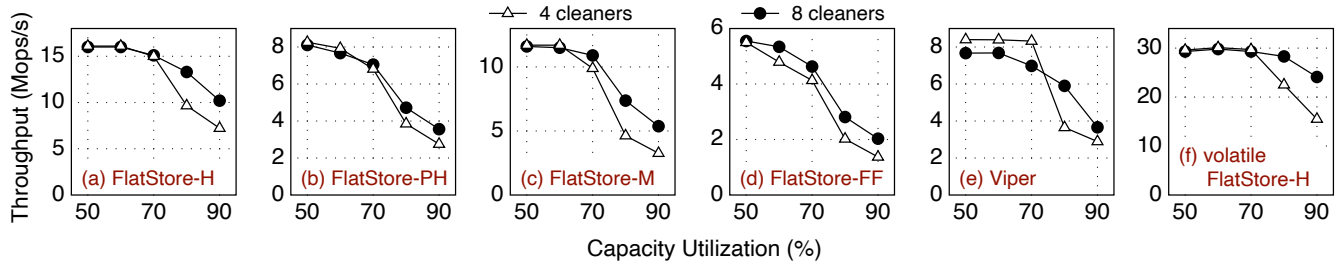

Figure 2: Throughput decline at different capacity utilizations. *FlatStore-H*: with CCEH in DRAM. *FlatStore-PH*: with CCEH in PM. *FlatStore-M*: with Masstree in DRAM. *FlatStore-FF*: with FastFair in PM. *Viper*: with CCEH in DRAM. *volatile FlatStore-H*: both the index (CCEH) and log in DRAM.

compaction, cleaners copy all alive objects from the old segment to a reserved segment and update references to these objects in the index. There are two methods to identify the liveness of each object in the segment. One method is checking whether the object is still pointed by the reference in the index (e.g., FlatStore [12]). Another one is checking the deleted flag (usually 1 bit) in the metadata header of objects; the deleted flag is set when the corresponding object is updated or deleted (e.g., Viper [8]). Both of the two methods have shortcomings on PM, which we will analyze in §2.2. After all valid objects in the old segment have been copied to the reserved segment and their references have been updated, the old segment is cleaned and turned into a free segment.

2.2 Compaction Overhead Analysis on PM

The compaction overhead already matters in DRAM-based log-structured KV stores [35, 39]. Worse still, *the compaction overhead becomes more severe on PM*, as cleaner threads need to contend PM’s limited bandwidth with foreground service threads. Further, necessary but expensive persistence instructions and PM’s high access latency make the overhead of copying objects and updating references higher, especially when the index is persistent.

Experiments. To analyze the compaction overhead of PM-based log-structured KV stores in depth, we evaluate state-of-the-art systems including FlatStore [12]³ and Viper [8]⁴.

We evaluate four versions of FlatStore, including FlatStore-H (FlatStore with CCEH [37], a hash table, in DRAM as a volatile index), FlatStore-PH (FlatStore with CCEH in PM as a persistent index), FlatStore-M (FlatStore with Masstree [34], a trie-like concatenation of B+-trees, in DRAM), and FlatStore-FF (FlatStore with FastFair [20], a B+tree, in PM) to show different cases. Like FlatStore-H, Viper also uses CCEH in DRAM as its volatile index. We measure the performance with a YCSB-A workload, where 200 million KV objects are randomly loaded first, then service threads perform a write-intensive workload (50% Get

and 50% Put) with Zipfian distribution (skewness parameter 0.99) until the system throughput converges to a stable value. The value size is 48 bytes, a representative value of small objects according to recent real-world workloads analysis [9]. We restrict the capacity utilization from 50% to 90% (the percentage of space occupied by alive data). We set the service thread count to 12, and the cleaner thread count to 4 or 8. All threads are bound to a single socket, which is equipped with three Intel Optane DCPMMs.

Figure 2 shows their throughput at different capacity utilizations. From the results we observe that: (1) *The throughput of all systems drops significantly at high capacity utilization, especially for systems with a tree-based or persistent index.* (2) *Simply augmenting more CPU resources for compaction (8 cleaner threads) has limited improvements for log-structured KV stores on PM*, and also intensifies the contentions. Note that the garbage collection overhead will be much larger under uniform workloads; see detailed results in §4.2.3.

We also evaluate the situation that both index and log locate on DRAM (volatile FlatStore-H, Figure 2(f)) to simulate an in-DRAM log-structured KV store. The throughput decline is mitigating than the PM-based KV stores. Using 8 cleaners has obvious improvements on DRAM because DRAM has abundant bandwidth. However, adding more threads on compaction is not cost-effective and has less benefit in PM-based systems as PM does not scale well with multiple threads due to PM’s idiosyncrasies [46]. This shows that PM’s peculiarities aggravate garbage collection overhead.

Overhead analysis. Taking test cases with 4 cleaners and 80% capacity utilization above as examples, we analyze the compaction overheads and find out that there exist four inefficiencies on compaction.

(1) *The high latency of random access in the index.* Lots of random accesses are introduced by two operations on the index, checking references for identifying liveness and updating references after copying alive objects. These two operations require multiple random accesses in the index and these accesses have no cache locality since alive objects in compaction are usually cold.

Viper sidesteps checking references with deleted flags in PM; yet, updating references costs half of the compaction

³As the original FlatStore is a networked system, we implement it as an embedded KV store, and remove the network-related features for simplicity.

⁴We use the variable-sized object version of Viper and enhance it with multi-threaded compaction.

time. FlatStore identifies the liveness of each object by checking the reference instead of using the deleted flag to avoid small random writes. Thus, cleaners in FlatStore need to access the index twice for each alive object, one for checking liveness and one for updating the reference. FlatStore spends 60% of compaction time on the index in FlatStore-H. The overhead becomes more severe when it comes to tree-based or persistent indexes, which reach about 80% and 90% of compaction time in FlatStore-M and FlatStore-FF, respectively. The latency of a search or an update operation in FastFair reaches several microseconds due to PM's high latency.

(2) **Excessive small random access on PM.** Service threads perform excessive PM accesses for garbage information. To maintain the size of garbage data of each candidate segment, service threads read the metadata of the stale object to get its size when the object is updated or deleted. These reads on PM not only incur high latency but also pollute cache. In addition, marking deleted flags in segments would introduce extra small random PM writes. Though marking deleted flags facilitate garbage collection, it is harmful to limited PM bandwidth.

(3) **Expensive persistence instructions.** Though copying alive objects conducts sequential reads and writes, it still costs heavier than copying on DRAM, not only due to the low bandwidth but also because of necessary but expensive persistence instructions (i.e., `flush` and `fence`).

(4) **A large amount of data copying on PM.** The performance slowdown presents superlinear scaling with capacity utilization. Cleaners have to do compaction much promptly at high utilization, and segments to compact have less time to accumulate stale objects. Accordingly, at high capacity utilization, cleaners have to copy bulk of data in segments to reclaim free space. The large amount of data copying contends the limited PM bandwidth with service threads.

To summarize, traditional compaction approaches do not consider the peculiarities of PM, hence squandering limited PM bandwidth. On the other hand, existing log-structured KV stores completely decouple the index and log. Therefore, there has little room to facilitate garbage collection without particular assistance from the index.

3 Design

Motivated by the analysis above, we propose PACMAN, a PM-aware compaction approach for log-structured KV stores on PM. PACMAN solves the deficiencies in conventional compaction approaches according to the characteristics of PM, boosting the system performance at high capacity utilization. PACMAN introduces several core design principles to realize efficient compaction.

- **Avoid onerous index traversal.** PACMAN offloads reference search operations during compaction to foreground service threads without extra effort. With the information offered by service threads, cleaner threads can locate and update references effortlessly (§3.1).

- **Reduce excessive small PM accesses.** PACMAN removes avoidable PM accesses by leveraging tagged pointer and storing frequently-accessed metadata in DRAM (§3.2).
- **Redesign the compaction pipeline to cater to peculiarities of PM.** PACMAN divides the compaction pipeline into two major phases, copying valid objects and updating references. For each phase, cleaner threads process objects in a batched manner. Subsequently, PACMAN can reduce the number of persistence orderings and leverage non-temporal stores and software prefetching (§3.3).
- **Separate hot and cold objects to reduce excessive data copying on PM.** PACMAN uses a hotspot set to distinguish hot and cold objects and stores them in different segments to facilitate compaction. PACMAN can also replace the set silently to handle hotspot shift without blocking foreground service threads (§3.4).

3.1 Traversing Index with Shortcut

Traversing the index has expensive overhead due to the random access pattern, especially for persistent index. PACMAN introduces a technique called `shortcut` to alleviate this overhead in compaction. In this section, we take tree-based (including trie-based) indexes as an example.

In existing compaction approaches, after copying a valid object from an old segment to a new segment, the cleaner needs to traverse the index, locate and update the reference. When locating an entry, the cleaner starts from the root node and then traverses multiple internal nodes to the deepest leaf node. The pointer-chasing path contains several random accesses, and has much higher latency on PM. According to our analysis (§2.2), these reference update operations constitute the most considerable part of overhead in compaction.

However, we observe that the root-to-leaf path was already traversed when the object was created or updated. To prevent the cleaner from traversing the high latency path again, PACMAN leverages the traversal that was done before.

When creating or updating an object, in addition to insert or update of the reference in the index, service threads also record the address of leaf node which contains the reference in the log. We name this additional information `shortcut`. Objects thereupon have a `shortcut` to their reference in the index. During compaction, cleaners could take the shortcut to quickly locate the leaf node in the index. Then, cleaners still need to search the exact entry in the leaf node. To accelerate the last mile, PACMAN also records the position number of the entry in the shortcut. In this way, the reference search operation is offloaded to service threads but without extra effort. Figure 3 shows an example of a shortcut. The `Node Addr` points to the node, and the `KV Pos` records the entry position number of the array.

Handling shortcut invalidation. In addition, PACMAN needs to handle the possible invalidation of the shortcut in two situations. ① The address of an index entry may change (e.g.,

Figure 3: Structure of shortcut (taking a tree-based index as an example). The value in an index’s KV pair is a reference which points to the object in the log. KV Pos is the position number of the associated KV pair (i.e., 2 in this figure).

caused by shift operations in a sorted tree-based index) and thus the shortcut may not point to the original reference. ② The original node pointed by shortcut may have been deallocated, and the original address space may be reclaimed or re-allocated for other usages. Accessing the address wrongly could result in program crash.

The first situation (i.e., Node Addr points to a valid node, but KV Pos is wrong) can be handled easily by conducting some checks. The cleaner will check the header of the node and compare the key indicated by KV Pos to infer that whether the shortcut is correct. These checks are identical as in a normal insert operation. PACMAN attempts to reduce penalty of an incorrect shortcut. For example, in a tree-based index, the cleaner will check if the key still exists in the original leaf node or the sibling node. Thus, shortcuts can tolerate shift operations to a certain extent. If the shortcut is completely invalid, the cleaner updates the reference by falling back to the normal update operation. The penalty of an invalid shortcut is about one or several useless memory accesses and can be further reduced by prefetch technique (§3.3).

To avoid the second situation (i.e., Node Addr does not point to a valid node), instead of directly freeing the space of deleted nodes, PACMAN reserves the deallocated space for future allocations. The deleted nodes are marked as deleted by some means (e.g., a deleted bit in node header or all bytes of the header are set to 0). When creating a new node, PACMAN first attempts to re-use a reserved and same-typed node space. Generally, an index typically has only one or a few fixed types of nodes (e.g., 4 types of nodes in ART [29]), so it is easy to realize the re-allocation. In this way, PACMAN guarantees that the address space of deleted nodes is still valid and this situation turns into the first situation.

Optimizing space overheads. PACMAN stores shortcuts inside the same log segment with their associated objects, which

squeezes the available space and increases compaction pressure. Thus, the benefits of shortcuts are overshadowed especially when the capacity utilization is extremely high and the average object size is small.

PACMAN reduces the space overheads of shortcuts to minimize the punishment of storing shortcuts. First, the size of a shortcut is compressed to 48 bits, including 43-bit Node Addr and 5-bit KV Pos. The Node Addr is compressed based on two opportunities: 1) Current virtual address only uses 47 bit (for user-space virtual address, the 47-63th bits are 0); 2) Memory allocators (e.g., malloc [1], PMDK [4]) allocate objects with at least 16-byte alignment by default. The size of Node Addr can be further reduced according to the specific alignment of nodes in the index (e.g., 512-byte leaf nodes in FastFair). Second, PACMAN doesn’t store shortcuts for objects reclaimed in compaction and hot objects with the help of hot-cold data separation (§3.4). The objects reclaimed in compaction are almost coldest, and the reserved segment are less likely to be compacted again. Hot objects tend to be updated soon and become stale, and shortcuts are useless for stale objects. Besides, shortcut should be disabled when its acceleration cannot cover the punishment of sacrificing more space (e.g., for a hash table-based index and at an extremely high capacity utilization).

Limitation. Shortcut is unsuitable for KV stores with a LSM-based index (e.g., ChameleonDB [50]). Since KV entries in the LSM-based index are moved frequently due to LSM compactions, shortcuts can only stay valid for a transient time.

3.2 Reducing Excessive PM Accesses

Existing garbage collection approaches do not fit persistent memory management as they take no notice of random memory accesses. The introduced small random accesses will cause I/O amplification in PM. To address this issue, PACMAN 1) embeds size information in the reference to reduce PM read, and 2) stores frequently-accessed metadata in DRAM to reduce small random writes on PM.

Embedding size information in the reference. When updating an object, the service thread needs to update the size of total garbage data of each segment for compaction candidate selection. However, getting the size of the stale object needs to read its metadata from PM. To avoid these random PM reads, PACMAN embeds the size of an object in the upper 16 bits of its reference. Therefore, the address and size of the object’s stale version can be acquired from the index together. Because 16 bits can express 64 KiB at most (or larger if objects are allocated obeying to some alignments), PACMAN sets the upper bits of reference to 0 for objects larger than 64 KiB and has to read their metadata when updated or deleted. Fortunately, most objects have small size according to the recent real-world workloads analysis [9].

DRAM-resident garbage information. Since checking references to distinguish the liveness of objects has significant

overhead, especially when the index is on PM, PACMAN turns to deleted flags to store the liveness information. Marking deleted flags in objects' headers on PM will introduce numerous small random writes. To eschew the detrimental effects of small random writes on PM, PACMAN adopts a bitmap on DRAM for each segment. PACMAN locates the corresponding bit of a variable-sized object with its reference directly. We denote the minimum size of an object as `MIN_SIZE` (8 bytes of key, 8 bytes of value, plus the size of metadata header). PACMAN reserves one bit per `MIN_SIZE`. The position of the deleted flag is calculated by dividing the offset within the segment by `MIN_SIZE`. Though this approach leaves some bits unused thereby wasting a small amount of DRAM space, PACMAN can quickly locate the corresponding deleted flags for variable-sized log items. Even in the most extreme case, where the size of the key, value, and header are both 8 bytes, the bitmaps consume DRAM about 0.5% of the log space.

Besides bitmaps, PACMAN stores the size of garbage data of each segment in DRAM which is frequently updated.

3.3 Redesigning the Compaction Pipeline

Traditional compaction algorithms (e.g., memory compaction in RAMCloud and Viper) update the reference right after copying a valid object. Nevertheless, this pattern has several shortcomings on PM without consideration of PM's idiosyncrasies. PACMAN reorganizes the pipeline in a batch pattern as shown in Figure 4. The new algorithm separates the phases of copying objects and updating references, and processes objects in a batched pattern. The cleaner first collects all valid objects from the old segment to a volatile buffer (step ①), and then copies them together to PM (step ②). After that, the cleaner updates their references. Different from using a normal index update operation, the cleaner updates references by a special index update operation (`update_pacman`, lines 43-52) that takes the object's shortcut to locate the reference. Besides, to handle race condition on the index, `update_pacman` carries an extra old value of the reference (`old_addr`) to update the reference in a compare-and-swap semantics (explained later). Subsequently, PACMAN applies the following three optimizations to cater to PM's idiosyncrasies.

(1) Reducing ordering and launch concurrent flushes. In traditional algorithms, for each relocated object, an ordering point is required to ensure that the object has been flushed to PM before updating its reference. These fences are expensive as they stall CPU pipelines.

However, after separating the copying phase and the updating phase, only one fence instruction is needed between the two phases (line 15). PACMAN eliminates the ordering points (`fence`) after update references (step ④). Doing so will not break crash consistency. This is because the old segment is still available until the compaction is finished. Even if an inopportune crash happens before reference updates being flushed to PM (during step ⑤), after restart, for those objects whose references have not been updated or persisted, they can

```

1  NUM_BATCH_FLUSH = 32; // number of concurrent flushes
2  void compact_pacman(Segment segment) {
3      Buffer buffer; // temporal buffer in DRAM
4      vector<ObjectMeta> meta_vec;
5      // iterate objects in this segment
6      for (valid object old_obj : segment) {
7          // ①. generate temporal new object into buffer
8          tmp_new_obj = make_object(old_obj, buffer.offset);
9          buffer.append(tmp_new_obj);
10         meta_vec.push_back(ObjectMeta(old_obj, tmp_new_obj));
11     }
12
13     // ②. copy buffer to reserved segment by ntstore
14     ntstore(reserved_segment, buffer);
15     fence();
16
17     vector<EntryAddr> entry_addr_vec; // for batch persist
18     // iterate valid objects in buffer
19     for (size_t i = 0; i < meta_vec.size(); i++) {
20         // ③. prefetch next object's entry in index
21         prefetch(meta_vec[i + 1].shortcut);
22
23         // ④. update reference
24         (Shortcut, key, old_addr, new_addr) = meta_vec[i];
25         EntryAddr entry_addr;
26         index.update_pacman(Shortcut, key, new_addr, old_addr,
27                             &entry_addr);
28
29         // ⑤. batch persist
30         entry_addr_vec.push_back(entry_addr);
31         if (entry_addr_vec.size() >= NUM_BATCH_FLUSH) {
32             // launch concurrent flushes
33             for (entry_addr : entry_addr_vec) {
34                 persist(entry_addr);
35             }
36             fence();
37             entry_addr_vec.clear();
38         }
39     }
40 }
41
42 // customized index update operation
43 bool Index::update_pacman(Shortcut shortcut, KeyType key,
44                           ValueType new_addr, ValueType old_addr,
45                           EntryAddr *entry_addr) {
46     // find entry by key with the help of shortcut
47     ...
48     *entry_addr = &entry; // record entry address
49     // update only if old_addr matched, e.g., using CAS
50     bool success = CAS(&entry.value, old_addr, new_addr);
51     return success;
52 }

```

Figure 4: Pseudo-code of the PACMAN compaction algorithm and customized index update operation.

still be acquired from the old segment.

Furthermore, PACMAN adopts lazy and batched flushes on reference updates to take advantage of concurrent asynchronous flushes [17], such as `clwb` and `clflushopt`. PACMAN records addresses of updated entries in the index, and launches multiple asynchronous flushes on them, which reduces the average flush latency (step ⑤).

(2) Using non-temporal store to copy valid objects. In copying phase, PACMAN first collects valid objects in volatile segments (step ①), then uses non-temporal store (`ntstore`) to copy them to PM (step ②) for three benefits. First, `ntstore`

has higher bandwidth for large (over 256 B) write than normal store [46]. Second, `ntstore` bypasses the cache and avoids unnecessary cache pollution. Third, `ntstore` can also avoid repeated flushes on the same cache line due to non-aligned writes, which incurs dramatical delay [12].

Though flushes are not necessary for data persistence in new generation CPUs with support of eADR [2], sequential writes (e.g., copying objects) without flushes will turn into random writes on PM due to the random eviction of CPU cache [23]. Therefore, the batch pattern is still beneficial on new CPUs with eADR for adopting `ntstore`.

(3) Leveraging prefetching on PM. Since most valid objects being collected are cold, their references in the index are less likely to stay in cache, which results in high memory access latency, especially for PM indexes. Fortunately, with the shortcut, PACMAN can easily prefetch the index node or entry of the next valid object when updating the current object's reference (step ③), hiding the high access latency with update operation. Thanks to shortcuts and the redesigned pipeline, the reference update operations are quite lightweight, which makes prefetching's effect much more evident.

Handling race condition on the index. The contention between cleaner threads and service threads should be handled properly. A service thread may update an object while a cleaner thread copies the old version of this object and updates its reference. In such a case, the new version of the object updated by the service thread will be covered by the old version of the object. The batched compaction pipeline increases the possibility of this race condition.

One naive approach is holding a lock and blocking service threads during the whole time of relocating an object (lookup reference, copy object, and update reference) [39]. PACMAN minimizes the critical section on updating references, which updates references in a compare-and-swap pattern. Specifically, cleaner threads update references via a customized index update operation (i.e., `update_pacman`) that carries an extra old value of the reference (`old_addr` in step ④). In `update_pacman`, only when the original value of the index entry matches the old value `old_addr`, which means no race condition has happened, the reference can be updated to `new_addr`. If the update fails, the reclaimed object in new segment is marked as stale.

Comparing with FlatStore's compaction pipeline. Though FlatStore [12] also optimize the compaction pipeline by separating the copying phase and the reference updating phase to reduce the fence instructions, it suffer from severe performance issue. Specifically, as FlatStore conducts the index traversal twice for each valid object (i.e., check the liveness and update the reference), the batch pattern exacerbates the overhead on the index. Results in a long reuse distance between the two index traversals for each alive object, causing updating reference not to take the benefit of cache brought by checking reference. By contrast, PACMAN eliminates the first in-

dex traversal by checking in-DRAM deleted flags and reduces the second traversal overhead by prefetching and shortcuts.

3.4 Separating Hot-Cold Data

PACMAN leverages hot-cold data separation to reduce the amount of valid data copying on PM and corresponding reference updates during compaction. Specifically, service threads append hot objects in their per-thread segment and cold objects in another per-thread cold segment. Though hot-cold data separation is a well-known technique to improve garbage collection efficiency [10, 18, 36], we elaborately design how to 1) identify hotspots and 2) handle hotspots shift in the context of the low-latency key-value store on PM.

Identifying hotspots in a lightweight pattern. PACMAN uses a small read-only hash set of hot objects for service threads to distinguish hotspots. The identification of hotspots should be lightweight enough to not increase too much extra latency. Previous work could distinguish the hotspots without maintaining the hotness of objects, such as by data type [28] or hash-based partition [10]. However, these methods are not feasible for PACMAN due to the lack of type semantics or the per-thread logs. Dynamically maintaining hotspots set is not ideal, because it introduces extra operations to another index, resulting in contention and crash thrashing.

Handling hotspots shift and generating new hotspots set. As the access patterns keep changing in real-world workloads, PACMAN uses a lightweight mechanism to detect hotspots and generate new hotspots set. First, service threads keep counting the hit ratio of the old hotspots set to detect whether a hotspots shift has happened. Second, if the hit ratio is lower than a customized threshold which means the hotspots have shifted and the original hot set is stale, service threads record the keys of updated objects in their local circular buffers by sampling. A background thread collects the keys recorded by service threads, sorts these keys using a heap, and generates a new hot set. Third, the background thread changes the pointer of hot set to the new one using CAS. After waiting for a grace period through an RCU-like barrier, the background thread confirms that no service threads are accessing or will access the old hot set, then frees the old hot set safely. Note that the background thread consumes negligible CPU resources as the hotspots shift in real-world workloads is not frequently (at least second-level) [9, 21]. It doesn't matter if service threads identify hot keys inaccurately since it only determines the location of objects. Moreover, cold objects get another chance to be separated from hot objects by compaction.

Though checking the read-only hash set is lightweight, it would bring no benefit but extra overheads in uniform workloads. In the second step above, if the occurrence of the hottest key is close to the occurrence of the coldest key (e.g., less than 3×), the background thread clears the new hot set.

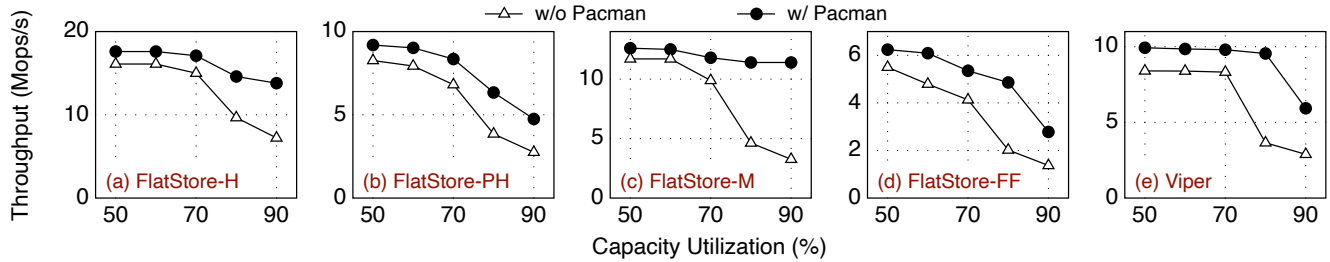

Figure 5: Impact of capacity utilization.

3.5 Recovery

The recovery of the log and the index is similar to existing work [12]. We mainly discuss recovery related to PACMAN.

Shortcut. For KV stores with a volatile index, all shortcuts are invalid after a restart. However, since all segments have to be scanned to rebuild the index, new valid shortcuts are rebuilt in the meantime. For KV stores with a persistent index, to make shortcuts still valid after a restart, PACMAN stores the offset from the base address of the PM pool for the index (e.g., `PMEMobjpool` in PMDK [4]) in the `Node Addr` instead of the virtual address of the node.

DRAM-resident information. Though the DRAM-resident information is unavailable after recovery, the loss of this information has no impact on service threads.

For KV stores with a volatile index, since the index needs to be recovered by scanning all segments, the bitmaps are recovered together with the index at the same time. To distinguish the latest and stale objects, PACMAN compares their version number and retains the latest reference in the index. For KV stores with a persistent index, the volatile bitmaps and metadata only cripple the garbage collection after recovery for a while. Cleaner threads scan the segments and recover the bitmaps by checking references in the index. Then the scanned segments become candidates for compaction.

Crash of compaction. After a restart, unfinished compaction does not need to resume. If a crash happens before the reference updating phase (before line 16 in Figure 4), after a restart, the new segment is still marked as a free segment as nothing has happened. If a crash happens in the middle of the reference updating phase (after line 16 in Figure 4), after a restart, background threads will scan these segments and distinguish redundant objects as described above.

4 Evaluation

In this section, we use a series of experiments to evaluate PACMAN. After describing our setup (§4.1), we first conduct experiments to show the overall performance of PACMAN on PM-based log-structured KV stores under various workloads (§4.2). Then, we analyze the benefit of each optimization of PACMAN with different cases (§4.3). Last, we compare log-structured KV stores with PACMAN against other KV stores on PM with a production workload (§4.4).

4.1 Experimental Setup

All experiments are conducted on a server with Intel Xeon Gold 6240 CPUs. Each CPU has 18 physical cores (36 logical cores with hyper-threading). Each socket is equipped with three 128 GB Intel Optane DC Persistent Memory (DCPMM) DIMMs and 96 GB DRAM. We bind all threads to a single socket to avoid NUMA effect [25, 46]. The Optane DIMMs are configured in App Direct mode.

We apply PACMAN to four versions of FlatStore [12] and Viper [8] we have evaluated in §2.2. FlatStore adopts a log batching technique to reduce the persisting overhead. Viper leverages PM-specific access patterns and employs CCEH [37] in DRAM as its index.

We set the upper limit of the hotspot set size (§3.4) to 128K in all experiments. We co-locate the background thread for generating new hotspot set (§3.4) with a random cleaner thread. The `MIN_SIZE` (§3.2) is set to 32, which means that the deleted flag bitmaps use 1 bit in DRAM for every 32 bytes in segments, which is 0.4% of the whole log size. We use 8-byte keys in all evaluated systems. Unless otherwise stated, we restrict the capacity utilization to 80%. Also, the value size is fixed at 48 for simplicity, because performance mainly depends on the average object size but not the exact size distribution [39] and the value size is corresponding to the recent real-world workloads [9].

4.2 Overall Performance

4.2.1 Impact of Capacity Utilization

We show how PACMAN mitigates the performance decline at high capacity utilization with the same experiments as in §2.2, in which 12 service threads perform write-intensive (50% Put, Zipfian distribution with parameter 0.99) workloads and 4 cleaners conduct the compaction work. Figure 5 shows the results, from which we make three observations.

First, PACMAN obviously curtails the performance decline at high capacity utilization. FlatStore-M with PACMAN maintains throughput above 90% even at extremely high capacity utilization (90%). Due to the huge overhead of compaction, original systems can not fully utilize their performance at high utilization. PACMAN improves the efficiency of compaction according to PM’s peculiarities, and therefore reduces the compaction overhead. Though the performance declines of FlatStore-PH

Figure 6: YCSB workloads performance. (*FlatStore-H*, *FlatStore-PH*, and *Viper* don't support scan operations in YCSB-E.)

and FlatStore-FF with PACMAN at 80% utilization still exceed 20%, they are much better than the original systems.

Second, PACMAN also enhances the performance at low capacity utilization, which is because PACMAN reduces small random accesses on PM and saves PM's limited bandwidth. The improvement on Viper is more evident since Viper marks deleted flags and modifies locks on PM.

Third, systems using PACMAN with 4 cleaners also outperform the original systems with 8 cleaner threads (see §2.2). PACMAN saves CPU resources for compaction but brings more improvements, which is not only due to the efficient compaction, but also because of the reduction in contentions on both the index and PM resources [46].

4.2.2 YCSB Benchmark

In this section, we evaluate the basic performance with YCSB [13] benchmark. Table 1 shows the characteristics of workloads. We omit the YCSB-D as it has similar traits to YCSB-B. We set 24 threads to perform workloads after random prefilling 200 million objects, and 4 cleaners for all evaluated systems. Each service thread performs 20 million operations. The capacity utilization is restricted to 80%.

Workload	Feature	Read-Write-Scan %
A	write-intensive	50-50-0
B	read-intensive	95-5-0
C	read-only	100-0-0
E	scan-intensive	0-5-95

Table 1: YCSB workloads description.

The experimental results are presented in Figure 6, from which we have two observations.

First, under write-intensive workload (YCSB-A), PACMAN improves the performance of each system by 1.5-1.8×. PACMAN improves Viper most among these systems, which is because PACMAN on Viper not only increases the compaction efficiency but also reduce small random writes on PM.

In this workload, 4 cleaner threads are insufficient for systems without PACMAN. The cleaner threads' CPU utilizations are all above 95%. For evaluated systems with PACMAN, there are a few unused CPU cycles. For example, with PACMAN the cleaner threads' CPU utilization is 81% in FlatStore-H and 92% in FlatStore-FF. The random prefilling phase invalidates a part of shortcuts. For example, the invalidation ratio of short-

cuts is about 25% in FlatStore-FF and 58% in FlatStore-M. FlatStore-FF has lower invalidation ratio because FastFair has larger leaf node than Masstree and can tolerate more shift operations. Note that we regard the shortcut as valid if the entry can be found in the node indicated by the shortcut or its sibling node.

Second, under read-dominated workloads (YCSB-B, C, and E), systems with PACMAN have similar performance with the original systems. This is because PACMAN does not directly influence read and scan operations, their performance under read-dominated workloads is similar.

4.2.3 Sensitivity Analysis

In this section, we evaluate how workload characteristics affect PACMAN. The default configurations are the same as in §4.2.1. We only show results of FlatStore-H with PACMAN in Figure 7 as a representative sample.

Uniform workloads. In uniform workloads, the system's performance drops compared with that in skewed workloads (Figure 5(a)), which is because of poor locality and much severe garbage collection overhead. The raw FlatStore-H drops more than half at 80% capacity utilization. However, PACMAN still curtails the throughput decline within 15% at 80% utilization and 50% at 90% utilization.

Thread scalability. Due to the compaction overhead, the raw FlatStore-H can not scale well with multiple threads. On the contrary, with only 4 cleaners, FlatStore-H with PACMAN can scale linearly up to about 20 threads.

Value size. The throughput of both systems drops with the value size getting larger because larger objects consume more bandwidth. PACMAN enhances the throughput of FlatStore-H by 50-70% as the value size varies from 32 to 512, which shows that value size has little impact on PACMAN.

Write ratio. Since the compaction overhead increases with write ratio, the improvement of PACMAN on FlatStore-H is more significant with higher write ratio, reaching to 2.3× when the write ratio is 100%. A strange phenomenon is that FlatStore-H with PACMAN has higher throughput when the write ratio is 80% than 60%. We find that cold segments have shorter ages due to the faster write rate. Thus, cleaners are more likely to select hot segments to compact according to the cost-benefit strategy, which has lesser overhead.

Number of objects. With the capacity utilization fixed at 80%, we vary the number of objects to prefill. The number of ob-

Figure 7: Sensitivity Analysis (on FlatStore-H). (a) Uniform workloads. (b) Thread scalability. (c) Different value sizes. (d) Different write ratios. (e) Different numbers of objects.

jects has two effects on the performance. On one hand, the CPU cache miss rate gets higher with the larger memory footprint (both the index and the log space). On the other hand, as the log space gets larger, the system writes more segments when compaction is triggered and has more time to accumulate stale objects. Thus, the candidate segments for compaction have less live data and the compaction is less expensive. For different numbers of objects, PACMAN can improve the performance by 35-60%.

4.3 Analysis of Techniques

In this section, we analyze the performance benefit of each technique by applying them one by one. To differentiate results more obviously, we stress the system with an artificial workload at a high capacity utilization level (80%) modeled after prior work [39], in which the system throughput is heavily limited by compaction. After loading 200 million KV objects, 12 service threads overwrite these objects following a Zipfian access distribution with skewness parameter 0.99, and 2 cleaner threads perform the compaction work. The workload proceeds for a while until the system throughput and compaction overhead converge to a stable value.

We only show results of PACMAN on FlatStore-H and FlatStore-FF since their results are representative.

Figure 8 shows the contribution of each technique to the throughput and corresponding compaction bandwidth (bytes of cleaned segments per second). The applying order is determined by the dependencies between these techniques (e.g., the shortcut relies on hot-cold separation to reduce its space overhead). Specifically, we gradually apply to the *raw* systems with *reducing* avoidable PM accesses (§3.2), hot-cold data *separation* (§3.4), *shortcut* (§3.1), and the redesigned *batching* compaction pipeline (§3.3).

The results show that all techniques contribute to the improved performance more or less in some cases.

① **Reducing.** Storing garbage information in DRAM and embedding size information in reference eschew the avoidable PM random accesses. Especially in FlatStore, this technique avoids checking references in the index for identifying liveness of objects. Therefore, it brings about 80% improvements on FlatStore with a tree-based index (i.e., FlatStore-FF and

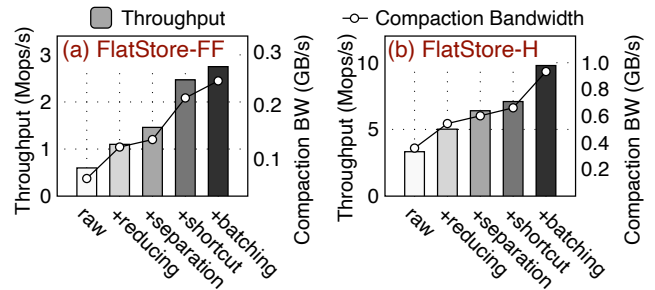

Figure 8: Contributions of techniques to throughput and compaction bandwidth.

FlatStore-M), and about 50% on FlatStore-H.

② **Separation.** Hot-cold data separation improves the system performance about 30%. The improvement of system throughput is more than the compaction bandwidth. This is because that hot-cold data separation alleviates the mixture of stale and valid objects in a segment, thus decreasing the amount of valid objects moving and compaction time.

③ **Shortcut.** Though PACMAN trades some available log space for storing shortcuts, shortcuts still boost the system performance by about 70% for FlatStore-FF and about 45% for FlatStore-M (not shown in the figure) even at high capacity utilization. Moreover, since we do not store shortcuts for hot objects, the rate of successfully using shortcuts to update references is 55% in FlatStore-FF in this experiment. The effect is not obvious for systems with a hash table-based index, since the benefit brought by shortcuts is overshadowed by the additional overhead of storing shortcuts. Since PACMAN only stores shortcuts for inserted cold objects, and we assume that about half of inserted objects are cold, the space overhead is less than 4% for 64B objects. Note that this space overhead has been paid by PACMAN.

④ **Batching.** The batching compaction pipeline and corresponding optimizations bring another 40% improvement on FlatStore-M and FlatStore-H. However, batching has smaller effect on FlatStore with a persistent index, which is because the main overhead of compaction comes from operations on the persistent index.

Put them together, PACMAN increases the compaction bandwidth, and improves the system throughput by about 3× for

Figure 9: Facebook ETC throughput and latency. (Y axis in P99 Put Lat. is in log scale.)

FlatStore-H and 4.6× for FlatStore-FF.

The results of PACMAN on Viper are similar to FlatStore-H, except for *reducing* and *batching*. As Viper uses deleted flags in objects, *reducing* on Viper has smaller effect than FlatStore. However, due to the inefficiency of Viper’s original compaction, the batching compaction algorithm significantly improves Viper’s performance.

4.4 Comparison with Other KV Stores

In this section, we compare FlatStore with PACMAN (denoted by suffix *-Pac* in Figure 9) against other three representative KV stores on PM, *ChameleonDB* [50], *pmemkv* [6], and *PMem-RocksDB* [3, 5]. *ChameleonDB* adopts a LSM-based hash index tracking KV objects in the log. We implement *ChameleonDB* since it is not open-source. Our implementation can achieve approximate performance in its paper when not considering garbage collection. As *ChameleonDB* does not provide their garbage collection approach, we implement its garbage collection like *WiscKey* [33] for their similar structures, but with a hot-cold data separation (§3.4). *pmemkv* internally leverages *PMDK* [4] for object allocation, which is a non-copying allocator. We set *pmemkv*’s storage engine to *cmap*, a persistent concurrent hash map. *PMem-RocksDB* is based on *RocksDB* [16], a LSM-tree-based key-value store. *PMem-RocksDB* locates SSTables and write ahead log (WAL) on PM. We follow the recommended configurations [5] except for enabling the key-value separation of *PMem-RocksDB*, since it offloads the object management to *PMDK*, which is similar to *pmemkv*. Note that we do not restrict the capacity of *pmemkv* and *PMem-RocksDB*.

We compare these systems with a production workload from Facebook ETC memcached pool [7]. Specifically, the workload has trimodal object size distribution, where the size of an object can be small (1-13 bytes), median (14-300 bytes) and large (larger than 300 bytes). This distribution is representative in real-world productions, as it also resembles the workloads of UP2X at Facebook [9]. We use skewed distribution (Zipfian parameter 0.99) for small and median objects, and uniform distribution for large objects as prior work [12, 14]. After random prefilling each system with 200 million objects, each thread performs 20 million operations of write-intensive workload (50% Get and 50% Put).

For a fair comparison, 1) we only include FlatStore-PH and FlatStore-FF as all compared systems have a persistent

index; 2) we disable the log batching in FlatStore as a normal embedded KV store. All systems use 24 service threads and 4 background threads (for compaction and *PMem-RocksDB*’s flush) except for *pmemkv*. As *pmemkv* does not need garbage collection, we set *pmemkv* with 28 service threads. We report their throughput and latency in Figure 9.

Throughput. From the throughput results, we have the following observations.

The log-structured approach has great performance advantages. Even without PACMAN, FlatStore-PH outperforms *pmemkv* as unordered KV stores, and FlatStore-FF outperforms *PMem-RocksDB* as ordered KV stores. However, the garbage collection overhead overshadowed this advantage. Due to the efficient compaction, PACMAN improves the performance of original systems, especially for FlatStore-FF as it has more severe compaction overheads.

PMem-RocksDB has the lowest throughput even though efforts have been endeavoured to optimize *RocksDB* with persistent memory. This is because *RocksDB* was born for SSD, and some design is not suitable for PM. For example, the memtable, WAL, software caching, and file-based management are less effective when the storage device changes from disk or flash to PM.

Though *pmemkv* does not need garbage collection, it has a low performance. Since the value size varies in this workload, *pmemkv* needs to allocate new object by *PMDK*’s *pmemobj* allocator if the size exceeds previous allocated size.

ChameleonDB has much lower performance than expectation. We also evaluate *ChameleonDB* with unlimited log space (i.e., no compaction) that can achieve similar performance to a KV store with a volatile hash table-based index (not shown in the figure). However, the garbage collection of *ChameleonDB* is much difficult due to its LSM-based index. The LSM-based index inserts a new KV pair to memtable directly without looking for the former entry of the same key. Therefore, cleaners are unaware of the garbage information and have to copy bulk of cold data. Its performance decreases sharply at higher capacity utilization due to the inefficient garbage collection. *ChameleonDB* requires a more elaborate garbage collection approach which considers both KV separation [10, 41] and PM’s peculiarities.

Latency. The median Get latency of each system accords with their index’s overhead. *ChameleonDB* has the lowest latency due to its efficient DRAM-PM-hybrid index.

For PMem-RocksDB, the notorious write stalls in LSM-trees [49] result in high Put tail-latencies. The dilatory flush and compaction not only block foreground write operations, but also lead to multiple SSTable levels, which makes Get operations inefficient. Besides, for low-latency devices like PM, bloom filters aimed at reducing storage I/Os can introduce non-negligible latencies in Get operations.

As pmemkv turns to transaction and logging for atomic in-place updates, it has the highest median Put latency and tail latency among all evaluated systems with a high thread count. First, transactions are more likely to be aborted with a high thread count. Second, the low-performance crash consistency mechanism of pmemkv makes index access inefficient.

4.5 Recovery

We evaluate the recovery with FlatStore-H and FlatStore-FF. We randomly prefill 200 million objects of 256B value size with 80% capacity utilization, in which the log space is 63.3 GB. Then we perform 100 million update operations to disorder all segments. We set 8 threads for the recovery.

For FlatStore-H, garbage information and shortcuts are restored with the volatile index in the meantime. It takes 14 seconds to recover all these things in FlatStore-H. For FlatStore-FF, it takes 102 ms to recover the states of segments. Note that the system is ready for service at this moment. Then, the 8 threads recover information for garbage collection (e.g., deleted flag bitmaps) in background, which takes 37 seconds.

5 Related Work

PM-based KV stores. There has been plenty of research on high-performance KV indexes [11, 20, 26, 27, 32, 37, 38, 43, 50, 51] and KV storage systems [8, 12, 22, 24, 30, 42, 49]. In this paper, we focus on log-structured KV stores on PM.

Log-structured memory storage systems. The log-structured design has been widely adopted in storage systems. RAMCloud [39] is a distributed KV store that uses log-structured memory to achieve high memory utilization. It uses memory to serve requests from clients and disk to store backup copies of data. FASTER [20] designs a hybrid log that spans main memory and storage. Nibble [35] is a concurrent log-structured in-memory KV store that uses a scalable multi-head log allocator with a concurrent index. It can scale up to hundreds of cores with ultra-large volumes of memory. MICA [31] and Segcache [47] are in-memory caching systems using the log-structured approach.

The log-structured approach is also embraced by many persistent memory systems. FlatStore [12], RStore [30], and Viper [8] are all DRAM-PM hybrid KV stores that leverage a volatile index on DRAM and log-structured storage on PM. To reduce small writes on PM, FlatStore proposes pipelined horizontal batching to batch small-sized requests from multiple cores, achieving high throughput without sacrificing low latency. Viper assigns threads to different PM

regions to minimize the thread-to-DIMM ratio, and stores data in DIMM-aligned storage segments. NOVA [45] is a scalable persistent memory file system that maintains separate logs for each inode. LSNVMM [19] is a log-structured transactional memory system that takes advantage of copy-on-write to avoid redo/undo logging.

Optimizations on garbage collection. The main overhead of log-structured storage systems comes from garbage collection. RAMCloud designs an elaborate garbage collection approach to enable high memory utilization. RAMCloud decouples the garbage collection on the memory logs and backups. Hence, memory can have higher utilization and backup disks bear less garbage collection work. In-place updates can reduce the pressure of garbage collection [20, 31]. However, the in-place updates could lead to internal memory fragmentation. Furthermore, for persistent memory, in-place updates without expensive logging cannot guarantee crash consistency. Hot-cold separation is beneficial to garbage collection. Log-structured file systems such as F2FS [28] separate data by their types. HashKV [10] partitions KV objects by hashing. They separate hot and cold objects to some extent. Yang et al. [48] propose a PM-aware garbage collector in JVM. They separate the read-mostly phase and the write-only phase to fully utilize PM bandwidth. However, they adopt PM for merely increasing memory capacity and do not provide persistence guarantee.

The peculiarities of persistent memory make the problem of memory compaction more severe. To the best of our knowledge, PACMAN is the first work that optimizes compaction for log-structured key-value store on PM.

6 Conclusion

Garbage collection overhead in log-structured KV stores becomes more severe on PM. We summarize that the culprit is that existing approaches are unawareness of PM's characteristics. In this paper, we analyzed the inefficiencies of existing compaction approaches in log-structured KV stores on PM. According to the analysis, we design, implement, and evaluate PACMAN, an efficient PM-aware compaction approach for log-structured KV store on PM. PACMAN introduces several techniques to streamline garbage collection with the consideration of PM idiosyncrasies. PACMAN significantly boosts the compaction bandwidth and improves the performance of state-of-the-art systems at high capacity utilization. Our implementation of PACMAN is publicly available at <https://github.com/thustorage/pacman>.

Towards Latency Awareness for Content Delivery Network Caching

Gang Yan

SUNY-Binghamton University

Jian Li

SUNY-Binghamton University

Abstract

Caches are pervasively used in content delivery networks (CDNs) to serve requests close to users and thus reduce content access latency. However, designing latency-optimal caches are challenging in the presence of *delayed hits*, which occur in high-throughput systems when multiple requests for the same content occur before the content is fetched from the remote server. In this paper, we propose a novel timer-based mechanism that provably optimizes the mean caching latency, providing a theoretical basis for the understanding and design of latency-aware (LA) caching that is fundamental to content delivery in latency-sensitive systems. Our timer-based model is able to derive a simple ranking function which quickly informs us the priority of a content for our goal to minimize latency. Based on that we propose a lightweight latency-aware caching algorithm named LA-Cache. We have implemented a prototype within Apache Traffic Server, a popular CDN server. The latency achieved by our implementations agrees closely with theoretical predictions of our model. Our experimental results using production traces show that LA-Cache consistently reduces latencies by 5%-15% compared to state-of-the-art methods depending on the backend RTTs.

1 Introduction

Content delivery networks (CDNs) carry more than 50% of today's Internet traffic [17] by caching a variety of contents such as videos, music, software downloads, etc. and delivering thousands of millions of user requests each day. CDNs deploy hundreds of thousands of servers across the world to serve user requests. If the requested content is available in the server near the user, a cache hit occurs and the user experiences a quicker response with a lower latency. Otherwise, a cache miss occurs and the requested content has to be fetched from the remote server with a dramatically increased latency. As a result, there has been a renewed focus on increasing cache hits [11, 16, 31, 40], which can significantly improve the content delivery of the Internet.

The recent trends of improving caching efficiency in terms of *maximizing caching hits* mostly focus on designing different content caching algorithms, including but not limited to GDSF [15], ARC [44], CAR [6], LHD [7], A-LRU [37], AdaptSize [11], CACA [29], LRB [53], RL-Cache [35], RL-Bélády [58], DeepCache [45] and LHR [59]. However, most of these algorithms assume that the user-perceived latency upon a cache hit is *negligible* (i.e., zero delay). Though this assumption has been widely used in the caching literature, some recent efforts start linking it to the potential performance degradation when *minimizing the end-user latency* in the presence of *delayed hits* [27, 55]. Notably, the latest series of works [4, 42] reveals that a *delayed hit* can occur in real-world systems, especially in high-throughput systems when multiple requests to the same content occur before the requested content is fetched from the remote server. As a result, the aforementioned caching algorithms fail to minimizing user-perceived latency in the presence of delayed hit since they are designed under the assumption that delayed hits does not exist. See Section 2 for more detail.

Despite the insightful findings in [4, 42], there remains a major *gap* between the delayed hits observation and the goal of efficient *online* latency-aware caching algorithm design. This is due to the fact that delayed hits were *only* identified and overcome through a hard *offline* optimization problem assuming that all contents are the *same size*, and the fetching latency from remote server upon a cache miss is *uniform* across different contents. However, it is well-known that content sizes often vary widely in production CDNs from a few bytes [46] to several gigabytes [31]. Additionally, the fetching latencies upon cache misses in production systems may vary over time due to the network conditions (e.g., bandwidth), and differ across content sizes since large contents often require longer fetching latencies (e.g., multiple RTTs). These facts introduce an additional layer of complexity in the design of *online* algorithms for minimizing latency in the presence of delayed hits, which largely remain elusive in the literature.

This paper closes this gap by developing a novel and lightweight timer-based mechanism to account for the impact

of delayed hits for contents with variable sizes and different fetching latencies that provably optimizes the mean caching latency. This provides a theoretical basis for the understanding and design of latency-aware caching that is fundamental to content delivery in latency-sensitive systems. In this approach, each content is associated with a timer indicating the fetching latency between the cache and remote server, which can be variable across different contents and systems. Upon a cache miss, all requests (i.e., delayed hits) arriving at the cache during a certain time period dictated by its timer suffer a corresponding latency before these requests are truly served. This approach is able to explicitly characterize the expected average latency of a caching system in the presence of delayed hits. This further enables us to derive a simple ranking function which can quickly prioritize contents for the purpose of minimizing latency.

This paper makes the following research contributions:

- To the best of our knowledge, our proposed timer-based model is the first to provide a theoretical basis for understanding the impact of delayed hits in latency-sensitive caching systems in an online manner. This enables us to design a lightweight online latency-aware caching algorithm which can capture the variable fetching latency and different content sizes in real-world systems.
- Using this timer-based model, we explicitly characterize the mean latency of each content in the presence of delayed hits and derive a simple ranking function to prioritize contents so as to minimize the mean latency. We then propose a lightweight latency-aware caching algorithm named LA-Cache.
- We have implemented the LA-Cache prototype within Apache Traffic Server, a popular CDN server, and evaluate the performance of LA-Cache using production traces. Our empirical results are in close alignment with our theoretical model predictions. Furthermore, we show that LA-Cache consistently outperforms conventional caching algorithms by reducing the latency by 5%-15% depending on the backend RTTs.

The rest of the paper is organized as follows. We introduce the motivations and opportunities in designing latency-aware caching in Section 2. We present the model for delayed hits and explicitly characterize the mean latency in Section 3. We propose the latency-aware algorithm LA-Cache in Section 4, and present its prototype design in Section 5. Evaluation results are shown in Section 6. We discuss related work in Section 7 and conclude the paper in Section 8. Additional results are presented in the supplementary material.

2 Background and Motivation

We begin by motivating the existing of delayed hits in latency-sensitive systems and showing the fundamental limitations of

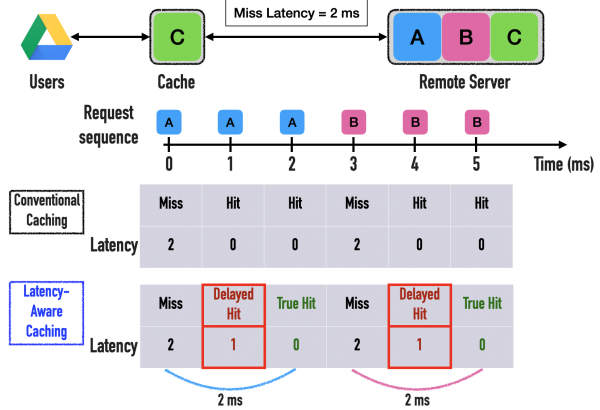

Figure 1: A motivating example for latency-aware caching where delayed hits occur. Suppose that the remote server stores all three contents named A, B, and C, the cache size is 1, and the miss latency (i.e., the Round-trip Time (RTT)) between the cache and the remote server is 2 ms. We also have a request sequence of A,A,A,B,B,B, ... with a new request arriving at the cache every 1 ms.

existing algorithms.

2.1 A Motivating Example

As a motivating example, we consider a basic delayed hit scenario in real-world systems as shown in Figure 1. Upon the first request to content ‘A’, a cache miss occurs and the cache must fetch content ‘A’ from the remote server with a latency of 2 ms. The next two requests to content ‘A’ can be directly served from the cache and experience a latency corresponding to a cache hit, which is assumed to be zero in conventional caching algorithms. Similar process happens for the requests to content ‘B’. Since it takes 2 ms to fetch content ‘A’ from the remote server, how is it possible for the second request to content ‘A’ that arrived just 1 ms after the miss was served with a zero latency? Clearly, something is wrong.

Contrast to the ideal assumption in conventional caching algorithm design, the following *actually happens*. Upon the first request to content ‘A’, a cache miss is claimed and a fetch is triggered with a latency of 2 ms. Since the RTT is 2 ms, content ‘A’ will only arrive in the cache at time $t=2$ ms. As a result, the request at $t=1$ ms is queued behind the original miss, and must wait (at least) 1 ms to be served. At time $t=2$ ms, content ‘A’ arrives at the cache and all queued requests (including the one just arrived) are resolved. Similar process happens for the requests to content ‘B’. These requests (e.g., requests to content ‘A’ at $t=1$ ms and to content ‘B’ at $t=4$ ms) are called *delayed hits* since they neither suffer the latency of a cache miss¹ nor that of a true cache hit (e.g., requests to

¹We interchangeably use the terms of “miss latency”, “fetching latency”

Figure 2: Conventional caching algorithms fail to minimize latency: As the fetching latency (the value of L) increases, conventional caching algorithms outperform the Bélady’s offline MIN algorithm in term of mean latency on a 256GB cache. For example, LRU-4 outperforms Bélady when L is greater than 50 ms in the Bilibili trace.

content ‘A’ at $t=2$ ms and to content ‘B’ at $t=5$ ms).

In general, delayed hits occur in *high-throughput systems* when multiple requests to the same content occur before the requested content is fetched from the remote server [4, 27, 42, 55]. This phenomenon has become increasingly perceptible due to the growing ratio between system throughputs and latencies in a wide range of systems. For example, the wide-area latency between a CDN forward proxy and a central data center is only marginally improving, while newer technologies boast order-of-magnitude throughput improvement with the network links moving from 10 Gbps to 400 Gbps [24]. The fundamental problem is that latencies are closer and closer to limits imposed by the speed of light, while throughputs keep growing unboundedly. Hence, minimizing the impact of delayed hits is a key performance objective in latency-aware caching systems.

2.2 Limitations of Existing Algorithms

The above example indicates that conventional caching algorithms fail to capture the impact of delayed hits, which can be significant especially in systems with high latency to the remote server. One reason contributes to this failure is that conventional caching algorithms are designed to maximize cache hits under the assumption that all cache hits result in zero delay, i.e., they equally treat delayed hits and true hits. To that end, the latency measured by conventional caching algorithms significantly *underestimate true latency* in the presence of delayed hits. Some so-called “cache hits” will experience latencies closer to the high latency of a cache miss than the low latency of a true hit in practice.

As a consequence of this discrepancy, conventional caching algorithms fail to minimize latency although some caches were deployed for this purpose, which were actually treated equivalently to maximize cache hits regardless of delayed hits.

and “RTT” in this paper.

Figure 3: The illustration of our proposed timer-based model for a particular content i in the presence of delayed hits.

For example, the Bélady’s offline MIN algorithm² [8] is the well-known optimal algorithm in maximizing cache hits and minimizing latency when all contents are of the same size and delayed hits are treated as true hits. However, Bélady is no longer optimal in minimizing latency in the presence of delayed hits, as illustrated in Figure 2 (More details in Section 6). Therefore, *the goal of maximizing cache hits for most conventional caching algorithms and the goal of minimizing latency are not equivalent, in the presence of delayed hits*³. We need to design new online algorithms for latency-sensitive caching systems.

3 Model for Latency Minimization

We consider the problem of minimizing latency for content delivery given delayed hits in latency-sensitive systems. In particular, we aim at designing a latency-aware caching policy that minimizes *the mean latency of all requests*. For ease of exposition, we denote the latency to fetch a particular content i from the remote server as L_i , which can vary across contents and servers. Therefore, the latency is (a) L_i upon a cache miss, (b) between 0 and L_i upon a delayed hit, and (c) 0 upon a true cache hit.

3.1 Modeling Delayed Hits

Our key insight is to build a novel connection between delayed hits and the timer-based caching policy. Figure 3 shows such a novel connection for a particular content i . More specifically, each content i has a timer value L_i which represents the latency to retrieve the content from the remote server upon a cache miss. In other words, upon a cache miss at time t , a request is sent to the remote server and content i will be

²The Bélady’s offline MIN algorithm always evicts the content with the furthest next request.

³It has been shown [42] that the latency objective is not antimonotone for caching problems with delayed hits. In other words, a caching algorithm that improves average caching latency under delayed hits might even lower the true hit rate. Hence optimizing caching latency is fundamentally different from optimizing cache hits.

fetched and inserted into the cache after L_i time slots, i.e., at time $t + L_i$. The timer counts down and until the timer expires, any new requests for content i during $[t, t + L_i)$ are called *delayed hits*. These requests are queued behind the original cache miss occurred at time t , and resolved at time $t + L_i$ with a corresponding latency of $t + L_i - t'$ for the request occurred at time t' . The request arrives at time $t + L_i$ is satisfied immediately with a latency of 0, and hence is called the true hit.

3.2 Mean Latency of All Requests

Suppose that the requests for content i arrive at the cache according to a Poisson process⁴ with rate λ_i . Let D_i be the expected aggregated latency experienced by the arrival of requests for content i (i.e., delayed hits) upon a cache miss. The probability of not finding content i in the cache is the cache miss probability m_i , which satisfies $m_i = \frac{1}{1 + \lambda_i L_i}$ derived in the context of timer-based caches [25].

Proposition 1. *The expected latency experienced by the request arrival of content i is $\left(1 + \frac{1}{1 + \lambda_i L_i}\right) \frac{L_i}{2}$.*

Proof. We first compute the expected aggregated latency for content i . Upon a cache miss, the request is sent to the remote server and content i is fetched and inserted into the cache after L_i time slots. Thus, the latency of a cache miss is L_i . A delayed hit occurs for every arrival of content i during time $[t, t + L_i)$ since the content i has not been inserted into the cache yet, and the corresponding latency for request at time $t' \in [t, t + L_i)$ is $t + L_i - t'$. Thus *the expected aggregated latency by all delayed hits* in the interval of $[t, t + L_i)$ is

$$D_i := \int_t^{t+L_i} \lambda_i(t + L_i - x) dx = \frac{\lambda_i L_i^2}{2}. \quad (1)$$

Since the requests for content i follow a Poisson process, the expected number of requests, i.e., the expected number of delayed hits is $\lambda_i L_i$. Hence, the expected latency for each delayed hit is $\frac{\lambda_i L_i^2}{2} / \lambda_i L_i = \frac{L_i}{2}$. Then *the mean latency experienced by the requests of content i* is a weighted sum of the latency from the cache miss and the latency from delayed hits, which satisfies

$$\bar{D}_i = m_i L_i + (1 - m_i) \frac{L_i}{2} = \left(1 + \frac{1}{1 + \lambda_i L_i}\right) \frac{L_i}{2}. \quad (2)$$

□

⁴Poisson arrivals are widely used in the literature, e.g., [32, 36, 38, 41, 43]. However, our model holds for general stationary process [5] at the cost of complicated notations [25, 26]. We relax the Poisson arrivals assumption for our algorithm design, implementation and empirical evaluation.

Corollary 1. *The mean latency experienced by all requests to N distinct contents satisfies*

$$\bar{D} := \sum_{i=1}^N \lambda_i \bar{D}_i = \sum_{i=1}^N \frac{\lambda_i L_i}{2} \left(1 + \frac{1}{1 + \lambda_i L_i}\right). \quad (3)$$

Remark 1. *The main advantage of our proposed timer-based model for delayed hits is that it can be easily deployed in latency-sensitive systems to provide a precise and theoretically-validated latency. Although real-world systems do not have strict Poisson arrivals for any content (see Section 6), we will show in Section 6 that our proposed theoretical model with Poisson assumptions works well in practice.*

Remark 2. *Timer-based caches have been extensively studied in the community [9, 14, 23, 25, 26, 33, 48–50] which are used to store frequently requested contents in computer systems. In a timer-based cache, a timer value is set when a content is first cached and evict the content when the timer expires. While our timer-based delayed hits model serves a different purpose, some of the theoretical analysis of timer caches directly apply (e.g., the decoupling nature of contents in timer cache analysis). This novel connection between timer-based delayed hits and traditional timer-based caches allows us to bring to bear the analytical work done in the conventional caching domain into latency-sensitive systems.*

4 Latency-Aware Cache

Our novel and lightweight timer-based model for delayed hits provides us an opportunity to design a *latency-aware* (LA) caching policy that achieves optimal latency for any given request sequence with variable content fetching latency from remote server.

Having characterized the mean latency experienced by all requests (see Corollary 1), we turn to derive a simple *ranking function* that can quickly prioritize contents so as to minimize latency⁵. Ranking function has been widely used in the design of conventional caching algorithms. For example, the classic Least Recently Used (LRU) [18] (or its variants) which are employed in major CDNs today, is based on a ranking function of content request recency, while Least Frequency Used (LFU) ranks contents by how frequently they have been

⁵We build a novel connection between delayed hits and timer-based caches for the sake of characterizing the mean latency of each content in the presence of delayed hits. See Remark 2. In particular, the fetching latency upon a cache miss is analogous to a timer. Need to mention that we are not considering the conventional timer-based caches, where each content is decoupled by the timer. Instead, our timer-based model serves a different purpose. For our latency-aware caching policy design, all contents are coupled by the cache capacity constraint and hence a ranking function (which is derived using the timer-based model, see equation (4)) is needed to make caching decisions. We use the term “timer-based model” since we can bring some analytical results from traditional timer-based cache domain into latency-minimization analysis, such as the expression of m_i .

requested. However, all these ranking functions prioritize contents for maximizing cache hits whereas we seek a ranking function so as to minimizing latency.

Our ranking function is inspired by the theoretically-sounded latency derived from the timer-based model for delayed hits, which in particular the following two intuitions. First, we consider the metric of aggregated latency computed in (1), which is the sum of latency due to a cache miss and any delay hits in the next L_i time slots which occur before the corresponding content is fetched and inserted into the cache. Intuitively, a content with a higher latency cost increases the average latency more than a content with a lower latency cost, and hence should be prioritized. Second, we consider the metric of mean latency for each request of a content, which is computed in (2). It is clear that a burst of requests to a content can contribute more to the average latency than a sparse of requests to a content. Following these two intuitions, we derive a ranking function based on both the aggregated latency and the mean latency for each content i as

$$\tilde{f}(i) = \frac{\text{Aggregated latency}}{\text{Mean latency for each request}} = \frac{D_i}{\bar{D}_i} = \frac{\lambda_i L_i (1 + \lambda_i L_i)}{2 + \lambda_i L_i}. \quad (4)$$

Now we introduce the *latency-aware* policy based on the above ranking function, abbreviated as LA-Cache. LA-Cache always places in the cache the C contents with the largest value of their corresponding ranking functions, i.e., if $\tilde{f}(1) \geq \tilde{f}(2) \geq \dots \geq \tilde{f}(N)$, then contents $1, 2, \dots, C$ are cached given that the cache size is C .

Proposition 2. *LA-Cache achieves the minimum mean latency experienced by all requests compared to any other online policies.*

Proof. This is clear from the definition of LA-Cache policy since both the ranking function (4) and the expected latency for each content i in (2) (resp. (3)) are monotonically increasing in $\lambda_i L_i$. \square

Remark 3. *Given (3) (resp. (2)), it can be easily shown that \bar{D} (resp. \bar{D}_i) is increasing in $\lambda_i L_i$, which can be interpreted as the expected number of delayed hits upon a cache miss for content i . Since our ranking function (4) is also increasing in $\lambda_i L_i$, it is clear that LA-Cache prioritizes caching bursty contents (We will formally define and evaluate the burstiness of a content using a burstiness measure [34] in Section 6). Intuitively this is correct since a bursty content usually refers to a large number of requests in a shorter time period. This will result in a larger aggregated latency for the content upon a cache miss. As a result, prioritizing such a content can reduce the latency.*

4.1 From Theory to Practice

The above ranking function is defined under the assumption that the content sizes in the system are equal. However, the

Figure 4: The architecture of our ATS prototype.

content sizes in production system usually vary significantly from a few bytes [46] to several gigabytes [31]. To overcome this drawback, we redefine the ranking function by incorporating the content size s_i , satisfying

$$f(i) = \frac{\tilde{f}(i)}{s_i} = \frac{\lambda_i L_i (1 + \lambda_i L_i)}{(2 + \lambda_i L_i) s_i}. \quad (5)$$

For the notation abuse, we call the policy using this refined ranking function as LA-Cache in the rest of the paper.

To compute the ranking function and obtain the ranking function based policy LA-Cache, the content arrival rate λ_i is needed⁶. This is straightforward for synthetic workload; however, the content arrival rate is usually unknown and varying over time in real-world systems. To this end, we use estimation techniques to approximate the request rates. For any content i , let X_j^i denote the random variable corresponding to the inter-arrival times for the requests for content i , and \bar{X}^i be its mean. We can approximate the mean inter-arrival time as $\hat{X}^i = \sum_{j=1}^K X_j^i / K$. It can be easily shown that \hat{X}^i is an unbiased estimator of $1/\lambda_i$. However, keep tracking of all X_j^i 's for each content j from the very beginning will increase the overhead. As it is well-known that content request processes in production systems are highly dynamic and non-stationary, we further consider a sliding time window, and only use the X_j^i 's within the window to estimate \hat{X}^i . In Section 6, we will use this estimator to compute the ranking function for evaluating our algorithm.

5 Implementation

We implement the LA-Cache prototype within Apache Traffic Server (ATS) [2], a popular CDN server. An LA-Cache cache simulator has also been implemented for the sake of comparison with a wide range of state-of-the-art caching algorithms. The two implementations are written in C++.

5.1 LA-Cache Prototype

ATS is a multi-threaded and event-based CDN caching server with a space-efficient in-memory lookup data structure as

⁶Again, L_i indicates the content retrieval latency upon a cache miss (related to RTTs of the system). In our experiments, we evaluate the impact of its value on the system performance. See Section 6.

	Description
LRU	Recency-based heuristic.
LRU-K	Recency-based heuristic. Evict content with the oldest K-th reference in the past.
LHD [7]	Using a ranking function of the content expected hit density.
2Q [52]	Manage caching decisions through a FIFO queue and a LRU queue.
Delay	An offline heuristic knows future request latency caused by evicting a content from cache now.
LRU-MAD [4]	Calculate content average latency from history and then combine with LHD as a ranking function.

Table 1: Overview of state-of-the-art caching algorithms.

an index to the cache. A typical ATS configuration consists of a disk/SSD cache and a memory cache. To achieve high performance, ATS is accessed using asynchronous I/Os. The overview of our LA-Cache prototype is presented in Figure 4.

Upon a new request, ATS implements the following steps. Based on the URL, it looks up the local caches to check whether the corresponding content is available. If the requested content is already in the caches (i.e., a true hit), then the request is immediately satisfied by replaying a response back to the user. Otherwise, the request is sent to the kernel, which maintains the request history received from users, i.e., a separate queue for each cache miss (see Section 1). If the current request belongs to one queue, then it will be added to the queue (i.e., a delayed hit). Otherwise, the kernel sets up a new queue for the content (i.e., a miss), and the request is forwarded to the original remote server. To deal with real traces, the requests are sent to a proxy server in the recorded order (via the trace replayer). All users and the master server communicate with each other by the TCP protocol.

We implement LA-Cache on top of ATS. To do so, we replace the lookup data structures for ATS cache with the LA-Cache described in Section 4. The content admission⁷ and look-up processes can be implemented asynchronously. These two processes are used to update parameters so as to make eviction decision⁸. In particular, the eviction process is run by scheduling cache admissions in a lock-free queue. It implements eviction rule to select one eviction candidate when the cache is full. But as for the flash abstraction layer which is very important in production system (i.e., we have

⁷Content admission decides whether to cache the content upon a cache miss.

⁸Eviction process determines which content to evict when the cache is full.

Dataset	CDN-A	CDN-B	Bilibili	Wiki
Duration (Hours)	24	9.9	18.7	0.1

Figure 5: The production traces used in our evaluation comes from different CDNs and thus exhibit different request patterns.

no access, e.g., RIPQ [56]), we only emulate the workings due to some difficulties, reading offsets randomly and writing sequentially to the disk. Since the memory cache is usually small which has little impact on hit probability [11], we keep this part of ATS unchanged. In summary, we implement the framework by only modifying about 100 lines of codes in ATS. The LA-Cache framework library contains about 600 lines of codes.

5.2 LA-Cache Simulator

We implement an LA-Cache simulator that includes a wide range of conventional caching algorithms. For ease of exposition, we only report the results for the “best-performing” algorithms as summarized in Table 1. Finally, our implementation benefits from existing caching simulators such as lib-CacheSim [39] and LRB simulators [53].

Availability. The code for the prototype design, the cache simulator as well as all evaluations in Section 6 are available at <https://github.com/GYan58/la-cache>.

Figure 6: CDF of inter-arrival times for real trace and synthetic trace for two representative contents.

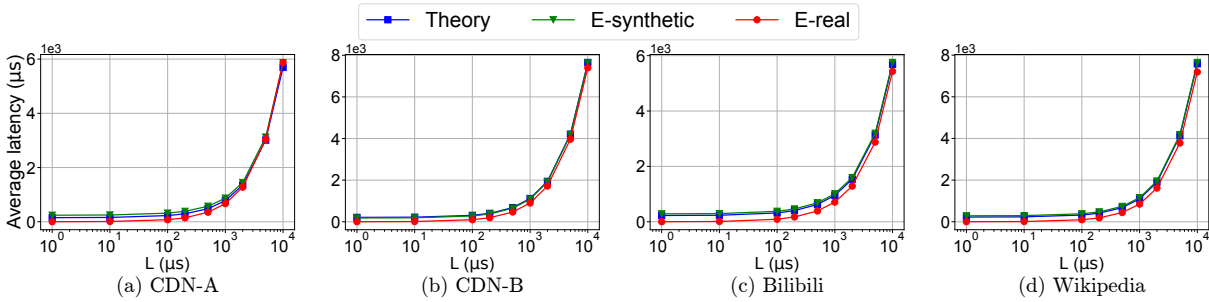

Figure 7: Comparison between theoretical and empirical results of mean latency for production traces. The mean latency graph for the *Theory*, the *E-real* and the *E-synthetic* is slightly offset for ease of visualization.

6 Evaluation

In this section, we evaluate our LA-Cache prototype. We also conduct simulations to compare LA-Cache to a wide range of state-of-the-art algorithms using production traces. Our results address the following questions:

- How accurate is our timer-based model for delayed hits given that real-world systems do not have strict Poisson arrivals (Section 6.2)?
- What is the benefit of using our LA-Cache prototype compared to existing CDN production systems in terms of latency and implementation overhead (Section 6.3)?
- What is the performance of LA-Cache compared to state-of-the-art algorithms on a wide range of production CDN traces under various cache settings (e.g., different fetching latency and cache sizes) (Section 6.4)?

6.1 Methodology

Traces. We consider production traces from four CDNs, two of which chose to remain anonymous. (1) CDN-A collected from several nodes in one continent serves a mixture of web and video traffic; (2) CDN-B captures mobile video behaviors collected from one live streaming system; (3) Bilibili [12, 29], collected from a Video-on-Demand (VoD) provider with millions of HTTP requests; and (4) a Wikipedia (Wiki) trace [53] collected on a west-coast node serving photos and other

media content. We summarize the trace characteristics in Table 2 and present two key distributions of these traces in Figure 5. The traces typically span several tens to hundreds of thousands of requests, and tens of thousands of contents with sizes varying from 10KB to 10^4 MB. The total bytes requested are on the order of TBs; however, the active bytes⁹ are on average on the order of GBs. As a result, we choose the cache size in the range of 128GB to 1,024GB for different traces in our evaluation. For ease of readability, we only present results using a 256GB cache and a 512GB cache for each trace in the rest of this section. Similar observations hold for other cache sizes and hence are omitted. Finally, the average inter-request time is 6.5 ms for CDN-A, 9.1 ms for CDN-B, 1.1 ms for Bilibili and 5.4 ms for Wikipedia.

Baselines. We compare LA-Cache with a wide range of state-of-the-art algorithms. For ease of exposition, we only show the few “best-performing” algorithms (see Table 1) in the following figures.

Performance evaluation. We evaluate the performance of these algorithms using four production workloads described above with different fetching latencies and cache sizes. All results are generated by running on Ubuntu 18.04 with an Intel(R) Core(TM) i7-6700HQ processor and a 8GB RAM.

⁹A content is said to be active at time t in a trace if t lies between its first and last requests. The total size of active contents at time t is defined as active bytes [35].

Figure 8: The latencies of LA-Cache and unmodified ATS using a 256GB cache.

		CDN-A		CDN-B		Bilibili		Wikipedia	
Metric	Experiment	LA-Cache	ATS	LA-Cache	ATS	LA-Cache	ATS	LA-Cache	ATS

Table 3: Resource usage for LA-Cache and ATS in max (throughput-bound) and normal (production-speed) experiments.

6.2 Accuracy of Timer-based Model

We first show that our proposed timer-based model for delayed hits (see Sections 3 and 4) is accurate.

Non-Poisson arrivals in production traces. We first show that production traces do not have strict Poisson arrivals for any content. To that end, we generate a synthetic trace based on the real trace, where each content follows Poisson arrivals with the same average arrival rate as in the corresponding trace. We analyze the distribution of the inter-arrival times for the corresponding contents from the real and synthetic traces. It is clearly shown in Figure 6 that they are visibly different. Similarly trends hold for other contents in all production traces considered in this paper, i.e., production traces do not have strict Poisson arrivals for any content.

Comparison between theoretical and empirical results.

We now show that despite the fact that production traces may not be strictly Poisson, our proposed timer-based model with Poisson assumption works well in practice. To this end, we compare the theoretically computed average latency (calculated using Equation (3)) to the empirically computed latency. In particular, we compare three results: (i) *Theory*: theoretical latency for the trace; (ii) *E-real*: empirical latency for the trace; and (iii) *E-synthetic*: empirical latency for the synthetic Poisson trace with same content arrival rates as the trace as described earlier. Figure 7 compares the curves for all three cases in four production traces. We observe that the theoretical latency matches very well with the empirical latency for

the synthetic trace while the empirical latency for the real trace only differs slightly with the other two.

6.3 Latency Reduction of LA-Cache Prototype

We first compare our LA-Cache prototype to the ATS production systems in mean latency and implementation overhead as shown in Figure 8 and Table 3. The average RTT is 200 ms.

Latencies. Figure 8 compares the mean latency, the 90-th percentile latency (P90 latency) and the 99-th percentile latency (P99 latency) of LA-Cache and unmodified ATS using four production traces with a 256GB cache. LA-Cache consistently reduces the latency compared to ATS by 5%-20% on average¹⁰.

Implementation overhead. We then compare the implementation overhead of our LA-Cache prototype against unmodified ATS. We measure the throughput, CPU and memory utility under the “max” experiments, as shown in Table 3. We see that LA-Cache has no measurable throughput overhead but the peak CPU utilization increases to 27.4% from 2.8% for ATS under CDN-A, 28.2% from 3.7% for ATS under

¹⁰P90 (resp. P99) latency is the value of top 10% (resp. 1%) latency. Though P90 (resp. P99) latencies of LA-Cache are not significantly better than ATS, it only means that the largest latency values are similar. More importantly, it is obvious that the mean latency, a key metric for real system, of LA-Cache significantly outperforms ATS, i.e., LA-Cache improves mean latency greatly for most content requests.

Figure 9: Comparison of mean latency improvement between LA-Cache and state-of-the-art algorithms relative to LRU using a 256GB cache.

Figure 10: Comparison of mean latency improvement between LA-Cache and state-of-the-art algorithms relative to LRU using a 512GB cache.

CDN-B, 27.1% from 2.8% for ATS under Bilibili and 28.5% from 4.0% under Wikipedia. However, we note that most production servers, even at their busiest mode, have sufficient CPU headroom.

We replay our traces using its original timestamps and measure the latencies corresponding to cache misses, delayed hits and true hits. We call this “normal” experiments as shown in Table 3. It is clear that LA-Cache leads to significant latency reduction compared to ATS. More specifically, LA-Cache reduces the 90-th percentile latency (P90 latency) by 4%, the 99-th percentile latency (P99 latency) by 3%, and the overall average latency by 10% compared to ATS.

Finally, we measure the peak memory overhead for all traces and cache sizes, we observe that LA-Cache uses at most 1.1% of the cache size to store metadata. As we will show later, such a small loss in available caching space is more than offset by LA-Cache’s significant latency reduction.

From our above experiments in ATS, we believe that LA-Cache is a practical design for today’s CDNs and can be easily implemented in existing production CDN servers with modest resource overhead.

6.4 LA-Cache vs. State-of-the-art Algorithms

We further compare LA-Cache to a large number of state-of-the-art caching algorithms using four production traces with

a wide range of fetching latencies and cache sizes.

Latency. Figures 9 and 10 compare the mean latency improvement of LA-Cache and state-of-the-art caching algorithms with respect to LRU with different fetching latencies using a 256GB and a 512GB cache, respectively. We choose LRU as the baseline since major CDNs today still employ LRU or its variants for content caching. The comparisons with respect to the offline Bélády are relegated to the supplementary material for ease of readability.

Our LA-Cache consistently outperforms the best state-of-the-art algorithms, i.e., “the best-performing” algorithms in Table 1. Overall, LA-Cache reduces the latency by 5%-15% on average. Note that LA-Cache is robust across all traces in latency reduction whereas no existing state-of-the-art algorithms could robustly reduce the latency across all traces. In particular, LA-Cache outperforms LHD-MAD and LRU-MAD, two recently proposed latency-aware caching algorithms [4]. Our interpretation is that our LA-Cache naturally offers a variable fetching latency for different contents as well as fully captures the varying content sizes whereas LHD-MAD or LRU-MAD are designed under the assumption that contents are of equal size, which is not the case in production systems (see Figure 5).

Impact of cache size. We further characterize the impact of cache size on the latency reduction of LA-Cache compared to state-of-the-art algorithms. Based on the results above,

Figure 11: Comparison of the mean latency improvement between LA-Cache and state-of-the-art algorithms relative to LRU as a function of cache sizes.

Figure 12: Improvement from the burstiness of content requests relative to LRU using a 256GB cache.

we only focus on the comparison with two latency-aware algorithms LRU-MAD and LHD-MAD. We compute the latency reduction compared to LRU for all traces while using a fixed value of $L=1$ ms. From Figure 11, we observe that LA-Cache’s improvement is between 4% and 30% compared to the widely deployed LRU. Finally, we see that LA-Cache outperforms LRU-MAD and LHD-MAD between 3% and 13% across different cache sizes.

Impact of burstiness. As motivated earlier in Section 2 as well as the design of our LA-Cache in Section 4, it is clear that a burst of requests to a content could contribute to the average latency more than a sparse of requests to a content. Now we turn to the question of *whether our intuition of burstiness indeed maps on the latency reduction of LA-Cache compared to state-of-the-art algorithms?*

To answer this question, we first need a measure to quantify the burstiness of a trace. A widely used metric is called the Goh-Barabasi score¹¹ [28]. However, it does not capture the impact of inter-arrival times, which play a significant role in delayed hits. To this end, we use a new burstiness measure [34] that not only captures the mean, variance of request sequences but also the inter-arrival times. The large the burstiness value, the busy the requests are. We refer interested readers to [34] for a detailed discussion¹².

¹¹The value of Goh-Barabasi score is between -1 to 1, with -1 being a regular request sequence, 0 being a random request sequence and 1 being a bursty request sequence.

¹²The Goh-Barabasi score is a statistical measure of burstiness in a se-

quence of events and is defined as $B = \frac{r-1}{r+1}$, where $r = \sigma/\mu$ is the coefficient of variation, σ and μ denote the standard deviation and the mean of inter-arrival times, respectively. However, the behavior of this score may not be robust with respect to finite-size request sequence. [34] redefined the burstiness score as $\frac{\sqrt{n+1}r - \sqrt{n-1}}{(\sqrt{n+1}-2)r + \sqrt{n-1}}$ where n is the sample size (i.e., number of requests in the sequence). This new score has been shown to quantify the burstiness in the empirical dataset without finite-size effects.

We characterize the burstiness of each content and the corresponding latency improvement of this content due to the latency-aware caching algorithms in Figures 12 and 13, where we consider the setting as above with a fixed value of $L=1$ ms. We observe that bursty contents (with a large burstiness value) incur a lower latency compared to LRU in general. Furthermore, we indeed observe that LA-Cache prioritizes more bursty requests compared to other state-of-the-art algorithms, which contributes to the latency reduction of LA-Cache. As a result, the overall mean latency is reduced. For example,

¹³We compute a weighted average burstiness score over all requests in the trace using the new burstiness measure [34], where the weight for each content is proportional to the total number of requests for this content.

Figure 13: Improvement from the burstiness of content requests relative to LRU using a 512GB cache.

for Wiki in Figure 12 (d), it is obvious that LA-Cache prioritizes more bursty requests compared to LRU-MAD and LHD-MAD. This leads to a latency improvement of 22% for LA-Cache, while the improvements for LRU-MAD and LHD-MAD are 2% and 9%, respectively, as shown in Figure 9 ($L = 10^3 \mu s$). This phenomenon can also be observed when compared with the offline Bélády (see supplementary material). These observations further validate our intuitions on designing a ranking function to prioritize bursty contents so as to minimize latency (see Section 4).

7 Related Work

Caching algorithm design has been extensively studied over years. However, most of the previous works have focused on improving caching hit probabilities. We classify them by admission or eviction. The widely used admission algorithms include AdaptSize [11], TinyLFU [19] and SecondHit [40], and among others where static features such as content sizes are used for admission [1, 20]. A large number of works proposed eviction algorithms from classic Least Recently Used (LRU) [18], RANDOM, FIFO, to more sophisticated ones that are more difficult to implement in practice, e.g., LRU-K [47], LFU-DA [3, 51], GDSF [15], ARC [44], CAR [6] and among others, where recency, frequency or their combinations are usually used for eviction decision [7, 13, 30].

Recently, machine learning has been used for caching algorithm design. On the one hand, some focus on learning content popularities for content eviction via deep neural networks (DNNs), e.g., DeepCache [45], FNN-Cache [22], Pop-Cache [54] and PA-Cache [21] or by approximating or imitating offline optimal Bélády for content eviction, e.g., LFO [10], LRB [53]. On the other hand, some algorithms learn to decide whether or not to admit a content upon a request (i.e., *content admission*) via reinforcement learning (RL), e.g., RL-Cache [35], CACA [29], RL-Bélády [58] and among others [57, 60]. Again, most of these designs are focusing on improving cache hits rather than minimizing caching latency.

Closest to our work is [4, 42]. In particular, [42] provides a lower bound on the performance of caching policies when

delayed hits exist. [4] characterizes the impact of delayed hits and proposes an online approximation algorithm MAD based on a hard offline optimization problem. However, MAD fails to account for variable fetching latency and different content sizes, which are the cases in production CDNs and are both captured by our LA-Cache.

8 Conclusion

In this paper, we designed latency-aware caching in the presence of delayed hits, and proposed a novel timer-based mechanism to capture the impact of delayed hits which provably optimizes the mean caching latency. Furthermore, our model captured variable fetching latency and different content sizes, providing a theoretical basis for the understanding and design of latency-aware caching for content delivery in latency-sensitive systems. Using our timer-based model, we proposed a lightweight latency-aware caching algorithm LA-Cache. We implemented a LA-Cache prototype within Apache Traffic Sever. Using production traces, we showed that LA-Cache consistently outperformed state-of-the-art algorithms on latency reduction with modest resource overhead.

A Supplementary Material

A.1 Analysis of Real Request Traces

In this subsection, we provide the detailed analysis of four production traces used in this paper, as discussed in Section 6.

The content popularity distribution (Figure 5(a)) shows that most traces follow approximately a Zipf distribution with the Zipf parameter α between 0.56 and 1.24.

The content inter-arrival time distribution (Figure 5(b)) - the distribution of the time between two consecutive request arrivals - further distinguishes these traces. It is clear that the requested contents in CDN-A have the largest variations since CDN-A contents have the smallest inter-arrival times, i.e., most contents are only requested over a shorter time period. In contrast, CDN-B, Bilibili and Wikipedia serve millions of different customers and hence exhibit largely independent requests with random inter-request times, which is consistent with the content popularity distribution.

A.2 Comparison with Offline Optimum Bélády

We also compare the performance in term of latency reduction to the offline optimum Bélády. From Figures 14 and 15,

Figure 14: Comparison of the mean latency improvement between LA-Cache and state-of-the-art algorithms relative to Bélády using a 256GB cache.

Figure 15: Comparison of the mean latency improvement between LA-Cache and state-of-the-art algorithms relative to Bélády using a 512GB cache.

we observe again that LA-Cache outperforms other state-of-the-art algorithms, and importantly LA-Cache can outperform Bélády as the fetching latency increases. For example, LA-Cache outperforms Bélády when L is greater than 0.8 ms in CDN-B, and when L is greater than 60 ms in Bilibili.

Finally, we characterize the impact of cache size when compared with the offline optimum Bélády. From Figure 16, we observe that LA-Cache consistently outperforms LRU-MAD and LHD-MAD across a wide range of cache sizes. More interestingly, LA-Cache outperforms Bélády.

Impact of burstiness. Complementary to the results presented in Figure 12, the burstiness of each content and the corresponding latency improvement of this content due to the latency-aware caching algorithms with respect to the offline Bélády with 256GB and 512GB cache are presented in Figure 17 and Figure 18, respectively. Again, we observe that LA-Cache prioritizes more bursty requests compared to other state-of-the-art algorithms, which contributes to the latency reduction of LA-Cache.

Figure 16: Comparison of the mean latency improvement between LA-Cache and state-of-the-art algorithms relative to Bélády as a function of cache sizes.

Figure 17: Improvement from the burstiness of content requests relative to the offline Bélády using a 256GB cache.

Figure 18: Improvement from the burstiness of content requests relative to the offline Bélády using a 512GB cache.

A.3 Hit Rate Comparison

Although we focus on designing latency-optimal caching in the presence of delayed hits, in which the goal of maximizing cache hits and the goal of minimizing latency are not equivalent (see Section 2.2), we argue that the latency improvements in turn also contribute to the cache hits performance. In most of existing works, the user-perceived latency upon cache hits is negligible, which is not true in the presence of “delayed hits” due to network latency. As a result, a content request results in three outcomes, i.e., miss, delayed hit, and true hit (see Introduction and Fig. 1). We observe that LA-Cache improves the true hit ratio up to 7% as shown in Figures 19 and 20, and “all hits” (true hit plus delayed hit) up to 9% as shown in Figures 21 and 22.

Figure 19: Comparison of true hits between LA-Cache and state-of-the-art algorithms using a 256GB cache.

Figure 20: Comparison of true hits between LA-Cache and state-of-the-art algorithms using a 512GB cache.

Figure 21: Comparison of all hits between LA-Cache and state-of-the-art algorithms using a 256GB cache.

Figure 22: Comparison of all hits between LA-Cache and state-of-the-art algorithms using a 512GB cache.

Hashing Design in Modern Networks: Challenges and Mitigation Techniques

Abstract

Traffic load balancing across multiple paths is a critical task for modern networks to reduce network congestion and improve network efficiency. Hashing which is the foundation of traffic load balancing still faces practical challenges. The key problem is there is a growing need for more hash functions because networks are getting larger with more switches, more stages, and increased path diversity. Meanwhile, topology and routing become more agile in order to efficiently serve traffic demands with stricter throughput and latency SLAs. On the other hand, current generation switch chips only provide a limited number of uncorrelated hash functions. We first demonstrate why the limited number of hashing functions is a practical challenge in today's datacenter network (DCN) and wide-area network (WAN) designs. Then, to mitigate the problem, we propose a novel approach named *color recombining* which enables hash functions to reuse via leveraging topology traits of multi-stage DCN networks. We also describe a novel framework based on *coprime* theory to mitigate hash correlation in generic mesh topologies (i.e., spineless DCN and WAN). Our evaluation using real network trace data and topologies demonstrate that we can reduce the extent of load imbalance (measured by the coefficient of variation) by an order of magnitude.

1 Introduction

Traffic load balancing is critical to the reliability and efficiency of modern datacenter and wide-area networks [16, 34, 37]. One widely deployed technique for traffic load balancing is Equal-Cost Multi-Path (ECMP) routing [16], where packets forwarding to a destination are load-balanced over multiple paths based on hashing of the packet header that takes place in switch hardware. ECMP and its variant Weighted-Cost Multi-Path (WCMP) [37] allow proper utilization across abundant paths available in modern networks. Hashing on header fields allows packets of the same flow to follow the same path without incurring packet reordering. As ECMP/WCMP offers

a number of nice properties, including stateless operation and no reordering, it is the de facto standard for traffic load balancing in large IP networks [1, 28, 37].

Switch hashing is the foundation of traffic load balancing in modern multi-path networks. To optimally load balance traffic and utilize full available bandwidth in multi-path networks using ECMP/WCMP, hash function allocation across a network should adhere to the following rule: *no correlated hash functions should appear on the same forwarding path in the absence of color recombining* (§3). Unfortunately, commodity switch chips only support a limited number of hash functions. For example, the software development kit for Broadcom switches supports *RTAG7* [9], a hashing scheme utilizing seven hash functions; the Cisco Nexus 5500 Series offers eight versions of *CRC8* [8]; the switches deployed in our datacenters have six independent hash functions. It is difficult to implement a large set of complex hash functions because hash computation becomes a bottleneck at high line rates [17, 19] and switch chip architects often need to trade-off between high line rate and hash function complexity.

Because of the limited number of hash functions provided in switch chips, a challenge in network design is that the reuse of correlated or even identical hash functions in different switches along the same end-to-end path for a flow causes *traffic polarization and inherent load imbalance*. Many network operators have observed this problem before [7, 11, 14, 18, 25]. One example is the Cisco Express Forwarding (CEF) Polarization phenomenon [7], where different switches repeatedly use the same hashing algorithm, resulting in a switch selecting a small portion of links for all traffic destined for one prefix, while other links were underutilized. Another example is the hashing imperfection problem observed by a large cloud provider [18, 25], where correlated hash functions lead to network congestion and even high priority traffic losses which directly impact application performance. In this paper, we use the term *hash correlation* to describe the association between hash functions in different switches that leads to traffic polarization.

Researchers and network operators have proposed a few

approaches to mitigate hash correlations. One class of methods uses variations of available hash functions. The most common approach uses hash functions with different seeds to avoid hash correlation. However, contrary to conventional wisdom, seeds are not as effective as expected as we will show theoretically and experimentally in this paper. Another approach uses Time-To-Live (TTL) in the packet header for hashing. There are two ways of using TTL: a) using TTL as part of hashing input, which has the following limitations in production: 1) it breaks traceroute because probe packets are hashed/pathed differently at the same hop; 2) IP in IP tunneling [12] (a common technique for network virtualization in the cloud) commonly uses the inner IP headers because they have more entropy than the outer IP headers, but the inner headers' TTL does not change. It's also hard to select outer header TTL and inner headers because switches do not have enough bit vectors. b) choosing a different hash function based on TTL [14], in addition to 1) and 2) mentioned in a), the challenges are: 3) it also requires modifying switch hardware, which presents administrative and commercial barriers to implementation since switch chips deployed in most datacenters do not support this operation currently; and 4) it is still constrained by the limited number of hash functions implemented in ASIC.

This paper focuses on fixed-function switches which are still the majority of devices in datacenters in the industry today. Hyperscalers cannot replace all switches with programmable ones in the near future. In this paper, we first demonstrate that the limited number of hash functions in commodity switch chips poses a practical challenge in modern DCNs and WANs and hinders the development of more advanced network topology and routing designs. To overcome this challenge, we propose two novel techniques that improve hashing, the cornerstone of traffic load balancing, substantially while respecting the limited number of independent hash functions available in commodity switches— 1) for widely adopted, multi-stage Clos DCNs, we propose a *color recombining* approach by comparing the effect of hash functions on traffic to light passing through multiple triangular prisms: the color recombining technique leverages the trait of multi-stage Clos topology where polarized traffic gets recombined to *color white* after passing through a multi-stage Clos. Color recombining enables us to reuse certain hash functions along the forwarding path without causing hash correlations. We discuss hashing design for one of the multi-stage Clos DCNs, Jupiter [26], and how the color recombining technique helps reduce the required number of independent hash functions; 2) for non-hierarchical mesh networks such as spineless DCN [13, 32] and WAN, we propose a novel framework residing in the Software Defined Networking (SDN) [20] controller. The framework mitigates the effect of hash correlations by the selection of the divisors n (n is also known as group size in ECMP/WCMP routing) used to map a flow's hash value h to the output port over which a packet is forwarded, i.e., $h\%n$.

Specifically, we establish that *when ECMP/WCMP group sizes at different switches are coprime, then the effects of underlying correlations between hash functions are reduced significantly*. We add a small amount of logic to the SDN controller to ensure the group sizes of switches with correlated hash functions are coprime. As a software-only approach, this coprime-based approach is compatible with commodity switch chips.

To summarize, the contributions of our work are as follows:

1. Details the hashing design in *multi-stage Clos DCN* and proposes a *color recombining* method to allow hash function reuse and to reduce the number of hash functions needed in multi-stage Clos DCNs;
2. Identifies an approach based on the *coprime* theory to mitigate hash correlations for generic *mesh networks* such as *spineless DCN* and *WAN* that require a large number of independent hash functions, and proposes algorithms to coprime group sizes for both ECMP and WCMP routing;
3. Evaluation results based on real network trace data and topologies demonstrate color recombining and coprime techniques' effectiveness in mitigating hash correlation—they can reduce the extent of load imbalance (measured by the coefficient of variation, CV) by approximately an order of magnitude.

The color-recombining approach uses topology and forwarding structures that are common in Clos networks and requires no hardware or software changes except hash function reconfiguration. The coprime-based method works with any topologies (e.g., mesh networks) but it requires controller software changes and only resolves polarization when the conditions described in §4 are met.

In addition to the technical contributions, we also would like to call for switch vendors' attention to offer better hashing support in future generations of chips to facilitate flexible network designs.

2 Background and Motivation

In this section, we first motivate why hashing is an important problem in modern DCNs and WANs. Then, we provide the background of ECMP and WCMP. Finally, we introduce the traffic polarization issue caused by hash correlation and reveal the fact that the current generation of switch chips only provides a limited number of independent hash functions which poses a practical challenge to traffic load balancing in modern networks.

The implications of bad hashing are twofold. First, bad hashing leads to *traffic polarization* that endangers reliability (due to reduced path diversity), wastes network bandwidth, cancels efficiency gains of traffic engineering, and inevitably

Figure 1: Illustration of Jupiter DCN (5-stage Clos). For simplicity, only one *Middle Block* of each *Server Block* and one *Spine Block* of the spine layer is shown.

Figure 2: Illustration of a *Stargate* site in the mesh-connected B4 WAN. Figure is adapted from [15].

increases network cost. Second, bad hashing causes *inherent traffic load imbalance* and leads to network congestion that affects application performance.

2.1 Hashing is a Practical Challenge in Network Designs

There are several trends that make hashing an increasingly important problem in modern networks: 1) both datacenter and wide-area networks are getting bigger with more switches and stages; 2) modern networks are very dense and have a large number of paths between any two nodes; 3) topology and routing become more agile and flexible in order to improve network efficiency and availability, e.g., the move from spinefull DCN to reconfigurable spineless [13, 32] and the use of non-shortest path routing to improve availability and performance [15]; and 4) emerging applications (such as distributed machine learning) are becoming more throughput hungry while demanding stricter network SLA guarantees. These new trends pose challenges to commodity switches' hashing capability, which is the cornerstone of traffic load balancing.

2.1.1 Multi-stage Clos DCN

Modern DCN connects a massive amount of compute/storage nodes, runs critical services, such as Search Serving, Video Serving, Geo & Map, Cloud, and Gaming, etc, and has very large path diversity; therefore, hashing and traffic load balancing are crucial. We use the Jupiter topology [26, 35] (as illustrated in Figure 1) as the case study of multi-stage Clos DCNs. We denote a *Server Block* (aka Pod) as SB and the

Figure 3: Spineless DCN [32] to simulate hash correlation's impact on traffic load balancing.

5 switch stages as S_1 to S_5 . So the longest forwarding path is when a packet is routed from a ToR in SB_i to another ToR in SB_j and the hop sequence is $S_1(SB_i) \rightarrow S_2(SB_i) \rightarrow S_3(SB_i) \rightarrow S_4 \rightarrow S_5 \rightarrow S_4 \rightarrow S_3(SB_j) \rightarrow S_2(SB_j) \rightarrow S_1(SB_j)$ where i, j are server block indices. To achieve optimal load balancing performance, hashing needs to follow the following property: no correlated hash functions should appear on the same forwarding path. Naively we need $O(2L)$ (more precisely, $max_number_of_hops - 1$) independent hash functions, where L is the number of layers (or stages) of the fabric. In the case of Jupiter, 8 hash functions are needed. Unfortunately, there are only 6 uncorrelated hash functions provided by the switch chips deployed in our datacenters and the requirement of 8 independent hash functions already makes the commodity switch's hashing capacity stretched. We will discuss how we reduce the number of hash functions needed for multi-stage Clos DCN in Section 3.

2.1.2 Spineless DCN

Recently, there are new *spineless* DCN topologies [13, 32] which reduce cost and enable faster tech refresh, but require more hash functions. Figure 3 is an example of spineless DCN topology. In spineless DCN, server blocks are directly connected via a mesh and the spine blocks are completely removed to reduce network cost (including the cost of both spine switches and the associated optics) significantly and to enable faster switch generation evolution. Also, non-shortest path routing is used to improve routing path diversity for high availability and enable traffic engineering to optimize network link utilization.

While spineless DCNs are cost-effective and efficient, hashing design becomes more challenging because the number of hash functions required depends on the number of server blocks instead of the number of layers as in multi-stage DCNs. Taking the Gemini [32] spineless DCN as an example, assuming that we only allow at most one transit server block in routing, then the longest forwarding path of a packet is: $S_1(SB_i) \rightarrow S_2(SB_i) \rightarrow S_3(SB_i) \rightarrow S_3(SB_j) \rightarrow S_2(SB_j) \rightarrow S_3(SB_j) \rightarrow S_3(SB_k) \rightarrow S_2(SB_k) \rightarrow S_1(SB_k)$ where i, j, k are the indices of three randomly chosen server blocks. The key challenge is that we need to make sure there are no correlated hash functions for any i, j, k combinations. So spineless DCN requires $O(N)$ hash functions where N is the number of server

blocks. N ranges from 10s to 100s in a typical fabric, so it is very challenging to design hashing with the limited hash functions provided by current-generation switch chips.

2.1.3 WAN

Traffic engineering and load balancing are critical to improving WAN's performance and reducing operational costs. Mesh-connected WANs have the same hashing design challenge where the number of uncorrelated hash functions required is subject to the scale of the network. For example, Figure 2 shows the topology of a Stargate site of the B4 WAN [15]. Each site is composed of up to 4 supernodes where a supernode is a 2-stage Clos with links to WAN, Data Center, and other supernodes in the same site. B4 site-level topology is a partially connected mesh and non-shortest path routing is employed for both availability and efficiency (i.e., traffic engineering) purposes. Similar to spineless DCNs, to ensure optimal load balancing performance, we need $O(N)$ hash functions, where N is the number of sites in the WAN. Note that B4 grew $7\times$ larger from 2012 to 2017 [15]. We will discuss the hash correlation mitigation technique for mesh networks such as spineless DCNs and WANs in Section 4.

2.2 ECMP/WCMP Traffic Load Balancing

Equal-Cost Multiple-Path (ECMP) [16] – a routing and traffic load balancing strategy that allows traffic between a source and destination node to be transmitted across multiple paths – identifies a set of routes, each of which is equal-cost towards the destination. The routes identified are referred to as an *ECMP group*. An ECMP group is defined at flow-level. When forwarding a packet, the routing strategy decides which next-hop path to use based on a hashing algorithm. That is, the route of a packet is determined by the mapping from the hash value to an egress port, i.e., $h \% n$, where h is the hash value, and n is the number of output ports in the ECMP group. The typical IP packet header fields used for hashing input are: source IP, destination IP, transport protocol, TCP/UDP ports, and IPv6 flow label.

Each route in an ECMP group has an equal chance for traffic forwarding. For example, Figure 4a shows the traffic from source IP prefix to destination IP prefix uses four equal-cost paths, which are labeled in four colors, where H_1 and H_2 are two independent hash functions.

When switch hashes packets across multiple paths according to customized weights instead of uniform ones, this variant of ECMP is called Weighted-Cost Multi-Pathing (WCMP) [37]. And the set of routes identified for a flow is referred to as a WCMP group. WCMP can be implemented via replicating ECMP table entries in the switch to approximate the intended WCMP weights. For example, if there are 2 output ports of a flow f , denoted by p_1, p_2 , and the intended weights are 2:1, then the WCMP group can be implemented

as p_1, p_1, p_2 (p_1 is duplicated as 2 entries to achieve the 2:1 traffic split).

2.3 Hash Correlation Causes Traffic Polarization and Load Imbalance

2.3.1 Limited Number of Hash Functions Leads to Hash Correlation

ECMP/WCMP is widely deployed in modern DCNs and WANs which have a large path diversity to improve traffic load balancing performance and reduce network congestion. Switches are configured with hash functions that compute hash values based on packet headers and forward packets via selecting one out of multiple next-hops based on the hash value and the ECMP/WCMP group size.

However, current-generation switch chips were designed for small-scale DCNs or large but sparse ISP networks and only provide a handful of independent hash functions. For example, the switch chips used in our datacenters provide six independent hash functions. The software development kit for Broadcom switches supports RTAG7 [9], a hashing scheme utilizing seven hash functions. The Cisco Nexus 5500 Series offers eight versions of CRC8 [8]. CRC and XOR are two popular hashing algorithms because these two algorithms have been used in communication systems with mature and efficient ASIC implementation, which includes plenty of circuit optimization [33]. As discussed in Section 2.1, the number of independent hash functions needed is far beyond (orders of magnitude difference) what is provided today, especially for spineless DCN and WAN.

In fact, it is difficult to implement a large set of uncorrelated hash functions because complex hash functions become a bottleneck at high line rates [17, 19]. For example, the authors in [19] discovered that the generation of Cyclic Redundancy Codes (CRCs) represents the main bottlenecks in iSCSI protocol processing. Switch chip architects often need to trade-off between high line rate and hash function complexity and we are not aware of any switch chips with cryptographic hash functions today due to computation complexity concerns.

In an ideal world where all the switches on the forwarding path are configured with completely independent hash functions, there would be no hash correlation. Due to the limited hash functions, we have to reuse them, which leads to hash correlation and traffic polarization. *Polarization* is a term used to describe what happens to light as it travels through a filter. Only light rays that have a certain characteristic get through the filter. We can take the same term and apply it to network traffic. Traffic polarization is the effect when a set of packets choose a particular path and the redundant paths remain completely unused [7]. Traffic polarization reduces path diversity and causes sub-optimal use of redundant paths and results in traffic load imbalance and network congestion. For example, Figure 4b shows that switches s_1, s_2 and s_3 employ the same

(a) Illustration example of ECMP. (b) ECMP with hash correlation.

Figure 4: ECMP with and without hash correlation. In (b), two out of four paths are unused due to hash correlation.

hash function (H_1). The hash correlation between switches s_2 (s_3) and s_1 causes traffic polarization. Figure 5 explains the problem: hash value on s_2 (s_3) is the same as s_1 , and thus flows are only forwarded to s_4 from s_2 and s_7 from s_3 . As a result, traffic from source to destination only uses two routing paths instead of four as in Figure 4a. Traffic polarization endangers reliability, wastes network capacity, and leads to hot links and network congestion under high traffic loads.

2.3.2 Random Seeds Are Not Effective

Since the shortage of independent hash functions available in switches prevents simply assigning independent hash functions to different switches, switch vendors suggest deriving multiple hash functions from one via using a switch-specific seed [7]: a seed is an initial value to start the CRC computation via XORing the input data. Because switch chip’s port count is powers of 2 and ports are typically divided into two equal-size directions (e.g., up-facing and down-facing) in modern networks, ECMP groups with an even number of ports are prevailing. However, we found that seeds do not work for an ECMP group of an even number of ports. For example, based on Theorem 1, all packets on switch s_2 (Figure 4b) from switch s_1 have the same routing choice even if they use different seeds for the same CRC; the proof of Theorem 1 can be found in the appendix.

Theorem 1 *If $crc_b(x \oplus z_1) \% 2 = crc_b(y \oplus z_1) \% 2$, $crc_b(x \oplus z_2) \% 2 = crc_b(y \oplus z_2) \% 2$, where x and y denote the data with the same size in bytes, z_1 and z_2 are two seeds of b bits, and b is the integer to denote the number of bits of the CRC, and \oplus denotes eXclusive OR (XOR).*

The above theorem indicates that choosing two random seeds does not create two independent hash functions from one CRC polynomial. Please note CRC polynomials are the most widely implemented hash functions in switch hardware, e.g., Broadcom’s RTAG7 is a hash family with 6 CRC16s and 1 CRC32. Applying a random seed is a linear operation and it can not decorrelate a hash function’s output effectively.

To confirm our theoretical analysis, we also build a spineless DCN topology (shown in Figure 3) to simulate traffic load balancing performance with hash functions provided

Figure 5: Hash correlation leads to correlated load balancing decisions. Figure 6: Normalized link utilization for perfect hashing and per-stage hashing

by a switch vendor. The topology is composed of three *Server Blocks* and each server block contains 64 ToRs (each ToR is assigned a /24 IP prefix). All these three server blocks have the same radix of 256. The three server blocks are connected in a full mesh (i.e., this is a spineless DCN [32]), so there are exactly 128 links between each server block pair. To simplify the analysis, we generate flows (the source IP and destination IP of a flow is randomly chosen from the source ToR and destination ToR’s IP prefix range respectively) following a uniform traffic pattern, i.e., all the server block pairs have the same amount of flows and the flow size distribution follows empirical datacenter flow size measurement in [4].

We compare two hashing schemes: one is *perfect hashing*¹ on each switch; and the other is *per-stage hashing with random seed* where the switches in different stages are configured with different functions provided by the switch vendor and each switch in the network is provided a completely independent and random seed. We measure the amount of traffic landed on the links between server blocks and show the normalized link utilization distribution in Figure 6. We can see from Figure 6 that the link utilization is close to uniform when using perfect hashing (which is expected) while per-stage hashing with random seeds leads to considerable traffic imbalance (max/min link utilization is 1.33). This experiment confirms that random seed does not solve the hash correlation problem.

3 Hashing Design in Multi-stage Networks

In this section, we describe the hashing design for multi-stage Clos DCNs. We first start with a strawman solution, *per-stage hashing with random seed*, then introduce *per-port hashing* scheme which requires more hashing functions than what is provided by commodity switches. In order to reduce the number of independent hash functions needed, we propose a novel approach named *color recombining* by leveraging topology traits of multi-stage Clos networks where polarized traffic is recombined into non polarized traffic and hash function reuse is allowed. We use Jupiter topology [26] as the case study here but the techniques proposed in this section can

¹Using the Mersenne Twister pseudo-random number generator in C++.

Figure 7: Illustration of color recombining concept.

be generalized to other multi-stage Clos DCNs. At the end of this section, we will provide details on why the hashing design for multi-stage Clos does not work in spineless DCNs and WANs.

One naive hashing design for Jupiter is *per-stage hashing with random seed* which means we assign a different hash function to each stage of switches and each switch is fed with a random seed. However, as we revealed in §2, random seed does not solve the hash correlation problem. Instead, we propose *per-port hashing* which means we apply hash function based on the input port of the switch. In total, there are 5 stages of switches in Jupiter as shown in Figure 1 and we apply two hash functions (one for upward traffic and the other for downward traffic) per switch except S_1 and S_5 . S_1 is ToR so only upward traffic requires a hash function; there is no need to have two hash functions in S_5 because we do not need to distinguish upward and downward traffic. Therefore, we need 8 independent hash functions to implement per-port hashing in Jupiter. And we can prove that for any routing path, there is no hash correlation. Taking the longest forwarding path as an example: a flow is routed from a ToR in the source server block to another ToR in the destination server block. So the forwarding path is S_1 (source ToR) $\rightarrow S_2 \rightarrow S_3 \rightarrow S_4 \rightarrow S_5 \rightarrow S_4 \rightarrow S_3 \rightarrow S_2 \rightarrow S_1$ (destination ToR). At each hop, a unique hash function is used so there is no hash correlation.

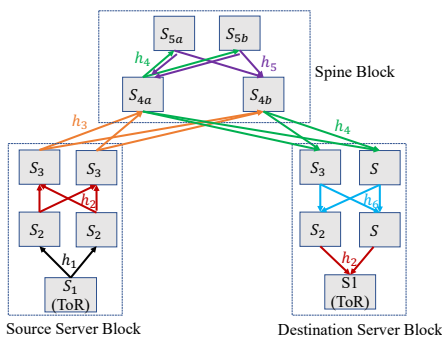

Figure 8: Per-port hashing with color recombining in Jupiter.

Per-port hashing design is clean and elegant (i.e., hash function allocation is static and easy to configure) for multi-stage Clos networks such as Jupiter, but the number of hash functions required is larger than what is provided by commodity switch chips. To reduce the number of hash function needed by per-port hashing, we identify and propose the *color recombining* technique via exploiting topology properties of

Figure 9: Per-port hashing works if only direct path (i.e., shortest path) routing is allowed in spineless DCN.

multi-stage Clos to enable hash function reuse. We compare traffic going through a hash function to light passing through a triangular prism: light passes through prism and gets separated to its component colors; analogously, network traffic goes through the hash function and gets forwarded to multiple paths. For example, Figure 7 shows that H_1 can be reused in switch s_2 because traffic becomes *color white* after passing through the middle triangular prism, where color white denotes the combined traffic before splitting or after recombining. We use the term *color recombining* to denote the recombining of polarized/dispersed traffic. Our key insight is that *in multi-stage Clos networks, certain stages of switches serve as the middle triangular prism in Figure 7 and combine polarized traffic to color white*.

As shown in Figure 8, there are two places traffic becomes "color white" in Jupiter – a) after passing the spine block and bouncing back to S_{4b} switches and b) after reaching the destination server block's S_2 switches. For a), h_4 is applied on S_{4a} towards the S_{5a} and S_{5b} direction. S_{5a} and S_{5b} apply an orthogonal hash function h_5 , and therefore, the same portion (50%) of $S_{4a} \rightarrow S_{5a}$ and $S_{4a} \rightarrow S_{5b}$ goes to S_{4b} . Effectively, the traffic of $S_{4a} \rightarrow S_{5a}$ and $S_{4a} \rightarrow S_{5b}$ towards S_{4b} recombines and h_4 can be reused. We define "polarized traffic w.r.t h_4 " as the unequally bucketized traffic through $S_{4a} \rightarrow S_{5a}$ and $S_{4a} \rightarrow S_{5b}$ respectively due to h_4 . For b), traffic gets polarized w.r.t h_2 on S_2 , however, after traffic reaching destination server block's S_2 chips, each S_2 is designed to receive the same portion of polarized traffic w.r.t h_2 , therefore h_2 can be reused on S_2 for downward traffic hashing. The sufficient condition of color recombining is *there exists a "color recombining stage" such that each switch in this stage receives the same portion of polarized traffic w.r.t H_x and after this color recombining stage, H_x can be reused without incurring hash correlation*. With color recombining, we effectively reduce the number of independent hash functions needed in Jupiter from 8 to 6 and all of the switch chips we use can meet this number.

Per-port hashing with color recombining inherits the pros of per-port hashing while requiring less hash functions from commodity switches. However, we found that this scheme breaks for the emerging spineless DCN topology [32]. In spineless DCN, both direct paths and transit paths are employed to route traffic because network architects want to a) increase path diversity to improve availability and b) per-

Figure 10: Per-port hashing breaks (h_3 appears twice on the forwarding path) in spineless DCN with non-shortest path routing.

form traffic engineering to hedge against unpredictable traffic spikes. Figure 9 shows that if we restrict routing to direct paths only, the per-port hashing scheme still works. However, as shown in Figure 10, we need to use h_3 twice for the flows traversing through a transit server block where the packet forwarding path is S_1 (source ToR) $\rightarrow S_2 \rightarrow S_3 \rightarrow S_3 \rightarrow S_2 \rightarrow S_3 \rightarrow S_3 \rightarrow S_2 \rightarrow S_1$ (destination ToR). Please note that traffic traversing through the transit server block bounces through S_2 chips for load balancing purposes. As mentioned in Section 2, we need $O(N)$ independent hash functions where N is the number of server blocks. N is a large number in our fabrics, so we need to identify more generic techniques to mitigate hash correlation. In Section 4, we will discuss the *coprime* technique for mesh topologies such as spineless DCN or WAN.

4 Mitigating Correlation for Mesh Networks

In this section, we describe a generic approach based on *coprime theory* to mitigate hash correlations in mesh networks. We first provide a theory about coprime in §4.1. Following it, we describe how the coprime theorem can be used to mitigate hash correlations for both ECMP and WCMP, in §4.2 and §4.3, respectively.

4.1 The Coprime Theorem

The key idea of the coprime theory is the modulo operation on coprime numbers (e.g., 127 and 128 are two coprime numbers) makes a hash function’s output uncorrelated. Considering one hash function H hashed to $\{0, 1, \dots, \hat{H}\}$, we propose to apply the modulo operation of two coprime values to derive two independent hash functions H_1 and H_2 from H , where \hat{H} is the highest hash value.

Below we explain how we use the coprime theory to mitigate hash correlation between two switches. In a switch, we use a hash function to choose the next hop via performing a modulo operation, i.e., $H(x)\%m$, where $H(x)$ is a hash value on a packet x , and m is the number of next hops in the ECMP

or WCMP group. Considering a scenario where two switches on a forwarding path both use H to choose the next hop, there exists hash correlation and traffic polarization as described in Figure 4b. Instead of using the same hash function H in these two switches, as denoted in Equation 1, we can use the derived H_1 ($H_1 = H\%q_1$) on the first switch to choose a next hop among m_1 next hops and H_2 ($H_2 = H\%q_2$) on the second switch, hashed to m_2 next hops. q_1 and q_2 are coprime numbers. The theorem 2 shows the two hash functions have no correlations.

$$H_i = H\%q_i, i \in \{1, 2\} \quad (1)$$

where q_1 and q_2 are two coprime values, and $q_i < \hat{H}$.

Theorem 2 $\forall i, \forall j, \Pr(H_2(x)\%m_2 = j | H_1(x)\%m_1 = i) \simeq \Pr(H_2(x)\%m_2 = j)$ if the following two conditions are satisfied:

Condition 1: $q_1 \gg m_1$ or $q_1\%m_1 = 0$, and $q_2 \gg m_2$ or $q_2\%m_2 = 0$;

Condition 2: $\hat{H} \gg q_1q_2$.

where q_1 and q_2 are two coprime values, m_1 and m_2 are the number of next hops, and x is a packet.

The theorem shows that the hash value of $H_2\%m_2$ is independent with the hash value of $H_1\%m_1$ for an input x when choosing proper coprimes q_1 and q_2 (q_1 and q_2 should be chosen to meet condition 1 and 2 of Theorem 2). The proof of Theorem 2 can be found in the appendix.

4.2 Coprime for ECMP

Based on Theorem 2, we propose a coprime-based approach to mitigate hash correlations along a routing path. When two hash functions are correlated, we just choose two coprimes and apply an extra modulo operation to derive two independent hash functions as in Equation 1.

While it may seem to be intuitive and easy to add an extra modulo operation to the hash value in a switch, but this requires switch hardware modification and no switch chips we are using provide this functionality. Even if switch vendors provide this functionality in their next generation chips, we have to replace all our existing switches, which is daunting and costly.

Instead, we propose to duplicate the ECMP group entries to match the coprime value in the SDN controller and interact with the switch flow and group tables via the existing OpenFlow [21] interface. Figure 11 shows the procedure of the method. We explain this using an example. Assuming that there are two egress ports in the ECMP group for IP prefix 10.1.2.0/24. Suppose one hash correlation occurs, we choose a coprime value of 5 to mitigate the hash correlation. Instead of modifying switch hardware to achieve two modulo operations $h\%5\%2$ (h is a hash value returned from the hash function) to choose an egress port, we duplicate 2 physical

egress ports into 5 logical ports in the ECMP group which are mapped to 2 physical egress ports. In this way, we only need one modulo operation, that is, $h\%5$, to determine the logical port and finally the physical egress port. Duplicating ECMP group entries to match the coprime value is supported by today's commodity switches and we only need to add a small amount of logic into the SDN controller. Note that Figure 11 shows that one flow table contains many IP prefixes/flows sharing the same group (multi-path) table in the switch, so we need to use an offset added to $hash\ value\ \%group\ size$ to index each IP prefix/flow.

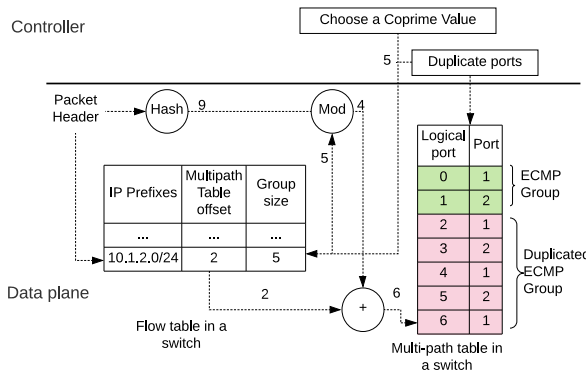

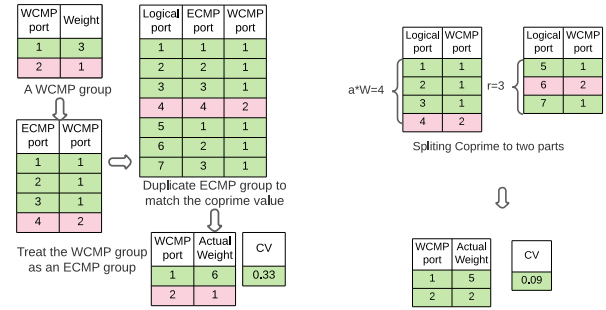

Figure 11: The procedure of applying a coprime number to mitigate hash correlation without requiring an extra modulo operation.

There are two technical challenges of the *coprime ECMP group size* method mentioned above: 1) increased switch memory usage, especially for large coprime values. The memory usage is increased by $O(q/m)$ times, where q and m is the coprime and original ECMP group size, respectively; and 2) ECMP precision loss – i.e., the difference between intended weights and actual weights of different egress ports of an ECMP group. In order to save switch memory, we may want to choose small coprime values. However, small coprime value contradicts condition 1 in Theorem 2; furthermore, we also need to tolerate the ECMP precision loss introduced by a small coprime value. When coprime ECMP group size, some ports are duplicated for $\lfloor q/m \rfloor$ times, and others are duplicated for $\lfloor q/m \rfloor + 1$ times. So when q/m is small, this introduces ECMP precision loss.

We use the coefficient of variation (CV) to measure how effective a coprime value is. Suppose we have m links, and the expected portion of traffic is $p_i = 1/m$ per link. After using coprime q , the actual traffic distribution is $\hat{p}_i = (\lfloor q/m \rfloor + I(i \leq q\%m))/q$, where $I(\cdot)$ is an indicator function, $i \in \{0, m-1\}$ is the port id, and when $i \leq q\%m$, $I(\cdot) = 1$. The CV is computed for \hat{p}_i . In our implementation of the coprime method, we minimize CV while obeying the ECMP table size limit offered by switch chips.

(a) Naive coprime: the WCMP group is treated as an ECMP group value 7 is split into the first $\hat{q} = a * W = 4$ and the remaining $r = 3$, where $a = \lfloor q/W \rfloor = 1$.

Figure 12: Illustration and comparison of the naive and improved algorithm to coprime WCMP groups.

4.3 Coprime for WCMP

As discussed in [37], topology asymmetry introduced by link or switch failures requires Weighted-Cost Multi-Path (WCMP) to distribute traffic in proportion to downstream hops' capacities. In this section, we extend the coprime-based method from ECMP to WCMP.

One straightforward method, denoted by *naive coprime*, is to treat a WCMP group as an ECMP group of W ECMP ports, where W is the sum of the weights, i.e., $W = \sum_i w_i$ and w_i is the weight of port i . We duplicate the W ECMP ports to q logical ports just as an ECMP group, where q is a coprime value. However, the weights after duplication could deviate significantly from the intended WCMP weights. One example is shown in Figure 12a: there are two ports in the WCMP group, and their weights are 3 and 1, that is, $w_1 = 3$ and $w_2 = 1$. This WCMP group can be treated as an ECMP group with $W = 4$ ECMP ports. Suppose, we choose a coprime value 7, and after duplication, the actual weights are $\hat{w}_1 = 6$ and $\hat{w}_2 = 1$, which are significantly different from the intended WCMP weights. We use the CV of $\{\hat{w}_i/w_i\}$ to quantify the difference. As shown in Figure 12a, the CV is 0.33.

To reduce the difference between the actual weights after coprime WCMP group size and the expected WCMP weights, we propose an improved algorithm to duplicate entries in the WCMP group, denoted by *split coprime*. Suppose the WCMP group has m ports, the weight is w_i for port i , $W = \sum_i w_i$, and the chosen coprime value is q . We split the coprime value to two parts: $\hat{q} = a * W$ and $r = q\%W$, where $a = \lfloor q/W \rfloor$. It is intuitive to duplicate the ports to \hat{q} logical ports, that is, each WCMP port are duplicated for exactly $w_i * a$ times. We duplicate m ports to left r entries in the following manner: each port i is replicated for $\lfloor r/m \rfloor + I(i < r\%m)$ times, where $I(\cdot)$ is an indicator function, and when $i < r\%m$, $i \in \{0, 1, \dots, m-1\}$, $I(\cdot) = 1$. Figure 12b illustrates the procedure of co-priming a WCMP group: the

coprime value $q = 7$ is split into $\hat{q} = 4$ and $r = 3$; for \hat{q} , the two WCMP ports are duplicated for w_i times, and $w_1 = 3$ and $w_2 = 1$; For r , port 1 is replicated for two times and port 1 for once. With this improved algorithm, the CV is much smaller than the naive way of simply treating a WCMP group as an ECMP group.

For WCMP, the memory cost of coprime is negligible because even without coprime, we need to do WCMP quantization (i.e., approximating fractional weights via duplicating ECMP table entries) [37] to ensure the number of WCMP entries in a group doesn't exceed a pre-defined limit.

5 Evaluation

We conducted simulations using three types of network topologies and real-world traffic traces. We also evaluated on a hardware testbed with hundreds of switches and large-scale production fabrics.

5.1 Experiment Setup

Traffic traces We use CAIDA trace dataset [5] from a high-speed Chicago monitor on a commercial backbone link: each 1-second segment has 475.37k packets and 12.91k 5-tuple flows on average. Hashing is the foundation of traffic load balancing in multi-path networks and it is applied at the flow-level in ECMP/WCMP routing, therefore we focus on flow-level statistics rather than packet-level in our simulation to quantify the goodness of a hashing design. To map a traffic trace to a network topology we evaluate, we randomly assign each IP in the traffic trace to one host in our topology.

Network topologies We employ three types of topologies in our evaluation (Table 1): 1) the simplified multi-stage Clos (Jupiter) DCN topology as depicted in Figure 1; 2) a spineless DCN which has eight server blocks and the connection among server blocks is DRing [13]. Each server block contains 8 S_3 chips and 8 S_2 chips (each chip has 16 ports). Every server block is directly connected to 4 neighboring server blocks and each server block pair has 16 direct links; 3) two ISP topologies [27]. The routing strategy for the ISPs is k -shortest ($k = 4$) path routing [31] in our simulation.

Figure 13: The normalized link utilization of eight links from one ECMP group for color recombining and per-stage hashing.

Topology	#Nodes	#Links
Spinefull DCN (Figure 1)	2 server blocks	128
Spineless DCN (DRing [13])	8 server blocks	512
ISP1 (small)	69	146
ISP2 (large)	122	371

Table 1: The topologies used in our simulation.

Hash functions We use one of the most widely used hash function family, RTAG7 [10], which includes seven hash functions (6 CRC16s and 1 CRC32) in our simulation.

Metrics We employ the Coefficient of Variation (CV), which is defined as δ/μ (δ is the standard deviation and μ is the mean of a set of data points), to quantify the goodness of hashing. CV is a commonly used statistical measure of the dispersion of data points around the mean. For an ECMP group with m output ports and the associated link utilization set $\{x_i\}$, $1 \leq i \leq m$, CV is computed against set $\{x_i\}$ directly. For a WCMP group with m output ports whose weights are w_i , $1 \leq i \leq m$, CV is computed against set $\{x_i/w_i\}$.

5.2 Color Recombining for Multi-stage DCN

We first study the traffic load-balancing performance of the proposed per-port hashing with color recombining (denoted as *color recombining* below) scheme for multi-stage DCN and compare with per-stage hashing with random seed (denoted as *per-stage hashing*). For per-stage hashing, we assign an independent hash function for each stage and initialize each hash function with a random seed.

We present normalized link utilization of eight links from one ECMP group in Figure 13. It shows that all eight links have similar link utilization of around 0.67 for color recombining, but the per-stage hashing approach shows severe non-uniformity. In color recombining, we only reuse hash functions when color recombining happens, which eliminates hash correlation; but in per-stage hashing, certain hash functions are reused without considering correlations and random seeds are linear operations that can not decorrelate the reused hash functions.

We also compute the CV for each ECMP group and draw the CDF of CVs in Figure 14. All the CVs are under 0.05 for color recombining, but per-stage hashing's CV can be above 0.6 (note that a CV of 1 means the standard deviation is equal to the mean). In other words, per-port hashing with the color recombining approach reduces CV by approximately an order of magnitude compared with per-stage hashing with random seeds. Large CV value means links in the same ECMP group are not properly utilized and results in wasted network capacity and unnecessary hot links that lead to network congestion under heavy traffic load.

Figure 14: The CDF plot of CVs of each ECMP group. Compare color recombining with per-stage hashing.

Figure 15: The CDF plot of CVs of each ECMP group. Compare coprime with per-stage hashing.

Figure 19: The number of ECMP groups of CV > 0.1.

Figure 20: The normalized link utilization of 16 links connecting two server blocks.

5.3 Coprime for Spineless DCN

In the spineless DCN, all eight server blocks are connected in a DRing topology [13]. We choose two coprime values for every server block pair to mitigate the hash correlation between them. We compare coprime with the per-stage hashing where each server block uses 3 randomly chosen hash functions from the RTAG7 hash family and each function is supplied a random seed. We conduct experiments to evaluate the coprime-based approach for both ECMP and WCMP.

5.3.1 Coprime for ECMP

We show the normalized link utilization from 16 links connecting two server blocks in Figure 20. All links have the utilization of around 0.75 for the coprime-based approach,

where the coprime values are 8 (note each ECMP group has 8 ports because each S_3 chip of a server block has 8 up-facing ports) and 57 for the two server blocks, respectively. However, using per-stage hashing, the max/min link utilization ratio is above 2. Due to the shortage of independent hash functions, per-stage hashing has to reuse certain identical hash functions (even though they are provided with random seeds), and this raises traffic polarization as shown in Figure 20.

For quantification, the coprime-based approach outperforms per-stage hashing by reducing the CV by about 80%. For the coprime-based approach, all CVs are under 0.1, but for per-stage hashing, the CV can be as high as 0.5, as shown in Figure 15.

The coprime value matters when mitigating hash correlation: a large coprime value is more effective than a small one. We evaluate five different coprime values from 9 to 73, and show the CVs in Figure 16. It shows that the CV can be close to 0.4 when the coprime value is 9. When increasing the coprime value to 73, the improvement is not significant compared to 57. The result is consistent with our analysis in the end of § 4.2, which describes a trade-off between memory usage and ECMP precision. How to choose a coprime value depends on the memory a switch has and the level of imbalance one can tolerate.

5.3.2 Coprime for WCMP

To evaluate coprime for WCMP, we simulate a scenario where the first half links in an ECMP group have $2\times$ capacity, and therefore, the weights for those links are 2 and the remaining ones are 1. In this evaluation, we focus on two ways to duplicate the WCMP ports to match the coprime value: one is the *naive coprime* where a WCMP group is regarded as an ECMP as shown in Figure 12a; the other one (denoted as *split coprime*) is to split the coprime value into two parts as described in Figure 12b.

We draw the CDF plot of CVs per WCMP group in Figure 17. It shows that all CVs are under 0.075 when using the split coprime algorithm, while CV can reach 0.12 when using the naive coprime algorithm. We also observe split coprime reduces CV by approximately 60% for some WCMP groups compared with naive coprime. Our results indicate that split coprime should be preferred over naive coprime because it reduces CV using the same amount of switch memory.

5.4 Coprime for WAN

The coprime-based approach works for WAN topologies. We use the two ISP networks in Table 1 to evaluate load balancing performance of the coprime technique. We compare the coprime method with a random hash allocation approach (denoted as *Random* in Figure 18), where each switch randomly chooses an independent hash function from RTAG7 hash family and applies a random seed.

Our result shows that the coprime-based approach reduces CVs by about one order of magnitude compared with the random method. We compute all CVs for the link utilizations in every ECMP group and draw the CDF plot of CVs in Figure 18. When using the random method, CV can be as large as 1, which means only one link in the ECMP group is used, and others are idle. On the other hand, applying a coprime value to the ECMP group increases load balancing performance significantly, with CV lower than 0.1.

We also study how many independent hash functions are enough to eliminate traffic imbalance. We conduct an experiment by increasing the number of hash functions and gather the number of ECMP groups of $CV > 0.1$, caused by hash correlations. For this experiment, we introduce more CRC hash functions [24] beyond RTAG7, without considering the hardware implementation limitation. The result is shown in Figure 19. It shows that the small ISP (ISP 1) requires at least 40 hash functions to eliminate the correlations. However, the larger ISP (ISP 2) still has nearly 200 correlations when using 40 hashes. This result implies that even if chip vendors provide more hash functions in their next generation chips, it might be not sufficient for a large topology, e.g., B4 WAN grew $7\times$ larger in 5 years [15]. On the other hand, the coprime-base algorithm can be commonly used for topologies of arbitrary sizes.

Figure 21: The normalized link utilization of one S_3 switch over 1-hour time window from the hardware testbed.

Figure 22: The normalized link utilization of four links from one spine block towards one server block over 1-hour time window from the production fabric after applying color recombining.

5.5 Hardware Testbed Evaluation and Production Fabric Deployment

We constructed a hardware testbed using the spineless DCN topology (Figure 3). There are 4 server blocks and hundreds of switches in this hardware testbed. The testbed serves a few Tbps traffic generated by production-grade applications and is carried by TCP and UDP. Within each server block, we apply a per-port hashing scheme as Figure 9 shows and in total 5 independent hash functions are used. We allow both shortest path routing and non-shortest path routing, i.e., we allow traffic to transit through an intermediate server block to reach a destination server block. To mitigate the hash correlation problem as illustrated in Figure 10, we apply the coprime scheme to coprime ECMP group size on S_3 switches – for traffic originating a server block, ECMP group size is coprime to 128; for traffic transiting a server block, ECMP group size is coprime to 127. Therefore, we can ensure there is no hash correlation for both shortest and non-shortest routing paths. We show the normalized link utilization of one S_3 switch over 1-hour time window in Figure 21. We observe excellent load balancing performance with a CV of 0.02.

Color-recombining has been deployed in our production multi-stage Clos fabrics for several years and significantly reduced load imbalance due to hash correlation. The deployment of color-recombining is the following: after deciding which hash functions can be reused, we simply configure the switches with the designated hash functions. We studied the hashing performance result of color-recombining in pro-

duction multi-stage Clos fabrics and the normalized link utilization of one representative spine block towards one server block from S_4 to S_3 direction is shown in Figure 22. The spine block's port speed is 40Gbps. As we discussed in Section 3 (Figure 8), hash function h_4 is reused to load balance traffic leaving spine blocks from S_4 to S_3 direction. But due to the color-recombining technique, polarized traffic due to h_4 are merged into color white when leaving S_4 chips, as a result, we observe very nice load balancing performance with a CV of 0.03.

6 Related Work

Traffic Load Balancing There are many prior works to address an important limitation of ECMP/WCMP: load balancing performance degrades when there is a large traffic entropy, i.e., when elephant flows collide on the same path, network congestion arises. For example, previous works [3, 28] propose to split elephant flows into smaller "flowlets" that can be load-balanced over different paths; other works [2, 30] propose to reschedule elephant flows after detecting collisions. MPTCP [29] is a transport protocol that uses subflows to transmit over multiple paths. These works rely on the assumption that there is no hash correlation. Our work is complementary and all load balancing schemes benefit from our improved hashing design, which is the corner stone of load balancing.

Hashing in Networks The universal algorithm [7] adds a 32-bit router-specific value to the hash function; however, as we show theoretically and experimentally in §2.3, random seeds do not work well. The paper [36] proposes to mitigate hash function correlation by randomly setting the VLAN-id for each switch. However, randomizing the VLAN-id increases network management complexity. The paper [14] selects a different hash function for a different value of the TTL field. However, this approach is still constrained by the limited number of hash functions and it also requires modifying switch hardware. The novelty of this paper is that our approaches work with commodity switch hardware without any hardware modification or switch upgrade, which is costly and daunting in large-scale networks.

Decorrelate Hashing Researches have already relied on prime numbers to design independent hash functions. For example, the universal hash functions employs the prime number as the divisor [6, 23], where primes are special case of coprimes. Our work extends prior theory and applies it to improve traffic load balancing in modern networks.

The patent by A. Meyer [22] uses co-primes to solve the storage collision for hash tables, that is, how to insert an item into the hash table when collision occurs; however, their method is different from ours where they add a co-prime offset to the original hash output, and this is similar to choosing an initial value for the hash function. We have proved that random initial values (including co-prime ones) do not work for an ECMP group of even size in Theorem 1.

7 Conclusions

This paper tackles a real but underestimated problem in network traffic load balancing, i.e., traffic polarization caused by hash correlations. This paper proposes two novel approaches to mitigate hash correlation: 1) a color recombining technique which exploits topology traits of Clos networks to allow hash function reuse and to reduce the number of needed independent hash functions in multi-stage Clos DCN and 2) a generic coprime-based technique to mitigate hash correlation for non-hierarchical mesh networks such as spineless DCN and WAN. Evaluations results based on real traffic trace and topologies show that the proposed techniques can reduce the extent of load imbalance, quantified by coefficient of variance (CV), by one order of magnitude. The limited hashing capability offered by current switch silicon reduces network reliability, efficiency and poses challenges to modern large-scale networks. We believe that novel approaches that work with current switch hardware are valuable. We also hope our use cases of more flexible topology and routing designs can motivate switch vendors to provide better hashing support in the future.

A Proofs of Theorems

Proof of Theorem 1 (CRC Seed) The CRC seed is also known as the initial value, where we can initialize the CRC

value via XORing the seed with the input byte. Suppose the input is denoted by x , and the two random seeds are z_1 and z_2 . In order to prove random seeds are not effective, we only need to prove the following two rules:

If $\text{crc}_b(x) \oplus \text{crc}_b(y) = \text{crc}_b(x \oplus z_1) \oplus \text{crc}_b(y \oplus z_1)$;

If $\text{crc}_b(x) \oplus \text{crc}_b(y) = \text{crc}_b(x \oplus z_2) \oplus \text{crc}_b(y \oplus z_2)$.

Let $z_1 = \text{crc}_b(t)$. Based on the rolling property of the CRC function, we get:

$$\text{crc}_b(x \oplus z_1) = \text{crc}_b((t \ll b_x) | x) = \text{crc}_b(t \ll b_x) \oplus \text{crc}_b(x).$$

where b_x is the binary length of x , \oplus is XOR and $|$ is bitwise and. We also have

$$\text{crc}_b(y \oplus z_1) = \text{crc}_b(t \ll b_x) \oplus \text{crc}_b(y).$$

If $\text{crc}_b(x)$ and $\text{crc}_b(y)$ are both even (odd), $\text{crc}_b(t \ll b_x) \oplus \text{crc}_b(x)$ and $\text{crc}_b(t \ll b_x) \oplus \text{crc}_b(y)$ are both even or odd, that is, $\text{crc}_b(x \oplus z_1)$ and $\text{crc}_b(y \oplus z_1)$ are both even(odd).

It is the same for $\text{crc}_b(x \oplus z_2) = \text{crc}_b(y \oplus z_2)$

Proof of Theorem 2 (co-primes) Let U, W, U' and W' denote the distribution of the hashing output of $H^{m_1}, H^{m_2}, H^{q_1 m_1}$ and $H^{q_2 m_2}$, respectively. When $\hat{H} \gg q_1 q_2$ (condition 2 in Theorem 2), $\forall i' \in [0, q_1 - 1], j' \in [0, q_2 - 1], i \in [0, m_1 - 1]$, and $j \in [0, m_2 - 1]$, we have,

$$\Pr(U' = i', W' = j') = 1/(q_1 q_2)$$

When condition 1 is not satisfied in Theorem 2, there exists hash correlation brought by $q_1 m_1$ and $q_2 m_2$ because the mapping from $q_1 (q_2)$ to $m_1 (m_2)$ has a remainder. This mapping causes the non-uniform distribution of q_1 integers over m_1 slots, where $q_1 m_1$ slots get $\lfloor q_1/m_1 \rfloor + 1$ integers each, and $m_1 - q_1 m_1$ slots get $\lfloor q_1/m_1 \rfloor$ integers each. We denote this non-uniformity by the term *the approximation error*. Note that when q_1 increases, the difference between $(\lfloor q_1/m_1 + 1 \rfloor)/q_1$ and $(\lfloor q_1/m_1 \rfloor)/q_1$ can be reduced, and thus, we can quantify the approximation error by Equation (2).

$$\text{err} = (q_1 m_1)/q_1 + (q_2 m_2)/q_2 \quad (2)$$

where err denotes the approximation error. When condition 1 is satisfied, $\text{err} \approx 0$. Let $S(i) = \{i' | i' \% i = 0\}$, and $S(j) = \{j' | j' \% j = 0\}$, we have,

$$\begin{aligned} \Pr(W = j | U = i) &= \frac{\sum_{i' \in S(i), j' \in S(j)} P(U' = i', W' = j')}{\sum_{i' \in S(i)} P(U' = i')} \\ &= \frac{(q_1/m_1)(q_2/m_2)(1/(q_1 q_2))}{(q_1/m_1)(1/q_1)} \\ &= 1/m_2 = \Pr(W = j) \end{aligned} \quad (3)$$

Firebolt: Finding Bugs in Programmable Data Plane Generators

^{*}Tsinghua University [†]Alibaba Group

Abstract

Programmable data planes (DP) enable flexible customization of packet processing logic with domain-specific languages such as P4. To relieve developers from lengthy codes and tedious hardware details, many researches propose DP program generators that take high-level intents as input and automatically convert intents into DP programs. Generators must be correct, otherwise they may produce buggy programs or DP logic that is inconsistent with intents. Nevertheless, existing verification tools are designed to verify individual DP programs, not generators. They either cannot achieve high bug coverage or cannot debug generators with high scalability.

This paper presents *Firebolt*, a blackbox testing tool designed to dig out faults in DP program generators, including security vulnerabilities, intent violations, and generator crash. *Firebolt* achieves high bug coverage by using syntax-guided intent generation to construct a comprehensive, syntactically correct, and semantically valid intent set. To avoid intent explosion, *Firebolt* designs an intent space pruning approach that eliminates redundant intents while preserving representative ones. For high scalability, *Firebolt* automatically formalizes DP programs and intents for verification. We apply *Firebolt* to three popular open-source DP generators. Evaluation results demonstrate that *Firebolt* can detect $2\times$ bugs with 0.1% to 0.01% human efforts compared to existing tools.

1 Introduction

Programmable network devices [1, 2] together with domain-specific programming languages (e.g. P4 [3]) have enabled many in-data-plane (DP) network functions, such as monitoring [4–6], security [7–9], routing [10–12] and so on. Meanwhile, booming DP functions heavily burden programmers with lengthy codes (100s to 1000s lines of code, LoC [13]) and manual consideration of tedious hardware constraints [14]. To this end, a growing body of research proposes DP generators [14–27], which provide high-level declarative primitives to easily express *intents*, and a compiler to convert intents into platform-specific DP programs and table entries. DP generators can reduce LoC by 80% [14] with resource optimizations that would otherwise require manual efforts. Above benefits encourage researchers and industries to design various DP generators for network monitoring [16, 17] and even *mission-critical* functions like routing [14] or security [21, 22].

Considering the prevalence of DP generators, guaranteeing their *correctness* becomes a must-be-solved problem. However, our study (§2) reveals that three types of mistakes including program security vulnerabilities such as out-of-bound register access, intent-program inconsistency, and generator crash, may happen to advanced DP generators [16, 17, 21], which can result in serious mistakes such as missing attacks and undesired packet processing procedure.

Unfortunately, little attention has been devoted to guaranteeing the correctness of DP generators. Existing tools focus on finding security vulnerabilities in DP programs [28–34], or verifying the consistency between high-level intents and DP programs [28–31]. However, these tools are not designed for debugging DP generators and thus fall short in two aspects: (1) *Coverage*. Existing verification tools aim to verify individual intent-program pairs instead of finding all bugs in advanced DP generators. As intents are numerous, even infinite, verification tools can hardly cover all generator faults. (2) *Scalability*. To check intent-program consistency, verification tools require massive human-written specifications of intents (100s to 1000s of LoC) for one program, which is error-prone and time-consuming.

This paper presents *Firebolt*, a blackbox testing tool designed to dig out DP generator faults including security vulnerabilities, intent violations, and crash with high coverage and scalability. The key idea of *Firebolt* is thoroughly constructing intents as test cases to achieve high coverage, and automatically producing specifications of intents with little human intervention for verification to achieve high scalability.

However, realizing such a tool is challenging in three aspects: *intent generation* that should contain every reasonable intent, *intent explosion* that results in unacceptably long testing time due to numerous intents, and *intent diversity* that hampers automatic specification derivation for verification. In response, *Firebolt* proposes the following innovative designs.

- *Intent generation*. *Firebolt* should generate a comprehensive intent space containing every reasonable intent for high coverage. However, random composition of intent grammar symbols can produce infinite intents, which is impractical for testing. We first generate syntactically correct intents based on intent grammar in Backus-Naur form (§4.1). We then identify semantic dependencies between grammar symbols and filter semantically valid intents (§4.2).

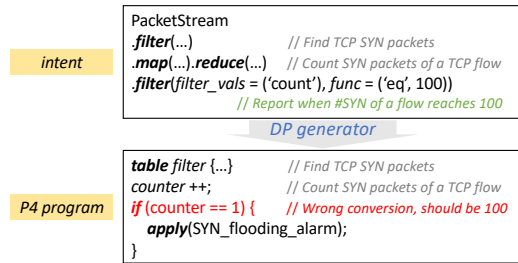

Figure 1: False SYN flooding alarms due to intent violation.

- *Intent explosion.* Due to wide parameter range and cyclic symbol reference, there may still exist massive or even infinite redundant intents that are syntactically correct and semantically valid, which compromises testing efficiency. To handle intent explosion, we design *intent space pruning* to eliminate redundant intents while keeping representative ones (§4.3). Remaining intents are input into generators to find crash bugs or to generate DP programs for verification.
- *Intent diversity.* The high diversity of intents and corresponding DP programs for one generator and across generators makes it challenging to devise a uniform approach for verification. To achieve high scalability, *Firebolt* first formalizes all DP programs into unified Z3 formulas [35] (§5.1). Next, instead of manually translating (1000s of) intents into specifications, we write specifications for intent grammar symbols, and automatically compose symbol specifications into the intent specifications (§5.2). Finally, we uniformly verify intent specifications and Z3 formulas to detect intent violations and security vulnerabilities (§5.3).

We apply *Firebolt* to three popular open-source DP generators, *i.e.*, Marple [16], Sonata [17], and Poise [21]. In all test cases of the three generators, *Firebolt* discovered 19 bugs including 3 security vulnerabilities, 13 intent violations, and 1 crash bug, while existing verification tools merely cover 10. Moreover, *Firebolt* requires 0.1% to 0.01% human-written LoC compared to existing tools under equal bug coverage.

2 Motivation

If a DP generator fails to faithfully translate programmer intents (intent violations), or produces logically flawed programs (security vulnerabilities), or even crashes under reasonable input intents, it adversely affects production efficiency and introduces instability into online DP functions. Below we present two example bugs that have been detected by *Firebolt* to reveal the consequences of faulty generators.

#1: False SYN flooding alarm due to intent violation. As presented in Figure 1, a SYN flooding monitoring function counts per-flow TCP SYN packet number. If a counter exceeds a threshold, a SYN flooding alarm is produced. However, due to a bug in Sonata [17], an advanced monitoring function generator, the threshold is wrongly configured as 1 instead of the originally intended 100, which results in massive false alarms that completely violates the monitoring goal.

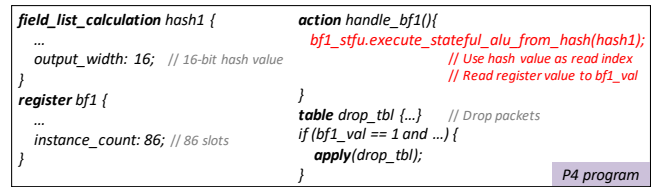

Figure 2: Connection legality misjudgement due to security vulnerabilities.

#2: Connection legality misjudgement due to security vulnerabilities. Poise [21] takes intents as input and generates context-aware security policies in programmable devices. It generates an in-DP bloom filter to track illegal connections. However, the bloom filter has 86 slots but is indexed by a 16-bit variable (0 to 65535), as shown in Figure 2. If the index exceeds 86, a random value outside the bloom filter will be returned. Such a vulnerability could incur wrong judgement of connection legality and lead to potential security leakage.

To eliminate above mistakes, programmers have to review generated DP programs and check intent-program consistency, which costs extra human efforts. Some recent tools are designed to find security vulnerabilities in DP programs [28–34] or verify the intent-program consistency [28–31]. However, using these tools to debug DP generators requires massive human efforts to verify each intent-program pair, and cannot fully cover all intents. Therefore, on modifying the intent or expressing a new intent, these tools must be repetitively executed to ensure program correctness. Unfortunately, doing so brings the scalability problem. To verify intent-program consistency, 100s to 1000s of LoC must be written manually to convert intents into specifications [16, 31]. Such LoC is comparable to the DP program, which is error-prone, time-consuming, and not scalable.

Instead of verifying individual programs, we propose *Firebolt* to debug generators. *Firebolt* thoroughly generates intents as test cases to detect generator faults, and automatically derives specifications from intents to improve scalability.

3 Overview

The key idea of *Firebolt* is thoroughly constructing intents as test cases to achieve high coverage, and automatically producing verification specifications to achieve high scalability. *Firebolt* workflow includes two major steps, *i.e.*, intent generation and program verification, as shown in Figure 3.

§4 - Intent generation. To thoroughly explore the intent space and cover all generator faults with little redundancy, *Firebolt* takes the intent grammar and semantic constraints of a DP generator as input and generates all possible and correct intents. Meanwhile, *Firebolt* losslessly prunes the generated intent space to eliminate redundancy and produces final test cases, which are then input into DP generators to generate DP programs or to find crash bugs.

Figure 3: Workflow of Firebolt.

§5 - Program verification. To automatically verify the correctness of generated DP programs, the key is to derive the specification of intents for verification. *Firebolt* provides a general and high-level specification to express every intent grammar symbol, and automatically derives the specification of each intent based on per-symbol specifications. Meanwhile, *Firebolt* formalizes the output DP programs using Z3 formulas. Finally, *Firebolt* checks whether the Z3 formulas (1) are consistent with intent specifications and (2) have security vulnerabilities.

4 Intent Generation

The design goal of intent generation is producing a group of intents that (1) thoroughly covers all correct intents so that all generator faults can be discovered and (2) possesses little redundancy so that generator testing can be efficient. To achieve the above goals, we start by comprehensive intent generation with both syntactical correctness (§4.1) and semantic validity (§4.2) in mind. Next we analyze the source of redundant intents and propose the intent space pruning approach (§4.3).

4.1 Syntax-Guided Intent Generation

A DP generator must expose the intent grammar for expressing intents. For example, as shown in Figure 1, Sonata [17] provides primitives like *filter*, *map*, and *reduce* and parameters like *eq* and *count*. The intent grammar describes lawful function calls, parameter ranges, and syntax, which serves as the foundation to generate possible intents from scratch.

We refer to syntax-guided synthesis [36, 37], a common approach in program synthesis that finds the desired program by searching the program space described by a grammar. We leverage its idea and redefine the intent generation problem as: given the grammar G of a DP generator, we need to explore the intent space and generate all syntactically correct intents.

Intent grammar formalization. Syntax-guided intent generation takes grammar as input. However, different generators can provide grammar in various formats [14, 16, 17]. We need to formalize grammars of generators into a unified expression. We observe that Backus-Naur form (BNF) [38] is the most common context-free grammar (CFG) [39] for describing the

Algorithm 1 Syntax-Guided Intent Generation

```

1: function SYGUG( $G$ )
2:    $Q = \text{Queue}(G.n_r)$  ▷ Initialize
3:   while  $Q.size() > 0$  do
4:      $n = Q.front()$ 
5:      $Q.pop()$ 
6:     if  $n.has\_nt()$  then
7:        $A = n.first\_nt$ 
8:       for  $A \rightarrow \beta \in G.R[A]$  do
9:          $n = \alpha A \gamma \xrightarrow{A \rightarrow \beta} n_1 = \alpha \beta \gamma$  ▷ Grow graph
10:         $Q.push(n_1)$ 
11:      end for
12:    else
13:      OUTPUT( $n$ ) ▷ Output generated intent
14:    end if
15:  end while
16: end function

```

syntactic structure of programming languages. Most DP generators [14, 16, 21–23] provide a BNF syntax specification. Thus, *Firebolt* uses BNF for grammar formalization.

Note that *Firebolt* can also work with non-BNF grammars by adopting the expansion rules of these grammars during syntax-guided intent generation.

Preliminaries of BNF. Dark rectangle in Figure 4 shows partial BNF expression of Marple [16] intent grammar. A grammar G expressed in the BNF format is a quadruple $\langle N, S, \Sigma, R \rangle$, where (1) N is a finite set of non-terminal symbols that can be expanded to one or more terminal and non-terminal symbols, (2) S is the start symbol in N , (3) Σ is a finite set of terminal symbols that can appear in an intent, (4) R is a finite subset of $N \times (N \cup \Sigma)^*$, where each member $(A, \beta) \in R$ is called an expansion rule and is written as $A \rightarrow \beta$. A sequence of non-terminal and terminal symbols in $(N \cup \Sigma)^*$ is called a *sentential form*, which represents an intermediate intent.

Syntax-guided intent generation. With a grammar G in BNF format, a possible intent must start with S and then be replaced with expansion rules in R until there are no non-terminal symbols that need to be expanded, *i.e.*, it ends with a composition of terminal symbols in Σ . Therefore, generating all possible syntactically correct intents can be visioned as growing a single-rooted (S) graph with one or more rules in R , and collecting all leaf nodes ended with any one symbol in Σ .

We formalize the above process as follows. We define the intent generation graph $\mathcal{G} = \langle \mathcal{N}, \mathcal{E} \rangle$ as a directed labeled graph derived from grammar $G = \langle N, S, \Sigma, R \rangle$, with the nodes $\mathcal{N} \subseteq (N \cup \Sigma)^*$ and the edges $\mathcal{E} \subseteq \mathcal{N} \times \mathcal{N} \times R$. Each node in \mathcal{N} has a sentential form which can be derived from the start symbol S . Each edge in \mathcal{E} represents a non-terminal symbol expansion according to an expansion rule. At node n_1 whose sentential form is $\alpha A \gamma$, where A is a non-terminal symbol, we can apply the expansion rule $A \rightarrow \beta \in R$ and derive a child node n_2 with a new sentential form $\alpha \beta \gamma$. \mathcal{G} has a root node n_r with sentential form S , and many (maybe infinite) leaf nodes.

Algorithm 1 depicts the procedure of growing graph \mathcal{G} using *depth first search*. We maintain a *queue* Q to store nodes in \mathcal{G} . First, Q is initialized with the root node n_r (line 2). Then, in each iteration (line 3-15), we pop the first node n in Q . If n has no non-terminal symbols in its sentential form, we output n as an intent (line 13). Otherwise, we find the first non-terminal symbol A in n , and apply all possible expansion rules of A to generate child nodes (line 9), which are then appended to Q for further expansion. We repeat this process until Q is empty and all syntactically correct intents are generated.

4.2 Semantic Constraint Injection

Syntax-guided intent generation can cover syntactically correct intents. Nonetheless, some syntactically correct intents do not make sense, or, say, are semantically invalid [40]. Below we first introduce two types of semantically invalid intents. Next we identify semantic constraints between grammar symbols, and present the semantic constraint expression and injection mechanisms to filter semantically valid intents.

Semantically invalid intents. Besides conforming to the syntax, intents must also comply with semantic constraints. Below we identify two types of semantically invalid intents.

- *Uncompilable intents.* Syntactically correct intents cannot guarantee successful compilation. Typical examples include a variable that is not declared before it is referenced, a variable reference whose dimension is inconsistent with the declaration, or a variable that is repeatedly defined. Numerous such intents violate the semantic constraints of the intent grammar, and therefore should be ruled out.
- *Incomplete intents.* Some intents are semantically incomplete. For example, the *map* primitive in Marple [16] distributes incoming data according to certain match fields, and assigns a computing expression to process a temporary variable, which is meaningless if it is not referenced later. Therefore, an intent with a *map* primitive in the end of a query is considered incomplete and should be ruled out.

Semantic constraint identification. The existence of semantically invalid intents indicates that the above mentioned syntax-guided intent generation graph contains unreasonable leaf nodes (incomplete intents) or even invalid expansion rules (branches) for intermediate nodes (uncompliant intents). Thus, we should identify semantic constraints of intent grammar, and leverage the constraints to supervise the intent generation process. Overall, we classify the constraints into *exclusion constraints* and *dependency constraints*.

- *Exclusion constraints:* indicate that if an expansion rule r_1 on a node n_1 exists, the expansion rule r_2 on a node n_2 is not valid. We formally express them as:

$$\text{if } \exists r_1 \text{ on } n_1, \text{ then } \nexists r_2 \text{ on } n_2$$

A typical example is that one variable name (such as the name of a packet stream) cannot be defined repeatedly.

- *Dependency constraints:* indicate that only if an expansion rule r_1 on a node n_1 exists, the expansion rule r_2 on a node

```

(prog)          ::= (aggFun)* (streamStmt)+           Marple.bnf
(streamStmt)    ::= (streamName) = (streamQuery)
(streamName)    ::= R(number)
(streamQuery)   ::= (map) | ...
(map)          ::= map ((streamName), [(mapCol)], [(mapExpr)])

```

Example 1: StreamName cannot be defined repeatedly

```

if ∃ (r1) on (n1), ∄ (r2) on (n2), (n2) ↔ (n1)
(n1) : *, (prog)(streamStmt)(streamName),*
(r1) : (streamName) →*
(n2) : *, (prog)(streamStmt)(streamName),*
(r2) : (r1)

```

Example 2: Map query operates on a stream that has been defined

```

if ∃ (r1) on (n1), ∃ (r2) on (n2), (n2) → (n1)
(n1) : *, (prog)(streamStmt)(streamQuery)(map)(streamName),*
(r1) : (streamName) ↦ T
(n2) : *, (prog)(streamStmt)(streamName),*
(r2) : (r1)
(n1).(streamStmt) ≠ (n2).(streamStmt)

```

Figure 4: Semantic constraint examples in Marple [16].

n_2 is valid. We formally express them as:

$$\text{if } \exists r_1 \text{ on } n_1, \text{ then } \exists r_2 \text{ on } n_2$$

A typical example is that a *Map* primitive must operate on a stream that has been previously defined.

With the above classification in mind, we thoroughly analyze the intent grammar and derive semantic constraints. Missing constraints can result in some semantically invalid intents left as test cases and slightly compromise the testing efficiency, which is considered acceptable. However, wrongly-written constraints will incur wrong deletion of semantically valid intents and impair generator fault coverage. Therefore, we must guarantee the correctness of the constraints. We have investigated several advanced generators [16, 17, 21] and observe that each of them corresponds to <20 semantic constraints, which is acceptable for manual inspection.

Semantic constraint expression and injection. Identified semantic constraints should be uniformly encoded for injection. To clearly express a constraint, we need to clearly specify the constraint type (\exists or \nexists) and elements (r_1 , n_1 , r_2 , and n_2). Next we showcase two semantic constraints in Marple [16].

Example 1 shown in Figure 4 presents an exclusion constraint. A Marple program $\langle prog \rangle$ includes multiple streams $\langle streamStmt \rangle$, each with name $\langle streamName \rangle$. The names of streams should not be defined repeatedly. n_1 and n_2 describe the node where stream names are defined. Naturally, there exists an expansion trace from the start symbol $\langle prog \rangle$ to the current symbol $\langle streamName \rangle$. We use \leftrightarrow to indicate that the two nodes can appear in any order on the path. We use $*$ to match any expansion traces in n and any expansion rules in r . By making $r_2 = r_1$, the constraint prevents $\langle streamName \rangle$ from taking duplicate values of r_1 in any other node n_2 .

Example 2 in Figure 4 presents a dependency constraint. If a $\langle map \rangle$ query in Marple operates on a stream with a name other than T (the name of the original input stream in Marple),

this stream should be previously defined. We use $n_2 \rightarrow n_1$ to constrain the ordering between two nodes, *i.e.*, n_2 should be an ancestor node of n_1 . By making $r_2 = r_1$, the constraint guarantees that a stream is defined before referenced.

We present all identified semantic constraints of Marple [16], Sonata [17], and Poise [21] in Appendix A. During intent generation, an expansion rule r on node n is rejected if it violates exclusion constraints, and a leaf node is rejected if not all dependency constraints are satisfied on its path.

4.3 Intent Space Pruning

Despite we guarantee the syntactical correctness and semantic validity of intents, the massive expansion rules and their combinations may still build an extremely large or even infinite intent space, due to two reasons, as illustrated in Figure 5.

- *Wide parameter range.* A non-terminal symbol may have many possible expansion rules, which corresponds to a large node degree. For example, a 16-bit integer has 65536 possible values. Worse still, if a sentential form has multiple such non-terminal symbols, the exponential combination can lead to an explosion of the intent space.
- *Cyclic symbol reference.* A non-terminal symbol may return to itself after expansion, *i.e.*, the cyclic symbol reference, which corresponds to an infinite depth of the intent derivation graph. For example, an arithmetic expression has an expansion rule of $\langle S \rangle ::= \langle S \rangle + \langle S \rangle$. The circular expansion leads to an infinite number of possible intents.

For all generated intents of a DP generator, we observe that most intents would not cause any bugs, while many could cause the same bug. To strike a balance between coverage and efficiency, we propose the following two mechanisms to prune the intent space without losing intent representativeness.

Method #1: Intra-symbol representativeness. To handle wide parameter range, we propose to *keep representative expansion rules*, which include three categories.

- *Boundary rules.* Boundary values in numbers, including minimum and maximum values (e.g., 0 and 65535 for a 16-bit parameter), usually represent some extreme cases or conditions, and should be included in the test cases.
- *Random rules.* In addition to boundary values, we should take random values from values other than boundary values (e.g. one value from 1 to 65534 for a 16-bit parameter).
- *Previously selected rules.* When the same non-terminal symbol is expanded multiple times in a sentential form, the choices of expansion rules are actually correlated. In this case, the previously selected random rules should also be included in the latter non-terminal symbol expansions. For example, Marple [16] uses the query name to identify a query. Suppose a former expansion rule defines the name of a query Q , and a latter expansion rule references the name of a query (maybe query Q , maybe not), value Q should be included in the latter rule to keep representativeness.

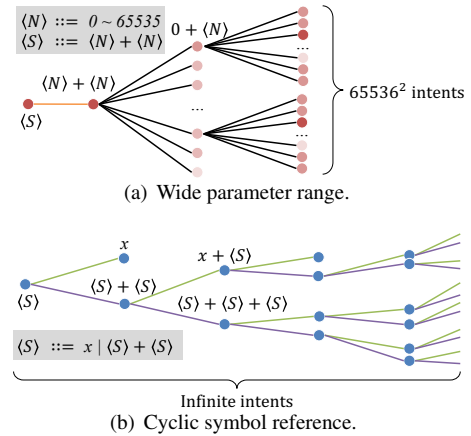

Figure 5: Two types of intent space explosion.

Method #2: Inter-symbol combination representativeness.

For cyclic symbol reference, we can think of an expansion circle as a non-terminal symbol returning to itself with zero to many intermediate non-terminal symbols. To handle cyclic symbol reference induced intent explosion, we should break infinite symbol recurrence without losing representativeness.

To this end, we refer to the combinatorial testing (CT) theory [41] for software testing in the software engineering field. Provided that a software is composed of multiple features, the CT theory indicates that a minimal set of test cases for the software should include *individual* features and combinations of *two* distinct features, which are enough to effectively test the software and find most bugs. If a test case containing three or more features causes a software bug, the root cause may still lie in the interaction of two features among them.

Inspired by the CT theory, to effectively test the DP generator with high efficiency, we can first extract all distinct features, *i.e.*, combination of non-terminal symbols, according to the intent grammar. Then, we prune the intent space and only keep sentential forms that are either (1) individual features, or (2) possible combinations of n distinct features, where $n = 2$. Our evaluation results in §6.2 reveal that using a higher combination factor (e.g. $n = 3$) cannot find more bugs in the DP generator, which proves the effectiveness of applying the CT theory for DP generator testing.

Finally, we introduce how we extract distinct features, *i.e.*, combinations of non-terminal symbols. Recall that the CT theory limits the recurrence of the same feature to two times. Therefore, each feature should only include distinct symbols. Suppose an intent grammar has k non-terminal symbols. By picking a random number (1 to k) of distinct symbols and organizing them in all possible sequences, we can generate $N = \sum_{i=1}^k A_i^i$ features where A stands for the permutation symbol, *i.e.*, $A_n^m = n!/(n-m)!$. With the combination factor $n = 2$, there exist at most $(N + A_N^2)$ sentential forms composed of non-terminal symbols. Suppose there are s terminal symbols and p parameter value options, we produce at most $(N + A_N^2) \times s \times p$ test cases, which are *finite* and feasible for testing. Our evaluation results in §6.2 show that using the

above pruning methods, *Firebolt* will generate <10K intents for testing three advanced DP generators [16, 17, 21].

So far, we have thoroughly explored the intent space to generate syntactically correct and semantically valid intents with little redundancy. We feed these reasonable intents into the DP generator to find crash bugs or to generate DP programs for verification, which we will introduce in the next section.

5 Program Verification

In this section, we introduce how *Firebolt* verifies the correctness of the generated DP programs from two aspects, *i.e.*, whether there are potential security vulnerabilities, and whether the DP programs are consistent with corresponding intents. We use Z3 [35], a Satisfiability Modulo Theories (SMT) solver, which can take (1) Z3 *formulas* and (2) Z3 *assertions* as input, and formally verify whether the formulas satisfy the assertions. In the rest of this section, we first introduce how we automatically formalize the generated DP programs as Z3 formulas (§5.1). Next, to avoid manually converting 1000s of intents into Z3 assertions, we provide a general and flexible specification to express every symbol of the intent grammar, and automatically compose symbol specifications into intent specifications, which will then be converted into Z3 assertions (§5.2). Finally, we check intent-program consistency and detect security vulnerabilities (§5.3).

5.1 DP Program Formalization

We use the popular P4₁₆ language as an example to illustrate how to formalize DP programs into Z3 formulas. P4₁₄ programs can be first converted into P4₁₆ programs using open-source P4 compiler suite [13] and then formalized into Z3 formulas by *Firebolt*. Gauntlet [42] has proposed approaches to convert partial P4 programs into Z3 formulas, but does not cover the formalization of P4 *table entries* and *externs*, which are essential to faithfully convert P4 programs. Our formalization solution is built atop Gauntlet. Below we first introduce the idea and capability of Gauntlet, and then introduce how we formalize externs and table entries.

Formalizing each programmable block. A P4₁₆ program is composed of several programmable blocks (*e.g.*, packet parser, ingress control flow, egress control flow, packet deparser, etc.). We provide an example of a P4 *match-action table* residing in the control flow block in the head of Figure 6. For each block, Gauntlet performs the following conversion.

- *Input parameter* → *free Z3 variable*. Two special types of Z3 variables, *i.e.*, Z3_INVALID and Z3_UNDEFINED, are defined to represent invalid and undefined parameter values.
- *Function* → *Z3 operation* that refers to input Z3 variables. For example, a table lookup function is converted into a reference to the resulting action index. Operations like parameter initialization or invalidation can refer to Z3_INVALID and Z3_UNDEFINED special variables.

Part of P4₁₆ Program: Match-Action Table

```
action a0 (z) {y = z;}
table t0 {
  key = k0 : exact;
  actions = {
    no_op;
    a0;
  }
  default_action = no_op;
}
```

Table entries of t0:	
1 =>	a0(1)
2 =>	a0(2)

Input free Z3 variables:

```
(_ BitVec 32) k0 // Match key of table t0
(_ BitVec 32) t0_index // Action index of table t0
(_ BitVec 32) a0_z // Parameter of action a0
```

Output Z3 expressions (with table entries):

```
(_ BitVec 32) y = (ite (= k0 1) 1 (ite (= k0 2) 2
Z3_UNDEFINED))
```

Output Z3 expressions (without table entries):

```
(_ BitVec 32) y = (ite (= t0_index 1) a0_z Z3_UNDEFINED)
```

Figure 6: Examples of formalizing match-action tables.

- *Output parameter* → *output Z3 expression* that is the result of executing Z3 operations on the input Z3 variables.

Formalizing table entries. Gauntlet assumes that the contents of the table are unknown, and does not include the configuration of table entries in the output Z3 expressions. However, generating correct table entries is also critical for the DP generator, as table entries also reflect intents. For instance, a *filter*(ip.src=192.168.1.1) intent segment in Sonata indicates that subsequent operations will operate on special flows, which corresponds to a table entry in generated DP programs.

To formalize table entries, we use a nested if-then-else statement to imitate a match-action table call, as shown in Figure 6. When table entries are provided, for each parameter modified by the table (parameter *y* in this example), we use an if-then branch to express the modification in Z3 expressions as follows: if the key of incoming data matches a specific table entry ($k0 = 1$ or $k0 = 2$), the corresponding action is executed ($y = 1$ or $y = 2$). If the key does not match any entry, the default action is executed (y is not assigned an initial value, and is therefore undefined). When no table entry is specified, we assume that all actions in the table are executable. We use a free Z3 variable (*t0_index*) to indicate the index of the action to be executed, and a separate free Z3 variable for each action parameter (*a0_z* for parameter *z*). A table call can then be represented by a nested if-then-else statement with each branch representing the execution of one action.

Formalizing externs. P4 programs often operate on extern objects such as stateful memory and hash calculations. Gauntlet interprets externs as a function call that returns an arbitrary value. However, an accurate translation of externs is critical, since externs can maintain program internal states and may be modified and referenced. For example, the SYN flooding alarm program shown in Figure 1 maintains a counter that will later be compared to a threshold, which should be embedded in the Z3 formula. Below we introduce our approaches to handle stateful memory and hash calculation, respectively.

```

Part of P416 Program: Register Reading and Writing
register<bit<32>>(32w1024) reg;
reg.read(r_index, r_value);      // r_value = reg[r_index]
reg.write(w_index, w_value);    // reg[w_index] = w_value

Input free Z3 variables:
(_ BitVec 32) reg_read_value
(_ BitVec 32) r_index, w_index, w_value
Output Z3 expressions:
(_ BitVec 32) reg_instance_count = 32w1024
(_ BitVec 10) reg_write_index = w_index
(_ BitVec 32) reg_write_value = w_value
(_ BitVec 10) reg_read_index = r_index
(_ BitVec 32) r_value = reg_read_value
(a) Register reads and writes

Part of P416 Program: Hash Calculation
// Update hash_table_index with hash value
hash(hash_table_index, HashAlg.crc32, 32w0, inKey, 32w1024);

Input free Z3 variables:
(_ BitVec 32) crc32_hash_value // Hash value
(_ BitVec 96) inKey           // Hash key
Output Z3 expressions:
(_ BitVec 32) hash_table_index = crc32_hash_value
(_ BitVec 32) crc32_hash_width = 32w0
(_ BitVec 128) crc32_hash_field = inKey
(_ BitVec 32) crc32_hash_size = 32w1024
(b) Hash calculation

```

Figure 7: Examples of converting externs into Z3 formulas.

- *Stateful memory.* We take register, an indexed array of stateful cells, as an example to illustrate our approach, which also applies to other types of stateful memory such as counters. A naive method to formalize a register is to define a free Z3 variable to represent the initial value and generate an output Z3 expression to represent the new value for each cell in the register. In this way, register reading can be converted into referencing the Z3 variable, and register writing can be converted into updating the Z3 expression. Then formalizing a register array with n instances requires $2 * n$ Z3 variables and expressions. Furthermore, we notice that for most commercial switches, a register array can be read/written only once in the switch pipeline. Thus, we only need to maintain the index and values for at most two register cells, as shown in Figure 7(a). Besides, we use another Z3 variable to store the size of the register, which can be used to detect out-of-bound register access in §5.3.
- *Hash calculation.* Hash is used to map large data to fixed-size values. We define a free Z3 variable to represent the computed hash value. Meanwhile, we store the parameters that impact the hash value, e.g., the hash key and hash size, in the output expressions, as shown in Figure 7(b). Then, we can flexibly adjust the effect of the hash mapping by imposing the mapping relationship between the hash value and hash parameters when checking the Z3 expressions. For example, a conflict-free hash implies the one-to-one mapping between the hash key and hash value. In this way, we can avoid the complex hardware-specific hash calculation while maintaining the properties of hash operations.

5.2 Intent Formalization

The intent generation process can produce thousands of (§6) intents for one DP generator. Manually converting intents that are composed of different symbols of the same generator, or intents belonging to different generators, is time-consuming and not scalable. We observe that intents are generated by expanding non-terminal symbols. Therefore, instead of converting each intent, our key idea is first writing the specifications of each symbol in the grammar, and then automatically composing symbol specifications into intent specifications, which will finally be converted into Z3 assertions.

Symbol specification. To uniformly express highly-diversified intent grammar symbols across generators, we need to design an expression format that should be *general* enough to specify various symbols, and *flexible* enough for composition. The reason why we do not directly use Z3 assertions as the specification is that Z3 assertions are logical expressions that are low-level and counter-intuitive.

We propose to uniformly express each symbol as a high-level *function* written in python-like expressions. The function specification satisfies above requirements. It is general enough to specify the format and semantics of input, logic, and return values of individual symbols, and flexible enough for composition by sequentially performing function calls and correlating input and output of different functions.

Specifically, we regulate that one function consists of two segments, a declaration function `DECL_FUNC` that defines internal states of symbols, and an execution function `EXEC_FUNC` that describes the processing logic of input parameters, internal states, and output values. Stateless symbols such as a flow *filter* maintain no internal states and therefore can be expressed with only `EXEC_FUNC`. A typical execution function often takes network packets as input, and starts by `PARSE`-ing input packets into a series of header fields, e.g., Ethernet \rightarrow IPv4 \rightarrow TCP. For each packet, we also generate standard metadata fields regulated by the P4 grammar, such as the output port. Next, symbol logic can operate on packet headers, metadata fields, and symbol internal states by packet modification, counting, forwarding, or other actions, and finally provide return values or return directly.

Figure 8 takes the `<groupby>` symbol in Marple [16] as an example to illustrate how to construct a stateful symbol specification. An entire `<groupby>` symbol is formatted as `<groupby> ::= groupby(<stream>, <columns>, <aggFunc>)`, which groups *streams* according to specific *columns* with the aggregation function *aggFunc*. In the declaration function `DECL_FUNC`, a key-value storage is declared for each possible option `<var>` in the child symbol `<aggFunc>`. The `EXEC_FUNC` updates the internal states with no packet parsing, modification, or forwarding. First, we initialize a variable *tuple* with the tuple contained in the input stream whose name is `<streamName>`. Then we get the aggregation key from the aggregation field in `<columns>`. Using the aggregation key,

```

# (groupby) ::= groupby ((streamName), (columns), (aggFunc))
# (aggFunc) ::= def (aggFun) ((vars), (columns)): (codeBlock)
DECL_FUNC() =
  states = []
  for var in <aggFunc>.<vars>.exec():
    KEY_VALUE_STORAGE REG_NAME_var
    states.append(REG_NAME_var)
EXEC_FUNC(stream_list) =
  tuple = <streamName>.exec(stream_list)
  key = tuple[<columns>.exec()]
  old_state = [reg[key] for reg in states]
  new_state = <aggFunc>.exec(old_state, tuple)
  states.update(key, new_state)
  tuple.append(new_state)
  return tuple

```

Figure 8: An example for constructing stateful specifications of non-terminal symbols: $\langle groupby \rangle$ in Marple [16].

we read the old states and execute the aggregation function $\langle aggFunc \rangle$. The output values of the aggregation function are used to update states of $\langle groupby \rangle$. Also, the output states are included in *tuple* for future usage in subsequent symbols.

Symbol specification composition. For each generated intent, *Firebolt* constructs its specification based on its generation path, i.e., the non-terminal symbol expansion process and the final terminal symbols. Starting from the semantics of the start symbol, *Firebolt* recursively appends the semantics of child symbols in the expansion rules by sequentially connecting their **FUNCs** to automatically construct the final specification.

Specification conversion into Z3 assertions. A Z3 assertion is a series of algebra expressions connected with logical operators, e.g. $(x > 10) \&\&(y < 5)$. We use a special type of Z3 assertions, i.e., $implies(f, g)$, to verify DP programs. $implies$ is an implication operator, which assumes a condition expression f on the input Z3 variables and asserts that the output satisfies the implication expression g . After expressing intents as a series of functions, we can identify how each parameter (e.g., header fields, forwarding port, and internal states) is modified by the functions. Therefore, we develop a tool that can automatically convert the functions into the $implies$ Z3 assertions that will be used to verify the DP programs.

5.3 Program Correctness Verification

With the Z3 formulas representing semantics of DP programs and intents formalized into Z3 assertions, we first check whether each P4 program is consistent with the corresponding intent. Then, we summarize security vulnerabilities from the literature, and introduce how to detect them in each program.

Intent-program consistency. To verify consistency, we take the Z3 formulas as input and use the Z3 constraint solver [35] to verify the Z3 assertions, i.e., a set of $implies(f, g)$. Specifically, we need to check the following three types of consistency, each with a different set of f and g .

- *Packet parsing consistency.* It indicates that parsed headers and header fields are ordered consistently with the original

intent, and each header field is parsed correctly. During DP program formalization, when formalizing the parser block, *Firebolt* treats the entire input packet header as a free Z3 variable, and outputs individual Z3 expressions to represent different header fields. We verify the parsing consistency by asserting that for each header field in the parsing part of the intent specification, (1) there is a corresponding output Z3 expression, (2) a failed parsing implies an invalid value. For example, the first 16 bits of the Ethernet header should be 0x800. The parsing of Ethernet fails if an Ethernet header does not start with 0x800, and (3) a successful parsing implies a correct parsed value. For example, given the condition that the first 16 bits of the header are 0x800, we should be able to obtain the Ethernet.dstAddr field by extracting specific bits from the input header variable.

- *Packet deparsing consistency.* It refers to the correct order and values of headers and header fields in the output packet. The checking of the deparser block is similar to the parser block. We omit details here for brevity.
- *Packet processing consistency.* Packet processing includes packet modification, forwarding and state updates, and corresponds to the behavior of several programmable blocks of a P4 program, e.g., both the ingress control flow and the egress control flow. To construct a complete Z3 formula, we first concatenate the Z3 formulas of individual related programmable blocks into a complete block. For each output Z3 expression of a block, if it is an input Z3 free variable of latter blocks, we replace the corresponding input with the current output, and recompute the output expressions of latter blocks. We iterate this process until the output of a block is no longer referenced by any blocks, which becomes the final output of the DP program and completes the Z3 formula for packet processing. Then, for each modified packet field and metadata in the Z3 formula, we extract related operators and construct an individual Z3 expression, which can be checked against corresponding intent specifications.

Security vulnerabilities. Security vulnerabilities are intrinsic flaws of DP programs without corresponding intents. For example, out-of-bound register access may cause unexpected behaviors and even online risks, and is never intended. We observe that security vulnerabilities can be converted into special Z3 assertions and verified against DP programs as introduced above. Therefore, we summarize security vulnerabilities highlighted by previous literature [28–32, 34], and introduce how to express them as Z3 assertions.

- *Invalid header access* may occur when the validity of a header is not checked before referencing it. To detect this bug, for each output Z3 expression, we assert that (1) each referenced header (Z3_h) belongs to a branch in an if-then-else statement, and (2) the if-condition in this branch includes a validity check (i.e., $Z3_h \neq Z3_INVALID$).
- *Implicit packet drops* occur when the egress_port is not specified. To detect this bug, in the output Z3 expression

Table 1: (1) Bugs detected by *Firebolt*, and (2) efficiency of *Firebolt* when debugging the three DP generators.

DP Generator Under Test	# Generated Intent	# Detected Bugs / # Intents Causing Bugs			Human-written LoC			Test-Case Size (Min / Max)			Running Time (Total / Average)	
		Crash Bug	Security Vulnerability	Intent Violation	Intent Grammar	Semantic Constraints	Per-Symbol Specification	Intent LoC	P4 Program LoC	# Table Entries	Intent Generation	Program Verification
Marple	7341	1 / 12	1 / 7329	2 / 23	93	70	323	1 / 32	211 / 481	0 / 0	168s / 23ms	1204s / 164ms
Sonata	7912	0 / 0	2 / 7912	5 / 243	34	10	178	1 / 19	253 / 375	7 / 43	27s / 3ms	926s / 162ms
Poise	2362	0 / 0	2 / 2362	6 / 362	25	25	132	1 / 12	704 / 893	1 / 12	23s / 10ms	355s / 150ms

of `egress_port`, we assert that no branch results in the undefined special variable, *i.e.*, `Z3_UNDEFINED`.

- *Out-of-bound register access* occurs when the read/write index exceeds the register array size. Since we use separate output Z3 expressions to record the read/write index and the array size in §5.1, we can detect this bug by comparing the array size and the index range. For direct access, where *index* is assigned an exact value, we assert that $index < size$. For non-direct access, *i.e.*, the *index* expression includes symbolic variables, such as hash values, we assert that the range of the symbolic variables is within the allowed range.
- *Decapsulation errors* happen when invalid headers are deparsed in the deparser. To detect this bug, we assert that for each output header expression, no branch results in the invalid special variable (*i.e.*, `Z3_INVALID`).
- *Forbidden writes* happen when a P4 program tries to write certain metadata values which are read-only, but the P4 compiler allows the program to write them. To detect this bug, we assert that for all read-only metadata fields, the values remain unchanged, *i.e.*, the output values are the original undefined values (*i.e.*, `Z3_UNDEFINED`).

6 Evaluation

We implement *Firebolt* with ~1200 lines of Python code for intent generation, and ~800 lines of C++ code for program verification. Our verifier is built atop Z3 [35], and can verify both P4₁₆ and P4₁₄ programs with the aid of P4 compiler suite [13]. All experiments were conducted in a Ubuntu 16.04 virtual machine with 4GB RAM and two 2.3GHz CPU cores.

We use *Firebolt* to test three popular open-source DP generators, including two for network telemetry, *i.e.*, Marple [16, 43] and Sonata [17, 44], and one for security policy enforcement, *i.e.*, Poise [21, 45]. Marple and Sonata both use sequential composition of data flow operators to construct telemetry queries, while Marple is more complicated by supporting self-defined variable names in each query and dependencies between queries. Poise is relatively simpler and enforces security policies by filtering customized packet header fields. Finally, we implement two advanced DP program verification tools (*i.e.*, Aquila [31] and p4v [30]) for comparison.

Our evaluation intends to answer the following questions.

- *Bug coverage.* We first discuss all discovered generator bugs by *Firebolt*. (§6.1) Next, we prove the bug coverage of *Firebolt* by (1) showing the intent representativeness of *Firebolt*, and (2) comparing the number of bugs discovered

by *Firebolt* and existing verification tools over open-source intents and programs of the generators. (§6.2)

- *Efficiency.* We introduce (1) the human efforts required by *Firebolt* to debug the generators, (2) the size of intents, P4 programs, and table entries that are generated and verified by *Firebolt*, and (3) the running time of intent generation and program verification. (§6.3)
- *Scalability.* We first compare the human efforts, *i.e.*, lines of hand-written codes, required by *Firebolt* and existing verification tools to debug the three generators. Then we evaluate the time required by *Firebolt* when verifying larger programs and more table entries. (§6.4)

6.1 Bug Analysis

As shown in Table 1, we find that all three generators have bugs, and discover 5 security vulnerabilities, 13 intent violations, and 1 crash bug in total. Below we introduce the detected bugs. To the best of knowledge, this is the first effort that comprehensively analyze and reason DP generator faults.

Security vulnerability. *Firebolt* finds security vulnerabilities in all generated programs of all three DP generators.

- *Invalid header access* is a common bug. All generated programs refer to some headers without checking validity.
- *Out-of-bound register access* is found in Poise, which may use a hash value that exceeds the size of the the register as the read/write index for the register.
- *Implicit drops* happen in Sonata. Generated programs never explicitly specify the egress port of input packets.

Intent violation. Due to the high intent diversity, intent violations are the most insidious bugs that cannot be easily detected by the developers of DP generators. Next we introduce intent violations in the three DP generators, respectively.

For Sonata, *Firebolt* finds 5 types of intent violation bugs in 243 generated programs out of 7912 programs in total.

- *Bug #1: Incorrect query combination.* When a *filter* query with the *eq* (=) function follows a *reduce* query, Sonata converts it into comparing the result of *reduce* and the default value of 1, regardless of the true value in the filter query. This bug may lead to false attack alarm (§2).
- *Bug #2, #3, #4: Missing/Incomplete table entries.* Sonata designs a *filter(k, v, f)* symbol to filter packets whose key (*k*) fields satisfy function (*f*) of value (*v*) fields. To implement a *filter* query in DP programs, both match-action tables and table entries should be generated. However, there are three

Table 2: The number of detected bugs and generated intents with different intent space pruning methods.

Pruning Method	# Detected Bugs			# Generated Intents			
	Marple	Sonata	Poise	Marple	Sonata	Poise	
Intra-Symbol	None	① ① ①② ②	①	> 50K	> 50K	> 50K	
	$r=1$	①①①② ①②①②③④⑤	①②①②③④⑤⑥	7341	7912	2362	
	$r=2$	①①①② ①②①②③④⑤	①②①②③④⑤⑥	14812	12384	3804	
Inter-Symbol	None	①	①② ②③	①②①②③④⑤⑥	> 50K	> 50K	2362
	$n=1$	①①①② ①② ②③④⑤	①②①②③④⑤⑥	2346	3523	2362	
	$n=2$	①①①② ①②①②③④⑤	①②①②③④⑤⑥	7341	7912	2362	
	$n=3$	①①①② ①②①②③④⑤	①②①②③④⑤⑥	> 50K	> 50K	2362	

○ Crash Bug ● Security Vulnerability ● Intent Violation

cases where table entries can be missing or incomplete. First, when a *filter* query operates on a variable, e.g., a counter, table entries are forgotten. Second, when a *filter* query has a *mask* function, Sonata translates it into an LPM table, but forgets to include the prefix length in table entries. Third, when a *filter* query has a *geq* (\geq) function and does not follow a *reduce* query, no table entries are generated.

- *Bug #5: Incorrect mask translation.* Sonata uses bit-wise AND for *mask* operations in a *map* query. It translates the mask m into $0xFF...F$ (F occurs $m/4$ times). When the mask length is not a multiple of 4, the translation is incorrect.

For Poise, *Firebolt* finds 6 types of intent violation bugs in 362 generated programs out of 2362 programs in total.

- *Bug #1: Incorrect list comparer.* Poise provides list comparer (*in* and *notin*) to check whether a value is in a list. However, *notin* is wrongly equated with *in* when translated.
- *Bug #2, #3, #4: Incorrect comparison operator.* Poise translates the comparison operators ($>$ and $<$) into a match-action table with *range* match and a table entry representing the comparison range. However, this range incorrectly includes the boundary value that should be excluded. That is, $>$ and $<$ are translated into \geq and \leq . Besides, Poise sets a default range (0~10000) for comparisons without considering the real range of variables.
- *#5: Missing table entries.* Poise provides the *monitor* expression *count(p)* that counts the number of packets satisfying a predicate p . However, table entries are not generated. Thus, no packets would satisfy the predicate and be counted.
- *#6: Missing action parameters.* Poise uses registers to maintain states. However, for some registers, the read/write actions do not specify the index to read or write.

For Marple, *Firebolt* finds 2 types of intent violations in 23 generated programs out of 7329 generated programs in total.

- *Bug #1: Incorrect infinity translation.* Marple uses *infinity* to represent a variable that exceeds its pre-defined upper limit. However, it assigns a fixed value $2^{31} - 1$ to *infinity* without considering the actual upper bound.
- *Bug #2: Incorrect key storage.* Marple uses 32-bit registers to store keys in the *groupby* query. When storing a value with a width greater than 32 bits, e.g., the ingress timestamp, the stored value would be the truncation of the value.

Table 3: Detected bugs by existing verification tools.

DP Generator Under Test	# Intents	# Detected Bugs		
		Crash Bug	Security Vulnerability	Intent Violation
Marple	14	0	1 (①)	0
Sonata	13	0	2 (①②)	1 (②)
Poise	7	0	2 (①②)	4 (②③④⑥)

Crash bug. *Firebolt* finds one crash bug in Marple, while Sonata and Poise do not report any crash bugs. Marple converts the division expression $(a/2^b)$ into a right-shift operation $(a \gg b)$, but sets the maximum shift width to a fixed value of 8. According to the code, the generator would crash when the exponent b satisfies a legal value of $8 < b < \log_2 a$.

6.2 Bug Coverage

To evaluate the bug coverage of *Firebolt*, first, we compare the bugs detected using different intent space pruning methods to demonstrate that the intent generation approach of *Firebolt* is able to thoroughly cover the intent space to find bugs. Then, we compare the bugs detected between *Firebolt* and existing verification tools to demonstrate that the automatic testing of *Firebolt* can detect more bugs, compared to verifying hand-written test cases using existing tools.

Intent representativeness. We examine whether our two intent space pruning methods (§4.3) compromise intent representativeness by checking the bug coverage of generated intents. For each type of pruning method, we configure the extent of the other method as the default value (the number of random rules $r = 1$ for intra-symbol and the combination factor $n = 2$ for inter-symbol), vary the pruning extent of the current method, and check the resulting bug coverage. As there exist infinite possible intents, obtaining all intents is impractical. We randomly generate 50K intents ($> 10 \times$ intents generated by *Firebolt*) as the baseline.

We present the results in Table 2. The *None* row represents the baseline, where only 6 bugs are discovered (19 by *Firebolt*). This is because a limited number of intents (50K) represent a very small fraction of the entire intent space. Intra-symbol pruning can greatly reduce the intent space, but increasing the number of random rules (r) from 1 to 2 does not increase the bug coverage. For inter-symbol pruning, we can see that a small combination factor ($n = 1$) can find many bugs, but misses one interactive bug, i.e., Sonata’s *reduce-then-filter* bug, which can be found when $n = 2$. Further increasing the combination factor ($n = 3$) cannot find more bugs, but greatly increases generated intents from O(1K) to above 50K.

Therefore, compared to random intent generation, *Firebolt* intent pruning can maintain representativeness with much fewer test cases. Moreover, the recommended pruning extent is $r = 1$ for intra-symbol pruning and $n = 2$ for inter-symbol pruning, which is adequate for comprehensive bug detection.

Comparison with existing tools. We compare the bug coverage of *Firebolt* with that of existing verification tools [30, 31]. For existing verification tools, we collect all open-source

manually-written intents [43–45] as input to find as many bugs as possible. For each collected intent, we manually write the corresponding specification for each verification tool and perform program verification. The results are shown in Table 3. With a limited number of $O(10)$ hand-written intents, the existing verification tools can only discover 10 bugs out of 19 by *Firebolt*, and cannot find other bugs undetected by *Firebolt*. This highlights the high bug coverage of *Firebolt* over existing tools. By delving into these open-source intents, we find that the developers of DP generator did make an effort to write different examples, but the hand-written test cases struggle to efficiently find all bugs in DP generators.

To find more bugs with existing tools, we can use the (1000s of) intents generated by *Firebolt* as input for existing tools. However, doing so requires manually writing specifications for 1000s of intents, which is time-consuming and error-prone. We will analyze the scalability issues in §6.3.

6.3 Efficiency

Next, we evaluate the debugging efficiency of *Firebolt* by counting the lines of input human-written codes (Figure 3), the lines of intents that *Firebolt* generates, the size of generated test cases (including intents, P4 programs, and table entries), and the running time for intent generation and program verification. We summarize the results in Table 1.

Human-written LoC. In general, *Firebolt* requires a limited number of $O(10)$ LoC for intent grammar, $O(10)$ LoC for semantic constraints, and $O(100)$ LoC for per-symbol specifications. Although the per-symbol specifications occupy the majority of human-written LoC, writing specifications is also required for existing verification tools, and *Firebolt* is still the most efficient. We further discuss *Firebolt* scalability in §6.4.

Test case size. As *Firebolt* utilizes pruning mechanisms to generate representative intents, the resulting intents are relatively small, *i.e.*, from one LoC to 10s of LoC. For the same reason, only a few table entries are generated. Marple even has no output table entries, since it uses flexible expressions in the P4 program to implements the intents. Finally, corresponding P4 programs are often with 100s of LoC. This is because generated programs contain many necessary components for all intents such as the definition of headers and parsers. Thus, even the smallest P4 program contains 100s of LoC.

Running time. *Firebolt* generates $O(1K)$ intents for each DP generator. Intent generation and program verification in all scenarios can be done within 25 minutes. DP generators with more semantic constraints (*e.g.*, Marple) take more time to generate a correct intent (23ms vs 3ms for Sonata). This is because relatively more semantically invalid intermediate sentential forms will be detected and rejected during generation.

6.4 Scalability

Manual effort. We compare the manual efforts (*i.e.*, lines of specifications) required by *Firebolt* and existing verification

Table 4: Comparing lines of human-written specifications.

DP Generator Under Test	Verifying One Program	Verifying All Generated Programs	Finding All Bugs (1 Bug / 1 Program)
p4v	$O(1K)$	$O(1M)$	$O(10K)$
Aquila	$O(100)$	$O(100K)$	$O(1K)$
Firebolt	$O(100)$		

Figure 9: Time needed to verify larger P4 programs with more table entries.

tools, Aquila [31] and p4v [30], to debug a DP generator with equal bug coverage. This means that both *Firebolt* and verification tools take thousands of intents generated by *Firebolt* as input. As shown in Table 4, *Firebolt* requires $O(100)$ of per-symbol LoC to automatically generate the specifications of all intents. In comparison, verification tools require $O(100)$ to $O(1K)$ LoC to convert one intent. Converting all intents means $O(100K)$ to $O(1M)$ LoC. Under equal bug coverage, *Firebolt* consumes merely 0.1% to 0.01% manual efforts compared to existing tools. Moreover, human-written specifications can be faulty, which further reflects the scalability of *Firebolt*.

Scaling to larger test case. We evaluate the scalability of *Firebolt* when verifying larger P4 programs with more table entries. We use several open-source or vendor-supplied P4 programs instead of the small programs generated by *Firebolt*.

First, we measure the time required by *Firebolt* to verify P4 programs of different sizes. For each program, we manually write <3 entries for each table, and also write the corresponding specifications for verification. As shown in Figure 9(a), *Firebolt* requires more time for verification as the complexity of the P4 program increases. Nevertheless, even the most complex switch.p4 can be verified in 8 minutes.

Next, we compare the verification time when installing different numbers of table entries to the same P4 program fabric.p4. As shown in Figure 9(b), the number of table entries has a larger impact on the verification time than the size of P4 program. When the number of entries does not exceed 1500, *Firebolt* can complete the verification in <30 minutes. When the number of entries exceeds 2000, *Firebolt* takes >100 minutes for verification. The increase is not linear because the table entries are converted into if-then-else branches, resulting in an exponential increase in the size of the generated Z3 formulas. This non-linear scalability of verification time with table entries has also been recognized in other verification works [31] and solved using encoding optimizations. Currently, *Firebolt* by design generates small test cases without losing bug coverage using intent space pruning. For upcoming generators, we may encounter larger intents, programs, and table entries that become more time-consuming

to verify. In that case, *Firebolt* can refer to the optimization techniques in existing verification tools [30, 31] to accelerate the verification of individual intent-program pairs.

7 Discussion

Human effort required by *Firebolt*. *Firebolt* requires three inputs, including grammar, semantic constraints, and per-symbol specification to debug a DP generator. First, the grammar should already be provided by the designers of DP generators [14, 16, 21–23] so that the DP generator can be used correctly by others. Second, accurate semantic constraints also help to better use the DP generator. We summarize the semantic constraints of three advanced DP generators in Appendix A. They all have <20 semantic constraints that can be classified into four types, *i.e.*, banned variable redefinition, necessary variable definition, illegal variable reference, and special ones. The former three types account for the majority of the constraints and are closely related to variable definitions and references. Semantic constraints can shrink the intent space, and missing some semantic constraints will not affect the bug coverage but merely produce more intents. Third, *Firebolt* requires manually writing per-symbol specification. However, compared with existing tools, *Firebolt* saves significant human efforts by automatically composing per-symbol specifications into intent specifications.

Cross-platform generality of *Firebolt*. The formalization phase of *Firebolt* considers extern behaviors because they are critical for the correctness of DP generators. However, the semantics of extern behaviors are target-specific. Currently, *Firebolt* supports two common extern implementations including stateful memory and hash calculation. Since externs can be taken as arithmetic operations on some variables (*e.g.*, temporal variable, metadata field, and packet header), they can always be converted into logical Z3 formulas. As a future work, we would like to extend *Firebolt* to support user-defined extern semantics to improve cross-platform generality.

8 Related Work

Data plane generator. To simplify DP programming, a growing body of research proposes data plane generators which convert high-level intents into platform-specific DP programs. DP generators provide primitives to specify developer intents in different domains, *e.g.*, query primitives for monitoring tasks [15–20], measurement and control primitives to specify security policies [21, 22] and routing policies [23], and some other intent languages for their own purposes [14, 24–27]. DP generators greatly relieve the burden of DP programming, but their own correctness is not guaranteed. In this paper, we design a blackbox-based testing system to debug them.

Data plane program verifier. Several efforts have been proposed to verify DP programs. P4-assert [28] and Vera [29] translate P4 programs into other language models (SEFL

and C) and rely on existing symbolic execution framework (SymNet [46] and Klee [47]) to analyze the behavior of the resulting programs. p4v [30] and Aquila [31] use Dijkstra’s classic verification approach by formalizing the P4 program in Guarded Command Language (GCL) and using the Z3 theorem prover [35] to check whether the specifications hold. Some other tools, such as bf4 [32] and P6 [34], utilize various techniques such as static verification, code changes and runtime checking to ensure that the deployed P4 program is bug-free. However, using these tools to debug DP generators cannot cover all generator bugs and requires massive manual efforts to verify each possible intent-program pair. Different from all of them, *Firebolt* can automatically generate representative intents as test cases for high coverage and automatically produce intent specifications for high scalability.

Testing in networking. Testing is a popular technique to find bugs in network systems by generating and running many test cases. Metha [48] tests network verification tools by generating network configurations as test cases and comparing the tool’s output with that of the actual router. p4pktgen [49] tests P4 programs by generating test cases using symbolic execution. Gauntlet [42] and P4Fuzz [50] both test the P4 compiler by generating random P4 programs. If the intermediate representation (IR) of the compiler is accessible, Gauntlet compares the transformed programs after different compiler passes, otherwise it generates packets to test the behavior of the P4 program to debug the compiler. P4Fuzz compares the output of different compilers to find potential bugs. *Firebolt* also uses generation-based testing to debug DP generators. However, unlike existing work to test specific targets, *Firebolt* needs to handle a variety of DP generators. *Firebolt* adopts a syntax-guided approach to generate test cases and designs generic methods to verify the correctness of each test case.

9 Conclusion

This paper presents *Firebolt*, a blackbox testing tool designed to debug DP generators. We propose syntax-guided intent generation with semantic constraint injection and intent space pruning techniques, and program verification with automatic intent and program formalization. By evaluating three popular open-source DP generators, we show the high bug coverage and scalability of *Firebolt* compared to existing solutions.

This work does not raise any ethical issues.

Appendix A Semantic Constraints of Advanced DP Program Generators

Table 5 lists the identified semantic constraints for Marple [16], Sonata [17], and Poise [21]. The semantic constraints can be classified into four categories, *i.e.*, banned variable redefinition, necessary variable definition, illegal variable reference to generate *compilable* intents, and other special constraints to generate *complete* intents. For each category, we give an example of how the constraint can be expressed with the formal *if-then* expressions in §4.2.

Table 5: Summary of semantic constraints of Marple [16], Sonata [17], and Poise [21].

Constraints		Description	Type	Expression
Marple	Banned Variable Redefinition (3)	#1: Each query has a stream name, which cannot be repeatedly defined.	Exclusion	#1 as an example: $if \exists r_1 \text{ on } n_1, \nexists r_2 \text{ on } n_2, n_1 \leftrightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_1 \rangle: \langle streamName \rangle \rightarrow *$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$
		#2: Each aggregation function has a function name, which cannot be repeatedly defined.		
		#3: A aggregation function may define multiple aggregation states. The aggregation state names cannot be repeatedly defined.		
	Necessary Variable Definition (8)	#4~7: Each query (<i>map/groupby/filter/zip</i>) operates on a stream, which should be either defined or the default input stream T.	Dependency	#4 as an example: $if \exists r_1 \text{ on } n_1, \exists r_2 \text{ on } n_2, n_1 \rightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle streamName \rangle, *$ $\langle r_1 \rangle: \langle streamName \rangle \nrightarrow T$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$
		#8: <i>groupby</i> queries take an aggregation function name as input. The function should be defined.		
		#9: <i>groupby</i> queries may include self-defined variables in the aggregation key. The variables should be defined.		
#10: <i>filter</i> queries may reference self-defined variables in its predicate. The variables should be defined.				
Illegal Variable Reference (2)	#11: <i>map</i> queries may reference self-defined variables. The variables should be defined.	Exclusion	#12 as an example: $if \exists r_1 \text{ on } n_1, \nexists r_2 \text{ on } n_2, n_1 \leftrightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle map_col \rangle, *$ $\langle r_1 \rangle: \langle map_col \rangle \rightarrow *$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle map_col \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$	
	#12: <i>map</i> queries assign specified or self-defined variables to computed expressions, where the variables should not be assigned repeatedly.			
Special Semantic Constraints (1)	#13: <i>zip</i> queries merge fields in <i>different</i> streams.	Exclusion	#14 as an example: $if \exists r_1 \text{ on } n_1, \exists r_2 \text{ on } n_2, n_1 \rightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle, *$ $\langle r_1 \rangle: \langle streamQuery \rangle \rightarrow \langle map \rangle$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle streamQuery \rangle \rightarrow \langle filter \rangle \langle groupby \rangle \langle zip \rangle$	
	#14: An intent should not end with a <i>map</i> query.
