Message from the NSDI ’20 Program Co-Chairs

Welcome to NSDI ’20!

NSDI is traditionally the top venue for papers on networked and distributed systems, and this year we continue that tradition with an excellent program featuring yet another record number of amazing papers. The research and experiences described in this year’s program include a wide range of topics including analytics, data center network architecture, distributed systems, host networking, machine learning, modern network hardware, monitoring and diagnosis, operating systems, privacy, security, wireless networking and deployed industrial experience.

This year, we continued the changes put into place during last year’s conference, including two deadlines and the possibility of a “one shot” revision process. We received 354 submissions (79 in the Spring cycle and 275 in the Fall cycle), and we accepted a record 65 papers, resulting in an 18.3% acceptance rate. These papers were carefully selected by a panel of 57 experts spanning academia and industry.

The review process was double-blind. We had two rounds of reviews per cycle, providing papers that advanced to the second round at least five reviews. We strove to include valuable feedback in all these reviews, so we hope it benefited all authors who submitted their work. After writing reviews, we held online discussions to select papers to be discussed further at PC meetings or to be accepted without further need for discussion. We discussed 24 papers during the Spring PC meeting (conducted online via video conferencing software) and 90 papers during the 1.5-day Fall PC meeting held on the UC San Diego campus in La Jolla, Calif.

We’d like to thank the many, many people whose work was necessary to arrange this conference. Foremost, we thank all the authors who chose to send their strong work to NSDI. We also thank the program committee whose diligence, professionalism, expertise, excitement, and courtesy made the review process go smoothly and successfully. Special thanks to those of them who took on extra responsibilities beyond the considerable ones PC members already have. Thank you to Ivan Beschastnikh and Ravi Netravali for serving as poster co-chairs. We’d like to thank Sujata Banerjee and Rebecca Isaacs for handling chair conflict papers. We’d like to thank Ellen Zegura, Laurant Vanbever, and Aditya Akella for selecting the best papers and the community award paper. We’d like to thank the members of the Test of Time Awards committee: Aditya Akella, Katerina Argyraki, Sujata Banerjee, Paul Barham, Miguel Castro, Nick Feamster, Jon Howell, Arvind Krishnamurthy, Jay Lorch, Jeff Mogul, Timothy Roscoe, Srinivasan Seshan, Alex Snoeren, and Minlan Yu. We’d like to thank the NSDI steering committee as well as the co-chairs of NSDI 2019, Minlan Yu and Jay Lorch.

We would like to thank Jennifer Folkestad, who organized the in-person PC meeting on UC San Diego’s campus, the PC dinner, and then an entirely different second PC dinner on an hour’s notice after the first restaurant caught fire moments before we were to arrive.

We’re so very grateful to the USENIX staff, including Casey Henderson, Ginny Staubach, Jasmine Murcia, Jessica Kim, Michele Nelson, and Sarah TerHune, for the extraordinary levels of support they provided.

Expanding across time to deliver bandwidth efficiency and low latency

William M. Mellette, Rajdeep Das, Yibo Guo, Rob McGuinness, Alex C. Snoeren, and George Porter
University of California San Diego

Abstract

Datacenters need networks that support both low-latency and high-bandwidth packet delivery to meet the stringent requirements of modern applications. We present Opera, a dynamic network that delivers latency-sensitive traffic quickly by relying on multi-hop forwarding in the same way as expander-graph-based approaches, but provides near-optimal bandwidth for bulk flows through direct forwarding over time-varying source-to-destination circuits. Unlike prior approaches, Opera requires no separate electrical network and no active circuit scheduling. The key to Opera's design is the rapid and deterministic reconfiguration of the network, piece-by-piece, such that at any moment in time the network implements an expander graph, yet, integrated across time, the network provides bandwidth-efficient single-hop paths between all racks. We show that Opera supports low-latency traffic with flow completion times comparable to cost-equivalent static topologies, while delivering up to 4× the bandwidth for all-to-all traffic and supporting up to 60% higher load for published datacenter workloads.

1 Introduction

Datacenter networks are tasked with providing connectivity between an ever-increasing number of end hosts whose link rates improve by orders of magnitude every few years. Preserving the "big-switch" illusion of full bisection bandwidth [2, 21] by augmenting the internal switching capacity of the network accordingly is increasingly cost prohibitive and likely soon infeasible [35]. Practitioners have long favored over-subscribed networks that provide all-to-all connectivity, but at only a fraction of host-link speeds [21, 41]. Such networks realize cost savings by dramatically reducing the amount of in-network capacity (in terms of both the number and rate of links and switches internal to the network fabric), providing full-speed connectivity between only a subset of hosts, and more limited capacity between others.

The catch, of course, is that any under-provisioned topology inherently biases the network toward certain workloads. Traditional over-subscribed Clos topologies only support rack-local traffic at full line rate; researchers have proposed alternate ways of deploying a limited amount of switching capacity—either through disparate link and switch technologies [31, 38, 40, 44], non-hierarchical topologies [27, 29, 42, 43], or both [20, 34]—that can deliver higher performance for published workloads [4, 39] at similar costs. Because workloads can be dynamic, many of these proposals implement reconfigurable networks that allocate link capacity in a time-varying fashion, either on a fixed schedule [34, 40] or in response to recent demand [20, 31, 44]. Unfortunately, practical reconfigurable technologies require non-trivial delay to retarget capacity, limiting their utility for workloads with stringent latency requirements.

Under-provisioned networks often incorporate some flavor of indirect traffic routing to address inopportune traffic demands; because application workloads do not always align well with the structure of the network, some traffic may transit longer, less-efficient paths. The benefits of indirection come at significant cost, however: traversing more than a single hop through the network imposes a "bandwidth tax." Said another way, x bytes sent over a direct link between two end points consume only x bytes of network capacity. If that same traffic is instead sent over k links, perhaps indirecting through multiple switches, it consumes $(k \cdot x)$ bytes of network capacity, where $(k-1)x$ corresponds to the bandwidth tax. Hence, the effective carrying capacity of a network, i.e., net the bandwidth tax, can be significantly less than its raw switching capacity; aggregate tax rates of 200–500% are common in existing proposals.

Reconfigurable networks seek to reduce the overall bandwidth tax rate of a given workload by provisioning direct links between end points with the highest demands, eliminating the tax on the largest, "bulk" flows whose completion time is gated by available network capacity, rather than propagation delay. The time required to identify such flows [31, 44] and reconfigure the network [20, 34], however, is generally orders-of-magnitude larger than the one-way delay of even an indirect route through the network, which is the main driver of completion times for small flows. Hence, dynamic networks face a fundamental trade-off between amortizing the overhead of reconfiguration against the inefficiency of sub-optimal configurations. The upshot is existing proposals are either unsuitable for latency sensitive traffic (which is frequently shunted to an entirely separate network in so-called hybrid architectures [31, 34, 38]), or pay substantial bandwidth tax to provide low-latency connectivity, especially when faced with dynamic or unpredictable workloads.

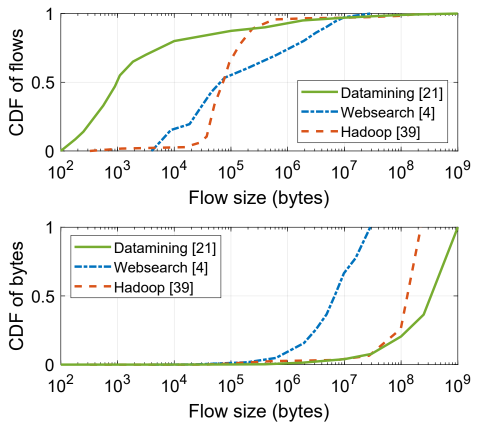

Figure 1: Published empirical flow-size distributions.

Opera is a network architecture that minimizes the bandwidth tax paid by bulk traffic—which makes up the vast majority of the bytes in today's networks [4, 39]—while ensuring low-latency delivery for the (small fraction of) traffic that cannot tolerate added delays. Opera implements a dynamic, circuit-switched topology that constantly reconfigures a small number of each top-of-rack (ToR) switch's uplinks, moving through a series of time-varying expander graphs (without requiring runtime circuit selection algorithms or network-wide traffic demand collection). Opera's ever-changing topology ensures that every pair of end points is periodically allocated a direct link, delivering bandwidth-efficient connectivity for bulk traffic, while indirecting latency-sensitive traffic over the same, low-diameter network to provide near-optimal flow completion times.

By strategically pre-configuring the assignment of rack-to-rack circuits at each instant in time such that those circuits form an expander graph, Opera can always forward low-latency traffic over an expander without waiting for any circuits to be (re-)configured. Thus, on a per-packet basis, Opera can choose to either (1) immediately send a packet over whatever static expander is currently instantiated, incurring a modest tax on this small fraction of traffic, or (2) buffer the packet and wait until a direct link is established to the ultimate destination, eliminating the bandwidth tax on the vast majority of bytes. Our simulation results show this trade-off results in up to a 4× increase in throughput for shuffle workloads compared to cost-equivalent static topologies. Moreover, for published, skewed datacenter workloads, Opera delivers an effective 8.4% bandwidth tax rate, resulting in up to a 60% increase in throughput while maintaining equivalent flow completion times across all flow sizes. We further validate the stability of this result across a range of workloads, network scales, and cost factors.

2 Network efficiency

The reality of datacenter networks is one of non-stop change: developers are continuously deploying new applications and updating existing applications, and user behavior is in a constant state of flux. As a result, operators cannot risk designing networks that support only a narrow range of workloads, and instead must choose a design that supports a wide range of workloads, applications, and user behavior.

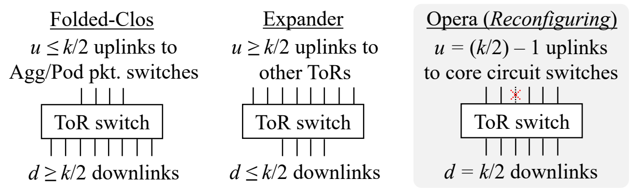

Figure 2: Oversubscribed folded-Clos networks allocate fewer uplinks than downlinks, and static expander-graph-based networks typically allocate more upward ports than downward ports. In Opera, the ToR switch is provisioned 1:1. When a circuit switch is reconfiguring, the associated ToR port cannot carry traffic through that uplink.

2.1 Workload properties

One saving grace of the need to service a wide range of workloads is the likelihood that there will, in fact, be a spectrum of needs in practice. A concrete example is the distribution of flow sizes, which is known to be highly skewed in today's networks: Figure 1 shows data published by Microsoft [4, 21] (Websearch and Datamining) and Facebook [39] (Hadoop) depicting the distributions of traffic according to individual flows (top) and total number of transmitted bytes (bottom) that we consider in this paper. The vast majority of bytes are in bulk flows, not the short, latency-sensitive ones, suggesting that to make the most out of available capacity, an ideal network must seek to minimize the bandwidth tax paid on bulk traffic while not substantially impacting the propagation delay experienced by short flows.

While there are myriad ways to measure a network's suitability for a given workload, flow completion time (FCT) is frequently offered as a useful figure of merit [14] due to its applicability across a wide range of workloads. The flow completion time of small flows is constrained by the underlying network's propagation delay. Thus, lowering the network diameter and/or reducing queuing reduces the FCT for this type of traffic. On the other hand, the FCT of bulk traffic is governed by the available capacity along a flow's path.

Because the FCT of short flows is dictated by propagation delay, such traffic is commonly referred to as "latency-sensitive" or, equivalently, "low-latency". (While applications may be equally sensitive to the FCT of larger flows, their FCT is dominated by available bandwidth.) In today's networks, flows are classified into these categories either explicitly (e.g., by application type, port number, or sender-based rules), or implicitly (e.g., by remaining flow size for shortest-remaining-time-first (SRTF) scheduling). Opera is agnostic to the manner in which traffic is classified; for our purposes latency-sensitive and short flows are synonymous. Because latency-sensitive traffic's impact on network capacity is negligible in today's workloads, it suffices to use priority queuing to ensure short flows receive unimpeded service while allowing bulk traffic to consume any remaining capacity [7, 22]. The challenge is to simultaneously provide high-capacity paths while maintaining a short path length.

2.2 The "big switch" abstraction

If cost (and practicality) were no object, a perfect network would consist of one large, non-blocking switch that connects all the end points. It is precisely such a "big switch" illusion that scale-out packet-switched network fabrics based on folded-Clos topologies [2, 21, 37] were designed to provide. These topologies rely on multiple stages of packet switches interconnected with shuffle networks. The abundance of packet switches at each stage and surfeit of links between them ensures that there is sufficient capacity to support any mixture of (admissible) inter-server communication. Proposals such as Hedera [3], pHost [19], HULL [5], NDP [24], PIAS [7], and Homa [36] introduce flow scheduling techniques that assign traffic to well-chosen paths to maximize throughput while minimizing in-network queuing when servicing a mixture of bulk and low-latency traffic.

2.3 Reduced capacity networks

While full-bandwidth "big switch" network designs are ideal in the sense that they provide operators with the maximum flexibility to deploy services, schedule jobs, and disaggregate storage and compute, they are impractical to construct at scale. Indeed, published reports confirm the largest datacenter networks in existence, while based upon folded-Clos topologies, are not fully provisioned [15, 41]. Moreover, some have observed that packet-switching technology may not be able to keep up as link rates surpass 400 Gb/s, so it is unclear how much longer the "big switch" abstraction will even be feasible [35]. Hence, researchers and practitioners alike have considered numerous ways to under-provision or "over-subscribe" network topologies.

One way to view over-subscription in a rack-based datacenter is to consider how each individual ToR switch is provisioned. Consider a scenario in which servers in a cluster or datacenter are organized into racks, each with a k-radix ToR packet switch that connects it to the rest of the network. We say that a ToR with d connected servers has d "downward" facing ports. A ToR with u ports connected to the rest of the network has u "upward" facing ports, or uplinks. (In a fully populated ToR, $d+u=k$.) In this context, we now overview existing proposals for interconnecting such racks.

Over-subscribed Fat Trees: As shown in the left-most portion of Figure 2, designers can build M:1 over-subscribed folded-Clos networks in which the network can deliver only $(1/M = u/d)$ the bandwidth of a fully-provisioned design. Common values of $(d:u)$ are between 3:1 and 5:1 [41]. The cost and bandwidth delivered in folded-Clos networks scale almost linearly according to the over-subscription factor, and so decreasing overall cost necessitates decreasing the maximum network throughput—and vice versa. Routing remains direct, however, so over-subscription does not introduce a bandwidth tax; rather, it severely reduces the available network capacity between end points in different racks. As a result, application frameworks such as MapReduce [13] and Hadoop [18] schedule jobs with locality in mind in an effort to keep traffic contained within a rack.

Expander topologies: To address the limited cross-network bandwidth available in over-subscribed Fat Trees, researchers have proposed alternative reduced-capacity network topologies based on expander graphs. In these proposals, the u uplinks from each ToR are directly connected to other ToRs, either randomly [42] or deterministically [27, 29, 43], reducing the number of switches and inter-switch links internal to the network itself. Expander-graph-based network topologies are sparse graphs with the property that there are many potential short paths from a given source to a particular destination.

Because there are no in-network switches, packets must "hop" between ToRs a number of times to reach their ultimate destination, resulting in a bandwidth tax. An expander graph with an average ToR-to-ToR hop count of L_{Avg} pays an overall bandwidth tax rate of $(L_{Avg}-1)\times$ in expectation because individual packets must indirect across a number of in-network links. The average path lengths for large networks can be in the range of 4–5 hops, resulting in a bandwidth tax rate of 300–400%. Moreover, a recent proposal [29] employs Valiant load balancing (VLB)—which imposes an additional level of explicit indirection—to address skewed traffic demands, doubling the bandwidth tax in some circumstances. One way that expanders counter-act their high bandwidth tax rate is by over-provisioning: ToRs in expander topologies typically have more upward-facing ports than down ($u > d$, as shown in the center of Figure 2)—and, hence, far more upward-facing ports than over-subscribed Fat Trees—which provides more in-network capacity. Said another way, the impact of the bandwidth tax is reduced by a factor of u/d.

Reconfigurable topologies: In an effort to reduce the bandwidth tax, other proposals rely on some form of reconfigurable link technology, including RF [28, 45], free-space optical [20, 23], and circuit switching [16, 31, 38, 40, 44]. Most reconfigurable topologies dynamically establish end-to-end paths within the network core in response to traffic demand, although RotorNet [34] employs a fixed, deterministic schedule. In either case, these networks establish and tear down physical-layer links over time. When the topology can be matched to the demand—and setting aside latency concerns—traffic can be delivered from source to destination in a single hop, avoiding any bandwidth tax. In some cases, similar to expander-based topologies, they employ 2-hop VLB [34, 40], resulting in a 100% bandwidth tax rate.

A fundamental limitation of any reconfigurable topology, however, is that during the time a link/beam/circuit (for simplicity we will use the latter term in the remainder of the paper) is being provisioned, it cannot convey data. Moreover, most proposals do not provision links between all sources and destinations at all times, meaning that traffic may incur significant delay as it waits for the appropriate circuit to be provisioned. For existing proposals, this end-to-end delay is on the order of 10–100s of milliseconds. Hence, previous proposals for reconfigurable network topologies rely on a distinct, generally packet-switched, network to service latency-sensitive traffic. The requirement for a separate network built using a different technology is a significant practical limitation and source of cost and power consumption.

3 Design

We start with an overview of our design before working through an example. We then proceed to describe how we construct the topology of a given network, how routes are chosen, how the network moves through its fixed set of configurations, and address practical considerations like cabling complexity, switching speeds, and fault tolerance.

3.1 Overview

Opera is structured as a two-tier leaf-spine topology, with packet-switched ToRs interconnected by reconfigurable circuit switches as shown in Figure 5. Each of a ToR's u uplinks are connected to one of u circuit switches, and each circuit switch has a number of ports equal to the number of ToRs in the network. Opera's design is based around two fundamental starting blocks that follow directly from the requirements for small network diameter and low bandwidth tax.

Expansion for short paths: Because the FCT of short, latency-sensitive flows is gated by end-to-end delay, we seek a topology with the lowest possible expected path length. Expander-based topologies are known to be ideal [27]. Expanders also have good fault-tolerance properties; if switches or links fail, there are likely to be alternative paths that remain. Thus, to efficiently support low-latency traffic, we require a topology with good expansion properties at all times.

Reconfigurability to avoid the bandwidth tax: A fully-connected graph (i.e. full mesh) could avoid a bandwidth tax entirely, but is infeasible to construct at scale. Rather than providing a full mesh in space, reconfigurable circuit switches offer the ability to establish, over time, direct one-hop paths between every rack pair using a relatively small number of links. Because bulk flows can generally amortize modest reconfiguration overheads if they result in increased throughput, we incorporate reconfigurability into our design to minimize the bandwidth tax on bulk traffic.

Opera combines the elements of expansion and reconfigurability to efficiently (and simultaneously) serve both low-latency and bulk traffic with low FCTs. Similar to RotorNet [34], Opera incorporates reconfigurable circuit switches that cyclically set up and tear down direct connections between ToRs, such that after a "cycle time" of connections, every ToR has been connected to every other ToR. We leverage ToR-uplink parallelism to stagger the reconfigurations of multiple circuit switches, allowing "always-on" (albeit ever-changing) multi-hop connectivity between all ToR pairs.

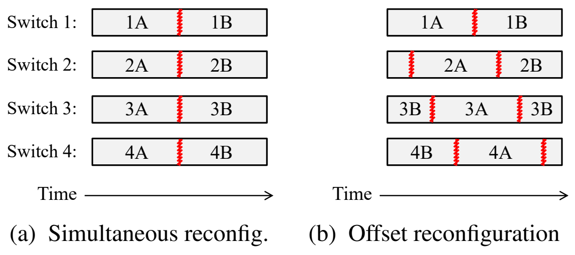

Figure 3: Reconfiguring all switches in unison (a) leads to periodic disruptions; staggered reconfigurations (b) ensure some paths are always available.

Critically, the combination of circuits at any time forms an expander graph. Thus, during a single cycle, every packet has a choice between waiting for a bandwidth-tax-avoiding direct connection, or being immediately sent over a multi-hop path through the time-varying expander. The end result is a single fabric that supports bulk and low-latency traffic as opposed to two separate networks used in hybrid approaches. As we will show, Opera does not require any runtime selection of circuits or system-wide collection of traffic demands, vastly simplifying its control plane relative to approaches that require active circuit scheduling, such as ProjecToR [20] and Mordia [38]. We leave to future work the possibility (and complexity) of adjusting Opera's matchings over long timescales to, for example, adapt to diurnal traffic patterns.

3.1.1 Eliminating reconfiguration disruptions

Circuit switches impose a technology-dependent reconfiguration delay, necessitating that flows be re-routed before reconfiguration. Even in a network with multiple circuit switches, if all switches reconfigure simultaneously (Figure 3a), the global disruption in connectivity requires routes to reconverge. For today's switching technologies, this would lead to traffic delays that could severely impact the FCTs of short, latency-sensitive flows. To avoid this scenario and allow for low-latency packet delivery, Opera offsets the reconfigurations of circuit switches. For example, in the case of small topologies with few switches, at most one switch may be reconfiguring at a time (Figure 3b), allowing flows traversing a circuit with an impending reconfiguration to be migrated to other circuits that will remain active during that time period (for large-scale networks with many circuit switches, it is advantageous to reconfigure more than one switch at a time as described in Appendix C). As a result, while Opera is in near-constant flux, changes are incremental and connectivity is continuous across time.

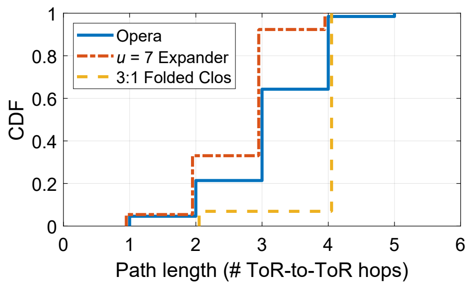

Figure 4: CDF of path lengths for equal-cost 648-host Opera, 650-host $u = 7$ expander, and 648-host 3:1 folded-Clos networks. (CDFs staggered slightly for clarity.)

3.1.2 Ensuring good expansion

While offsetting reconfigurations guarantees continuous connectivity, it does not, by itself, guarantee complete connectivity. Opera must simultaneously ensure that (1) multi-hop paths exist between all racks at every point in time to support low-latency traffic, and (2) direct paths are provisioned between every rack-pair over a fixed period of time to support bulk traffic with low bandwidth tax. We guarantee both by implementing a (time-varying) expander graph across the set of circuit switches.

In Opera, each of a ToR's u uplinks is connected to a (rotor) circuit switch [33] that, at any point in time, implements a (pre-determined) random permutation between input and output ports (i.e., a "matching"). The inter-ToR network topology is then the union of u random matchings, which, for $u \geq 3$, results in an expander graph with high probability [6]. Moreover, even if a switch is reconfiguring, there are still $u-1$ active matchings, meaning that if $u \geq 4$, the network will still be an expander with high probability, no matter which switch is reconfiguring. In Opera, we let $u = k/2$ where k is $O(10)$ to $O(100)$ ports for today's packet switches (depending on the configured per-port bandwidth).

Figure 4 shows the distribution of path lengths in one example 648-host network considered in our evaluation, where $u = 6$. Opera's path lengths are almost always substantially shorter than those in a Fat Tree that connects the same number of hosts, and only marginally longer than an expander with $u = 7$ which we argue later has similar cost, but performs poorly for certain workloads. Clearly, ensuring good expansion alone is not an issue with modest switch radices. However, Opera must also directly connect each rack pair over time. We achieve this by having each switch cycle through a set of matchings; we minimize the total number of matchings (and thus the time required to cycle through them) by constructing a disjoint set.

3.2 Example

Figure 5 depicts a small-scale Opera network. Each of the eight ToRs has four uplinks to four different circuit switches (with one potentially down due to reconfiguration at any particular moment). By forwarding traffic through those ToRs, they can reach any ToRs to which they, in turn, are connected. Each circuit switch has two matchings, labeled A and B (note that all matchings are disjoint from one another). In this example topology, any ToR-pair can communicate by utilizing any set of three matchings, meaning complete connectivity is maintained regardless of which matchings happen to be implemented by the switches at a given time. Figure 5 depicts two network-wide configurations. In Figure 5a switches 2–4 are implementing matching A, and in Figure 5b, switches 2–4 implement matching B. In both cases switch 1 is unavailable due to reconfiguration.

In this example, racks 1 and 8 are directly connected by the configuration shown in Figure 5b, and so the lowest bandwidth-tax way to send bulk data from 1 to 8 would be to wait until matching B is instantiated in switch 2, and then to send the data through that circuit; such traffic would arrive at ToR 8 in a single hop. On the other hand, low-latency traffic from ToR 1 to ToR 8 can be sent immediately, e.g. during the configuration shown in Figure 5a, and simply take a longer path to get to ToR 8. The traffic would hop from ToR 1 to ToR 6 (via switch 4), then to ToR 8 (via switch 2), and incur a 100% bandwidth tax. Although not highlighted in the figure, similar alternatives exist for all rack pairs.

3.3 Topology generation

The algorithm to generate an N-rack Opera topology is as follows. First, we randomly factor a complete graph (i.e. $N \times N$ all-ones matrix) into N disjoint (and symmetric) matchings. Because this factorization can be computationally expensive for large networks, we employ graph lifting to generate large factorizations from smaller ones. Next, we randomly assign the N matchings to u circuit switches, so that each switch has N/u matchings assigned to it. Finally, we randomly choose the order in which each switch cycles through its matchings. These choices are fixed at design time, before the network is put into operation; there is no topology computation during network operation.

Because our construction approach is random, it is possible (although unlikely) that a specific Opera topology realization will not have good expander properties at all points across time. For example, the combination of matchings in a given set of $u-1$ switches at a particular time may not constitute an expander. In this case, it would be trivial to generate and test additional realizations at design time until a solution with good properties is found. This was not necessary in our experience, as the first iteration of the algorithm always produced a topology with near-optimal properties. We discuss the properties of these graphs in detail in Appendix E.

3.4 Forwarding

We are now left to decide how to best serve a given flow or packet: (1) send it immediately over multi-hop expander paths and pay the bandwidth tax (we refer to these as "indirect" paths), or (2) delay transmission and send it over one-hop paths to avoid the bandwidth tax (we refer to these as "di-

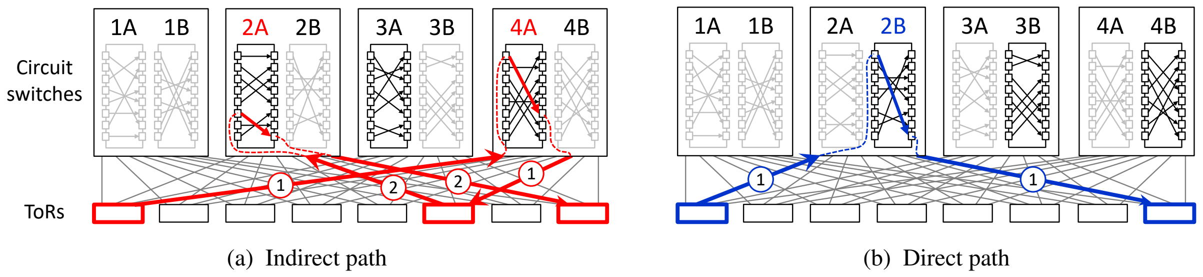

Figure 5: An Opera topology with eight ToR switches and four rotor circuit switches (from RotorNet [34]). Two different paths from rack 1 to rack 8 are highlighted: (a) a two-hop path in red, and (b) a one-hop path in blue. Each direct inter-rack connection is implemented only once per configuration, while multi-hop paths are available between each rack-pair at all times.

rect" paths). For skewed traffic patterns that, by definition, leave spare capacity in the network, two-hop paths based on Valiant load balancing can be used to carry bulk traffic in Opera. Our baseline approach is to make the decision based on flow size. Since the delay in waiting for a direct path can be an entire cycle time, we only let flows that are long enough to amortize that delay use direct paths, and place all other traffic on indirect paths. However, we can do even better if we know something about application behavior. Consider an all-to-all shuffle operation, where a large number of hosts simultaneously need to exchange a small amount of data with one another. Although each flow is small, there will be significant contention, extending the flow completion time of these flows. Minimizing bandwidth tax is critical in these situations. With application-based tagging, Opera can route such traffic over direct paths.

3.5 Synchronization

Opera employs reconfigurable circuit switches, and so its design requires a certain level of synchronization within the system to operate correctly. In particular, there are three synchronization requirements that must be met: (1) ToR switches must know when core circuit switches are reconfiguring, (2) ToR switches must update their forwarding tables in sync with the changing core circuits, and (3) end hosts must send bulk traffic to their local ToR only during the timeslots when the ToR is directly connected to the destination (to prevent excessive queueing in the ToR). In the first case, since each ToR's uplink is connected directly to one of the circuit switches, the ToR can monitor the signal strength of the transceiver attached to that link to re-synchronize with the circuit switch. Alternatively, the ToR could rely on IEEE 1588 (PTP), which can synchronize switches to within ± 1 µs [1]. For low-latency traffic, end hosts simply transmit packets immediately, without any coordination or synchronization. For bulk traffic, end hosts transmit when polled by their attached ToR. To evaluate the practicality of this synchronization approach, we built a small-scale prototype based on a programmable P4 switch, described in Section 6.

Opera can tolerate arbitrary bounds on (de-)synchronization by introducing "guard bands" around each configuration, in which no data is sent to ensure the network is configured as expected when transmissions do occur. To analyze the impact of guard bands, we hold the circuit timings constant and reduced the effective time of the slot during which data can be transmitted. Each µs of guard time contributes a 1% relative reduction in low-latency capacity and a 0.2% reduction for bulk traffic. In practice, if any component becomes de-synchronized beyond the guard-band tolerance, it can simply be declared failed (see Section 3.6.2).

3.6 Practical considerations

While Opera's design draws its power from graph-theoretic underpinnings, it is also practical to deploy. Here, we consider two real-world constraints on networks.

3.6.1 Cabling and switch complexity

Today's datacenter networks are based on folded-Clos topologies which use perfect-shuffle cabling patterns between tiers of switches. While proposals for static expander graphs alter that wiring pattern [42] leading to concerns about cabling complexity, Opera does not. In Opera, the interconnection complexity is contained within the circuit switches themselves, while the inter-switch cabling remains the familiar perfect shuffle. In principle, Opera can be implemented with a variety of electronic or optical circuit switch technologies. We focus on optical switching for our analysis due to its cost and data-rate transparency benefits. Further, because each circuit switch in Opera must only implement N/u matchings (rather than $O(N!)$), Opera can make use of optical switches with limited configurability such as those proposed in RotorNet [34], which have been demonstrated to scale better than optical crossbar switches [17, 33].

3.6.2 Fault tolerance

Opera detects, shares, and recovers from link, ToR, and circuit switch failures using common routing protocol practices. We take advantage of Opera's cyclic connectivity to detect and communicate failures: each time a new circuit is configured, the ToR CPUs on each end of the link exchange a short sequence of "hello" messages (which contain information of new failures, if applicable). If no hello messages are received within a configurable amount of time, the ToR marks the link in question as bad. Because all ToR-pair connections are established every cycle, any ToR that remains connected

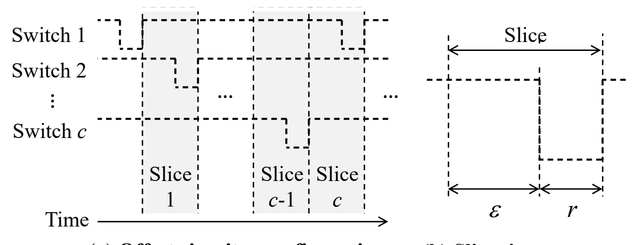

Figure 6: (a) A set of c circuit switches with offset reconfigurations forms a series of topology slices. (b) The time constants associated with a single slice: ε is the worst-case end-to-end delay for a low-latency packet to traverse the network and r is the circuit switch reconfiguration delay.

to the network will learn of any failure event within two cycles (<10ms). Upon receiving information of a new failure, a ToR recomputes and updates its routing tables to route around failed components.

4 Implementation

Here, we describe the implementation details of Opera. To ground our discussion, we refer to an example 108-rack, 648-host, $k = 12$ topology (we evaluate this topology along with a larger one in Section 5).

4.1 Defining bulk and low-latency traffic

In Opera, traffic is defined as low-latency if it cannot wait until a direct bandwidth-efficient path becomes available. Thus the division between low-latency and bulk traffic depends on the rate at which Opera's circuit switches cycle through direct matchings. The faster Opera steps through these matchings, the lower the overhead for sending traffic on direct paths, and thus the larger the fraction of traffic that can utilize these paths. Two factors impact cycle speed: circuit amortization and end-to-end delay.

Circuit amortization: The rate at which a circuit switch can change matchings is technology dependent. State-of-the-art optical switches with the large port counts needed for practical datacenter deployment have reconfiguration delays on the order of 10 µs [20, 34, 38]. A 90% amortization of this delay would limit circuit reconfigurations to every 100 µs. In Opera, each switch cycles through N/u matchings, which could range from 10 matchings for small networks (e.g. $N = 320$ racks and $u = 32$ uplinks) to 32 matchings for larger networks (e.g. $N = 4096$ racks and $u = 128$ uplinks). This means any flow than can amortize a 1–3 ms increase in its FCT could take the bandwidth-efficient direct paths (and shorter flows would take indirect paths).

End-to-end delay: Perhaps surprisingly, a second timing constraint, end-to-end delay, has a larger impact on cycle time. In particular, consider a low-latency packet that is emitted from a host NIC. At the first ToR, the packet is routed toward its destination, and in general, at each hop along the way, each ToR routes the packet along an expander-graph path. If, during the packet's journey, the circuit topology changes, it is possible the packet could be caught in a loop or redirected along a sub-optimal path. Dropping the packet immediately (and expecting the sender to resend it) would significantly delay the flow completion time of that flow.

Our approach, depicted in Figure 6, to avoid the problems described above, requires that subsequent circuit reconfigurations be spaced by at least the sum of the end-to-end delay under worst-case queuing, ε, and the reconfiguration delay, r. We refer to this time period ε+r as a "topology slice". Any packets sent during a slice are not routed through the circuit with an impending reconfiguration during that slice. This way, packets always have at least ε time to make it through the network before a switch reconfigures.

The parameter ε depends on the worst-case path length (in hops), the queue depth, the link rate, and propagation delay. Path length is a function of the expander, while the data rate and propagation delay are fixed; the key driver of ε is the queue depth. As explained in the following section, we choose a shallow queue depth of 24 KB (8 1500-byte full packets + 187 64-byte headers). When combined with a worst-case path length of 5 ToR-to-ToR hops (Figure 4), 500-ns propagation delay per hop (100 meters of fiber), and 10-Gb/s link speed, we set ε to 90 µs. In our example 108-rack network, there are 6 circuit switches, meaning the inter-reconfiguration period of a single switch is 6ε, yielding a duty cycle of 98%. Further, our example network has N/u = 108/6 = 18 matchings per switch, yielding a cycle time of $N \times \varepsilon$ = 10.8 ms. We use this cycle time of 10.8 ms in our simulations in Section 5. For these time constants, flows $\geq$15 MB will have an FCT well within a factor of 2 of their ideal (link-rate-limited) FCT. As we will show in Section 5, depending on traffic conditions, shorter flows may benefit from direct paths as well.

4.2 Transport protocols

Opera requires transport protocols that can (1) immediately send low-latency traffic into the network, while (2) delaying bulk traffic until the appropriate time. To avoid head-of-line blocking, NICs and ToRs perform priority queuing. Our design replaces the typical TCP stack with the protocols below, but keeps the familiar sockets application interface.

4.2.1 Low-latency transport

As discussed in the previous section, minimizing the cycle time is predicated on minimizing the queue depth for low-latency packets at ToRs. The recently proposed NDP protocol [24] is a promising choice because it achieves high throughput with very shallow queues. We find that 12-KB queues work well for Opera (each port has an additional equal-sized header queue). NDP also has other beneficial characteristics for Opera, such as zero-RTT convergence and no packet metadata loss to eliminate RTOs. Despite being designed for fully-provisioned folded Clos networks, we find in simulation that NDP works well with minimal modification in

Opera, despite Opera's continuously-varying topology. Other transports, like the recently proposed Homa protocol [36], may also be a good fit for low-latency traffic in Opera, but we leave this to future work.

4.2.2 Bulk transport

Opera's bulk transport protocol is relatively simple. We draw heavily from the RotorLB protocol proposed in RotorNet [34], which buffers traffic at end hosts until direct connections to the destination are available. When bulk traffic is heavily skewed, and there is necessarily spare capacity elsewhere in the network, RotorLB automatically transitions to using two-hop routing (i.e. Valiant load balancing) to improve throughput. Unlike low-latency traffic, which can be sent at any time, bulk traffic admission is coordinated with the state of the circuit switches, as described in Section 3.5. In addition to extending RotorLB to work with offset reconfigurations, we also implemented a NACK mechanism to handle cases where large bursts of priority-queued low-latency traffic can cause bulk traffic queued at the ToR to be delayed beyond the transmission window and dropped at the ToR. Retransmitting a small number of packets does not significantly affect the FCT of bulk traffic. Unlike TCP, RotorLB does not rely on retransmission timeouts, which could otherwise cause bandwidth throttling for bulk traffic.

4.3 Packet forwarding

Opera relies on ToR switches to route packets along direct or multi-hop paths depending on the requested network service model. We implement this routing functionality using the P4 programming language. Each ToR switch has a built-in register that stores the current network configuration, updated either in-band or via PTP. When a packet arrives at the first ToR switch, the packet's metadata is updated with the value of the configuration register. What happens next, and at subsequent ToR switches, depends on the value of the DSCP field. If that field indicates a low-latency packet, the switch consults a low-latency table to determine the next hop along the expander path, and then forwards the packet out that port. If the field indicates bulk traffic, the switch consults a bulk traffic table which indicates which circuit switch—if any—provides a direct connection, and the packet is forwarded to that port. We measure the amount of in-switch memory required to implement this P4 program for various datacenter sizes in Section 6.2.

5 Evaluation

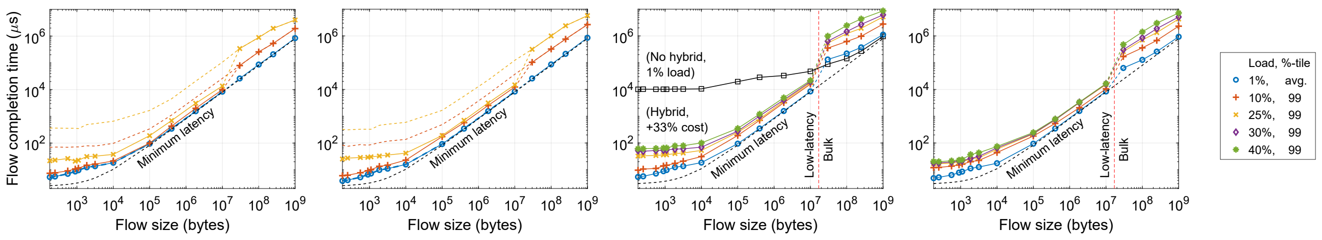
We evaluate Opera in simulation. Initially, we focus on a concrete 648-host network, comparing to cost-equivalent folded-Clos, static expander, non-hybrid RotorNet, and (non-cost-equivalent) hybrid RotorNet networks. We then validate against a range of network sizes, skewed workloads, and underlying cost assumptions. We use the `htsim` packet simulator [26], which was previously used to evaluate the NDP protocol [24], and extend it to model static expander networks and dynamic networks. We ported our RotorNet simulator [34] to `htsim`, first validating its performance against prior results. We also modify NDP to handle $<$1500 byte packets, which is necessary for some workloads considered. Both the folded-Clos and static expander use NDP as the transport protocol. Opera and RotorNet use NDP to transport low-latency traffic and RotorLB for bulk traffic. Because Opera explicitly uses priority queuing, we simulate the static networks with idealized priority queuing where appropriate to maintain a fair comparison. Following prior work [20, 29], we set the link bandwidth to 10 Gb/s. We use a 1500-byte MTU and set the propagation delay to 500 ns between ToRs (equivalent to 100 meters of fiber).

5.1 Real-world traffic

We start by considering Opera's target scenario, a workload with an inherent mix of bulk and low-latency traffic. Here we consider the Datamining workload from Microsoft [21], and use a Poisson flow-arrival process to generate flows. We vary the Poisson rate to adjust the load on the network, defining load relative to the aggregate bandwidth of all host links (i.e., 100% load means all hosts are driving their edge links at full capacity, an inadmissible load for any over-subscribed network). As shown in the top portion of Figure 1, flows in this workload range in size from 100 bytes to 1 GB. We use Opera's default configuration to decide how to route traffic: flows $<$15 MB are treated as low-latency and are routed over indirect paths, while flows $\geq$15 MB are treated as bulk and are routed over direct paths.

Figure 7 shows the performance of Opera as well as cost-comparable 3:1 folded-Clos and $u = 7$ static expander networks for various offered loads. We also compared to a hybrid RotorNet which faces one of the six ToR uplinks to a multi-stage packet switched network to accommodate low-latency traffic (for 1.33$\times$ the cost), and a cost-equivalent non-hybrid RotorNet with no packet switching above the ToR. Appendix B discusses the tradeoffs for a hybrid RotorNet in more detail. We report the 99th percentile FCT except in the case of 1% load, where the variance in the tail obscures the trend and so report the average instead. Note that Opera priority queues all low-latency flows, while by default the static networks do not. For fairness, we also present the expander and folded Clos with "ideal" priority queuing—that is, removing all flows $\geq$15 MB. For reference, we also plot the minimum achievable latency in each network, derived from the end-to-end delay and link capacity.

The static networks start to saturate past 25% load: folded Clos have limited network capacity, and expanders have high bandwidth tax. Opera, on the other hand, is able to service 40% load despite having lower innate capacity than the cost-comparable expander. Opera offloads bulk traffic onto bandwidth-efficient paths, and only pays bandwidth tax on the small fraction (4%) of low-latency traffic that transits indirect paths, yielding an effective aggregate bandwidth tax of 8.4%



(a) 3:1 folded Clos (b) $u = 7$ expander (c) RotorNet (d) Opera

Figure 7: FCTs for the Datamining workload. All networks are cost comparable except hybrid RotorNet, which is 1.33× more expensive. In (a) and (b), dashed lines are without priority queuing, and solid lines are with ideal priority queuing.

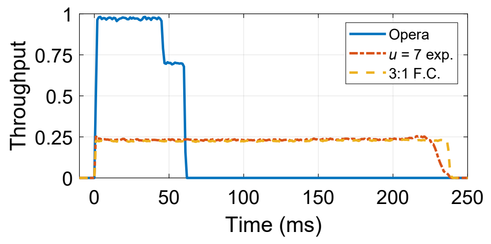


Figure 8: Network throughput over time for a 100-KB all-to-all Shuffle workload. Opera carries all traffic over direct paths, greatly increasing throughput. (The small "step" down in Opera's throughput around 50 ms is due to some flows taking one additional cycle to finish.)

for this workload. Hybrid RotorNet, even with 1/6th of its core capacity packet-switched (for 33% higher cost than the other networks), delivers longer FCTs than Opera for short flows at loads >10%. A non-hybrid (i.e. all-optical-core) RotorNet is cost-equivalent to the other networks, but its latency for short flows is three orders of magnitude higher than the other networks, as shown in Figure 7c.

5.2 Bulk traffic

Opera's superiority in the mixed case stems entirely from its ability to avoid paying bandwidth tax on the bulk traffic. We highlight this ability by focusing on a workload in which all flows are routed over direct paths. We consider an all-to-all shuffle operation (common to MapReduce style applications), and choose the flow size to be 100 KB based on the median inter-rack flow size reported in a Facebook Hadoop cluster [39] (c.f. Figure 1). Here we presume the application tags its flows as bulk, so we do not employ flow-length based classification; i.e., Opera does not indirect any flows in this scenario. We let all flows start simultaneously in Opera, as RotorLB accommodates such cases gracefully, and stagger flow arrivals over 10 ms for the static networks, which otherwise suffer from severe startup effects. Because the shuffle operation correlates the start times of all flows, this workload can drive the network to 100% utilization.

Figure 8 shows the delivered bandwidth over time for the different networks. The limited capacity of the 3:1 Clos and high bandwidth tax rates of the expander significantly extend the FCT of the shuffle operation, yielding 99th-percentile FCTs of 227 ms and 223 ms, respectively. Opera's direct paths are bandwidth-tax-free, allowing higher throughput and reducing the 99th-percentile FCT to 60 ms.

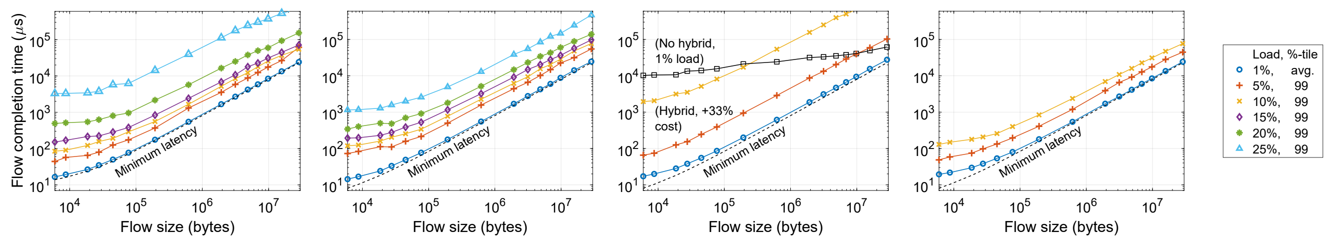
5.3 Only low-latency flows

Conversely, workloads in which all flows are routed over indirect low-latency paths represents the worst case for Opera, i.e., it always pays a bandwidth tax. Given our 15 MB threshold for bulk traffic, it is clear from the bottom portion of Figure 1 that the Websearch workload [4] represents such a case. A lower threshold would avoid the bandwidth tax, but would require a shorter cycle time to prevent a significant increase in FCT for these short "bulk" flows.

Figure 9 shows the results for the Websearch workload, again under a Poisson flow arrival process. As before, the cost-equivalent all-optical RotorNet suffers from long FCTs. Hybrid RotorNet (with 1/6th of its capacity packet switched for 33% higher cost) can only admit just over 10% load, at which point the throughput saturates. At more than 5% load, its FCTs are significantly higher than the other networks. All other networks provide equivalent FCTs across all flow sizes for loads at or below 10%, at which point Opera is not able to admit additional load. Both the 3:1 folded Clos and expander saturate (slightly) above 25% load, but at that point both deliver FCTs nearly 100× worse than at 1% load. While Opera forwards traffic analogous to the expander in this scenario, it has only 60% the capacity and pays an additional 41% bandwidth tax due to its longer expected path length.

5.4 Mixed traffic

To drive home Opera's ability to trade off low-latency capacity against lower effective bandwidth taxes, we explicitly combine the Websearch (low-latency) and Shuffle (bulk) workloads from above in varying proportions. Figure 10 shows the aggregate network throughput as a function of Websearch (low-latency) traffic load, defined as before as a fraction of the aggregate host link capacity. We see that for low Websearch load, Opera delivers up to 4× more throughput than the static topologies. Even at 10% Websearch load (near its maximum admissible load), Opera still delivers almost 2× more throughput. In essence, Opera "gives up" a factor of 2 in low-latency capacity (due to its relatively under-



(a) 3:1 folded Clos (b) $u = 7$ expander (c) RotorNet (d) Opera

Figure 9: FCTs for the Websearch workload. All networks are cost comparable except hybrid RotorNet, which is 1.33× more expensive. Opera carries all traffic over indirect paths, and supports up to 10% low-latency traffic load with near-equivalent FCTs to the 3:1 folded Clos and $u = 7$ expander.

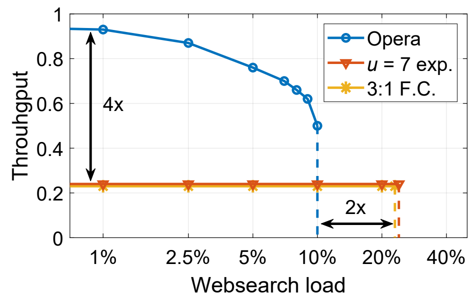


Figure 10: Network throughput vs. Websearch traffic load for a combined Websearch/Shuffle workload.

provisioned ToRs) to gain a factor of 2–4 in bulk capacity from its vastly lower effective bandwidth tax.

Facebook has reported that only 25% of traffic is attributed to bulk-dominated Hadoop jobs, but also that the total average network load is less than 1% [39]. Even if the other 75% of traffic was solely low-latency flows, Opera can accommodate this light overall load with little-to-no degradation in FCT while significantly improving throughput for Hadoop traffic, which has a high momentary peak load due to the correlated start times of constituent flows.

5.5 Fault tolerance

Next, we demonstrate Opera's ability to maintain and re-establish connectivity in the face of component failures by injecting random link, ToR, and circuit switch failures into the network. We then step through the topology slices and record (1) the number of ToR pairs that were disconnected in the worst-case topology slice and (2) the number of unique disconnected ToR pairs integrated across all slices. Figure 11 shows that Opera can withstand about 4% of links failing, 7% of ToRs failing, or 33% (2 out of 6) of circuit switches failing without suffering any loss in connectivity. Opera's robustness to failure stems from the good fault tolerance properties of expander graphs. As discussed in Appendix F, Opera has better fault tolerance than a 3:1 folded Clos, and is less tolerant than the $u = 7$ expander (which has higher fanout). Maintaining connectivity under failure does require some degree of path stretch in Opera; Appendix F discusses this in more detail.

5.6 Network scale and cost sensitivity

Finally, we examine Opera's relative performance across a range of network sizes and cost assumptions. We introduce a parameter α, which is defined following [29] to be the cost of an Opera "port" (consisting of a ToR port, optical transceiver, fiber, and circuit switch port) divided by the cost of a static network "port" (consisting of a ToR port, optical transceiver, and fiber). A full description of this cost-normalization method is presented in Appendix A. If $\alpha > 1$ (i.e. circuit switch ports are not free) then a cost-equivalent static network can use the extra capital to purchase more packet switches and increase its aggregate capacity.

We evaluated workloads previously analyzed in [29] using `htsim`: (1) hot rack, which is a highly skewed workload where one rack communicates with one other rack; (2) skew[0.1,1], (10% of racks are hot [29]), (3) skew[0.2,1] (20% hot); and (4) host permutation, where each host sends to one other non-rack-local host. For each workload, we considered a range of relative Opera port costs (reallocating any resulting cost savings in the static networks to increase their capacity). We considered both $k = 12$ and $k = 24$ ToR radices, corresponding to 648-host and 5,184-host networks. Figure 12 shows the results for $k = 24$; the $k = 12$ case has nearly identical cost-performance scaling and is presented in Appendix D, along with path length scaling analysis.

The throughput of the folded Clos topology is independent of traffic pattern, whereas the throughput of the expander topology decreases as workloads become less skewed. Opera's throughput initially decreases with a decrease in skew, then increases as the traffic becomes more uniform. As long as $\alpha < 1.8$ (Opera's circuit switch ports cost less than a packet switch port populated with an optical transceiver), Opera delivers higher throughputs than either an expander or folded Clos for permutation traffic and moderately skewed traffic (e.g. 20% of racks communicating). In the case of a single hot rack, Opera offers comparable performance to a static expander. In the case of shuffle (all-to-all) traffic, Opera delivers 2× higher throughput than either the expander or folded Clos even for $\alpha = 2$. As discussed further in Appendix A, we believe $\alpha = 1.3$ is achievable today with certain optical switching technologies.

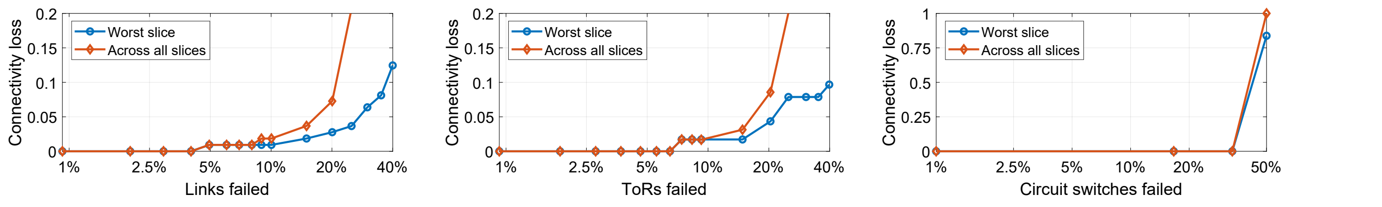

Figure 11: Fault tolerance in a 648-host, 108-rack Opera network with 6 circuit switches and $k = 12$ port ToRs. Connectivity loss is the fraction of disconnected ToR pairs. In cases involving ToR failures, connectivity loss refers to non-failed ToRs.

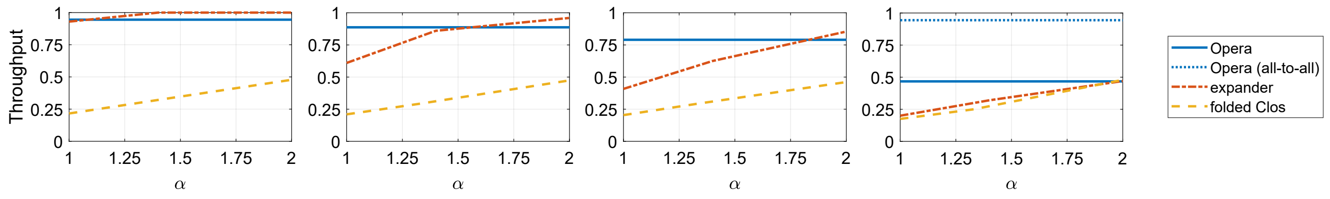

Figure 12: Throughput for (left to right) hotrack, skew[0.1,1], skew[0.2,1], and permutation workloads for $k = 24$ ports.

Opera does not offer an advantage for skewed and permutation workloads when the relative cost of its ports is significantly higher than packet switches ($\alpha > 2$), or in deployments where more than 10% of the link rate is devoted to urgent, delay-intolerant traffic, as described in Section 5.3.

6 Prototype

Priority queueing plays an important role in Opera's design, ensuring that low-latency packets do not get buffered behind bulk packets in the end hosts and switches, and our simulation study reflects this design. In a real system, low-latency packets that arrive at a switch might temporarily buffer behind lower-priority bulk packets that are being transmitted out an egress port. To better understand the impact of this effect on the end-to-end latency of Opera, we built a small-scale hardware prototype.

The prototype consists of eight ToR switches, each with four uplinks connected to one of four emulated circuit switches (the same topology shown in Figure 5). All eight ToR and four circuit switches are implemented as virtual switches within a single physical 6.5-Tb/s Barefoot Tofino switch. We wrote a P4 program to emulate the circuit switches, which forward bulk packets arriving at an ingress port based on a state register, regardless of the destination address of the packet. We connect the virtual ToR switches to the four virtual circuit switches using eight physical 100-Gb/s cables in loopback mode (logically partitioned into 32 10-Gb/s links). Each virtual ToR switch is connected via a cable to one attached end host, which hosts a Mellanox ConnectX-5 NIC. There are eight such end hosts (one per ToR switch) each configured to run at 10 Gb/s.

An attached control server periodically sends a packet to the Tofino's ASIC that updates its state register. After configuring this register, the controller sends RDMA messages to each of the attached hosts, signaling that one of the emulated circuit switches has reconfigured. The end hosts run two processes: an MPI-based shuffle program patterned on the Hadoop workload, and a simple "ping-pong" application that sends low-latency RDMA messages to a randomly selected receiver, which simply returns a response back to the sender. The relatively low sending rate of the ping-pong application did not require us to implement NDP for this traffic.

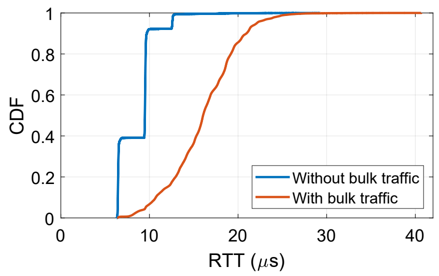

Figure 13: RTT values for low-latency traffic with and without bulk background traffic in the prototype.

6.1 End-to-end latency

Figure 13 shows the observed application-level latency of sending a ping message from a random source to a random destination (and back). We plot this distribution both with and without bulk background traffic. The latency observed without bulk traffic is due to a combination of the path length and the time to forward a packet through Tofino's P4 program, which we observe to be about 3 µs per hop, resulting in latency of up to 9 µs depending on path length. The observed tail is due to RoCE/MPI variance at the end hosts. In the presence of bulk traffic, low-latency packets potentially need to queue behind bulk packets currently being sent from the egress port. Because we emulate circuit switches within the Barefoot switch, each transit of a circuit-switch introduces additional latency that would not be present in a deployment, adding additional latency. For our testbed there are as many as eight serialization points from source to destination, or 16 for each ping-pong exchange. Each serialization point can introduce

#Racks	#Entries	% Utilization
108	12,096	0.7
252	65,268	3.8
520	276,120	16.2
768	600,576	35.3
1008	1,032,192	60.7
1200	1,461,600	85.9

Table 1: Number of entries and resulting resource utilization for Opera rulesets for datacenters of varying sizes.

as much as 1.2 µs (one MTU at 10 Gb/s), or 19.2 µs in total, as shown in Figure 13. The distribution is smooth because when low-latency packets buffer behind bulk packets currently exiting the switch, the amount of remaining time is effectively a random variable.

6.2 Routing state scalability

Opera requires more routing state than a static topology. A straightforward implementation would require the tables in each switch to contain $O(N_{rack})^2$ entries as there are N_{rack} topology slices and $N_{rack}-1$ possible destinations within each slice. We use Barefoot's Capilano compiler tool to measure the size of the ruleset for various datacenter sizes, and compare that size to the capacity of the Tofino 65x100GE switch. The ruleset consists of both bulk and low-latency non-rack-local rules. The resulting number of rules and the percent utilization of the switch's memory are shown in Table 1. Because the practical rulesize limit may be lower than the compiler-predicted size due to hash collisions within the switch, we loaded the generated rules into a physical switch to validate that the rules would fit into the resource constraints. These results show that today's hardware is capable of holding the rules needed to implement Opera, while also leaving spare capacity for additional non-Opera rules.

7 Related work

Opera builds upon previous network designs focused on cluster and low-latency environments. In addition to the folded-Clos and expander graph topologies described thus far, a number of additional static and dynamic network topologies have been proposed for clusters and datacenters.

Static topologies: Dragonfly [30] and SlimFly [8] topologies connect localized pools of high cross-section bandwidth with a sparse inter-cluster set of links, and have been adopted in HPC environments. Diamond [12] and WaveCube [9] statically interconnect switches with optical wavelength MUXes, resulting in a connected topology without reconfiguration. Quartz [32] interconnects switches into rings, and relies on multi-hop forwarding for low-latency traffic.

Dynamic topologies: Several dynamic network topologies have been proposed, which we can group into two categories: those that cannot support low-latency traffic and those that can. In the former case, Helios [16], Mordia [38], and C-Through [44] aim to reactively establish high-bandwidth connections in response to observed traffic patterns; they all rely on a separate packet-switched network to support low-latency traffic. RotorNet [34] relies on deterministic reconfiguration to deliver constant bandwidth between all endpoints, and requires endpoints inject traffic using Valiant load balancing to support skewed traffic. RotorNet requires a separate packet-switched network for low latency traffic.

ProjecToR [20], on the other hand, always maintains a "base mesh" of connected links that can handle low-latency traffic while it opportunistically reconfigures free-space links in response to changes in traffic patterns. The authors initially evaluated the use of a random base network, ruling it out due to poor support of skew. Instead, they proposed a weighted matching of sources and sinks, though it is not clear what the expected diameter of that network would be in general. Similar to ProjecToR, Opera maintains an "always on" base network which consists of a repeating sequence of time-varying expander graphs, which has a well-known structure and performance characteristics.

There are also reconfigurable network proposals that rely on multi-hop indirection to support low-latency traffic. In OSA [10], during reconfiguration some end-to-end paths may not be available, and so some circuit-switch ports can be reserved specifically to ensure connectivity for low-latency traffic. Megaswitch [11] could potentially support low-latency traffic in a similar manner.

8 Conclusions

Static topologies such as oversubscribed folded-Clos and expander graphs support low-latency traffic but have limited overall network bandwidth. Recently proposed dynamic topologies provide high bandwidth, but cannot support low-latency traffic. In this paper, we propose Opera, which is a topology that implements a series of time-varying expander graphs that support low-latency traffic, and when integrated over time, provide direct connections between all endpoints to deliver high throughput to bulk traffic. Opera can deliver a $4\times$ increase in throughput for shuffle workloads and a 60% increase in supported load for skewed datacenter workloads compared to cost-equivalent static networks, all without adversely impacting the flow completion times of short flows.

Appendix

A Cost-normalization approach

In this section, we detail the method we used to analyze a range of cost-equivalent network topologies at various network scales and technology cost points. We begin by defining α as the cost of an Opera "port" (consisting of a ToR port, optical transceiver, fiber, and circuit switch port) divided by the cost of a static network "port" (consisting of a ToR port, optical transceiver, and fiber), following [29].

We can also interpret α as the cost of the "core" ports (i.e. upward-facing ToR ports and above) per edge port (i.e. server-facing ToR port). Core ports drive the network cost because they require optical transceivers. Thus, for a folded Clos we can write $\alpha = 2(T-1)/F$ (where T is the number of tiers and F is the oversubscription factor). For a static expander, we can write $\alpha = u/(k-u)$ (where u is the number of ToR uplinks and k is the ToR radix).

We use a $T = 3$ three tier (i.e. three layer) folded Clos as the normalizing basis and keep the packet switch radix (k) and number of hosts (H) constant for each point of network comparison. To determine the number of hosts as a function of k and α, we first solve the for the oversubscription factor as a function of α: $F = 2(T-1)/\alpha$ (note $T = 3$). Then, we find the number of hosts H in a folded Clos as a function of F, k, and α: $H = (4F/(F+1))(k/2)^T$ (note $T = 3$, and F is a function of α). This allows us to compare networks for various values of k and α, but we also estimate α given technology assumptions described below.

Opera's cost hinges largely on the circuit switching technology used. While a wide variety of technologies could be used in principle, using optical rotor switches [34] is likely the most cost-effective because (1) they provide low optical signal attenuation (about 3 dB) [33], and (2) they are compatible with either single mode or multimode signaling by virtue of their imaging-relay-based design [33]. These factors mean that Opera can use the same (cost) multimode or simglemode transceivers used in traditional networks, unlike many other optical network proposals that require expensive and sophisticated telecom grade gear such as wavelength tunable transceivers or optical amplifiers. Based on the cost estimates of commodity components taken from [29] and rotor switch components (summarized in Table 2), we approximate that an Opera port costs about 1.3× more than a static network port (i.e. α=1.3).

B Hybrid cost-performance tradeoff

In Section 5, we evaluated the performance of a hybrid RotorNet which faced one of the six available ToR uplinks to a multi-stage packet switched network (for 1.33× the cost of the other networks evaluated). Here, we consider the tradeoff between FCT and cost for a broader range of hybrid packet switched bandwidths. To consider small fractions of packet switched bandwidth, we allow the bandwidth of a single ToR uplink to be split arbitrarily between the packet and circuit

Component	Static	Opera
SR transceiver	\$80	\$80
Optical fiber (\$0.3/m)	\$45	\$45
ToR port	\$90	\$90
Optical fiber array	-	\$30 †
Optical lenses	-	\$15 †
Beam-steering element	-	\$5 †
Optical mapping	-	\$10 †
Total	\$215	\$275
α ratio	1	1.3

Table 2: Cost per "port" for a static network vs. Opera. A "port" in a static network consists of a packet switch port, optical transceiver, and fiber. A "port" in Opera consists of a packet switched (ToR) port, optical transceiver, and fiber, as well as the components needed to build a rotor switch. The cost of rotor switch components is amortized across the number of ports on a given rotor switch, which can be 100s or 1,000s; we present values in the table assuming 512 port rotor switches. († per duplex fiber port)

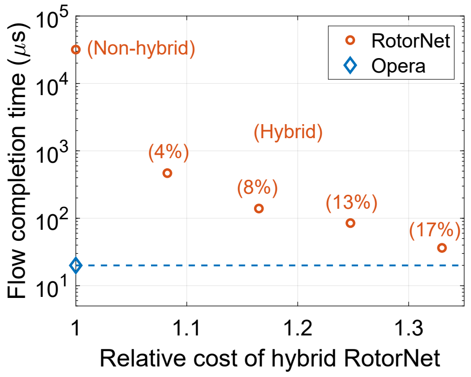

Figure 14: Flow completion times as a function of the cost incurred by adding more packet switched bandwidth to a hybrid RotorNet. The FCTs for Opera are shown for reference. FCTs are shown for 1 kB flows in the Datamining workload running at 25% load. The percent values for hybrid RotorNet indicate the percent of total network bandwidth allocated to the packet switched portion of the network.

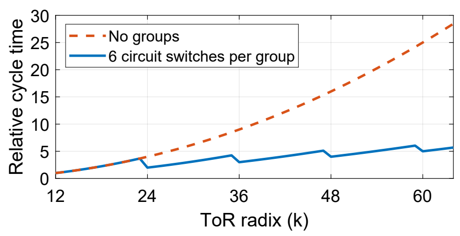

Figure 15: Relative cycle time is improved at larger scale by grouping circuit switches and allowing one switch in each group to reconfigure simultaneously.

networks. Figure 14 shows the resulting tradeoff between cost and the FCTs for 1 kB flows in the Datamining workload running at 25% load (similar trends were observed for other loads and flow sizes). As cost is reduced in hybrid RotorNet (by allocating a smaller percent of total network bandwidth to the packet switched network), FCTs begin to rise substantially due to increased network congestion.

C Reducing cycle time at scale

Larger Opera networks are enabled by higher radix ToR switches, which commensurately increase the number of circuit switches. To prevent the cycle time from scaling quadratically with the ToR radix, we allow multiple circuit switches to reconfigure simultaneously (ensuring that the remaining switches deliver a fully-connected network at all times). As an example, doubling the ToR radix doubles the number of circuit switches, but presents the opportunity to cut the cycle time in half by reconfiguring two circuit switches at a time. This approach offers linear scaling in the cycle time with the ToR radix, as shown in Figure 15. Assuming we divide circuit switches into groups of 6, parallelizing the cycle of each group, the cycle time increases by a factor of 6 from a $k = 12$ (648-host network) to a $k = 64$ (98,304-host network), corresponding to a flow length cutoff for "bulk" flows of 90 MB in the latter case.

D Additional scaling analysis

Figure 16 shows the performance-cost scaling trends for various traffic patterns for networks with $k = 12$ port ToRs. Comparing with Figure 12, we observed nearly identical performance between networks with $k = 12$ and $k = 24$, indicating the (cost-normalized) network performance is nearly independent of scale for all networks considered (folded Clos, static expanders, and Opera).

To analyze this result at a more fundamental level, we evaluated the average and worst-case path lengths for ToR radices between $k = 12$ and $k = 48$ for both Opera and static expanders at various cost points (α). Figure 17 shows that the average path lengths converge for large network sizes (the worst-case path length for all networks including Opera was 4 ToR-to-ToR hops for $k = 24$ and above). Given that the network performance properties of static expanders are

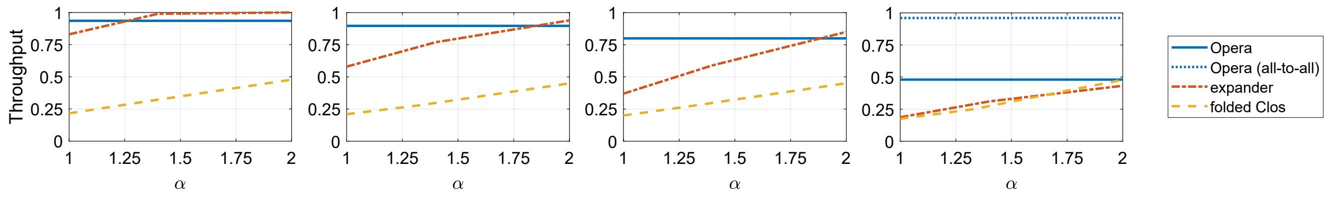

Figure 16: Throughput for (left to right) hotrack, skew[0.1,1], skew[0.2,1], and permutation workloads for $k = 24$ ports.

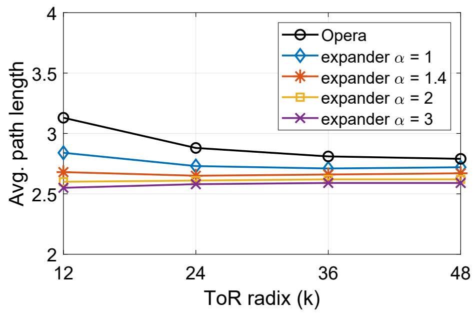

Figure 17: Path lengths for different network sizes (from $k = 12$ with ≈ 650 hosts to $k = 48$ with ≈ 98,000 hosts) and relative cost assumptions (α).

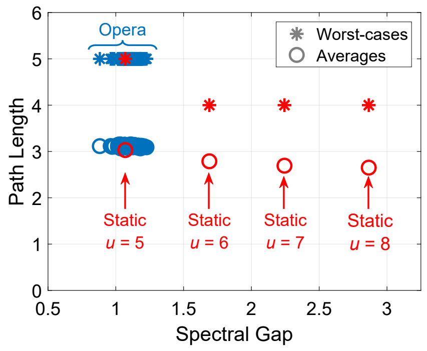

Figure 18: Average and worst-case path lengths and spectral gap for Opera and static expander networks. All networks use $k = 12$-port ToR switches and have between 644 and 650 hosts. Each data point for Opera corresponds to one of its 108 topology slices.

correlated with their path length properties [6], Figure 17 supports our observation that the cost-performance properties of the networks do not change substantially with network size.

E Spectral efficiency and path lengths

The *spectral gap* of a network is a graph-theoretic metric indicating how close a graph is to an optimal Ramanujan expander [25]. Larger spectral gaps imply better expansion. We evaluated the spectral gap for each the 108 topology slices in the example 648-host 108-rack Opera network analyzed in the text, and compared it to the spectral gaps of a number or randomly-generated static expanders with varying d:u ratios. All networks used $k = 12$ radix ToRs and were constrained to have a nearly-equal number of hosts. The results are shown in Figure 18. Note that expanders with larger u require more ToR switches (i.e., cost more) to support the same number of hosts.

Interestingly, when the number of hosts is held constant, we observe that the average and worst-case path length is not a strong function of the spectral gap. Further, we see that Opera comes very close to the best average path length achievable with a static expander, indicating that it makes good use of the ToR uplinks in each topology slice. Opera achieves this good performance despite the fact that we have imposed additional constraints to support bulk traffic with low bandwidth tax: unlike a static expander, Opera must provide a set of $N_{racks} = 108$ expanders across time, and those expanders are constructed from an underlying set of disjoint matchings.

F Additional failure analysis

Opera recomputes paths to route around failed links, ToRs, and circuit switches, and in general these paths will be longer than those under zero failures. Figure 19 shows the correlation between the degree of each type of failure and the average and maximum path length (taken across all topology slices).

For reference, we also analyzed the fault tolerance properties of the 3:1 folded Clos and $u = 7$ expander discussed in the paper. Figure 20 shows the results for the 3:1 Clos and Figure 21 shows results for the $u = 7$ expander. We note that Opera has better fault tolerance properties than the 3:1 folded Clos, but the $u = 7$ expander is better yet. This is not surprising considering the $u = 7$ expander has significantly more links and switches, as well as higher fanout at each ToR.

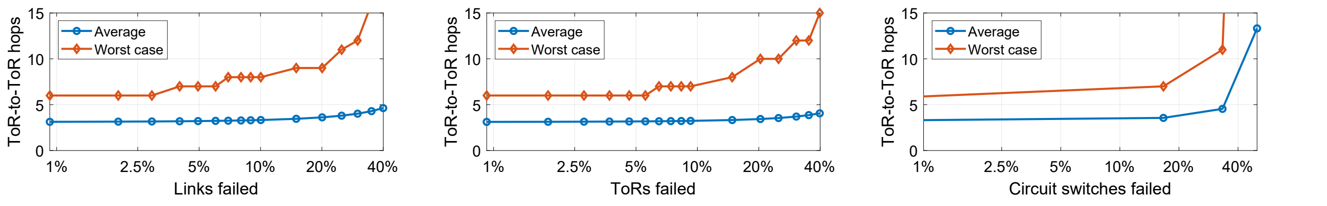

Figure 19: Average and worst-case path length of a 108-rack Opera network with 6 circuit switches and $k = 12$ port ToRs, for various failure conditions. Path length is reported for all finite-length paths. Figure 11 indicates how many ToR-pairs are disconnected (i.e. have infinite path length).

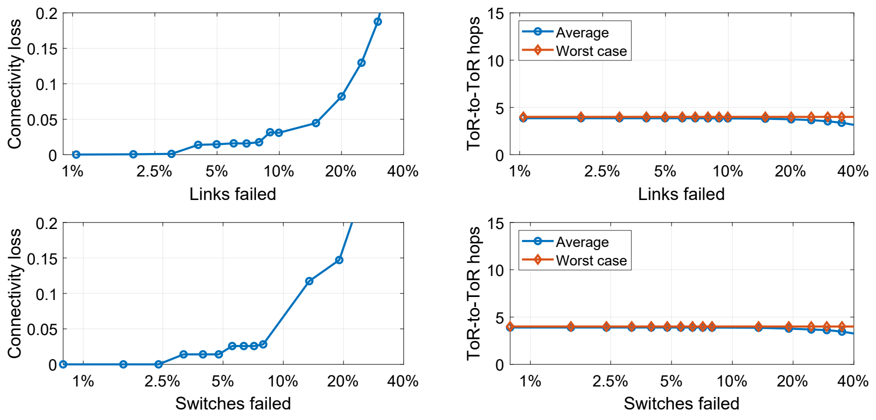

Figure 20: Connectivity loss and impact on path lengths in the 3:1 folded Clos for link failures (top two) and ToR failures (bottom two).

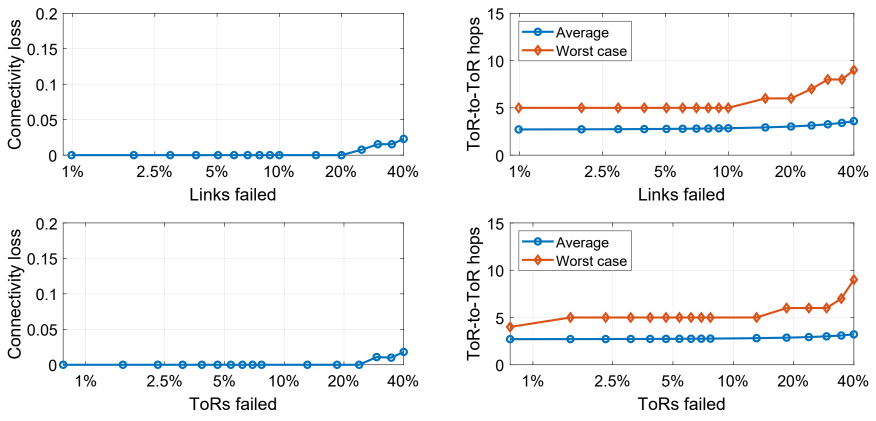

Figure 21: Connectivity loss and impact on path lengths in the $u = 7$ expander for link failures (top two) and ToR failures (bottom two).

Re-architecting Congestion Management in Lossless Ethernet

Abstract

The lossless Ethernet is attractive for data centers and cluster systems, but various performance issues, such as unfairness, head-of-line blocking and congestion spreading, etc., impede its large-scale deployment in production systems. Through fine-grained experimental observations, we inspect the interactions between flow control and congestion control, and are aware that the radical cause of performance problems is the ineffective elements in the congestion management architecture for lossless Ethernet, including the improper congestion detection mechanism and inadequate rate adjustment law.

Inspired by these insights and findings obtained in experiment investigations, we revise the congestion management architecture, and propose the Photonic Congestion Notification (PCN) scheme, which consists of two basic components: (*i*) a novel congestion detection and identification mechanism to recognize which flows are really responsible for congestion; (*ii*) a receiver-driven rate adjustment method to alleviate congestion in as short as 1 RTT. We implement PCN using DPDK NICs and conduct evaluations using testbed experiments and simulations. The results show that PCN greatly improves performance under concurrent burst workload, and significantly mitigates PFC PAUSE messages and reduces the flow completion time under realistic workload.

1 Introduction

Recently, lossless network has become an attractive trend in data centers and cluster computing systems. Generally, retransmission caused by packet loss readily leads to goodput decrease, completion time increase, and even missing application deadlines [9, 10, 50]. In addition, scaling transport protocols such as Remote Direct Memory Access (RDMA) and Fibre Channel (FC) over data center requires reliable transmission without packet loss due to network congestion [3, 15].

The lossless InfiniBand (IB) [16] is popular in HPC (High performance Computing) cluster systems, but modern data center has already been built with IP/Ethernet technologies that are also dominated in traditional Internet. The data center operators and cloud builders may do some IB, but much less ubiquitous than Ethernet. Furthermore, they are reluctant to simultaneously deploy and manage two separate networks within the same data center [39, 49]. IEEE DCB (Data Center Bridging) [4] is naturally imparted appeal as an enhanced capability of Ethernet, which enables Ethernet to be a consolidated switching fabric that can replace traditionally separated fabrics for special purposes, such as FC for storage, IPC (Interprocess Communication) for HPC, and Ethernet for LAN traffic. Converged Ethernet has significant performance, cost, and management advantages over maintaining separate switching fabrics [8]. To enable lossless semantics for a consolidated Ethernet, both hop-by-hop flow control PFC (Priority-based Flow Control) [6] and end-to-end congestion control QCN (Quantized Congestion Notification) [5] are developed in the link layer to enhance traditional Ethernet. The scalable lossless Ethernet switching fabric is definitely one of the potential candidates for building future data centers to accommodate promising applications, such as RDMA over Converged Ethernet (RoCE) [15], NVMe Over Fabrics [42] and resource disaggregation [23], etc..

Over the last decade, the rise of various Online Data-Intensive (OLDI) applications [31] and virtualized services [40] generate increasingly diverse traffic patterns and specific characteristics, e.g., incast, burst and mixture of mice/elephant flows, etc. [12, 25, 44]. Because it is unclear whether the lossless Ethernet can work effectively in large-scale data centers with such complex traffic, we conduct empirical and experimental investigations to attain the in-depth understanding of congestion management (CM) architecture in lossless Ethernet. The detailed observation and conjoint analysis uncover the radical root of some performance issues, such as congestion spreading and being susceptible to burst traffic. In the light of these insights, we re-architect CM in lossless Ethernet. The key findings and main contributions are summarized as follows.

• Revealing the inadequate elements in existing CM architecture for lossless Ethernet, including: a) The congestion detection mechanism cannot exactly identify congested or uncongested flows when they are churned in the same queue, so that it is unlikely to notify different sources to make discriminative rate adjustments. b) The slow evolution-based rate adjustment of end-to-end congestion control mismatches the fast operations of hop-by-hop flow control.

• Developing a novel CM scheme named Photonic Congestion Notification (PCN), which includes: a) A subtle congestion detection and identification mechanism, which can distinguish real congested flows so as to make a proper rate adjustment for congested or uncongested flows even if they are churned in the same accumulated queue. b) A receiver-driven rate adjustment rule, which can speed up the convergence of rate regulation, and is robust to burst traffic and adaptable to link capacity.

• Implementing PCN using DPDK NICs and conducting evaluations using both testbed experiments and ns-3 simulations. Extensive simulations in the large-scale network with synthesized traffic from real workload show that PCN suppresses PFC PAUSEs by 12%, 47% and 90% compared to QCN, DCQCN and TIMELY respectively, and reduces latency by at most 10x, 11.3x and 13.2x.

2 Background

2.1 Traffic Features in Data Centers

A variety of applications in data centers generate flows with a wide spectrum of traffic patterns and distributions. For example, web search service usually generates short and burst flows. On the other hand, the log file processing introduces few but long-lived flows to transmit bulk of data. Investigations on traffic in many operation data centers show the wide distribution traffic patterns [41]. The size of flows may range from 0.05KB to more than 100MB, and the distribution is quite scattered. Among all traffic, mice flows, which finish sending all packets before receiving any ACK, cannot be adjusted by the end-to-end congestion control scheme. Furthermore, many measurements [18, 19, 33, 41] indicate that the occurrence of mice flow is not only frequent but also bursty. The highly dynamic entering/leaving of mice flows would greatly shock queue length in switches and then the end-to-end latency [12, 13, 44]. Although these flows do not react to the congestion control scheme, they severely disturb the normal operations of the congestion management of switching fabric in data centers or cluster systems.

2.2 Congestion Management in lossless Ethernet

To guarantee losslessness and provide satisfying job completion time under such diverse traffic patterns, congestion management becomes critical and challenging in lossless Ethernet. IEEE DCB [4] specifies a framework for CM consisting of two basic functions, including end-to-end congestion control and hop-by-hop flow control.

The end-to-end congestion control regulates source sending rate actively according to the congestion information reflected by measured variables, such as switch queue length or RTT. Representative solutions include QCN developed by IEEE 802.1 Qau [5], the Layer-3 scheme DCQCN [49], and the RTT-based scheme TIMELY [36]. Although these protocols can constrain the switch queue length and accordingly reduce the packet loss ratio, there is not enough guarantee of zero packet loss. Actually, the uncontrollable burst may be already lost before sources are aware of network congestion, especially when the congestion control loop delay is relatively large or the degree of burst and concurrency is heavy. What is worse, a large number of congestion control mechanisms [5, 21, 27, 36, 38, 49] start flows at the line rate to accelerate the completion of mice flows, which exacerbates the loss problem.

To avoid packet loss due to uncontrollable burst, Priority-based Flow Control (PFC) is defined by IEEE 802.1Qbb [6] to ensure losslessness. With PFC, a switch sends a PAUSE frame to its upstream device (a switch or a NIC) to stop transmission when the ingress queue length exceeds a certain threshold. And a RESUME frame is sent when the queue drains below another threshold. Although PFC can guarantee zero packet loss due to network congestion, it leads to some performance issues such as head-of-line blocking (HLB), unfairness and even deadlock [26, 28, 45, 46, 49]. When PFC is triggered incessantly, the local congestion spreads back to both congested and uncongested sources, and then the network throughput and flow completion time are drastically harmed. The fundamental solution for these performance issues is to eliminate persistent congestion by end-to-end congestion control schemes such that PFC is not triggered incessantly [46, 49].

In total, the end-to-end congestion control needs PFC to prevent packet loss due to transient congestion of uncontrollable burst, and PFC also needs end-to-end congestion control to eliminate persistent congestion. That is, the end-to-end congestion control and hop-by-hop lossless flow control are complementary to each other in lossless Ethernet.

3 Experimental Observation and Insights

3.1 Observations

Although both end-to-end congestion control and hop-by-hop flow control can meet their goals independently under the diverse traffic patterns, their interaction would induce unexpected issues. (1) When burst short flows enter into the network, existing flows in the network would still suffer from the PFC-related side-effects, i.e., congestion spreading and unfairness. (2) After burst leaving the network, congestion control would not efficiently and timely reallocate available bandwidth.

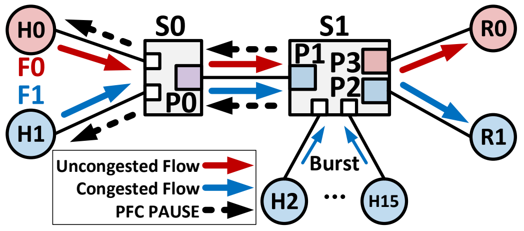

Figure 1: Compact and typical network scenario.

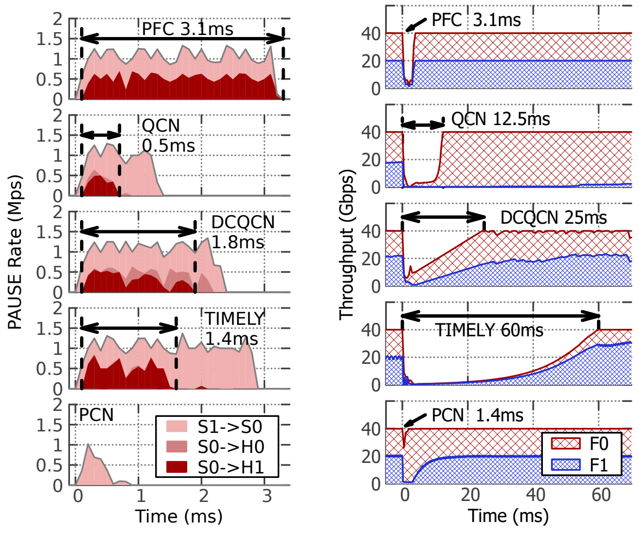
Most existing work considerably concerns the single element in the CM of lossless Ethernet (e.g., congestion control [36, 49]) or special symptoms (e.g., HLB [7], deadlock [28, 29, 45]), but unconsciously overlooks the interaction of congestion control and flow control under diverse traffic patterns, thus is likely to shield the essential cause of aforementioned performance issues. Subsequently, we first conduct a careful, fine-grained and multi-variable observation, and then infer the radical root of special symptoms and issues.

Specifically, we define a compact and typical network scenario, which is not too complex to hinder us capturing the basic principles of both key elements and core mechanisms in the CM of lossless Ethernet. At the same time, it should have sufficiently common features so as to ensure the obtained conclusions and insights are without loss of generality. As shown in Fig.1, we choose a basic unit of a typical network topology in data center, like Clos [22] and Fat-Tree [11], where 16 senders and 2 receivers are connected by two switches. All links are 40Gbps, with a propagation delay of $5\mu s$. The traffic is a mixture of long-lived flows and concurrent burst mice flows. In detail, H0 and H1 start long-lived flows to R0 and R1, respectively. Assume that F0 and F1 achieve their fair bandwidth allocation of the 40Gbps bottleneck link from switch S0 to S1 at the beginning of simulation. At time 0, each sender of H2$\sim$H15 generates 16 short flows to R1 at line rate (i.e., 40Gbps) simultaneously, and the size of each flow is 64KB. Since each mice flow only lasts for $12.8\mu s$ ($<$1 RTT), it is uncontrollable by the end-to-end congestion control mechanisms. These uncontrollable burst flows last for about 3ms in total. We conduct simulations with ns-3 to investigate various CM schemes including PFC, PFC+QCN, PFC+DCQCN, and PFC+TIMELY. All parameters are set to the default values recommended by the related standard [5, 6] and literature [36, 49], and the details are given in § 7. The results are presented in Fig.2.

When PFC is solely employed, the input port P1/S1 pauses its upstream port P0/S0 to avoid packet drops, and the port P2/S1 is congested by concurrent burst flows. Subsequently, "Pause" spreads upstream along with the long flow, and both H0 and H1 are eventually paused. We measure the *PAUSE Rate* (i.e., the rate of transmitting PAUSE messages), and the instantaneous throughput. As shown in Fig.2(a), a congestion tree, which roots from S1, spreads to H0 and H1, appears



(a) Pause rate (b) Throughput

Figure 2: Interactions between PFC and existing congestion controls.

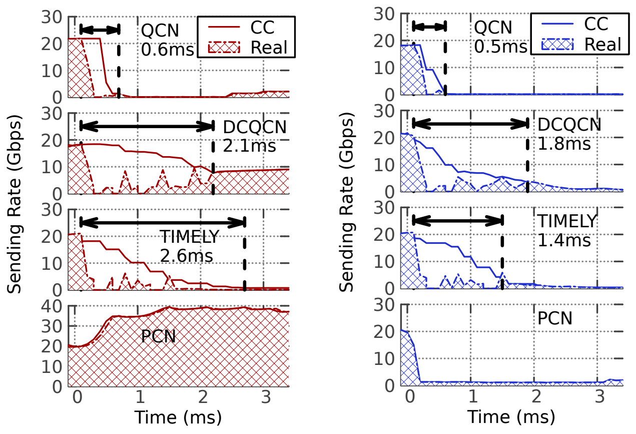
and lasts for 3.1ms (>100 RTT) until the burst mice flows finish. During this process, both the congested flow F1 and uncongested flow F0 face great throughput loss as shown in Fig.2(b), no matter whether they are responsible for the real congestion at port P2/S1.

When QCN, DCQCN or TIMELY works with PFC jointly, the congestion tree still appears, as shown in Fig.2(a). However, its lasting time is reduced to 0.5ms ($\approx$17RTT), 1.8ms ($\approx$57RTT) and 1.4ms ($\approx$47RTT). Surprisingly, the two long flows F0 and F1 may fail to recover to their initial throughput quickly after both concurrent burst flows and congestion tree disappear. As illustrated in Fig.2(b), the throughput loss unexpectedly lasts for 12.5ms with QCN, 25ms with DCQCN and 60ms with TIMELY, respectively, even if the concurrent burst flows last for only 3ms. Totally, the performance of PFC+QCN, PFC+DCQCN and PFC+TIMELY is worse than PFC in this scenario.

3.2 Interaction Issues

To understand the long duration of congestion tree and unexpected great throughput loss, we analyze the dynamic behaviors of flows in detail, and reveal the interaction issues between hop-by-hop flow control and end-to-end congestion controls. We believe that careful analysis and rigorous reasoning from interactive behavior could enlighten us the root causes of various performance issues reported by existing work [26, 34, 37].

1) PFC confuses congestion detection. In above experiments, an ideal end-to-end congestion control scheme should only throttle F1 to 2.5Gbps and allocate flow F0 the remaining



(a) Uncongested flow F0 (b) Congested flow F1

Figure 3: The responsiveness of different congestion controls.

bandwidth (37.5Gbps) of bottleneck link from S0 to S1. However, this ideal bandwidth allocation cannot be achieved even existing congestion controls (QCN, DCQCN and TIMELY) are employed. To explore the cause of this phenomenon, we record the sending rate regulated by the end-to-end congestion control and the real sending rate of the uncongested flow F0 and congested flow F1. The results are presented in Fig.3(a). When congestion tree exists, both the queue length and RTT increase at port P0/S0. Because senders infer congestion according to the feedback information (i.e., queue length or RTT), F0 is also regarded as congested. Hence, the sending rate of F0 is reduced by QCN, DCQCN and TIMELY, even if it contributes nothing to the real congestion point at P2/S1. Therefore, after the congestion tree disappears (as marked by the dash line in Fig.3(a)), the sending rate of F0 is very low although it escapes from the collateral damage of PFC.

In summary, it takes some time for congestion controls to eliminate congestion tree. In this transient process, the large queue length and RTT due to congestion spreading caused by PFC would mislead congestion controls to decrease the sending rate of victim flows (F0 in this example).

2) The slow evolution-based rate adjustment of end-to-end congestion control mismatches the fast hop-by-hop operations of PFC. Fig.3 also unveils the reason why the congestion tree is still created and lasts for tens of RTTs with QCN, DCQCN and TIMELY. Although F0 and F1 are throttled immediately when the concurrent burst mice flows enter, it takes a long time for QCN, DCQCN and TIMELY to reduce the sending rates (the regulation time of different congestion controls are marked in Fig. 3). However, PFC works hop-by-hop and thus the congestion spreads very fast. During the rate decrease of F0 and F1, PFC is triggered incessantly. So the real sending rates of F0 and F1 are mainly determined by PFC rather than end-to-end congestion control, thus the throughput of both F0 and F1 are small. This is why the congestion tree spreading still occurs even if the end-to-end congestion control is employed.

This problem is attributed to the mismatch between the slow evolution-based rate adjustment of end-to-end congestion control and the fast operations of hop-by-hop flow control. More specifically, when the available bandwidth reduces suddenly due to the concurrent burst mice flows, the end-to-end congestion control schemes have no idea of the target rate thus only make rate decrease based on the current sending rate step by step, which is at most 50% per update period. Moreover, the update period is about 20μs (time of transmitting 100 packets) for QCN, 50μs for DCQCN and at least 12.5μs (time of sending 64KB segment) for TIMELY. What's more, when the throughput of F0 and F1 is very small, DCQCN may not receive a single packet in one update period, and would start rate increase automatically. As a result, tens of update periods may be needed to decrease F1's rate to approach the remaining available bandwidth, as shown in Fig.3.

3) The rate increase is inadaptable to dynamic network conditions. After the concurrent burst mice flows vanish and the congestion tree disappears, the sending rates of both F0 and F1 have been throttled, and need to increase step by step. QCN and DCQCN increase the sending rate towards the target rate stored at previous rate decrease in a binary-search way and raise the target rate linearly with a pre-configured value periodically. TIMELY adds the sending rate with a fixed value in each update period. Briefly, all rate increasing methods are linear. Consequently, they fail to take full use of available bandwidth immediately after the disturbance of concurrent burst mice flows. This is why flows F0 and F1 need much longer time to recover to full throughput as presented in Fig.2(b). Moreover, the step of rate increase in each update period needs to be configured adaptively according to network bandwidth. For example, the parameters of QCN, DCQCN and TIMELY tuned for 40Gbps link may be too conservative for 100Gbps link, but too aggressive for 1Gbps link. The tuning of parameters would become difficult in practice.

4 Principles

The root cause of all aforementioned performance issues can be concluded as the existing end-to-end congestion control scheme cannot cooperate with hop-by-hop flow control well. To address these issues, we revisit the architecture of CM. We first present a discussion about which elements in existing congestion management introduce these performance issues, and then propose the ways to overcome these incongruities by re-architecting the CM for lossless Ethernet. Briefly, the principles are threefold.

1. The uncongested flow becomes a victim because the existing congestion management cannot identify real congested flows. The operation of PFC would back pressure congestion and contaminate current congestion signals

(a) Real-congestion.

(b) Non-congestion.

(c) Quasi-congestion.

Figure 4: Different states of egress port.

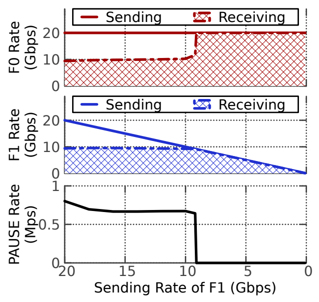


Figure 5: Relationship of PAUSE and receiving rate.

(i.e., queue length and RTT). We need to find out a new mechanism to properly distinguish which flows are really responsible for congestion.

2. Congestion spreading is caused by the slow evolution-based rate decreasing mechanism, thus a fast and accurate rate decreasing solution is indispensable.

3. When burst traffic vanishes, the long-lived flows mainly rely on the linear rate increase to share the released bandwidth, which leads to sluggish convergence and bandwidth waste. Therefore, a prompt rate increasing mechanism should be developed.

4.1 Congestion Detection and Identification

Traditionally, the end-to-end congestion control detects the network congestion based on the measured variables like switch queue length and RTT. However, this congestion detection mechanism is confused by PFC in lossless Ethernet. We need to revise the congestion detection and identification mechanism to avoid this confusion and then correctly identify which flows are really congested.

4.1.1 Detecting Congestion

To aid detecting congestion, we classify the egress ports of switches into the following three states.

Real-Congestion: The ports in real-congestion fully utilize the egress links and the excessive incoming packets accumulate in the buffer, as shown in Fig.4(a). For example, in the previous simulation, when the concurrent burst mice flows start, port P2/S1 is in real-congestion.

Non-Congestion: As illustrated in Fig.4(b), no packets accumulate in the buffer of egress ports, and thus the incoming packet is transmitted immediately. That is, the egress links work normally with utilization less than 100%. The port P3/S1 in above simulation is always in non-congestion.

Quasi-Congestion: The ports in quasi-congestion also keep certain queue length, but the associated egress link is not fully utilized due to PAUSE and RESUME, as depicted in Fig.4(c). Therefore, it is unknown whether the incoming rate of packets exceeds the link capacity or not. For example, in the previous simulation, port P0/S0 turns into quasi-congestion in face of PFC triggers. However, because flows passing through this port would suffer large queue length and delay, the congestion detection mechanism in existing congestion controls (e.g., QCN, DCQCN and TIMELY) dogmatically judges that these flows experience congestion.

Consequently, to distinguish these different states of the egress ports, especially the quasi-congestion state, the impacts of PFC should be taken into consideration when detecting congestion.

4.1.2 Identifying Congested Flows

Owing to the impact of PFC, packets from both congested and uncongested flows are likely to backlog in the same queue length in egress port, which is paused by its downstream ingress port. Therefore, it may be proper to predict potential congestion depending on the queue length of egress port, but indeed unwise to make congestion judgment and provide indiscriminate information to all flow sources, just like QCN and DCQCN. TIMELY also hardly distinguishes whether the flow actually traverses the real congested port by merely measuring RTT and its variations.

To avoid the confused congestion information in existing CM architecture to perturb the normal interaction between flow control and congestion control, and even lead to mutual damage, we advocate decoupling congestion detection and identification functions during re-architecting the CM of lossless Ethernet. The switch is responsible for detecting congestion and providing congestion signals through monitoring the related network status. The end systems synthesize relevant information to judge congestion and identify whether its flow is really congested.

4.2 Receiver-Driven Rate Decrease

The ideal congestion control scheme should throttle the congested flows towards a proper rate directly. To achieve this goal, we need to obtain this proper rate at first. In lossless Ethernet, the proper rate should not trigger PFC but can still keep high throughput. To find this rate, we should answer the following two sub-questions: 1) what is the minimum rate for congested flows to not lose throughput? 2) what is the maximum rate for congested flows to not trigger PFCs?

The first answer is intuitive. It should be the arrival rate of receiver. We define it as *Receiving Rate*. On one hand, the path of congested flows must have at least one real congested port, thus the sum of receiving rates of all flows just achieves the capacity of bottleneck link. On the other hand, if the congested flow decreases rate to less than its receiving rate, there must be idle bandwidth on the bottleneck link, which means that this flow can actually send more data. Thus, the receiving rate is the minimum rate for the congested flows to not lose throughput. The power of receiving rate has also introduced in recent designs like Fast TCP [32], NDP [27] and Homa [38]. They both take advantage of receiving rate to achieve fast convergence when detecting congestion.

Fortunately, the receiving rate is also the answer to the second sub-question. That is, when the sending rate does not exceed the receiving rate, the packets of congested flows do not accumulate at the ingress port of congested switches and then PFCs are not triggered. What's more, this phenomenon occurs regardless of whether the egress port of the same switch is congested or not.

To vividly illustrate this phenomenon, we repeat the experiment in the network scenario given in § 3.1. We start H2∼H4 at line rate to simulate uncontrollable bursts. And both the congestion-irrelevant flow F0 and congestion-relevant flow F1 are controlled by rate limiters. The sending rate of F0 is fixed at its fair allocation (i.e., $20Gbps$), and the sending rate of F1 varies from $20Gbps$ to 0 step by step manually. When the simulation is running, both flows are throttled by their fixed rate limiters and PFC. The sending rates set in rate limiters and receiving rates at the receiver side for these two long flows, as well as the generating rate of PAUSE frames on ingress port p1/S1, are drawn in Fig.5. Obviously, when the sending rate of congestion-relevant flow F1 exceeds 9.5Gbps, its receiving rate is only 9.5Gbps. At the same time, the ingress port p1/S1 generates PFC PAUSEs persistently and the congestion-irrelevant flow F0 is collaterally damaged. On the contrary, when the sending rate of F1 does not exceed 9.5Gbps, no PAUSE frame is generated from port p1/S1 and the congestion-irrelevant flow F0 can achieve its expected throughput. This experiment indicates that throttling congested flows to their receiving rate can prevent more PFC triggers on the associated egress ports, and then suppress congestion spreading in this branch of congestion tree.

Consequently, we obtain a valuable insight, that is **decreasing the rate of congested flows to their receiving rate directly**. It inspires us to design a receiver-driven rate decreasing algorithm to work in harmony with PFC in lossless Ethernet, which will be elaborated in the following.

4.3 Gentle-to-Aggressive Rate Increase

The rate increase should accelerate non-congested flows to rapidly share available bandwidth and then keep at full utilization stably simultaneously. The rate-increase rule of a non-congested flow is needed in two cases.

1) The flow has just turned its state from congested to non-congested. According to our receiver-driven rate decrease principle, the flow rate has reduced to its receiving rate, which implies no PFC trigger and no throughput loss. Thus, the flow has little space for rate increase. Therefore, the rate of this flow should be increased gently.

CNP
Receiver (NP)
• Identify Congested Flows
• Rate Estimator
• Congestion Notification

Figure 6: PCN framework.

2) The flow has remained in the non-congested state for several continuous update periods. In this case, the flow can increase more aggressively to occupy the available bandwidth. Since our receiver-driven rate-decrease rule can sharply reduce the overflowed traffic, the rate increasing mechanism can be designed more aggressively to fulfill network bandwidth quickly.

Therefore, we obtain a suggestion, that is **increasing the rate of non-congested flows gently at first and then aggressively**. It guides us to design a gentle-to-aggressive rate increasing algorithm that can guarantee stability and fast convergence simultaneously.

5 PCN

In this section, based on the principles in § 4, we re-architect congestion management for lossless Ethernet and propose Photonic Congestion Notification (PCN)[1], which is designed to be a rate-based, end-to-end congestion control mechanism to work with PFC in harmony. As shown in Fig.6, PCN is composed of three parts: reaction point (RP), congestion point (CP) and notification point (NP). In general, the CP, which always refers to the congested switch, marks passing packets using a Non-PAUSE ECN (NP-ECN) method to detect whether the egress ports are in real congestion. Notice that a packet marked with NP-ECN does not definitely mean encountering congestion, it requires NP to make the final decision. The NP, i.e., the receiver, identifies the congested flows, calculates their receiving rate and sends the congestion notification packets (CNP) to RP periodically. The RP, which is always the NIC of senders, adjusts the sending rate of each flow according to the information in CNPs. Subsequently, we introduce each part of PCN in details.

5.1 CP Algorithm

We develop the NP-ECN method to detect congestion and generate the congestion signal. The CP algorithm follows the state machine in Fig.7. Suppose that when one egress port of a switch receives a RESUME frame from its downstream

[1]We liken current schemes (e.g. QCN, DCQCN and TIMELY) to quantum, because they can only quantify the network congestion as a whole, but cannot provide different congestion notifications for congested flows and non-congested victim flows, which seems in *quantum entanglement*. And as an analogy, our design is like the photon, which breaks down the entanglement, i.e., directly recognizing the congested flows and allocating them the appreciate rates.

node, there are N packets in the associated waiting queue. NP-ECN will set its counter PN=N. Then the port restarts to transmit packets. Each time a packet is transmitted, the counter is decremented by one, until all of the N paused packets have been transmitted. For these N packets, they will not be marked. And for the later packets that have not been paused and correspondingly PN=0, the switch will mark them with ECN in the traditional method, with the threshold as zero.

In this way, all packets in the real-congestion egress ports will be marked with ECN. On the contrary, the packets are never marked with ECN in the non-congestion ports. And for quasi-congestion ports, the paused packets are not marked with ECN. Meanwhile, when the queue of ingress port is not empty, the packets arriving and leaving the ports in RESUME status are marked with ECN, namely, packets in quasi-congestion ports are partially marked with ECN. In PCN, CP only works for marking a congestion signal on packets and lets the NP node finally determine whether the flow is congested.

It is noted that NP-ECN mechanism can be implemented easily based on the commercial switch equipped with both ECN and PAUSE functions. Compared to the traditional ECN method in commodity switches, the NP-ECN method of PCN requires one more counter per port, and several more lines of logic. The space and computing complexities of modification are both O(1).

5.2 NP Algorithm

The functions of NP include identifying congested flows, estimating receiving rate and sending Congestion Notification Packets (CNP) periodically. T denotes the CNP generation period.

Identifying congested flows: NP identifies the congested flows based on the ECN signal marked by the NP-ECN mechanism. A flow is regarded to be congested if 95% packets received in CNP generation period T are marked with ECN. The value 95% is set empirically to filter some tiny disturbances in practice, such as queue oscillation and priority schedule, which make that one or more packets of real-congested flows are unlikely marked with ECN.

Estimating receiving rate: The receiving rate is calculated directly with T divided by the total size of arrived packets. Noticeably, the receiving rate of flow may be so small that just one packet arrives in several CNP generation periods. To address this special case, PCN also records the inter-arrival time of packets at the NP. When the inter-arrival time is larger than T, NP estimates the receiving rate by replacing T by the inter-arrival time.

Generating CNPs: The NP sends CNPs to notify the source of flow with the receiving rate in period T, which is set to be $50\mu s$ similar to DCQCN. Moreover, PCN generates CNP explicitly when the flow needs either rate-decrease or rate-increase, different from DCQCN which only generates CNPs to notify rate-decrease. And the CNP is not generated when none of its packets is received in period T. In details, the format of CNP packets is compatible with the CNP packet in RoCEv2 [15], as shown in Fig.9. The main information encapsulated by CNP includes 1-bit ECN in the IPv4/IPv6 header and 32-bit RecRate in the reserved segment, which carries the receiving rate normalized by $1Mbps$. The state machine of NP algorithm is summarized in Fig.8.

5.3 RP Algorithm

Algorithm 1 describes the pseudo code of how RP adjusts the sending rate according to the information in CNP. In the beginning, flows start at the line rate to improve flow completion time (FCT) for short flows.

Rate Decrease: When RP receives a CNP with ECN-marked, it conducts a rate decrease following the rule in line 6. Instead of resetting the sending rate to the receiving rate di-

11:    $w \leftarrow w \cdot (1 - w) + w_{\max} \cdot w$
12: until End of flow
```

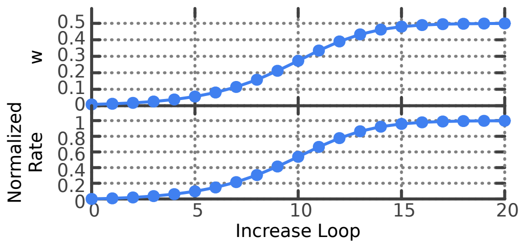

Figure 10: Evolution of w and rate when a sender receives continuous CNP notifying rate increase.

rectly as discussed in § 4.2, a small discount $w_{\min}$ is conducted, such that the build-up queue in switches can be drained out. Accordingly, during draining the build-up queue, the *recRate* may be larger than the *sendRate*, the sending rate should be non-increasing in line 6.

Rate Increase: When RP receives a CNP without ECN-marking, it makes rate adjustments following the law in line 10 and 11. Specifically, the RP increases the sending rate by computing a weighted average of its current value and the line rate. This rate increase law is effective in multiple folds.

(1) The ideal sending rate can be reached as it always stays between the current sending rate and the line rate.

(2) Since the value of w is identical for all flows, the slow flows increase more aggressively than fast flows, which is beneficial to fairness.

(3) The weight w changes automatically from the minimum value $w_{\min}$ to the maximum value $w_{\max}$ such that PCN can realize the gentle-to-aggressive rate increase as discussed in § 4.3. For example, when $w_{\min} = 1/128$, $w_{\max} = 0.5$, and CNPs without ECN-marking are received successively, the evolution of w and the sending rate from 0 to the lineRate are presented in Fig.10. The sending rate grows by no more than 10% of the line rate in the first 5 CNPs, but increases to 95% of the line rate after only 15 CNPs.

(4) Any parameter configurations are not specially required to adapt to the upgrade of link capacity from 1Gbps to even 400Gbps.

5.4 Discussion

As discussed in §4, the main root of performance issues in current lossless Ethernet is the improper interaction between PFC and end-to-end congestion control schemes. We demonstrate that PCN solves the core problems in lossless Ethernet using a minimal implementation cost.

Implementation requirement: To implement PCN, a little switch modification is needed. Compared to the traditional ECN method in commodity switches, the NP-ECN method of PCN (see Fig.7) only requires one more counter per port, and several more lines of logic. The space and computing complexities of modification are both O(1).

Benefits: To demonstrate the advantages of PCN, we enable PCN and repeat the simulations in § 3.1, and the results are also inserted into Fig.2 and Fig.3, respectively. The results in Fig.2(a) tell that PAUSE in both S0->H0 and S0->H1 links are completely avoided and only a handful of PAUSE fleetingly appears in the S1->S0 link, but congestion spreading is quickly suppressed and congestion tree is not generated. The results in Fig.3 confirm that PCN can help the uncongested flows grab idle bandwidth quickly, and regulate the congested flows to proper rates correctly and promptly. PCN increases F0 to fully utilize network bandwidth during concurrent bursts. After the concurrent burst vanishes, F0 and F1 fairly share bandwidth without wasting network resources or triggering PFC PAUSEs as shown in Fig.2(b).

6 Theoretical Analysis and Parameter Setting

6.1 Theoretical Analysis

We build a fluid model of PCN and analyze its performance, including convergence, fairness, and stability. The main conclusions are summarized in the following propositions and the detailed analyses are listed in Appendix A.

Proposition 1. *PCN can achieve convergence of total rate towards the bottleneck capacity as fast as in only one control loop, i.e., one RTT.*

Proposition 2. *PCN can always fairly share the bottleneck link, i.e., $R_i \rightarrow \frac{C}{N}$ regardless of the initial sending rates and parameter settings, where R_i is the receiving rate of flow i, N is the number of sources sharing the bottleneck link, and C is the link capacity.*

Proposition 3. *PCN is stable and the oscillation of both the queue length and rate are bounded in the steady state. The maximum oscillation ranges of queue length (ΔQ) and receiving rate of flow i (ΔR_i) are*

$$\Delta Q = (N - 2 + w_{\min}) w_{\min} CT \tag{1}$$

$$\Delta R_i \rightarrow w_{\min} C \tag{2}$$

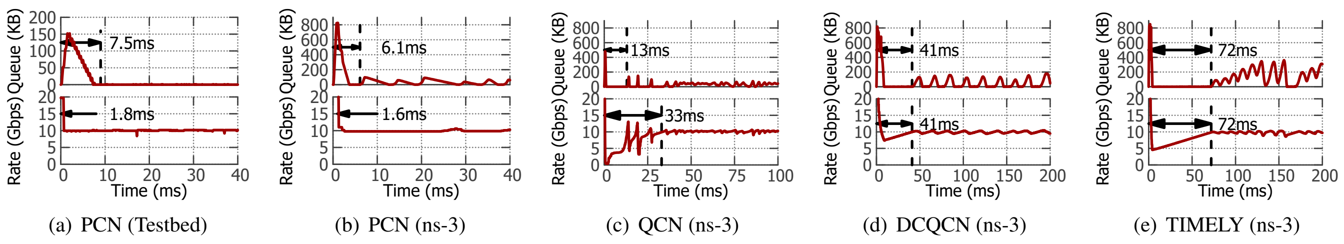

Figure 11: Dynamic behavior of PCN, DCQCN and TIMELY.

6.2 Parameter Settings

Based on the above conclusions, we can obtain some practical guidelines towards parameter settings, including the CNP generating period T, and the minimum and maximum value of weight factor w.

CNP generating period T: It should be identical for all flows. It is noteworthy that T is also the control loop period, thus a large T will damage the responsiveness of PCN. However, in practice, there exists an inherent control loop delay, i.e., RTT. If T is smaller than RTT, PCN is hardly aware of status change in the last control loop, which leads to overmuch adjustments and considerable oscillations. Therefore, the recommended T should be the maximum value of RTT in networks, which can be estimated in advance.

Minimum weight $w_{\min}$: The value of $w_{\min}$ should make a trade-off between fast convergence and stability. A large/small $w_{\min}$ will speed up/slow down the convergence of queue length, but make the flow oscillate more/less aggressively at steady state. According to Proposition 2, Equation (1) and (2), we recommend the proper value of w to be $0.1/N$, which limits the aggregate rate oscillation not exceeding $0.1C$ and the queue oscillation less than $0.1CT$.

Maximum weight $w_{\max}$: The value of $w_{\max}$ determines how aggressively a flow increases when the network is detected under-utilized continuously. Thus an aggressive $w_{\max}$ is recommended, i.e., $w_{\max} = 0.5$.

7 Evaluation

We evaluate the performance of PCN in a variety of settings using testbed experiments (§ 7.1) and ns-3 simulations (§ 7.1 $\sim$ 7.4), and compare it against QCN, DCQCN and TIMELY. The functional modules of our simulator are developed based on the open project for DCQCN [48] and code snippet (per-packet pacing version) for TIMELY [35], and all parameters are set to the default values recommended by the related literatures [36,49]. All experiments enable PFC with $X_{OFF} = 512KB$.

7.1 Basic Properties

In this subsection, we verify the basic function of PCN using simple synthetic microbenchmarks.

Testbed setup: Since current commodity switches do not provide the interface to modify the ECN-marking logic, we implement PCN upon DPDK [1]. We plug two Intel 82599 NICs to one PowerEdge R530 server to act as PCN's CP. Each NIC has two 10Gbps Ethernet ports and the server is equipped with dual Intel Xeon E5-2620 v3 CPUs (6 cores, 2.4GHz). Thus, the server can work as a four-port switch. By deploying DPDK in the server, both PFC and NP-ECN are implemented based on the reference test-pipeline project [2].

DPDK also enables the implementation of our special packet processing required at NICs. On the sender side, the rate limiter at a per-packet granularity is employed for rate adjustment. On the receiver side, PCN receives packets, records ECN marking information, and sends back CNP packets periodically.

Scenario: We use a dumbbell topology where 3 pairs of sender and receiver share the same 10Gbps bottleneck link. Specially, the number of flows on one of three pairs is twice of that on other two. We run this experiment on both hardware testbed and ns-3 simulator for cross-validation. In both testbed experiments and simulations, the RTT is measured to be about $500\mu s$, thus the same configuration is kept in simulations.

Fine-grained observation: First, four long-lived flows are launched and the dynamic behaviors of PCN, QCN, DCQCN and TIMELY is observed. The evolutions of queue length in bottleneck and the aggregate sending rate are depicted in Fig.11. As illustrated in Fig.11(a) and 11(b), PCN exhibits the same performance on the testbed and simulator. Comparing Fig.11(b) to 11(c), 11(d) and 11(e), PCN outperforms QCN, DCQCN and TIMELY in terms of fast convergence and stability.

In both testbed experiment and simulation, PCN regulates the aggregate sending rate to the bottleneck capacity within 2ms (4 RTT), which is 20x, 25x and 45x faster than that with QCN, DCQCN and TIMELY, which is benefited from the receiver-driven rate-decrease method of PCN. It can throttle the incoming traffic to match the bottleneck capacity directly, rather than explore the available bandwidth round by round. Consequently, PCN can limit the bottleneck queue length

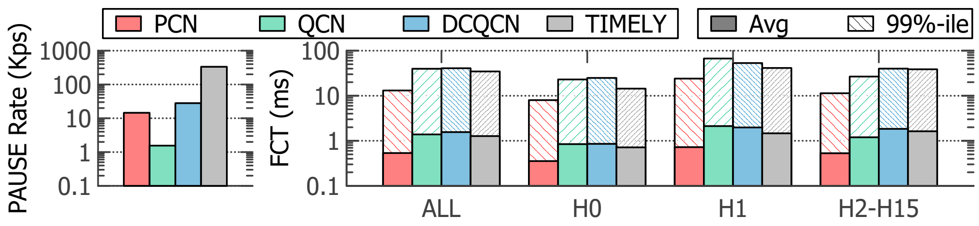

Figure 12: Generating rate of PAUSEs and FCT under concurrent burst.

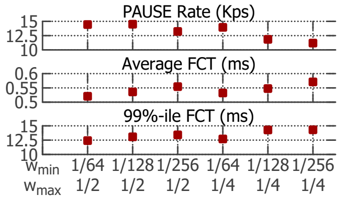

Figure 13: Performance of PCN with different w_{min} and w_{max}.

at a very low level (about several packets) in no more than 7.5ms (∼15 RTT), while it costs 13ms (∼26 RTT) for QCN, 41ms (∼80RTT) for DCQCN and 72ms (∼144 RTT) for TIMELY.

In the steady state, PCN oscillates with low amplitude in both testbed experiment and simulation. The queue length almost approaches zero and the aggregate sending rate keeps near 10Gbps. QCN has the similar performance. However, both DCQCN and TIMELY lead to large oscillations and high buffer occupancy. This advantage comes from the congestion detection method of PCN. The threshold of queue length for ECN marking is set to zero, rather than a positive value.

7.2 Burst Tolerance

One advantage of PCN is robustness against PFC triggers caused by concurrent burst flows. Next, we use the basic scenario in Fig.1 to evaluate PCN in the typical head-of-line scenario. All links are 40Gbps with $5\mu s$ propagation delay, hosts $H0 \sim H15$ generate flows according to the heavy-tailed Hadoop workload [44] with exponentially distributed inter-arrival time. Specially, the workload generators at hosts $H2 \sim H15$ are set to be synchronous to simulate concurrent bursts. The target load at the two bottleneck links is set to 0.6. We measure the pause rate and flow completion time (FCT) of PCN and compare them with QCN, DCQCN and TIMELY.

The left subgraph in Fig.12 shows the generating rate of PFC PAUSEs. QCN triggers the smallest PAUSEs, and PCN can prevent at least 53% and 92% of PFC PAUSEs compared to DCQCN and TIMELY, respectively. And the average and 99_{th} percentile FCTs from different hosts are drawn in the right subgraph in Fig.12. The solid bar at the bottom indicates the average FCT and the upper stripe bar shows the 99_{th} percentile value. Clearly, PCN performs better than QCN, DCQCN and TIMELY for all kinds of hosts.

1) Actually, QCN avoids PAUSEs by drastically reducing the sending rate, which likely leads to poor link utilization and high FCT for long-lived flows. On the contrary, PCN can prevent PAUSEs without harming throughput, and then achieves 2.25x∼3.03x shorter FCT than QCN.

2) For the victim host H0, PCN achieves 2.4x and 2.0x faster average FCT compared to DCQCN and TIMELY, which is mainly benefited from a fact that PCN can mitigate PFC triggers between two switches. For the concurrent burst from $H2 \sim H15$, PCN can keep the buffer at egress port P2 nearly empty, and thus obtain an improvement of 3.5x and 3.4x in the 99_{th} percentile FCT compared to DCQCN and TIMELY. And for host H1, whose flows traverse two congested switches, the flow transmission speed of PCN is at least 2.2x of DCQCN and 1.7x of TIMELY.

Table 1: Flow size distribution of realistic workloads.

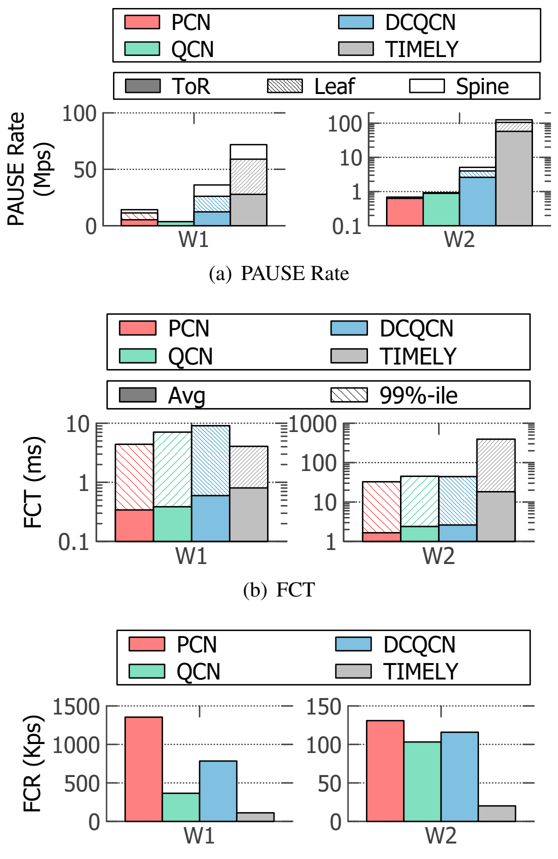
7.3 Parameter sensitivity

As discussed in § 6.2, the minimal and maximal of weight factor w_{min} and w_{max} determine the convergence speed and oscillation amplitude in steady state. To evaluate the parameter sensitivity, we repeat the concurrent burst simulation with different w_{min} and w_{max} values. Fig.13 shows the result. With the changes of w_{min} and w_{max}, PCN can always achieve the satisfied performance. As w_{max} decreases, switch S0 receives fewer PFC PAUSEs from its downstream device, but the 99%-tile of FCT grows a little. Meanwhile, the value of w_{min} has almost no impact on pause rate, but the small w_{min} increases FCT slightly. The results indicate that our recommended parameter settings are proper.

7.4 Realistic Workloads

In this subsection, we evaluate the performance of PCN with realistic workload.

Scenario: We consider an 8-pod clos network. Each pod consists of 2 Leafs, 4 ToRs, and 64 hosts, and communicates with other pods through 8 spines. The link capability is 10Gbps below ToRs and 40Gbps above them, and the link delay is $5\mu s$. The over-subscription ratio is 1:1 at the ToR switch layer, so does in other layers. To support multi-path



(a) PAUSE Rate

(b) FCT

(c) FCR

Figure 14: Performance for realistic workloads.

capability, Equal Cost Multi Path (ECMP) routing scheme is used. In this configuration, the congestion tends to occur at the last hop. When PFC is employed to guarantee losslessness, the root congestion at the last hop may spread to the whole network.

Workloads: We choose two different workloads, whose flow size distribution is listed in Table 1. These two workloads are typical traffic pattern in operation data centers: (1) most flows are short, and (2) most traffic is constituted by few but large flows. The difference is that W2 contains more heavy-tailed flows.

We generate over 50 thousands of flows with exponentially distributed inter-arrival time, and configure the target load at 0.6 for ToR down-links. The source and destination of each flow are arbitrarily selected with a random in-cast ratio ranging from 1 to 15.

Fig.14 presents the results. The generating rates of PFC PAUSEs from different switch layers are drawn in Fig.14(a), where the solid bat at the bottom indicates the PAUSE rate from the ToRs, the middle stripe bar denotes that from the Leafs, and the top empty bar shows that from the Spines. In Fig.14(b), we draw the statistical FCT of all flows, and Fig.14(c) shows the flow completion rate (FCR) i.e., the number of completed flows per second. Subsequently, we compare the performance of PCN with QCN, DCQCN and TIMELY under different workloads.

(1) W1 contains the most S size flows in number and the most L size flows in bytes. Under this workload, the network congestion condition would change dramatically. Although PCN triggers 5.73x more PFC PAUSEs than QCN, it achieves 1.60x faster 99%-ile FCT and 3.70x larger FCR. This is because QCN reduces the sending rate of large flows so drastically that the network becomes seriously underload. Since PCN can rapidly detect the congestion point and adjust the rate of congested flows, short flows experience a low queuing delay and complete quickly. This can improve the overall FCT and increase FCR. Compared with DCQCN and TIMELY, PCN avoids 64% and 75% PFC PAUSEs, speeds up 1.75x and 2.35x in average FCT, and obtains 1.73x and 12.16x FCR, respectively.

(2) W2 is significantly heavy-tailed, where the S size flows occupy almost 80% of the number and less than 1% of the bytes, while the XL size flows only take less than 10% of the number but occupy almost all bytes. Under this workload, PCN suppresses 35%/89%/99% PAUSEs, speeds up 1.44x/1.57x/10.96x in average FCT and achieves 1.27x/1.13x/6.5x more FCR compared with QCN, DCQCN and TIMELY, respectively.

7.5 External Evaluations

Furthermore, we conduct external evaluations to explore PCN's performance in more scenarios. The detailed descriptions are in Appendix B, and the main findings are five folds.

Flow Scalability: PCN can hold as many as 1024 concurrent long flows, guaranteeing few PFC PAUSEs, low and stable queue length, near-full network utilization, as well as good fairness.

Adversarial Traffic: When facing dynamic flows entering and exiting with an interval of 10∼100 control loops, the end-to-end congestion control schemes fail to start the fast rate increasing algorithm. Compared with QCN, DCQCN and TIMELY, PCN can alleviate but not fully eliminate the interruption from adversarial traffic.

Multiple Bottlenecks: In the parking lot scenario with N bottlenecks, PCN allocates bandwidth following *proportional fairness*. That is, it allocates $\frac{1}{N+1}$ of capacity to the flow that passes all N bottlenecks.

Multiple Priorities: When concurrent burst in higher priority leads to severe oscillation of available bandwidth in lower priority, PCN triggers less PAUSE compared with DCQCN and TIMELY. Consequently, PCN outperforms other schemes in speeding up the overall flow completion.

Deadlock: PCN can not essentially prevent PFC deadlock, neither can other end-to-end congestion control schemes, but can significantly decrease the probability of deadlock. Compared to DCQCN and TIMELY, PCN can reduce 79.2% and 96.7% of deadlocks, respectively.

8 Related Work

The lossless switching fabric is a lasting topic. Here we only present a brief survey on the related work of lossless Ethernet and its congestion management, as well as receiver-driven rate control schemes.

Scaling RDMA over data centers. There are two lines in scaling RDMA over data centers. The first line, such as DCB [4] and RoCE [15, 26], attempts to enhance Ethernet with lossless property using PFC. It requires little modification to the well-tested RDMA transport stack but involves new issues caused by PFC. So an appropriate end-to-end congestion control scheme is needed. And the second line, such as Resilient RoCE [34] and IRN [37], tries to improve the RDMA transport stack to tolerate packet loss. Thus it can scale RDMA over lossy networks. We prefer the first line. We think the lossless Ethernet is more potential. On one hand, not just for RDMA, lossless Ethernet makes it easier to enable various well-tested transport protocols in data centers. It does not require NICs to support selective retransmission using the limited storage resources. On the other hand, lossless Ethernet can avoid retransmission of lost packets, and then can improve both network latency and throughput performance.

Lossless Ethernet switching fabric. It is always attractive to build cost-effective, efficient and large-scale lossless switching fabric leveraging commodity Ethernet chips. The related studies broadly follow three fundamental ways, which are reservation, explicit allocation, and congestion management. TDMA Ethernet [47] advocates reserving slots by deploying TDMA MAC layer. Fastpass [43] conducts explicit bandwidth allocations by a centralized arbiter to determine the time at which each packet should be transmitted and the path it should take. Whether TDMA Ethernet or Fastpass, they leverage non-conflict bandwidth access to build lossless Ethernet. However, due to slot wastage and unneglectable signal overheads, their flexibility and scalability in large-scale and ultra-high speed networks need to be further validated in practice. The third approach is to enhance traditional lossy Ethernet by introducing congestion management.

Congestion management for lossless Ethernet. IEEE DCB task group [4] defines the congestion management framework and develops concrete mechanisms, including PFC [6] and QCN [5], to enhance traditional Ethernet to be Converged Ethernet where losslessness should naturally be indispensable. To enable RoCE deployment in large-scale IP-routed data center networks, DCQCN [49] is developed through replacing the congestion notification mechanism defined in QCN with ECN in Layer 3, and then stitching together pieces of rate adjusting laws from QCN [5] and DCTCP [12]. TIMELY [36] follows the implicit congestion detection mechanism developed by TCP Vegas [20] and uses delay measurements to detect congestion, and then adjusts transmission rates according to RTT gradients. Both explicit and implicit congestion detection mechanisms in existing end-to-end congestion control schemes cannot identify the real congested flows, thus the performance issues in lossless Ethernet, such as HoL, congestion spreading and unfairness, are hardly solved essentially. In addition, IEEE 802.1 pQcz [7] has been supplemented to prevent PFC harming victim flows by isolating congestion. However, modification of current commodity switches is required to add more functions. In comparison, the congestion detecting mechanism in our PCN can correctly identify congested flows, moreover is practicable and back-compatible, which endows fundamental advantages for congestion management in lossless Ethernet.

Receiver-driven rate control. Recently, a series of receiver-driven rate control schemes have been proposed, such as ExpressPass [21], NDP [27] and Homa [38]. ExpressPass proactively controls congestion even before sending data packets by shaping the flow of credit packets in receivers. Both NDP and Homa also use the receiver-driven method to allocate priority to different flows in lossy data center networks. The receiver-driven rate adjustment in our PCN not only has the similar benefit of matching the incoming traffic load to the network capacity in one RTT, but also can drastically mitigate PFC triggers in one RTT as well, which is especially appropriate for lossless Ethernet.

9 Conclusion

This paper re-architects congestion management for lossless Ethernet, and proposes Photonic Congestion Notification (PCN), which is appropriate for lossless Ethernet by two ingenious designs: (*i*) a novel congestion detection and identification mechanism to recognize which flows are really responsible for congestion; (*ii*) a receiver-driven rate adjustment scheme to alleviate congestion in as fast as one loop control round, i.e., one RTT. PCN can be easily implemented on commodity switches with a little modification. Extensive experiments and simulations confirm that PCN greatly improves performance, and significantly mitigates PFC PAUSE messages and reduces the flow completion time under realistic workload.

A Theoretical Analysis

We build a fluid model of PCN to exhibit PCN's good performance of fast convergence, fairness, and stability. The main symbols are summarized in Table 2.

A.1 Fluid Model

Suppose N sources share the bottleneck link with capacity C. For each source i $(i = 1, \cdots, N)$ and each CNP generating time $t_k = kT (k = 1, 2, \cdots)$, $R_i(k), \widehat{R_i}(k)$ and $Q(k)$ denote the sending rate and receiving rate of source i, and the queue length in bottleneck link, respectively. Clearly, the queue length $Q(k)$ evolutes as follows

$$Q(k+1) = \max\{0, Q(k) + [\sum R_i(k) - C]T\} \tag{3}$$

As the associated egress port is not paused by its downstream device and excessive packets are accumulated in buffer, we regard the flow through this port is congested. Define the congestion indicator function $p(k)$

$$p(k) = \begin{cases} 0, & if\ Q(k+1) = 0 \\ 1, & if\ Q(k+1) > 0 \end{cases} \tag{4}$$

When N sources share the bottleneck capacity C by the sending ratio $\eta_i(k) = \frac{R_i(k)}{\sum_{j=1}^{N} R_j(k)}$. If the link is underflow, all incoming traffic can arrive their receiver side. Consequently, the receiving rate of each source satisfies

$$\widehat{R_i}(k) = p(k)\eta_i(k)C + (1 - p(k))R_i(k) \tag{5}$$

With probability $p(k)$ and receiving rate $\widehat{R_i}(k)$, source i will change its sending rate and the weight factor according to the corresponding adjustment rule. Thus, we have,

$$\begin{aligned} R_i(k+1) = p(k)\widehat{R_i}(k)(1 - w_{\min}) + \\ (1 - p(k))[R_i(k)(1 - w(k)) + Cw(k)] \end{aligned} \tag{6}$$

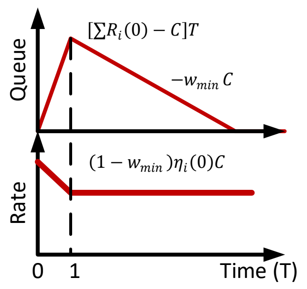
and

$$\begin{aligned} w(k+1) = p(k)w_{\min} + \\ (1 - p(k))[w(k)(1 - w(k)) + w_{\max}w(k)] \end{aligned} \tag{7}$$

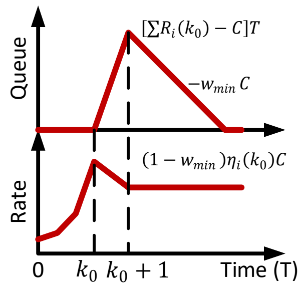
The dynamic behavior of PCN congestion management system can be described using Equation (3), (4), (5), (6) and (7). Based on this fluid model, we analyze PCN's properties in terms of convergence, fairness, and stability.

Variable	Description
R_i	Sending rate of Flow i
η_i	Bandwidth allocation ratio, $\eta_i = \frac{R_i}{\sum R_i}$
$\widehat{R_i}$	Receiving rate of Flow i
w	Weight factor
Q	Bottleneck queue length
T	CNP generating period
k	Sequence of CNP generating periods
C	Bottleneck link capacity

Table 2: Variables of fluid model



(a) $\sum R_i(0) > C$



(b) $\sum R_i(0) \le C$

Figure 15: Convergence of PCN.

A.2 Performance Analysis

A.2.1 Convergence

Without loss of generality, assume the queue associated with bottleneck link is empty and the sending rate of N flows is arbitrary at initial time 0. Hence, there are two cases.

(1) $\sum R_i(0) > C$: If the total rate exceeds the bottleneck capacity, the corresponding queue increases and all flows conduct the rate-decrease adjustment, thus,

$$\begin{cases} Q(1) &= [\sum R_i(0) - C]T \\ R_i(1) &= (1-w_{\min})\eta_i(0)C \end{cases}$$

Note that the total rate $\sum R_i(1) = (1-w_{\min})C < C$, thus the buffer will be drained out in next several periods. When the port is in congestion, the rate-decrease algorithm takes effect. Since $\frac{R_i(1)}{\sum R_i(1)} = \frac{R_i(0)}{\sum R_i(0)}$, we have

$$\begin{cases} Q(k) &= [\sum R_i(0) - C]T - (k-1)w_{\min}CT \\ R_i(k) &= (1-w_{\min})\eta_i(0)C \end{cases} \tag{8}$$

Equation (8) implies that the total sending rate $\sum R_i(k)$ converges to $(1-w_{\min})C$ in one control loop, while the queue length approaches to zero after $\lceil 1 + \frac{\sum R_i(0) - C}{w_{\min}C} \rceil$ control loops. The detail evolutions are illustrated in Fig.15(a).

(2) $\sum R_i(0) \le C$: If the total rate is less than the bottleneck capacity, all flows run the rate-increase algorithm. Eventually, the total sending rate will exceed the link capacity after K_0 control loops, where $K_0 < 10$ according to Fig.10. Therefore, we have $\sum R_i(k_0) > C$ and $Q(k_0) = 0$. Subsequently, the dynamic behavior of both queue and aggregate rate drawn in Fig.15(b) are similar with those in above case.

In a word, PCN can achieve convergence of total rate towards the bottleneck capacity as fast as in only one control loop, and drain out backlog packets.

A.2.2 Fairness

Suppose the above convergence phase ends at the start of k_1 control loop, where the buffer has been drained out, and the sending rate of flow i is increased from $(1-w_{\min})\eta_i(k_0)C$, then,

$$\begin{cases} Q(k_1) &= 0 \\ R_i(k_1) &= (1-w_{\min})^2\eta_i(k_0)C + w_{\min}C \end{cases} \tag{9}$$

and

$$\eta_i(k_1) = \frac{R_i(k_1)}{\sum R_i(k_1)} = \frac{(1-w_{\min})^2\eta_i(k_0) + w_{\min}}{(1-w_{\min})^2 + Nw_{\min}} \tag{10}$$

Note that $\sum R_i(k_1) = [1 + (N-2+w_{\min})w_{\min}]C > C$, the bottleneck link becomes real congested and the RP conducts the rate-decrease adjustment in the next period, thus we have

$$\begin{cases} Q(k_1+1) &= (N-2+w_{\min})w_{\min}CT \\ R_i(k_1+1) &= (1-w_{min})\eta_i(k_1)C \end{cases} \tag{11}$$

Since the aggregate sending rate will become below C, the backlog packets in queue will be drained out at a rate of $w_{\min}C$ per period and the sending rate is kept, then

$$\begin{cases} Q(k_1+k) &= (N-k-1+w_{\min})w_{\min}CT \\ R_i(k_1+k) &= (1-w_{min})\eta_i(k_1)C \end{cases}$$

Obviously, the buffer will become empty again at the starting of k_1+N control loop, and the sending rate of flow i is increased from $(1-w_{\min})\eta_i(k_1)C$, thus

$$\begin{cases} Q(k_1+N) &= 0 \\ R_i(k_1+N) &= (1-w_{\min})^2\eta_i(k_1)C + w_{\min}C \end{cases} \tag{12}$$

and

$$\eta_i(k_1+N) = \frac{(1-w_{\min})^2\eta_i(k_1) + w_{\min}}{(1-w_{\min})^2 + Nw_{\min}} \tag{13}$$

Comparing equation (9) and (12), we can find that PCN repeats the one period of rate-increase and N-1 periods of rate-decrease, as illustrated in Fig.16. And from equation (10) and (12), we also obtain the following dynamic evolution of bandwidth allocation ratio of each flow,

$$\begin{aligned} \eta_i(k_1+kN) &= a\eta_i(k_1+(k-1)N) + b \\ &= a^k\eta_i(k_1) + \textstyle\sum_{j=0}^{k-1} a^j b \\ &= a^{k+1}\eta_i(k_0) + \textstyle\sum_{j=0}^{k} a^j b \end{aligned}$$

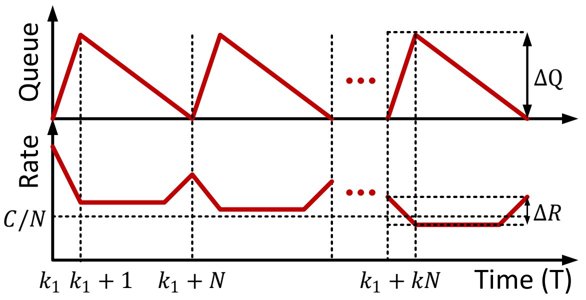


Figure 16: Dynamic behavior of PCN.

where $a = \frac{(1-w_{\min})^2}{(1-w_{\min})^2+Nw_{\min}} \in (0,1)$, $b = \frac{w_{\min}}{(1-w_{\min})^2+Nw_{\min}}$. Consequently, as $k \to \infty$, there is

$$\eta_i(k_1+Nk) \to \frac{b}{1-a} = \frac{1}{N} \tag{14}$$

That is, PCN can always achieve fair bandwidth allocation regardless of the initial sending rates of flows and parameter settings.

A.2.3 Stability

Finally, we show the steady state behavior of PCN. As illustrated in Fig.16, the queue length varies between 0 and $Q(k_1+1)$ periodically. Based on equation (11), the maximal queue oscillation ΔQ satisfies

$$\Delta Q = Q(k_1+1) = (N-2+w_{\min})w_{\min}CT \tag{15}$$

Similarly, the sending rate also changes in each N control loops. As Fig.16 shows, the aggregate rate increases in k_1+kN period and decreases in k_1+kN+1 period. Note that each flow achieves fair bandwidth allocation ratio in the steady state, i.e., $\eta_i \to \frac{1}{N}$, thus we can obtain the following derivation based on equation (11) and (12),

$$\begin{aligned} R_i(k_1+kN) &= (1-w_{\min})\eta_i C + w_{\min}C \\ &\to [1+(N-1)w_{\min}]\tfrac{C}{N} \\ R_i(k_1+kN+1) &= (1-w_{\min})\eta_i C \\ &\to (1-w_{\min})\tfrac{C}{N} \end{aligned}$$

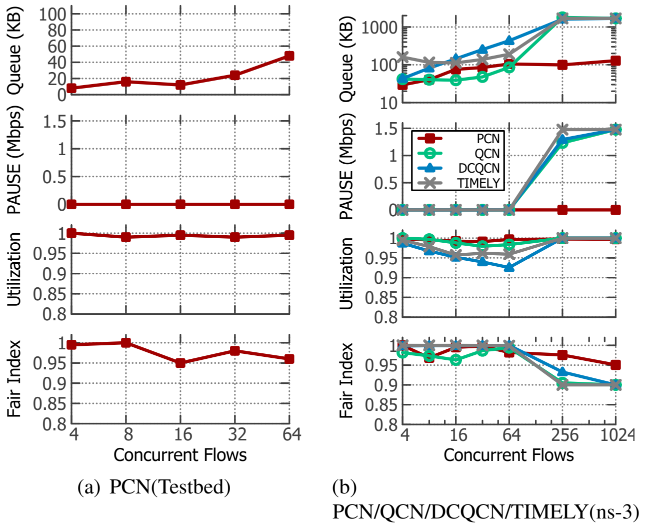
Therefore, the rate oscillation ΔR_i around the fair share $\frac{C}{N}$ satisfies

$$\Delta R_i \to w_{\min}C \tag{16}$$

Equation (15) and (16) indicate the oscillations of both the queue and rate are bounded in steady state, i.e., the stability of PCN is fine.

B External Evaluations

In this section, we will explore how PCN performs in artificial cases, including *flow scalability*, *adversarial traffic*, *multiple bottlenecks*, *multiple priorities* and *deadlock*.



(a) PCN(Testbed) (b) PCN/QCN/DCQCN/TIMELY(ns-3)

Figure 17: Flow scalability test.

B.1 Flow Scalability

Using the simple 3-dumbbell topology in §7.1, we vary the number of flows from 4 to 64 (testbed) and 1024 (ns-3) to test the performance of PCN under more flows. The queue length, pause rate, link utilization and fairness are measured and calculated, and the results are presented in Fig.17.

First, we measure the average queue occupancy and pause rate as the number of concurrent flows increases. In PCN, the average queue length is no more than 60KB and 100KB in the testbed and ns-3 simulator, respectively. At the same time, there are no PAUSE frames generated. In contrast, with $4 \sim 256$ flows, DCQCN's queue length grows with the number of flows, QCN and TIMELY keep the queue length around $50KB \sim 100KB$ and $100 \sim 200KB$, respectively. But QCN, DCQCN and TIMELY maintain a very high queue occupancy beyond 256 flows, which indicates the end-to-end congestion control fail to take effect. As for QCN, DCQCN and TIMELY, PFC is rarely triggered when the number of flows is less than 256, but persistent PAUSE frames are generated.

Second, we measure the utilization of bottleneck link. PCN achieves near 100% utilization in all case with both testbed and ns-3 simulator. QCN, DCQCN and TIMELY have a little under-utilization with the increase of concurrent flows, but recover full utilization with more than 256 flows. However, this recovery of link utilization is due to PFC rather than the end-to-end congestion control schemes.

Finally, we calculate the Jain's fairness index [30] using the throughput of each flow at $500ms$ interval. With a large number of flows, the fairness index of QCN, DCQCN and TIMELY drops significantly. Because they can not prevent PFC from persistent triggers, the inherent unfairness problem of PFC exhibits. On the opposite, PCN achieves good fairness in all cases.

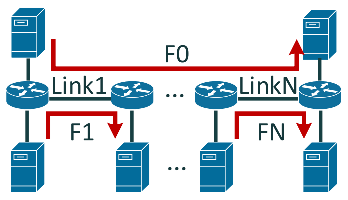
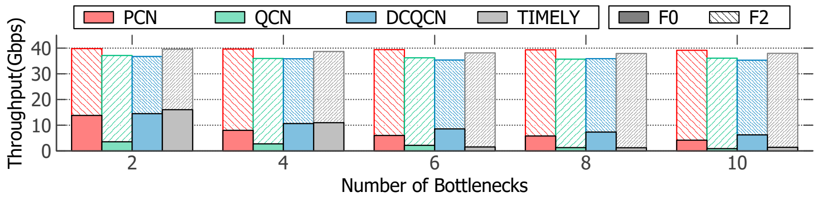
(b) Link S1→R1

Figure 18: Performance of various schemes under adversarial traffic.



(a) Parking-lot Topology



(b) Throughput of Link1

Figure 19: Performance of various schemes under multi-bottleneck scenario.

B.2 Adversarial Traffic

Subsequently, we test PCN using an adversarial traffic pattern. In the basic scenario in Fig.1, we set long flows F0 and F1 transmit persistently, and burst flows from H2∼H15 to R1 enter and exit the network at different intervals, varying from 50μs (1 control loop) to 5000μs (100 control loops). We simulate PCN, QCN, DCQCN and TIMELY, and measure the throughput of the two bottlenecks (link S0→S1 and S1→R1) and different flows. The results are drawn in Fig.18.

The first bottleneck, link S0→S1, is irrelative with the burst flows. Fig.18(a) shows that under PCN, QCN and TIMELY, link S0→S1 can achieve near-full utilization. But when the burst flows becomes more frequent, DCQCN trends to loss as high as 15% of throughput. This is because switch S1 pauses S0 when the burst flows make P2|S1 congested, and DCQCN conducts improper rate decrease for the victim flow F0.

The second bottleneck, link S1→R1, is frequently interrupted by the burst flows. Fig.18(b) exhibits that when the flow arrival interval shrinks, the congestion-relative flow F1 occupies lower throughput but the link utilization becomes larger. The performance issue occurs when the flow arrival interval is a little large (>500μs, 10 control loops). This means, their rate increase phase is interrupted by new-arrival flows. We can see that PCN keeps the link throughput at 30Gbps, while QCN, DCQCN and TIMELY remains at 23Gbps, 25Gbps and 29Gbps, respectively. That is, PCN can alleviate, but not eliminate, the interruption from adversarial traffic.

B.3 Multiple Bottlenecks

In a multi-bottleneck scenario, the NP-ECN method of PCN's CP may encounter several issues. On one hand, when the first congestion point marks ECN on all packets, the second congestion point may be paused, thus some flows are the victim but they have been marked with ECN already. On the other hand, flows through multiple congestion points may have a larger probability to be marked with ECN, resulting in unfairness. To test how PCN performs in multiple bottleneck scenario, we conduct a series of simulations using the parking lot topology in Fig.19(a). There are N bottlenecks and $N+1$ flows, where we set $N = 2,4,6,8,10$. F0 passes all the bottlenecks while other flows pass only one bottleneck. We measure the throughput of F0 and F1, and their sum is the throughput of link1. The result is drawn in Fig.19(b). Obviously, link1 achieves the similar utilization regardless of the number of bottlenecks. PCN can always provide more than 98% of link utilization, while the link utilization under QCN and DCQCN

Scheme	S(P1)	M(P2)	L(P3)	XL(P4)
PCN	0	0	0.10	171.49
QCN	0	0	0.28	110.49
DCQCN	0	0	0.26	175.02
TIMELY	0	0	1.09	210.36

Table 3: Generating rate of PFC PAUSEs for multiple priorities.

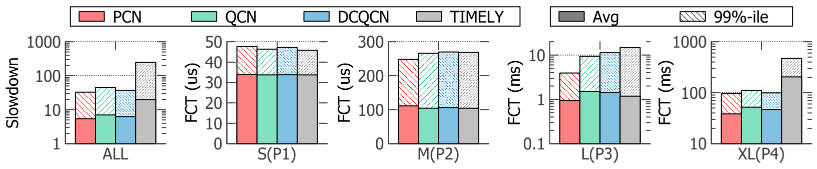


Figure 20: Average/99%-ile flow completion time for multiple priorities.

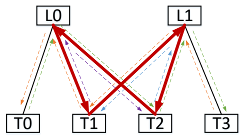
and TIMELY is 90%, 88% and 95%, respectively. Meanwhile, F0 is allocated less bandwidth than F2. Actually, the bandwidth allocation of PCN conforms to *proportional fairness*, where F0 obtains about $\frac{1}{N+1}$ of the capacity. QCN allocates F0 less than the proportional fairness. DCQCN allocates F0 more than the proportional fairness, but also less than the *max-min fairness*, i.e, half of the capacity.

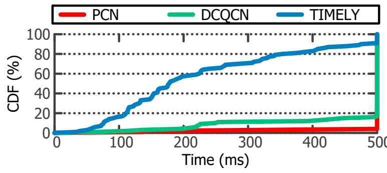
B.4 Multiple Priorities

The switching fabric in data center typically provides multiple priorities to improve performance, especially for minimizing flow completion time. The principle "short flow first" has been adopted in a series of works such as pHost [24], pFabric [14] and PIAS [17]. However, the concurrent burst in higher priority may trigger more PAUSE in lower priority, and impact the end-to-end congestion control schemes. To demonstrate and confirm this fact, we configure W1 and repeat the simulation in § 7.4, where the flows are classified into four priorities according to their size, namely, the S size flows are in the first priority and the XL flows are gathered in the fourth priority. The switches forward packets following the strict priority scheduling.

The generating rate of PFC PAUSEs and FCT for different priorities are listed in Table 3 and shown in Fig.20. For S and M flows in these two high priorities, few PFC PAUSE messages generate regardless of congestion control schemes. Thus, these flows can obtain almost the same FCT under three congestion control schemes. On the contrary, for the L and XL flows in the two low priorities, PFC PAUSEs can not be avoided. In this case, PCN triggers less PAUSE compared with DCQCN and TIMELY. QCN reduces PAUSE generated for XL flows by underutilizing available bandwidth. PCN outperforms the other three schemes in speeding up the overall flow completion time.



(a) Deadlock Topology



(b) Statistical Results

Figure 21: Performance of various schemes under deadlock scenario.

B.5 Deadlock Scenario

A common concern in Lossless Ethernet is that PAUSE can lead to deadlocks [28]. To explore PCN's effort to avoiding deadlock, we conduct a simple simulation using the topology illustrated in Fig.21(a). It comes from one pod in the clos network used in § 7.4, but link L0-T3 and link L1-T0 are failed, such that there is a *cycle buffer dependency* (CBD) as the red line draws. We simulate PCN, DCQCN and TIMELY with the W2 workload. The target load is 0.6 at ToR downlinks with in-cast ratio ranging from 1 to 15. Each scheme is tested for 1000 times and every simulation lasts for 500ms. We record the time when deadlock occurs, and draw the statistical results in Fig.21(b). Among the 1000 simulations, PCN only encounters with deadlock for 28 times, while DCQCN and TIMELY are deadlocked for 134 and 870 times, respectively. The advantage of PCN comes from the positive effect of mitigating PFC triggers and stopping congestion spreading.

Measuring Congestion in High-Performance Datacenter Interconnects

Abstract

While it is widely acknowledged that network congestion in High Performance Computing (HPC) systems can significantly degrade application performance, there has been little to no quantification of congestion on credit-based interconnect networks. We present a methodology for detecting, extracting, and characterizing regions of congestion in networks. We have implemented the methodology in a deployable tool, *Monet*, which can provide such analysis and feedback at runtime. Using *Monet*, we characterize and diagnose congestion in the world's largest 3D torus network of *Blue Waters*, a 13.3-petaflop supercomputer at the National Center for Supercomputing Applications. Our study deepens the understanding of production congestion at a scale that has never been evaluated before.

1 Introduction

High-speed interconnect networks (HSN), e.g., Infiniband [48] and Cray Aries [42]), which uses credit-based flow control algorithms [32, 61], are increasingly being used in high-performance datacenters (HPC [11] and clouds [5, 6, 8, 80]) to support the low-latency communication primitives required by extreme-scale applications (e.g., scientific and deep-learning applications). Despite the network support for low-latency communication primitives and advanced congestion mitigation and protection mechanisms, significant performance variation has been observed in production systems running real-world workloads. While it is widely acknowledged that network congestion can significantly degrade application performance [24, 26, 45, 71, 81], there has been little to no quantification of congestion on such interconnect networks to understand, diagnose and mitigate congestion problems at the application or system-level. In particular, tools and techniques to perform runtime measurement and characterization and provide runtime feedback to system software (e.g., schedulers) or users (e.g., application developers or system managers) are generally not available on production systems. This would require continuous system-wide, data collection on the state of network performance and associated complex analysis which may be difficult to perform at runtime.

The core contributions of this paper are (a) a methodology, including algorithms, for quantitative characterization of congestion of high-speed interconnect networks; (b) introduction of a deployable toolset, *Monet* [7], that employs our congestion characterization methodology; and (c) use of the the methodology for characterization of congestion using 5 months of operational data from a 3D torus-based interconnect network of *Blue Waters* [1, 27, 60], a 13.3-petaflop Cray supercomputer at the National Center for Supercomputing Applications (NCSA) at the University of Illinois at Urbana-Champaign. The novelty of our approach is its ability to use *percent time stalled* (P_{Ts})[1] metric to detect and quantitatively characterize congestion hotspots, also referred to as *congestion regions (CRs)*, which are group of links with similar levels of congestion.

The *Monet* tool has been experimentally used on NCSA's *Blue Waters*. *Blue Waters* uses a Cray Gemini [21] 3D torus interconnect, the largest known 3D torus in existence, that connects 27,648 compute nodes, henceforth referred to as *nodes*. The proposed tool is not specific to Cray Gemini and *Blue Waters*; it can be deployed on other k-dimensional mesh or toroidal networks, such as TPU clouds [3], Fujitsu TOFU network-based [18, 20] K supercomputer [70] and upcoming post-K supercomputer [10][2]. The key components of our methodology and the *Monet* toolset are as follows:

Data collection tools: On *Blue Waters*, we use vendor-provided tools (e.g., `gpcdr` [35]), along with the Lightweight Distributed Metric Service (LDMS) monitoring framework [17]. Together these tools collect data on (a) the network (e.g., transferred/received bytes, congestion metrics, and link failure events); (b) the file system traffic (e.g., read/write bytes); and (c) the applications (e.g., start/end time). We are released raw network data obtained from *Blue Waters* [57] as well as the associated code for generating *CRs* as artifacts with this paper [7]. To the best of our knowledge, this is the first

[1]P_{Ts}, defined formally in Section 2, approximately represents the intensity of congestion on a link, quantified between 0% and 100%.

[2]The first post-K supercomputer is scheduled to be deployed in 2021.

such large-scale network data release for an HPC high-speed interconnect network that uses credit-based flow control.

A network hotspot extraction and characterization tool, which extracts *CRs* at runtime; it does so by using an unsupervised region-growth clustering algorithm. The clustering method requires specification of congestion metrics (e.g., percent time stalled (P_{Ts}) or stall-to-flit ratios) and a network topology graph to extract regions of congestion that can be used for runtime or long-term network congestion characterization.

A diagnosis tool, which determines the cause of congestion (e.g., link failures or excessive file system traffic from applications) by combining system and application execution information with the CR characterizations. This tool leverages outlier-detection algorithms combined with domain-driven knowledge to flag anomalies in the data that can be correlated with the occurrence of CRs.

To produce the findings discussed in this paper, we used 5 months of operational data on *Blue Waters* representing more than 815,006 unique application runs that injected more than 70 PB of data into the network. Our key findings are as follows:

- *While it is rare for the system to be globally congested, there is a continuous presence of highly congested regions (CRs) in the network, and they are severe enough to affect application performance*. Measurements show that (a) for more than 56% of system uptime, there exists at least one highly congested CR (i.e., a CR with a $P_{Ts} > 25\%$), and that these CRs have a median size of 32 links and a maximum size of 2,324 links (5.6% of total links); and (b) highly congested regions may persist for more than 23 hours, with a median duration time of 9 hours[3]. With respect to impact on applications, we observed 1000-node production runs of the NAMD [77] application [4] slowing down by as much as 1.89× in the presence of high congestion compared to median runtime of 282 minutes.
- *Once congestion occurs in the network, it is likely to persist rather than decrease, leading to long-lived congestion in the network*. Measurements show that once the network has entered a state of high congestion ($P_{Ts} > 25\%$), it will persist in high congestion state with a probability of 0.87 in the next measurement window.
- *Quick propagation of congestion can be caused by network component failures.* Network component failures (e.g., network router failures) that occur in the vicinity of a large-scale application can lead to high network congestion within minutes of the failure event. Measurements show that 88% of directional link failures [5] caused the formation of CRs with an average $P_{Ts} \geq 15\%$.
- *Default congestion mitigation mechanisms have limited efficacy.* Our measurements show that (a) 29.8% of the 261 triggers of vendor-provided congestion mitigation mechanisms failed to alleviate long-lasting congestion (i.e., congestion driven by continuous oversubscription, as opposed to isolated traffic bursts), as they did not address the root causes of congestion; and (b) vendor-provided mitigation mechanisms were triggered in 8% (261) of the 3,390 high-congestion events identified by our framework. Of these 3,390 events, 25% lasted for more than 30 minutes. This analysis suggests that augmentation of the vendor-supplied solution could be an effective way to improve overall congestion management.

In this paper, we highlight the utility of congestion regions in the following ways:

- We showcase the effectiveness of *CRs* in detecting long-lived congestion. Based on this characterization, we propose that *CR* detection could be used to trigger congestion mitigation responses that could augment the current vendor-provided mechanisms.
- We illustrate how *CRs*, in conjunction with network traffic assessment, enable congestion diagnosis. Our diagnosis tool attributes congestion cause to one of the following: (a) system issues (such as launch/exit of application), (b) failure issues (such as network link failures), and (c) intra-application issues (such as changes in communication patterns within an application). Such a diagnosis allows system managers to take cause-specific mitigating actions.

This paper's organization is illustrated in Figure 1. We present background information on the Gemini network, performance data, and congestion mitigation mechanisms in Section 2. In Section 3, we present our data collection methodology and tools. In Section 4, we present our methodology for characterizing congestion. We present our measurement-

driven congestion characterization results in Section 5. In Section 6, we discuss the further utility of our methodology to inform targeted responses, and in Section 7, we discuss its use in diagnosing the root causes of congestion. We address related work in Section 8 and conclude in Section 9.

2 Cray Gemini Network and Blue Waters

A variety of network technologies and topologies have been utilized in HPC systems (e.g., [19, 21, 31, 36, 42, 59, 62, 75]). Depending on the technology, routing within these networks may be statically defined for the duration of a system boot cycle, or may dynamically change because of congestion and/or failure conditions. More details on HPC interconnects can be found in Appendix A. The focus of this paper is on NCSA's Cray XE/XK *Blue Waters* [1] system, which is composed of 27,648 nodes and has a large-scale (13,824 x 48 port switches) Gemini [21] 3D torus (dimension 24x24x24) interconnect. It is a good platform for development and validation of congestion analysis/ characterization methods as:

- It uses directional-order routing, which is predominantly static[6]. From a traffic and congestion characterization perspective, statically routed environments are easier to validate than dynamic and adaptive networks.
- *Blue Waters* is the best case torus to study since it uses topology-aware scheduling (TAS) [41, 82], discussed later in this section, which has eliminated many congestion issues compared to random scheduling.
- *Blue Waters* performs continuous system-wide collection and storage of network performance counters.

2.1 Gemini Network

In Cray XE/XK systems, four *nodes* are packaged on a *blade*. Each *blade* is equipped with a mezzanine card. This card contains a pair of *Gemini [21] ASICs*, which serve as network switches. The Gemini switch design is shown in Figure 2. Each Gemini ASIC consists of 48 *tiles*, each of which provide a duplex link. The switches are connected with one another in 6 directions, X+/-, Y+/- and Z+/-, via multiple links that form a 3D torus. The number of links in a direction, depends on the direction as shown in the figure; there are 8 each in X+/- and, Z+/- and 4 each in Y+/-. It is convenient to consider all links in a given direction as a *directionally aggregated link*, which we will henceforth call a *link*. The available bandwidth on a particular link is dependent on the link type, i.e., whether the link connects compute cabinets or *blades*, in addition to the number of tiles in the link [76]. X, Y links have aggregate bandwidths of 9.4 GB/s and 4.7 GB/s, respectively, whereas Z links are predominantly 15 GB/s, with 1/8 of them at 9.4 GB/s. Traffic routing in the Gemini network is largely static and changes only when failures occur that need to be routed around. Traffic is directionally routed in the X, Y, and Z dimensions, with the shortest path in terms of hops in + or - chosen for each direction. A deterministic rule handles tie-breaking.

To avoid data loss in the network [7], the Gemini HSN uses a credit-based flow control mechanism [61], and routing is done on a per-packet basis. In credit-based flow control networks, a source is allowed to send a quantum of data, e.g., a flit, to a next hop destination only if it has a sufficient number of credits. If the source does not have sufficient credits, it must stall (wait) until enough credits are available. Stalls can occur in two different places: within the switch (resulting in a *inq stall*) or between switches (resulting in an *credit stall*).

Definition 1 ***: A Credit stall*** *is the wait time associated with sending of a flit from an output buffer of one switch to an input buffer of another across a link.*

Definition 2 ***: An Inq stall*** *is the wait time associated with sending of a flit from the output buffer of one switch port to an input buffer of another between tiles within the same network switch ASIC.*

Congestion in a Gemini-based network can be characterized using both *credit* and *inq* stall metrics. Specifically, we consider the *Percent Time Stalled* as a metric for quantifying congestion, which we generically refer to as the *stall value*.

Definition 3 ***: Percent Time Stalled*** *(P_{Ts}) is the average time spent stalled (T_{is}) over all* tiles *of a directional network link or individual intra-Gemini switch link over the same time interval (T_i): $P_{Ts} = 100 * T_{is}/T_i$.*

Depending on the network topology and routing rules, (a) an application's traffic can pass through switches not directly associated with its allocated nodes, and multiple applications can be in competition for bandwidth on the same network links; (b) stalls on a link can lead to back pressure on prior switches in communication routes, causing congestion to spread; and (c) the initial manifestation location of congestion cannot be directly associated with the cause of congestion. Differences in available bandwidth along directions, combined with the directional-order routing, can also cause back pressure, leading to varying levels of congestion along the three directions.

2.2 Congestion Mitigation

Run-time evaluations that identify localized areas of congestion and assess congestion duration can be used to trigger *Congestion Effect Mitigating Responses (CEMRs)*, such as resource scheduling, placement decisions, and dynamic application reconfiguration. While we have defined a CEMR as a response that can be used to minimize the negative effects of network congestion, Cray provides a software mechanism [33] to directly alleviate the congestion itself. When a

[6]When network-link failures occur, network routes are recomputed; that changes the route while the system is up.

[7]The probability of loss of a quantum of data in credit-flow networks is negligible and mostly occurs due to network-related failures.

variety of network components (e.g., tiles, NICs) exceeds a high-watermark threshold with respect to the ratio of stalls to forwarded flits, the software instigates a *Congestion Protection Event* (CPE), which is a *throttling* of injection of traffic from all NICs. The CPE mechanism limits the aggregate traffic injection bandwidth over *all* compute nodes to less than what can be ejected to a *single* node. While this ensures that the congestion is at least temporarily alleviated, the network as a whole is drastically under-subscribed for the duration of the *throttling*. As a result, the performance of all applications running on the system can be significantly impacted. *Throttling* remains active until associated monitored values and ratios drop below their low-watermark thresholds. Applications with sustained high traffic injection rates may induce many CPEs, leading to significant time spent in globally throttling. Bursts of high traffic injection rates may thus trigger CPEs, due to localized congestion, that could have been alleviated without the global negative impact of *throttling*. There is an option to enable the software to terminate the application that it determines is the top congestion candidate, though this feature is not enabled on the *Blue Waters* system. The option to terminate application in a production environment is not acceptable to most developers and system managers as it will lead to loss of computational node-hours used by the application after the last checkpoint.

While some of this congestion may be alleviated by CEMRs such as feedback of congestion information to applications to trigger rebalancing [29] or to scheduling/resource managers to preferentially allocate nodes (e.g., via mechanisms such as slurm's [79] node weight), some may be unavoidable since all networks have finite bandwidth.

On *Blue Waters* a topology-aware scheduling (TAS) [41, 82] scheme is used to decrease the possibility of application communication interference by assigning, by default [12], node allocations that are constrained within small-convex prisms with respect to the HSN topology. Jobs that exceed half a torus will still route outside the allocation and possibly interfere with other jobs and vice versa; a non-default option can be used to avoid placement next to such jobs. The I/O routers represent fixed, and roughly evenly distributed, proportional portions of the storage subsystem. Since the storage subsystem components, including I/O routers, are allocated (for writes) in a round robin (by request order) manner independent of TAS allocations, storage I/O communications will generally use network links both within and outside the geometry of the application's allocation and can also be a cause of interference between applications.

3 Data Sources and Data Collection Tools

This section describes the datasets and tools used to collect data at scale to enable both runtime and long-term characterization of network congestion. We leverage vendor-provided and specialized tools to enable collection and real-time streaming of data to a remote compute node for analysis and characterization. Data provided or exposed on all Cray Gemini systems includes: OS and network performance counter data, network resilience-related logs, and workload placement and status logs. In this study, we used five months (Jan 01 to May 31, 2017) of production network performance-related data (15 TB), network resilience-related logs (100 GB), and application placement logs (7 GB). Note that the methodologies addressed in this work rely only on the availability of the data, independent of the specific tools used to collect the data.

Network Performance Counters: Network performance-related information on links is exposed via Cray's `gpcdr` [35] kernel module. Lustre file system and RDMA traffic information is exposed on the nodes via `/proc/fs` and `/proc/kgnilnd`. It is neither collected nor made available for analysis via vendor-provided collection mechanisms. On Blue Waters, these data are collected and transported off the system for storage and analysis via the Lightweight Distributed Metric Service (LDMS) monitoring framework [17]. In this work, we use the following information: directionally aggregated network traffic (bytes and packets) and length of stalls due to credit depletion; Lustre file system read and write bytes; and RDMA bytes transmitted and received. LDMS samplers collect those data at 60-second intervals and calculate derived metrics, such as the percent of time spent in stalls (P_{Ts}) and percent of total bandwidth used over the last interval. LDMS daemons synchronize their sampling to within a few *ms* (neglecting clock skew) in order to provide coherent *snapshots* of network state across the whole system.

Network Monitoring Logs: Network failures and congestion levels are monitored and mitigated by Cray's *xtnlrd* software. This software further logs certain network events in a well-known format in the *netwatch* log file. Significant example log lines are provided in Cray documents [33, 34]. Regular expression matching for these lines is implemented in LogDiver [66], a log-processing tool, which we use to extract the occurrences, times, and locations of link failures and CPEs.

Workload Data: Blue Waters utilizes the Moab scheduler, from which application queue time, start time, end time, exit status, and allocation of nodes can be obtained. The workload dataset contains information about 815,006 application runs that were executed during our study period. A detailed characterization of *Blue Waters* workloads can be found in Appendix B and *Blue Waters* workload study [58].

Note that we will only be releasing network data. Worload data and network monitoring logs will not be released due to privacy and other concerns.

4 *CR* Extraction and Characterization Tool

This section first describes our motivation for choosing congestion regions (CRs) as a driver for characterizing network congestion, and then describes our methodology (implemented as the *Monet* tool) for extracting *CRs* over each data collection interval and the classification of those CRs based on severity.

4.1 Why Congestion Regions?

We seek to motivate our choice to characterize congestion regions (*CRs*) and the need for estimates for severity in terms of the stall values. We first show that the charcterization of hotspot links individually do not reveal the spatial and growth characteristics which is needed for diagnosis. Then, we show how characterizing *CRs* is meaningful.

Characterizing hotspot links individually do not reveal regions of congestion. Figure 3 characterizes the median, 99%ile and 99.9%ile duration of the hotspot links by generating the distribution of the duration for which a link persists to be in congestion at $P_{Ts} \geq P_{Ts}$Threshold value. For example, 99.9%ile duration for hotspot links with $P_{Ts} \geq 30$ is 400 minutes (6.67 hours). The measurements show that the median duration of hotspot link at different P_{Ts} thresholds is constantly at ~ 0, however, 99.9%ile duration of hotspot links linearly decreases with increasing P_{Ts} threshold value. Although such characterizations are useful to understand congestion at link-level, they hide the spatial characteristics of congestion such as the existence of multiple pockets of congestion and their spread and growth over time. The lack of such information makes it difficult to understand congestion characteristics and their root cause.

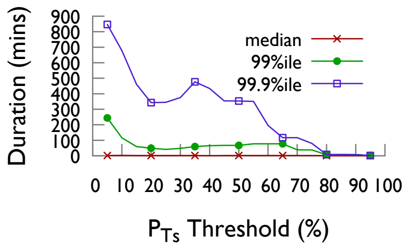

Figure 3: Duration of congestion on links at different P_{Ts} thresholds

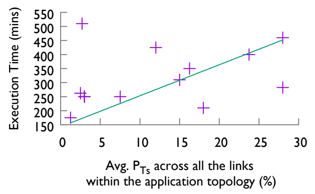
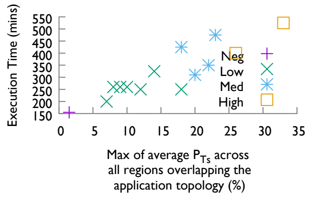


(a) Not using **CRs**



(b) Using **CRs**

Figure 4: Correlating congestion with NAMD application runtime

***CRs* captures relationship between congestion-level and application slowdown efficiently.** In order to determine possible severity values and show effectiveness of *CRs* in determining application slowdown, we extracted from the production Blue Waters dataset a set of NAMD [77][8] runs each of which ran on 1000 nodes with the same input parameters. We chose NAMD because it consumes approximately 18% of total node-hours available on Blue Waters[9]. Figure 4a shows the execution time of each individual run with respect to the *average* P_{Ts} over all links within the allocated application topology. (Here we leverage TAS to determine severity value estimates based on the values within the allocation; that is not a condition for the rest of this work.) Figure 4a shows that execution time is perhaps only loosely related to the average P_{Ts}; with correlation of 0.33 . In contrast, 4b shows the relationship of the application execution time with the *maximum* average P_{Ts} over all *CRs* (defined in 4.2) within the allocated topology; with correlation of 0.89. In this case, execution time increases with increasing maximum of average P_{Ts} over all regions. We found this relationship to hold for other scientific applications. This is a motivating factor for the extraction of such *congestion regions* (*CRs*) as indicators of 'hot-spots' in the network. We describe the methodology for *CR* extraction in the next section.

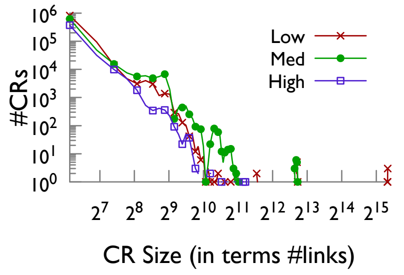
In addition, we selected approximate ranges of P_{Ts} values, corresponding to increasing run times, to use as estimates for the severity levels as these can be easily calculated, understood and compared. These levels are indicated as symbols in the figure. Explicitly, we assign 0-5% average P_{Ts} in a *CR* as *Negligible* or *'Neg'*, 5-15% as *'Low'*, 15-25% as *'Medium'*, and > 25% as *'High'*. These are meant to be qualitative assignments and not to be rigorously associated with a definitive performance variation for all applications in all cases, as the network communication patterns and traffic volumes vary among HPC applications. We will use these ranges in characterizations in the rest of this work. More accurate determinations of impact could be used in place of these in the future, without changing the validity of the *CR* extraction technique.

4.2 Extracting Congestion Regions

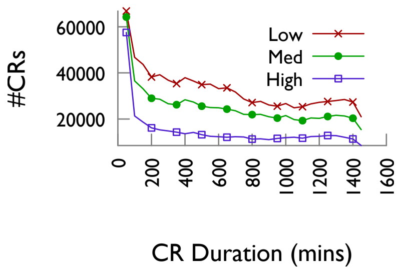
We have developed an unsupervised clustering approach for extracting and localizing regions of congestion in the network by segmenting the network into groups of links with similar congestion values. The clustering approach requires the following parameters: (a) network graph (G), (b) congestion measures (v_s for each vertex v in G), (c) neighborhood distance metric (d_δ), and (d) stall similarity metric (d_λ). The network is represented as a graph G. Each link in the network is represented as a vertex v in G, and two vertices are connected if the corresponding network links are both connected to the same switch (i.e., the switch is an edge in the graphs). For each vertex v, the congestion measures(s) are denoted by the vector v_s, which is composed of credit stalls and inq

[8]NAMD has two different implementations: (a) uGNI shared memory parallel (SMP)-based, and (b) MPI-based. In this work, unstated NAMD refers to uGNI SMP-based implementation. uGNI is user level Generic Network Interface [83].

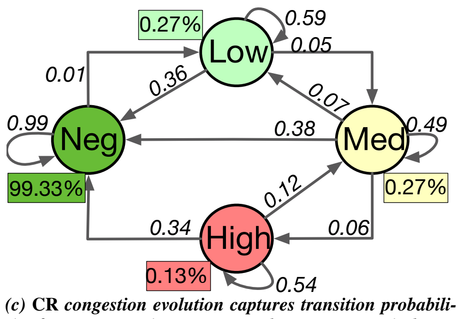
[9]This was best effort extraction and the NAMD application runs may not be exactly executing the same binary or processing the same data, as user may have recompiled the code with a different library or used the same name for dataset while changing the data. There is limited information to extract suitable comparable runs from historical data that are also subject to allocation and performance variation.



(a) Distribution of CR sizes.



(b) Distribution of CRs.



(c) **CR** *congestion evolution captures transition probabilities from one severity* **state** *to another. Percentage in boxes indicates percentage of total link-hours spent in that* **state**.

Figure 5: **CR** *size, duration, evolution characterization. # of* **CRs** *across* **'Low'**, **'Medium'**, *and* **'High'** *are 9.4e05, 7.3e05, and 4.2e05 respectively.*

stalls, which we use independently. Distance metrics d_δ and d_λ are also required, the former for calculating distances between two vertices and the latter for calculating differences among the stalls v_s. We assign each vertex the coordinate halfway between the logical coordinates of the two switches to which that vertex is immediately connected, and we set d_δ to be the L1 norm between the coordinates. Since the Blue Waters data consists of directionally aggregated information as opposed to counters on a per-tile-link (or buffer) basis, then, in our case, d_λ is simply the absolute difference between the two credit-stall or the two inq-stall values of the links, depending on what kinds of regions are being segmented. We consider credit and inq stalls separately to extract *CRs*, as the relationship between the two types of stalls is not immediately apparent from the measurements, and thus require two segmentation passes. Next, we outline the segmentation algorithm.

Segmentation Algorithm The segmentation algorithm has four stages which are executed in order, as follows.

- Nearby links with similar stall values are grouped together. Specifically, they are grouped into the equivalence classes of the reflexive and transitive closure of the relation $\sim_r$ defined by $x \sim_r y \Leftrightarrow d_\delta(x,y) \leq \delta \wedge d_\lambda(x_s - y_s) \leq \theta_p$, where x, y are vertices in G, and δ, θ_p are thresholds for distance between vertices and stall values, respectively.
- Nearby regions with similar average stall values, are grouped together through repetition of the previous step, but with regions in place of individual links. Instead of using the link values v_s, we use the average value of v_s over all links in the region, and instead of using θ_p, we use a separate threshold value θ_r.
- CRs that are below the size threshold σ are merged into the nearest region within the distance threshold δ.
- Remaining CRs with $< \sigma$ links are discarded, so that regions that are too small to be significant are eliminated.

The optimum values for the parameters used in segmentation algorithms, except for δ, were estimated empirically by knee-curve [63] method, based on the number of regions produced. Using that method, the obtained parameter values [10] are: (a) $\theta_p = 4$, (b) $\theta_r = 4$, and (c) $\sigma = 20$. In [63], the authors conclude that the optimum sliding window time is the knee of the curve drawn between the sliding window time and the number of clusters obtained using a clustering algorithm. This decreases truncation errors (in which a cluster is split into multiple clusters because of a small sliding window time) and collision errors (in which two events not related to each other merge into a single cluster because of a large sliding window time). We fixed δ to be 2 in order to consider only links that are two hops away, to capture the local nature of congestion [47]. It should be noted that the region clustering algorithm may discard small isolated regions (size $\leq \sigma$) of high congestion. If such *CRs* do cause high interference, they will grow over time and eventually be captured.

Our algorithm works under several assumptions: (a) congestion spreads locally, and (b) within a CR, the stall values of the links do not vary significantly. These assumptions are reasonable for k-dimensional toroids that use directional-order routing algorithm. The methodology used to derive *CRs* is not dependent on the resource allocation policy (such as TAS). The proposed extraction and its use for characterization is particularly suitable for analysis of network topologies that use directional- or dimensional-order routing. In principle, the algorithm can be applied to other topologies (such as mesh and high-order torus networks) with other metrics (such as stall-to-flit ratio). Furthermore, the region extraction algorithm does not force any shape constraints; thus *CRs* can be of any arbitrary shape requiring us to store each vertex associated with the *CR*. In this work, we have configured the tool to store and display bounding boxes over CRs, as doing so vastly reduces the storage requirements (from TBs of raw data to 4 MB in this case), provides a succinct summary of the network congestion state, and eases visualization.

We validate the methodology for determining the parameters of the region-based segmentation algorithm and its applicability for *CR* extraction by using synthetic datasets, as described in Appendix D.

4.3 Implementation and Performance

We have implemented the region-extraction algorithm as a modified version of the region growth segmentation algorithm [78] found in the open-source PointCloud Library (PCL) [9] [4]. The tool is capable of performing run-time extraction of *CRs* even for large-scale topologies. Using the

[10] stall thresholds are scaled by 2.55× to represent the color range (0-255) for visualization purposes

Blue Waters dataset, Monet mined *CRs* from each 60-second snapshot of data for 41,472 links in $\sim$7 seconds; Monet was running on a single thread of a 2.0 GHz Intel Xeon E5-2683 v3 CPU with 512 GB of RAM. Thus, on Blue Waters *Monet* can be run at run-time, as the collection interval is much greater than CR extraction time. Since Monet operates on the database, it works the same way whether the data are being streamed into the database or it is operating on historical data.

5 Characterization Results

In this section, we present results of the application of our analysis methodology to five months of data from a large-scale production HPC system (*Blue Waters*) to provide characterizations of *CRs*. Readers interested in understanding traffic characteristics at the link and datacenter-level may refer to a related work [16].

5.1 Congestion Region Characterization

Here we assess and characterize the congestion severity.

CR-level Size and Severity Characterizations: Figure 5a shows a histogram[11] of *CR* sizes in terms of the number of links for each congested *state* (i.e., not including *'Neg'*). Figure 5b show a histogram of the durations of *CRs* across *'Low'*, *'Medium'* and *'High'* congestion levels. These measurements show that unchecked congestion in credit-based interconnects leads to:

- High growth and spread of congestion leading to large *CRs*. The max size of *CRs* in terms of number of links was found to be 41,168 (99.99% of total links), 6,904 (16.6% of total links), and 2,324 (5.6% of total links) across *'Low'*, *'Medium'* and *'High'* congestion levels respectively, whereas the 99th percentile of the[12] *CR* size was found to be 299, 448, and 214 respectively.
- Localized congestion hotspots, i.e., pockets of congestion. *CRs* rarely spread to cover all of the network. The number of *CRs* decreases (see Figure 5a) with increasing size across all severity *states* except for *'Low'* for which we observe increase at the tail. For example, there are $\sim$16,000 CRs in the *'High'* which comprise 128 links but only $\sim$141 CRs of size $\sim$600.
- Long-lived congestion. The *CR* count decreases with increasing duration, however there are many long-lived *CRs*. The 50%ile, 99%ile and max duration of *CRs* across all states were found to be 579 minutes (9.7 hours), 1421 minutes (23.6 hours), and 1439 minutes (24 hours) respectively, whereas the 50%ile, 99%ile and max P_{Ts} of *CRs* was found to be 14%, 46%, and 92%, respectively. *CR* duration did not change significantly across *'Low'*, *'Medium'*, and *'High'*.

CR Evolution and State Probability: Figure 5c shows the transition probabilities of the *CR* states. The percentage in the box next to each *state* shows the percentage of total link-hours[13] spent in that *state*. It can be interpreted as the probability that a link will be congested at a severity *state* at a given time. For example, there is a probability of 0.10% that a link will be in the *'High'*. These measurements show that:

- The vast majority of link-hours (99.3% of total link-hours) on Blue Waters are spent in *'Neg'* congestion. Consideration of a grosser congestion metric, such as the average stall time across the entire network, will not reveal the presence of significant *CRs*.
- Once a *CR* of *'Low'*, *'Medium'* or *'High'* congestion is formed, it is likely to persist (with a probability of more than 0.5) rather than decrease or vanish from the network.

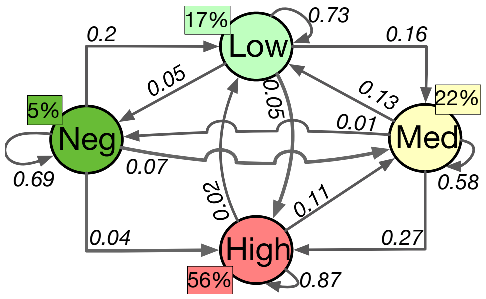


Figure 6: **Network** *congestion evolution captures transition probabilities from one severity* **state** *to another. Percentage numbers in boxes indicates percentage of total system wall clock time spent in that* **state.**

5.2 Network-level Congestion Evolution and Transition Probabilities

In this section, we assess and characterize the overall network congestion severity state. The overall network congestion severity *state* is the *state* into which the highest CR falls. That assignment is independent of the overall distribution of links in each *state*. Figure 6 shows the probabilities that transitions between network *states* will occur between one measurement interval and the next. The rectangular boxes in the figure indicate the fraction of time that the network resides in each *state*. These measurements show the following:

- While each *individual* link of the entire network is most often in a *state* of *'Neg'* congestion, there exists at least one *'High'* CR for 56% of the time. However, *'High'* CRs are small; in Section 5.1, we found that 99th percentile size of *'High'* is 214 links. Thus, the *Blue Waters* network *state* is nearly always non-negligible (95%), with the "High" *state* occurring for the majority of the time.
- There is a significant chance that the current network *state* will persist or increase in severity in the next measurement period. For example, there is an 87% chance that it will stay in a *'High' state*.
- A network *state* is more likely to drop to the next lower *state* than to drop to *'Neg'*.
- Together these factors indicate that congestion builds and subsides slowly, suggesting that it is possible to fore-

[11] plotted as lines and every tenth point marked on the line using a shape for clarity.

[12] We will use %ile to denote percentile in the rest of the paper.

[13] Link-hours are calculated by $\sum$(#links in *Region*) $\times$ (measurement time-window) for each *state*.

cast (within bounds) congestion levels. Combined with proactive localized congestion mitigation techniques and CEMRs, such forecasts could significantly improve overall system performance and application throughput.

5.3 Application Impact of CR

The potential impact of congestion on applications can be significant, even when the percentage of link-hours spent in non-*'Neg'* congested regions is small. While we cannot quantify congestion's impact on all of the applications running on Blue Waters (as we lack ground truth information on particular application runtimes without congestion), we can quantify the impact of congestion on the following:

- Production runs of the NAMD application [77]. The worst-case NAMD execution runtime was 3.4× slower in the presence of high *CRs* relative to baseline runs (i.e., negligible congestion). The median runtime was found be 282 minutes, and hence worst-case runtime was 1.86× slower than the median runtime. This is discussed in more detail in Section 4.1.
- In [16], authors show that benchmark runs of PSDNS [74] and AMR [2] on 256 nodes slowed down by as much as 1.6× even at low-levels of congestion ($5\% < P_{Ts} \leq 15\%$).

To find a upper bound on the number of potentially impacted applications, we consider the applications whose allocations are directly associated with a router in a *CR*. Out of 815,006 total application runs on Blue Waters, over 16.6%, 12.3%, and 6.5% of the unique application runs were impacted by *'Low'*, *'Medium'*, and *'High'* CRs, respectively.

5.4 Congestion Scenarios

In this section, we show how *CRs* manifest under different congestion scenarios: (a) system issues (e.g. changes in system load), (b) network-component failures (e.g. link failures), and (c) intra-application contention. Since the *CRs* are described as bounding boxes with coordinates described in relation to the 3D torus, they can easily be visualized in conjunction with applications' placements at runtime on the torus. *CRs* of *'Neg'* congestion are not shown in the figures.

Congestion due to System Issues: Network congestion may result from contention between different applications for the same network resources. That can occur because of a change in system load (e.g. launches of new applications) or change in application traffic that increases contention on shared links between applications.

Figure 7(i) shows four snapshots, read clockwise, of extracted *CRs*, including size and severity state, for different time intervals during a changing workload. Figure 7(i)(a) shows that *'Low'* (blue) *CRs* when most of the workload consists of multiple instances of MPI-based *NAMD* [77]. The overall network state was thus *'Low'*. The *CRs* remained relatively unchanged for 40 minutes, after which two instances of NAMD completed and *Variant Calling* [37] was launched. Three minutes after the launch, new *CRs* of increased severity

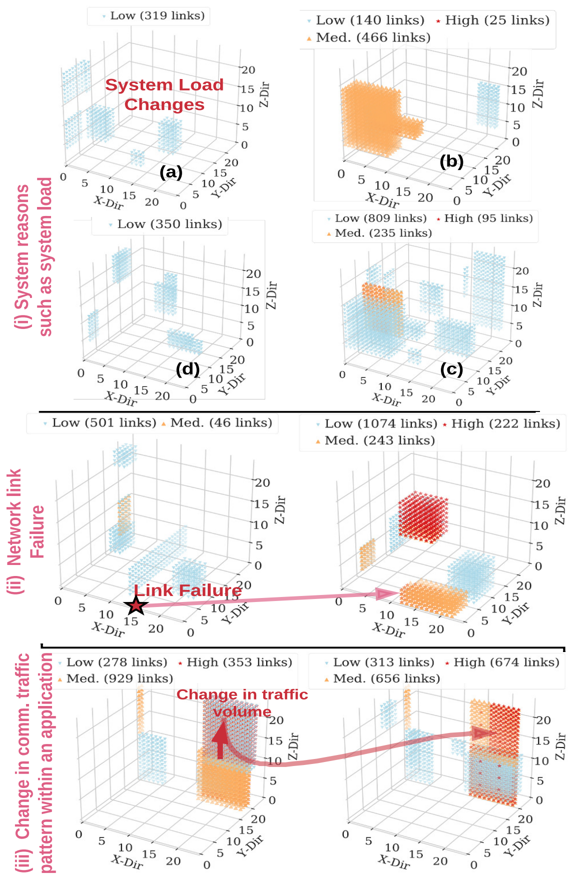

Figure 7: ***Case studies: network congestion is shown due to (i) system issues (such as introduction of new applications), (ii) failures (such as network link failure), and (iii) change in communication pattern within the application.***

occurred (Figure 7(i)(b,c)). The *'High'* (red) [14] and *'Medium'* (orange) severity *CRs* overlapped with the applications.

The increase in the severity of congestion was due to high I/O bandwidth utilization by the *Variant Calling* application. The overall network state remained *'High'* for ∼143 minutes until the *Variant Calling* application completed. At that time, the congestion subsided, as shown in Figure 7(i)(d).

Congestion Due to Network-component Failures: Network-related failures are frequent [55, 68] and may lead to network congestion, depending on the traffic on the network and the type of failure. In [55], the mean time between failures (MTBF) for directional links in Blue Waters was found to be approximately $2.46e06$ link-hours (or 280 link-years). Given the large number of links (41,472 links) on Blue Waters, the expected mean time between failure of a link across the system is about 59.2 hours; i.e., Blue Waters admins can expect one directional-link failure every 59.2 hours.

Failures of directional links or routers generally lead to

[14] not visible and hidden by other regions.

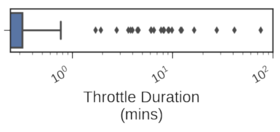
occurrences of *'High' CRs*, while isolated failures of a few switch links (which are much more frequent) generally do not lead to occurrences of significant *CRs*. In this work we found that 88% of directional link failures led to congestion; however, isolated failures of switch links did not lead to significant *CRs* (i.e., had *'Neg' CRs*).

Figure 7(ii) shows the impact of a network blade failure that caused the loss of two network routers and about 96 links (x,y,z location of failure at coordinates (12,3,4) and (12,3,3)). Figure 7(ii)(a) shows the congestion *CRs* before the failure incident and Figure 7(ii)(b) shows the *CRs* just after the completion of the network recovery. Immediately after failure, the stalls increased because of the unavailability of links, requiring the packets to be buffered on the network nodes. The congestion quickly spread into the geometry of nearby applications in the torus. Failure of a blade increased the overall size (in number of links) of *'Low' CRs* by a factor of 2, and of *'Medium' CRs* by a factor of 4.2, and created previously non existent *'High' CRs* with more than 200 links.

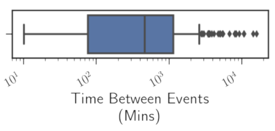
Congestion Due to Intra-Application Issues: Congestion within an application's geometry (intra-application contention) can occur even with TAS. Figure 7(iii) shows congestion *CRs* while the uGNI-based shared memory parallel (SMP) *NAMD* application on more than 2,000 nodes. The application is geometrically mapped on the torus starting at coordinates (15, 18, 0) and ending at coordinates (1, 21, 23) (wrapping around). The congestion *CRs* alternate between the two states shown (state 1 shown in Figure 7(iii)(a), and state 2, shown in Figure 7(iii)(b)) throughout the application run-time because of changes in communication patterns corresponding to the different segments of the NAMD code.

Intra-application contention is less likely to elevate to cause global network issue, unless the links are involved in global (e.g., I/O) routes, or if the resulting congestion is heavy enough to trigger the system-wide mitigation mechanism (see Section 2.2).

Importance of diagnosis: In this section, we have identified three high-level causes of congestion, which we categorize as (a) system issues, (b) network-component failures, and (c) intra-application contention. For each cause, system managers could trigger one of the following actions to reduce/manage congestion. In the case of intra-application congestion, an automated MPI rank remapping tool such as TopoMapping [46], could be used to change traffic flow bandwidth on links to reduce congestion on them. In the case of inter-application congestion (caused by system issues or network failures), a node-allocation policy (e.g., TAS) could use knowledge of congested regions to reduce the impact of congestion on applications. Finally, if execution of an application frequently causes inter-application congestion, then the application should be re-engineered to limit chances of congestion.



(a) Box plot of duration of throttling



(b) Box plot of time between triggers of congestion mitigation events

Figure 8: Characterizing Cray Gemini congestion mitigation events.

6 Using Characterizations: Congestion Response

In this section, we first discuss efficacy of Cray CPEs and then show how our *CR*-based characterizations can be used to inform effective responses to performance-degrading levels of congestion.

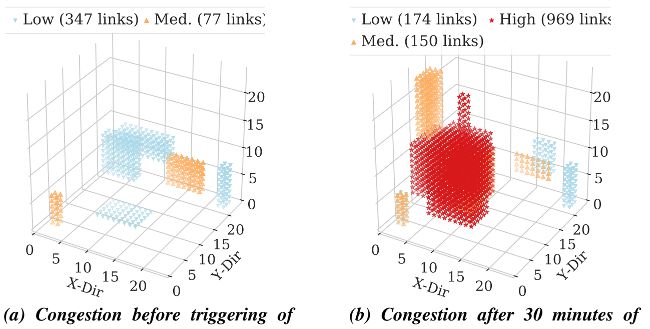
Characterizing Cray *CPEs*: Recall from Section 2 that the vendor-provided congestion mitigation mechanism throttles all NIC traffic injection into the network irrespective of the location and size of the triggering congestion region. This mitigation mechanism is triggered infrequently by design and hence may miss detections and opportunities to trigger more targeted congestion avoidance mechanisms. On Blue Waters, congestion mitigation events are generally active for small durations (typically less than a minute), however, in extreme cases, we have seen them active for as long as 100 minutes. Each throttling event is logged in *netwatch* log files.

We define a *congestion mitigation event (CME)* as a collection of one or more throttling events that were coalesced together based on a sliding window algorithm [63] with a sliding window of 210 seconds, and we use this to estimate the duration of the vendor-provided congestion mitigation mechanisms. Figure 8a and 8b shows a box plot of duration of and time between *CMEs* respectively. The analysis of *CMEs* shows that :

- CMEs were triggered 261 times; 29.8% of which did not alleviate congestion in the system. Figure 9 shows a case where the size and severity of *CRs* increases after a series of throttling events.
- The median time between triggers of CMEs was found to be 7 hours. The distribution of time between events is given in Figure 8b.
- CMEs are generally active for small durations (typically less than a minute), however, in extreme cases, we have seen them active for as long as 100 minutes.
- 8% of the application runs were impacted with over 700 of those utilizing $>$ 100 nodes.

These observations motivate the utility of augmenting the vendor supplied solution of global traffic suppression to manage exceptionally high congestion bursts with our more localized approach of taking action on *CRs* at a higher system-level of granularity to alleviate sources of network congestion.

***CR*-based congestion detection to increase mitigation effectiveness:** *CR* based characterizations can potentially im-



(a) Congestion before triggering of CPE

(b) Congestion after 30 minutes of CPE

Figure 9: A case in which a congestion protection event (CPE) failed to mitigate the congestion

prove congestion mitigation and CEMR effectiveness by more accurately determining which scenarios should be addressed by which mechanisms and by using the identified *CRs* to trigger localized responses more frequently than Cray *CMEs*. That approach is motivated by our discovery (see Section 5.2) that the network is in a *'High'* congestion *state* the majority of the time, primarily because of *CRs* of small size but significant congestion severity.

We define a *Regions Congestion Event (RCE)* as a time-window for which each time instance has at least one region of '*High'* congestion. We calculate it by combining the *CR* evaluations across 5-minute sliding windows. Figure 10 shows boxplots of (a) average credit P_{TS} across all extracted *CRs* during RCEs', (b) average inq P_{TS} across all RCEs', (c) times between RCE, and (d) durations of the RCEs'. These measurements show

- Relative to the vendor-provided congestion mitigation mechanisms, our characterization results in 13× more events (3390 RCEs) upon which we could potentially act.
- Vendor provided congestion mitigation mechanisms trigger on 8% (261 of 3390) of RCEs.
- The average P_{TS} of maximum inq- and credit-stall across all extracted regions present in *RCEs* is quite high, at 33.8% and 27.4%, respectively.
- 25% of 3390 RCEs lasted for more than 30 minutes, and the average duration was found to be approximately an hour.

CRs discovery could also be used for informing congestion aware scheduling decisions. Communication-intensive applications could be preferentially placed to not contend for bandwidth in significantly congested regions or be delayed from launching until congestion has subsided.

7 Using Characterizations: Diagnosing Causes of Congestion

Section 5.4 identifies the root causes of congestion and discusses the the importance of diagnosis. Here we explore that idea to create tools to enable diagnosis at runtime.

7.1 Diagnosis Methodology and Tool

We present a methodology that can provide results to help draw a system manager's attention to anomalous scenarios and potential offenders for further analysis. We can combine system information with the *CR*-characterizations to help diagnose causes of significant congestion. Factors include applications that inject more traffic than can be ejected into the targets or than the traversed links can transfer, either via communication patterns (e.g., all-to-all or many-to-one) or I/O traffic, and link failures. These can typically be identified by observation(s) of anomalies in the data.

Mining Candidate Congestion-Causing Factors For each congestion Region, CR_i, identified at time T, we create two tables $\mathscr{A}_{CR_i}(T)$ and $\mathscr{F}_{CR_i}(T)$, as described below.

$\mathscr{A}_{CR_i}(T)$ *table*: Each row in $\mathscr{A}_{CR_i}(T)$ corresponds to an application that is within $N_{hops} \leq 3$ hops away from the bounding box of the congestion region CR_i. $\mathscr{A}_{CR_i}(T)$ contains information about the application and its traffic characteristics across seven *traffic features*: (a) application name, (b) maximum read bytes per minute, (c) maximum write bytes per minute, (d) maximum RDMA read bytes per minute, (e) maximum RDMA write bytes per minute, (f) maximum all-to-all communication traffic bytes per minute, and (g) maximum many-to-one communication traffic bytes per minute, where the maximums are taken over the past 30 minutes, i.e., the most recent 30 measurement windows. The list of applications that are within N_{hops} away from congestion region CR_i are extracted from the *workload data*. The measurements for features (a) to (e) are extracted by querying network performance counter data, whereas we estimate the features (f) and (g) are estimated from Network performance counter data by taking several bisection cuts over the application geometry and comparing node traffic ingestion and ejection bytes among the two partitions of the bisection cut.

$\mathscr{F}_{CR_i}(T)$ *table*: Each row in $\mathscr{F}_{CR_i}(T)$ corresponds to an application that is within $N_{hops} \leq 3$ away from the congestion boundary of CR_i. $\mathscr{F}_{CR_i}(T)$ contains information about failure events across three *failure features*: (a) failure timestamp, (b) failure location (i.e., coordinates in the torus), and (c) failure type (i.e., switch link, network link, and router failures). Lists of failure events that are within N_{hops} away from congestion region CR_i are extracted from *network failure data*.

Identifying Anomalous or Extreme Factors: The next step is to identify extreme application traffic characteristics or network-related failures over the past 30 minutes that have led to the occurrence of CRs. For each traffic feature in $\mathscr{A}_{CR_i}(T)$, we use an outlier detection method to identify the top k applications that are exhibiting anomalous behavior. The method uses the numerical values of the features listed in table $\mathscr{A}_{CR_i}(T)$. Our analysis framework uses a median-based outlier detection algorithm proposed by Donoho [40] for each CR_i. According to [40], the median-based method is more robust than mean-based methods for skewed datasets. Because *CRs* due to network-related failure events [15] are rare relative to congestion caused by other factors, all failure events that

[15]In this paper, we do not consider the effect of lane failures on congestion.

(d) ***Boxplot of duration of congestion.***

Figure 10: Characterization of Regions Congestion Events (RCE).

occur within N_{hops} of CR_i in the most recent 30 measurement windows are marked as anomalous.

Generating Evidence: The last step is to generate evidence for determining whether anomalous factors identified in the previous step are truly responsible for the observed congestion in the *CR*. The evidence is provided in the form of a statistical correlation taken over the most recent 30 measurement time-windows between the moving average stall value of the links and the numerical traffic feature(s) obtained from the data (e.g., RDMA read bytes per minute of the application) associated with the anomalous factor(s). For failure-related anomalous factors, we calculate the correlation taken over the most recent 30 measurement time-windows between the moving average of observed traffic summed across the links that are within N_{hops} away from the failed link(s) and the stall values[16]. A high correlation produces the desired evidence. We order the anomalous factors using the calculated correlation value regardless of the congestion cause. Additionally, we show a plot of stall values and the feature associated with the anomalous factor(s) to help understand the impact of the anomalous factor(s) on congestion.

The steps in this section were only tested on a dataset consisting of the case studies discussed in Section 5.4 and 7 because of lack of ground truth labels on root causes. Creation of labels on congestion causes requires significant human effort and is prone to errors. However, we have been able to generate labels by using the proposed unsupervised methodology, which provides a good starting point for diagnosis.

7.2 Comprehensive Congestion Analysis

In this section, we describe an example use case in which our analysis methodologies were used to detect and diagnose the congestion in a scenario obtained from real data for which the ground truth of the cause was available. The overall steps involved in using our methodologies, included in our *Monet* implementation, for congestion detection and diagnosis are summarized in Figure 11 and described in Section 7. Not all of the steps discussed below are currently automated, but we are working on automating an end-to-end pipeline.

Step 1. Extraction of CR. Figure 11(a) shows that our analysis indicated wide spread high-level congestion across the system (see the left graph in Figure 11(a)). An in-depth analysis of the raw data resulted in identification/detection of congestion regions (see the top-right graph in Figure 11(a)).

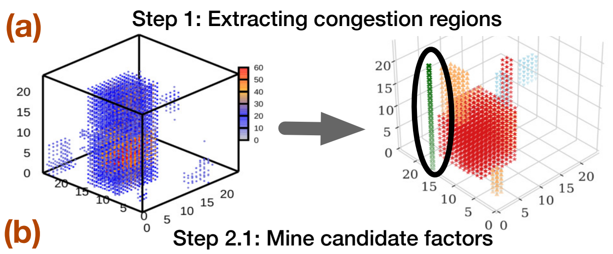
Step 2. Congestion diagnosis. There are 3 steps associated with diagnosing the cause of the congestion.

Step 2.1. Mining candidate factors. To determine the cause of the congestion, we correlated the CR-data with application-related network traffic (for all applications that overlapped with or were near the congestion regions) and network information to generate candidate factors that may have led to congestion. In this example, there were no failures; hence, this analysis generated only application-related candidate factors $\mathscr{A}_{CR_i}$, as shown in Figure 11.

Step 2.2. Identifying anomalous factors. Next, we utilized the application traffic characteristics from candidate factors observed over the last 30 minutes (i.e., many-to-one or all-to-all traffic communication, and file system statistics such as read or write bytes) to identify anomalous factors by using a median-based outlier detection algorithm. In our example, as indicated in Figure 11(b), the offending application was "Enzo" which was running on 32 nodes allocated along the "Z" direction at location (X,Y,Z) = (0,16,16) (indicated by a black circle in Figure 11(a)). At the time of detection, "Enzo" was reading from the file system at an average rate of 4 GB/min (averaged over past 30 minutes and with a peak rate of 70 GB/min), which was 16x greater than the next-highest rate of read traffic by any other application in that time-window. The $\mathscr{A}_{CR_i}(T)$ for RDMA read bytes/min was 70 GB/min. The tool identified the RDMA read bytes/min of the "Enzo" application as the outlier feature. Hence, "Enzo" was marked as the anomalous factor that led to the congestion.

Step 2.3. Generating evidence. Once the potential cause had been established, further analysis produced additional evidence (e.g., distribution and correlation coefficient associated with link stalls in the congestion time window) to validate/verify the diagnosis results produced in Step 2.2. Figure 11(c), in the top graph, shows a plot of the sum of stall rates on all links for all the Gemini routers local to the compute nodes used by the offending application, (i.e., Enzo) (normalized to the total stall rate throughout the duration of the application run). The two peaks (marked) in this top plot correspond to the increase in read bytes (normalized to total read bytes during the application run) shown in the bottom plot. Note that abnormal activity (an excessive amount of traffic to the file system) occurred around 10:10 AM (as shown Figure 11(c)), which was about 20 minutes before the severe congestion developed in the system (seen in Figure 11(a)). A

[16]Increase in traffic near a failed link leads to congestion as shown in Section 5.4.



(b)

Step 2.1: Mine candidate factors

$\mathscr{A}_{CR_i}(T)$

App	RDMA Read	RDMA write	all-to-all	many-to-one
Enzo	70 GiB	~0	~0	1.7 GB/min
Engine_	4/1 GiB/min		~0	~0
...	..	...	...	...

* Traffic measurements max over last 30 minutes (GiB/min)

Step 2.2: Identify anomalous factors

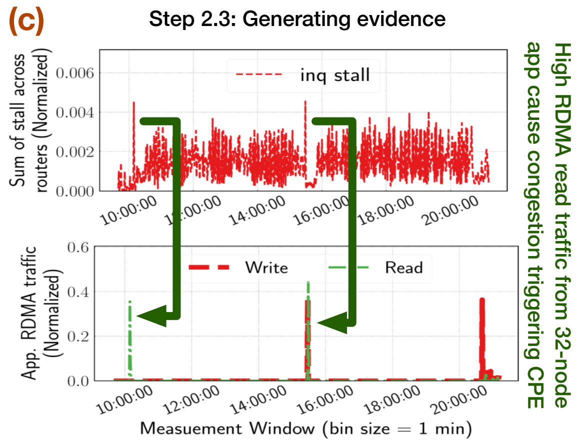


Figure 11: Detection and Diagnosis methodology applied to real-scenario

"Medium" level of congestion was detected in the system spanning a few links (i.e., the congestion region size was small) at the time of the increased read traffic. Thus the cause was diagnosed to be "Enzo". Although, in this example scenario, the Cray congestion mitigation mechanism was triggered, it was not successful in alleviating the network congestion. Instead, the CR size grew over time, impacting several applications. "Enzo" was responsible for another triggering of the congestion mitigation mechanism at 3:20 PM (see the top graph in Figure 11(c)). Monet detected and diagnosed it correctly.

8 Related Work

There is great interest in assessing performance anomalies in HPC systems with the goal of understanding and minimizing application performance variation [25, 86, 86, 88]. Monitoring frameworks such as Darshan [65], Beacon [87] and Kaleidoscope [54] focuses on I/O profiling and performance anomaly diagnosis. Whereas, our work focuses on assessing network congestion in credit-flow based interconnection networks. Typically congestion studies are based on measurements of performance variation of benchmark applications in production settings [25, 88] and/or modeling that assumes steady state utilization/congestion behavior [23, 52, 64, 73], and thus do not address full production workloads.

There are research efforts on identifying hotspots and mitigating the effects of congestion at the application or system-layer (e.g., schedulers). These approaches include (a) use of application's own indirect measures, such as messaging rates [25], or network counters from switch that are accessible only from within an allocation [38, 49, 50, 76], and therefore miss measurements of congestion along routes involving switches outside of the allocation; and (b) use of global network counter data [17, 26, 28, 30], however, these have presented only representative examples of congestion through time or executed a single application on the system [26].

In contrast, this work is the first long-term characterization of high-speed interconnect network congestion of a large-scale production system, where network resources are shared by nodes across disparate job allocations, using global network counters. The characterizations and diagnosis enabled by our work can be used to inform application-level [29] or system-level CEMRs (e.g., use of localized throttling instead of network-wide throttling). Perhaps, the closest work to ours is [22] which is an empirical study of cloud data center networks with a focus on network utilization and traffic patterns, and Beacon [87] which was used on TaihuLight [43] to monitor interconnection network inter-node traffic bandwidth. Like others, these works did not involve generation and characterization of congestion regions, diagnosis of congestion causes, nor a generalized implementation of a methodology for such, however, we did observe some complimentary results in our system (e.g., the existence of hot-spot links, the full bisection bandwidth was not always used, assessment of persistence of congestion in links).

Finally, for datacenter networks, efforts such as ExpressPass [32], DCQCN [89], TIMELY [69] focus on preventing and mitigating congestion at the network-layer whereas efforts such as PathDump [84], SwitchPointer [85], PathQuery [72], EverFlow [90], NetSight [51], LDMS [17] and TPP [53] focus on network monitoring. These approaches are tuned for TCP/IP networks and are orthogonal to the work presented here. Our approach is complementary to these efforts as it enables characterization of congestion regions (hotspots) and identification of congestion causing events.

9 Conclusions and Future Work

We present novel methodologies for detecting, characterizing, and diagnosing network congestion. We implemented these capabilities and demonstrated them using production data from NCSA's 27,648 node, Cray Gemini based, Blue Waters system. While we utilized the scale and data availability of the Blue Waters system to validate our approach, the methodologies presented are generally applicable to other credit-based k-dimensional meshes or toroidal networks. Our future work will involve extending the presented techniques to other network technologies and topologies (see Appendix C).

A HPC Interconnect Background

Here we briefly give an overview of HPC interconnects and dive deeper into the details of torus networks.

A.1 Interconnection Networks

An interconnection network is a programmable system that transports data between terminals. The main design aspects of interconnection networks are (1) topology, (2) routing, (3) flow control, and (4) recovery. Topology determines the connection between compute nodes and network nodes (routers, switches, etc.). Routing, flow control, and recovery heavily depend on the topology of the interconnection system. The most widely used topologies in high-performance computing (HPC) are (1) Fat-Tree (e.g. Summit [13]), (2) DragonFly (e.g., Edison [15]), and (3) Torus (e.g., Blue Waters [67]).

A.2 Torus Networks

Torus networks can support $N = k^n$ nodes which are arranged in a *k-ary n-cube* grid (i.e., nodes are arranged in regular n-dimensional grid with k nodes in each dimension). In the case of Blue Waters, $n = 3$. In torus networks, each node serves simultaneously as an input terminal, output terminal and switching node of the network. Torus networks are regular (i.e., all nodes have the same degree) and are also edge-symmetric (useful for load-balancing). Torus networks are very popular for exploiting physical locality between communicating nodes, providing low latency and high throughput. However, the average hop count to route packets to a random node is high compared with other network topolgoies such as Fat-Tree or DragonFly. On the other hand, extra hop counts provide path diversity, which is required for building fault-tolerant architecture.

Routing involves selection of the path from the source node (src) to destination node (dst) among many possible paths in a given topology. In torus networks, routing is done through the directional-order routing algorithm. Directional-order routing does the following:

- Routes the packet in X+/-, Y+, or Z+ until the dimension is resolved,
- Routes the packet in Y+/- or Z+ until the Y dimension is resolved, and
- Routes the packet in Z+/- until the Z dimension is resolved, at which point the packet must have arrived at its destination.

B Workload Information

On Blue Waters, all jobs execute in non-shared mode, without any co-location with another job on the same compute node. Users can submit batch or interactive jobs using Moab/Torque [14] and configure several parameters for job resource request such as: (i) number of nodes, (ii) the number of cores, and (iii) the system walltime (i.e., requested clock time for the job). Blue Waters puts a 48-hour walltime restriction. Blue Waters uses Integrated System Console (ISC) [44] to parse and store the job records and its associated metrics (performance and failure) in its database.

In [39], Di Martino *et al.* provided detailed characterization of more than 5 million HPC application runs completed during the first 518 production days of Blue Waters. However, for completeness, this section provides the workload characteristics of the jobs running on Blue Waters during our study period. Due to loss of data caused by a failure, we do not have workload information for Jan 2017 and hence the workload data shown here is from Feb 2017 - July 2017. During our study period, 2,219k jobs were executed by 467 unique users. We characterize the job characteristics in terms of i) job type, and ii) job size.

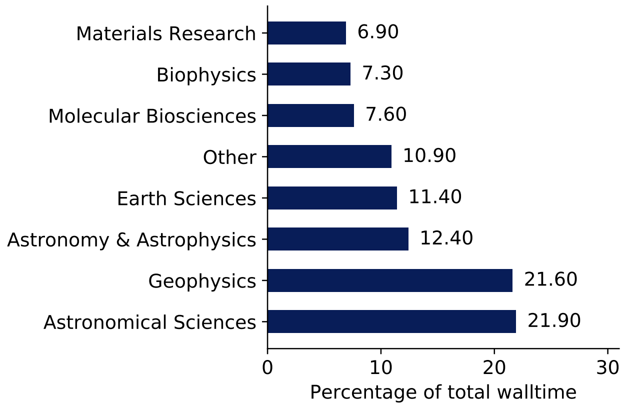
B.1 Job type

Blue Waters workload is predominantly composed of scientific applications. The most prolific scientific fields are summarized in Figure 12a in terms of node-hours. The top scientific discipline during our study period was 'Astronomical Sciences' (21.9%). However, the top scientific disciplines changes over time based on resource allocation awards given by US National Science Foundation and University of Illinois.

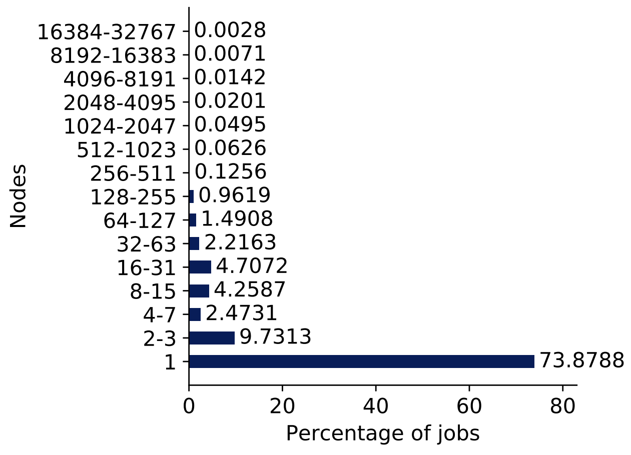
Definition 4 Node-seconds: *is the product of the number of nodes and the wallclock time (in seconds) used by a job. The metric captures the scale of the job's execution across space and time.*

B.2 Job Size

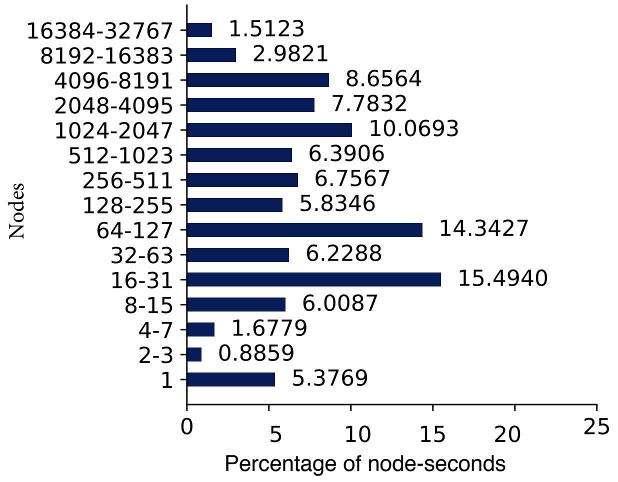
Figure 13b shows a bar plot summarizing relationship between percentage by node-seconds (see Def. 4) and percentage of jobs, whereas Fig. 13a shows a bar plot summarizing relationship between number of nodes and percentage of jobs. 74% of the jobs are single-node jobs. However, these jobs contribute *only* 5% by node-seconds. The large-scale jobs by number are small, they contribute to 94% of the total node-seconds.



(a) Breakdown of wallclock time of scientific application domains



(a) Percentage of jobs by node count



(b) Percentage of node-seconds

Figure 13: Characteristics of jobs running on Blue Waters.

C Existence of Congestion Hotspots and Regions in DragonFly Interconnect

Here we characterize hotspot links on Edison [15], a 2.57 petaflops production system, to showcase continued existence of network congestion problems on a current state of the art network interconnect. Edison uses Cray Aries interconnect which is based on DragonFly topology and uses adaptive routing [59]. We use one week of LDMS data that was collected from Edison at one second interval, and amounts to 7.7 TB. Our analyses shows 1) presence of long duration hotspot links, and 2) performance variability on a current state of the art network interconnect.

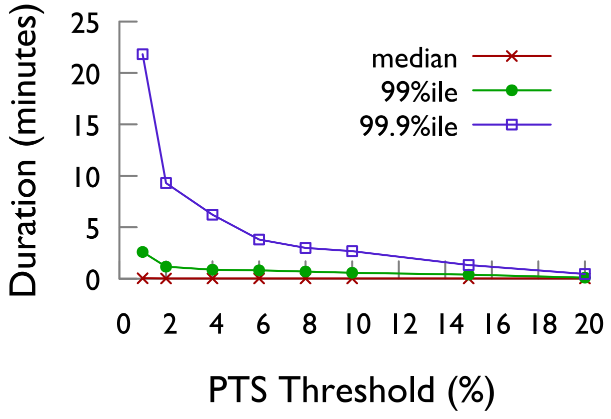


Figure 14: Distribution of hotspot link duration in Edison [replicated from [56]]

Figure 14 characterizes the median, 99%ile and 99.9%ile duration of the hotspot links by generating the distribution of the duration for which a link persists to be in congestion at $P_{Ts} \geq P_{Ts}$ Threshold. While the 99.9%ile hotspot duration is an order of magnitude lesser compared to the observed results in Gemini (see Figure. 3), which can be explained by the low diameter topology and use of congestion-aware routing policies in Aries. The duration of hotspot is longer than a minute for congestion thresholds less than 15% P_{Ts}. More details on characterization for Edison can be found in [56].

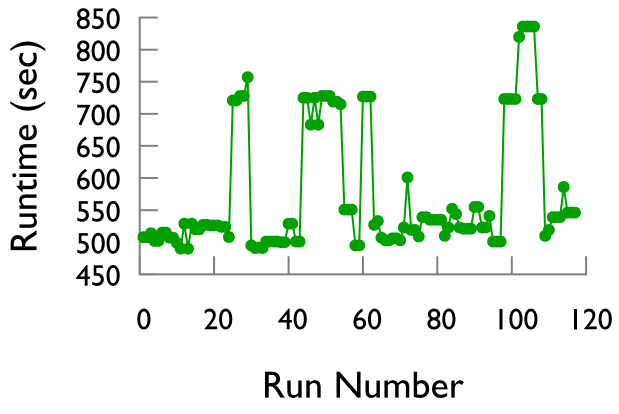

Figure 15: Variation of MILC runtime on Edison

Although the hotspot link duration has significantly decreased, the performance variation due to congestion continues to be a problem. For example, we observed significant performance variation of up to 1.67× compared to baseline for MILC application [25] on Edison (see Figure 15). MILC is a communication-heavy application susceptible to congestion on the interconnect. The reason for slowdown of the application can be attributed to presence of congestion in the links which rapidly evolves (i.e., a link may not be continuously congested but there is always groups of congested links). Preliminary analysis of network congestion counters obtained from Edison [15] suggests existence of congestion regions that evolve rapidly. Our future work will focus on applying and extending our methodology to other interconnects technologies that use different topology other than torus (e.g., Fat-Tree or DragonFly) or use adaptive-routing (e.g., UGAL [59]). In emerging network technologies, vastly more network performance counters are available that can be used for detecting congestion and hence there is an increased need for algorithmic methods for discovering and assessing congestion at system and application-level.

D Validation of Congestion Regions Generated by Region Segmentation

Validation of the region segmentation algorithm was done by inspecting visualizations of both the unsegmented and segmented congestion data. We also generated synthetic congestion data and evaluated our algorithm's performance on it as a sanity check.

D.1 Results Analysis Discussion

As we do not have any ground truth for our clustering algorithm and the credit and inq stall on each link widely varies across the system with time (as discussed in previous subsection), we attempted some sanity checks in order to validate that the algorithm produced a sensible clustering of the data. To facilitate this, we implemented visualization tools for visualizing both the raw, unsegmented data, as well as the final, segmented data. We then ran our algorithm on the congestion data that was recorded at times when we knew there were congestion events (e.g. when Cray congestion protection events were triggered), as well as at multiple randomly sampled timepoints. We then visualized both sets of data and manually inspected the regions generated, checking visually to see if they lined up with the visualization of the raw congestion data. For samples that we inspected, the algorithm worked well for segmenting the data.

As a further test, we generated random congestion data following a simplified model and scored our algorithm's effectiveness at classifying those data. The data was created by randomly generating regions of congestion in a 24 x 24 x 24 cube representing the 3D torus of the Blue Waters Gemini interconnect. Each congestion region was created by randomly generating a) a cuboid in which each dimension was between 3 and 9 links inclusive, b) a random stall value s between 20% and 50%, and c) a random integer from $\{0, 1\}$. Depending on the value of the random integer, s was added to the credit-stall or inq-stall of all the links in the cuboid. Finally, after all regions were added random Gaussian noise with $(\mu, \sigma) = (0, 2.5)$ was added to both the credit- and inq-stalls of all the links in the cube to simulate small variances in the stall values of each link.

We then ran our algorithm on 100 samples, each with a random number of regions (from 1 to 8 inclusive), and assigned a score as well as calculating the precision and recall for that sample. We scored the match as follows: for a single sample, let $A_i, i = 1 \cdots n$ be the actual regions and $B_i, i = 1 \cdots m$ be the regions the algorithm produced. A single sample was then assigned the score $(\frac{1}{n}\sum_{i=1}^{n}\frac{|A_i \cap B_{j_i}|}{|A_i \cup B_{j_i}|})(\frac{n}{\max(n,m)})$, where $|A_i|$ represents the number of links in the enclosed region, and the B_{j_i} are the regions that "best" overlap their respective A_i. The B_{j_i} are chosen by going through the regions A_i in order from smallest to largest, and choosing j_i such that B_{j_i} has the largest possible overlap with A_i. Regions created by segmentation that have both inq- and credit-stall $< 5\%$ are considered insignificant and were excluded from this processing.

This scoring assigns a score of 1 to a perfect match, which degrades to 0 when a) the mismatch between the true and the matching generated region increases, or when b) the algorithm generates more regions than true regions.

Based on that scoring, the algorithm achieved an average score of 0.81 (maximum 1.0) with parameters $(\theta_p = 12, \theta_r = 8, \theta_d = 2, \theta_s = 20)$ over 100 samples, with an average precision of 0.87 and an average recall of 0.89.

D.2 Summary

While it is not possible to fully validate the efficacy of our segmentation algorithm, the synthetic datasets generated give us a degree of confidence that the algorithm does the right thing on simple models of congestion that satisfy our assumptions (i.e. that congestion tends to spread locally) and work well with noise. The comparison between the datasets before and after the segmentation suggests that algorithm does still work reasonably well in practice, on real datasets.

The region segmentation algorithm was applied to 5 months of production data collected as part of the operational environment of a system. The data was obtained from Blue Waters through various tools and counters(e.g., network performance counters, link-aggregated data, scheduler and log files) and hence is reliant on the correctness. The reliability of the system software for synchronized data collection at regular intervals (LDMS) is dependent on the system operation staff which supports it and performance details for this software are available in its documention.

SP-PIFO: Approximating Push-In First-Out Behaviors using Strict-Priority Queues

ETH Zürich

Abstract

Push-In First-Out (PIFO) queues are hardware primitives which enable programmable packet scheduling by providing the abstraction of a priority queue at line rate. However, implementing them at scale is not easy: just hardware designs (not implementations) exist, which support only about 1k flows.

In this paper, we introduce SP-PIFO, a programmable packet scheduler which closely approximates the behavior of PIFO queues using strict-priority queues—*at line rate, at scale, and on existing devices*. The key insight behind SP-PIFO is to dynamically adapt the mapping between packet ranks and available strict-priority queues to minimize the scheduling errors with respect to an ideal PIFO. We present a mathematical formulation of the problem and derive an adaptation technique which closely approximates the optimal queue mapping without any traffic knowledge.

We fully implement SP-PIFO in P4 and evaluate it on real workloads. We show that SP-PIFO: (i) closely matches PIFO, with as little as 8 priority queues; (ii) scales to large amount of flows and ranks; and (iii) quickly adapts to traffic variations. We also show that SP-PIFO runs at line rate on existing hardware (Barefoot Tofino), with a negligible memory footprint.

1 Introduction

Until recently, packet scheduling was one of the last bastions standing in the way of complete data-plane programmability. Indeed, unlike forwarding whose behavior can be adapted thanks to languages such as P4 [7] and reprogrammable hardware [2], scheduling behavior is mostly set in stone with hardware implementations that can, at best, be configured.

To enable programmable packet scheduling, the main challenge was to find an appropriate abstraction which is flexible enough to express a wide variety of scheduling algorithms and yet can be implemented efficiently in hardware [22]. In [23], Sivaraman et al. proposed to use Push-In First-Out (PIFO) queues as such an abstraction. PIFO queues allow enqueued packets to be pushed in arbitrary positions (according to the packets rank) while being drained from the head.

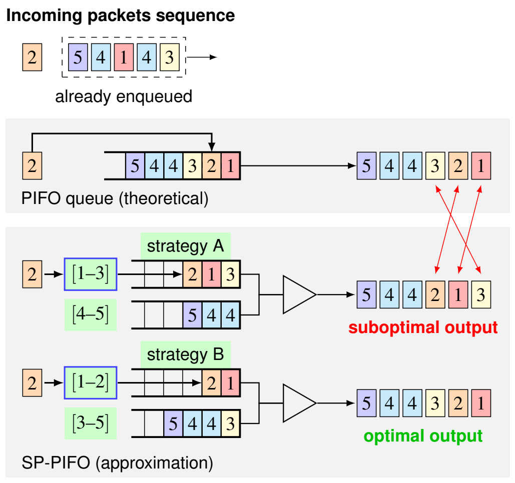

Figure 1: SP-PIFO approximates the behavior of PIFO queues by adapting how packet ranks are mapped to priority queues.

While PIFO queues enable programmable scheduling, implementing them in hardware is hard due to the need to arbitrarily sort packets at line rate. [23] described a possible hardware design (not implementation) supporting PIFO on top of Broadcom Trident II [1]. While promising, realizing this design in an ASIC is likely to take years [6], not including deployment. Even ignoring deployment considerations, the design of [23] is limited as it only supports ~1000 flows and relies on the assumption that the packet ranks increase monotonically within each flow, which is not always the case.

Our work In this paper, we ask whether it is possible to approximate PIFO queues at scale, in existing programmable data planes. We answer positively and present SP-PIFO, an adaptive scheduling algorithm that closely approximates PIFO behaviors on top of widely-available Strict-Priority (SP) queues. The key insight behind SP-PIFO is to dynamically adapt the mapping between packet ranks and SP queues in order to minimize the amount of scheduling mistakes relative to a hypothetical ideal PIFO implementation.

Example First, we provide an intuition how SP-PIFO approximates PIFO behaviors using SP queues in Fig. 1. The example illustrates the scheduling behavior of two SP-PIFO systems which receive the input packet sequence $\boxed{2}\boxed{5}\boxed{4}\boxed{1}\boxed{4}\boxed{3}$. By convention, we write the first packet being enqueued on the far-right ($\boxed{3}$) and the last one on the far-left ($\boxed{2}$). Similarly to [23], we also consider that lower-rank packets have higher priority (and use corresponding color codes). The figure illustrates the scheduling decision of each system for the sixth packet ($\boxed{2}$), assuming the first 5 have been enqueued already.

A PIFO queue always schedules incoming packets perfectly, leading to the sorted output $\boxed{5}\boxed{4}\boxed{4}\boxed{3}\boxed{2}\boxed{1}$. In contrast, the quality of the scheduling of a SP-PIFO scheme depends on: (i) the number of SP queues available (here, two); and (ii) the mapping of packet ranks to those queues. Fig. 1 illustrates two such mapping strategies. Strategy A maps ranks 1–3 (resp. 4–5) to the highest (resp. lowest) SP queue, while Strategy B maps ranks 1–2 (resp. 3–5) to the highest (resp. lowest) SP queue. We see that Strategy B is capable of perfectly sorting the input sequence, i.e. it behaves like a perfect PIFO queue. In contrast, Strategy A leads to sub-optimal packet inversions, e.g. $\boxed{1}$ is incorrectly scheduled after $\boxed{3}$.

Insights The key challenge in SP-PIFO is to design adaptation strategies that can: (i) closely approximate PIFO behavior; and (ii) be implemented in programmable data planes. These are hard challenges as the best mapping strategy depends on the traffic mix and the actual ranks being enqueued, both of which can change on a per-packet basis.

SP-PIFO approximates the best mapping strategy by dynamically shifting the ranks mapped to each queue to reduce the scheduling mistakes it observes in real time. We show that SP-PIFO's adaptation strategy achieves almost the same performance as provably-correct adaptation strategies while being implementable in programmable data planes.

Performance We use SP-PIFO to implement a wide variety of scheduling objectives ranging from minimizing flow completion times to achieving max-min fairness. For all cases, we show that SP-PIFO achieves performance on-par with the state-of-the-art. We also demonstrate that SP-PIFO runs at line rate on existing programmable hardware.

Contributions Our main contributions are:

- A novel approach for approximating PIFO queues using strict-priority queues (§3).
- An adaptation algorithm which dynamically adapts the queue mapping according to the network conditions, closely-approximating an optimal scheme (§4).
- An implementation[1] of SP-PIFO in Java and P4 (§5).
- A comprehensive evaluation showing SP-PIFO effectiveness in approximating perfect PIFO behavior with as little as 8 queues and on actual hardware switches (§6).

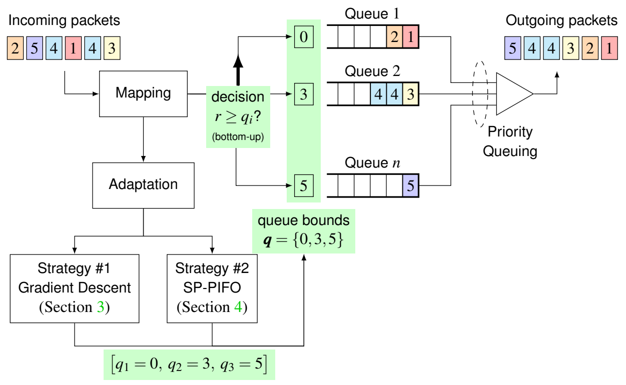

Figure 2: Overview of SP-PIFO data-plane pipeline.

2 Overview

In this section, we provide an informal overview of how SP-PIFO manages to closely approximate PIFO behaviors. At a high level, SP-PIFO is a priority-queuing scheduling discipline (see Fig. 2) which maps incoming packets to n priority queues. SP-PIFO assumes that packets are tagged with a rank indicating the intended scheduling order, with lower ranks being preferred over higher ones. Packets enqueued in a queue are scheduled according to their order of arrival (i.e., First-In First-Out), after *all* packets enqueued in any higher-priority queue have been scheduled. Unlike classical priority-queuing disciplines [20], SP-PIFO dynamically adapts the mapping between the packet ranks and the priority queues according to the observed network conditions. In particular, SP-PIFO adapts the mapping so as to minimize the scheduling "unpifoness", that is, the number of times a higher-rank packet is scheduled *before* an enqueued lower-rank packet. We refer to such scheduling mistakes as *inversions*.

Mapping SP-PIFO maps each incoming packet to queues according to the queue *bounds*. These queue bounds identify, for each queue i, the smallest packet rank that can be enqueued. Whenever a packet is received, SP-PIFO scans the queue bounds bottom-up, starting from the lowest-priority queue, and enqueues the packet in the first queue with a bound smaller or equal to the packet rank. Given a packet with rank $r \in \mathbb{Z}_{\geq 0}$ and n priority queues, let $\boldsymbol{q}$ be the vector of queue bounds $(q_1, \cdots, q_n) \in \mathbb{Z}^n$ such that $0 \leq q_1 \leq q_2 \leq \cdots \leq q_n$. For instance, consider a vector $\boldsymbol{q} = \{0,3,5\}$ indicating the bounds of 3 priority queues, with 0 (resp. 5) indicating the bound of the highest- (resp. lowest-) priority queue. Given $\boldsymbol{q}$, SP-PIFO enqueues packets with rank 2 in the first (highest-priority) queue, packets with rank 3 in the second queue and packets with rank 10 in the third (lowest-priority) queue.

Adaptation "Unpifoness" can be minimized across multiple packets, e.g. by monitoring the rank distribution over periodic time windows and adapting the bounds through a gradient descent, or on a per-packet basis (see Fig. 2). Depending on the characteristics of the rank distribution, the first strategy can provably converge to the optimal mapping. Unfortunately, its requirements exceed the capabilities of existing programmable data planes. SP-PIFO addresses these two limitations: it works for *any* rank distribution, on existing hardware. SP-PIFO dynamically adapts **q** such that the resulting scheduling closely approximates an ideal PIFO queue, minimizing the amount of observed *inversions* by dynamically shifting the ranks mapped to each queue. SP-PIFO operates online, *without* prior knowledge of the incoming packet ranks.

SP-PIFO's adaptation mechanism consists of two stages: a *push-up* stage where future low-rank (i.e. high-priority) packets are pushed to higher-priority queues; and a *push-down* stage where future high-rank (i.e. low-priority) packets are pushed down to lower queues.

Stage 1: Push-up Whenever SP-PIFO enqueues a packet, it updates the corresponding queue bound to the rank of the enqueued packet. Doing so, SP-PIFO aims at ensuring that future lower-ranked packets will not be enqueued in the same queue, but in a more preferred one. Intuitively, SP-PIFO "pushes up" packets with low ranks to the highest-priority queues, where they will drained first. Of course, as the number of queues is finite—and often, much smaller than the number of ranks—this is not always possible, leading to inversions.

Stage 2: Push-down Whenever SP-PIFO detects an inversion in the highest-priority queue (i.e., the packet rank is smaller than the highest-priority queue bound), it decreases the queue bound of *all* queues. Doing so, SP-PIFO ensures that future higher-rank packets will be enqueued in lower-priority queues. Intuitively, after an inversion, SP-PIFO "pushes down" packets with high ranks to the lower-priority queues in order to prevent them from causing inversions in the highest-priority queue. SP-PIFO decreases the queue bounds according to the magnitude of the inversion, i.e. the difference between the packet rank and the corresponding queue bound: the bigger the inversion, the more ranks are pushed down.

Example Fig. 3 illustrates the execution of SP-PIFO with two priority queues when receiving $\boxed{1}\boxed{2}\boxed{5}\boxed{4}\boxed{1}\boxed{4}\boxed{3}$. Without loss of generality, we consider that the queue bounds are initialized to 0. SP-PIFO enqueues the first packet ($\boxed{3}$) in the lowest-priority queue and updates its queue bound to 3. Likewise, SP-PIFO also enqueues the second packet, $\boxed{4}$, in the lowest-priority queue. As its rank (4) is higher than the queue bound (3), it then updates the queue bound to 4.

The same process is applied to the subsequent packets until the second $\boxed{1}$ is encountered, creating an inversion (grayed area in Fig. 3). Indeed, SP-PIFO enqueues $\boxed{1}$ in the highest-priority queue *after* having enqueued $\boxed{2}$. Once the inversion is detected, SP-PIFO adapts the queue bounds to 1 and $5-1=4$, respectively. Observe that if $\boxed{1}$ and $\boxed{2}$ keep arriving, the bound of the lowest-priority queue will decrease, eventually reaching 2. At this point, future $\boxed{1}$ will not experience inversions anymore as they will have a dedicated queue.

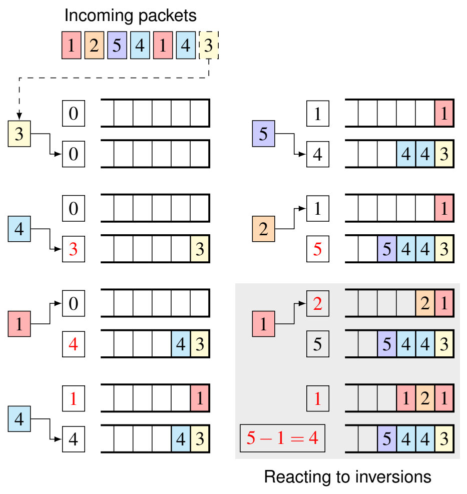

Figure 3: SP-PIFO mapping and adaptation mechanisms.

3 SP-PIFO design

In this section, we describe the theoretical basis supporting the design of SP-PIFO. We first phrase the problem of finding the optimal queue bounds as an empirical risk minimization problem in which a loss function—how "unpifo" the current mapping is—is minimized (§3.1). We then develop an algorithm based on gradient descent which provably converges to the optimal bounds for stable rank distributions (§3.2). We show how the convergence requirements make the algorithm impractical (§3.3). In the following, we present SP-PIFO which relaxes the requirements at the benefit of practicality (§4).

3.1 Problem statement

Let $\mathcal{U} : \mathrm{R}^n \times \mathrm{R}_{\geq 0} \rightarrow \mathrm{R}_{\geq 0}$ be a loss function such that $\mathcal{U}(\boldsymbol{q}, r)$ quantifies the approximation error of scheduling a packet with rank r based on queue bounds $\boldsymbol{q}$ compared to an ideal PIFO queue. Intuitively, a smaller loss equals a better approximation. Note that $\mathcal{U}$ stands for *unpifoness*.

The adaptation goal is to find the optimal queue bounds $\boldsymbol{q}^*$ that minimize the expected loss for all possible ranks. Let $\mathcal{Q}$ be the space of all valid bound vectors and $\mathcal{R}$ the distribution of packet ranks, then the optimal queue bounds $\boldsymbol{q}^*$ are:

$$\boldsymbol{q}^* = \arg\min_{\boldsymbol{q} \in \mathcal{Q}} \mathop{\mathbb{E}}_{r \sim \mathcal{R}} \left[\, \mathcal{U}(\boldsymbol{q}, r) \, \right] \tag{1}$$

Finding $\boldsymbol{q}^*$ directly is intractable though. Indeed, evaluating the expected loss $\mathcal{U}$ is impossible since the distribution of packet ranks $\mathcal{R}$ is unknown. We address this problem by considering the *empirical loss* $\mathcal{U}_{emp}$ observed over a set $\mathcal{D}$ of i.i.d. rank samples. Doing so, we phrase the problem of finding $\boldsymbol{q}^*$ as an *empirical risk minimization* (ERM) problem:

$$\boldsymbol{q}^* = \arg\min_{\boldsymbol{q} \in \mathcal{Q}} \frac{1}{|\mathcal{D}|} \sum_{r \in \mathcal{D}} \mathcal{U}_{emp}(\mathcal{D}, \boldsymbol{q}, r) \tag{2}$$

Evaluating empirical losses For a given rank r, we measure the empirical loss $\mathcal{U}_{emp}$ as the *expected* number of inversions that r would encounter, if the rank distribution $\mathcal{D}$ was scheduled given the queue bounds $\boldsymbol{q}$, weighted by the *cost* that each inversion would cause to the system performance. This cost can be just a constant value, if all inversions are treated the same, or it can measure the magnitude of the inversion (i.e., how big is the difference between ranks causing it). Since r receives inversions only from higher ranks in the distribution, $\mathcal{U}_{emp}$ can be rewritten as:

$$\mathcal{U}_{emp}(\mathcal{D},\boldsymbol{q},r) = \frac{1}{|\mathcal{D}|}\sum_{\substack{r'\in\mathcal{D}\\ r'>r}} \text{cost}_{\boldsymbol{q}}(r',r) \tag{3}$$

Having formulated the adaptation goal as an empirical risk minimization, we aim to solve it by analyzing how changes in $\boldsymbol{q}$ influence the empirical risk, and trying to design an iterative algorithm capable of converging to the minimal risk.

3.2 Gradient-based adaptation algorithm

We first introduce a greedy, gradient-based algorithm, which provably converges to the optimal queue bounds $\boldsymbol{q}^*$ provided that the rank distribution stays constant. The algorithm builds upon the fact that inversions cannot occur between ranks mapped to different priority queues. This allows to instantiate the empirical risk minimization in eq. 2 at a *queue level* by simply adding the individual losses of each queue. Letting $\mathcal{U}(q_i)$ be the loss function corresponding to the queue with bound q_i, this is:

$$\boldsymbol{q}^* = \underset{\boldsymbol{q}\in Q}{\arg\min} \sum_{q_i\in\boldsymbol{q}} \mathcal{U}(q_i) \tag{4}$$

Letting $p_{\mathcal{D}}(r)$ and $p_{\mathcal{D}}(r')$ be the empirical probability of ranks r and r', respectively, both mapped to the queue with bound q_i, we can define the unpifoness of the queue as:

$$\mathcal{U}(q_i) = \sum_{\substack{q_i\le r<q_{i+1}\\ r<r'<q_{i+1}}} p_{\mathcal{D}}(r)\cdot p_{\mathcal{D}}(r')\cdot \text{cost}(r',r) \tag{5}$$

Overview Considering this problem instantiation, the greedy algorithm first computes the rank distribution over a set of k packets before minimizing the expected per-queue unpifoness by incrementing (resp. decrementing) the queue bounds. Specifically, after processing the k-th packet, the greedy algorithm selects, for each queue, the bound that most decreases the overall system unpifoness. Although comparing the performance of all bound combinations is not possible, we introduce an efficient computation mechanism that allows to prune the search space while preserving convergence. We prove the optimality of the algorithm in Appendix A.

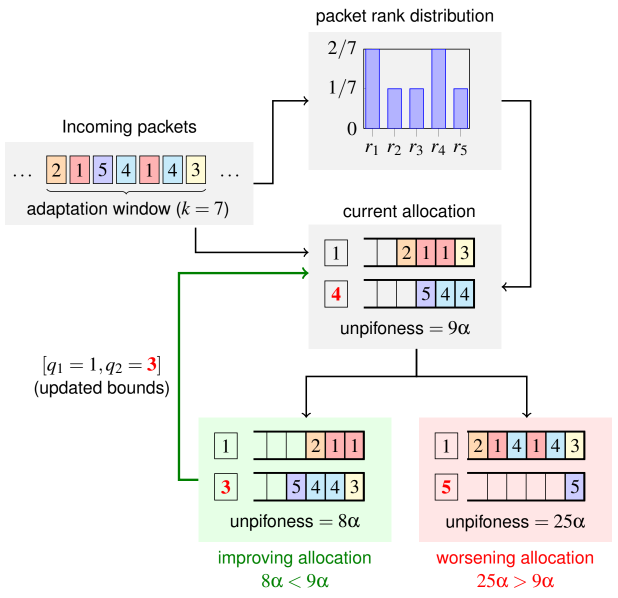

Figure 4: The gradient-based algorithm greedily minimizes the expected *unpifoness*.

Example We illustrate the execution of the algorithm in Fig. 4. We assume a system with two priority queues and assume that the packet sequence 2 1 5 4 1 4 3 is received over and over again. We set the adaptation window k to 7 packets. We initialize the queue bounds to 1 and 4.

The algorithm starts by computing the observed rank distribution after receiving the 7-th packet. Here, it estimates the probability of receiving a packet of rank 1 as $p(1) = 2/7$. Similarly, $p(2) = 1/7$, $p(3) = 1/7$, $p(4) = 2/7$ and $p(5) = 1/7$. It then computes the expected unpifoness that this distribution would have generated with the current queue bounds (eq. 3). For the higher-priority queue, this is $\mathcal{U}_1 = p(1)\cdot p(2)\cdot cost(2,1) + p(1)\cdot p(3)\cdot cost(3,1) + p(2)\cdot p(3)\cdot cost(3,2) = (2/7\cdot 1/7)\cdot(2-1)+(2/7\cdot 1/7)\cdot(3-1)+(1/7\cdot 1/7)\cdot(3-2)$. This equation can be simplified to $\mathcal{U}_1 = 7\alpha$ where $\alpha = (1/7\cdot 1/7)$. Similarly, $\mathcal{U}_2 = p(4)\cdot p(5)\cdot cost(5,4) = 2\alpha$, adding up a total of $\mathcal{U} = 9\alpha$.

Next, the algorithm compares the expected unpifoness that would be obtained if the queue bound was incremented (gradient up) or decremented (gradient down) and adapts the queue bound in the direction resulting in the biggest decrease of unpifoness.

Gradient up Incrementing q_2 from 4 to 5 means that only rank $\{5\}$ would be mapped to the lower-priority queue. The resulting unpifoness is $\mathcal{U} = 25\alpha$. The higher unpifoness (25α instead of 9α) indicates that, by incrementing q_2, the system gets further away from the PIFO behavior. Note that the increase in unpifoness comes from the higher-priority queue as rank $\{5\}$ gets an exclusive queue.

Gradient down In contrast, the system unpifoness reduces from 9α to 8α when decrementing q_2 from 4 to 3. Indeed, $\mathcal{U}_1 = p(1) \cdot p(2) \cdot cost(2,1) = 2\alpha$, and $\mathcal{U}_2 = p(3) \cdot p(4) \cdot cost(4,3) + p(3) \cdot p(5) \cdot cost(5,3) + p(4) \cdot p(5) \cdot cost(5,4) = 6\alpha$, adding up to $\mathcal{U} = 8\alpha$. As such, the adaptation mechanism updates the queue bound: $q_2 = 3$.

The above process repeats every 7-th packet, estimating the rank distribution before greedily adapting the queue bounds.

3.3 Limitations

While the adaptation algorithm described above provably converges to the optimal mapping (see A.1), two key limitations make it impractical. First, it is not currently implementable in existing programmable data planes due to resource constraints. Second, the algorithm only converges for stable rank distributions, which is rarely the case, and its convergence time directly depends on the distribution size, which can be large. We explain how to overcome these limitations in §4.

Hardware restrictions Monitoring the rank distributions over periodic adaptation windows requires a high amount of memory and computational resources, both of which are scarce in current programmable data planes. In particular, implementing the greedy algorithm in hardware (see A.2) requires to: (i) store the value of each queue bound; (ii) compute the current unpifoness; and (iii) estimate the unpifoness obtained by incrementing or decrementing each queue bound. As we explain in A.3, the amount of resources required to run the algorithm on a practical number of queues (8 queues or more) exceeds the capabilities of current switch designs.

Convergence In A.4, we study the performance of the gradient-based algorithm and analyze the effects on convergence when the adaptation window, the number of queues, and the rank range is modified. We show that, for the algorithm to converge, the rank distribution needs to be stable in time. However, this is unrealistic in most practical scenarios where not only the rank distribution *is unknown* but also varies through time (e.g., virtual times in fair-queuing schemes).

4 Our approach: SP-PIFO

We now present SP-PIFO, an approximation of the gradient-based adaptation algorithm (§3.2) which is implementable in existing data planes and rapidly adapts to varying rank distributions. SP-PIFO substitutes the gradient computation by a simpler adaptation process which minimizes the probability of inversions *per packet*, rather than per k-packets.

In the following, we first show how to instantiate the empirical risk minimization problem (eq. 2) at the packet level and describe how SP-PIFO solves it (§4.1). We then systematically characterize how SP-PIFO handles inversions (§4.2).

4.1 Per-packet adaptation algorithm

The SP-PIFO adaptation algorithm (alg. 1) is based on two competing stages that act in opposing direction. We show that this combination manages to strike a balance in the number of inversions observed by all queues, resulting in a good PIFO approximation. In the following, we first show how to phrase the empirical risk minimization problem at the per-packet level before describing both mechanisms.

Problem statement In contrast to §3.2, we aim at minimizing the cost generated by scheduling each individual packet. Formally, we aim to find the optimal bound vector $\boldsymbol{q}^*$ that minimizes the unpifoness for all enqueued packets $\mathcal{P}$:

$$\boldsymbol{q}^* = \arg\min_{\boldsymbol{q} \in \mathcal{Q}} \mathcal{U}(\mathcal{P}, \boldsymbol{q}) \tag{6}$$

Let $r(p)$ be the rank of a given packet $p \in \mathcal{P}$, and let $r_p(p,\ \boldsymbol{q})$ be the rank *perceived* as a result of the mapping decision, which is identified as the highest rank amongst those of packets sharing the same queue. Considering that the objective for the bound vector $\boldsymbol{q}$ is to perfectly approximate PIFO behaviors, we can estimate the unpifoness at enqueue as:

$$\mathcal{U}(\mathcal{P}, \boldsymbol{q}) = \sum_{p \in \mathcal{P}} \text{cost}_{\boldsymbol{q}}(p) \tag{7}$$

where

$$\text{cost}_{\boldsymbol{q}}(p) = r_p(p,\ \boldsymbol{q}) - r(p) \tag{8}$$

Computing the rank perceived requires determining the highest rank among all packets sharing the queue at any given moment. This not only requires to keep track of all ranks in each queue, but also selecting the highest, which is computationally expensive. Since one of the premises of SP-PIFO is to be implementable in the data plane, we relax this condition and keep track of only a single parameter q_i per queue. These parameters, the bounds $\boldsymbol{q}$, simplify the cost estimation of a potential mapping decision at enqueue.

We discuss how we update these parameters as well as the tradeoffs of this relaxation below.

Stage 1: "Push-up" The first stage increases $\boldsymbol{q}$ to minimize the unpifoness of the queue to which the incoming packet is mapped. Specifically, the mapping process scans the queues bottom-up and enqueues the packet in the first queue that satisfies $r(p) \geq q_i$. It then increases q_i to the rank of the enqueued packet. By doing so, the mechanism minimizes (i) the cost for each packet p (at enqueue time); as well as (ii) the impact that this decision may have on future packets.

This mapping process guarantees a zero-cost packet allocation for all packets within a queue. That is, as we effectively keep track of the highest rank per queue, we ensure that no packet with lower rank is mapped to the same queue. This holds for all queues except for the highest-priority queue. There, packets are enqueued even if $r(p) < q_1$.

Algorithm 1 SP-PIFO adaptation algorithm

```
Require: An incoming packet with rank $r$.

```

Stage 2: "Push-down" As illustrated in §2, the first stage can lead to inversions in the highest-priority queue. The second stage aims at counteracting that effect by reducing the number of ranks enqueued in the highest-priority queue. This is achieved by decreasing *all* queue bounds by some given amount. Different decreasing strategies exist. In SP-PIFO, we decrease each q_i proportionally to the cost of the inversion. That is, we decrease all queue bounds by $q_1 - r(p)$. This choice is both (i) practical, as it can be efficiently implemented in hardware; and (ii) functional, as it results in a reasonable balance between inversions in the highest-priority queue and shifts in the other queues. Below, we provide some insights on the nature of this balance and why it is important for a good PIFO approximation. We simulate the performance of different decreasing strategies in §4.2.

Tradeoffs Unlike the gradient-based algorithm (§3.2), SP-PIFO may converge to a sub-optimal solution exhibiting inversions. One can distinguish three sources of inversions. First, there can be inversions in the highest-priority queue. These inversions are proportional to the probability of observing packets with rank $r(p) < q_1$. Second, after the "push-down" stage, the queue bounds do not necessarily match the highest rank packet in the queue anymore. This may lead to inversions for future packets and is proportional to how often, and how much, queue bounds are decreased. Finally, because only the highest rank in a queue is tracked, it can happen that a packet is enqueued in a higher-priority queue because $r(p) < q_i$, while $r(p)$ is greater than the *lowest* rank in queue i, causing an inversion. This is proportional to the number of ranks between the minimum rank in the queue and the queue bound.

Average-case analysis The exact amount of inversions introduced by each of these three sources is hard to quantify as queue bounds are shifting with (almost) every packet. Yet, *on average*, we can show that the dynamics of SP-PIFO counteract all three sources. On the one hand, it equalizes the probability of $r(p) < q_1$ with the probability of packets being mapped to a specific queue, striking a balance between inversions because there are no higher-priority queues, and inversions because of queue bound mismatch. Furthermore, for this equalizing, the probabilities of specific ranks are weighted more if they are far away from queue bounds, which keeps queues more compact to reduce the chance of overlap.

As a result, on average workloads, SP-PIFO provides a good approximation, and can adapt to arbitrary rank distributions. Nevertheless, there are adversarial packet orderings circumventing these mechanisms, resulting in large unpifoness (§7). We provide the theoretical foundations for these statements in Appendix B and verify them by simulation in §4.2.

4.2 SP-PIFO analysis

We now dive deeper into understanding SP-PIFO using switch-level simulations. We compare its behavior to that of an ideal PIFO queue, along with several well-known scheduling schemes (e.g., FIFO). We first describe the high-level behavior using a uniform rank distribution (§4.2.1), before systematically exploring the design space (§4.2.2).

Methodology We implement various scheduling schemes (including SP-PIFO, FIFO, and our gradient-based algorithm) in Netbench [3, 15], a packet-level simulator. We analyze the performance of a single switch scheduling 1500 flows of 1MB (fixed), which start according to a Poisson distribution. We run the simulation during one second. We limit the transmission through an output link of 10 Gbps which corresponds to an average port utilization of 75%. We measure the number of inversions *generated by each rank* at *dequeue*. Whenever a packet is polled, we check whether its rank is higher than any of the ranks remaining at any of the queues. When this occurs, we count an inversion *to the rank generating it* (i.e., the one of the polled packet), making sure that inversions are counted at most once per polled-packet, regardless of the number of packets affected by it.

We compare four scheduling schemes: (i) SP-PIFO (§4); (ii) the gradient-based algorithm (§3, see implementation in A.2); (iii) a strict-priority scheme fixed to the optimal mapping for a uniform distribution (i.e., bounds distributed uniformly across ranks, $q_i = 12i$); and (vi) a FIFO queue, as baseline. All strict-priority schemes (SP schemes) use 8 queues of 10 packets, while the FIFO queue has a capacity of 80 packets.

4.2.1 Characterizing general SP-PIFO behavior

We start by showcasing how SP-PIFO handles inversions by analyzing its behavior under a uniform rank distribution. That is, we tag the packets with a rank drawn from a uniform distribution (between 0 to 100).

Fig. 5a illustrates the number of inversions generated by each rank for the different SP schemes in comparison with FIFO. We see that a FIFO queue generates a uniform number of inversions across all ranks (since they all share the same queue). In contrast, SP schemes (all the others in Fig. 5a) generate a progressively-higher number of inversions as rank val-

ues increase. This occurs as higher ranks are mapped to lower-priority queues, which drain packets less frequently. Since those queues have a higher occupancy on average, the potential number of inversions increases. This behavior, however, is not preserved for the lowest-priority queue (the far-right peak in the graph) as a result of starvation. Despite having the largest average queue size, this queue drains fewer packets and, as such, the number of inversions it sees decreases.

For the fixed-queue bounds, we see that a saw-shape delineates the inversions observed across ranks in different queues, reaching the x axis for the ranks corresponding to the queue bounds. Indeed, the lowest rank within each queue never generates inversions since the other ranks sharing the queue have higher values. The second-lowest rank can only generate inversions to the lowest, and the progression continues until the highest rank, which can generate inversions to all the lower ranks sharing the queue.

When considering the gradient-based greedy algorithm (which is optimal) and SP-PIFO, we see that the saw-shape vanishes. This is because queue bounds are not fixed anymore and successive packets of a given rank can be mapped to multiple queues. In particular, since the rank distribution sampled at each adaptation window varies, the queue-bound design in the gradient-based algorithm oscillates. In SP-PIFO, as a higher variability is produced, the number of inversions delineates the *envelope* of the optimal schemes.

4.2.2 Characterizing SP-PIFO design space

We now systematically explore the design space of SP-PIFO along four dimensions: the number of queues, the adaptation strategy when encountering an inversion (in the push-down stage, §4.1), the utilization levels, and the rank distributions.

SP-PIFO manages to approximate the optimal algorithms in all rank distributions and utilization levels, with as little as 8 queues. The best performances are obtained under low utilizations and with 32 queues.

Number of queues (Fig. 5b) When using only 8 queues, SP-PIFO is already within ∼20–29% of the gradient-descent algorithm and the optimal mapping. With 32 queues, it gets even closer, producing only ∼22% more inversions than the optimal and achieving on-par behavior to the gradient-descent algorithm. Overall, it improves FIFO performance ∼3.3× (resp. ∼10×) when only 8 (resp. 32) queues are used.

Push-down strategies (Fig. 5c) We evaluate four adaptation strategies for decreasing each queue bound in the push-down stage: (i) to the value of the next-higher queue bound (“Queue Bound”); (ii) by the cost of the inversion ($q_1 - r(p)$, the strategy in SP-PIFO, “Cost”); (iii) by the rank of the packet causing the inversion (“Rank”); and (iv) by 1 (“1”).

The best performance is obtained for “Queue Bound”, which produces ∼15% more inversions than the gradient-based algorithm. This is followed by “Cost” and “Rank”, with ∼22%, and “1” with ∼33%. While the three first techniques produce similar results, the “push down” effect of “1” is too small to balance the “push up” stage, resulting in many inversions. While “Queue Bound” is marginally better than “Cost”, it is more costly to implement, thus SP-PIFO uses the latter.

Utilization (Fig. 5d) SP-PIFO performance is close to the gradient-based algorithm. For utilizations below 60%, SP-PIFO is on-par with the gradient-based algorithm. The number of inversions slightly increases at higher utilizations: 26% and 38% for 80% and 90%.

Rank distributions (Fig. 6) We analyze the performance of SP-PIFO under four alternative rank distributions: exponential, inverse exponential, Poisson and convex. SP-PIFO performs better than FIFO and is close to the gradient-based algorithm for each distribution.

The performance of SP-PIFO is better for rank distributions in which more ranks appear in higher-priority queues. The number of inversions for SP-PIFO in convex and exponential distributions is only ∼21–24% higher than the gradient-based algorithm. The corresponding numbers for Poisson and inverse exponential amount to ∼49–55%. In all cases, SP-PIFO performs between ∼2.5–3.5× better than a FIFO, with only 8 priority queues.

5 Implementation

In this section, we describe our implementation of SP-PIFO in $P4_{16}$ [7] and $P4_{14}$.[2] Our implementation follows the algorithm described in §4 and spans 190 ($P4_{16}$) and 735 ($P4_{14}$) lines of code. It performs three main operations: (i) computing/extracting the rank from a packet header; (ii) mapping packets to queues (§2); and (iii) updating the queue bounds.

Rank computation We implemented and tested multiple rank computation functions such as LSTF [17], STFQ [23], and FIFO+ [9] in $P4_{16}$. We note that the reduced memory usage in SP-PIFO leaves room to compute ranks directly on the switch. That said, most ranking algorithms can directly be computed by the end-hosts [17].

Mapping We store the queue-bound values in individual registers and access them sequentially using an `if-else` conditional tree. For each register access, we leverage the ALU to perform three operations: (i) we read the queue-bound value and compare it to the packet rank; (ii) we notify the queue-selection result to the control flow using a single-bit metadata; and (iii) we update the queue-bound value to the packet rank if the queue is selected. In the ALU of the last queue, instead of transferring the mapping decision to the control flow using a binary metadata, we first check whether an inversion has occurred before transferring the potential inversion cost using larger metadata.

Adaptation When the mapping process detects an inversion, we need to update all queue bounds. While accessing multiple registers is not restricted by the P4 specification [10], current architectures do not support it (among others, to guarantee line rate). We address this problem by relying on the packet-resubmission primitive to access the queue bounds a second time and update them with the measured inversion cost. While resubmission can possibly break the line-rate guarantees, we only require it occasionally, upon inversions.

[2]The $P4_{14}$ code is used for running SP-PIFO on the Tofino platform [2].

Memory requirements Our implementation only requires n registers where n is the number of queues. We leverage n ALUs to access registers during the mapping process and $n-1$ additional ALUs to update registers from the resubmission pipeline in case of inversions. We use $n-1$ bits of metadata to access the mapping results of non-top-priority queues in their respective ALUs from the control flow (i.e., a single 1-bit metadata field for each queue) and an extra 32-bit field for the top-priority queue to (potentially) transfer the inversion cost.

Regarding the number of stages, our implementation uses more stages than the number of queues in order to perform the sequential access to queue-bound registers during the mapping process. Note that alternative designs would be possible but would come at the expense of line-rate guarantees.

6 Evaluation

We now evaluate SP-PIFO performance and practicality. We first use packet-level simulations to evaluate how SP-PIFO approximates well-known scheduling objectives under realistic traffic workloads (§6.1). We then evaluate SP-PIFO scheduling performance when deployed on hardware switches (§6.2).

6.1 Performance analysis

We consider two scheduling objectives: (i) minimizing Flow Completion Times (FCTs); and (ii) enforcing fairness. We consider that ranks are set at the end hosts for the former objective and computed in the switch for the latter. For both objectives, we show that SP-PIFO scheduling capabilities achieve near-optimal performance, with as little as 8 queues.

Methodology We integrated SP-PIFO in Netbench [3, 15], a packet-level simulator. Similar to [4], we use a leaf-spine topology with 144 servers connected through 9 leaf and 4 spine switches. We set the access and leaf-spine links to 1Gbps and 4Gbps, respectively. This results in a theoretical end-to-end Round-Trip-Time (RTT) of 32.12μs when crossing the spine (4 hops) and 26μs under the leaf (2 hops). We generate traffic flows following two widely-used heavy-tailed workloads: pFabric web application and data mining [4]. Flow arrivals are Poisson-distributed and we adapt their starting rates to achieve different utilization levels. We use ECMP and draw source-destination pairs uniformly at random.

6.1.1 Minimizing Flow Completion Times

Rank definition & benchmarks We minimize FCTs by implementing the pFabric algorithm [4] which sets the packet ranks according to their remaining flow sizes. Specifically, we compare pFabric performance when run on top of PIFO and SP-PIFO. We also analyze TCP NewReno with traditional drop-tail queues and DCTCP with ECN-marking drop-tail

Figure 8: pFabric: FCT statistics across different flow sizes in web search workload.

queues. Our pFabric implementation does not consider starvation prevention. As suggested in [4], we approximate pFabric rate control by using standard TCP with a retransmission time-out of 3 RTTs, balancing the difference in RTOs between schemes with the proportional queue size. That is, we use an RTO of 96μs and 8 queues×10 packets for SP-PIFO (resp. 1 queue×80 packets in PIFO), and an RTO of 300μs and 146KB drop-tail queues for both TCP and DCTCP, with ECN marking at 14.6KB, i.e. ∼10 packets.

Summary Fig. 7 and Fig. 8 depict the average and 99th percentile FCTs of large (≥ 1MB) and small flows (< 100KB) for both data mining and web search workloads. We see that SP-PIFO achieves close-to-PIFO performance in both distributions. When comparing performance across flow sizes, we see that SP-PIFO achieves better performance for small flows. This is not surprising since those flows are mapped into higher-priority queues. As discussed in §4.2, strict-priority schemes provide higher unpifoness protection for packets mapped into higher-priority queues.

When comparing the two traffic distributions, we see that SP-PIFO performs better under the data mining workload. This is again expected. While both distributions are heavy-tailed, the data mining one is more skewed [4] and therefore easier to handle for SP-PIFO. Indeed, the probability of having large flows simultaneously sharing the same port (potentially blocking smaller flows) is lower for the data mining workload.

Data mining (Fig. 7) The average FCTs achieved by PIFO and SP-PIFO are similar for small flows, i.e. within ∼0.4–11%. Concretely, SP-PIFO outperforms DCTCP and TCP by a factor of ∼2–5× and ∼8–30×, respectively. When considering the 99th percentile, the gap between PIFO and SP-PIFO slightly accentuates to ∼9.6–26.6%. Still, SP-PIFO outperforms DCTCP and TCP by a factor of ∼1.5–4.7× and ∼12.5–22×, respectively. The largest performance gap between PIFO and SP-PIFO occurs at low utilization. In this regime, the number of packets scheduled is low and the transient adaptation of SP-PIFO is more visible. Whenever the utilization is >40%, the difference is consistently below 20%. Finally, SP-PIFO and PIFO still perform similarly among large flows: within ∼1.9–9%, representing improvements with respect to TCP and DCTCP of ∼1.4–2.7× and ∼1.5–2.8×, respectively.

Web search (Fig. 8) The results are similar to the data mining one, with slightly worse performance for SP-PIFO, especially amongst big flows. Indeed, since the distribution is less skewed, bigger flows have higher chances to reach higher-priority queues, blocking transmissions of smaller flows. Still, we see that the performance of SP-PIFO is within ∼16.54–32.5% of PIFO for small flows, and between ∼1.3–4.4× and ∼4.7–16.7× better than DCTCP and TCP. Even at the 99th percentile, the difference between SP-PIFO and PIFO stays within ∼20.7–32%. Note that, while the percentages might seem high, the values we are looking at are very small.

Figure 9: Fairness: FCT statistics for all flows at different loads, over the web search workload.

6.1.2 Enforcing fairness across flows

Rank definition & benchmarks We enforce fairness across flows by implementing the Start-Time Fair Queueing (STFQ) rank design [13] on top of PIFO and SP-PIFO. We benchmark our solution with AFQ [21] (§8). We analyze the performance for different flow sizes and number of queues. Specifically, we use 8 queues×10 packets in SP-schemes (resp. 1 queue×80 packets for single-queue schemes) and 32 queues×10 packets in SP-schemes (resp. 1 queue×320 packets for single-queue schemes). For AFQ, we select the bytes-per-round parameter which gives the best performance. In our testbed, this is 320 and 80 BpR for the 8-queue and 32-queue scenario, respectively. As in [21], we use DCTCP as transport layer for AFQ, PIFO and SP-PIFO (with an RTO of 300μs). We set ECN marking to 48KB, i.e. ∼32 packets. We generate traffic following the pFabric web search distribution.

Summary Fig. 9a and Fig. 9b depict the average FCTs of small flows across different levels of utilization, when 8 queues and 32 queues are used. Fig. 9c depicts the FCTs across flow sizes at 70% utilization and for 32 queues. In all cases SP-PIFO achieves near-PIFO behavior and is on-par performance with AFQ (current state-of-the-art).

Impact of the utilization (Fig. 9a & Fig. 9b) SP-PIFO stays within ∼23–28% (resp. ∼21–28%) of ideal PIFO across all levels of utilization when 8 queues (resp. 32) are used. Even in the highest utilizations, it is consistently below ∼26% (resp. ∼25%). SP-PIFO performance is at the level of AFQ, within ∼3–10% (resp. ∼0.5–11%), generating improvements of ∼1.4–2.3× and ∼2.7–4.2× (resp. ∼1.4–2.3× and ∼3.7–7.4×) over DCTCP and TCP. The fact that SP-PIFO performance is equivalent with 8 and 32 queues is not surprising: as the bandwidth-delay product is low, only a reduced queue size is required for efficient link utilization.

Impact of flow sizes (Fig. 9c) At 70% utilization, we see that SP-PIFO lies within ∼10–30% of PIFO performance for all flow sizes and is on-par with AFQ. The only exception is for very small flows (<10K) in which AFQ performs 20% better. SP-PIFO improves DCTCP and TCP behaviors for small flows, within ∼1.5–3X and ∼2–13X, respectively. Considering the 99th percentile, we see that SP-PIFO stays within ∼8–35% of PIFO and improves between ∼12–78% and ∼1.5–10.76× with respect to DCTCP and TCP.

Impact of the number of queues (Fig. 10) We analyze the impact of the number of queues on average FCTs for both AFQ and SP-PIFO. We set the BpR at MSS for all queue configurations, as in [21], avoiding AFQ dropping packets too often for cases of fewer queues. We see that while AFQ has a higher sensitivity with respect to the number of queues, SP-PIFO preserves a similar level of performance, without any configuration or prior traffic knowledge.

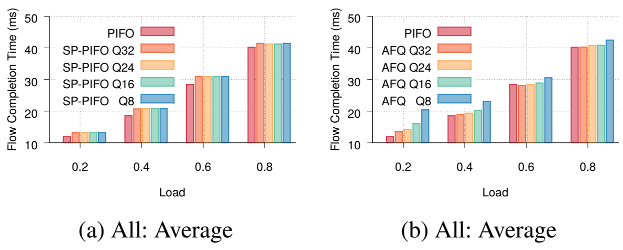
6.2 Hardware testbed

We finally evaluate our hardware-based implementation of SP-PIFO on the Barefoot Tofino Wedge 100BF-32X platform [2]. We perform two experiments. First, we analyze the bandwidth allocated by SP-PIFO to flows with different ranks when scheduled over a bottleneck link. Second, we measure the impact on the FCT when SP-PIFO runs pFabric. We show that SP-PIFO efficiently schedules traffic at potentially Tbps.

Bandwidth shares We transmit 8 UDP flows of 20Gbps between two servers. We generate the flows progressively, in increasing order of priority (decreasing rank). We use 4 priority queues and schedule the flows over a 10Gbps interface. We generate the flows using Moongen [12] and use an intermediate switch to amplify them to the required throughput.

Fig. 11 depicts the flows' bandwidth and how SP-PIFO manages to virtually extend the number of queues. As expected, the first 4 flows receive the complete bandwidth, since they are mapped to dedicated queues. As the number of flows exceeds the number of queues, flows start to share queue space and see a reduced bandwidth.

Flow completion times We simultaneously generate 1000 TCP flows of different sizes, going from 1GB to 100GB in steps of 100MB, and schedule them over a bottleneck link of 7Gbps. We set the rank of each flow to the absolute flow size,



(a) All: Average

(b) All: Average

Figure 10: Fairness: FCT statistics for all flows at different loads, when the number of queues is modified.

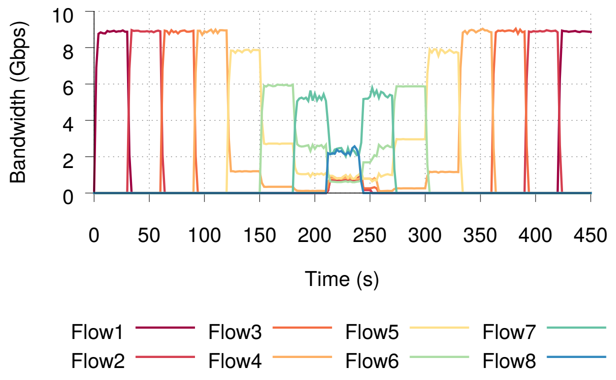


Figure 11: Tofino: Bandwidth allocation under progressive flow generation with increasing priorities.

following [4]. We compare the FCTs achieved by SP-PIFO scheduling and the ones achieved by a FIFO queue.

Fig. 12 shows the resulting FCTs. As expected, the FIFO queue leads to increased FCTs by not considering flow size. In contrast, SP-PIFO prioritizes short flows over long ones, minimizing their FCTs and the overall transmission time.

7 Discussion

In this section, we discuss the limitations of SP-PIFO and how we can mitigate them. We first discuss intrinsic limitations that come from using PIFO as a scheduling scheme. We then discuss specific limitations of SP-PIFO together with the problem of adversarial workloads. Finally, we suggest potential hardware primitives that could facilitate PIFO implementations in the future.

PIFO-inherited limitations Individual PIFO queues suffer from two main limitations. First, they cannot rate-limit their egress throughput preventing them from implementing non-work-conserving scheduling algorithms. SP-PIFO also shares the same limitation. Second, PIFO queues cannot directly implement hierarchical scheduling algorithms. Yet, as proposed by [23], multiple SP-PIFO schemes (i.e., using different set of priority queues) can be grouped as a tree to approximate hierarchical scheduling algorithms. The key challenge consists

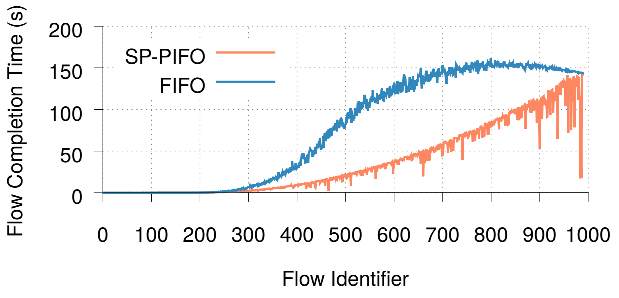

Figure 12: Tofino: FCT statistics across different flow sizes with pFabric ranks.

in figuring out how to allow access of multiple queues with existing traffic manager capabilities. While this is orthogonal to this paper, one option would be to recirculate packets, enabling access to the traffic manager (and therefore the queues) multiple times in the same pipeline. Doing so, while limiting the impact on performance, is an interesting open question.

SP-PIFO-specific limitations The main limitation of SP-PIFO is that, as an approximation scheme, it cannot guarantee to perfectly emulate the behavior of a theoretical PIFO queue for all ranks. We note two things. First, our evaluation (§6) shows that, for realistic workloads, SP-PIFO performance is often on-par with PIFO performances. Second, we note that SP-PIFO *can* provide strong PIFO-like guarantees *for some ranks* by dedicating some queues to them at the price of reduced performance for the other ranks. We believe this is an interesting tradeoff as current switches can support up to 32 queues per port [21].

Adversarial workloads We have argued that, on average, SP-PIFO can adapt to any kind of rank distribution. This has certain limitations. First, we assume that all queues are drained at some point. Nonetheless, a malicious host could send a large number of high-priority packets and, as a result, packets in lower-priority queues would never be drained. Such "starvation" attacks are common to any type of priority scheme. For instance, a malicious host could try to grab a bigger slice of the network resources by setting ranks to 0 in slack-based algorithms [4,9,17] or resetting flow identifiers in fair-queuing schemes [23]. The problem of starvation in strict-priority scheduling is also well-known in the context of QoS and is typically addressed by policing high-priority traffic at the edge of the network [18].

Aside from starvation attacks we also assume that, for a given rank distribution, the particular order of ranks is random. In practice, this is reasonable. While the ranks for individual flows might have some structure (e.g., monotonically-increasing ranks), when various flows are scheduled together the ordering of their packet ranks is randomized. Yet, attackers could try to coordinate large numbers of flows to create adversarial orderings, which "outplay" the adaptation mechanisms (§B.3). Nevertheless, any non-malicious flow which is active at the same time can thwart such strategies by randomly breaking the adversarial order. Aside from that, the network could be monitored to detect such adversarial attacks.

Facilitating PIFO in the future On a forward-looking perspective, we note some improvements in hardware primitives that would facilitate PIFO implementations in the future. As we already discussed in §5, a higher number of stages would facilitate per-queue state storage and a higher number of queues would directly increase PIFO performance. Further than that, multiple and dynamic memory access between the ingress and egress pipelines would allow state updates after inversions in the highest-priority queue without having to rely on resubmission techniques. In the same direction, access to queue information from the ingress pipeline or an enhanced flexibility in the management of strict-priority queues directly from the data plane would enable more accurate unpifoness prediction at enqueue, opening the doors to higher-performance SP-PIFO algorithms.

8 Related work

Programmable packet scheduling While scheduling has been extensively studied over the years, the idea of making it programmable is relatively recent [17,22]. In [24], Sivaraman et. al. suggested programmable scheduling by proving that the best scheduling algorithm to use depends on the desired performance objective. In [17], Mittal et. al. made the observation that, despite certain algorithms accept configurations to approximate a wide range of objectives, a universal packet scheduling outperforming in all scenarios does not exist.

Several abstractions for programmable scheduling have been proposed afterwards. In addition to PIFO [24], Eiffel [19] presents an alternative queue structure which approximates fine priorities by exploiting the characteristics that define packet ranks in most scenarios to diminish the required computational complexity. In contrast to [19, 24], which rely on new hardware designs, SP-PIFO shows that efficient programmable packet scheduling can be achieved today, at scale, and on existing devices.

Exploiting priority queues Other (recent) schemes leverage multiple priority queues for specific performance objectives. They highlight the need of programmable scheduling in existing devices [16], and illustrate how rank designs producing close-to-optimal results can already be implemented in existing data planes. For enforcing fairness, FDPA [8] simplifies the computational cost of per-flow virtual counters or individual user queues in traditional-fair-queuing schemes by using arrival-rate information at a user level. AFQ [21], instead, emulates ideal fair queuing by implementing per-flow counters on a count-min sketch and dynamically rotating priorities in a strict-priority scheme to imitate the round-robin behavior. SP-PIFO differs by fixing queue priorities and dynamically adapting the mapping of packets to those queues. This actually makes SP-PIFO implementable *at line rate* in existing data planes.

pFabric [4] and PIAS [5] show the use of priority queues in flow completion time minimization. While pFabric relies in general on a PIFO-queue design, [4] includes experiments in which flows are mapped to priority queues based on their size. While pFabric experiments use thresholds fixed from the knowledge of flow distributions, SP-PIFO adapts the mapping design automatically per-packet, without any traffic knowledge required in advance. PIAS [5] approaches the case of unknown flow sizes and uses Multi-level Feedback Queues (MLFQ) [11] to achieve the desired Shortest Job First (SJF) behavior, by gradually switching flows from higher to lower-priority queues as their number of transmitted bytes increase.

In contrast to these proposals, SP-PIFO supports a much wider range of performance objectives. SP-PIFO (like PIFO [24]) can be used to implement *any* scheduling algorithm in which the relative scheduling order does not change with future packet arrivals. As illustrated in the evaluation section (§6), the algorithms presented in AFQ [21], FDPA [8], pFabric [4] and PIAS [5] can be used as ranking designs (i.e., setting packet ranks to scheduling virtual rounds, estimated arrival rates, shortest remaining processing time of flows, or number of packets transmitted under the MLFQ aging design) to be run on top of SP-PIFO.

9 Conclusions

We presented SP-PIFO, a programmable packet scheduler which closely approximates the theoretical behavior of PIFO queues, today, on programmable data planes. The key insight behind SP-PIFO is to dynamically adapt the mapping between the packet ranks and a (fixed) set of strict-priority queues.

Our evaluation on realistic workloads shows that SP-PIFO is practical: it closely approximates PIFO behaviors and, in many cases, perfectly matches them. We also confirm that SP-PIFO runs on actual programmable hardware.

Overall, we believe that our work shows that the benefits of programmable packet scheduling—experimenting with new scheduling algorithms—can be fulfilled today, in existing networks.

Acknowledgments

A Gradient-based algorithm

In this appendix we detail the greedy iterative algorithm presented in §3.2. We first motivate and proof how the algorithm converges to the optimal solution (A.1). Second, we show how to effectively prune the search space making computation efficient while keeping convergence (A.2). Finally, we analyze its implementation (A.3) and convergence requirements (A.4).

A.1 Greedy optimization

The algorithm (alg. 2) iteratively minimizes the risk by adjusting queue bounds, one queue and one step at a time, until reaching convergence. At each iteration, the algorithm predicts, for every q_i, whether moving the bound by one (in either direction) decreases the expected risk, and moves the bound in the direction of maximum decrease. In the following, we discuss first, how the algorithm can predict the expected change in risk, and second, why checking a single step is sufficient to converge.

Algorithm 2 Greedy optimization

```
Require: $k$: Step size, $\boldsymbol{q}_{\text{init}}$: Initial bounds
 1: procedure ADAPTATION
 2:     $\mathcal{D} \leftarrow \emptyset$
 3:     $\boldsymbol{q} \leftarrow \boldsymbol{q}_{\text{init}}$                       ▷ Initialize bounds
 4:     for all $p$: incoming packet do
 5:         $\mathcal{D} \leftarrow \mathcal{D} \cup \{rank(p)\}$             ▷ Collect samples
 6:         if $|\mathcal{D}| = k$ then                        ▷ Adapt bounds
 7:             $\mathcal{P} \leftarrow$ COMPUTERANKPROBABILITES($\mathcal{D}$)
 8:             repeat
 9:                 $\boldsymbol{q} \leftarrow$ UPDATEMAPPING($\boldsymbol{q}$, $\mathcal{P}$)
10:             until $\boldsymbol{q}$ converges
11:             $\mathcal{D} \leftarrow \emptyset$                          ▷ Reset samples
12: function UPDATEMAPPING($\boldsymbol{q}$, $\mathcal{P}$)
13:     for $q_i \in \boldsymbol{q}$ do
14:         $\Delta^+ \leftarrow$ RISKFROMINCREMENT($q_i$, $\mathcal{P}$)
15:         $\Delta^- \leftarrow$ RISKFROMDECREMENT($q_i$, $\mathcal{P}$)
16:         if $(\Delta^+ \leq 0)$ and $(\Delta^+ \leq \Delta^-)$ then
17:             $q_i \leftarrow q_i + 1$
18:         else if $(\Delta^- \leq 0)$ and $(\Delta^- < \Delta^+)$ then
19:             $q_i \leftarrow q_i - 1$
        return $\boldsymbol{q}$
```

Risk difference In §3.2, we demonstrated that the risk can be analyzed on a per-queue basis from the cost of mapping packets with different ranks to the same queue. Consequently, changes in the risk resulting from changing the bound vector $\boldsymbol{q}$ can be analyzed by comparing the risk difference in affected queues. To be precise, every change of a single element q_i in $\boldsymbol{q}$ affects two queues, queue i and $i-1$, as ranks are either moved from i to $i-1$ (increase in q_i) or moved from $i-1$ to i (decrease in q_i).

Theorem 1 *Let $r^* = q_i$, let Q_i be the set of ranks mapped to queue i (before any changes). Increasing q_i by 1 changes the risk by:*

$$\Delta_i^+ = p(r^*)\Big(\sum_{r\in Q_{i-1}} p(r)cost(r^*,r) - \sum_{r\in Q_i} p(r)cost(r,r^*)\Big) \tag{9}$$

Let $r^* = q_i - 1$. Decreasing q_i by 1 changes the risk by:

$$\Delta_i^- = p(r^*)\Big(\sum_{r\in Q_i} p(r)cost(r^*,r) - \sum_{r\in Q_{i-1}} p(r)cost(r,r^*)\Big) \tag{10}$$

Proof Increasing q_i effectively removes the lowest rank from queue i, which now becomes the highest rank in queue $i-1$. As the new highest rank in queue $i-1$, it causes possible inversions and therefore risk for *all* other ranks in queue $i-1$, resulting in the first, positive term in eq. 9. Conversely, as the lowest rank in queue, it was prone to receive inversions from any other element in the queue, supposing a risk in queue i that is removed with the change. This risk reduction results in the second, negative, term.

The proof for decreasing q_i is symmetrical, with the main difference that now, rank q_{i-1} is the one changing from queue $i-1$ to queue i.

Greedy step Based on the theory presented, the algorithm computes the risk and either (for every q_i):

(a) Does not move q_i, if neither incrementing or decrementing reduces the expected risk.

(b) Increments q_i, if incrementing decreases the risk more than decrementing.

(c) Decrements q_i, if decrementing decreases the risk more than incrementing.

This effectively prunes the search space. At every iteration, the algorithm only requires a constant amount of comparisons, and it does not explore directions further in case they increase the risk. In the following, we show why deciding not to explore a direction further after a single step is reasonable.

Theorem 2 *Let Δ_i^+ and Δ_i^- denote the prospective in- and decreases from incrementing/decrementing q_i by 1. Let Δ_i^{++} and Δ_i^{--} denote the in- and decreases from incrementing/decrementing q_i by more than 1. Let the cost function used to compute the differences be non-decreasing in $|r^* - r|$ and 0 if and only if $r^* = r$. Then:*

1. *If $\Delta_i^+ > 0$, then $\Delta_i^{++} > 0$.*

2. *If $\Delta_i^- > 0$, then $\Delta_i^{--} > 0$.*

Proof

1: If $\Delta_i^+ > 0$,

$$\sum_{r \in Q_{i-1}} p(r)\text{cost}(r^*, r) > \sum_{r \in Q_i} p(r)\text{cost}(r, r^*) \tag{11}$$

Let $r^{**} = q_i + 1$, i.e. the second-lowest rank in queue i, which would be moved if we move the queue bound by more than 1. Moving both r^* and r^{**} would cause the following change in risk:

$$\Delta_i^{++} = \tag{12}$$

$$p(r^*)(\sum_{r \in Q_{i-1}} p(r)\text{cost}(r^*, r) - \sum_{r \in Q_i} p(r)\text{cost}(r, r^*)) + \tag{13}$$

$$p(r^{**})(\sum_{r \in Q_{i-1}} p(r)\text{cost}(r^{**}, r) - \sum_{r \in Q_i} p(r)\text{cost}(r, r^{**})) \tag{14}$$

Note that we can omit the cost between r^* and r^{**} in eq. 14: as the cost function is by definition symmetric, the additional increase in the left-hand term is exactly equal in magnitude to the additional decrease in the right-hand term, and thus they cancel each other. Thus we omit the term to not clutter the notation. Next, again by definition of the cost function, if $r^{**} > r^* > r$, then $cost(r^{**}, r) \geq cost(r^*, r)$, and if $r > r^{**} > r^*$, then $cost(r, r^{**}) \leq cost(r, r^*)$. Additionally, we note that the order of arguments in the cost function does not matter, as it is symmetrical. Applied to the risk of the lower- and higher-priority queue respectively (eq. 14), this gives:

$$\begin{gathered}\sum_{r \in Q_{i-1}} p(r)cost(r^{**}, r) \geq \sum_{r \in Q_{i-1}} p(r)cost(r^*, r) \\ \sum_{r \in Q_i} p(r)cost(r, r^{**}) \leq \sum_{r \in Q_i} p(r)cost(r, r^*)\end{gathered} \tag{15}$$

And in conclusion, the left hand term in eq. 14 is larger than the left hand term in eq. 13, and the right hand term in eq. 14 is smaller then the left hand term in eq. 13. Consequently, if eq. 13 is positive, eq. 14 must also be positive (as probabilities are always positive), proving that if one step does increase the risks, two steps will also increase the risk. The exact same procedure can be repeated for larger step sizes, which we omit here.

2: This proof is conceptually identical to the other direction, and we will thus omit it. The guiding principle is the same: moving more than one rank can only cause higher increase in risk in the queue the ranks are moved to, and lower decrease in risk in the queue the ranks are taken from, compared to the previous ranks. Thus, if already moving one rank causes a higher increase in risk in one queue than decrease in the other, moving additional ranks does not change this.

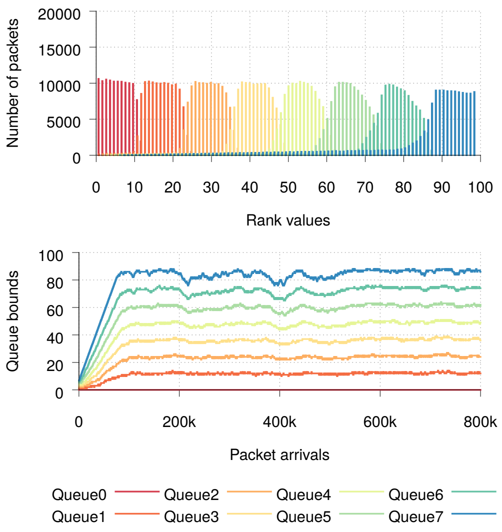

Figure 13: Greedy convergence for uniform rank distribution.

Conclusion We have explained how the greedy algorithm only requires exploring the direction which offers a potential decrease in risk, and we have proved how the risk does not decrease with the distance between ranks (it cannot be better to have a bigger inversion, only equal or worse). This allows the greedy algorithm to quickly decide if a direction is not worth investigating, effectively pruning the search space.

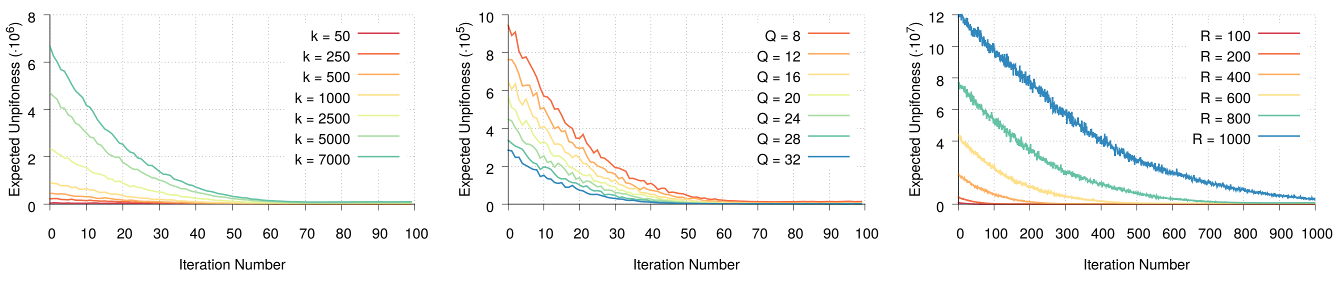
A.2 Efficient computation

As tracking the complete rank distribution at each iteration might be too expensive in terms of memory, and repeating the adaptation until convergence too costly in terms of complexity, we show in the following lines how the mathematical formulation of the problem allows a simplified implementation which only requires 4 counters per queue.

From the empirical probability definition, $p_{\mathcal{D}}(r) = |r_{\mathcal{D}}|/|\mathcal{D}|$, we can rewrite eq. 9 and eq. 10 as:

$$\begin{aligned}\Delta_i^+ &= \frac{|q_i|}{|\mathcal{D}|^2} \cdot (\sum_{r \in Q_{i-1}} |r|\text{cost}(q_i, r) - \sum_{r \in Q_i} |r|\text{cost}(r, q_i)) \\ \Delta_i^- &= \frac{|q_i - 1|}{|\mathcal{D}|^2} \cdot (\sum_{r \in Q_i} |r|\text{cost}(q_i - 1, r) - \sum_{r \in Q_{i-1}} |r|\text{cost}(r, q_i - 1))\end{aligned} \tag{16}$$

Since the queue bound q_i stays constant throughout the adaptation window, each of the summations in eq. 16 can be implemented through a counter which gets updated every time a new packet arrives, with its carried rank. Note that the number of counters required increases linearly with the number of queues. Also, observe that the counters in eq. 16, only allow the computation of one step in the gradient. However, this is enough since, as can be seen in Fig. 13, the one-step version manages to converge in practice.



(a) Convergence vs. adaptation window (b) Convergence vs. number of queues (c) Convergence vs. rank range

Figure 14: Greedy algorithm adaptation microbenchmark.

A.3 Implementation requirements

With the computation presented in A.2, implementing the gradient-based algorithm on top of n priority queues, requires n registers for queue-bound storage and $(4 \cdot n)$ registers for the gradient computation. The mapping process §2 requires packets to potentially read all the queue-bound values (i.e., for packets scheduled in the highest-priority queue). In the same direction, while most packets only need to update the two counters corresponding to their queue, the k_{th} packet in each sequence needs to access *all* counters to perform the adaptation decision. This supposes being able to read $n + (4 \cdot n)$ different registers for a single packet (without even considering the updates). Since existing devices only support up to 12-16 stages, with a single register access per stage [14], the implementation of the greedy algorithm is not feasible for a practical number of queues (i.e., $n \geq 8$).

A.4 Convergence analysis

We now show how the greedy-algorithm performance varies when modifying the three main degrees of freedom: (i) the adaptation window (i.e., the number of packets that are monitored before the adaptation mechanism is executed); (ii) the number of queues available in the strict-priority scheme; and (iii) the number of ranks in the distribution. For that, we analyze the unpifoness evolution of a single switch running the greedy algorithm for a uniform rank distribution from 0 to 100 until convergence. We compute unpifoness as specified in §3.1, based on the packets scheduled and the queue bounds used during the adaptation window.

Effects of varying the adaptation window Fig. 14a shows the unpifoness evolution when we run the greedy algorithm on top of a strict-priority scheme of 8 queues, and we vary the adaptation window from 50 to 7000 packets. We observe that, for the algorithm to converge, the adaptation window needs to be broad enough to cover a *complete* sample of the rank distribution (i.e., one that characterizes all its representative behaviors). In our case, any adaptation window below 100 packets can not characterize completely the rank distribution. Indeed, Fig. 14a depicts how the greedy algorithm correctly converges as soon as more than 200 packets are monitored per iteration. In general, the broader the adaptation window, the more precise the rank distribution estimate, and the better the adaptation decision. However, while a too narrow adaptation window can suppose missing important information of the rank distribution and breaking convergence guarantees, a too broad adaptation window can make the algorithm too slow to converge, negatively impacting the performance.

Finally, the greedy algorithm only converges if the rank distribution has a smaller variability than the adaptation rate (i.e., the rank distribution is stable during the time it takes for the algorithm to converge). Relating it to the previous point, simpler rank distributions, which require narrower adaptation windows, can afford higher levels of variability. In contrast, complex distributions which take longer to adapt and are required to keep stable longer for the algorithm to converge.

Effects of varying the number of queues Fig. 14b depicts the case in which we fix an adaptation window of 1000 packets, and modify the number of queues from 8 to 32. All queues have a constant size of 10 packets. We see how the higher number of queues the lower the unpifoness, and the better the PIFO approximation. This is expected since each queue can be perceived as an opportunity to sort packets with different ranks, and therefore to reduce the number of inversions. Also, we can see how the number of iterations required by the algorithm to converge does not directly depend on the number of queues. This results from the fact that each adaptation decision analyzes (and, if required, updates) potential redesigns for *all* the different queue bounds.

Effects of varying the number of ranks Fig. 14c presents the effects of modifying the range of the uniform rank distribution from 100 to 1000 ranks, when we fix the number of queues to 8 and the adaptation window to 1000 packets. As expected, under the same number of queues, a higher number of ranks implies an increase in unpifoness. Also, as the rank ranges get closer to the adaptation window, the distribution estimates get worse, and the adaptation gets tougher.

B Theoretical analysis of SP-PIFO

SP-PIFO is a highly-dynamic probabilistic system. In particular, its queue bounds $\boldsymbol{q}$ change with nearly every incoming packet. Nevertheless, in this section we show that the system has an attractive equilibrium $\boldsymbol{q}^*$ (B.1), how this equilibrium balances the different causes of inversions (B.2), and we discuss the limitations and open question of our analysis (B.3).

B.1 Stable equilibrium

Queue-bound dynamics Consider SP-PIFO as a discrete-time system, where each time step corresponds to an arriving packet. Let $\boldsymbol{q}^t$ be the queue bounds at step t, when the t-th packet arrives. Then, the queue bounds at step $t+1$ are:

$$\boldsymbol{q}^{t+1} = \boldsymbol{q}^t + \Delta(r^t) \tag{17}$$

where r^t is the rank of the t-th packet, and $\Delta(r^t)$ is the change this packet causes on the queue bounds. The queue-bound change is given by the "push-down" and "push-up" stages of SP-PIFO, respectively. If the packet causes an inversion in the highest-priority queue, all queue bounds are *decreased* by $q_1^t - r^t$. Otherwise, there is exactly one queue i such that $q_i^t \leq r^t < q_{i+1}^t$, and only q_i is set to r^t, or equivalently, is *increased* by $r^t - q_i^t$. Finally, let $p(r^t)$ be the probability of rank r for the t-th packet. Then, the expected value of the queue bounds at step $t+1$, and the expected difference to the queue bounds at step t are, respectively: [3]

$$\mathrm{E}\left[q_i^{t+1}\right] = \mathrm{E}\left[q_i^t\right] \tag{18}$$
$$+ \underbrace{\sum_{q_i^t \leq r^t < q_{i+1}^t} p(r^t)(r^t - q_i^t)}_{\Delta_i^+(\boldsymbol{q}^t, r^t)} \tag{19}$$
$$- \underbrace{\sum_{r^t < q_1^t} p(r^t)(q_1^t - r^t)}_{\Delta^-(\boldsymbol{q}^t, r^t)} \tag{20}$$
$$\Leftrightarrow \mathrm{E}\left[q_i^{t+1} - q_i^t\right] = \Delta_i^+(\boldsymbol{q}^t, r^t) - \Delta^-(\boldsymbol{q}^t, r^t) \tag{21}$$

Equilibrium As expected, we can see from eq. 21 that the change of queue bounds is determined by the "push-up" (Δ_i^+) and "push-down" (Δ^-) stages working against each other. Indeed, if Δ_i^+ is larger than Δ^-, the queue bound increases, and vice versa. The system has an equilibrium $\boldsymbol{q}^*$, where $\Delta_i^+ = \Delta^-$ and the expected change is 0. Note that this equilibrium depends on the rank probability.

Attraction The equilibrium $\boldsymbol{q}^*$ is attractive, i.e. if $q_i^t < q_i^*$, $\mathrm{E}[q_i^{t+1} - q_i^t] > 0$, and vice versa. For small perturbations, this is straightforward. Assume that all queue bounds are in equilibrium, except q_i. If $q_i^t < q_i^*$, then $\Delta_i^+(\boldsymbol{q}^t, r^t) > \Delta_i^+(\boldsymbol{q}^*, r^t)$, because the sum in eq. 19 has (i) more (non-negative) terms; and (ii) each term is weighted stronger, as the difference $r^t - q_i^t$ is larger. On the other hand, $\Delta^-(\boldsymbol{q}^t, r^t)$ is either equal to $\Delta^-(\boldsymbol{q}^*, r^t)$ (for $i > 1$) or even smaller (for $i = 1$, as there are less, and lesser weighted, terms in the sum 20). Thus, the increase is larger than the decrease, and the expected change to q_i is positive. The argument for $q_i^t > q_i^*$ is symmetrical.

For larger disturbances, the equilibrium is also attractive, but it might take more than a single time step, as the "push-up" stage for q_i also depends on q_{i+1}: if both $q_i < q_i^*$ and $q_{i+1} < q_{i+1}^*$, the "push-up" might be too weak to pull q_i towards the equilibrium. However, this is not the case for the lowest-priority queue q_n, for which the "push-up" does not depend on another queue. Thus, lower-priority queues (at least q_n) might be pulled towards the equilibrium at first, while other q_i are not. Notice that an expected increase of q_{i+1}^t increases the "push-up" mechanism for q_i^{t+1} and decreases it for q_{i+1}^{t+1} (eq. 19). Eventually, as the lower-priority queue bound is getting closer to the equilibrium, the higher-priority queue bound is also pulled towards the equilibrium. This continues until the highest-priority queue, where an expected increase of q_1^t also increases the "push-down" mechanism for all bounds at step $t+1$ (eq. 20). As a result, over multiple time steps, the expected effects of the "push-up" and "push-down" stages equalize, eventually pulling all q_i towards q_i^*.

B.2 Balance

As explained in §4, there are three main reasons for unpifoness: (i) inversions in the highest-priority queue, after which all queue bounds are decreased; (ii) inversions in a lower-priority queue after its queue bound has been decreased; (iii) inversions in a lower-priority queue, if its highest rank "overtakes" the lowest rank of a higher-priority queue.

As we can see in eq. 19, eq. 20, and eq. 21, all these factors play a role in the dynamics of SP-PIFO. At the equilibrium, the probability of "push-down", which is exactly the probability of an inversion in the highest-priority queue (weighted by its severity), is equalized with the probability of a packet being mapped to any other queue (again weighted, more on this below). While this does not directly correspond to inversions, the more packets are mapped to lower-priority queues, the higher is the probability of an inversion in those queues after a "push-down". SP-PIFO thus keeps a balance between inversions (i) and (ii), as decreasing (i) would require a stronger "push-down", which would then increase (ii), and vice versa.

Finally, as mentioned above, the ranks in a queue are weighted by how far they are away from the queue bound ($r^t - q_i^t$). This penalizes long (in terms of distinct ranks) queues, which helps to reduce (iii), as the probability for one queue "overtaking" another increases the further the actual queue bound is from the highest-rank packet in the queue, which increases with the length of the queue.

[3] For queue $i = n$, there is no q_{i+1}^t and there is no upper bound on r^t.

B.3 Assumptions and limitations

The analysis presented above is based on a few assumptions, which we argue are justified, yet pose some open questions.

First, we assume that there exists a finite distribution of ranks. This is given in practice. Since ranks need to be processed and stored in hardware, which offers restricted resources, rank ranges must have a limited size.

Second, although SP-PIFO can rapidly adapt to varying rank distributions (in particular faster than the greedy algorithm), we assume that the rank distribution is stable enough such that an equilibrium can exist at all. However, it remains an open question whether there is a point in which the rank-distribution variation might be too fast for the system to actually converge to an equilibrium. In that (hypothetical) case, the analysis presented herein would not be useful to provide any additional insights on the performance of SP-PIFO.

Finally, we assume that the ranks appear in random order, independently from each other. At the first glance, this may seem irrational, as many scheduling algorithms have some structure in the way how ranks are assigned to packets for a given flow. Nevertheless, in practical scenarios, many flows are scheduled together, and even though the ranks for individual flows might be structured, the combined ranks of packets across flows become randomized.

Adversarial workloads Based on the previous assumptions, we have shown that SP-PIFO is attracted towards an expected equilibrium, in which the different sources of unpifoness are balanced. However, there are also some limitations.

On the one hand, this equilibrium exists only in expectation, and the queue bounds are also only attracted to it in expectation. The actual queue bounds depend on the order in which packets arrive, as do inversions. So, even though on average, assuming a random rank ordering, the system might be balanced, there exist particular *adversarial* rank orderings, which "outplay" the two stages to create events of large unpifoness. An adversary might attempt to abuse this by coordinating a large number of flows to force an adversarial ordering of packet ranks. As an example, she might try to increase all queue bounds as much as possible before triggering a "push-down" reaction (e.g., by generating sequences of monotonically-increasing packet ranks). With the sudden decrease in queue-bound values, the high-rank packets mapped in the queues would generate inversions to the new packets.

Nevertheless, any non-malicious coexisting flow can easily thwart such strategies, by just randomly breaking the adversarial order. Still, it might be interesting to classify all adversarial orderings, and subsequently monitor the network to actively detect such type of attacks.

AccelTCP: Accelerating Network Applications with Stateful TCP Offloading

Abstract

The performance of modern key-value servers or layer-7 load balancers often heavily depends on the efficiency of the underlying TCP stack. Despite numerous optimizations such as kernel-bypassing and zero-copying, performance improvement with a TCP stack is fundamentally limited due to the *protocol conformance overhead* for compatible TCP operations. Unfortunately, the protocol conformance overhead amounts to as large as 60% of the entire CPU cycles for short-lived connections or degrades the performance of L7 proxying by 3.2x to 6.3x.

This work presents AccelTCP, a hardware-assisted TCP stack architecture that harnesses programmable network interface cards (NICs) as a TCP protocol accelerator. AccelTCP can offload complex TCP operations such as connection setup and teardown completely to NIC, which simplifies the host stack operations and frees a significant amount of CPU cycles for application processing. In addition, it supports running connection splicing on NIC so that the NIC relays all packets of the spliced connections with zero DMA overhead. Our evaluation shows that AccelTCP enables short-lived connections to perform comparably to persistent connections. It also improves the performance of Redis, a popular in-memory key-value store, and HAProxy, a widely-used layer-7 load balancer, by 2.3x and 11.9x, respectively.

1 Introduction

Transmission Control Protocol (TCP) [24] is undeniably the most popular protocol in modern data networking. It guarantees reliable data transfer between two end-points without overwhelming either end-point nor the network itself. It has become ubiquitous as it simply requires running on the Internet Protocol (IP) [23] that operates on almost every physical network.

Ensuring the desirable properties of TCP, however, often entails a severe performance penalty. This is especially pronounced with the recent trend that the gap between CPU capacity and network bandwidth widens. Two notable scenarios where modern TCP servers suffer from poor performance are handling short-lived connections and layer-7 (L7) proxying. Short-lived connections incur a serious overhead in processing small control packets while an L7 proxy requires large compute cycles and memory bandwidth for relaying packets between two connections. While recent kernel-bypass TCP stacks [5, 30, 41, 55, 61] have substantially improved the performance of short RPC transactions, they still need to track flow states whose computation cost is as large as 60% of the entire CPU cycles (Section §2). An alternative might be to adopt RDMA [37, 43] or a custom RPC protocol [44], but the former requires an extra in-network support [7, 8, 70] while the latter is limited to closed environments. On the other hand, an application-level proxy like L7 load balancer (LB) may benefit from zero copying (e.g., via the `splice()` system call), but it must perform expensive DMA operations that would waste memory bandwidth.

The root cause of the problem is actually clear – the TCP stack must maintain mechanical protocol conformance regardless of what the application does. For instance, a key-value server has to synchronize the state at connection setup and closure even when it handles only two data packets for a query. An L7 LB must relay the content between two separate connections even if its core functionality is determining the back-end server.

AccelTCP addresses this problem by exploiting modern network interface cards (NICs) as a TCP protocol accelerator. It presents a dual-stack TCP design that splits the functionality between a host and a NIC stack. The host stack holds the main control of all TCP operations;

it sends and receives data reliably from/to applications and performs control-plane operations such as congestion and flow control. In contrast to existing TCP stacks, however, it accelerates TCP processing by selectively offloading *stateful* operations to the NIC stack. Once offloaded, the NIC stack processes connection setup and teardown as well as connection splicing that relays packets of two connections entirely on NIC. The goal of AccelTCP is to extend the performance benefit of traditional NIC offload to short-lived connections and application-level proxying while being complementary to existing offloading schemes.

Our design brings two practical benefits. First, it significantly saves the compute cycles and memory bandwidth of the host stack as it simplifies the code path. Connection management on NIC simplifies the host stack as the host needs to keep only the established connections as well as it avoids frequent DMA operations for small control packets. Also, forwarding packets of spliced connections directly on NIC eliminates DMA operations and application-level processing. This allows the application to spend precious CPU cycles on its main functionality. Second, the host stack makes an offloading decision flexibly on a per-flow basis. When an L7 LB needs to check the content of a response of select flows, it opts them out of offloading while other flows still benefit from connection splicing on NIC. When the host stack detects overload of the NIC, it can opportunistically reduce the offloading rate and use the CPU instead.

However, performing stateful TCP operations on NIC is non-trivial due to following challenges. First, maintaining consistency of transmission control blocks (TCBs) across host and NIC stacks is challenging as any operation on one stack inherently deviates from the state of the other. To address the problem, AccelTCP always transfers the ownership of a TCB along with an offloaded task. This ensures that a single entity solely holds the ownership and updates its state at any given time. Second, stateful TCP operations increase the implementation complexity on NIC. AccelTCP manages the complexity in two respects. First, it exploits modern smart NICs equipped with tens of processing cores and a large memory, which allows flexible packet processing with C and/or P4 [33]. Second, it limits the complexity by resorting to a stateless protocol or by cooperating with the host stack. As a result, the entire code for the NIC stack is only 1,501 lines of C code and 195 lines of P4 code, which is small enough to manage on NIC.

Our evaluation shows that AccelTCP brings an enormous performance gain. It outperforms mTCP [41] by 2.2x to 3.8x while it enables non-persistent connections to perform comparably to persistent connections on IX [30] or mTCP. AccelTCP's connection splicing offload achieves a full line rate of 80 Gbps for L7 proxying of 512-byte messages with only a single CPU core. In terms of real-world applications, AccelTCP improves the performance of Redis [17] and HAProxy [6] by a factor of 2.3x and 11.9x, respectively.

The contribution of our work is summarized as follows. (1) We quantify and present the overhead of TCP protocol conformance in short-lived connections and L7 proxying. (2) We present the design of AccelTCP, a dual-stack TCP processing system that offloads select features of stateful TCP operations to NIC. We explain the rationale for our target tasks of NIC offload, and present a number of techniques that reduce the implementation complexity on smart NIC. (3) We demonstrate a significant performance benefit of AccelTCP over existing kernel-bypass TCP stacks like mTCP and IX as well as the benefit to real-world applications like a key-value server and an L7 LB.

2 Background and Motivation

In this section, we briefly explain the need for an NIC-accelerated TCP stack, and discuss our approach.

2.1 TCP Overhead in Short Connections & L7 Proxying

Short-lived TCP connections are prevalent in data centers [31, 65] as well as in wide-area networks [54, 64, 66]. L7 proxying is also widely used in middlebox applications such as L7 LBs [6, 36] and application-level gateways [2, 19]. Unfortunately, application-level performance of these workloads is often suboptimal as the majority of CPU cycles are spent on TCP stack operations. To better understand the cost, we analyze the overhead of the TCP stack operations in these workloads. To avoid the inefficiency of the kernel stack [38, 39, 60], we use mTCP [41], a scalable user-level TCP stack on DPDK [10], as our baseline stack for evaluation. We use one machine for a server (or proxy) and four clients and four back-end servers, all equipped with a 40GbE NIC. The detailed experimental setup is in Section §6.

Small message transactions: To measure the overhead of a short-lived TCP connection, we compare the performance of non-persistent vs. persistent connections with a large number of concurrent RPC transactions. We spawn 16k connections where each transaction exchanges one small request and one small response (64B) between a client and a server. A non-persistent connection performs only a single transaction while a persistent connection repeats the transactions without

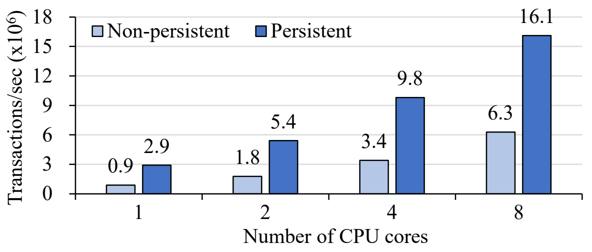

Figure 1: Small packet (64B) performance with non-persistent and persistent connections

a closure. To minimize the number of small packets, we patch mTCP to piggyback every ACK on the data packet.

Figure 1 shows that persistent connections outperform non-persistent connections by 2.6x to 3.2x. The connection management overhead is roughly proportional to the number of extra packets that it handles; two packets per transaction with a persistent connection vs. six [1] packets for the same task with a non-persistent connection. Table 1 shows the breakdown of the CPU cycles where almost 60% of them are attributed to connection setup and teardown. The overhead mainly comes from TCP protocol handling with connection table management, TCB construction and destruction, packet I/O, and L2/L3-level processing of control packets.

Our experiments may explain the strong preference to persistent connections in data centers. However, not all applications benefit from the persistency. When application data is inherently small or transferred sporadically [32, 69], it would result in a period of inactivity that taxes on server resources. Similarly, persistent connections are often deprecated in PHP applications to avoid the risk of resource misuse [28]. In general, supporting persistent connections is cumbersome and error-prone because the application not only needs to keep track of connection states, but it also has to periodically check connection timeout and terminate idle connections. By eliminating the connection management cost with NIC offload, our work intends to free the developers from this burden to choose the best approach without performance concern.

Application-level proxying: An L7 proxy typically operates by (1) terminating a client connection (2) accepting a request from the client and determining the back-end server with it, and creating a server-side connection, and (3) relaying the content between the client and the back-end server. While the key functionality of an L7 proxy is to map a client-side connection to a back-end server, it consumes most of CPU cycles on relaying the packets between the two connections. Packet

[1]SYN, SYN-ACK, ACK-request, response-FIN, FIN-ACK, and ACK.

Connection setup/ teardown	TCP processing and state update	24.0%	60.5%
	TCP connection state init/destroy	17.2%	
	Packet I/O (control packet)	10.2%	
	L2-L3 processing/forward	9.1%	
Message delivery	TCP processing and state update	11.0%	29.0%
	Message copy via socket buffer	8.4%	
	Packet I/O (data packet)	5.1%	
	L2-L3 processing/forward	4.5%	
Socket/epoll API calls			5.6%
Timer handling and context switching			3.5%
Application logic			1.4%

Table 1: CPU usage breakdown of a user-level TCP echo server (a single 64B packet exchange per connection)

	64B	1500B
L7 proxy (mTCP)	2.1 Gbps	5.3 Gbps
L7 proxy with splice() (mTCP)	2.3 Gbps	6.3 Gbps
L3 forward at host (DPDK)	7.3 Gbps	39.8 Gbps
L3 forward at NIC [2]	28.8 Gbps	40.0 Gbps

Table 2: L7 proxying and L3 forwarding performance on a single CPU core

relaying incurs a severe memory copying overhead as well as frequent context switchings between the TCP stack and the application. While zero-copying APIs like splice() can mitigate the overhead, DMA operations between the host memory and the NIC are unavoidable even with a kernel-bypass TCP stack.

Table 2 shows the 1-core performance of a simple L7 proxy on mTCP with 16k persistent connections (8k connections for clients-to-proxy and proxy-to-backend servers, respectively). The proxy exchanges n-byte (n=64 or 1500) packets between two connections, and we measure the wire-level throughput at clients including control packets. We observe that TCP operations in the proxy significantly degrade the performance by 3.2x to 6.3x compared to simple packet forwarding with DPDK [10], despite using zero-copy splice(). Moreover, DMA operations further degrade the performance by 3.8x for small packets.

Summary: We confirm that connection management and packet relaying consume a large amount of CPU cycles, severely limiting the application-level performance. Offloading these operations to NIC promises a large potential for performance improvement.

2.2 NIC Offload of TCP Features

There have been a large number of works and debates on NIC offloading of TCP features [35, 47, 50, 57]. While AccelTCP pursues the same benefit of saving CPU cycles

[2]All 120 flow-processing cores in Agilio LX are enabled.

and memory bandwidth, it targets a different class of applications neglected by existing schemes.

Partial TCP offload: Modern NICs typically support partial, fixed TCP function offloads such as TCP/IP checksum calculation, TCP segmentation offload (TSO), and large receive offload (LRO). These significantly save CPU cycles for processing large messages as they avoid scanning packet payload and reduce the number of interrupts to handle. TSO and LRO also improve the DMA throughput as they cut down the DMA setup cost required to deliver many small packets. However, their performance benefit is mostly limited to large data transfer as short-lived transactions deal with only a few of small packets.

Full Stack offload: TCP Offload Engine (TOE) takes a more ambitious approach that offloads entire TCP processing to NIC [34, 67]. Similar to our work, TOE eliminates the CPU cycles and DMA overhead of connection management. It also avoids the DMA transfer of small ACK packets as it manages socket buffers on NIC. Unfortunately, full stack TOE is unpopular in practice as it requires invasive modification of the kernel stack and the compute resource on NIC is limited [12]. Also, operational flexibility is constrained as it requires firmware update to fix bugs or to replace algorithms like congestion control or to add new TCP options. Microsoft's TCP Chimney [15] deviates from the full stack TOE as the kernel stack controls all connections while it offloads only data transfer to the NIC. However, it suffers from similar limitations that arise as the NIC implements TCP data transfer (e.g., flow reassembly, congestion and flow control, buffer management). As a result, it is rarely enabled these days [27].

In comparison, existing schemes mainly focus on efficient large data transfer, but AccelTCP targets performance improvement with short-lived connections and L7 proxying. AccelTCP is complementary to existing partial TCP offloads as it still exploits them for large data transfer. Similar to TCP Chimney, AccelTCP's host stack assumes full control of the connections. However, the main offloading task is completely the opposite: AccelTCP offloads connection management while the host stack implements entire TCP data transfer. This design substantially reduces the complexity on NIC while it extends the benefit to an important class of modern applications.

2.3 Smart NIC for Stateful Offload

Smart NICs [1, 3, 14, 25] are gaining popularity as they support flexible packet processing at high speed with programming languages like C or P4 [33]. Recent smart NICs are flexible enough to run Open vSwitch [62], Berkeley packet filter [49], or even key-value lookup [53], often achieving 2x to 3x performance improvement over CPU-based solutions [16]. In this work, we use Netronome Agilio LX as a smart NIC platform to offload stateful TCP operations.

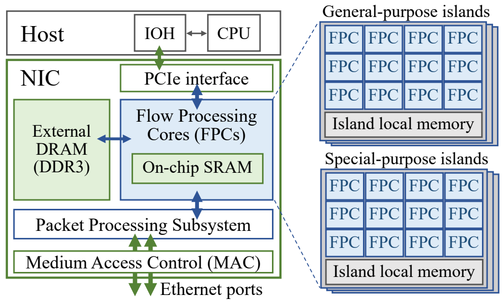

Figure 2: Architecture of SoC-based NIC (Agilio LX)

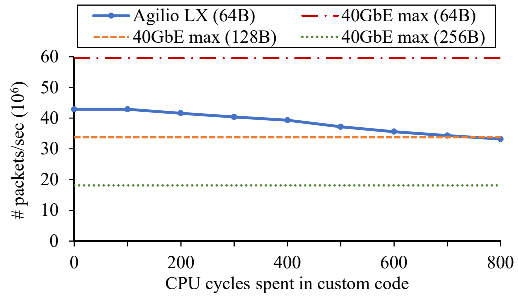

Figure 3: Packet forwarding performance on Agilio LX

As shown in Figure 2, Agilio LX employs 120 flow processing cores (FPCs) running at 1.2GHz. 36 FPCs are dedicated to special operations (e.g., PCI or Interlaken) while remaining 84 FPCs can be used for arbitrary packet processing programmed in C and P4. One can implement the basic forwarding path with a match-action table in P4 and add custom actions that require a fine-grained logic written in C. The platform also provides fast hashing, checksum calculation, and cryptographic operations implemented in hardware.

One drastic difference from general-purpose CPU is that FPCs have multiple layers of non-uniform memory access subsystem – registers and memory local to each FPC, shared memory for a cluster of FPCs called "island", or globally-accessible memory by all FPCs. Memory access latency ranges from 1 to 500 cycles depending on the location, where access to smaller memory tends to be faster than larger ones. We mainly use internal memory (IMEM, 8MB of SRAM) for flow metadata and external memory (EMEM, 8GB of DRAM) for packet contents. Depending on the flow metadata size, IMEM can support up to 128K to 256K concurrent flows. While EMEM would support more flows, it is 2.5x slower. Each FPC

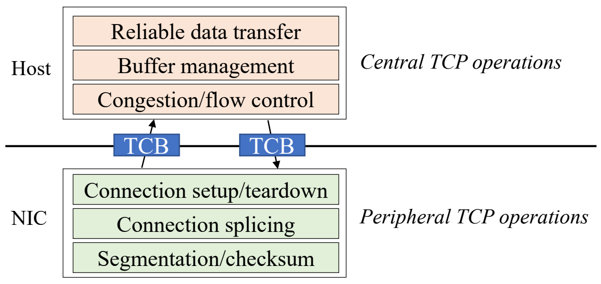

Figure 4: Split of TCP functionality in AccelTCP

can run up to 8 cooperative threads – access to slow memory by one thread would trigger a hardware-based context switch to another, which takes only 2 cycles. This hides memory access latency similarly to GPU.

Figure 3 shows the packet forwarding performance of Agilio LX as a function of cycles spent by custom C code, where L3 forwarding is implemented in P4. We see that it achieves the line rate (40 Gbps) for any packets larger than 128B. However, 64B packet forwarding throughput is only 42.9 Mpps (or 28.8 Gbps) even without any custom code. We suspect the bottleneck lies in scattering and gathering of packets across the FPCs. The performance starts to drop as the custom code spends more than 200 cycles, so minimizing cycle consumption on NIC is critical for high performance.

3 AccelTCP Design Rationale

AccelTCP is a dual-stack TCP architecture that harnesses NIC hardware as a TCP protocol accelerator. So, the primary task in AccelTCP's design is to determine the target for offloading. In this regard, AccelTCP divides the TCP stack operations into two categories: *central* TCP operations that involve application data transfer and *peripheral* TCP operations required for protocol conformance or mechanical operations that can bypass the application logic. Central TCP operations refer to all aspects of application data transfer – reliable data transfer with handling ACKs, inferring loss and packet retransmission, tracking received data and performing flow reassembly, enforcing congestion/flow control, and detecting errors (e.g., abrupt connection closure by a peer). These are typically complex and subject to flexible policies, which demands variable amount of compute cycles. One can optimize them by exploiting flow-level parallelism [5, 30, 41, 59] or by steering the tasks into fast and slow paths [48] on kernel-bypass stacks. However, the inherent complexity makes it a poor fit for NIC offloading as evidenced by the full stack TOE approach.

Peripheral operations refer to the remaining tasks whose operation is logically independent from the application. These include traditional partial NIC offload tasks [3], connection setup and teardown, and blind relaying of packets between two connections that requires no application-level intervention. Peripheral tasks are either stateless operations with a fixed processing cost or lightly stateful operations that synchronize the states for reliable data transfer. We mainly target these operations for offloading as they can be easily separated from the host side that runs applications.

Connection management offload: State synchronization at the boundary of a connection is a key requirement for TCP, but it is a pure overhead from the application's perspective. While NIC offload is logically desirable, conventional wisdom suggests otherwise due to complexity [15, 48]. Our position is that one can tame the complexity on recent smart NICs. First, connection setup operations can be made stateless with SYN-cookies [20]. Second, the common case of connection teardown is simple state transition, and modern smart NICs have enough resources to handle a few exceptions.

Connection splicing offload: Offloading connection splicing to NIC is conceptually complex as it requires state management of two separate connections on NIC. However, if the application does not modify the relayed content, as is often the case with L7 LBs, we can simulate a single logical connection with two physical connections. This allows the NIC to operate as a fast packet forwarder that simply translates the packet header. The compute cycles for this are fixed with a small per-splicing state.

To support the new offload tasks, we structure the dual-stack design with the following guidelines.

1. Full control by the host side: The host side should enforce full control of offloading, and it should be able to operate standalone. This is because the host stack must handle corner cases that cannot benefit from offload. For example, a SYN packet without the timestamp option should be handled by the host stack as SYN-cookie-based connection setup would lose negotiated TCP options (Section §4). Also, the host stack could decide to temporarily disable connection offload when it detects the overload of the NIC.

2. Single ownership of a TCB: AccelTCP offloads stateful operations that require updating the TCB. However, maintaining shared TCBs consistently across two stacks is very challenging. For example, a send buffer may have unacknowledged data along with the last FIN packet. The host stack may decide to deliver all data packets for itself while it offloads the connection teardown to NIC simultaneously. Unfortunately, handling

[3]Such as checksum calculation, TSO, and LRO.

ACKs and retransmission across two stacks require careful synchronization of the TCB. To avoid such a case, AccelTCP enforces an exclusive ownership of the TCB at any given time – either host or NIC stack holds the ownership but not both. In the above case, the host stack offloads the entire data to the NIC stack and forgets about the connection. The NIC stack handles remaining data transfer as well as connection teardown.

3. Minimal complexity on NIC: Smart NICs have limited compute resources, so it is important to minimize complex operations on NIC. A tricky case arises at connection teardown as the host stack can offload data transfer as well. In that case, the host stack limits the amount of data so that the NIC stack avoids congestion control and minimizes state tracking of data packets.

4 AccelTCP NIC Dataplane

In this section, we present the design of AccelTCP NIC stack in detail. Its primary role is to execute three offload tasks requested by the host stack. Each offload task can be enabled independently and the host side can decide which flows to benefit from it. The overall operation of NIC offload is shown in Figure 5.

4.1 Connection Setup Offload

An AccelTCP server can offload the connection setup process completely to the NIC stack. For connection setup offload, the server installs the metadata such as local IP addresses and ports for listening on NIC, and the NIC stack handles all control packets in a three-way handshake. Then, only the established connections are delivered to the host stack.

AccelTCP leverages SYN cookies [20] for stateless handshake on NIC. Stateless handshake enables a more efficient implementation as most smart NICs support fast one-way hashing functions in hardware [1, 3, 14]. When a SYN packet arrives, the NIC stack responds with an SYN-ACK packet whose initial sequence number (ISN) is chosen carefully. The ISN consists of 24 bits of a hash value produced with the input of the 4-tuple of a connection and a nonce, 3 bits of encoded maximum segment size (MSS), and time-dependent 5 bits to prevent replay attacks. When an ACK for the SYN-ACK packet arrives, the NIC stack verifies if the ACK number matches (ISN + 1). If it matches, the NIC stack passes the ACK packet up to the host stack with a special marking that indicates a new connection and the information on negotiated TCP options. To properly handle TCP options carried in the initial SYN, the NIC stack encodes all negotiated options in the TCP Timestamps option [22] of the SYN-ACK packet [9]. Then, the NIC stack can retrieve the information from the TSecr value echoed back with the ACK packet. In addition, we use extra one bit in the timestamp field to differentiate a SYN-ACK packet from other packets. This would allow the NIC stack to bypass ACK number verification for normal packets. The TCP Timestamps option is popular (e.g., enabled on 84% of hosts in a national-scale network [51]), and enabled by default on most OSes, but in case a client does not support it, the NIC stack hands the setup process over to the host stack.

One case where SYN cookies are deprecated is when the server must send the data first after connection setup (e.g., SMTP server). In this case, the client could wait indefinitely if the client-sent ACK packet is lost as the SYN-ACK packet is never retransmitted. Such applications should disable connection setup offload and have the host stack handle connection setup instead.

4.2 Connection Teardown Offload

The application can ask for offloading connection teardown on a per-flow basis. If the host stack decides to offload connection teardown, it hands over the ownership of the TCB and remaining data in the send buffer to the NIC stack. Then, the host stack removes the flow entry from its connection table, and the NIC stack continues to handle the teardown.

Connection teardown offload is tricky as it must maintain per-flow states while it should ensure reliable delivery of the FIN packet with the offloaded data. To minimize the complexity, the host stack offloads connection teardown only when the following conditions are met. First, the amount of remaining data should be smaller than the send window size. This would avoid complex congestion control on NIC while it still benefits most short-lived connections. [4] Second, if the application wants to confirm data delivery at close(), the host stack should handle the connection teardown by itself. For example, an application may make close() to block until all data is delivered to the other side (e.g., *SO_LINGER* option). In that case, processing the teardown at the host stack is much simpler as it needs to report the result to the application. Fortunately, blocking close() is rare in busy TCP servers as it not only kills the performance, but a well-designed application-level protocol may avoid it. Third, the number of offloaded flows should not exceed a threshold, determined by available memory size on NIC. For each connection teardown, the host stack first checks the number of connection closures being handled by the NIC, and the host stack carries out the connection teardown if the number exceeds the threshold.

[4] RFC 6928 [21] suggests 10 MSS as the initial window size.

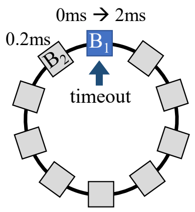
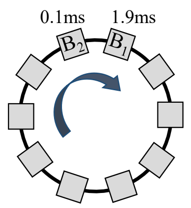
(a) At T



(b) At $T + 0.1$ ms



(c) At T + 0.2 ms

Figure 6: Timer bitmap wheel for RTO management on NIC. T_{RTO} represents the remaining time until retransmission.

The NIC stack implements the teardown offload by extending the TSO mechanism. On receiving the offload request, it stores a 26-byte flow state [5] at the on-chip SRAM (e.g., 8MB of IMEM), segments the data into TCP packets, and send them out. Then, it stores the entire packets at the off-chip DRAM (e.g., 8GB of EMEM) for potential retransmission. This would allow tracking over 256k concurrent flows being closed on NIC.

Timeout management: The teardown process requires timeout management for packet retransmission and for observing a timeout in the TIME_WAIT state. AccelTCP uses three duplicate ACKs and expiration of retransmission timeout (RTO) as a trigger for packet retransmission. For teardown offload, however, RTO is the main mechanism as the number of data packets is often too small for three duplicate ACKs. Also, any side that sends the FIN first would end up in the TIME_WAIT state for a timeout. A high-performance server typically avoids this state by having the clients initiate the connection closure, but sometimes it is inevitable. AccelTCP supports the TIME_WAIT state, but it shares the same mechanism as RTO management for the timer.

Unfortunately, an efficient RTO implementation on NIC is challenging. For multicore CPU systems, a list or a hash table implementation would work well as each CPU core handles only its own flows affinitized to it without a lock. However, smart NICs often do not guarantee flow-core affinity, so a list-based implementation would incur huge lock contention with many processor cores.

We observe that RTO management is write-heavy as each offloaded flow (and each packet transmission) would register for a new RTO. Thus, we come up with a data structure called *timer bitmap wheel*, which allows concurrent updates with minimal lock contention. It consists of N timer bitmaps where each bitmap is associated with a distinct timeout value. The time interval between two neighboring timer bitmaps is fixed (e.g., 100 us for Figure 6). When one time interval elapses, all bitmaps rotate in the clockwise direction by one interval, like Figure 6-(b). Bitmap rotation is efficiently implemented by updating a pointer to the RTO-expired bitmap every time interval. Each timer bitmap records all flows with the same RTO value, where the location of a bit represents a flow id (e.g., n-th bit in a bitmap refers to a flow id, n). When the RTO of a timer bitmap expires, all flows in the bitmap retransmit their unacknowledged packets. From the location of each bit that is set, one can derive the corresponding flow id and find the pointer to its flow state that holds all the metadata required for retransmission. Then, all bits in the bitmap are reset to zero and its RTO is reset to (N x (time interval)). RTO-expired flows register for a new RTO. When an ACK for the FIN of a flow arrives, the flow is removed from its RTO bitmap. One can implement an RTO larger than the maximum by keeping a counter in the flow state that decrements every expiration of the maximum RTO.

The timer bitmap wheel allows concurrent updates by multiple flows as long as their flow ids belong to different 32-bit words in the bitmap. Only the flows whose ids share the same 32-bit word contend for a lock for access. On the down side, it exhibits two overheads: memory space for bitmaps and bitmap scanning at RTO expiration. The memory consumption is not a big concern as it requires only 8KB for each bitmap for 64k concurrent flows being closed. We reduce the scanning overhead by having multiple cores scan a different bitmap region in parallel. Keeping a per-region counter might further

[5] a 4-tuple of the connection, TCP state, expected sequence and ACK numbers, and current RTO.

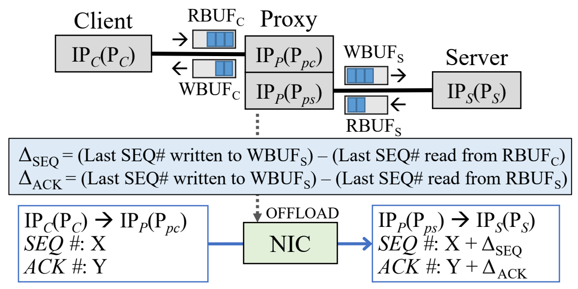


Figure 7: Connection splicing on NIC dataplane. IP_C, IP_P, IP_S: IP addresses of client, proxy, and server, P_C, P_S: port numbers of client and server, P_{pc}, P_{ps}: port numbers of proxy for the client side and the server side, $RBUF_C$, $RBUF_S$: read buffers on each side, $WBUF_C$, $WBUF_S$: write buffers on each side.

reduce the scanning overhead, but we find that the cost for counter update is too expensive even with atomic increment/decrement.

4.3 Connection Splicing Offload

Connection splicing offload on NIC allows zero-DMA data transfer. The key idea is to simulate a single connection by exploiting the NIC as a simple L4 switch that translates the packet header. An L7 proxy can ask for connection splicing on NIC if it no longer wants to relay packets of the two connections in the application layer. On a splicing offload request, the host stack hands over the states of two connections to NIC, and removes their TCBs from its connection table. The NIC stack takes over the ownership, and installs two L4 forwarding rules for relaying packets. The host stack keeps track of the number of spliced connections offloaded to NIC, and decides whether to offload more connections by considering the available memory on NIC.

Figure 7 shows the packet translation process. It simply swaps the 4-tuples of two connections and translates the sequence/ACK numbers and TCP/IP checksums of a packet with pre-calculated offsets. While the Figure assumes that the proxy does not modify any content, but one can easily support such a case. For example, if a proxy modifies request or response headers before splicing, the host stack only needs to reflect the extra delta in sequence and ACK numbers into the pre-calculated offsets. One limitation in our current scheme is that the proxy may not read or modify the packets any more after splicing offload.

Efficient TCP/IP checksum update: Translating a packet header requires TCP/IP checksum update. However, recalculating the TCP checksum is expensive as it scans the entire packet payload. To avoid the overhead, AccelTCP adopts *differential checksum update*, which exploits the fact that the one's complement addition is

```
1  On splicing offload for a flow from $IP_C(P_C)$ to $IP_S(P_S)$:
2      $CSO_{IP} \leftarrow IP_S + IP_C$
3      $CSO_{TCP} \leftarrow CSO_{IP} + P_S + P_{ps} - P_C - P_{pc} + \Delta_{SEQ} + \Delta_{ACK}$
4      **Store** $CSO_{IP}$ and $CSO_{TCP}$
5  For any next incoming packets from $IP_C(P_C)$ to $IP_S(P_S)$:
6      **Load** $CSO_{IP}$ and $CSO_{TCP}$
7      $CS_{IP} \leftarrow CS_{IP} + CSO_{IP}$
8      $CS_{TCP} \leftarrow CS_{TCP} + CSO_{TCP}$
9      If ($SEQ$ #) > $(-\Delta_{SEQ})$, then $CS_{TCP} \leftarrow CS_{TCP} - 1$
10     If ($ACK$ #) > $(-\Delta_{ACK})$, then $CS_{TCP} \leftarrow CS_{TCP} - 1$
```

Figure 8: Differential checksum update. CSO: checksum offset, CS: checksum. Other notations are in Figure 7. Note that + and − indicate 1's complement addition and subtraction.

both associative and distributive. Since only the 4-tuple of a connection and sequence and ACK numbers are updated, we only need to add the difference (or offset) of these values to the checksum. Figure 8 shows the algorithm. Upon splicing offload request, the NIC stack pre-calculates the offsets for IP and TCP checksums, respectively (Line 2-4). For each packet for translation, it adds the offsets to IP and TCP checksums, respectively (Line 7-8). One corner case arises if a sequence or an ACK number wraps around. In that case, we need to subtract 1 from the checksum to conform to 1's complement addition (Line 9-10).

Tracking teardown state: Since connection splicing operates by merging two connections into one, the NIC stack only needs to passively monitor connection teardown by the server and the client. When the spliced connection closes completely or if it is reset by any peer, the NIC stack removes the forwarding rule entries, and notifies the host stack of the closure. This allows reusing TCP ports or tracking connection statistics at the host.

5 AccelTCP Host Stack

The AccelTCP host stack is logically independent of the NIC stack. While our current implementation is based on mTCP [41], one can extend any TCP stack to harness our NIC offloading.

5.1 Socket API Extension

AccelTCP allows easy porting of existing applications by reusing the epoll()-based POSIX-like socket API of mTCP. In addition, it extends the API to support flexible NIC offloading as shown in Figure 9. First, AccelTCP adds extra socket options to `mtcp_setsockopt()` to enable connection setup and teardown offload to NIC. Note that the connection teardown offload request is advisory, so the host stack can decide not to offload the closure if the conditions are not met (Section §4.2). Second, AccelTCP adds `mtcp_nsplice()` to initiate splicing two connections on NIC. The host stack waits until all data

```
/* enable/disable setup and teardown offload
   - level  : IPPPROTO_TCP
   - optname: TCP_SETUP_OFFLOAD or TCP_TEARDOWN_OFFLOAD
   - optval : 1 (enable) or 0 (disable) */
int mtcp_setsockopt(mctx_t m, int sock, int level, int optname,
                    void *optval, socklen_t optlen);

/* offload connection splicing of two connections */
int mtcp_nsplice(mctx_t m, int sock_c, int sock_s, callback_t* cb);

/* notified upon a closure of spliced connections */
typedef void (*callback_t)(nsplice_meta_t * meta);
```

Figure 9: Socket API extension for AccelTCP

in the send buffer are acknowledged while buffering any incoming packets. Then, it installs forwarding rules onto NIC, sending the buffered packets after header translation. After calling this function, the socket descriptors should be treated as if they are closed in the application. Optionally, the application may specify a callback function to be notified when the spliced connections finish. Through the callback function, AccelTCP provides (i) remote addresses of the spliced connections, (ii) the number of bytes transferred after offloaded to NIC dataplane, and (iii) how the connections are terminated (e.g., normal teardown or reset by any peer).

5.2 Host Stack Optimizations

We optimize the host networking stack to accelerate small message processing. While these optimizations are orthogonal to NIC offload, they bring a significant performance benefit to short-lived connections.

Lazy TCB creation: A full TCB of a connection ranges from 400 to 700 bytes even on recent implementations [5, 41]. However, we find that many of the fields are unnecessary for short-lived connections whose message size is smaller than the initial window size. To avoid the overhead of a large TCB, AccelTCP creates the full TCB only when multiple transactions are observed. Instead, the host stack creates a small quasi-TCB (40 bytes) for a new connection. If the application closes the connection after a single write, the host stack offloads the teardown and destroys the quasi-TCB.

Opportunistic zero-copy: Recent high-performance TCP stacks [30, 61, 68] bypass the socket buffer to avoid extra memory copying. However, this often freezes the application-level buffer even after sending data, or overflows the host packet buffers if the application does not read the packets in a timely manner. AccelTCP addresses this problem by opportunistically performing a zero-copy I/O. When a stream of packets arrive in order, the application waiting for a read event will issue a read call. Then, the content of the packets is copied directly to the application buffer while any leftover is written to the receive socket buffer. When an application sends data on an empty socket buffer, the data is directly written to the host packet buffer for DMA'ing to NIC. Only when the host packet buffer is full, the data is written to the send socket buffer. Our scheme observes the semantics of standard socket operations, allowing easy porting of existing applications. Yet, this provides the benefit of zero-copying to most short-lived connections.

User-level threading: mTCP spawns two kernel-level threads: a TCP stack thread and an application thread on each CPU core. While this allows independent operations of the TCP thread (e.g., timer operations), it incurs a high context switching overhead. To address the problem, we modify mTCP to use cooperative user-level threading [13]. We find that this not only reduces the context switching overhead, but it also allows other optimizations like lazy TCB creation and opportunistic zero-copying.

6 Evaluation

We evaluate AccelTCP by answering following questions. First, does stateful TCP offloading and host stack optimizations demonstrate a high performance in a variety of workloads? (§6.1) Second, does it deliver the performance benefit to real-world applications? (§6.2) Finally, is the extra cost of a smart NIC justifiable? (§6.3)

Experiment setup: Our experimental setup consists of one server (or a proxy), four clients, and four back-end servers. The server machine has an Intel Xeon Gold 6142 @ 2.6GHz with 128 GB of DRAM and a dual-port Netronome Agilio LX 40GbE NIC (NFP-6480 chipset). Each client has an Intel Xeon E5-2640 v3 @ 2.6GHz, and back-end servers have a mix of Xeon E5-2699 v4 @ 2.2GHz and Xeon E5-2683 v4 @ 2.1GHz. The client and backend server machines are configured with Intel XL710-QDA2 40GbE NICs. All the machines are connected to a Dell Z9100-ON switch, configured to run at 40 GbE speed. For TCP stacks, we compare AccelTCP against mTCP [41] and IX [30]. All TCP stacks employ DPDK [10] for kernel-bypass packet I/O. Clients and back-end servers run mTCP patched to use cooperative user-level threading as AccelTCP. For IX experiments, we use two dual-port Intel X520-DA2 10GbE NICs, and enable all four ports bonded with a L3+L4 hash to balance the load as IX does not support 40GbE NICs. We verify that any single 10GbE port does not become the bottleneck based on port-level statistics at the switch. Hyperthreading is disabled for mTCP and AccelTCP, and enabled for IX when it improves the performance.

Our current prototype uses CRC32 to generate SYN cookies for connection setup. To prevent state explosion attacks, one needs to use a cryptographic hash function (such as MD5 or SHA2). Unfortunately, the API sup-

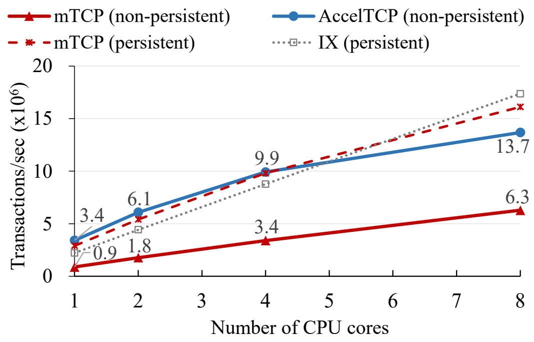

Figure 10: Throughputs of 64B packet transactions

Action	Mtps	Speedup
Baseline (w/o NIC offload)	0.89	1.0x
+ Enable setup offload (§4.1)	1.21	1.4x
+ Enable teardown offload (§4.2)	2.06	2.3x
+ Enable opportunistic TCB creation & opportunistic zero-copy (§5.2)	3.42	3.8x

Table 3: Breakdown of contribution by each optimization on a single CPU core (64B packet transactions)

port for hardware-assisted cryptographic operations in Agilio NICs is currently incomplete (for both C and P4 code), so we use CRC32 instead here.

6.1 Microbenchmark

We evaluate AccelTCP's performance for handling short-lived TCP connections and L7 proxying, and compare against the performance of the state-of-the-art TCP stacks: mTCP [41] and IX [30].

6.1.1 Short-lived Connection Performance

We evaluate the benefit of connection management offload by comparing the performance of TCP echo servers that perform 64B packet transactions with persistent vs. non-persistent connections. The TCP echo servers maintain 16k concurrent connections, and the performance results are averaged over one-minute period for five runs in each experiment. In the non-persistent case, a new connection is created immediately after every connection closure. AccelTCP offloads connection setup and offload to NIC while mTCP handles them using CPU. For IX, we evaluate only the persistent connection case as IX experiences a crash when handling thousands of concurrent connections with normal teardown.

Figure 10 compares the throughputs over varying numbers of CPU cores. AccelTCP achieves 2.2x to 3.8x better throughputs than non-persistent mTCP, comparable to those of persistent connections. Surprisingly, AccelTCP outperforms persistent connections by 13% to 54% for up to four CPU cores. This is because AccelTCP

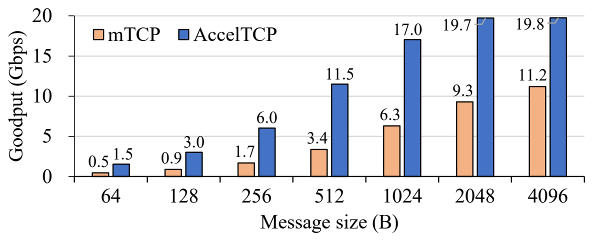

Figure 11: Performance of short-lived connections for varying message sizes on a single CPU core

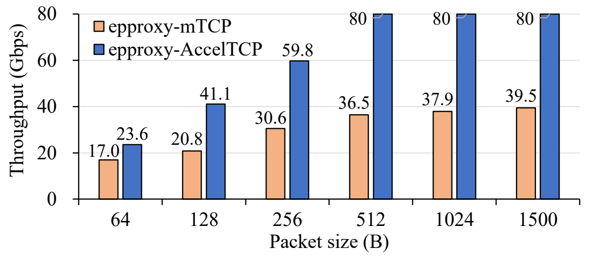

Figure 12: Comparison of L7 proxying throughputs

benefits from lazy TCB creation (§5.2) while persistent connections suffer from a CPU bottleneck. However, its eight-core performance is 22% lower than that of persistent IX, implying a bottleneck on NIC. Overall, connection management offload brings a significant performance benefit, which enables short-lived connections to perform comparably to persistent connections.

Table 3 shows the breakdown of performance in terms of the contribution by each optimization. We find that connection setup and teardown offload improve the baseline performance by 2.3x while other host stack optimizations contribute by extra 1.5x.

Figure 11 compares the goodputs over varying message sizes on a single CPU core. AccelTCP maintains the performance benefit over different message sizes with a speedup of 2.5x to 3.6x. The performance of messages larger than one MSS is limited at 20 Gbps, which seems impacted by our software TSO implementation on NIC. The current Agilio NIC SDK does not provide an API to exploit hardware TSO for programmable dataplane. We believe the single core performance would further improve with proper hardware support.

6.1.2 Layer-7 Proxing Performance

We now evaluate connection splicing offload with a simple L7 LB called epproxy that inspects the initial request, determines a back-end server, and relays the content between the client and the server. We measure the wire-level, receive-side throughput (including control packets) on the client side over different message sizes. Clients spawn 8k concurrent connections with epproxy, and the proxy creates 8k connections with back-

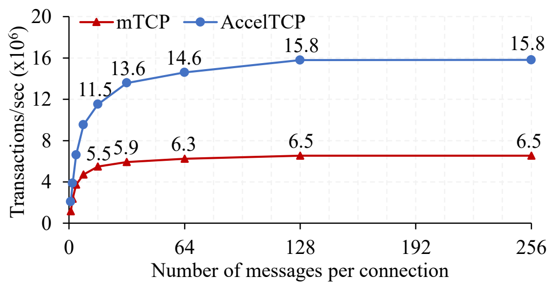

Figure 13: L7 proxying performance over varying numbers of message transactions per connection with 64B packets

end servers. We confirm that both clients and back-end servers are not the bottleneck. We configure epproxy-mTCP to use eight cores while epproxy-AccelTCP uses only a single core as CPU is not the bottleneck. All connections are persistent, and we employ both ports of the Agilio LX NIC here. The NIC is connected to the host via 8 lanes of PCIe-v3 [6].

Figure 12 shows that AccelTCP-proxy outperforms epproxy-mTCP by 1.4x to 2.2x even if the latter employs 8x more CPU cores. We make two observations here. First, the performance of epproxy-AccelTCP reaches full 80 Gbps from 512-byte messages, which exceeds the PCIe throughput of the NIC. This is because epproxy-AccelTCP bypasses host-side DMA and fully utilizes the forwarding capacity of the NIC. Second, epproxy-AccelTCP achieves up to twice as large goodput as the epproxy-mTCP. For example, epproxy-AccelTCP actually performs 2.8x more transactions per second than epproxy-mTCP for 64B messages. This is because AccelTCP splices two connections into a single one while mTCP relays two connections. For each request from a client, epproxy-mTCP must send an ACK as well as a response packet from the back-end server. In contrast, epproxy-AccelTCP replays only the response packet with a piggybacked ACK from the back-end server.

We move on to see if epproxy-AccelTCP fares well on non-persistent connections. Figure 13 shows the performance over varying numbers of message transactions per connection. AccelTCP performs 1.8x better at a single transaction, and the performance gap widens as large as 2.4x at 128 transactions per connection. This confirms that proxying non-persistent connections also benefit from splicing offload of AccelTCP.

6.2 Application Benchmark

We investigate if AccelTCP delivers the performance benefit to real-world applications.

Key-value store (Redis): We evaluate the effectiveness of AccelTCP with Redis (v.4.0.8) [17], a popular

[6]Theoretical maximum throughput is 63 Gbps according to [58].

	1-core	8-core
Redis-mTCP (kernel thread)	0.19 Mtps	1.38 Mtps
Redis-mTCP (user-level thread)	0.28 Mtps	1.94 Mtps
Redis-AccelTCP	0.44 Mtps	3.06 Mtps

Table 4: Redis performance for short-lived connections

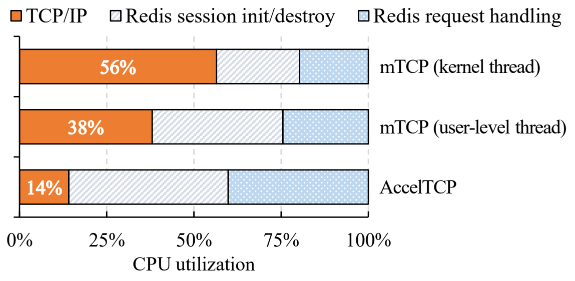

Figure 14: CPU breakdown of Redis on a single CPU core

in-memory key-value store. We use Redis on mTCP as a baseline server while we port it to use AccelTCP for comparison. We test with the USR workload from Facebook [29], which consists of 99.8% GET requests and 0.2% SET requests with short keys (< 20B) and 2B values. For load generation, we use a Redis client similar to memtier_benchmark [18] written in mTCP. We configure the Redis server and the clients to perform a single key-value transaction for each connection to show the behavior when short-lived connections are dominant.

Table 4 compares the throughputs. Redis-AccelTCP achieves 1.6x to 2.3x better performance than Redis-mTCP, and its performance scales well with the number of CPU cores. Figure 14 shows that mTCP consumes over a half of CPU cycles on TCP stack operations. In contrast, AccelTCP saves up to 75% of the CPU cycles for TCP processing. With AccelTCP, session initialization and destruction of Redis limits the performance. Our investigation reveals that the overhead mostly comes from dynamic memory (de)allocation (`zmalloc()` and `zfree()`) for per-connection metadata, which incurs a severe penalty for handling short-lived connections.

L7 LB (HAProxy): We see if AccelTCP improves the performance of HAProxy (v.1.8.0) [6], a widely used HTTP-based L7 LB. We first port HAProxy to use mTCP and AccelTCP, respectively, and evaluate the throughput with the SpecWeb2009[26]-like workload. The workload consists of static files whose size ranges from 30 to 5,670 bytes with an average file size of 728 bytes. For a fair comparison, we disable any header rewriting in the both version after delivering the first HTTP request. We spawn 8k persistent connections, using simple epoll-based clients and back-end servers running on mTCP. Table 5 compares the throughputs with with 1 core and

	1-core	8-core
HAProxy-mTCP	4.3 Gbps	6.2 Gbps
HAProxy-AccelTCP	73.1 Gbps	73.1 Gbps

Table 5: L7 LB performance for SpecWeb2009-like workload

	E5-2650v2	Gold 6142
mTCP (XL710-QDA2)	1.00	1.25
AccelTCP (Agilio LX)	1.93	1.96

Table 6: Comparison of normalized performance-per-dollar

8 cores. HAProxy-AccelTCP achieves 73.1 Gbps, a 11.9x better throughput than HAProxy-mTCP. The average response time of HAProxy-AccelTCP is 0.98 ms, 13.6x lower than that of HAProxy-mTCP. We observe that the performance benefit is much larger than in Section 6.1.2 because HAProxy has a higher overhead in application-level request processing and packet relaying.

6.3 Cost-effectiveness Analysis

AccelTCP requires a smart NIC, which is about 3-4x more expensive than a normal NIC at the moment. For fairness, we try comparing the cost effectiveness by the performance-per-dollar metric. We draw hardware prices from Intel [11] and Colfax [4] pages (as of August 2019), and use the performance of 64B packet transactions on short-lived connections. Specifically, we compare the performance-per-dollar with a system that runs mTCP with a commodity NIC (Intel XL710-QDA2, $440) vs. another system that runs AccelTCP with a smart NIC (Agilio LX, $1,750). For CPU, we consider Xeon E5-2650v2 ($1,170) and Xeon Gold 6142 ($2,950). For simplicity, we only consider CPU and NIC as hardware cost. Table 6 suggests that NIC offload with AccelTCP is 1.6x to 1.9x more cost-effective, and the gap would widen further if we add other fixed hardware costs.

7 Related Work

Kernel-bypass TCP stacks: Modern kernel-bypass TCP stacks such as mTCP [41], IX [30], SandStorm [55], F-Stack [5] deliver high-performance TCP processing of small message transactions. Most of them employ a fast user-level packet I/O [10], and exploit high parallelism on multicore systems by flow steering on NIC. More recently, systems like ZygOS [63], Shinjuku [42], and Shenango [59] further improve kernel-bypass stack by reducing the tail latency, employing techniques like task stealing, centralized packet distribution, and dynamic core reallocation. We believe that these works are largely orthogonal but complementary to our work as AccelTCP would enhance these stacks by offloading connection management tasks to NIC.

NIC offload: Existing TCP offloads mostly focus on improving large message transfer either by offloading the whole TCP stack [50] or by selectively offloading common send-receive operations [46]. In contrast, our work focuses on connection management and proxying whose performance is often critical to modern network workloads, while we intentionally avoid the complexity of application data transfer offloading. UNO [52] and Metron [45] strive to achieve optimal network function (NF) performance with NIC offload based on runtime traffic statistics. We plan to explore dynamic offloading of a subset of networking stack features (or connections) in response to varying load in the future. To offload TCP connection management, any L2-L4 NFs that should run prior to TCP stack (e.g., firewalling or host networking) must be offloaded to NIC accordingly. Such NFs can be written in P4 [40, 45, 56] and easily integrated with AccelTCP by properly placing them at ingress/egress pipelines of the NIC dataplane.

L7 proxing and short RPCs: Our connection splicing is inspired by the packet tunneling mechanism of Yoda L7 LB [36]. However, Yoda operates as a packet-level translator without a TCP stack, so it cannot modify any of relayed content. In contrast, an AccelTCP application can initiate the offload after any content modification. Also, AccelTCP packet translation runs on NIC hardware, promising better performance. Finally, we note that eRPC [44] achieves 5.0 Mtps RPC performance (vs. 3.4 Mtps of AccelTCP) on a single core. However, ePRC is limited to data center environments while AccelTCP is compatible to TCP and accommodates any TCP clients.

8 Conclusion

In this paper, we have presented AccelTCP that harnesses modern programmable NICs as a TCP protocol accelerator. Drawing the lessons from full stack TOE, AccelTCP's design focuses on minimizing the interaction with the host stack by offloading only select features of stateful TCP operations. AccelTCP manages the complexity on NIC by stateless handshake, single ownership of a TCB, and conditional teardown offload. In addition, it simplifies connection splicing by efficient packet header translation. We have also presented a number of optimizations that significantly improve the host stack.

We have demonstrated that AccelTCP brings a substantial performance boost to short-message transactions and L7 proxying. AccelTCP delivers a 2.3x speedup to Redis on a kernel-bypass stack while it improves the performance of HAProxy by a factor of 11.9. AccelTCP is available at `https://github.com/acceltcp`, and we hope our effort will renew the interest in selective NIC offload of stateful TCP operations.

Acknowledgments

We would like to thank our shepherd Andrew Moore and anonymous reviewers of NSDI 2020 for their insightful comments and feedback on the paper. We also thank Ilwoo Park for applying user-level threading to the mTCP stack. This work was supported by Institute of Information & Communications Technology Planning & Evaluation (IITP) grants funded by the Korea government (MSIT) (2018-0-00693, Development of an ultra low-latency user-level transfer protocol and 2016-0-00563, Research on Adaptive Machine Learning Technology Development for Intelligent Autonomous Digital Companion) as well as the SK-Hynix grant for Storage Media Solutions Center.

Appendix A. Host-NIC Communication Interface

The host and NIC stacks communicate with each other by piggybacking control information in the normal packets most time. It encodes the type of offload as unused EtherType values in the Ethernet header, and tags along other information in the special header between the Ethernet and IP headers.

Connection setup: When an application listens on a socket whose setup offload option is enabled, the host stack sends a special control packet to NIC, carrying the listening address/port and TCP options that must be delivered to the remote host during connection setup (e.g., MSS, Window scale factor, Selective ACK, etc.). To notify a new connection, the NIC stack sets the Ethertype of the ACK packet to 0x090A, and delivers the negotiated options in the TCP Timestamps option. The host stack extracts only the TCP options, and ignores the NIC-generated timestamp value.

Connection teardown: For teardown offload, the host stack creates a TSO packet that holds all remaining data in the send buffer, and sets the EtherType to 0x090B. It also encodes other information such as MSS (2 bytes), current RTO (4 bytes), and current TCP state (2 bytes) in the special header area. The NIC stack notifies the host stack of the number of connections being closed on NIC by either sending a control packet or tagging at any packet delivered to host.

Connection splicing: For splicing offload, the host stack uses 0x090C as EtherType, and writes the sequence and ACK number offsets (4 bytes each), and a 4-tuple of a connection in the special header. When the splicing offload packet is passed to the NIC stack, a race condition may arise if some packets in the flows are passed up to the host stack at the same time. To ensure correct forwarding, the host stack keeps the connection entries until it is notified that the splicing rules are installed at NIC. For reporting a closure of spliced connections, NIC creates a special control packet holding the connection information and traffic statistics with the EtherType, 0x090D, and sends it up to the host stack. By monitoring those control packets, the host stack can keep track of the number of active spliced connections on NIC.

Abstract

Data-center network stacks are moving into hardware to achieve 100 Gbps data rates and beyond at low latency and low CPU utilization. However, hardwiring the network stack in the NIC would stifle innovation in transport protocols. In this paper, we enable programmable transport protocols in high-speed NICs by designing Tonic, a flexible hardware architecture for transport logic. At 100 Gbps, transport protocols must generate a data segment every few nanoseconds using only a few kilobits of per-flow state on the NIC. By identifying common patterns across transport logic of different transport protocols, we design an efficient hardware "template" for transport logic that satisfies these constraints while being programmable with a simple API. Experiments with our FPGA-based prototype show that Tonic can support the transport logic of a wide range of protocols and meet timing for 100 Gbps of back-to-back 128-byte packets. That is, every 10 ns, our prototype generates the address of a data segment for one of more than a thousand active flows for a downstream DMA pipeline to fetch and transmit a packet.

1 Introduction

Transport protocols, along with the rest of the network stack, traditionally run in software. Despite efforts to improve their performance and efficiency [1,6,25,32], software network stacks tend to consume 30-40% of CPU cycles to keep up with applications in today's data centers [25,32,38].

As data centers move to 100 Gbps Ethernet, the CPU utilization of software network stacks becomes increasingly prohibitive. As a result, multiple vendors have developed hardware network stacks that run entirely on the network interface card (NIC) [8,10]. However, there are only two main transport protocols implemented on these NICs, both hardwired and modifiable only by the vendors:

RoCE. RoCE is used for Remote Direct Memory Access (RDMA) [8], using DCQCN [43] for congestion control and a simple go-back-N method for reliable data delivery.

TCP. A few vendors offload a TCP variant of their choice to the NIC to either be used directly through the socket API (TCP Offload Engine [10]) or to enable RDMA (iWARP [7]).

These protocols, however, only use a small fixed set out of the myriad of possible algorithms for reliable delivery [16,21,24,27,33,34] and congestion control [12,17,19,35,42,43] proposed over the past few decades. For instance, recent work suggests that low-latency data-center networks can significantly benefit from receiver-driven transport protocols [21,24,36], which is not an option in today's hardware stacks. In an attempt to deploy RoCE NICs in Microsoft data centers, operators needed to modify the data delivery algorithm to avoid livelocks in their network but had to rely on the NIC vendor to make that change [22]. Other algorithms have been proposed to improve RoCE's simple reliable delivery algorithm [31,34]. The long list of optimizations in TCP from years of deployment in various networks is a testament to the need for programmability in transport protocols.

In this paper, we investigate *how to make hardware transport protocols programmable*. Even if NIC vendors open up interfaces for programming their hardware, it takes a significant amount of expertise, time, and effort to implement transport protocols in high-speed hardware. To keep up with 100 Gbps, the transport protocol should generate and transmit a packet *every few nanoseconds*. It should handle *more than a thousand active flows*, typical in today's data-center servers [15, 37, 38]. To make matters worse, NICs are *extremely constrained* in terms of the amount of their on-chip memory and computing resources [30, 34].

We argue that transport protocols on high-speed NICs can be made programmable *without* exposing users to the full complexity of programming for high-speed hardware. Our argument is grounded in two main observations:

First, programmable *transport logic* is the key to enabling flexible hardware transport protocols. An implementation of a transport protocol performs several functionality such as connection management, data buffer management, and data transfer. However, its central responsibility, where most of the innovation happens, is to decide which data segments to transfer (data delivery) and when (congestion control), which we collectively call the *transport logic*. Thus, the key to programmable transport protocols on high-speed NICs is enabling users to modify the transport logic.

Second, we can exploit common patterns in transport logic to create reusable high-speed hardware modules. Despite their differences in application-level API (e.g., sockets and byte-stream abstractions for TCP vs. the message-based Verbs API for RDMA), and in connection and data buffer management, transport protocols share several common patterns. For instance, different transport protocols use different algorithms to detect lost packets. However, once a packet is declared lost, reliable transport protocols prioritize its retransmission over sending a new data segment. As another example, in congestion control, given the parameters determined by the control loop (e.g., congestion window and rate), there are only a few common ways to calculate how many bytes a flow can transmit at any time. This enables us to design an efficient "template" for transport logic in hardware that can be programmed with a simple API.

Using these insights, we design and develop Tonic, a programmable hardware architecture that can realize the *transport logic* of a broad range of transport protocols, using a simple API, while supporting 100 Gbps data-rates. Every clock cycle, Tonic generates the address of the next segment for transmission. The data segment is fetched from memory by a downstream DMA pipeline and turned into a full packet by the rest of the hardware network stack (Figure 1).

We envision that Tonic would reside on the NIC, replacing the hard-coded transport logic in hardware implementations of transport protocols (e.g., future RDMA NICs and TCP offload engines). Tonic provides a unified programmable architecture for transport logic, independent of how specific implementations of different transport protocols perform connection and data buffer management, and their application-level APIs. We will, however, describe how Tonic interfaces with the rest of the transport layer in general (§2) and how it can be integrated into Linux Kernel to interact with applications using socket API as an example (§5).

We implement a Tonic prototype in ∼8K lines of Verilog code and demonstrate Tonic's programmability by implementing the transport logic of a variety of transport protocols [13, 16, 23, 24, 34, 43] in less than 200 lines of code. We also show, using an FPGA, that Tonic meets timing for ∼100 Mpps, i.e., supporting 100Gbps of back-to-back 128B packets. That is, every 10ns, Tonic can generate the transport metadata required for a downstream DMA pipeline to fetch and send one packet. From generation to transmission, the latency of a single segment address through Tonic is ∼ 0.1µs, and Tonic can support up to 2048 concurrent flows.

2 Tonic as the Transport Logic

This section is an overview of how Tonic fits into the transport layer (§2.1), and how it overcomes the challenges of implementing transport logic on high-speed NICs (§2.2).

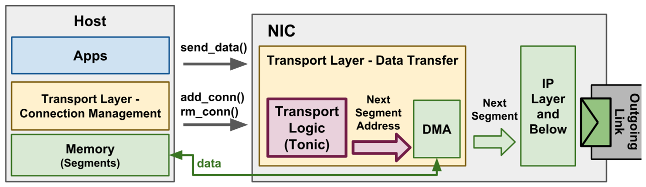

Figure 1: Tonic providing programmable transport logic in a hardware network stack on the NIC (sender-side).

2.1 How Tonic Fits in the Transport Layer

Sitting between applications and the rest of the stack, transport-layer protocols perform two main functions:
Connection Management includes creating and configuring endpoints (e.g., sockets for TCP and queue-pairs for RDMA) and establishing the connection in the beginning, and closing the connection and releasing its resources at the end.
Data Transfer involves delivering data from one endpoint to another, reliably and efficiently, in a stream of segments [1]. Different transport protocols provide different APIs for applications to request data transfer: TCP offers the abstraction of a byte-stream to which applications can continuously append data, while in RDMA, each "send" call to a queue-pair creates a separate work request and is treated as a separate message. Moreover, specifics of managing applications' data buffers differ across different implementations of transport protocols. Regardless, the transport protocol must deliver the outstanding data to its destination in multiple data segments that fit into individual packets. *Deciding which bytes comprise the next segment and when it is transmitted* is done by data delivery and congestion control algorithms, which we collectively call **transport logic** and implement in Tonic.

Figure 1 shows a high-level overview of how Tonic fits in a hardware network stack. To decouple Tonic from specifics of connection management and application-level APIs, connection setup and tear-down run outside of Tonic. Tonic relies on the rest of the transport layer to provide it with a unique identifier (*flow id*) for each established connection, and to explicitly add and remove connections using these IDs.

For data transfer on the sender side, Tonic keeps track of the number of outstanding bytes and transport-specific metadata to implement the transport logic, i.e., *generate the address of the next data segment* for each flow at the time designated by the congestion control algorithm. Thus, Tonic does not need to store and/or handle actual data bytes; it relies on the rest of the transport layer to manage data buffers on the host, DMA the segment whose address is generated in Tonic from memory, and notify it of new requests for data transmission on existing connections (see §5 for details).

The receiver-side of transport logic mainly involves generating control signals such as acknowledgments, per-packet

[1]We focus on reliable transport as it is more commonly used and more complicated to implement.

#	Observation	Examples
1	Only track a limited window of segments	TCP, NDP, IRN
2	Only keep a few bits of state per segment	TCP, NDP, IRN, RoCEv2
3	Lost segments first, new segments next	TCP, NDP, IRN, RoCEv2
4	Loss detection: Acks and timeouts	TCP, NDP, IRN
5	The three common credit calculation patterns: window, rate, and grant tokens	TCP, RoCEv2, NDP

Table 1: Common transport logic patterns.

grant tokens [21, 24, 36], or periodic congestion notification packets (CNPs) [43], while the rest of the transport layer manages receive data buffers and delivers the received data to applications. While handling received data can get quite complicated, generating control signals on the receiver is typically simpler than the sender. Thus, although we mainly focus on the sender, we reuse modules from the sender to implement a receiver solely for generating per-packet cumulative and selective acks and grant tokens at line rate.

2.2 Hardware Design Challenges

Implementing transport logic at line rate in the NIC is challenging due to two main constraints:

Timing constraints. The median packet size in data centers is less than 200 bytes [15, 37]. To achieve 100 Gbps for these small packets, the NIC has to send a packet every $\sim$10 ns. Thus, every $\sim$10 ns, the transport logic should determine which active flow should transmit which data segment next. To make this decision, it uses some state per flow (e.g., acknowledged data segments, duplicate acks, rate/window size, etc.) which is updated when various transport events happen (e.g., receiving an acknowledgment or a timeout). These updates could involve operations with non-negligible hardware overhead, such as searching bitmaps and arrays.

To allow for more time in processing each event while still determining the next data segment every $\sim$10 ns, we could conceivably pipeline the processing of transport events across multiple stages. However, pipelining is more tractable when incoming events are from *different* flows as they update different states. Processing back-to-back events for the *same* flow (e.g., generating data segments while receiving acknowledgments) requires updates to the same state, making it difficult to pipeline event processing while ensuring state consistency. Thus, we strive to process each transport event within 10 ns instead to quickly consolidate the state for the next event in case it affects the same flow.

Memory constraints. A typical data-center server has more than a thousand concurrent active flows with kilobytes of in-flight data [15, 37, 38]. Since NICs have just a few megabytes of high-speed memory [30, 34], the transport protocol can store only a few kilobits of state per flow on NIC.

Tonic's goal is to satisfy these tight timing and memory constraints while supporting programmability with a simple API. To do so, we identify common patterns across transport logic in various protocols that we implement as reusable fixed-function modules. These patterns allow us to optimize these modules for timing and memory, while simplifying the programming API by reducing the functionality users must specify. These patterns are summarized in Table 1, and are discussed in detail in next section, where we describe Tonic's components and how these patterns affect their design.

3 Tonic Architecture

Transport logic at the sender is what determines, for each flow, which data segments to transfer (data delivery) and when (congestion control). Conceptually, congestion control algorithms perform *credit management*, i.e., determine how many bytes a given flow can transmit at a time. Data delivery algorithms perform *segment selection*, i.e., decide which contiguous sequence of bytes a particular flow should transmit. Although the terms "data delivery" and "congestion control" are commonly associated with TCP-based transport protocols, Tonic provides a general programmable architecture for transport logic that can be used for other kinds of transport protocols as well, such as receiver-driven [21, 24, 36] and RDMA-based [8] transport protocols.

Tonic exploits the natural functional separation between data delivery and credit management to partition them into two components with separate state (Figure 2). The data delivery engine processes events related to generating, tracking, and delivery of segments, while the credit engine processes events related to adjusting each flow's credit and sending out segment addresses for those with sufficient credit.

At the cost of lightweight coordination between the two engines, this partitioning helps Tonic meet its timing constraints while concurrently processing multiple events (e.g., receipt of acknowledgments and segment transmission) every cycle. These events must read the current state of their corresponding flow, update it, and write it back to memory for events in the next cycle. However, concurrent read and write to memory in every cycle is costly. Instead of using a wide memory to serve all the transport events, the partitioning allows the data delivery and credit engines to have narrower memories to serve only the events that matter for their specific functionality, hence meeting timing constraints.

In this section, we present, in §3.1, how the engines coordinate to fairly and efficiently pick one of a few thousand flows every cycle for segment transmission while keeping the outgoing link utilized. Next, §3.2 and §3.3 describe fixed-function and programmable event processing modules in each engine, and how their design is inspired by patterns in Table 1. We present Tonic's solution for resolving conflicts when multiple events for the same flow are received in a cycle in §3.4, and its programming interface in §3.5.

3.1 Efficient Flow Scheduling

At any time, a flow can only transmit a data segment if it (1) has enough credit, and (2) has a new or lost segment to send. To be work conserving, Tonic must track the set

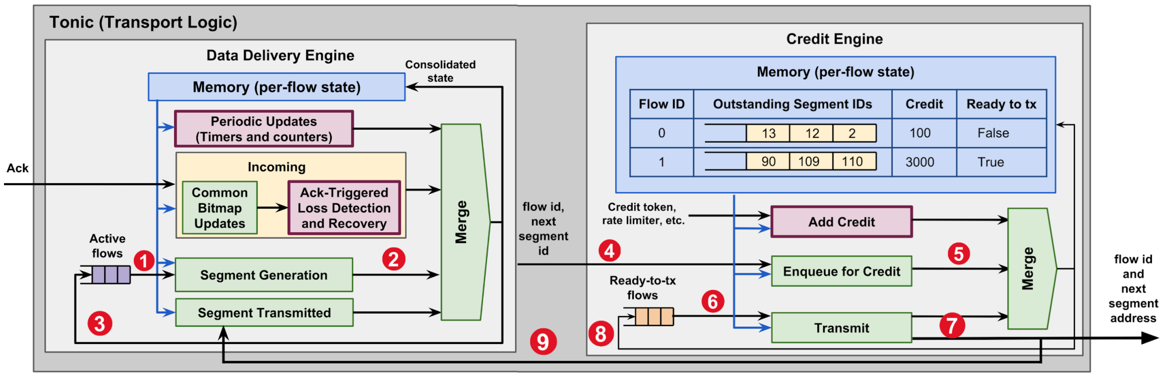

Figure 2: Tonic's architecture (dark red boxes (also with thick borders) are programmable, others are fixed)

of flows that are eligible for transmission (meet both of the above criteria) and only pick among those when selecting a flow for transmission each cycle. This is challenging to do efficiently. We have more than a thousand flows with their state partitioned across the two engines: Only the credit engine knows how much credit a flow has, and only the data delivery engine knows the status of a flow's segments and can generate the address of its next segment. We cannot check the state of all the flows every cycle across both engines to find the ones eligible for transmission in that cycle.

Instead, we decouple the *generation* of segment addresses from their *final transmission* to the DMA pipeline. We allow the data delivery engine to generate up to N segment addresses for a flow without necessarily having enough credit to send them out. In the credit engine, we keep a ring buffer of size N for each flow to store these outstanding segments addresses. When the flow has enough credit to send a segment, the credit engine dequeues and outputs a segment address from the buffer and signals the data delivery engine to decrement the number of outstanding segments for that flow.

This solves the problem of the partitioned state across the two engines. The data delivery engine does not need to keep track of the credit changes of flows for segment address generation. It only needs to be notified when a segment address is dequeued from the buffer. Moreover, the credit engine does not need to know the exact status of all flow's segments. If the flow's ring buffer is empty, that flow does not have segments to send. Otherwise, there are already segment addresses that can be output when the flow has enough credit.

Still, the data delivery engine cannot simply check the state of all the flows every cycle to determine those that can generate segments. Instead, we dynamically maintain the set of *active* flows in the data delivery engine, i.e., the flows that have at least one segment to generate and less than N outstanding segments (see red numbered circles in Figure 2). When a flow is created, it is added to the active set. Every cycle, one flow is selected and removed from the set for segment generation (Step 1). Once processed (Step 2), only if it has more segments to send and less than N outstanding segments, is it inserted back into the set (Step 3). Otherwise, it will be inserted in the set if, later on, the receipt of an ack or a signal from the credit engine "activates" the flow (Step 9). Moreover, the generated segment address is forwarded to the credit engine (Step 4) for insertion in the ring buffer (Step 5).

Similarly, the credit engine maintains the set of *ready-to-transmit* flows, i.e., the flows with one segment address or more in their ring buffers and enough credit to send at least one segment out. Every cycle, a flow is selected from the set (Step 6), one segment address from its ring buffer is transmitted (Step 7), its credit is decreased, and it is inserted back into the set if it has more segment addresses and credit for further transmission (Step 8). It also signals the data delivery engine about the transmission (Step 9) to decrement the number of outstanding segments for that flow.

To be fair when picking flows from the active (or ready-to-transmit) set, Tonic uses a FIFO to implement round-robin scheduling among flows in the set (see active list in [39]). The choice of round-robin scheduling is not fundamental; any other scheduler that meets our timing constraints can replace the FIFO to support other scheduling disciplines [40].

3.2 Flexible Segment Selection

With B bytes of credit, a flow can send $S = max(B, MSS)$ bytes, where MSS is the maximum segment size. In transport protocols, data delivery algorithms use acknowledgments to keep track of the status of each byte of data (e.g., delivered, lost, in-flight, and not transmitted), and use that to decide which contiguous S bytes of data to transmit next.

However, there are two main challenges in implementing data delivery algorithms in high-speed NICs. First, due to memory constraints, the NIC cannot store per-byte information. Second, with a few exceptions [8, 34], these algorithms are designed for software, where they could store and freely loop through large arrays of metadata to aggregate information. This computational flexibility has created significant diversity across these algorithms. Unfortunately, NIC hardware is much more constrained than software. Thus, we did not aim to support all data delivery algorithms. Instead, we looked for patterns that are common across a variety of algorithms while being amenable to hardware implementation.

3.2.1 Pre-Calculated Fixed Segment Boundaries

Data delivery algorithms could conceivably choose the next S bytes to send from anywhere in the data stream and produce segments with variable boundaries. However, since the NIC cannot maintain per-byte state, Tonic requires data to be partitioned into fixed-size segments (by a Kernel module or the driver, see §5) when the flow requests transmission of new data. This way, data delivery algorithms can use *per-segment* information to select the next segment.

Note that the fixed segment size can be configured for each flow based on its throughput and latency requirements. With message-based transport protocols (e.g., RoCEv2), having fixed segment boundaries fits naturally; the message length is known and the optimal segment size can be chosen from the beginning. For protocols with a byte-stream abstraction (e.g., TCP and NDP), the fixed segment size should be decided on the fly as data is added to the stream. It can be set to MSS (or larger if using TSO [18]) for high-bandwidth flows. For flows that generate small data segments and sporadically, the segment size can be set to a smaller value, depending on whether it is more desirable to consolidate multiple small segments into a larger one before notifying Tonic, or to transmit the small segment right away (§5). Regardless, to avoid storing per-byte state on the NIC, segment size should be decided outside of Tonic and changed infrequently.

3.2.2 Small Per-Segment State for a Limited Window

Independent of a flow's available credit, data delivery algorithms typically do not transmit a new segment if it is too far, i.e., more than K segments apart, from the first unacknowledged segment, to limit the state that the sender and receiver need to keep [2]. Still, in a 100 Gbps network with a 10μs RTT, K can get as large as $\sim$128 segments. Fortunately, we observe that storing the following per-segment state is enough for most data delivery algorithms: (1) Is the segment acknowledged (in presence of selective acknowledgments)? (2) If not, is it lost or still in flight? (3) If lost, is it already retransmitted (to avoid redundant retransmission)?

More specifically, we observe that, in the absence of explicit negative acknowledgments, data delivery algorithms accumulate evidence of loss for each segment from positive acknowledgments, e.g., duplicate cumulative (e.g., TCP NewReno [23]) or selective acks (e.g., IRN for RDMA and TCP SACK [16]). Once the accumulated evidence for a segment passes a threshold, the algorithm can declare it lost with high confidence. Typically, an evidence of loss for segment i is also an evidence of loss for every *unacknowledged* segment j with $j < i$. Thus, most of these algorithms can be rewritten to only keep track of the total evidence of loss for the first unacknowledged segment and incrementally compute the evidence for the rest as needed. Based on these observations (#1 and #2 in Table 1), we use a fixed set of bitmaps in Tonic's data delivery engine to track the status of a flow's segments and implement optimized fixed-function bitmap operations for updating them on transport events.

[2]In TCP-based protocols, K is the minimum of receive window and congestion window size. However, the limit imposed by K exists when transport protocols use other ways (e.g., rate) to limit a flow's transmission pace [8].

3.2.3 Concurrent Event Processing

For every flow, four main events can affect the generation of its next segment address. First, the receipt of an acknowledgment can either move the window forward and enable the flow to generate more segments, or signal segment loss and trigger retransmissions. Second, the absence of acknowledgments, i.e., a timeout, can also lead to more segments marked as lost and trigger retransmissions. Third, generation of a segment address increments the number of a flow's outstanding segments and can deactivate the flow if it goes above N. Fourth, segment address transmission (out of the credit engine) decrements the number of outstanding segments and can enable the flow to generate more segment addresses.

Tonic's data delivery engine has four modules to handle these four events (Figure 2). Every cycle, each module reads the state of the flow for which it received an event from the memory in the data delivery engine, processes the event, and updates the flow state accordingly. The flow state in the data delivery engine consists of a fixed set of variables to track the status of the current window of segments across events, as well as the user-defined variables used in the programmable components (Table 2). As an example of the fixed state variables, Tonic keeps a fixed set of bitmaps for each flow (observations in §3.2.2): The `acked` bitmap keeps track of selectively acknowledged segments, `marked-for-rtx` keeps track of lost segments that require retransmission, and `rtx-cnt` stores information about their previous retransmissions.

The following paragraphs briefly describe how each event-processing module affects a flow's state, and whether there are common patterns that we can exploit to implement all or parts of its functionality in a fixed-function manner.

Incoming. This module processes acknowledgments (and other incoming packets, see §3.3.3). Some updates to state variables in response to acknowledgments are similar across all data delivery algorithms and do not need to be programmable (e.g., updating window boundaries, and marking selectively acked segments in `acked` bitmap, see §3.2.2), whereas loss detection and recovery, which rely on acknowledgments as a signal, vary a lot across different algorithms and must be programmable by users (#4 in Table 1). Thus, the Incoming module is designed as a two-stage pipeline: a fixed-function stage for the common updates followed by a programmable stage for loss detection and recovery.

The benefit of this two-stage design is that the common updates mostly involve bitmaps and arrays (§3.2.2), which are implemented as ring buffers in hardware and costly to modify across their elements. For instance, in all data delivery algorithms, if an incoming packet acknowledges segment A cumulatively and segment S selectively, `wnd-start` is updated to `max(wnd-start, A)` and `acked[S]` to one, and the boundaries of all bitmaps and arrays are updated based on the new `wnd-start`. By moving these updates into a fixed function stage, we can (i) optimize them to meet Tonic's timing and memory constraints, and (ii) provide programmers with a dedicated stage, i.e., a separate cycle, to do loss detection and recovery. In this dedicated stage, programmers can use the updated state variables from the previous stage and the rest of the variables from memory to infer segment loss (and perform other user-defined computation discussed in §3.3.3).

Periodic Updates. The data delivery engine iterates over active flows, sending them one at a time to this module to check for retransmission timer expiration and perform other user-defined periodic updates (§3.3.3). Thus, with its 10 ns clock cycle, Tonic can cover each flow within a few microseconds of the expiry of its retransmission timer. This module must be programmable as a retransmission timeout is a signal for detecting loss (#4 in Table 1). Similar to the programmable stage of the Incoming module, the programmers can use per-flow state variables to infer segment loss.

Segment Generation. Given an active flow and its variables, this module generates the next segment's address and forwards it to the credit engine. Tonic can implement segment address generation as a fixed function module based on the following observation (#3 in Table 1): Although different reliable data delivery algorithms have different ways of inferring segment loss, once a lost segment is detected, it is only logical to retransmit it before sending anything new. Thus, the procedure for selecting the next segment is the same irrespective of the data delivery algorithm, and is implemented as a fixed-function module in Tonic. Thus, this module prioritizes retransmission of lost segments in `marked-for-rtx` over sending the next new segment, i.e., `highest_sent+1` and also increments the number of outstanding segments.

Segment Transmitted. This module is fixed function and is triggered when a segment address is transmitted out of the credit engine. It decrements the number of outstanding segments of the corresponding flow. If the flow was deactivated due to a full ring buffer, it is inserted into the active set again.

3.3 Flexible Credit Management

Transport protocols use congestion-control algorithms to avoid overloading the network by controlling the pace of a flow's transmission. These algorithms consist of a control loop that estimates the network capacity by monitoring the stream of incoming control packets (e.g., acknowledgments and congestion notification packets (CNPs)) and sets parameters that limit outgoing data packets. While the control loop is different in many algorithms, the credit calculation based on parameters is not. Tonic has efficient fixed-function modules for credit calculation (§3.3.1 and §3.3.2) and relegates parameter adjustment to programmable modules (§3.3.3).

State Variable	Description
acked	selectively acknowledged segments (bitmap)
marked-for-rtx	lost segments marked for retransmission (bitmap)
rtx-cnt	number of retransmissions of a segment (bitmap)
wnd-start	the address of the first segment in the window
wnd-size	size of the window ($min(W, rcved\_window)$)
highest-sent	the highest segment transmitted so far
total-sent	Total number of segments transmitted so far
is-idle	does the flow have segments to send?
outstanding-cnt	# of outstanding segments
rtx-timer	when will the rtx timer expire?
user-context	user-defined variables for programmable modules

Table 2: Per-flow state variables in the data delivery engine

3.3.1 Common Credit-Calculation Patterns

Congestion control algorithms have a broad range of ways to estimate network capacity. However, they enforce limits on data transmission in three main ways (#5 in Table 1):
Congestion window. The control loop limits a flow to at most W bytes in flight from the first unacknowledged byte. Thus, if byte i is the first unacknowledged byte, the flow cannot send bytes beyond $i+W$. Keeping track of in-flight segments to enforce a congestion window can get complicated, e.g., in the presence of selective acknowledgments, and is implemented in the fixed-function stage of the incoming module in the data delivery engine.
Rate. The control loop limits the flow's average rate (R) and maximum burst size (D). Thus, if a flow had credit c_0 at the time t_0 of the last transmission, then the credit at time t will be $min(R*(t-t_0)+c_0, D)$. As we show in §4, implementing precise per-flow rate limiters under our strict timing and memory constraints is challenging and has an optimized fixed-function implementation in Tonic.
Grant tokens. Instead of estimating network capacity, the control loop receives tokens from the receiver and adds them to the flow's credit. Thus, the credit of a flow is the total tokens received minus the number of transmitted bytes, and the credit calculation logic consists of a simple addition.

Since these are used by most congestion control algorithms[3], we optimize their implementation to meet Tonic's timing and memory constraints. Congestion window calculations are mostly affected by acks. Thus, calculation and enforcement of congestion window happen in the data delivery engine. For the other two credit calculation schemes, the credit engine processes credit-related event, and Tonic users can simply pick which scheme to use in the credit engine.

3.3.2 Event Processing for Credit Calculation

Conceptually, three main events can trigger credit calculation for a flow, and the credit engine has different modules to concurrently process them every cycle (Figure 2). First, when a segment address is received from the data delivery engine and is the only one in the flow's ring buffer, the flow could now qualify for transmission or remain idle based on

[3] Tonic's credit engine has a modular event-based design (§3.3.2), making it amenable for extension to future credit calculation schemes.

its credit (the Enqueue module). Second, when a flow transmits a segment address, its credit must be decreased and we should determine whether it is qualified for further transmission based on its updated credit and the occupancy of its ring buffer (the Transmit module). Third are events that can add credit to the flow (e.g., from grant tokens and leaky bucket rate limiters), which is where the main difference lies between rate-based and token-based credit calculation.

When using grant tokens, the credit engine needs two dedicated modules to add credit to a flow: one to process incoming grant tokens from the receiver, and one to add credit for retransmissions on timeouts. When using rate, the credit engine does not need any extra modules for adding credit since a flow with rate R bytes-per-cycle implicitly gains R bytes of credit every cycle and, therefore, we can compute in advance when it will be qualified for transmission.

Suppose in cycle T_0, the Transmit module transmits a segment from flow f, and is determining whether the flow is qualified for further transmission. Suppose that f has more segments in the ring buffer but lacks L bytes of credit. The Transmit module can compute when it will have sufficient credit as $T = \frac{L}{R}$ and set up a timer for T cycles. When the timer expires, f definitely has enough credit for at least one segment, so it can be directly inserted into `ready-to-tx`. When f reaches the head of `ready-to-tx` and is processed by the Transmit module again in cycle T_1, the Transmit module can increase f's credit by $(T_1 - T_0) * R - S$, where S is the size of the segment that is transmitted at time T_1 [4]. Note that when using rate, the credit engine must perform division and maintain per-flow timers. We will discuss the hardware implementation of these operations in §4.

3.3.3 Flexible Parameter Adjustment

Congestion control algorithms often have a control loop that continuously monitors the network and adjusts credit calculation parameters, i.e., rate or window size, based on estimated network capacity. Parameter adjustment is either triggered by incoming packets (e.g., acknowledgments and their signals such as ECN or delay in TCP variants and Timely, and congestion notification packets (CNPs) in DCQCN) or periodic timers and counters (timeouts in TCP variants and byte counter and various timers in DCQCN), and in some cases is inspired by segment losses as well (window adjustment after duplicate acknowledgments in TCP).

Corresponding to these triggers, for specifying parameter adjustment logic, Tonic's users can use the programmable stage of the "Incoming" module, which sees all incoming packets, and the "Periodic Updates" module for timers and counters. Both modules are in the data delivery engine and have access to segment status information, in case segment status (e.g., drops) is needed for parameter adjustment. The updated parameters are forwarded to the credit engine.

[4]Similarly, the Enqueue module can set up the timer when it receives the first segment of the queue and the flow lacks credit for its transmission.

As we show in §6.1.1, we have implemented several congestion control algorithms in Tonic and their parameter adjustment calculations have finished within our 10 ns clock cycle. Those with integer arithmetic operations did not need any modifications. For those with floating-point operations, such as DCQCN, we approximated the operations to a certain decimal point using integer operations. If an algorithm requires high-precision and complicated floating-point operations for parameter adjustment that cannot be implemented within one clock cycle [19], the computation can be relegated to a floating-point arithmetic module outside of Tonic. This module can perform the computation asynchronously and store the output in a separate memory, which merges into Tonic through the "Periodic Updates" module.

3.4 Handling Conflicting Events

Tonic strives to process events concurrently in order to be responsive to events. Thus, if a flow receives more than one event in the same cycle, it allows the event processing modules to process the events and update the flow's state variables, and reconciles the state before writing it back into memory (the Merge modules in Figure 2).

Since acknowledgments and retransmission timeouts are, by definition, mutually exclusive, Tonic discards the timeout if it is received in the same cycle as an acknowledgment for the same flow. This significantly simplifies the merge logic because several variables (window size and retransmission timer period) are *only* modified by these two events and, therefore, are never updated concurrently. We can resolve concurrent updates for the remaining variables with simple, predefined merge logic. For example, Segment Generation increments the number of outstanding segments, whereas Segment Transmitted decrements it; if both events affect the same flow at the same time, the number does not change. User-defined variables are updated in either the Incoming or the Periodic Updates module, and we rely on the programmer to specify which updated variables should be prioritized if both updates happen in the same cycle.

3.5 Tonic's Programming Interface

To implement a new transport logic in Tonic, programmers only need to specify (i) which of the three credit management schemes to use, (ii) the loss detection and recovery logic in response to acknowledgments and timeouts, and (iii) congestion-control parameter adjustment in response to incoming packets or periodic timers and counters. The first one is used to pick the right modules for the credit engine, and the last two are inserted into the corresponding programmable stages of the data delivery engine (Figure 2).

To specify the logic for the programmable stage of the Incoming module, programmers need to write a function that receives the incoming packet (ack or other control signals), the number of newly acknowledged segments, the `acked` bitmap updated with the information in the ack, the old and new value of `wnd-start` (in case the window moves forward due to a new cumulative ack), and the rest of the flow's state variables (Table 2) as input. In the output, they can mark a range of segments for retransmission in `marked-for-rtx`, update congestion-control parameters such as window size and rate, and reset the retransmission timer. The programming interface of the Periodic Updates module is similar.

In specifying these functions, programmers can use integer arithmetic operations, e.g., addition, subtraction, multiplication, and division with small-width operands, conditionals, and a limited set of read-only bitmap operations, e.g., index lookup, and finding the first set bit in the updated `acked` bitmap (see appendix F for an example program). Note that a dedicated fixed-function stage in the data delivery engine performs the costly common bitmap updates on receipt of acks (§3.2.3). We show, in §6.1.1, that a wide range of transport protocols can be implemented using this interface and give examples of ones that cannot.

4 Hardware Implementation

In this section, we describe the hardware design of the Tonic components that were the most challenging to implement under Tonic's tight timing and memory constraints.

High-Precision Per-Flow Rate Limiting. A flow with rate R bytes per cycle and L bytes to send will have sufficient credit for transmission in $T = \lceil \frac{L}{R} \rceil$ cycles. Tonic needs to do this computation in the credit engine but must represent R as an integer since it cannot afford to do floating-point division. This creates a trade-off between the rate-limiting precision and the range of rates Tonic can support. If R is in bytes per cycle, we cannot support rates below one byte per cycle or $\sim$1 Gbps. If we represent R in bytes per thousand cycles, we can support rates as low as 1 Mbps. However, $T = \lceil \frac{L}{R} \rceil$ determines how many thousand cycles from now the flow qualifies for transmission which results in lower rate conformance and precision for higher-bandwidth flows. To support a wide range of rates without sacrificing precision, Tonic keeps multiple representations of the flow's rate at different levels of precision and picks the most precise representation for computing T at any moment (details in Appendix B).

Efficient Bitmap Operations. Tonic uses bitmaps as large as 128 bits to track the status of segments for each flow. Bitmaps are implemented as ring buffers. The head pointer corresponds to the first unacked segment and moves forward around the buffer with new acks. To efficiently implement operations whose output depends on the values of *all* the bits in the bitmap, we must divide the buffer into smaller parts in multiple layers, process them in parallel, and join the results. One such operation, frequently used in Tonic, is finding the first set bit after the head. The moving head of the ring buffer complicates the implementation of this operation since keeping track of the head in each layer requires extra processing, making it difficult to compute within our 10 ns target. Instead, Tonic uses a light-weight pre-processing on the input ring buffer to avoid head index computation in the layers altogether (details in Appendix C).

Concurrent Memory Access. Every cycle, five modules in the data delivery engine, including both stages of the Incoming module, concurrently access its memory (§3.2.3). However, FPGAs only have dual-ported block RAMs, with each port capable of either read or write every cycle. Building memories with more concurrent reads and writes requires keeping multiple copies of data in separate memory "banks" and keeping track of the bank with the most recent data for each address[5] [26]. To avoid supporting *five* concurrent reads and writes, we manage to partition per-flow state variables into two groups, each processed by at most four events. Thus, Tonic can use two memories with four read and write ports instead of a single one with five, to provide concurrent access for all processing modules at the same time.

5 Integrating Tonic into the Transport Layer

Tonic's transport logic is intentionally decoupled from the specific implementation of other transport functionality such as connection management, application-level API, and buffer management. This section provides an example of how Tonic can interface with the Linux kernel to learn about new connections, requests for data transmission, and connection termination [6]. After creating the socket, applications use various system calls for connection management and data transfer. As Tonic mainly focuses on the sender sider of the transport logic, we only discuss the system calls and modifications relevant to the sender side of the transport layer.

Connection Management. `connect()` on the client initiates a connection, `listen()` and `accept()` on the server listen for and accept connections, and `close()` terminate connections. As connection management happens outside of Tonic, the kernel implementation of these system calls stays untouched. However, once the connection is established, the kernel maps it to a unique *flow id* in $[0, N)$, where N is the maximum number of flows supported by Tonic, and notifies Tonic through the NIC driver about the new connection.

Specifically, from the connection's Transmission Control Block (TCB) in the kernel, the IP addresses and ports of the communication endpoints are sent to Tonic alongside the flow id and the fixed segment size chosen for the connection. The kernel only needs to track the TCB fields used for connection management (e.g., IP addresses, ports, and TCP FSM), pointers to data buffers, and receiver-related fields. Fields used for data transfer on the sender, i.e., `snd.nxt`, `snd.una`, and `snd.wnd`, are stored in and handled by Tonic. Finally, after a call to `close()`, the kernel uses the connec-

[5] This overhead is specific to FPGAs, and can potentially be eliminated if the memory is designed as an ASIC.

[6] See appendix A for how Tonic can be used with RDMA.

tion's flow id to notify Tonic of its termination.

Data Transfer. `send()` adds data to the connection's socket buffer, which stores its outstanding data waiting for delivery. Tonic keeps a few bits of per-segment state for outstanding data and performs all transport logic computation in terms of segments. As such, data should be partitioned into equal-sized segments before Tonic can start its transmission (§3.2). Thus, modifications to `send()` mainly involve determining segment boundaries for the data in the socket buffer based on the connection's configured segment size and deciding when to notify Tonic of the new segments. Specifically, the kernel keeps an extra pointer for each connection's socket buffer, in addition to its `head` and `tail`, called `tonic-tail`. It points to the last segment of which Tonic has been notified. `head` and updates to `tonic-tail` are sent to Tonic to use when generating the next segment's address to fetch from memory.

Starting with an empty socket buffer, when the application calls `send()`, data is copied to the socket buffer, and `tail` is updated accordingly. Assuming the connection's configured segment size is C, the data is then partitioned into C-sized segments. Suppose the data is partitioned into S segments and $B < C$ remaining bytes. The kernel then updates `tonic-tail` to point to the end of the last C-sized segment, i.e., `head + C * S`, and notifies Tonic of the update to `tonic-tail`. The extra B bytes remain unknown to Tonic for a configurable time T, in case the application calls `send` to provide more data. In that case, the data are added to the socket buffer, data between `tonic-tail` and `tail` are similarly partitioned, `tonic-tail` is updated accordingly, and Tonic is notified of new data segments.

If there is not enough data for a C-sized segment after time T, the kernel needs to notify Tonic of the "sub-segment" (a segment smaller than C) and its size, and update `tonic-tail` accordingly. Note that Tonic requires all segments, except for the last one in a burst, to be of equal size, as all computations, including window updates, are in terms of segments. Thus, after creating a "sub-segment", if there is more data from the application, Tonic can only start its transmission when it is done transferring its current segments. Tonic notifies the kernel once it successfully delivers the final "sub-segment", at which point, `head` and `tonic-tail` will be equal, and the kernel continues partitioning the remaining data in the socket buffer and updating Tonic as before. Note that Tonic can periodically, with a configurable frequency, forward acknowledgments to the kernel to move `head` forward and free up space for new data in the socket buffer.

C and T can be configured for each flow based on its latency and throughput characteristics. For high-bandwidth flows, C can be set to MSS (or larger, if using TSO). For flows that sporadically generate small segments, setting C and T is not as straightforward since segments cannot be consolidated within Tonic. We discuss the trade-offs in deciding these parameters in detail in appendix D.

Other Considerations. As we show in §6, Tonic's current design supports 2048 concurrent flows, matching the working sets observed in data centers [15,37] and other hardware offloads in the literature [20]. If a host has more open connections than Tonic can support, the kernel can offload data transfer for flows to Tonic on a first-come first-serve basis, or have users set a flag when creating the socket and fall back to software once Tonic runs out of resources for new flows. Alternatively, modern FPGA-based NICs have a large DRAM directly attached to the FPGA [20]. The DRAM can potentially be used to store the state of more connections, and swap them back and forth into Tonic's memory as they activate and need to transmit data. Moreover, to provide visibility into the performance of hardware transport logic, Tonic can provide an interface for kernel to periodically pull transport statistics from the NIC.

Other Transport Layers. The above design is an example of how Tonic can be integrated into a commonly-used transport layer. However, TCP, sockets, and bytestreams are not suitable for all applications. In fact, several datacenter applications with high-bandwidth low-latency flows are starting to use RDMA and its message-based API instead [5,9,22,35]. Tonic can be integrated into RDMA-based transport as well, which we discuss in appendix A.

6 Evaluation

To evaluate Tonic, we implement a prototype in Verilog (∼8K lines of code) and a cycle-accurate hardware simulator in C++ (∼2K lines of code) [11]. The simulator is integrated with NS3 network simulator [4] for end-to-end experiments.

To implement a transport protocol on Tonic's Verilog prototype, programmers only need to provide three Verilog files: (i) `incoming.v`, describing the loss detection and recovery logic and how to change credit management parameters (i.e., rate or window) in response to incoming packets; this code is inserted into the second stage of the Incoming pipeline in the data delivery engine, (ii) `periodic_updates.v`, describing the loss detection and recovery logic in response to timeouts and how to change credit management parameters (i.e., rate or window) in response to periodic timers and counters; this code is inserted into the Periodic Updates module in the data delivery engine, and (iii) `user_configs.vh`, specifying which of the three credit calculation schemes to use and the initial values of user-defined state variables and other parameters, such as initial window size, rate, and credit.

We evaluate the following two aspects of Tonic:

Hardware Design (§6.1). We use Tonic's Verilog prototype to evaluate its hardware architecture for *programmability* and *scalability*. Can Tonic support a wide range of transport protocols? Does it reduce the development effort of implementing transport protocols in the NIC? Can Tonic support complex user-defined logic with several variables? How many per-flow segments and concurrent flows can it support?

End-to-End Behavior (§6.2). We use Tonic's cycle-accurate simulator and NS3 to compare Tonic's end-to-end behavior with that of hard-coded implementations of two protocols: New Reno [23] and RoCEv2 with DCQCN [43], both for a single flow and for multiple flows sharing a bottleneck link.

6.1 Hardware Design

There are two main metrics for evaluating the efficiency of a hardware design: (i) **Resource Utilization.** FPGAs consist of primitive blocks, which can be configured and connected to implement a Verilog program: *look-up tables (LUTs)* are the main reconfigurable logic blocks, and *block RAMs (BRAMs)* are used to implement memory. (ii) **Timing.** At the beginning of each cycle, each module's input is written to a set of input registers. The module must process the input and prepare the result for the output registers before the next cycle begins. Tonic must *meet timing* at 100 MHz to transmit a segment address every 10 ns. That is, to achieve 100 Gbps, the processing delay of every path from input to output registers in every module must stay within 10 ns.

We use these two metrics to evaluate Tonic's programmability and scalability. These metrics are highly dependent on the specific target used for synthesis. We use the Kintex Ultrascale+ XCKU15P FPGA as our target because this FPGA, and others with similar capabilities, are included as bump-in-the-wire entities in today's commercial programmable NICs [2, 3]. This is a conservative choice, as these NICs are designed for 10-40 Gbps Ethernet. A 100 Gbps NIC could potentially have a more powerful FPGA. Moreover, we synthesize *all* of Tonic's components onto the FPGA to evaluate it as a standalone prototype. However, given the well-defined interfaces between the fixed-function and programmable modules, it is conceivable to implement the fixed-function components as an ASIC for more efficiency. Unless stated otherwise, we set the maximum number of concurrent flows to 1024 and the maximum window size to 128 segments in all of our experiments [7].

6.1.1 Hardware Programmability

We have implemented the sender's transport logic of six protocols in Tonic as representatives of various types of segment selection and credit calculation algorithms in the literature. Table 3 summarizes their resource utilization for both fixed-function and user-defined modules, and the lines of code and bytes of user-defined state used to implement them. While we use the same set of per-flow state variables (Table 2) for all protocols, not all of them use all the variables in processing transport events. For instance, bitmaps are only used by protocols with selective acks. Thus, it is possible to reduce the resource utilization even more with some pre-processing to remove the irrelevant variables and computation from the Verilog design.

[7]A 100 Gbps flow with 1500B back-to-back packets over 15-μs RTT, typical in data centers, has at most 128 in-flight segments.

	User-Defined Logic		**Credit Type**	**Look up Tables (LUTs)**				**BRAMs**	
				User-Defined		**Fixed**			
	LoC	state(B)		total(K)	%	total(K)	%	total	%
Reno	48	8	wnd	2.4	0.5	109.4	20.9	195	20
NewReno	74	13	wnd	2.6	0.5	112.5	21.5	211	21
SACK	193	19	wnd	3.3	0.6	112.1	21.4	219	22
NDP	20	1	token	3.0	0.6	143.6	29.0	300	30
RoCE w/ DCQCN	63	30	rate	0.9	0.2	185.2	35.2	251	26
IRN	54	14	rate	2.9	0.6	177.4	33.9	219	22

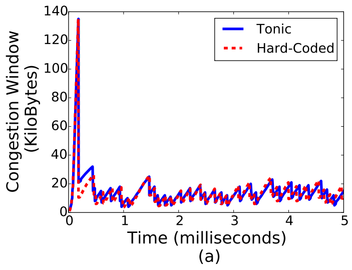
Table 3: Resource utilization of transport protocols in Tonic.

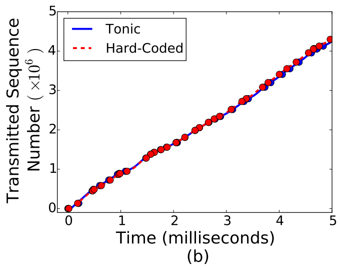
Reno [13] and New Reno [23] represent TCP variants that use only cumulative acks for reliable delivery and congestion window for credit management. Reno can only recover from one loss within the window using fast retransmit, whereas New Reno uses partial acknowledgments to recover more efficiently from multiple losses in the same window. SACK, inspired by RFC 6675 [16], represents TCP variants that use selective acks. Our implementation has one SACK block per ack but can be extended to more. NDP [24] represents receiver-driven protocols, recently proposed for low-latency data-center networks [21, 36]. It uses explicit NACKs and timeouts for loss detection and grant tokens for congestion control. RoCEv2 w/ DCQCN [43] is a widely-used transport for RDMA over Ethernet, and IRN [34] is a recent hardware-based protocol for improving RoCE's simple data delivery algorithm. Both use rate limiters for credit management.

Note that, as described in §3.2, not all data delivery algorithms are feasible for hardware implementation as is. For instance, due to memory constraints on the NIC, it is not possible to keep timestamps for *every* packet, new and retransmissions, on the NIC. As a result, transport protocols which rely heavily on per-packet timestamps, e.g., QUIC [27], need to be modified to work with fewer timestamps, i.e., for a subset of in-flight segments, to be offloaded to hardware.

Takeways. There are three key takeaways from these results:

- *Tonic supports a variety of transport protocols.*
- *Tonic enables programmers to implement new transport logic with modest development effort.* Using Tonic, each of the above protocols is implemented in less than 200 lines of Verilog code, with the user-defined logic consuming less than 0.6% of the FPGA's LUTs. In contrast, Tonic's fixed-function modules, which are reused across these protocols, are implemented in ∼8K lines of code and consume ∼60 times more LUTs.
- *Different credit management schemes have different overheads.* For transport protocols that use congestion window, window calculations overlap with and therefore are implemented in the data delivery engine (§3.3.1). Thus, their credit engine utilizes fewer resources than others. Rate limiting requires more per-flow state and more complicated operations (§4) than enforcing receiver-generated grant tokens but needs fewer memory ports for concurrent reads and writes (§3.3.2), overall leading to lower BRAM and higher LUT utilization for rate limiting.





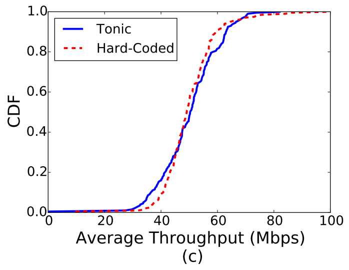


Figure 3: NewReno's Tonic vs hard-coded implementation in NS3 (10G line-rate): a) Congestion window updates (single flow, random drops), b) Transmitted sequence numbers with retransmission in large dots (single flow, random drops), and c) CDF of average throughput of multiple flows sharing a bottleneck link over 5 seconds (200 flows from 2 hosts to one receiver)

6.1.2 Hardware Scalability

We evaluate Tonic's scalability by examining how sources of variability in its architecture (programmable modules and various parameters) affect memory utilization and timing.

User-defined logic in programmable modules can have arbitrarily-long chains of dependent operations, potentially causing timing violations. We generate 70 random programs for `incoming.v` (the programmable stage of Incoming module in data delivery engine) with different numbers of arithmetic, logical, and bitmap operations, and analyze how long the chain of dependent operations gets without violating timing at 10ns. These programs use up to 125B of state and have a maximum dependency of 65 *logic levels* (respectively six and two times more than the benchmark protocols in Table 3). Each logic level represents one of several primitive logic blocks (LUT, MUX, DSP, etc.) chained together to implement a path in a Verilog program.

We plug these programs into Tonic, synthesize them, and analyze the relationship between the number of logic levels and latency of the max-delay path (Table 4). Programs with up to 32 logic levels consistently meet timing, while those with more than 43 logic levels do not. Between 32 and 42 logic levels, the latency of the max-delay path is around 10 ns. Depending on the mix of primitives on the max-delay path and their latencies, programs in that region can potentially meet timing. Our benchmark protocols have 13 to 29 logic levels on their max-delay path and all meet timing. Thus, Tonic not only supports our benchmark protocols, but also has room to support future more sophisticated protocols.

User-defined state variables increase the memory width affecting BRAM utilization. We add extra variables to SACK, IRN, and NDP to see how wide memories can get without violating timing and running out of BRAMs, repeating the experiment for each of the three credit management schemes as they have different memory footprints (Table 4). Tonic can support 448B of user-defined state with congestion window for credit management, 340B with rate, and 256B with grant tokens (Protocols in Table 3 use less than 30B).

Maximum window size determines the size of per-flow bitmaps stored in the data delivery engine to keep track of the status of a flow's segments, therefore affecting memory utilization, and the complexity of bitmap operations, hence timing. Tonic can support bitmaps as large as 256 bits (i.e., tracking 256 segments), with which we can support a single 100Gbps flow in a network with up to 30µs RTT (Table 4).

	Metric	Results	
Complexity of User-Defined Logic	logic levels	(0 ,31]	meets timing
		(31,42]	depends on operations
		(42,65]	violates timing
User-Defined State	bytes	256	grant token
		340	rate
		448	congestion window
Window Size	segments	256	
Concurrent Flows	count	2048	

Table 4: Summary of Tonic's scalability results.

Maximum number of concurrent flows determines memory depth and the size of FIFOs used for flow scheduling (§3.1). Thus, it affects both memory utilization and the queue operations, hence timing. Tonic can scale to 2048 concurrent flows in hardware (Table 4) which matches the size of the active flow set observed in data centers [15, 37] and other hardware offloads in the literature [20].

Takeways. Tonic has additional room to support future protocols that are more sophisticated with more user-defined variables than our benchmark protocols. It can track 256 segments per flow and support 2048 concurrent flows. With a more powerful FPGA with more BRAMs, Tonic can potentially support even larger windows and more flows.

6.2 End-to-End Behavior

To examine Tonic's end-to-end behavior and verify the fidelity of Tonic-based implementation of the transport logic in different protocols, we have developed a cycle-accurate hardware simulator for Tonic in C++. We use this simulator with NS3 to show that Tonic-based implementation of NewReno and RoCEv2 w/ DCQCN senders match their hard-coded NS3 implementation. Note that the goal of these simulations is to analyze and verify Tonic's end-to-end behavior. Tonic's ability to support 100Gbps line rate has already been demonstrated in §6.1 using hardware synthesis. Thus, in our simulations, we use 10Gbps and 40Gbps as line rate merely to make hardware simulations with multiple flows over seconds computationally tractable.

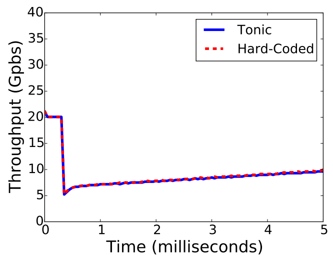

Figure 4: RoCEv2 w/ DCQCN in Tonic vs hard-coded in NS3 (40G line rate, one of two flows on a bottleneck link).

6.2.1 TCP New Reno

We implement TCP New Reno in Tonic based on RFC 6582, and use NS3's native network stack for its hard-coded implementation. Our Tonic-based implementation works with the *unmodified* native TCP receiver in NS3. In all simulations, hosts are connected via 10Gbps links to one switch, RTT is $10\mu s$, the buffer is 5.5MB, the minimum retransmission timeout is 200ms (Linux default), segments are 1000B large, and delayed acks are enabled on the receiver.

Single Flow. We start a single flow from one host to another, and randomly drop packets on the receiver's NIC. Figure 3(a) and 3(b) show the updates to the congestion window and transmitted sequence numbers (retransmissions are marked with large dots), respectively. Tonic's behavior in both cases closely matches the hard-coded implementation. The slight differences stem from the fact that in NS3's network stack, all the computation happens in the same virtual time step while in Tonic every event (incoming packets , segment address generation, etc.) is processed over a 100ns cycle (increased from 10ns to match the 10G line rate).

Multiple Flows. Two senders each start 100 flows to a single receiver, so 200 flows share a single bottleneck link for 5 seconds. The CDF of average throughput across the 200 flows for the Tonic-based implementation closely matches that of the hard-coded implementation (Figure 3(c)). We observe similarly matching distributions for number of retransmissions. When analyzing the flows' throughput in millisecond-long epochs, we notice larger variations in the hard-coded implementation than Tonic since Tonic, as opposed to NS3's stack, performs per-packet round robin scheduling across flows on the same host.

6.2.2 RoCEv2 with DCQCN

We implement RoCE w/ DCQCN [43] in Tonic, and use the authors' NS3 implementation from [44] for the hard-coded implementation. Our Tonic-based implementation works with the *unmodified* hard-coded RoCE receiver. In all simulations, hosts are connected via 40Gbps links to the same switch, RTT is $4\mu s$, segments are 1000B large, and we use the default DCQCN parameters from [44].

Single Flow. DCQCN is a rate-based algorithm which uses CNPs and periodic timers and counters for congestion control as opposed to packet loss in TCP. Thus, to observe rate updates for a single flow, we run two flows from two hosts to the same receiver for one second to create congestion and track the throughput changes of one as they both converge to the same rate. Tonic's behavior closely matches the hard-coded implementation (Figure 4). We also ran a single DCQCN flow at 100Gbps with 128B back-to-back packets and confirmed that Tonic can saturate the 100Gbps link.

Multiple Flows. Two senders each start 100 flows to a single receiver, so 200 flows share a single bottleneck link for one second. Both Tonic and the hard-coded implementation do per-packet round robin scheduling among the flows on the same host. As a result, all flows in both cases end up with an average throughput of 203 ± 0.2Mbps. Moreover, we observe a matching distribution of CNPs in both cases.

7 Related Work

Tonic is the first programmable architecture for transport logic in hardware able to support 100 Gbps. In this section, we review the most closely related prior work.

Commercial hardware network stacks. Some NICs have hardware network stacks with hard-wired transport protocols [8, 10]. However, they only implement two protocols, either RoCE [8] or a vendor-selected TCP variant, and can only be modified by their vendor. Tonic enables programmers to implement a variety of transport protocols in hardware with modest effort. In the absence of a publicly-available detailed description of these NICs' architecture, we could not compare our design decisions with theirs.

Non-commercial hardware transport protocols. Recent work explores hardware transport protocols that run at high speed with low memory footprint [30, 31, 34]. Tonic facilitates innovation in this area by enabling researchers to implement new protocols with modest development effort.

Accelerating network functionality. Several academic and industrial projects offload end-host virtual switching and network functions to FPGAs, processing a stream of already-generated packets [14, 20, 28, 29, 41]. Tonic, on the other hand, implements the transport logic in the NIC by keeping track of potentially a few hundred segments at a time to generate packets at line rate while running user-defined transport logic to ensure efficient and reliable delivery.

A Integrating Tonic within RDMA

Remote Direct Memory Access (RDMA) enables applications to directly access memory on remote endpoints without involving the CPU. To do so, the endpoints create a *queue pair*, analogous to a connection, and post requests, called *Work Queue Elements (WQEs)*, for sending or receiving data from each other's memory. While RDMA originated from InfiniBand networks, RDMA over Ethernet is getting more common in data centers [9, 22, 35]. In this section, we use RDMA to refer to RDMA implementations over Ethernet.

Once a queue pair is created, RDMA NICs can add the new "connection" to Tonic and use it to *on the sender side* to transfer data in response to different WQEs. Each WQE corresponds to a separate message transfer and therefore nicely fits Tonic's need for determining segment boundaries before starting data transmission.

For instance, in an RDMA Write, one endpoint posts a Request WQE to write to the memory on the other endpoint. Data length, data source address on the sender, and data sink addresses on the receiver are specified in the Request WQE. Thus, a shim layer between RDMA applications and Tonic can decide the segment boundaries and notify Tonic of the number of segments and the source memory address to read the data from on the sender. Once Tonic generates the next segment address, the rest of the RDMA NIC can DMA it from the sender's memory and add appropriate headers. An RDMA Send is similar to RDMA Write, except it requires a Receive WQE on the receiver to specify the sink address to which the data from the sender should be written. So, Tonic can still be used in the same way on the sender side.

As another example, in an RDMA Read, one endpoint requests data from the memory on the other endpoint. So, the responder endpoint should transmit data to the requester endpoint. Again, the data length, data source address on the responder, and data sink address on the requester are specified in the WQE. Thus, the shim layer can decide the segment boundaries and and transfer the data using Tonic.

Thus, Tonic can be integrated into RDMA NICs to replace the hard-coded transport logic on the sender-side of data transfer. In fact, two of our benchmark protocols, RoCE w/ DCQCN [43] and IRN [34], are proposed for RDMA NICs. That said, this is assuming there is a compatible receiver on the other side to generate the control signals (e.g., acknowledgments, congestion notifications, etc.) required by whichever transport protocol one chooses to implement on Tonic on the sender side.

While some implementations of RDMA over Ethernet such as iWarp [7] handle out-of-order (OOO) packets and implement TCP/IP-like acknowledgments, others, namely RoCE [8], assume a lossless network and have simpler transport protocols that do not require receivers to handle OOO packets and generate frequent control signals. However, as RDMA over Ethernet is getting more common in data centers, the capability to handle OOO packets on the receiver and generate various control signals for more efficient transport is being implemented in these NICs as well [34, 43].

Finally, Tonic provides in-order reliable data delivery within the same flow. Thus, messages sent over the same flow are delivered to the receiver in the same order. However, it is sometimes desirable to support out-of-order message delivery for a communication endpoint (e.g., a queue pair), for instance, to increase the performance of applications when messages are independent from each other, or when using "unconnected" endpoints (e.g., one sender and multiple receivers). It is still possible to support out-of-order message delivery using Tonic by creating multiple flows in Tonic for the same communication endpoint and using them concurrently. Extending Tonic to support out-of-order message delivery within the same flow is an interesting avenue for future work.

B High-Precision Per-Flow Rate Limiting

When using rate in the credit engine, if a flow with rate R bytes per cycle needs L more bytes of credit to transmit a segment, Tonic calculates $T = \lceil \frac{L}{R} \rceil$ as the time where the flow will have sufficient credit for transmission. It sets up a timer that expires in T cycles, and upon its expiry, queues up the flow in `ready-to-tx` for transmission (§3.3.2). Since Tonic cannot afford to do floating-point division within its timing constraints, R must be represented as an integer.

This creates a trade-off between the rate-limiting precision and the range of rates Tonic can support. If we represent R in bytes per cycle, we can compute the exact cycle when the flow will have enough credit, but cannot support rates lower than one byte per cycle or $\sim$1 Gbps. If we instead represent R in, say, bytes per thousand cycles, we can support lower rates (e.g., 1 Mbps), but $T = \lceil \frac{L}{R} \rceil$ will determine how many thousand cycles from now the flow can qualify for transmission. This results in lower rate conformance and precision for higher-bandwidth flows. As a concrete example, for a 20 Gbps flow, R would be 25000 bytes per thousand cycles. Suppose the flow has a 1500-byte segment to transmit. It will have enough credit to do so in 8 cycles but has to wait $\lceil \frac{1500}{25000} \rceil = 1$ thousand cycles to be queued for transmission.

Instead of committing to one representation for R, Tonic keeps multiple variables $R_1, \ldots, R_k$ for each flow, each representing flow's rate at a different level of precision. As the congestion control loop adjusts the rate according to network capacity, Tonic can efficiently switch between $R_1, \ldots, R_k$ to pick the most precise representation for computing T at any moment. This enables Tonic to support a wide range of rates without sacrificing the rate-limiting precision.

C Efficient Bitmap Operations

Tonic uses bitmaps as large as 128 bits to track the status of a window of segments for each flow. Bitmaps are implemented as ring buffers, with the head pointer corresponding to the first unacknowledged segment. As new acknowledgments arrive, the head pointer moves forward around the ring. To efficiently implement operations whose output depends on the values of *all* the bits in the bitmap, we must parallelize them by dividing the ring buffer into smaller parts, processing them in parallel, and joining the results. For large ring buffers, this divide and conquer pattern is repeated in multiple layers. As each layer depends on the previous one for its input, we must keep the computation in each layer minimal to stay within our 10 ns target.

One such operation finds the first set bit after the head. This operation is used to find the next lost segment for retransmission in the `marked-for-rtx` bitmap. The moving head of the ring buffer complicates the implementation of this operation. Suppose we have a 32-bit ring buffer A_{32}, with bits 5 and 30 set to one, and the head at index 6. Thus, $findfirst(A_{32}, 6) = 30$. We divide the ring into eight four-bit parts, "or" the bits in each one, and feed the results into an 8-bit ring buffer A_8, where $A_8[i] = OR(A_{32}[i : i+3])$. So, only $A_8[1]$ and $A_8[7]$ are set. However, because the set bit in $A_{32}[4 : 7]$ is *before* the head in the original ring buffer, we cannot simply use one as A_8's head index or we will mistakenly generate 5 instead of 30 as the final result. So, we need extra computation to find the correct new head. For a larger ring buffer with multiple layers of this divide and conquer pattern, we need to compute the head in each layer.

Instead, we use a lightweight pre-processing on the input ring buffer to avoid head index computation altogether. More specifically, using A_{32} as input, we compute A'_{32} which is equal to A_{32} except that all the bits from index zero to head (6 in our example) are set to zero. Starting from index zero, the first set bit in A'_{32} is always closer to the original head than the first set bit in A_{32}. So, $findfirst(A_{32}, 6)$ equals $findfirst(A'_{32}, 0)$ if A'_{32} has any set bits, and otherwise $findfirst(A_{32}, 0)$. This way, independent of the input head index H, we can always solve $findfirst(A, H)$ from two subproblems with the head index *fixed* at zero.

D Deciding C and T for Flows Using Tonic through the Socket API

In §5, we provide an example of how Tonic can be integrated into the Linux Kernel so that applications can use it through the Socket API. We introduce two parameters: (i) C, which is the flow's fixed segment size, and (ii) T, which is the duration that the Kernel waits for more data from the application before sending a "sub-segment" (a segment that is smaller than C) to Tonic. C and T can be configured for each flow based on its latency and throughput characteristics. For high-bandwidth flows, C can be set to MSS (or larger, if using TSO). For flows that only sporadically generate data segments, setting C and T, as we discuss below, is not as straightforward.

With a fixed C, increasing T results in more small segments being consolidated into C-sized segments before being sent to Tonic for transmission, but at the expense of higher latency. C determines the size of the segments and number of sub-segments generated by Tonic. Recall from §5 that a sub-segment is created when there is not enough data to make a full C-sized segment within T. Tonic needs all segments, except for the last sub-segment in a burst, to be of equal size. Thus, even if more data is added to the socket buffer after the sub-segment is sent to Tonic for transmission, Tonic has to successfully deliver all the previous segments before it can start transmitting the new ones. Thus, it is desirable to produce larger segments but fewer sub-segments. With a fixed T, increasing C results in larger segments. However, to produce fewer sub-segments, C should be picked such that in most cases, the data within a burst is divisible by C. Bursts are separated in time by T. So the choice of T affects the choice of C and vice versa.

For instance, if an application periodically generates 128-byte requests, C can be easily set to 128 and T based on the periodicity. As another example, for an application that periodically generates segments of widely-varying sizes, setting T to zero and C to the maximum expected segment size results in Tonic transmitting data segments as generated by the application without consolidation, potentially creating many sub-segments. For the same application, setting T to zero and C to the minimum expected segment size could result in Tonic generating many small segments as all segments will be broken into the minimum expected segment size. Note that these trade-offs become more pronounced if Tonic is to be used for flows that only sporadically generate data segments. For high-bandwidth flows, C can be set to MSS (or larger, if using TSO), and T depending on the application's traffic pattern and burstiness.

FileMR: Rethinking RDMA Networking for Scalable Persistent Memory

Jian Yang[*] UC San Diego
Joseph Izraelevitz University of Colorado, Boulder
Steven Swanson UC San Diego

Abstract

The emergence of dense, byte-addressable *nonvolatile main memories* (NVMMs) allows application developers to combine storage and memory into a single layer. With NVMMs, servers can equip terabytes of memory that survive power outages, and all of this persistent capacity can be managed through a specialized NVMM file system. NVMMs appear to mesh perfectly with another popular technology, remote direct memory access (RDMA). RDMA gives a client direct access to memory on a remote machine and mediates this access through a memory region abstraction that handles the necessary translations and permissions.

NVMM and RDMA seem eminently compatible: by combining them, we should be able to build network-attached, byte-addressable, persistent storage. Unfortunately, however, the systems were not designed to work together. An NVMM-aware file system manages persistent memory as files, whereas RDMA uses a different abstraction — memory regions to organize remotely accessible memory. As a result, in practice, building RDMA-accessible NVMMs requires expensive translation layers resulting from this duplication of effort that spans permissions, naming, and address translation.

This work introduces two changes to the existing RDMA protocol: file memory region (FileMR) and range-based address translation. These optimizations create an abstraction that combines memory regions and files: a client can directly access a file backed by NVMM file system through RDMA, addressing its contents via file offsets. By eliminating redundant translations, it minimizes the amount of translations done at the NIC, reduces the load on the NIC's translation cache and increases the hit rate by 3.8× - 340× and resulting in application performance improvement by 1.8× - 2.0×.

1 Introduction

How scalable computer systems store and access data is changing rapidly, and these changes are in part motivated by the blurring of lines between traditionally separate system components. Nonvolatile main memory (NVMM) provides byte-addressable memory that survives power outages, blurring the line between memory and storage. Similarly, remote direct memory access (RDMA) allows a client to directly access memory on a remote server, blurring the line between local and remote memory. At first glance, by combining NVMM and RDMA, we could unify storage, memory and network to provide large, stable, byte-addressable network-attached memory. Unfortunately, the existing systems used to manage these technologies are simultaneously overlapping and incompatible.

NVMMs merge memory and storage. The technology allows applications to access persistent data using load/store instructions, avoiding the need for a block-based interface utilized by traditional storage systems. NVMMs are managed by an NVMM-aware file system, which mediates access to the storage media. With an NVMM-aware file system, applications can map a file into their address space, and then access it using loads and stores instructions, drastically reducing the latency for access to persistent data.

RDMA merges local and remote memory. RDMA allows a client to directly access memory on a remote server. Once the remote server decides to allow incoming access, it registers a portion of its address space as an RDMA *memory region* and sends the client a key to access it. Using the key, the client can enlist the server's RDMA network interface (RNIC) to directly read and write to the server's memory, bypassing the CPU. RDMA is popular as it offloads most of the networking stack onto hardware and provides close-to-hardware abstractions, exhibiting much better latency compared to TCP/IP protocol.

Ideally, we could combine NVMM and RDMA into a unified network-attached persistent memory. Unfortunately, NVM file systems and the RDMA network protocol were not designed to work together. As a result, there are many redundancies, particularly where the systems overlap in memory. Only RDMA provides network data transfer and only the NVMM file system provides persistent memory metadata, but both systems implement protection, address translation, naming, and allocation across different abstractions: for RDMA, memory regions, and for NVMM file systems, files. Naively using RDMA and NVMM file systems together results in a duplication of effort and inefficient translation layers between their abstractions. These translation layers are expensive, especially since RNICs can only store translations for limited amount of memory while NVM capacity can be extremely large.

In this paper, we present a new abstraction, called a *file*

[*]Now at Google

memory region (FileMR), that combines the best of both RDMA and NVM file systems to provide fast, network-attached, file-system managed, persistent memory. It accomplishes this goal by offloading most RDMA-required tasks related to memory management to the NVM file system through the new memory region type; the file system effectively becomes RDMA's control plane.

With the FileMR abstraction, a client establishes an RDMA connection backed by *files*, instead of memory address ranges (i.e., an RDMA memory region). RDMA reads and writes are directed to the file through the file system, and addressed by the file offset. The translation between file offset and physical memory address is routed through the NVMM file system, which stores all its files in persistent memory. Access to the file is mediated via traditional file system protections (e.g., access control lists). To further optimize address translation, we integrate a *range-based translation* system, which uses address ranges (instead of pages) for translation, into the RNIC, reducing the space needed for translation and resolving the abstraction mismatch between RDMA and NVMM file systems.

Our FileMR design with range-based translation provides a way to seamlessly combine RDMA and NVMM. Compared to simply layering traditional RDMA memory regions on top of NVMM, FileMR provides the following benefits:

- It minimizes the amount of translation done at the NIC, reducing the load on the NIC's translation cache and improving hit rate by 3.8× - 340×.
- It simplifies memory protection by using existing file access control lists instead of RDMA's ad-hoc memory keys.
- It simplifies connection management by using persistent files instead of ephemeral memory region IDs.
- It allows network-accessible memory to be moved or expanded without revoking permissions or closing a connection, giving the file system the ability to defragment and append to files.

The rest of this paper is organized as follows. Section 2 describes the necessary background on RDMA and NVMM file systems. Section 3 describes the design of the FileMR. Section 4 describes our proposed changes to RDMA stack and RNICs, and Section 5 introduce two case studies. Section 6 provides experimental results. Section 7 discusses the applicability of the FileMR on real hardware. Section 8 describes related work, and Section 9 concludes.

2 Background

This section introduces background on both RDMA and NVMM and describes the motivation for introducing a new memory abstraction for RDMA, detailing the issue of redundant memory management mechanisms and the reasons existing systems cannot solve this problem.

2.1 RDMA Networking

RDMA has become a popular networking protocol, especially for distributed applications [2, 20–22, 34, 36, 43, 47, 55, 56, 62]. RDMA exposes a machine's memory to direct access from the RDMA network interface (RNIC), allowing remote clients to directly access a machine's memory without involving the local CPU.

The RDMA hardware supports a set of operations (called *verbs*). *One-sided* verbs, for instance, "read" and "write", directly access remote memory without requiring anything of the remote CPU, in fact, these verb bypasses the remote CPU entirely. *Two-sided* verbs, in contrast, require both machines to post matching requests, for instance, "send" and "receive", which transfer data between registered buffers with addresses chosen by sender and receiver applications locally.

To establish an RDMA connection, an application registers one or more *memory regions* (*MRs*) that grant the local RNIC access to part of the local address space. The MR functions as both a name and a security domain: To give a client access to a region, the local RNIC supplies the MR's virtual address, size and a special 32-bit "rkey". Rkeys are sent with any one-sided verb and allow the receiving RNIC to verify the client has direct access to the region. For two-sided verbs, a send/recv operation requires both the sender and receiver to post matching requests, each attached to some local, pre-registered, memory region, negating the need for rkeys.

To manage outstanding requests, RDMA uses *work queues* derived from the virtual interface architecture (VIA) [10]. After establishing a connection, an application can initiate an RDMA verb through its local RNIC by posting work queue entries (WQEs). These entries are written onto a pair of queues (a queue pair or "QP"); one queue for send/write requests and one for read/receive requests. Once the entry is written to the queue pair, the RNIC will execute the RDMA verb and access the remote machine. Once the verb is completed, the RNIC will acknowledge the verb's success by placing a "completion" in the "completion queue" (CQ). The application can poll for the completion from the completion queue to receive notification that the verb completed successfully.

2.2 Nonvolatile Main Memory

Nonvolatile main memory (*NVMM*) is nonvolatile memory directly accessible via a load/store interface. NVMM is comprised of multiple nonvolatile DIMMs that are attached to the CPU memory bus and sit alongside traditional DRAM DIMMs. One or multiple nonvolatile DIMMs can be combined to form a single contiguous physical address space exposed to the OS [42].

As NVMM is a persistent media, it requires management software to provide naming, allocation and protection, and it is generally managed by a file system. However, unlike traditional file systems built for slower block devices, NVMM-aware file systems play a critical role in providing efficient NVMM access — the DRAM-comparable latency of NVMM means software overhead can dominate performance. As a result, NVMM-aware file systems [7,57,59,60] avoid software overhead along the critical path in two ways:

First, they support the direct access `mmap()` (*DAX-mmap*) capability. DAX-mmap allows applications to map NVMM files directly into their address spaces and to perform data accesses via simple loads and stores. This scheme allows applications to bypass the kernel and file system for most data accesses, drastically improving performance for file access.

However, NVMM resides within the memory hierarchy, which can cause complications since caches are not persistent but can hold data that the application wants to persist. To persist data, cached writes to NVMM must be followed by cache-line flush or clean instructions to ensure the data is actually written back to NVMM, and non-temporal writes can bypass the CPU caches entirely. A store fence can enforce the ordering of the writes and guarantee the data will survive a power failure.

2.3 Managing RDMA and NVMM

Userspace RDMA accesses and NVMM mmapped-DAX accesses share a critical functionality: they allow direct access to memory without involving the kernel. Broadly speaking, we can divide both NVMM file systems and RDMA into a data plane that accesses the memory and a control plane that manages the memory exposed to user applications. The data plane is effectively the same for both: it consists of direct loads and stores to memory. The control plane, in contrast, differs drastically between the systems.

For both RDMA and NVMM file systems, the control plane must provide four services for memory management. First, it must provide naming to ensure that the application can find the appropriate region of memory to directly access. Secondly, it must provide access control, to prevent an application from accessing data it should not. Thirdly, it must provide a mechanism to allocate and free resources to expand or shrink the memory available to the application. Finally, it must perform translation between application level names (i.e., virtual addresses, or memory and file offsets) to physical memory addresses. In practice, this final requirement means that both RDMA and NVMM file systems must work closely with the virtual memory subsystem.

Table 1 summarizes the control plane metadata operations for RDMA and NVMM. These memory management functionalities are attached to different abstractions in RDMA and NVMM file systems. For RDMA we use abstractions such as memory regions and memory windows, and for NVMM file systems we use files.

Role	RDMA / File System	FileMR
Naming	Both (Redundant)	FS Managed
Permissions	Both (Redundant)	FS Managed
Allocation	Both (Redundant)	FS Managed
Appending	Not Allowed	FS Managed
Remapping	Not Allowed	FS Managed
Defragmentation	Not Allowed	FS Managed
Translation	Both (Incompatible)	FS Managed
Persistence	FS Only	FS Managed
Networking	RDMA	RDMA
CPU-Bypass	RDMA	RDMA

Table 1: **Control plane roles for RDMA and NVMM.** This table shows the features provided by RDMA and NVMM vs. FileMR.

2.3.1 Naming

Names provide a hardware-independent way to refer to physical memory locations. In RDMA applications, the virtual address of a memory region, along with its "host" machine's location (e.g., IP address or GID) serves as a globally (i.e., across nodes) meaningful name for regions of physical memory. These names are transient, since they become invalid when the application that created them exits, and inflexible since they prevent an RDMA-exposed page from changing its virtual to physical address mapping while accessible. To share a name with a client that wishes to directly access it via reads and writes, the host gives it the metadata of the MR. For two-sided verbs (i.e., send/receive) naming is ad-hoc: the receiver must use an out-of-band channel to decide where to place the received data.

NVMM-based file systems use filenames to name regions of physical memory on a host. Since files outlive applications, the file system manages names independent of applications and provides more sophisticated management for named memory regions (i.e., hierarchical directories and text-based names). To access a file, clients and applications on the host request access from the file system.

2.3.2 Permissions

Permissions determine what processes have access to what memory. In RDMA, the RDMA contexts are isolated and permissions are enforced in two ways. To grant a client direct read/write access to a memory location, the host shares a memory region specific "rkey." The rkey is a 32-bit key that is attached to all one-sided verbs (such as read and write) and is verified by the RNIC to ensure the client has access to the addressed memory region. For every registered region, the RNIC driver maintains the rkey, along with other RDMA metadata that provides isolation and protection in hardware-accessible structures in DRAM.

Permissions are established when the RDMA connection between nodes is created, and are granted by the application code establishing the connection. They do not outlive the process or survive a system restart. For two-sided verbs protection is enforced by the receiving application in an ad-hoc manner: The receiver uses an out-of-band channel to decide what permissions the sender has.

Access control for NVMM uses the traditional file system design. Permissions are attached to each file and designated for both individual users and groups. Unlike RDMA memory regions and their rkeys, permissions are a property of the underlying data and survive both process and system restart.

2.3.3 Allocation

RDMA verbs and NVMM files both directly access memory, so allocation and expansion of available memory is an important metadata operation.

For NVMM file systems, the file system maintains a list of free physical pages that can be used to create or extend files. Creation of a file involves marshalling the appropriate resources and linking the new pages into the existing file hierarchy. Similarly, free pages can be linked to or detached from existing files to grow or shrink the file. Changing the size of DAX-mmap'd files is easy as well with calls to `fallocate` and `mremap`.

Creating a new RDMA memory region consists of allocating the required memory resources, pinning their pages, and generating the rkey. Note that although many RNICs are capable of handling physical addresses [32], the physical address of a memory region is often out of the programmer's control (it depends, instead, on the implementation of `malloc`), and the page is pinned once the region is registered, leading to a fragmented physical address space.

In addition, changing the mapping of a memory region is expensive. For example, to increase the memory region size, the host server needs to deregister the memory region, reregister a larger region, and send the changes to any interested clients. The `rereg_mr` verb combines deregistration and registration but still carries significant overhead. MPI applications with public memory pool often use memory windows to provide dynamic access control on top of a memory region. This approach does not blend with NVMM file systems since it still requires static mappings of the underlying memory region.

Alternatively, programmers can add another memory region to the connection or protection domain. However, as memory regions require non-negligible metadata and RDMA does not support multi-region accesses, this solution adds significant complexity.

This fixed size limitation also prohibits common file system operations and optimizations, such as appending to a file, remapping file content, and defragmentation.

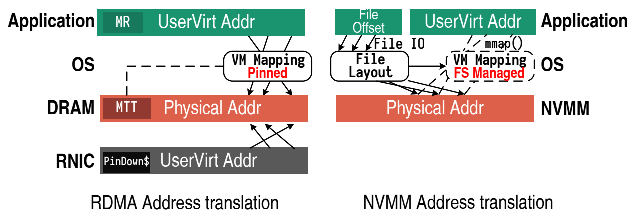

Figure 1: **Address translation for RDMA and NVMM.** RDMA (left) uses NIC-side address translation with pinning, while NVMM (right) allows the file system to maintain the layout of a file mapped to user address space.

2.3.4 Address Translation

RDMA and NVMM file system address translation mechanisms ensure that their direct accesses hit the correct physical page.

As shown in Figure 1, RDMA solves the problem of address translation by *pinning* the virtual to physical address, that is, as long as a memory region is registered, its virtual and physical addresses cannot change. Once this mapping is fixed, the RNIC is capable of handling memory regions registered on virtual address ranges directly: the RNIC translates from virtual addresses to physical addresses for incoming RDMA verbs. To do this translation, the NIC maintains a *memory translation table* (MTT) that holds parts of the system page tables.

The MTT flattens the translation entries for the relevant RDMA accessible pages and can be cached in the RNIC's onboard SRAM [54] to accelerate lookups of this mapping. The pin-down cache is critical for getting good performance out of RDMA — the pin-down cache is small (a few megabytes), a miss is expensive, and due to its addressing mechanism, most RNICs require all pages in a region be the same size. To circumvent these limitations, researchers have done significant work trying to make the most of the cache for addressing large memories [14, 22, 35, 36, 43, 48, 56, 62]. While complex solutions exist, the most common recommendation is to reduce the number of translations needed (e.g., addressing large contiguous memory regions with either huge pages or physical addresses).

The NVMM file system handles address translation in two ways, both different from RDMA. For regular reads and writes, the file system translates file names with offsets to physical addresses; this translation is done in the kernel during the system call. For memory mapped accesses, mmap establishes a virtual to physical address mapping from userspace directly to the file's contents in NVMM, loading the mapping into the page table. The file system only interferes on the page fault handling when a translation is missing between the user and physical addresses (i.e., a soft page fault); the file system is bypassed on normal data accesses.

The different translation schemes interfere with each other to create performance problems. If a page is accessible via

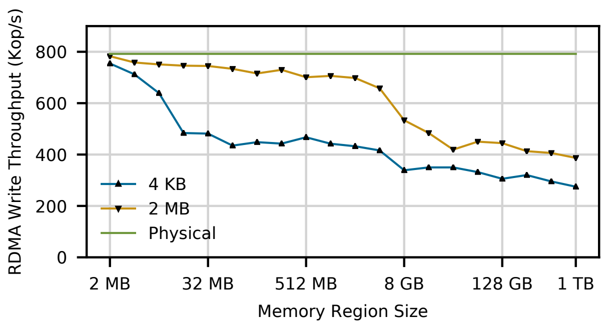

Figure 2: **RDMA Write performance over different memory region sizes.** This figure shows the throughput of 8-byte RDMA writes affected by the pin-down cache misses. Data measured on Intel Optane DC Persistent Memory with an Mellanox CX-3 RNIC.

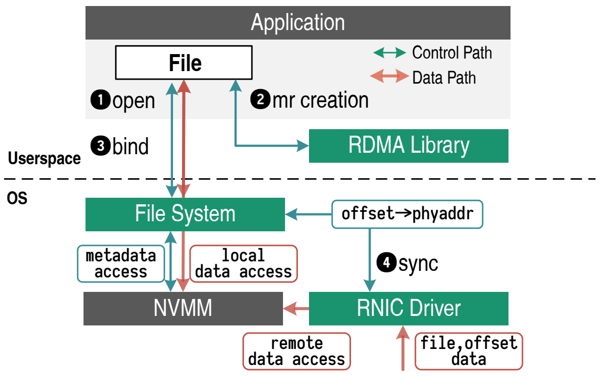

Figure 3: **FileMR: Control path and data path.** The user application communicates with the RDMA libraries and file system in control path, and access local and remote NVMM directly in datapath.

RDMA, it is pinned to a particular physical address, and furthermore, every page within the region must be the same size. Therefore the file system is unable to update the layout of the open file (e.g., to defragment or grow the file). As RDMA impedes defragmentation of files and prohibits mixing page sizes in RDMA accessible memory, memory regions backed by files must use many small pages to address large regions, overwhelming the pin-down cache and decimating RDMA performance.

Figure 2 shows the impact of pin-down cache misses on RDMA write throughput. Each work request writes 8 bytes to a random 8-byte aligned offset. When the memory region size is 16 MB, using 4 kB achieves 61.1% of the baseline (sending physical addresses, no TLB or pin-down cache misses) performance compared to 95.2% when using 2 MB hugepages. When the region size hits 16 GB, even 2 MB pages is not sufficient — achieving only 61.2% performance.

3 Design

FileMR is a new type of memory region that extends the existing RDMA protocol to provide file-based abstractions for NVMM. It requires minor changes to existing RDMA protocol and does not rely on any specific design of the file systems. FileMR can coexist with conventional RDMA memory regions, ensuring backward compatibility.

As shown in Table 1, the FileMR resolves the conflicts between RDMA and NVMM file systems that cause unnecessary restrictions and performance degradation through several innovations.

- **Merged control plane:** With an RDMA FileMR, a client uses a *file offset* to address memory, instead of a virtual or physical address. The FileMR also leverages the naming, addressing, and permissions of the file system to streamline RDMA access.
- **Range-based address translation:** The FileMR leverages the file system's efficient, extent-based layout description mechanism to reduce the amount of states the NIC must hold. As files are already organized in continuous extents, we extend this addressing mechanism to the RNIC, allowing the RNIC's pin-down cache to use a space efficient translation scheme to address large amounts of RDMA accessible memory.

The rest of this section continues as follows. We begin by describing the assumptions and definitions of FileMR, followed by the core mechanisms. Then, we describe the system architecture required to support our new abstraction.

3.1 Assumptions and Definitions

FileMR acts as an efficient and coordinated memory management layer across the userspace application, the system software, and the RDMA networking stack. This paper assumes the NVMM is actively managed by system software, and we describe it as a *file system*. Note that the concept of a file system is loosely defined: FileMR can be integrated with a kernel file system, a userspace file system, or a userspace NVMM library that accesses raw NVMM (also known as device-DAX) and provides naming, where a *file* maps to a corresponding entity.

This paper assumes NVMM is mapped to application address space in its entire lifecycle: As described in Section 2.2, the most prominent feature of NVMM is to have fine-grained persistency at a very low cost [63]. The design goal of FileMR is to enable remote NVMM accesses while retaining the simplicity and efficiency of local NVMM accesses. An alternative approach is to build holistic systems that manage both storage (NVMM) and networking (RDMA), these related work will be discussed in Section 8.2.

3.2 FileMR

Our new abstraction, the FileMR, is an RDMA memory region that is also an NVMM file. This allows the RDMA and NVMM control planes to interoperate smoothly. RDMA accesses to the FileMR are addressed by file offset, and the file system manages the underlying file's access permissions, naming, and allocation as it would any file. NVMM files are always backed by physical pages managed by the file system, so, when using a FileMR, the RDMA subsystem can simply reuse the translation, permission, and naming information already available in the file system metadata for the appropriate checks and addressing.

Figure 3 shows an overview of metadata and data access with FileMR. For metadata, before creating a FileMR, the application opens the backing file with the appropriate permissions (step ❶). Next, the application creates the FileMR (step ❷) and *binds* (step ❸) the region to a file, which completes the region's initialization. Binding the FileMR to the file produces a *filekey*, analogous to an rkey, that remote clients can use to access the FileMR. Once the FileMR is created and bound to a backing file, the file system will keep the file's addressing information in sync with the RNIC (step ❹).

For data access to a remote FileMR and its backing NVMM file, applications use the FileMR (with the filekey to prove its permissions) and a *file offset*. The RNIC translates between file offsets and physical addresses using translation information provided by the file system. In addition to one-sided read and write verbs to the FileMR, we introduce a new one-sided append verb that grows the region. When sending the append verb, the client does not include the remote address, and the server handles it like an one-sided write with address equal to current size of FileMR. It then updates the FileMR size and notifies the file system. As an optimization, to prevent faulting on every append message, the file system can preallocate translation entries beyond the size of a file. Even while the backing file is opened and accessible via a FileMR, local applications can continue to access it using normal file system calls or mmapped addresses — any change to the file metadata will be propagated to the RNIC.

3.3 Range-based Address Translation

NVMM file systems try to store file data in large, linear extents in NVMM. FileMR uses *range-based address translation* within the MTT and pin-down cache through a *RangeMTT* and *range pin-down* cache, respectively. This change is a significant departure from traditional RDMA page-based addressing. Unlike page-based translations, which translate a virtual to physical address using sets of fixed size pages, range-based translation (explored and used in CPU-side translation [5, 11, 23, 38]) maps a variably sized virtual address range to physical address. Range-based address translation is useful when addressing large linear memory regions (which NVMM file systems strive to create) and neatly leverages the

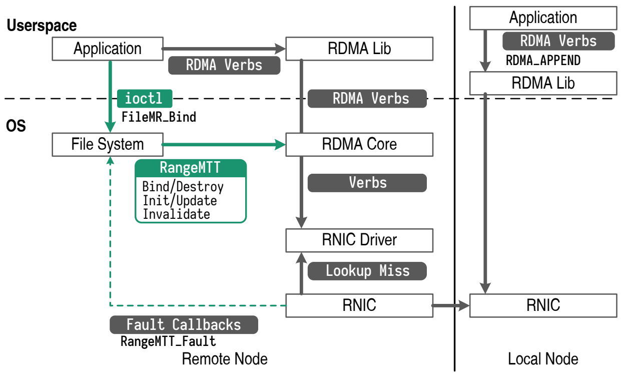

Figure 4: **Overview of FileMR components.** Implementing FileMR requires changes in file system, RDMA stack and hardware.

preexisting extent-based file organization.

For the FileMR, range-based address translation has two major benefits: both the space required to store the mapping and the time to register a mapping scale with the number of variable-sized extents rather than with the number of fixed size pages. Registering a page in the MTT and pin-down cache takes about 5 μs, this process requires locking memory descriptors and is hard to parallelize. As a result, a single core can only register memory at 770 MB/s with 4 kB pages. For NVMMs on the order of terabytes, the result registration time will be unacceptably long.

3.4 Design Overview

The implementation of the FileMR RDMA extension requires coordination and changes across several system components: the file system, the RNIC, the core RDMA stack, and the application. Figure 4 shows the vanilla RDMA stack (in grey) along with the necessary changes to adopt FileMR (in green).

To support the FileMR abstraction, the file system is required to implement the `bind()` function to associate a FileMR and a file, and, when necessary, notify the RDMA stack (and eventually the RNIC's RangeMTT and pin-down cache) when the bound file's metadata changes via callbacks (see Table 2). These callbacks allow the RNIC to maintain the correct range-based mappings to physical addresses for incoming RDMA requests.

Optionally, the file system can also register a set of callback functions triggered when RNIC cannot find a translation for an incoming address. This process is similar to on-demand paging [28, 29] and is required to support our new append verb, which both modifies the file layout and writes to it.

Supporting the FileMR abstraction also requires changes to the RNIC hardware. With our proposed RangeMTT, RNIC hardware and drivers would need to adopt range-based addressing within both the MTT and pin-down cache. Hardware range-based addressing schemes [5, 15, 23, 38] can be used to implement range-based address lookup. In our experiments

API	Description
`cm_bind()`	To notify RNIC of new bound file
`cm_init()`	To initialize RangeMTT entries
`cm_update()`	To update a RangeMTT entry
`cm_invalidate()`	To invalidate a RangeMTT entry
`cm_destroy()`	To destroy a file binding

Table 2: **File system to RNIC callbacks for FileMRs.** These callbacks are used by the file system to notify the RDMA stack and RNIC that file layouts (and consequently address mappings) have changed.

API	Description
`bind()`	Binds an opened file to FileMR
`ibv_reg_mr()`	Creates a FileMR with `FILEMR` flag
`ibv_post_send()`	Posts append w/ `APPEND` flag (`uverb`)
`ib_post_send()`	Posts append w/ `APPEND` flag (`kverb`)

Table 3: **New/changed RDMA methods.** These methods in the RDMA interface are new or have new flags under the FileMR system.

we simulate these changes using a software RNIC (see Section 4).

The FileMR also adds incremental, backwards compatible changes to the RDMA interface itself (see Table 3). It adds a new access flag for memory region creation to identify the creation of a FileMR. After its creation, the FileMR is marked as being in an unprovisioned state — the subsequent `bind()` call into the file system will allocate the FileMR's translation entries in the RangeMTT (via the `cm_bind` callback from the file system). The `bind()` method can be implemented with an `ioctl()` (for kernel-level file systems) or a library call (for user-level file systems). The FileMR also adds the new one-sided RDMA append verb. Converting existing applications to use FileMRs is easy as the applications only need to change its region creation code.

4 Implementation

We implemented the FileMR and RangeMTT for both the kernel space and userspace RDMA stack in Linux, and our implementations support the callbacks described in Table 2 and the changed methods in Table 3. The kernel implementation is based on Linux version 4.18, and userspace implementation is based on rdma-core (userspace) packages shipped with Ubuntu 18.04. Table 4 summarizes our implementation of FileMR with RangeMTT.

For our FileMR implementation on the NIC side, our implementation is based on a software-based RNIC: Software RDMA over Converged Ethernet (Soft-RoCE) [4, 25]. Soft-RoCE is a software RNIC built on top of ethernet's layer 2 and layer 3. It fully implements the ROCEv2 specification. Future research could work to build a FileMR compatible

	Item	Description
FileMR implementation on RDMA stack		
K	`ibcore`	Range-based TLB and FileMR kverbs
U	`libibverbs`	FileMR verbs in userspace
FileMR support on soft-RoCE		
K	`rxe`	Device driver and emu. RangeMTT.
U	`librxe`	Userspace driver
FileMR support for file system		
K	`nova`	a NVMM-aware file system
Applications adapting FileMR		
U	`novad`	Function stubs for remote file accesses
U	`libpmemlog`	NVMM log library

Table 4: **Summary of FileMR implementation.** This table shows the components modified to implement FileMR. The first column indicates the change is in kernel space (K) or userspace (U).

RNIC in real hardware.

To implement our RangeMTT, we followed the design introduced in Redundant Memory Mappings [23]: each FileMR points to a b-tree that stores offsets and lengths, and we use the offsets as indices. All RangeMTT entries are page-aligned addresses, since OS can only manage virtual memory in page granularity.

Unlike page-aligned RangeMTT, FileMR supports arbitrary sizes and allows sub-page files/objects. Each RangeMTT entry consists of a page address, a length field and necessary bits. These entries are non-overlapping and can have gaps for sparse files.

To support the append verb, the FileMR allows translation entries beyond its size. The append is one-sided but does not specify remote server addresses in the WR. On the server side, the RNIC always attempts to DMA to the current size of the FileMR and increases its size on success. When the translation is missing, the server can raise an IO page fault when IOMMU is available and a file system routine will be called to fulfill the faulty entries. Alternatively, if such support is unavailable, the server signals the client via a message similar to a receiver not ready (RNR) error.

Soft-RoCE manages the MTT entries as a flat array of 64-bit physical addresses with lookup complexity of O(1). We found similar design is implemented in hardware RNIC driver such as `mlx4`. For FileMR with a range pin-down cache miss, the entry lookup will traverse the registered data structures with higher time complexity (O(log(n))).

Soft-RoCE does not have a pin-down cache since the mappings are in DRAM. To emulate the RangeMTT, we built a 4096-entry 4-way associative cache to emulate the traditional pin-down cache, and a 4096-entry, 4-way associative range pin-down cache for FileMR. Each range translation entry consists of a 32 bit page address and a 32-bit length, which allows a maximal FileMR size of 16 TB (4 kB pages) or 8 PB (2 MB pages).

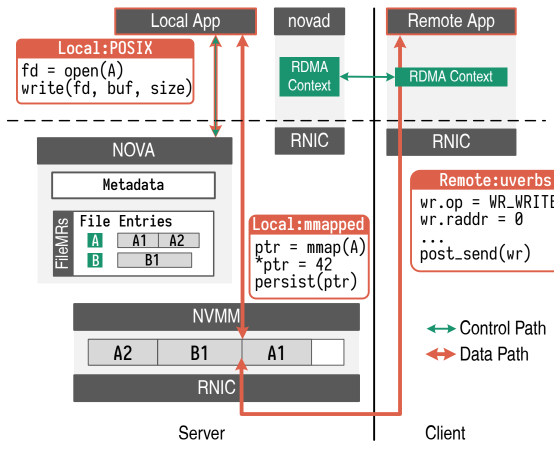

Figure 5: **Enabling remote NOVA accesses using FileMR.** Using FileMR, remote file accesses share a similar interface over RDMA as local NVMM accesses.

We adapted two applications to use FileMR. For a kernel file system, our implementation is based on NOVA [59], a full-fledged kernel space NVMM-aware file system with good performance. We also adapted the FileMR to libpmemlog, part of pmdk [40], a user-level library that manages local persistent objects, to build a remotely accessible persistent log.

5 Case Studies

In this section we demonstrate the utility of our design with our two case studies. In Section 5.1, we demonstrate how to use FileMR APIs to enable remote file accesses with consistent addressing for local and remote NVMM. In Section 5.2, we extend libpmemlog [40], a logging library designed for local persistent memory into a remotely accessible log, demonstrating how FileMR can be applied to userspace libraries.

5.1 Remote File Access in NOVA

In this section, we demonstrate an example usage of our FileMR by extending a local NVMM file system (NOVA [59]). By combining the NVMM file system, RDMA, and our new FileMR abstraction, we can support fast remote file accesses that entirely bypass the kernel.

NOVA is a log-structured POSIX-compliant local NVMM file system. In NOVA, each file is organized as a persistent log of variably sized extents, where the extents reside on persistent memory. The file data is allocated by the file system through per-cpu free lists and maintained as coalescing entries.

To handle metadata operations on the remote file system, we added an user-level daemon novad. The daemon opens the file to establish an FileMR, and receives any metadata updates (e.g. directory creation) from remote applications and applies them to the local file system.

On the client side, an application opens the file remotely by communicating with novad and receiving the filekeys. It can then send one-sided RDMA verbs to directly access remote NVMM. At the same time, applications running locally can still access the file with traditional POSIX IO interface, or map the file to its address space and issue loads and stores instructions.

Our combined system can also easily handle data replication. By using several FileMRs, we can simply duplicate a verb (with the same or different filekeys depending on the file system implementation) and send to multiple hosts, without considering the physical address of the files (so long as their names are equivalent).

5.2 Remote NVMM Log with libpmemlog

The FileMR abstraction only requires that the backing "file system" to appropriately implement the bind() method, RNIC callbacks, and have access to raw NVMM. For instance, a FileMR can be created by an application having access to the raw NVMM device. In this section, we leverage this flexibility and build a remote NVMM log based on libpmemlog.

We modify the allocator of libpmemlog to use the necessary FileMR callbacks — that is, whenever memory is allocated or freed for the log, the RNIC's RangeMTT is updated. The client appends to the log with the new append verb. On the server side, when the FileMR size is within the mapped RangeMTT, the RNIC can perform the translation while bypassing the server application. If not, a range fault occurs and the library expands the region by allocating and mapping additional memory.

6 Evaluation

In this section, we evaluate the performance of the FileMR. First, we measure control plane metrics such as registration cost, memory utilization of the FileMR, as well as the efficiency of RangeMTT. Then we evaluate application-level data plane performance from our two case studies and compare FileMR-based applications with existing systems.

6.1 Experimental Setup

We run our FileMR on servers configured to emulate persistent memory with DRAM. Each node has two Intel Xeon (Broadwell) CPUs with 10 cores and 256 GB of DRAM, with 64 GB configured as an emulated NVMM device. We setup Soft-RoCE on an Intel X710 10GbE NIC connected to a switch.

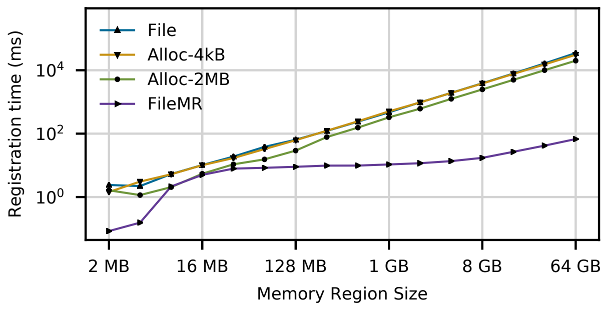

Figure 6: **FileMR registration time.** This figure shows the time consumed to register a fixed size memory region. The Y-axis is in log scale.

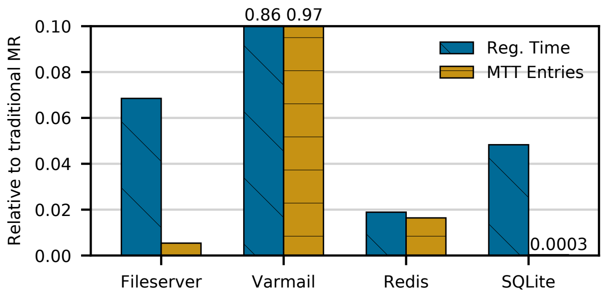

Figure 7: **FileMR on fragmented files.** Compared to traditional MRs, FileMR saves registration cost and RNIC translation entries.

Workload	# Files	Avg. Size	Description
Fileserver	7980	6.82 MB	File IOs
Varmail	4511	11.3 kB	Random IOs
Redis	2	561 MB	Write + Append
SQLite	1	109 MB	Write + Sync

Table 5: **Workload Characteristics.** Description of workloads to evaluate registration cost of FileMR and pin-down cache hit rate.

6.2 Registration Overhead

Allocated Regions We measure the time consumed in memory region registration using FileMRs versus conventional user-level memory regions backed by NOVA with 4 kB pages and anonymous buffers with 4 kB and 2 MB pages. This experiment demonstrates the use case when an application allocates and maps a file directly, without updating its metadata. For FileMR, we also include the time generating range entries from NOVA logs, which happens when an application opens the file for the first time.

As shown in Figure 6, registering a large size memory region consumes a non-trivial amount of time. It takes over 30 seconds to register a 64 GB persistent (**File**) and volatile (**Alloc-4K**) memory region with 4 kB pages. Using hugepages (**Alloc-2M**) reduces the registration cost to 20 seconds, while it only takes 67 ms for FileMR (three orders of magnitude lower). The FileMR registration time increases modestly as the region size grows mainly due to the internal fragmentation of the file system allocator.

For small files, NOVA only creates one or two extents for the file, while conventional MRs still interacts with the virtual memory routines of the OS, causing overhead.

Data Fragmentation FileMR benefits from the contiguity of the file data. The internal fragmentation of a file system can happen for two reasons: file system aging [19, 45] and using POSIX IO that changes file layout frequently. To evaluate the FileMR performance in a fragmented file system, we first warmed up the file system using four IO intensive workloads that issued POSIX IO requests: varmail and fileserver workloads in filebench [53], Redis [41] and SQLite [46] (using MobiBench [18]). Once the file system was warmed up and fragmented, we created memory regions over all files in NVMM. Table 5 summarizes the workloads.

As shown in Figure 7, running FileMR over the fragmented file still shows dramatic improvement on region registration time and memory consumption for MTT entries. Fileserver demonstrates the case with many files, where FileMR only creates 0.5% of the entries of traditional memory regions, and requires only 6.8% of the registration time. For a metadata-heavy workload (Varmail), FileMR only reduces the number of entries by 3% (due to the heavy internal fragmentation and small file size), but it still saves 20% on registration time because it holds the inode lock, which has less contention. Redis is a key-value store that persists an append-only file on the IO path, and flushes the database asynchronously — little internal fragmentation means that it requires 2% of the space and time of traditional memory regions. Similarly, SQLite also uses logging, resulting in little fragmentation, and drastic space and time savings.

6.3 Translation Cache Effectiveness

The performance degradation of RDMA over large NVMM is mainly caused by the pin-down cache misses (Figure 2). Since Soft-RoCE encapsulates RDMA messages in UDP and accesses all RDMA state in DRAM, we cannot measure the effectiveness of the cache through end-to-end performance.

Instead, we measure the cache hit ratio of our emulated pin-down cache and range pin-down cache for FileMR. We collect the trace of POSIX IO system calls for workloads described in Table 5, and replay them with one-sided RDMA verbs to a remote host.

Figure 8 shows the evaluation result. Our emulated range-based pin-down cache is significantly more efficient (3.8× - 340×) than the page-based pin-down cache. For large allocated files with a few entries, the range-based pin-down cache shows near 100% hit rate (not shown in figure).

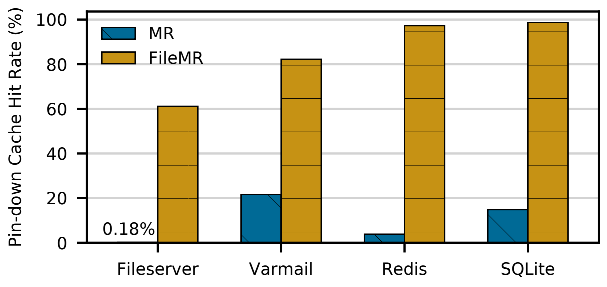

Figure 8: **Translation cache effectiveness.** FileMR significantly increases the effectiveness of the pin-down cache.

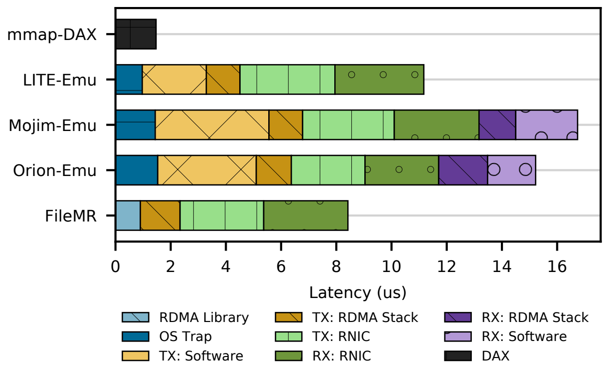

Figure 9: **Latency breakdown of accessing remote file.** FileMR can access remote file location without indirection on datapath.

6.4 Accessing Remote Files

To evaluate the datapath performance, we let a client access files on a remote server running novad (introduced in Section 5.1). The client issues random 1 kB writes using RDMA write verbs, and we measure the latency between the client application issuing the verb and the remote RNIC DMAs to the target memory address (`memcopy` for Soft-RoCE).

We compared FileMR with both mmapped local accesses and other distributed systems that provide distributed storage access. We implemented datapath-only versions of Mojim-Emu [64], LITE-Emu [56] and Orion-Emu [62] for Soft-RoCE. All these systems avoid translation overhead by sending physical addresses on the wire. We will further discuss these systems in Section 8.

In Figure 9, we show the latency breakdown of these systems. Note that the latencies of all systems are higher than a typical RDMA NIC, because Soft-RoCE is less efficient than a real RNIC. Also, we omit the latencies of UDP packet encapsulation and delivery, which dominate the end-to-end latency. It only takes 1.5 μs to store and persist 4 kB data to local NVMM. FileMR has lower latency than other systems because it eliminates the need for any indirection layer

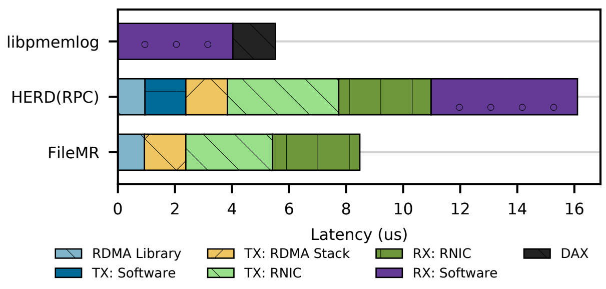

Figure 10: **Latency breakdown of accessing remote log.** With the append verb, Remote logging with FileMR achieves similar performance to local one.

(`msync()` system call for Mojim, shared memory write for LITE, and POSIX write for Orion).

6.5 Accessing Remote NVMM logs

Finally, we evaluate our introduction of the new append verb using our remote log implementation introduced in Section 5.2. We compare to a baseline `libpmemlog` on using local NVMM (bypassing the network), as well as with logging within the HERD RPC RDMA library [21, 22].

Figure 10 shows the latency breakdown of creating a 64 Byte log entry. It takes 5.5 μs to log locally with `libpmemlog`. FileMR adds 53% overhead for remote vs. local logging, while the HERD RPC-based solution adds 192% overhead.

7 Discussion

The current FileMR implementation relies on software-based RDMA protocols. In this section, we discuss the potential benefits and challenges of applying FileMR on hardware and other deeper changes to the RDMA protocol. We consider them to be the future work of this paper.

Data Persistence For local NVMM, a store instruction is persistent once data is evicted from CPU last-level cache (via cache flush instructions and memory fences). A mechanism called asynchronous DRAM refresh (ADR) ensures that the write queue on a memory controller is flushed to nonvolatile storage in the event of a power failure. There are no similar mechanisms in the RDMA world since ADR does not extend to PCIe devices. Making the task even more difficult, modern NICs are capable of placing data into CPU cache using direct cache access (DCA) [17], conceivably entirely bypassing NVMM.

The current workaround to ensure RDMA write persistency is to disable DCA and issue another RDMA read to the last byte of a pending write [9], forcing the write to complete and write to NVMM. Alternatively, the sender requests that the receiving CPU purposefully flush data it received; either embedding the flush request in an extra send verb or the immediate field of a write verb.

A draft standards working document has proposed adding a `commit` [50] verb to the RDMA protocol to solve the write persistency problem. A `commit` verb lists memory locations that need to be flushed to persistence. When the remote RNIC receives a commit verb, it ensures the all listed locations are persistent before acknowledging completion of the verb.

With the introduction of FileMR, implementing data persistence is simplified since there is no longer need to track modified locations at the client: the RNIC already maintains information about the files. A commit verb can simply request that all updates to a file are persisted, which is analogous to an `fsync` system call to a local file, which is usually light-weight. Even better, since the commit needs little state, a commit flag can be embedded to the latest write verb, reducing communication overhead.

Connection Management Several NVMM-based storage systems [30,43,56,62] store data across nodes, or use a model similar to distributed shared memory. This model requires establishing N^2 connections for N servers with NVMM. For user-level applications, the reliable connection transport enforces the protection domain within the scope of a process. Thus a cluster with N servers running p processes will establish $N^2 \times p^2$ connections.

Existing works [12, 12, 49] reduces this complexity by sharing queue pairs [49], multiplexing connections [27] or dynamically allocating connections [12] to reduce the RDMA states. These optimizations work well for MPI-based applications, but it is challenging to implement them for NVMM applications, especially for applications with fine-grained access control. In particular, a file system supports complex access control schemes, which may disallow sharing and multiplexing.

With the FileMR, the file permission is checked at the bind step, and so each server only requires a single connection to handle *all* file system requests, drastically reducing the amount of states required to store on the RNIC.

For NVMM, data replication is essential for reliability and availability. Existing RDMA-aware systems on distributed NVMM [6,33,43,62,64] transfer data multiple times to replicate NVMM because of the limitation (unreliable datagrams and two-sided verbs) of the existing RDMA protocol. The RDMA payload could be potentially multicasted by the current network infrastructure with FileMR, allowing a single RDMA verb to modify multiple copies of the same file.

Page Fault on NIC Some ethernet and RNICs support page fault or on-demand paging [28,29] (ODP). When using ODP, instead of pinning memory pages, the IOMMU marks the page as not present in IO virtual addresses. The RNIC will raise an interrupt to operating system when attempting DMA to a non-present page. The IO page fault handler then fills the entry with the mapping.

With ODP, a page fault is very expensive. In our experiment, it takes 475 μs to fulfill an IO page fault and complete a 8-byte RDMA write on a Mellanox CX-4 RNIC. In contrast, it only takes 1.4 μs to complete when the mapping is cached in the RNIC. In general, prefetching is a common way to mitigate the cost of frequent page faults. An optimization for ODP introduces `ioctl(advise_mr)` to hint prefetching [44], and recent research uses `madvise` system call to help prefetching local NVMM [8].

The design of FileMR is orthogonal to ODP, though it leverages the `append` verb. Fortunately, the file system is situated to provide better locality by prefetching ranges based on the file access pattern.

8 Related Work

The FileMR abstraction sits at the intersection of work in address translation, RDMA, and NVMM systems.

8.1 Address Translation

Reducing the cost of address translations has been the focus of work spanning decades. We here describe some common, general approaches and how they can be applied to RDMA and NVMM.

Using Hugepages Using hugepages is the standard way to reduce address transaction overhead and TLB pressure. In Linux, applications can explicitly allocate buffers from `libhugetlbfs`, which manages and allocates from a predefined page pool. An alternative is to allow the kernel to manage hugepages transparently using transparent hugepages (THP) [3, 37] or page swap [61] in the kernel, where the OS tries to allocate hugepages and merge smaller pages into hugepages (via compaction or swapping) in the background.

There are three drawbacks of using hugepages with RDMA and NVMM considered. First of all, applications [21,30,36] that use libraries such as `libhugetlbfs` will manage memory directly and bypass the file system. Second, transparent hugepage will violate the consistency of the MTT entries on the RNIC. Finally, since the current memory region uses a flat namespace, only one type of memory region is supported, which causes fragmentation when using hugepages. By introducing range-based translation, FileMR reduces the number of translation table entries significantly, while retain the support for file system managing the layout of the files.

Access Indirection Several existing works addressed the issue of accessing flat memory space by introducing an indirection layer for accesses and optimizing the communication cost.

LITE [56] uses physical memory region and lets all requests go into the kernel via shared memory. Remote Region [2] also redirects requests to kernel but consists of a pseudo-file system and a user library. Hotpot [43] and Mojim [64] use customized interfaces over memory mapped regions with support such as data replication and allocation. Storm [35] improves RDMA performance by introducing a new software stack that creates less RDMA states.

With the customized interface, these systems manage the data structures and RDMA states internally to reduce the state handled by RNICs. Programming with these interfaces is unintuitive, especially when working with an NVMM library that manages the data through memory-mapped files and handles allocations with its interface. Additionally, maintaining a physical memory region allows the remote server access arbitrary physical addresses, including DRAM.

Virtual Memory Contiguity As the size of the physical memory keeps increasing while the TLB size has grown slowly, several previous works discuss the contiguity of virtual memory address space. There are proposals on architecture support for coalesced [38], range [23] or segment [5] based address management, or accessing physical addresses with necessary permission checks [15]. In this paper, we assume the NIC hardware is capable of handling range-based entries using one of these mechanisms. Using software-based transparent page management [1, 61] can also increase the contiguity of virtual memory.

8.2 RDMA and NVMM

As discussed in the introduction, building systems that leverage the direct memory access of RDMA and NVMM is appealing. Significant work has already been completed.

Large RDMA Regions Creating memory regions over large memory with a flat namespace has become a popular choice for building RDMA-aware systems, even for those without a persistent memory component. Several systems use this strategy, including key-value stores [21, 34, 36], distributed memory allocators [2, 36, 55, 56], transactional systems, RPC protocols [20, 22, 47], and file systems [43, 62]. To better facilitate this use case, optimizations to the RDMA protocol such as on-demand paging [28, 29], dynamically connected transport [12], multi-path RDMA [31] have been purposed.

NIC Design PASTE [16] is a customized NIC designed for NVMM. It tightly couples the traditional networking stack with the NVMM file system. It provides a holistic design which performs naming and persistence in the networking stack. FileMR is designed for RDMA networking with NVMM file system, and supports general purpose verbs. FlexNIC [24] is a NIC that supports offloading software routines, such as key-value interface and packet classification down to the NIC. Floem [39] provides a programmable abstraction that describes the offload scheme. In contrary, FileMR focuses on a specific use case and can be further extended to support rich semantics.

Distributed File Systems Building distributed file systems by providing remote access at the file system level should provide remote access without interface changes. Orion [62] and Octopus [30] are two distributed NVMM-aware file systems. Orion is a kernel level file system that incorporates RDMA functionalities, and uses physical addresses for RDMA accesses. Octopus is a user level file system using FUSE [26] interface with hugepages to reduce page table entries. When using these file systems, all POSIX file accesses are intercepted and transferred with the file system routines.

There are two major issues in building distributed functionalities in the file system layer: the overhead of calling file systems routines and the granularity of access. In Linux, issuing system calls are expensive and involve multiple memory copies. In a DAX file system, the kernel still copies data from user buffers for security purposes. For mmapped data, the kernel supports "flushes" only in page granularity. These operations are expensive on large memories because the kernel needs to identify the dirty pages and persist them via memory flushes.

Large Memory and Persistent Connection This paper focuses on a particular way of utilizing RDMA networking: create memory regions over large, persistent memory with a flat namespace and maintain them for remote accesses during the application lifecycle. Alternative mechanisms for managing accessible RDMA, including using bounce buffers [52], registering a transient memory region for every access [51], and using tricks (DMA MR [62], Fast MR [58], FastReg MR [13]) require physical addresses in kernel space. We do not consider these solutions because they violate the file system's ability to manage the physical address space.

9 Conclusion

The conflicting systems on metadata management between NVMM and RDMA causes expensive translation overhead and prevents the file system from changing its layout. This work introduces two modifications to the existing RDMA protocol: the FileMR and range-based translation, thereby providing an abstraction that combines memory regions and files. It improves the performance of RDMA-accessible NVMMs by eliminating extraneous translations, while conferring other benefits to RDMA including more efficient access permissions and simpler connection management.

Acknowledgments

We thank our shepherd, Amar Phanishayee and the reviewers for their comments and suggestions. We would like to thank Tom Tapley for his insights and feedback, and Jiawei Gao for suggestions on improving the writing. TCP ≈ RDMA: CPU-efficient Remote Storage Access with i10

Jaehyun Hwang Qizhe Cai Ao Tang Rachit Agarwal
Cornell University

Abstract

This paper presents design, implementation and evaluation of i10, a new remote storage stack implemented entirely in the kernel. i10 runs on commodity hardware, allows unmodified applications to operate directly on kernel's TCP/IP network stack, and yet, saturates a 100Gbps link for remote accesses using CPU utilization similar to state-of-the-art user-space and RDMA-based solutions.

1 Introduction

The landscape of cloud infrastructure has changed rapidly over the last few years. Two trends stand out:

- First, network and storage hardware has improved significantly, *e.g.*, network access link bandwidth has transitioned from 1Gbps to 40Gbps or even 100Gbps [4, 37]; and, fast non-volatile memory express (NVMe) storage devices that deliver more than a million input/output operations per second (IOPS) are being widely deployed [15, 23].
- Second, the need for fine-grained resource elasticity and high resource utilization has led to large-scale deployments of disaggregated storage [40, 43]; also see [9, 11, 12, 23, 24]. As a result, increasingly more applications now access storage devices over the network.

These changes have shifted performance bottlenecks back to the software stack — while network and storage hardware is able to sustain high throughput, traditional remote storage access stacks (that make remote storage devices available as local block devices, *e.g.*, iSCSI [35] and light-weight servers based on Linux) have unsustainable CPU overheads. For instance, traditional iSCSI protocol is known to achieve merely 70K IOPS per CPU core due to its high protocol processing and synchronization overheads [12, 15, 23, 24]. While this was not a bottleneck for slower storage devices and/or networks, saturating a single modern NVMe storage device now requires 14 cores, and saturating a 100Gbps link now requires 40 cores!

Responding to this challenge, both academic and industrial communities have been taking a fresh look at the problem of designing CPU-efficient remote storage stacks. Recently standardized NVMe-over-Fabrics (NVMe-oF), specifically, NVMe-over-RDMA [3, 30] keeps the kernel storage stack, but moves the network stack to the hardware. A complementary approach argues for moving the entire storage and network stack to the user space [24]. These proposals can achieve high performance in terms of IOPS per core, but require changes in applications and/or network infrastructure; such changes would be acceptable, if utmost necessary.

This paper explores a basic question: *"are infrastructure changes really necessary for efficient remote storage access"?* Exploring this question may help clarify our response to the challenges introduced by the two cloud infrastructure trends discussed above. An affirmative answer would make a strong argument for user-space stacks and/or specialized network hardware. However, if performance similar to above solutions can be achieved by re-architecting the kernel, then it changes the lens through which we view the design and adoption of software stacks in future: for example, rather than every organization asking *whether* to perform a ground-up redesign of their infrastructure, organizations that are already adopting user-space stacks and/or modern network hardware could ask *how* to port kernel remote storage stacks to integrate with their infrastructure. Thus, while the rest of the paper occasionally descends into kernel minutiae, the question we are asking has important practical implications.

Our exploration of the above question led to design and implementation of i10, a new *remote* storage stack within the kernel. i10 demonstrates that, at least for applications that are throughput bound, performance similar to state-of-the-art user-space and RDMA-based solutions can be achieved with minimal modifications in the kernel. i10 offers a number of benefits. First, i10 requires no modifications outside the kernel; thus, existing applications can operate directly on top of i10 without any modifications, whatsoever. Second, i10 operates directly on top of existing TCP/IP kernel protocol stack; thus, it requires no modifications in the network stack and/or hardware. Third, i10 complies with recently standardized NVMe-oF specification [3]; thus i10 can work with all emerging NVMe devices. Finally, over benchmark workloads, i10 saturates a 100Gbps link using a commodity server with CPU utilization similar to state-of-the-art user-space stacks and NVMe-over-RDMA products [24, 30]. The last benefit is perhaps the most interesting one as it fills a gaping hole in our understanding of kernel bottlenecks: as we discuss in Figure 1 and §4, existing bottlenecks for remote storage access are neither in the storage stack nor in the network stack; rather, the inefficiency lies at the boundary of the two stacks!

i10 achieves the above benefits using a surprisingly simple design that integrates two ideas (§2):

End-to-end dedicated resources and batching. Using dedicated resources and batching to optimize the software stack is a well-known technique, also used in CPU-efficient network stacks [6, 13, 19, 29]; however, as we will show, performance bottlenecks being at the boundary of storage and network stacks means that prior solutions of dedicating resources at per-core granularity and batching packets at socket level are no longer sufficient. i10 dedicates resources at the granularity of an i10-ℓane, creating a highly optimized pipe between each (core, target) pair, where target refers to the storage stack at the remote server (and not necessarily individual storage devices at the remote server). i10-ℓanes have the property that all control and data packets in any queue are destined to the same destination, and are to be transmitted on the same TCP session; thus, they can be efficiently batched at the entrance of the pipe to reduce network processing overheads (§2).

Delayed Doorbells. When accessing a local NVMe device, existing storage stacks "ring the doorbell" (signal the storage device about a new request) immediately upon receiving the request. i10 observes that while this is efficient for relatively low-overhead communication over PCI express, immediately ringing the doorbell leads to high context switching overheads for remote accesses where requests traverse over a high-overhead network stack and network fabric. i10, thus, introduces the idea of "delayed doorbells", where the worker thread in the storage stack delays ringing the doorbell until multiple requests are processed (or a timeout event happens). i10 also shows how the granularity of dedicated resources and batching in i10 interplays well with delayed ringing of doorbells to achieve the final performance (§2, §4).

i10 design simplicity also enables i10 implementation in Linux with modest modifications, while operating directly on an unmodified TCP/IP stack over commodity hardware[1]. i10 evaluation, over both benchmark workloads and real applications, demonstrates that i10 achieves throughput-per-core comparable to NVMe-over-RDMA [30]. Compared to state-of-the-art in-kernel remote storage stacks like NVMe-over-TCP [26], which was incorporated within the Linux kernel in March 2019, i10 both enables new operating points (*e.g.*, being able to saturate 100Gbps links) and also reduces the CPU utilization by 2.5× for already feasible operating points. Moreover, i10 maintains these benefits for all evaluated workloads including varying read/write ratios, request sizes and device types. Finally, i10 scales well with number of cores and with number of remote storage devices.

Going back to our starting point, i10 answers the original question about the necessity of application and/or network infrastructure changes for throughput-bound applications. Of course, this is already a large class of applications; however, batching used in i10 leads to the same latency-throughput tradeoff as in CPU-efficient network stacks [6, 13, 19, 29]: at low loads, latencies may be high (albeit, still at hundred-microsecond granularity and within 1.7× of NVMe-over-RDMA latency over storage devices). While not completely

[1]i10 implementation, along with documentation that enables reproducing all results, is available at https://github.com/i10-kernel/.

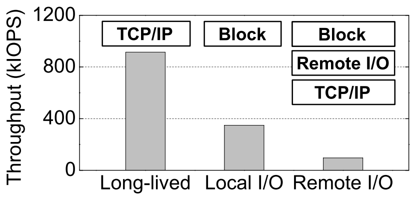

Figure 1: **Existing bottlenecks for remote storage access are at the boundary of the storage and network stacks.** The figure shows throughput-per-core for kernel network, local storage and remote storage stacks. We use 4KB random read requests between two servers with NVMe solid state drives connected via a 100Gbps link (detailed setup in §4). For long-lived flow, the network stack can sustain as much as ~30Gbps (roughly 915 kIOPS) per core using well-known optimizations (*e.g.*, TCP segmentation offload (TSO) and generic receive offload (GRO)); similarly, the storage stack for local I/O can sustain ~350 kIOPS per core. However, when integrated together with existing remote storage stacks, the achievable throughput reduces to 96 kIOPS (§4).

satisfying, our exploration has led us to believe that user-space stacks and RDMA-enabled solutions may be more useful for applications demanding absolutely minimal latency for each individual request. The question, however, remains open for such applications.

2 i10 Design

In this section, we describes the i10 design. We start with an overview (§2.1), followed by a detailed description of how i10 creates highly optimized i10-ℓanes using dedicated resources (§2.2), batching (§2.3) and delayed doorbells (§2.4). The next section provides some of the interesting implementation details for i10.

2.1 i10 Design Overview

i10 is designed and implemented as a shim layer between the kernel storage stack (specifically, the block device layer) and the kernel network stack. Figure 2 shows the high-level design of i10, including the i10 layer and end-to-end path between the host application and the target NVMe storage device. i10 does not control how applications are scheduled on the cores; each application may run on one or more cores, and multiple applications may share the same core. Applications submit remote read/write requests to the kernel through the standard read/write APIs; i10 requires no modifications to these APIs.

i10 achieves its goals using the core abstraction of an i10-ℓane— a dedicated pipe that is used to exchange both control and data plane messages along a set of dedicated resources. i10 creates i10-ℓanes and dedicates resources to each i10-ℓane at the granularity of (core, target)-pair, where target refers to the block device at the remote server (and not necessarily individual storage devices). For example, consider that (potentially more than one application running at) a core c submits read/write requests to two target servers `t1` and `t2`, each having multiple storage devices `d11, d12, ...` and `d21, d22, ...`. Then, i10 creates two i10-ℓanes, one `c` $\rightsquigarrow$ `t1` for all

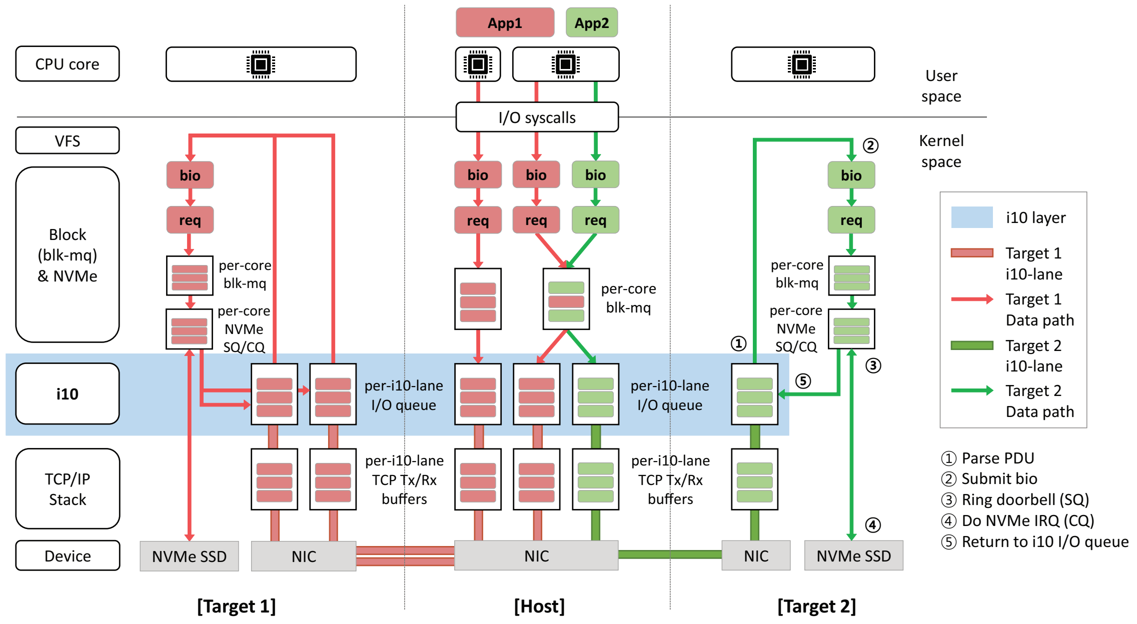

Figure 2: **End-to-end data path in i10 between one host and two target servers.** In this example, `app1` is sending read/write requests to `target1` using both core1 and core2, and `app2` is sending read/write requests to `target2` using core2. Thus, i10 creates three i10-ℓanes — one for each of (core1, target1), (core2, target1) and (core2, target2) pairs. Moreover, (green) requests submitted from `app2` are copied to the block layer request queue of core2 and (red) requests submitted from `app1` are copied to either the block layer request queue of core1 or core2 depending on which core the request comes from. While block layer request queues may contain requests going to different target servers (*e.g.*, the right block layer request queue at `host1`), each request is copied to the i10 I/O queue for i10-ℓane corresponding to the (core, target)-pair. Finally, if there were an `app3` running on `core2` sending requests to `target2`, it would completely share the i10-ℓane with `app2`.

requests going to the former set of storage devices and the other `c` $\rightsquigarrow$ `t2` for all requests going to the latter set of storage devices. Note that this is independent of the number of applications running on the core `c`. Moreover, if a single application running on two cores `c1 and c2` submits read/write requests to two target servers `t1` and `t2`, then i10 will create four i10-ℓanes, one for each (core, target) pair.

i10 uses three set of dedicated resources for each i10-ℓane (both at the host and at the target side). We first describe these dedicated resources and then discuss how they integrate into an end-to-end path between the host core and the target. The first dedicated resource is an I/O queue in the i10 layer (shown in the blue horizontal bar in Figure 2). The second is a dedicated TCP connection, along with its buffers, between the host and target i10 queues. Finally, a dedicated i10 worker thread for each core that interacts with i10 at the host side and for each core that is needed at the target side. Note that, for reasons that we will discuss in §2.2, i10 queues and TCP connections are at the per-lane granularity, and the i10 worker threads are at a per-core granularity.

We are now ready to describe the end-to-end path between the host core and the target. Upon receiving a request from a core, the block layer does its usual operations — generates a `bio` instance (that represents an in-flight block I/O operation in the kernel [28]), initializes the corresponding `request` instance using Linux kernel's support for multiple per-core block queues (`blk-mq`) [7, 14] and then, copies the request to the block layer's request queue for that core (these request queues are different from i10 queues). Finally, the block layer's `request` instance is converted to an i10 request; to be compliant with NVMe-oF standards, i10 requests are similar to a command Protocol Data Unit (PDU) [3]. Finally, using the context information within the block layer's request data structure, i10 requests are copied to the i10 queue for the corresponding i10-ℓane.

Having a dedicated queue for each i10-ℓane implies that all requests and data packets in a queue are destined to the same target server, and will be transmitted over the same TCP connection. Thus, i10 is able to batch multiple requests and data packets into i10 "caravans"[2], all to be processed and transmitted over the same TCP connection. This allows i10 to significantly reduce the network processing overheads by aggregating enough data to benefit from well-known optimizations like TSO and GRO. We discuss the precise details in §2.3.

i10 observes that the original NVMe specification was designed for accessing storage devices over PCI express (PCIe). Since PCIe provides a low-latency low-overhead communication between the storage stack and the local storage devices,

[2]i10 "caravans" are nothing but batches of requests; we use the term caravans to avoid confusion between i10 batches of requests and traditional batches — while traditional batches correspond to packets going to the same application port, i10 batches may be going to different storage devices, albeit within the same target server.

it was useful for the case of local access to "ring the doorbell" (provide a signal to the storage device that a new I/O request is ready to be served) immediately upon creating a request. However, in the case of remote accesses where requests traverse through a relatively high-latency high-overhead network, immediately ringing the doorbell leads to high context switching overheads for the worker threads. To alleviate these overheads, i10 introduces the idea of delayed doorbells, where the block layer worker thread processes multiple requests (or times out) before ringing the doorbell to wake up the i10 worker thread. This not only reduces the context switching overheads significantly, but also provides i10-ℓane queues with enough requests/data to generate right-sized caravans. We describe the precise mechanism in §2.4.

Finally, the i10 caravan is transmitted through the in-kernel socket interface. As shown in Figure 2, when the caravan arrives in the target-side i10 queue, i10 parses the caravan to regenerate the `bio` instances, corresponding requests and submits them to the block layer. Upon receiving the requests, the block layer executes the same steps as it does for accessing PCIe-connected local storage devices: the request is inserted to the NVMe submission queue and upon completion, the result is returned to the NVMe completion queue. After the local access, the result goes back to the block device layer, and finally is abstracted as a response caravan by i10 and sent back to the host server over the TCP connection.

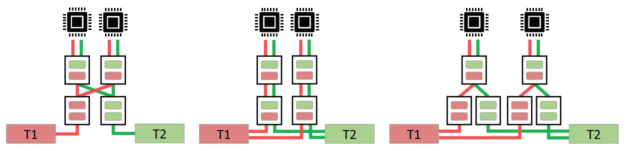
In the following three subsections, we present design details for the three building blocks of i10: i10-ℓane, i10 caravans, and delayed doorbells.

2.2 i10-ℓane

The two obvious options for creating i10-ℓane are (1) creating one i10-ℓane per target server, independent of the number of cores (Figure 3(a)); and (2) creating one i10-ℓane per core, independent of the number of target servers (Figure 3(b)). At high loads, the first option leads to high write contention among the block layer worker threads since they will need to write the `requests` to the same i10 queue. The second option is no better either — here, requests destined to different targets are forced to be in the same i10 queue resulting in preventing i10 caravans from batching enough requests, or high CPU overheads (for sorting requests to batch into the same caravans). Both these overheads become worse in the most interesting case of high-load regime. i10 avoids these overheads by creating an i10-ℓane for each (core, target)-pair (Figure 3(c)). That is, for applications that use P host cores to access data at T target servers, i10 creates $P \times T$ i10-ℓanes, independent of the number of storage devices at each target.

We now describe the resources dedicated to each i10-ℓane.

`blk-mq` level request queues. i10 exploits per-core request queue defined in the block layer (using `blk-mq` [7, 14]). Before the support for `blk-mq`, all block layer requests went to a single request queue per device. While queueing requests in a single queue could create head-of-line blocking, this design enabled scheduling so as to minimize the seek time on hard disks. For modern storage devices that support high-throughput random reads and writes using multiple cores, the equation is quite different due to two reasons: (1) multiple cores operating over a single queue becomes a performance bottleneck; and, (2) since seek time is not a problem, minimizing head-of-line blocking becomes more important. Thus, recent versions of Linux kernel enable the block layer to create per-core request queues and to maintain multi-queue context information for both `blk-mq` and underlying remote access layers. This enables i10 to efficiently demultiplex requests in `blk-mq` into individual i10-ℓane queues.



(a) per-target (b) per-core (c) per-target/per-core

Figure 3: **Creating i10-ℓane for each (core, target) pair is the right design.** The figure shows host cores, `blk-mq`, i10 queues, TCP connections, and target devices T1 and T2. For discussion, see §2.2.

i10 I/O queue. i10 creates one dedicated queue for each individual i10-ℓane. These queues are equivalent to the I/O queues from the NVMe standard [2] with the only difference that they communicate with a remote target server, not with local SSD devices. Once the requests from `blk-mq` are converted to NVMe-compatible command PDUs, they are inserted to i10 queues. The NVMe standard allows creating as many as 64K NVMe queues to enable parallel I/O processing; since we expect i10 to have no more than 64K simultaneously active i10-ℓanes at any server for most deployments, i10 design should not be limited by the number of available queues.

TCP socket instance. Each i10-ℓane maintains its own TCP socket instance and establishes a long lived TCP connection with the target, along with corresponding TCP buffers. The state needed to be maintained in the kernel for each individual TCP connection is already quite small. The only additional state that i10 requires is the mapping between the TCP connections and the corresponding i10-ℓane, which again turns out to be small (§5).

i10 worker thread. i10 creates a dedicated per-core worker thread whose responsibility is to conceptually move i10 caravans bidirectionally on i10-ℓanes. This worker thread starts executing when a doorbell is rung for any of the i10-ℓanes on the same core, and aggregates command PDUs in the queue of the corresponding i10-ℓane into caravans. The worker then moves the caravans to TCP buffers for the corresponding i10-ℓane. Finally, the worker thread goes into the sleep mode until a new doorbell is rung.

When the caravan reaches the target's TCP receive buffers,

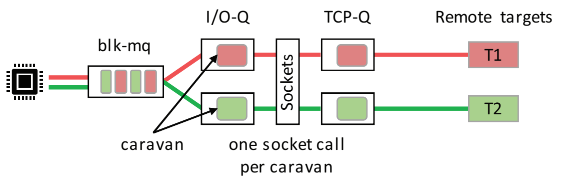


Figure 4: **Creating i10 caravans at the i10 queues is the right design for reducing per-request network processing overhead**. See discussion in §2.3.

the corresponding worker thread starts processing the requests in the caravan. First, it regenerates `bio` for each request in the caravan, followed by processing the requests as needed at the block layer. Upon receiving the signal from completion processing, the results are inserted into target's i10 queue and a caravan is created. It is not necessary for response caravans to have the same set of requests as in host caravans, because caravan's size can be different between host and target (§2.3).

2.3 i10 Caravans

Given that all requests in an i10 queue are going to the same destination over the same TCP connection, i10 batches multiple requests into an i10 caravan. This allows i10 to benefit from standard optimizations like TSO and GRO, which significantly reduces the network processing overheads. Our key insight here is that i10 queues are precisely the place to create caravans because of two reasons. First, at the block layer, the `blk-mq` is per-core and at any given point of time, may have requests belonging to different targets (as in Figure 3(c)); thus, batching the requests at the block layer would require significant CPU processing to sort the requests going to the same target device. Second, batching at the TCP layer would require i10 to process each request individually to send to TCP buffers, thereby creating one event per request; prior work [19] has shown that such per-request events results in high CPU processing overheads. By batching at its own queues, i10 reduces both of these overheads (Figure 4). We set the maximum amount of data carried by a caravan to be 64KB to align it with the maximum packet size supported by TSO. However, to prevent a single caravan from batching too many small-sized requests, each caravan may batch no more than a pre-defined aggregation size number of requests (§3).

2.4 Delayed Doorbells

The original NVMe specification was designed for accessing storage devices over PCI express (PCIe). Even though the standard itself does not prescribe how to use doorbells, the current storage stack simply rings the doorbell (that is, updates the submission queue doorbell register) whenever a request is inserted into the NVMe submission queue (Figure 5(a)). Since PCIe provides a low-latency low-overhead communication between the storage stack and the local storage devices, ringing the doorbell on a per-request basis reaches the maximum throughput of the device with minimal latency. However, in the case of remote accesses where requests traverse

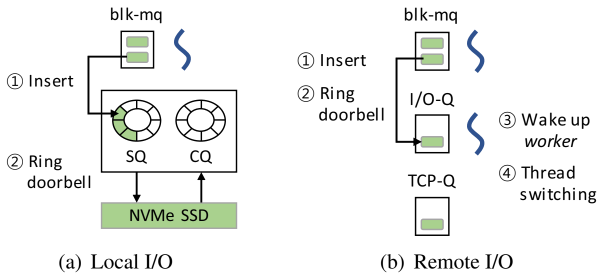

Figure 5: **Ringing the doorbell per request is effective for local PCIe-attached local storage, but not for remote storage access since the latter results in high context switching overhead.** See discussion in §2.4.

through a relatively high-latency high-overhead network, ringing the doorbell on a per-request basis results in high context switching overheads. In the specific context of i10, ringing the doorbell implies that as soon as the block layer thread inserts an i10 request to the i10 queue, it wakes up the i10 worker thread to handle the request immediately (Figure 5(b)). This incurs a context switch, which at high loads, could result in high CPU overheads (§4).

i10 alleviates these overheads using the idea of delayed doorbells. When an i10 queue is empty, a doorbell timer is set upon arrival of the first request. Then, the doorbell is rung either when the i10 queue has as many requests as a pre-defined aggregation size or when the timer reaches a timeout value, whichever happens earlier. Whenever the doorbell is rung, i10 caravans are created with all the requests in the i10 queue and the doorbell timer is unset. We note that delayed doorbells can be used independent of whether or not requests are batched into caravans. Moreover, this design will cause extra latency if applications generate low load (resulting in requests observing "timeout" amount of latency).

3 i10 Implementation Details

We implement i10 host and target in the Linux kernel 4.20.0. i10 implementation runs on commodity hardware (we do use the TSO and GRO features supported by most commodity NICs) and allows unmodified applications to operate directly on kernel's TCP/IP network stack. In this section, we discuss some interesting aspects of i10 implementation.

`kernel_sendpage()` vs. `kernel_sendmsg()`. There are two options to transmit i10 caravans via kernel socket interfaces. The first interface, `kernel_sendpage()` allows avoiding transmission-side data copy when sending each page of the data, but limits the aggregation size to be no more than 16. The second, `kernel_sendmsg()` takes a kernel I/O vector as a function argument and internally copies every scattered data of the I/O vector into a single socket buffer. This allows i10 aggregation size to be larger than 16, which leads to lower network processing overhead in some cases. Our tests reveal that `kernel_sendmsg()` achieves slightly better overall

CPU usage (that is, including data copy as well as network processing overheads), resulting in better overall throughput. Therefore, we use `kernel_sendmsg()` for i10 caravans to achieve better throughput.

i10 no-delay path. For latency-critical applications, it may be more important to avoid the latency incurred by i10 batching and delayed doorbells. For example, it may be desirable to execute a read request on file system metadata such as inode tables immediately upon submission so as to avoid blocking further read/write requests that cannot be executed without the response to the original request. For such cases, i10 supports a *no-delay path* — when such a latency-sensitive request arrives in i10 queue, i10 flushes all outstanding requests in the queue and processes the latency-sensitive request immediately. This is implemented using a simple check during the delayed doorbell ringing process: upon receiving a latency-sensitive request, the doorbell can be rung immediately, forcing i10 to create a caravan using all the outstanding requests along with the latency-sensitive request.

i10 parameters. In general, we expect throughput-per-core in i10 to improve with increasing aggregation size due to reduced network processing overheads. However, as we show in Appendix A in the technical report [16], increasing aggregation size beyond a certain threshold would result in marginal throughput improvements while requiring larger doorbell timeout values to be able to aggregate larger number of requests (thus, inflating per-request latency at low loads). This threshold — that is, the value that reaches the point of marginal improvements — of course, depends on kernel stack implementation. For our kernel implementation, we find 16 to be the best aggregation size with 50μs doorbell timeout value. We will use these parameters by default in our evaluation.

TCP buffer configuration. i10 caravans may be as large as 64KB. To this end, the TCP transmit buffer should have enough space for receiving caravans. However, TCP buffer size is generally adjusted by TCP's auto tuning mechanism — the Linux TCP implementation automatically increases the buffer size based on the bandwidth-delay product estimate for the transmit buffer, unless users specify a static buffer size via `setsockopt()`. Therefore, if the remaining transmit buffer is currently less than 64KB, the caravan would be fragmented even if kernel can provide more memory for the buffer resulting in higher processing overheads due to more than one socket call per caravan. For this reason, we explicitly use a fixed size of TCP buffers via `kernel_setsockopt()` at the session establishment stage. We set the buffer size to 8MB in this paper, which is sufficiently large to avoid caravan fragmentation.

4 i10 Evaluation

In this section, we evaluate an end-to-end implementation of i10. We first describe our evaluation setup (§4.1). We then start by evaluating i10 performance against state-of-the-art NVMe-over-RDMA (NVMe-RDMA) [30] and NVMe-over-TCP (NVMe-TCP) [26] implementations over a variety of settings including varying loads, varying number of cores, varying read/write request ratios and varying number of target servers (§4.2). Next, we use CPU profiling to perform a deep dive into understanding how different aspects of i10 design contribute to its performance gains (§4.3). Finally, we evaluate i10 over real applications (§4.4) and compare its performance with state-of-the-art user-space stacks (§4.5). Several additional evaluation results (including sensitivity analysis against aggregation size and doorbell timeout values, performance with variable request sizes, scalability with multiple applications sharing the same core, benefits of syscall batching, etc.) can be found in the technical report [16].

Table 1: **Experimental setup used in our evaluation.**

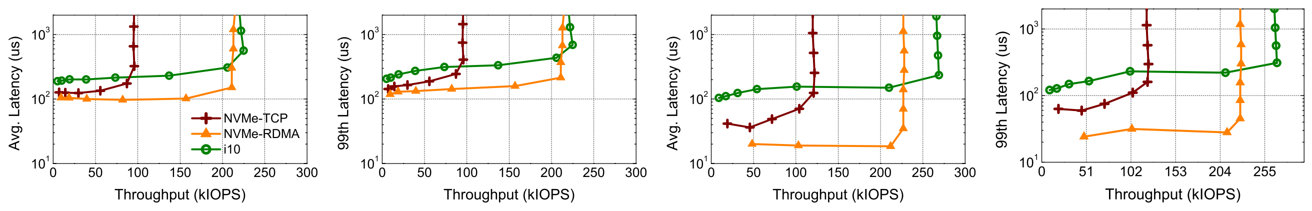
H/W configurations	
CPU	4-socket Intel Xeon Gold 6128 CPU @ 3.4GHz 6 cores per socket, NUMA enabled (4 nodes)
Memory	256GB of DRAM
NIC	Mellanox ConnectX-5 EX (100G) TSO/GRO=on, LRO=off, DIM disabled Jumbo frame enabled (9000B)
NVMe SSD	1.6TB of Samsung PM1725a
S/W configurations	
OS	Ubuntu 16.04 (kernel 4.20.0)
IRQ	`irqbalance` enabled
FIO	Block size=4KB, Direct I/O=on I/O engine=`libaio`, gtod_reduce=off CPU affinity enabled

4.1 Evaluation Setup

We use a testbed with two servers, each with 100Gbps links, directly connected without any intervening switches; while simple, this testbed allows us to ensure that bottlenecks are at the server-side thus allowing us to stress test i10. Both servers have the same hardware/software configurations (Table 1). Our NICs have one Ethernet port and one InfiniBand port, allowing us to evaluate both NVMe-TCP and NVMe-RDMA.

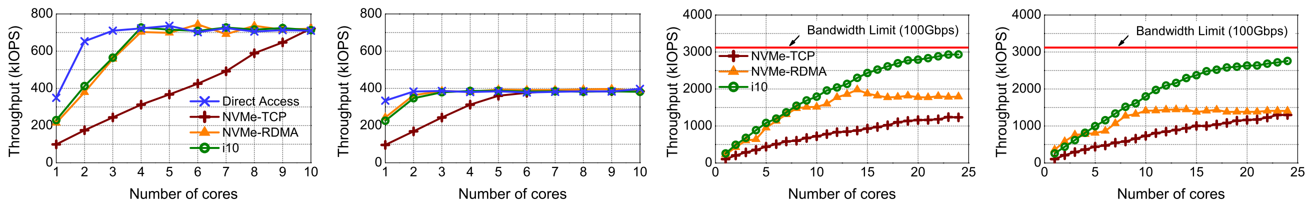
Our NICs support dynamically-tuned interrupt moderation feature that controls the network RX interrupt rate [41], which helps achieving maximum network throughput with minimum interrupts under heavy workloads; however, we disable it to show that i10 does not rely on special hardware features. Similarly, we do not optimize the Interrupt Request (IRQ) affinity configuration, but simply use the `irqbalance` provided by the OS. Finally, we use FIO [5] application for our microbenchmarks with a default I/O depth of 128. All I/O requests are submitted via the asynchronous I/O library (`libaio`) and direct I/O is enabled so as to bypass the kernel page cache and to make sure that I/O requests always go through the network to reach the target device.

i10 and NVMe-RDMA saturate our NVMe solid state



(a) Average Latency (SSD) (b) Tail Latency (SSD) (c) Average Latency (RAM) (d) Tail Latency (RAM)

Figure 6: **Single core performance (4KB random read)**: when compared to NVMe-TCP, i10 achieves significantly higher throughput-per-core with comparable latency; when compared to NVMe-RDMA, i10 achieves comparable throughput while achieving average and tail latency within 1.4× and 1.7×, respectively, for the case of SSDs.



(a) Read (SSD) (b) Write (SSD) (c) Read (RAM) (d) Write (RAM)

Figure 7: **Multi-core performance (4KB random read/write)**: i10 achieves throughput significantly better than NVMe-TCP and comparable to NVMe-RDMA while operating on commodity hardware; i10 and NVMe-RDMA also achieve near-perfect scalability with number of cores.

drives (SSD) with only 4 cores; hence, we also use RAM block device to evaluate multi-core scalability. In addition, our RAM-based experiments allow us to emulate i10 performance for the emerging Non-Volatile Main Memory devices as their performance is close to that of DRAM [45]. Unless otherwise stated, we use 4 cores for SSD-based and 16 cores for RAM-based evaluation.

4.2 Performance Evaluation

We now evaluate i10 performance across a variety of settings. All experiments in this subsection focus on host-side CPU utilization since target CPU was never the bottleneck (§4.3.2).

4.2.1 Single core performance

Figure 6 presents the single-core performance for all the evaluation schemes for both NVMe SSD and RAM block devices. The key takeaway here is that, when compared to NVMe-RDMA, i10 offers better throughput at high loads, but slightly higher latency (still at hundred-microsecond granularity) at low loads. Intuitively, when the load is high, i10 works with full-sized caravans without delayed doorbell timeouts, thus achieving high throughput. For low loads, i10 would wait for more requests to arrive in the i10 queue until the doorbell timer expires, which slightly increases its average end-to-end latency. However, we note that even for low loads, i10 average latency is comparable to that of NVMe-RDMA — *e.g.*, for the case of SSDs, where SSD access latency becomes the bottleneck, i10 achieves an average latency of 189μs while NVMe-RDMA achieves 105μs (Figure 6(a)). We observe similar trends for the tail (99th percentile) latency for the case of SSDs — as shown in Figure 6(b), i10's tail latency of 206μs is within 1.7× of NVMe-RDMA tail latency of 119μs, again since SSD access latency is the main bottleneck. For the case of RAM block device, i10 has higher average and tail latency compared to NVMe-RDMA since kernel overheads start to dominate; however, i10 still achieves comparable or better throughput per core. Finally, we also observe that all the three schemes perform better with RAM block device when compared to SSD since the former significantly reduces the access latency, not requiring any interrupt handling between device driver and RAM block device.

4.2.2 Scalability with number of cores

To understand i10 performance with increasing number of cores, we extend the previous single-core measurements to use up to 24 cores. Figure 7 presents the results. We observe that, for the case of random reads, i10 and NVMe-RDMA saturate the SSD with 4 cores, which is a factor 2.5× improvement over NVMe-TCP (Figure 7(a)), while direct access (where the requests go to local SSD) saturates the SSD using 3 cores. The case of random writes in Figure 7(b) is similar to Figure 7(a); both NVMe-RDMA and i10 saturate the maximum random write performance with 3 cores whereas NVMe-TCP requires 6 cores.

With RAM block device, i10 mostly outperforms both NVMe-TCP and NVMe-RDMA as shown in Figures 7(c) and Figures 7(d). Perhaps most interestingly, i10 is able to saturate the 100Gbps link, achieving 2.8M IOPS with ~20 cores. We observe that NVMe-RDMA stays around 1.5–2M IOPS after 10 cores for both random read and write workloads. While we believe that this performance saturation is not fundamental to NVMe-RDMA and is merely a hardware issue, we have not yet been able to localize the core problem; we note, however, that similar observations have been made

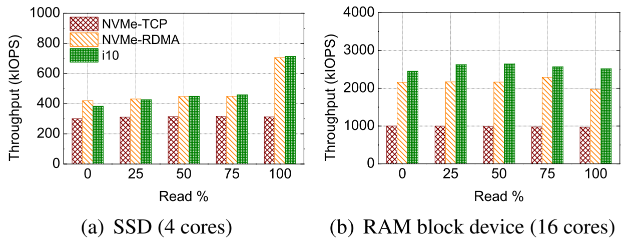


Figure 8: **i10 maintains its performance against NVMe-TCP and NVMe-RDMA with workloads comprising varying read/write ratios (4KB mixed random read/write)**.

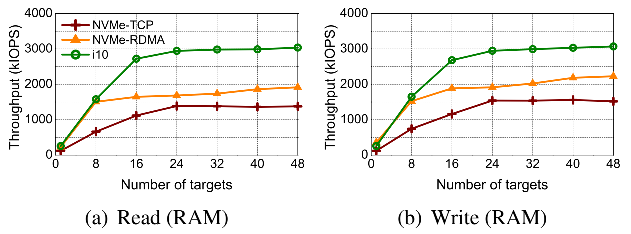

Figure 9: **i10 maintains its performance with increasing number of target devices (4KB random read and write).** The trend is similar to the multi-core/single-target case in Figure 7.

in other recent papers [31].

4.2.3 Performance with varying read/write ratios

Figure 8 presents results for workloads comprising varying ratio of read/write requests, varying from 0:100 to 100:0, for both SSD and RAM block device. For the case of SSD (Figure 8(a)), we observe that throughput in each case is limited by random write performance except that of the 100% read ratio case. This observation is consistent with the previous study that shows random write can interfere with random read because of wear leveling and garbage collection, where 75% read shows a similar IOPS with 50% read [24]. Consistent to results in previous subsections, both i10 and NVMe-RDMA saturate the SSD while requiring fewer cores than NVMe-TCP. With RAM block device (Figure 8(b)), the throughput changes with marginal fluctuation regardless of the read ratio; nevertheless, i10 continues to achieve comparable or better throughput than NVMe-RDMA across all workloads.

4.2.4 Scalability with multiple targets

We now evaluate i10 performance with increasing number of target devices, using up to 48 target RAM block devices. Here, we only focus on RAM devices since our testbed has a limited number of SSD devices. The setting here is that of each core running applications that access data from targets assigned to the application. The assignment is done in a round-robin manner — for up to 24 targets, each core will serve one target and for more than 24 targets, we assign the additional targets to the cores starting with core0 (*e.g.*, for 36 targets, the first 12 cores serve two targets each and the remaining 12 cores serve one target each).

In Figure 9, we observe that i10 outperforms both NVMe-TCP and NVMe-RDMA, saturating the 100Gbps link with 16 or more targets. The 24-target throughput is kept after 24 targets for all schemes as every host core is fully used (for i10, the 100Gbps link is already saturated). The overall trend is similar or even slightly better when compared to the RAM cases of the multi-core scalability scenario (Figure 7) as the I/O requests are processed in parallel across different i10-ℓanes. This result confirms that i10 maintains its performance benefits with increasing number of targets incurring little CPU contention across the various i10-ℓanes. For the scenarios where such CPU contention is severe (assuming an extremely large number of targets), the single-core/multi-target throughput is further studied in Appendix B in [16].

4.3 Understanding Performance Gains

We now evaluate how various design aspects of i10 contribute to its end-to-end performance, and then use CPU profiling to build a deeper understanding of i10 performance gains.

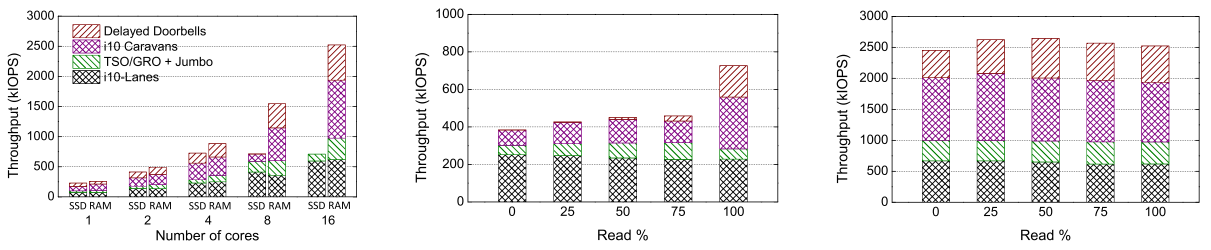
4.3.1 Performance contribution

Figure 10 shows that each of the design aspects of i10— i10-ℓane, i10 caravans, and delayed doorbells — are essential to achieve the end-to-end i10 performance. In Figure 10(a), we measure 4KB random read throughput increasing the number of cores from 1 to 16. The baseline is our i10-ℓane performance, which scales well with multiple cores. Enabling TSO/GRO and jumbo frames makes slightly further improvement over the i10-ℓane throughput. With NVMe SSD, i10 contribution is limited by the SSD performance (Figure 10(b)), but it is clear that with RAM block device, i10 caravans and delayed doorbells contribute to the performance improvement significantly, by 38.2% and 23.2% of the total throughput with 16 cores as shown in Figure 10(c). We also confirm that these improvement trends are maintained regardless of the read ratio for both SSD and RAM devices. The above results therefore indicate that all of the three building blocks are indeed necessary to design an end-to-end remote storage I/O stack that achieves the aforementioned benefits.

4.3.2 Understanding Bottlenecks

We now use CPU profiling for the 4-core case of SSD and the 16-core case of RAM block device in Figure 10(a), with the goal of understanding the bottlenecks for each of the three schemes. Our profiling results in Figure 12, Table 3 and Table 4 divide the entire remote access process into 7 components as described in Table 2. Our key findings are:

(1) i10 spends fewer CPU cycles in network processing: i10 improves upon NVMe-TCP by a factor of 2.7× in terms of CPU usage reduction in network processing parts (Network Tx and Rx combined) for both NVMe SSD and RAM block device, while showing comparable CPU utilization to NVMe-RDMA in the same parts. The main problem of NVMe-TCP is that it underutilizes the network capacity even with such high



(a) Throughput with varying # cores (b) Throughput (SSD) with varying read % (c) Throughput (RAM) with varying read %

Figure 10: **Each of i10-ℓane, caravans, delayed doorbells are necessary to achieve the end-to-end i10 performance**.

Table 2: **Taxonomy of CPU usage.**

Component	Description
Applications	Submit and receive requests/responses via I/O system calls (host). Ideally, all cycles would be spent in this component.
Block TX	Process the requests at the blk-mq layer and ring the doorbells to the remote storage access layer (host) or the local storage device (target).
Block RX	Receive the requests/responses from the network Rx queues or the local storage device.
Net TX	Send the requests/responses from the I/O queues (NVMe-RDMA uses Queue Pairs in the NIC).
Net RX	Process packets and insert into the network Rx queues (by the network interrupt handler).
Idle	Enter the CPU *Idle* mode.
Others	Include all the remaining overheads such as task scheduling, IRQ handling, spin locks, and so on.

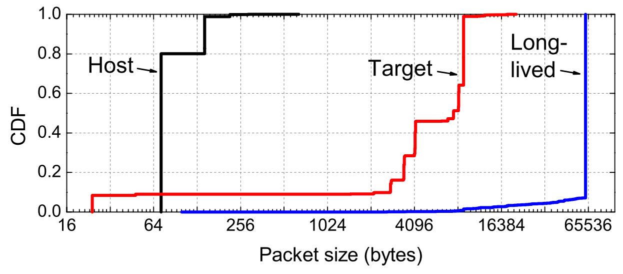


Figure 11: **For 4K random read, NVMe-TCP does not benefit from TSO** due to the packet sizes being mostly 72B at host and $<$ 9KB at target, much smaller than ideal 61KB packet size.

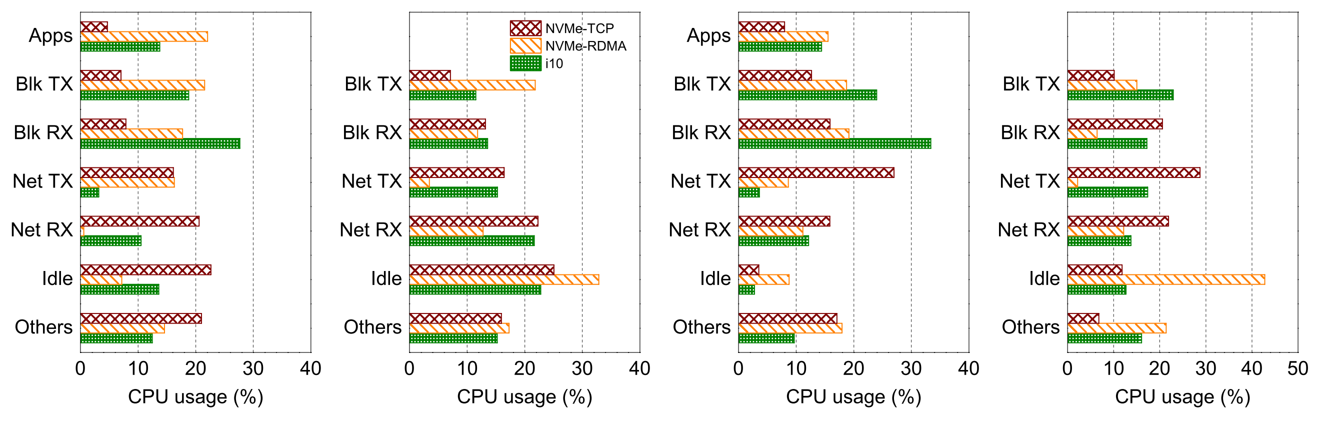
CPU usage in network processing. To investigate the reason further, we measure the packet sizes used in each TCP/IP processing for 4KB random read, comparing to a long-lived TCP connection that achieves ~30Gbps using a single core. Figure 11 reveals that about 80% of packet sizes generated by the host are 72 bytes, the I/O request PDU size of NVMe-TCP. This implies that almost every single small-sized request consumes CPU cycles for TCP/IP processing, increasing per-byte CPU usage. The target can generate a larger size of packets as it sends 4KB response data back to the host, but still most of them (98%) are under the jumbo frame size (9000 bytes) while the long-lived TCP connection generates mostly 61KB packets with TSO. i10 caravans help mitigate this bottleneck by generating 1152B packets (that is, 72B$\times$16) at the host and ~61KB packets at the target; i10 caravans are thus able to help reduce CPU usage by 30.12% and 31.14% for SSD and RAM block device in network processing parts, compared to the baseline i10 that uses only i10-ℓane.

(2) i10 minimizes context switching overheads: i10 achieves 1.7$\times$ CPU usage reductions over NVMe-TCP in *Others* part that includes task scheduling overheads. NVMe-TCP involves three kernel threads at the host — one for `blk-mq` that corresponds to the application thread, another for the remote I/O and TCP/IP Tx processing, and the third for the packet interrupt handling and TCP/IP Rx processing. This model avoids (i) slow responsiveness to other threads and/or (ii) long bottom half procedure for the incoming packet interrupts, but can incur high context switching overhead; our measurement indicates that each context switch takes 1–3μs per request, consuming more CPU cycles at the host. i10 amortizes this switching overhead using the idea of delayed doorbells; when compared to i10 design that does not use delayed doorbells, we observe reduction of CPU usage by 14.2% and 14.15% for NVMe SSD and RAM block device in the Others part. While the previous work mainly focuses on the target architecture [24], this host-side optimization turns out to be essential to improve the remote I/O throughput given that all the three remote storage access technologies consume more CPU cycles at the host regardless of the device type.

(3) i10 improves CPU efficiency allowing more cycles for applications: CPU resources saved in network processing and in context switching (using caravans and delayed doorbells) can be utilized by the applications, resulting in improved throughput per core. For instance, i10 allows applications to use 2.9$\times$ and 1.8$\times$ more CPU cycles for SSD and RAM devices, when compared to NVMe-TCP. NVMe-RDMA also shows 1.9$\times$ more CPU usage than NVMe-TCP on applications with RAM block device.

(4) i10 pushes the performance bottlenecks to the block layer: Tables 3 and 4 show that i10 pushes the performance bottlenecks from network processing and other lower layers (scheduling, etc., including in Others) to upper layers, making



(a) Host (SSD) (b) Target (SSD) (c) Host (RAM) (d) Target (RAM)

Figure 12: **CPU consumption at various system components for i10, NVMe-TCP and NVMe-RDMA**. i10 and NVMe-RDMA use significantly fewer CPU cycles for network processing and task scheduling (in Others) at the host while allowing applications to consume more CPU cycles, when compared to NVMe-TCP.

Table 3: **CPU usage contribution for 4KB random read with NVMe SSD**: i10 reduces CPU usages in network processing (Net TX and RX) using i10 caravans and in task scheduling (Others) using delayed doorbells, which allows more CPU cycles for applications and block layer. Here, i10-ℓane contribution is measured with enabling TSO/GRO and jumbo frames.

	Applications	Block TX	Block RX	Net TX	Net RX	Idle	Others
i10-ℓane	4.67	7.02	7.88	16.14	20.61	22.66	21.02
i10 Caravans	+9.85	+14.54	+16.41	-13.7	-16.42	-16.34	+5.66
Delayed Doorbells	-0.75	-2.76	+3.38	+0.73	+6.34	+7.26	-14.2
i10	13.77	18.8	27.67	3.17	10.53	13.58	12.48

Table 4: **CPU usage contribution for 4KB random read with RAM block device**. The trends are similar to the SSD case above.

	Applications	Block TX	Block RX	Net TX	Net RX	Idle	Others
i10-ℓane	8.0	12.68	15.9	27.0	15.84	3.51	17.07
i10 Caravans	+5.77	+10.88	+8.83	-24.79	-6.35	-1.07	+6.73
Delayed Doorbells	+0.63	+0.43	+8.66	+1.42	+2.67	+0.34	-14.15
i10	14.4	23.99	33.39	3.63	12.16	2.78	9.65

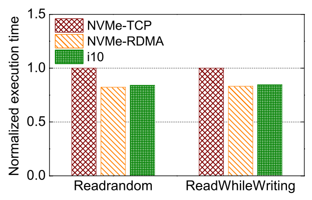
the block device layer a new bottleneck point in the kernel. i10 design did not attempt to perform changes in the block layer; however, it would be interesting to explore block layer optimizations to further improve end-to-end performance for remote (and even local) storage access.

We observe that RDMA still consumes a few CPU cycles to build and parse the command PDUs in network processing parts. In our profiling, one main difference between the SSD and RAM cases is that the RAM block device does not use IRQ to inform the I/O completion, but calls the the block layer functions immediately while in the SSD case, it still relies on the `nvme_irq` handling after the I/O is completed. This increases the IRQ handling overhead. Further, NVMe-RDMA generates another type of IRQ to call the block layer functions in the host after the network processing is done. This also slightly increases the IRQ handling overhead in the host.

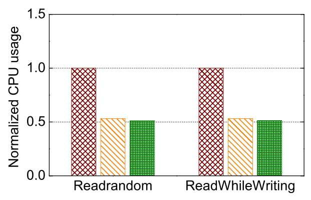
4.4 i10 performance with RocksDB

To evaluate i10 performance over real applications, we use RocksDB, a popular key-value store deployed in several production clusters [17]. We install RocksDB in the host server with a remote SSD device mounted with XFS file system. The RocksDB database and write-ahead-log files are stored on the remote device. To minimize the effect of the kernel page cache, we clear the page cache every 1 second during the experiment. We use `db_bench`, a benchmarking tool of RocksDB, for generating the two workloads using default parameters [18]: *ReadRandom* and *ReadWhileWriting*. Before running the workloads, we populate a 55GB database using the *bulkload* workload.

We measure the end-to-end execution time and kernel-side CPU utilization using a single core. In this experiment, the doorbell timeout value is set to 1ms as RocksDB is not an



(a) Execution time



(b) CPU usage in kernel

Figure 13: **i10 and NVMe-RDMA achieve** $1.2\times$ **lower latency and** $2\times$ **lower CPU utilization when compared to NVMe-TCP over SSD-based RocksDB.**

I/O bound application, and thus requires more time to aggregate appropriate number of requests. Figure 13 shows the performance of the three schemes, normalized by the NVMe-TCP performance. Again, we observe that i10 performs comparable to NVMe-RDMA while achieving almost $1.2\times$ improvements over NVMe-TCP in terms of execution time. The reason why this improvement is different with that of FIO benchmarks is that, RocksDB itself is the main CPU cycle consumer (up to 70% CPU usage) to perform data compression, key matching, etc. However, i10 still allows RocksDB to utilize more CPU resources by requiring $2\times$ lower CPU in the kernel across a fixed number of requests when compared to over NVMe-TCP. Our additional experiments with Filebench [39], presented in Appendix B in [16], indicate that if the application is I/O bound, i10 can achieve more than $2\times$ per-core throughput improvements over NVMe-TCP in a similar setup.

4.5 Comparison with ReFlex

Now we compare i10 with ReFlex, a user-level remote Flash access stack [24] using FIO. Unfortunately, despite significant effort, we were unable to install the remote block device kernel module for ReFlex [8] in our system[3], which is required for ReFlex host to run legacy Linux applications such as FIO. Thus, we make an indirect comparison with ReFlex, measuring i10 throughput using the same 10Gbps NICs used in [24] (that is, Intel 82599ES 10GbE NICs) and the same FIO script [8]. We also use 1-core i10 target as ReFlex target server uses 1-core per tenant. In this setup, i10 saturates the 10Gbps link with $\sim$3 cores, whereas ReFlex-FIO requires 6 cores according to [24]. This result still suggests that i10 would be a good option for remote storage I/O when we use legacy throughput-bound applications.

We also note that using IX [6]-based ReFlex clients achieves higher throughput; for instance, ReFlex reports achieving 850 kIOPS for 1KB read-only request using a single core [24], thus requiring only 2 cores to saturate a 10Gbps link. However, this requires the client server to run IX, precluding integration with unmodified legacy applications.

[3]The kernel module is based on an old version of kernel (4.4.0) that does not include relevant device drivers for our SAS SSD where the OS is installed. We also failed to boot with our NVMe SSD even with the up-to-date BIOS.

5 Discussion

We discuss a number of possible extensions for i10.

Can we apply i10 techniques to improve iSCSI performance? We believe that many of our optimizations may be useful to improve iSCSI [35] performance; for instance, the current Linux iSCSI implementation consumes CPU cycles inefficiently when sending I/O requests and responses, not fully utilizing TSO/GRO; moreover, it also runs a dedicated kernel thread for TCP/IP processing. i10 caravans and delayed doorbells alleviate precisely these bottlenecks, and thus may be useful for iSCSI.

Integrations with Emerging Transport Designs. i10 design and implementation was originally motivated by the question whether state-of-the-art performance for remote storage stacks can be achieved using simple modifications in the kernel. Thus, i10 design naturally integrates with existing network stack within the kernel. An intriguing future work would be to integrate i10 with emerging CPU-efficient network transport designs that use hardware offload.

Overheads of maintaining i10-ℓanes. Our i10-ℓane design does not introduce any additional overhead at either `blk-mq` or TCP/IP protocol layer, but simply exploits the existing per-core `blk-mq` that every request goes through regardless of whether it is remote access or not. The new overheads introduced by i10-ℓane are: i10 caravans, i10 queues, and TCP socket instances. To minimize memory usage and de-/allocation overheads of i10 caravan, each i10-ℓane maintains a single full-sized caravan instance (an array of kernel vectors that cover the aggregation size of requests and 64KB data) and reuse it whenever a new doorbell is rung. Memory requirement for maintaining per-(core, target) i10 I/O queues would be comparable to the current NVMe implementation, which creates per-(core, device) NVMe queues. Lastly, a dedicated socket requires small amount of state and thus, adds a minor memory overhead. We believe that such minor overheads are well worth the performance benefits achieved by i10.

Setting the right doorbell timeout value. In some extreme cases where a single host core needs to use many i10-ℓanes (that is, requests from a single core going to a large number of target servers), i10 may expose a throughput-latency tradeoff. Assuming the core generates requests at full rate, increasing number of i10-ℓanes means that the number of pending requests for each individual i10-ℓane will be reduced triggering doorbell timeout more often (see Appendix B in [16]). The tradeoff here is that to achieve throughput similar to the results in the previous section, we will now need larger delayed doorbell timeout value, resulting in relatively larger latency. This observation suggests that operators can set a higher timeout value when (1) applications are throughput bound; and/or (2) the number of targets per core increases. An interesting future work here is to explore setting the timeout value dynamically, depending on the "observed" load on the system.

Table 5: **Comparison of design decisions made in i10 with those in several prior works.**

	Storage stack	Network stack	API	App. event handling	Remote I/O event handling	Domain protection	Modification

6 Related Work

Table 5 compares i10 with several of the prior designs on optimizing the storage and network stacks. We briefly discuss some of the key related work below.

Existing remote storage I/O stacks. The fundamental performance bottlenecks of traditional remote storage stacks are well-understood [24]. For instance, iSCSI protocol [35] was designed to access remote HDDs over 1Gbps networks, achieving merely ∼70K IOPS per CPU core [12, 23, 24]. Similarly, a light-weight server for remote storage access based on Linux `libevent` and `libaio` achieves ∼75K IOPS per core [24]. Distributed file systems (*e.g.*, HDFS, GFS, etc.) are generally optimized for large data transfers, but are not so efficient for small-sized random read/write requests over high-throughput storage devices [10, 36]. i10 significantly improves throughput-per-core when compared to existing kernel-based remote storage stacks, achieving performance close to state-of-the-art user-space and RDMA-based products.

CPU-efficient network stacks within the kernel. Motivated by the fact that existing kernel *network* stacks were not designed for high network bandwidth links, there has been a significant amount of recent work on designing CPU-efficient network stacks [13, 27, 38, 42]. These stacks focus primarily on network stacks and are complementary to optimizing remote storage stacks; nevertheless, several optimization techniques (*e.g.*, syscalls batching/scheduling, per-core accept queue, etc.) introduced in these works may be useful for i10 as well. For instance, we demonstrate in Appendix B in [16] that syscall-level batching from [13, 38, 42], when integrated with i10, helps further improve the performance by 1.2×.

CPU-efficient user-space network stacks. The main motivation of this approach is that the kernel is extremely complex and high-overhead due to various overheads in system calls, process/thread scheduling, context switching, and so on. Prior studies reveal that the current kernel stack has limited network processing power in terms of the number of messages per second, so it is difficult to saturate network link capacity if the applications generate only small-sized messages, *e.g.*, under tens to hundreds of bytes [6, 19, 44].

To avoid these overheads, user-space solutions place the entire network protocol stack in the user space and directly access the NIC through the user-level packet I/O engines such as DPDK [1] and netmap [34], while bypassing the kernel [6, 19, 21, 22, 29, 32, 33]. By putting small-sized packets onto the NIC buffer directly in a batched manner, they significantly improve the messages per second performance. ReFlex [24] also implements the remote Flash access stack in the user space, on top of IX [6]. We note that modifying applications for using the user-level stacks might not be fundamental as recent new systems support the POSIX interfaces (*e.g.*, TAS [22], Strata [25], and SplitFS [20]). As we have discussed throughout the paper, i10's goals are not to beat the performance of user-space solutions but rather to explore whether similar performance can be achieved without modifications in the application and/or network infrastructure.

7 Conclusion

This paper presents design, implementation and evaluation of i10, a new in-kernel remote storage stack for high-performance network and storage hardware. i10 requires no modifications outside the kernel, and operates directly on top of kernel's TCP/IP network stack. We have demonstrated that i10 is still able to achieve throughput-per-core comparable to state-of-the-art user-space and RDMA-based solutions. i10 thus represents a new operating point for remote storage stacks, allowing state-of-the-art performance without any modifications in applications and/or network infrastructure.

NetTLP: A Development Platform for PCIe devices in Software Interacting with Hardware

Yohei Kuga[1], Ryo Nakamura[1], Takeshi Matsuya[2], Yuji Sekiya[1]

Abstract

Observability on data communication is always essential for prototyping, developing, and optimizing communication systems. However, it is still challenging to observe transactions flowing inside PCI Express (PCIe) links despite them being a key component for emerging peripherals such as smart NICs, NVMe, and accelerators. To offer the practical observability on PCIe and for productively prototyping PCIe devices, we propose NetTLP, a development platform for software PCIe devices that can interact with hardware root complexes. On the NetTLP platform, software PCIe devices on top of IP network stacks can send and receive Transaction Layer Packets (TLPs) to and from hardware root complexes or other devices through Ethernet links, an Ethernet and PCIe bridge called a NetTLP adapter, and PCIe links. This paper describes the NetTLP platform and its implementation: the NetTLP adapter and LibTLP, which is a software implementation of the PCIe transaction layer. Moreover, this paper demonstrates the usefulness of NetTLP through three use cases: (1) observing TLPs sent from four commercial PCIe devices, (2) 400 LoC software Ethernet NIC implementation that performs an actual NIC for a hardware root complex, and (3) physical memory introspection.

1 Introduction

PCI Express (PCIe) is a widely used I/O interconnect for storage, graphic, network, and accelerator devices [16, 24, 25]. Not limited to connect the peripheral devices, some high-performance interconnects adopt the PCIe protocol [5, 22, 35]. Moreover, specifications of future interconnects are designed by extending the PCIe protocol [10, 14]. Such versatility of PCIe is derived from the packet-based data communication and the flexibility of PCIe topology. The PCIe specification defines building blocks comprising PCIe topologies: endpoint, switches, bridges, and root complexes. PCIe packets flow through point-to-point PCIe links between the blocks, and motherboard manufacturers can expand the PCIe topologies with these blocks depending on the use cases.

Table 1: Comparison of platforms for prototyping PCIe devices from the viewpoints of software and hardware.

		PCIe device	
		Software	Hardware
Root Complex	Software	QEMU	–
	Hardware	NetTLP	FPGA/ASIC

By contrast to the spread of PCIe, it is still difficult for researchers and software developers to observe PCIe and prototype PCIe devices, although they are crucial for optimizing performance and developing future PCIe devices. Observing PCIe transactions is difficult because PCIe transactions are confined in hardware. PCIe is not just a simple fat-pipe between hardware elements; it also has several features for achieving high-performance communication, i.e., hardware interrupt, virtualization, and CPU cache operations. Utilizing these features is important for exploiting PCIe efficiently; however, the concrete behaviors of the transactions in PCIe links cannot be determined unless special capture devices for observing PCIe hardware are used.

In addition to the observation, prototyping PCIe devices lacks productivity. Field Programmable Gate Array (FPGA) is a major platform for prototyping PCIe devices [26, 40, 44, 45, 50]. However, developing all parts of a PCIe device on an FPGA still requires significant effort, such as the great devotion of the NetFPGA project [52] for networking devices. Another approach is to adopt virtualization or simulation, e.g., GEM5 [11, 23] and RTL simulators [4, 31]. QEMU [9], which is a famous virtualization platform, can be used for prototyping PCIe devices from the software perspective. QEMU enables researchers and developers to prototype new hardware architecture; however, its environment is fully softwarized. QEMU devices can communicate with only the emulated root complex and cannot communicate with the physical root complex and other hardware connected to the root complex.

The goal of this paper is to bridge the gap between software and hardware for PCIe, as shown in Table 1. Our proposed platform, called NetTLP, offers softwarized PCIe endpoints that can interact with hardware root complexes. By using NetTLP, researchers and software developers can prototype their PCIe devices as software PCIe endpoints and test the software devices with actual hardware root complexes through the PCIe protocol. This hybrid platform of software and hardware simultaneously improves both the observability of PCIe transactions and the productivity of prototyping PCIe devices.

The key technique for connecting softwarized PCIe endpoints to hardware root complexes is to separate the PCIe transaction layer into software and put the software transaction layer on top of IP network stacks. Our FPGA-based add-in card, called NetTLP adapter, delivers Transaction Layer Packets (TLPs) to a remote host over Ethernet and IP networks. The substance of the NetTLP adapter is implemented in software on the IP network stack of the remote host with LibTLP, which is a software implementation of the PCIe transaction layer. The NetTLP platform consisting of the adapter and library enables software PCIe devices on IP network stacks to interact with hardware root complex through the NetTLP adapter. Moreover, TLPs delivered over Ethernet links can be easily observed by IP networking techniques such as tcpdump and Wireshark.

In this paper, we describe NetTLP, the novel platform for software PCIe devices. To achieve the platform, we investigate PCIe from the perspective of packet-based communication (§2) and then describe the approach to connect the software PCIe devices with hardware root complexes and process TLPs in software (§3) and describe its implementation (§4). In addition to micro-benchmarks (§5), we demonstrate three use cases of NetTLP (§6): observing behaviors of a root complex and commercial devices at a TLP-level, prototyping an Ethernet NIC in software interacting with a physical root complex, and physical memory introspection using NetTLP.

The contributions of this paper include the following:

- We propose a novel platform for prototyping PCIe devices in software, while the software devices can communicate with physical hardware such as root complexes, CPU, memory, and other PCIe devices. This platform offers high productivity for prototyping PCIe devices with actual interactions with hardware.

- We provide observability of PCIe transactions confined in hardware by the softwarized PCIe endpoints on the IP network stack. Our modified tcpdump can distinguish the encapsulated TLPs in Ethernet by NetTLP, enabling us to easily capture TLPs in an IP networking manner.

- We present detailed observation results of PCIe transactions with a root complex and commercial peripherals: an Intel root complex, Intel X520 10 Gbps NIC, Intel XL710 40 Gbps NIC, Intel P4500 NVMe, and Samsung PM1724 NVMe. The observation results by NetTLP reveal differences in their behaviors on PCIe transactions, for example, different usage of TLP *tag* fields.

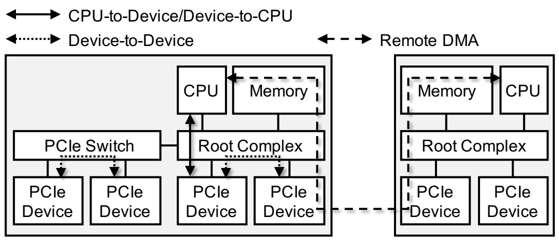

Figure 1: A PCIe topology and three communication models.

- We show a prototype of a nonexistent Ethernet NIC with NetTLP. This prototyping demonstrates the high productivity of the NetTLP platform; the NIC is certainly implemented in software, but it performs as an actual Ethernet NIC for a physical root complex.

- We demonstrate the possibility of developing memory introspection methods on NetTLP without implementing dedicated devices. As a proof-of-concept, we implemented two applications that gather process information from a remote host by DMA through NetTLP.

All source codes for hardware and software and captured data described in this paper are publicly available [1].

2 Background

PCIe is not only an interconnect, but also a packet-based data communication network. As with IP networks, PCIe has a layering model composed of a physical layer, a data link layer, and a transaction layer. The data link layer delivers PCIe packets across one hop over a PCIe link, while the transaction layer is responsible for delivering TLPs from a PCIe endpoint to a PCIe endpoint across the PCIe links. PCIe interconnect is composed of the following elements that are capable of supporting the layer functionalities: endpoints, switches, bridges, and root complexes. PCIe switches and root complexes route and forward PCIe packets in accordance with the addresses in memory-mapped I/O (MMIO) space or requester IDs. Any functionalities of PCIe stand at the packet-based communication, e.g., MSI-X for hardware interrupts is implemented by memory writes to specific memory addresses. Because of being such a packet-based network, PCIe topologies and their communication models are flexible, as depicted in Figure 1.

In IP networks, we can easily prototype and implement any part of the networks, such as end hosts, switches, and routers, and observe packets flowing in the networks; however, PCIe cannot do such things despite PCIe also being a packet-based network. PCIe was originally designed for I/O interconnects inside a computer; therefore, it is assumed that all the PCIe elements were implemented in hardware. This assumption and the current situation cause difficulty in investigating and developing PCIe and its elements.

For investigating PCIe, there are two major platforms: FPGA and QEMU. FPGA offers programmability on hardware for prototyping PCIe devices. By contrast, developing PCIe devices on FPGA still involves significant effort. Even when implementing a device, the device requires purpose-specific logic and various logic blocks such as PCIe core, DMA engine, memory controller, etc. Such functional blocks are not available, unlike software libraries. Moreover, we cannot observe the PCIe packets sent by the FPGA. We can see only part of the signals using logic analyzers, or expensive dedicated hardware. On the other hand, QEMU enables implementing PCIe devices on a full virtualized environment [15, 37]. However, QEMU does not implement the PCIe protocol, only DMA APIs. QEMU is used as a platform for researching new PCIe devices and discussing OS abstractions and implementations without real hardware and the PCIe protocol. Thus, QEMU PCIe devices cannot interact with the real host and hardware on the PCIe, although the features of root complexes have been evolving.

The two platforms have advantages and disadvantages: FPGA requires significant effort for prototyping and lacks observability, while QEMU devices cannot interact with hardware elements with the PCIe protocols. These disadvantages are because the platforms focus on only hardware or software. Root complexes and devices—the two major elements of PCIe—are hardware in FPGA or software in QEMU.

As a third platform, we advocate connecting software and hardware elements of PCIe. If PCIe devices are moved to software and connected to a hardware root complex, we achieve productive PCIe device prototyping in software and interactions with the real PCIe elements connected to the hardware root complex. Moreover, we can observe the PCIe transactions at the software PCIe device without resorting to dedicated hardware mechanisms. This relationship is similar to IP networks; IP network stacks at end hosts are software, while routers and switches are hardware.

3 NetTLP

To feasibly connect software PCIe devices and hardware root complexes, we propose to separate the transaction layer of PCIe into software, as illustrated in Figure 2. The transaction layer is responsible for the fundamental part of end-to-end PCIe communications: identifiers, i.e., memory addresses and requester IDs, routing, and issuing PCIe transactions. The softwarized transaction layer offers high productivity of PCIe device prototyping in software on top of the layer and observability of PCIe transactions by software.

To connect the softwarized transaction layer and the hardware data link layer, NetTLP has chosen a configuration that bridges a PCIe link and an Ethernet link. Because PCIe and Ethernet are packet-based networks, it is possible to deliver TLPs over Ethernet links by encapsulation. Once TLPs go to an Ethernet network, we can easily observe the TLPs like IP packets, implement the transaction layer in software, and prototype PCIe devices on top of software IP network stacks.

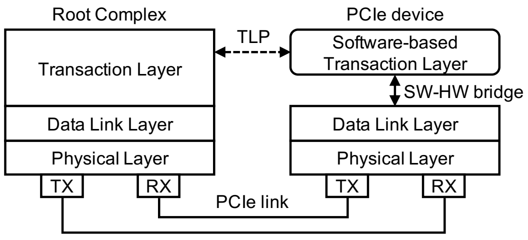

Figure 2: The layering model of PCIe and our approach that separates the transaction layer into software.

As with NetTLP, ExpEther [47, 48] and Thunderclap [29] also enable observing and manipulating TLPs. ExpEther extends PCIe links by delivering TLPs over Ethernet links. TLPs encapsulated by ExpEther would be observed on an Ethernet link between an ExpEther adapter and a hardware extension box in which peripheral devices are installed. In Thunderclap, Linux running on an ARM CPU on an FPGA processes TLPs with software. Similarly, some smart NICs can send and receive TLPs from CPUs on the NICs with abstracted DMA APIs [30, 33].

In contrast to the existing technologies, NetTLP focuses on prototyping new PCIe devices in software. For this purpose, manipulating TLPs with software is one of the essential functionalities. In addition, how devices and CPUs interact with each other must be designed flexibly. ExpEther does not focus on this point so that it extends PCIe links over Ethernet, and the software PCIe devices on Thunderclap pretend existing devices to reveal vulnerabilities through their drivers. In the NetTLP platform, researchers and developers can design how new software devices interact with CPUs through root complexes. More specifically, it is possible to design and implement the usage of registers of the software devices, e.g., descriptor rings, from scratch on the NetTLP platform. This functionality enables designing and implementing nonexistent devices and observing its interaction in software (Section 6.2).

3.1 Platform Overview

A key component of NetTLP delivering TLPs over Ethernet is a NetTLP adapter, which is an FPGA-based add-in card equipped with a PCIe link connected to the host and an Ethernet link. Another key component is LibTLP, which is a software library of the PCIe transaction layer on the IP network stack. The NetTLP platform is composed of two hosts, an adapter host having the NetTLP adapter and a device host where LibTLP-based applications are run, as illustrated in Figure 3.

The NetTLP adapter is responsible for the bridge between the hardware data link layer and the software transaction layer depicted in Figure 2. The NetTLP adapter delivers TLPs be-

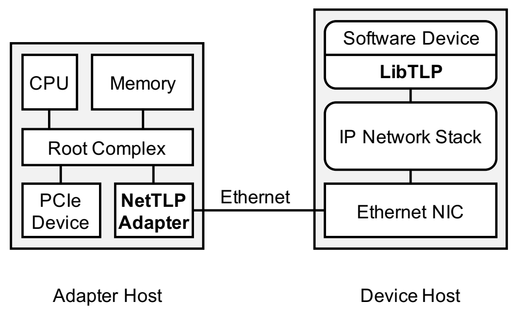

Figure 3: The overview of the NetTLP platform.

tween a host's PCIe link and the Ethernet link. When the NetTLP adapter receives TLPs from the PCIe link, the NetTLP adapter encapsulates each TLP in Ethernet, IP, UDP, and NetTLP header for sequencing and timestamping and sends the packets to the device host via the Ethernet link. When the NetTLP adapter receives a UDP packet from the Ethernet link, the NetTLP adapter checks whether the packet's payload is a TLP, decapsulates the packet, and sends the inner TLP to the PCIe link. As a result, from the perspective of the adapter host, all TLPs sent from the device host by the software are recognized as TLPs generated by the NetTLP adapter.

LibTLP implements the PCIe transaction layer in software and provides abstracted DMA APIs for applications. The applications on the device host can send and receive TLPs to the NetTLP adapter on the adapter host through UDP sockets. By using LibTLP, researchers and software developers can implement their own PCIe devices in software that perform actual behaviors of the NetTLP adapter for the root complex on the adapter host. In addition, splitting software PCIe devices and physical adapters on the distant hosts enables us to observe actual PCIe transactions flowing through the Ethernet link. We can capture the encapsulated TLPs by tcpdump at the device host or capture the TLPs on the Ethernet link by optical taps or port mirroring on Ethernet switches.

Although a NetTLP adapter is a single peripheral device, the NetTLP adapter can be applied to some PCIe communication models in PCIe topologies organized in Figure 1. Naturally, the NetTLP adapter and the software PCIe device can become a device on CPU-to-device and device-to-CPU communications. Applying the NetTLP adapter into device-to-device communication, also known as peer-to-peer DMA, realizes interactions between commercial PCIe devices and software PCIe devices. Section 6.1 shows TLPs sent from product devices by the NetTLP platform and peer-to-peer DMA integration. In addition, the NetTLP adapter can be considered a raw remote memory access device. Applications on the device host can issue DMA to any address of the memory on the adapter host through the NetTLP adapter. Section 6.3 demonstrates memory introspection methods exploiting the remote memory access by NetTLP.

3.2 TLP Processing in Software

Processing PCIe transactions in software is challenging because PCIe was originally designed to be processed by hardware. This section describes three issues to design NetTLP for achieving PCIe interactions between hardware and software.

Receiving burst TLPs: The first issue is that LibTLP needs to receive burst TLPs sent from the hardware. The minimum TLP length is 12 bytes when the TLP is a memory-read (MRd) TLP with the 32-bit address field, for instance. NetTLP adapter encapsulates TLPs with Ethernet, IP, UDP, and NetTLP headers; thus, the minimum encapsulated packet length is 64 bytes. This length is the same length as the minimum packet size of IP networks. Meanwhile, the flow control of PCIe is based on the credit system [7], and PCIe endpoints can send TLPs continuously as long as the credit remains. In particular, PCIe devices often send small TLPs using the TLP tag field to achieve high performance [21]. Because these TLP transmission intervals are continuous clock units, the throughput of encapsulated TLPs could momentarily be wire-rate on the Ethernet link with short packets.

To receive such burst TLPs by software, NetTLP exploits the TLP tag field to distribute receiving encapsulated TLPs among multiple hardware queues of an Ethernet NIC and CPU cores. The tag field is used to distinguish individual non-posted transactions that can be processed independently. The NetTLP adapter embeds the lower 4-bit of the tag values into the lower 4-bit of UDP port numbers when encapsulating TLPs. As a result, PCIe transactions to the NetTLP adapter are delivered through different UDP flows based on the tag field, and the device host can receive the flows by different NIC queues. This technique, called tag-based UDP port distribution, enables the software side to process TLPs on multiple cores associated with multiple NIC queues.

Completion Timeout: Another issue is the completion timeout. In accordance with PCIe specifications, root complexes and PCIe endpoints support a completion timeout mechanism on the PCIe transaction layer. When a requester send memory-read requests, the requester sets timeout periods for each request, and the completer need to send the completions within the periods. Hence, software PCIe devices on the NetTLP platform need to be able to send completions within the hardware-level timeout periods. The timeout period is configured in the PCIe configuration space. For instance, the minimum and maximum completion timeout periods of X520 NIC are 50 microseconds and 50 milliseconds, respectively [6]. Therefore, software PCIe devices built on LibTLP also must be capable of replying memory requests during such periods. Fortunately, Linux network stacks on general server machines are not too slow at the millisecond scale; therefore, we expect that LibTLP would meet the requirement. Section 5 examines this issue through a latency benchmark.

Encapsulation Overhead: To take TLPs to software on top of IP network stacks, NetTLP encapsulates TLPs with IP headers although encapsulation involves throughput reduction due to the header overhead. NetTLP encapsulates TLPs into multiple headers: 14-byte Ethernet, 4-byte FCS, 20-byte IP, 8-byte UDP, and 6-byte NetTLP headers. The throughput of data transfer over DMA on the NetTLP platform can be calculated with:

$$Throughput_{dma} = BW_{eth} \times \frac{TLP\_Data}{TLP\_hdr+TLP\_Data+Pkt\_Hdr+ETH\_Gap}$$

BW_{eth} is the Ethernet link speed, Pkt_Hdr is 52-byte for the headers and FCS mentioned above, and ETH_Gap is 20-byte for preamble and inter-frame gaps. From this formula, throughput with 256-byte TLP_Data (usual max payload size) and 12-byte TLP_hdr for 3DW memory-write TLP on 10 Gbps links is approximately 7.53 Gbps, which is the theoretical limitation with 10 Gbps Ethernet. Although throughput is required depending on use cases, the overhead is not significant for just prototyping software PCIe devices.

4 Implementation

We implemented the NetTLP adapter using an FPGA card and LibTLP on Linux. This section describes the details of the NetTLP adapter, APIs provided by LibTLP, hardware interrupts, and limitations of the NetTLP platform.

4.1 NetTLP Adapter

The NetTLP adapter was implemented using the Xilinx KC705 FPGA development board [51]. This board has Xilinx Kintex 7 FPGA, an Ethernet 10 Gbps port, and a PCIe Gen 2 4-lane link. We used the board because its PCIe Endpoint IP core enables user-defined logic to handle raw TLP headers. This feature is suitable for designing the NetTLP adapter. However, the Xilinx's newer PCIe IP core, which supports PCIe Gen 3, does not allow user-defined logic to handle raw TLP headers. Therefore, the current implementation of the NetTLP adapter does not support PCIe Gen 3.

Figure 4 shows the overview of the circuit diagram of the NetTLP adapter. The current NetTLP adapter has three base address register (BAR) spaces for different roles. BAR0 is used to configure the NetTLP adapter. The configurations through BAR0 support changing source and destination MAC addresses and source and destination IP addresses for encapsulating TLPs. The BAR2 space is used for the MSI-X table to support the hardware interrupts from software PCIe devices. The detail of MSI-X in NetTLP is described in Section 4.3. Both BAR0 and BAR2 memory spaces are implemented with Block RAM on the FPGA, and the NetTLP adapter has the Peripheral I/O (PIO) engine above the BAR0 and BAR2 to reply with completion TLPs for operations to the BARs.

BAR4 is different from BAR0 and BAR2; BAR4 space is connected to the Ethernet PHY and not connected to the PIO engine. All TLPs from the root complex or other devices to

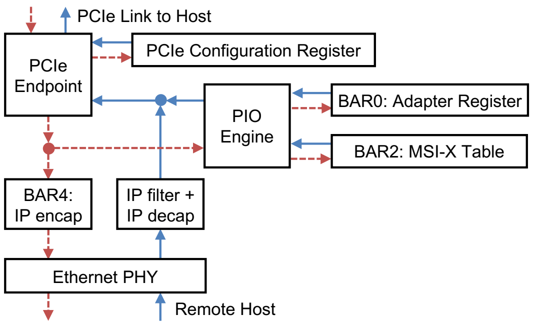

Figure 4: The circuit diagram of the NetTLP adapter.

the BAR4 space are encapsulated in Ethernet, IP, UDP, and NetTLP headers and transmitted to an external host via the Ethernet link. Namely, LibTLP on the device host communicates to the root complex on the adapter host through the memory region assigned to the BAR4.

When encapsulating TLPs to the BAR4, source and destination port numbers of the UDP headers are generated based on the tag field of their TLP headers. This is the tag-based UDP port distribution described in Section 3.2. In the current implementation, the UDP port numbers are generated with $0x3000 + (TLP\_Tag \wedge 0x0F)$. Thus, the NIC on the device host receives the TLPs by a maximum of 16 hardware queues. When the NetTLP adapter receives UDP packets from the device host, the IP filter logic checks whether the IP addresses match the configured addresses on BAR0. If the IP addresses and port numbers are correct, the packets are decapsulated, and the inner TLPs are sent to the host via the PCIe link.

The driver for the NetTLP adapter depends on types of software PCIe devices. If a software PCIe device is an Ethernet NIC, the driver is for the Ethernet NIC, and if a software PCIe device is an NVMe SSD, the driver is for the NVMe SSD. Regardless of the driver types, we implemented a simple driver that supports basic functionalities for the NetTLP adapter. This driver enables the NetTLP adapter, initializes MSI-X, and prepares a simple messaging API. The software PCIe device on the device host can obtain information about the NetTLP adapter, i.e., addresses of the BAR spaces of the adapter, PCIe bus and slot numbers, and MSI-X table. Users of the NetTLP platform can develop drivers for their software PCIe devices by extending the basic NetTLP driver.

4.2 LibTLP

LibTLP is a userspace library that implements the PCIe transaction layer. On top of the transaction layer implementation, the LibTLP provides a well-abstracted DMA API and a callback API for handling each type of TLPs.

Figure 5 shows the DMA API of LibTLP. A LibTLP instance that contains a socket descriptor, a tag value, and a destination address of a target NetTLP adapter is represented

```
ssize_t dma_read(struct nettlp *nt, uintptr_t addr, void *buf, size_t count);
ssize_t dma_write(struct nettlp *nt, uintptr_t addr, void *buf, size_t count);
```

Figure 5: The DMA API of LibTLP.

by a `nettlp` structure initialized by `nettlp_init()`. The DMA APIs for DMA reads and DMA writes are invoked by specifying a `nettlp` structure. As with the `read()` and `write()` system calls, `dma_read()` attempts to read up to `count` bytes into `buf` and `dma_write()` writes up to `count` bytes from `buf`. `addr` indicates a target address of a DMA transaction. The return values of the functions are the number of bytes read or written, or -1 and `errno` is set on error. For the DMA reads, applications can notice TLP loss or completion errors through the return value and `errno`.

In addition to the DMA API that issues DMAs to the memory on the adapter host, LibTLP provides a callback API for handling TLPs from the adapter host to the device host. The callback API allows applications to register functions for major TLP types: memory read (MRd), memory write (MWr), completion (Cpl), and completion with data (CplD). When the sockets of the `nettlp` structures receive TLPs, the registered functions are invoked for the TLPs. By using this API, the applications on the device host can respond to MRd TLPs from the root complex to the BAR4 on the NetTLP adapter by sending associated CplD TLPs, for instance.

4.3 Hardware Interrupt

For hardware interrupt, the NetTLP platform supports MSI-X, which is widely used by modern PCIe devices. MSI-X interrupt is invoked by sending a MWr TLP with particular data to a specified address from a device. The address and data for the interrupt are stored in an MSI-X table on a BAR space specified by the PCIe configuration space of the device. In other words, to send a hardware interrupt by MSI-X, it is necessary to refer to the MSI-X table on the BAR.

To achieve MSI-X on the NetTLP platform, there are two approaches: (1) placing the MSI-X table on the BAR4 and a software PCIe device on a device host holds the MSI-X table, and (2) placing the MSI-X table on other BAR spaces under the PIO engine and a software PCIe device on a device host gets the MSI-X table through other communication paths. The current implementation chooses the latter approach. The former approach does not need any other communication paths to obtain the MSI-X table from the adapter host. However, the MSI-X table is initialized by the NetTLP driver, so the software PCIe device must run on the device host before the NetTLP driver is loaded on the adapter host. Moreover, software PCIe device implementations must always be capable of maintaining the MSI-X table, even if they do not use MSI-X. These characteristics might inconvenience the development of software PCIe devices. For these reasons, we placed the MSI-X table on BAR2 under the PIO engine that is controlled by only the hardware logic of the NetTLP adapter. The software PCIe devices can obtain the content of the MSI-X table through the simple messaging API provided by the basic NetTLP driver.

4.4 tcpdump and Wireshark

To observe TLPs, we slightly modified tcpdump and implemented a Wireshark plugin. In the NetTLP platform, the encapsulated TLPs flow through the Ethernet link between the NetTLP adapter and the device host; hence, the TLPs can be easily captured by the monitoring tools of IP networking. The modified tcpdump can recognize the encapsulated TLPs and display the contents of TLPs on the popular tcpdump output. The Wireshark plugin also displays the contents of TLPs on the GUI. These tools offer researchers and developers a convenient method to observe TLPs.

4.5 Limitations

The current implementation of the NetTLP platform cannot handle the PCIe configuration space. The PCIe configuration space manages properties of the PCIe device such as Device ID, Vendor ID, and address regions of BAR spaces. The PCIe configuration space is stored in the memory of the PCIe device hardware. When the host boots up or re-scans PCIe devices, the devices use the CfgRd and CfgWr TLPs to communicate with the root complex to set up their PCIe configurations. In the current implementation of NetTLP adapter, the PCIe Endpoint IP core for Kintex 7 FPGA manages the PCIe configuration space as shown in Figure 4. The IP core does not allow user-defined logic to manipulate the configuration registers by raw TLPs. Therefore, the software PCIe devices cannot see and change their PCIe configurations. As a result, the current implementation does not support functionalities that require the manipulation of PCIe configuration registers, i.e., changing structures of MSI-X tables and SR-IOV.

5 Micro-benchmarks

To estimate performances of the software PCIe devices and applications, we conducted micro-benchmarks for the throughput and latency of DMAs on the NetTLP platform.

In the NetTLP platform, there are two directions of PCIe transactions: (1) from LibTLP to the NetTLP adapter, and (2) from the NetTLP adapter to LibTLP. They represent DMA reads and writes from a software PCIe device to a root complex, and DMA reads and writes from a root complex to a software PCIe device, respectively. In the former direction, we assume that PCIe transactions issued from the software PCIe device can be processed without packet loss because all of the components on the adapter host is hardware, which has higher bandwidth (the 16 Gbps PCIe Gen 2 4-lane link of the NetTLP adapter) than the 10 Gbps Ethernet link. In

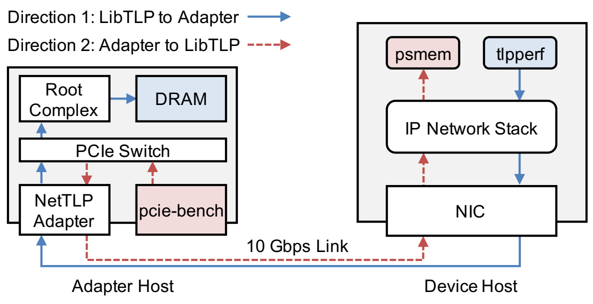

Figure 6: Benchmark setup.

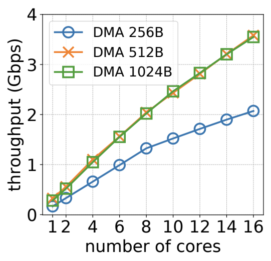

Figure 7: DMA Read throughput from LibTLP to the NetTLP adapter versus the number of CPU cores.

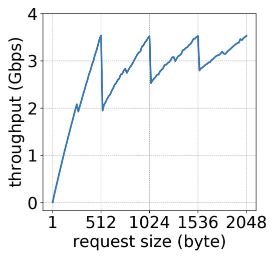

Figure 8: DMA Read throughput from LibTLP to the NetTLP adapter versus the request sizes.

the opposite direction, DMA reads from the root complex to the software PCIe devices also would not be dropped because the root complex does not send a memory read request until receiving a completion for the last read request (non-posted transaction). Based on this assumption, we measured throughput of DMA reads and writes from LibTLP (Section 5.1), and DMA reads from the NetTLP adapter (Section 5.2).

By contrast, the throughput of DMA writes from the root complex to the software PCIe device cannot be measured. The root-complex can send MWr TLPs up to the link speed of the NetTLP adapter without explicit acknowledgment (posted transactions). The current NetTLP adapter does not have mechanisms to notify congestion on the Ethernet link to the root complex; therefore, MWr TLPs are dropped if the 10 Gbps Ethernet link of the NetTLP adapter overflows. Notifying the overflow to the root complex and other devices is a future work. However, for recent peripherals such as Ethernet NICs and NVMe SSDs, usual use cases of memory writes to PCIe devices are updating registers on the devices from CPUs, and these do not require significant throughput. Therefore, we argue that the current NetTLP adapter is sufficient to prototype PCIe devices in software.

Figure 6 depicts the two directions and the components we used to generate PCIe transactions for the benchmarks. To generate PCIe transactions from LibTLP to the NetTLP adapter, we developed a LibTLP-based benchmark application called tlpperf. Users can send memory read and write requests to the memory on the adapter host through the NetTLP adapter from the device host by using tlpperf. For generating PCIe transactions in the opposite direction, we implemented a LibTLP-based pseudo memory device, called psmem, and slightly modified the pcie-bench [34]. psmem on the device host pretends a memory region associated with the BAR4 of the NetTLP adapter. As described in Section 4.1, TLPs to the BAR4 space of the NetTLP adapter are transmitted to the device host. When psmem receives a MWr TLP, psmem saves the data and the associating address. When psmem receives a MRd TLP, psmem sends CplD TLP(s) with proper data associating the requested address. In addition, to generate memory requests to the BAR4 of the NetTLP adapter, we modified pcie-bench implementation for NetFPGA-SUME. The modified pcie-bench can use the BAR4 space as the benchmark destination instead of main memory.

For the micro-benchmark, we prepared two machines for the adapter and device hosts. The adapter host was an Intel Core i9-9820X 10 core CPU and 32 GB DDR4 memory with an ASUS WS X299 SAGE motherboard. This motherboard has PCIe switches. The NetTLP adapter and the NetFPGA-SUME card for pcie-bench were installed on PCIe slots under the same PCIe switch. The device host was an Intel Core i9-7940X 12 core CPU, 32 GB DDR4 memory, and Intel X520 10 Gbps NIC with an ASUS PRIME X299-A motherboard. The device host was connected to the NetTLP adapter on the adapter host via a 10 Gbps Ethernet link. OSes were Linux kernel 4.20.2. Note that we enabled hyperthreading on the device host that had 12 physical cores to fully utilize 16 NIC queues by the tag-based UDP port distribution.

In the experiments described in this section, all the throughput results are goodput. The throughput does not include TLP and encapsulation headers. In addition, all memory requests in each iteration access the same address. We measured throughput and latency with random and sequential access patterns; however, there were no differences because of the memory access patterns in any experiment. The processing time for the software part is relatively dominant and obscures differences in performances because of the memory access patterns.

5.1 LibTLP to NetTLP Adapter

In the first benchmark, we measured the throughput of PCIe transactions from LibTLP to the memory on the adapter host through the NetTLP adapter. It is expected that the throughput would be limited by Linux kernel network stack performance where tlpperf runs because the data path on the adapter host is fully hardware and its links are the 16 Gbps PCIe Gen 2 4-lane link and the 10 Gbps Ethernet link.

Figure 7 shows the throughput of DMA reads issued by tlpperf on the device host. The key indicates request sizes of each DMA read request. As shown, the throughput linearly increases along with the number of CPU cores. This result

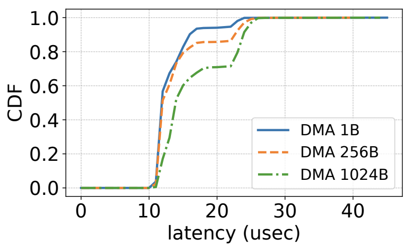

Figure 9: DMA Read latency from LibTLP to the NetTLP adapter.

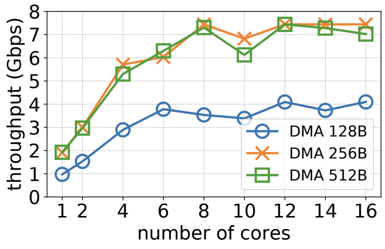

Figure 10: DMA Write throughput from LibTLP to the NetTLP adapter versus the number of CPU cores.

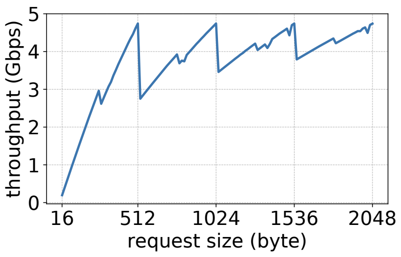

Figure 11: DMA Read throughput from the NetTLP adapter to LibTLP.

indicates that the tag-based UDP port distribution technique successfully utilizes multiple queues and multiple cores on the Linux-based device host. On the other hand, the read request size greater than 512-byte does not contribute to the throughput because the maximum read request size (MRRS) is 512-byte. The maximum throughput in this direction, which is approximately 3.6 Gbps, is less than the PCIe Gen 2 x1 link speed; however, the required throughput depends on applications and use cases. For example, Section 6 demonstrates use cases not depending on throughput. Note that the current LibTLP uses Linux Socket API; therefore, LibTLP would handle more UDP traffic with high-speed network I/O [28, 39].

Next, we measured the throughput of DMA reads from tlpperf with 16 cores while increasing the read request sizes by 16 bytes. The result shown in Figure 8 represents the *saw-tooth pattern*, which is also noted in the pcie-bench paper [34]. The saw-tooth pattern is caused by the packetized structure of the PCIe protocol. MRRS is 512-byte; therefore, when the request size is not a multiple of 512, the remaining bytes are transferred by a small size memory read. Such small-sized TLPs cause throughput reduction. Sizes of the small TLPs increase as the request sizes increase, so the throughput also increases until the request size exceeds the next multiple of 512. Slight reductions of the throughput after multiples of 256-byte are caused by the maximum payload size (MPS), which is 256-byte, in a similar manner. This result where the saw-tooth pattern appears as well as the hardware-based measurement by pcie-bench indicates that LibTLP correctly implements the packetization of the PCIe protocol.

In addition to the throughput, we measured the latency for DMA reads. The PCIe specification defines completion timeout; thus, evaluating the DMA read latency is crucial for prototyping PCIe devices in software. Figure 9 shows the result of 10000 DMA reads with 1-byte, 256-byte, and 1024-byte read requests generated by tlpperf. The latency increases with the request sizes; however, 99% latency is less than 27 microseconds regardless of the request sizes, and the maximum latency is 45 microseconds with 1024-byte DMA reads. These results correspond to the completion timeout range A (50 us to 10 ms). Therefore, we argue that prototyping PCIe devices in software with hardware root complexes is feasible from a latency perspective. According to the pcie-bench [34], DMA read latency inside a physical host is from 400 to 800 nanoseconds. Consequently, software processing for the network stack and the tlpperf application on the device host is dominant in the latency of the NetTLP platform.

We next measured the throughput of DMA writes from LibTLP. In contrast to DMA reads, DMA writes are posted transactions; therefore, we cannot measure the latency and throughput of DMA writes correctly. In this experiment, tlpperf calculates throughput when MWr TLPs are written to sockets. Figure 10 shows this measurement result. In addition to the DMA read results, DMA writes can also effectively use multiple cores and queues. In contrast to DMA reads, DMA writes reach the upper throughput with 256-byte DMA writes because MPS is 256-byte. Note that this throughput can be considered as transmitting throughput for UDP sockets of the Linux network stack.

5.2 NetTLP Adapter to LibTLP

For the second direction, we measured the throughput by generating PCIe transactions from the pcie-bench on the adapter host to the psmem running on the device host. Figure 11 shows the DMA read throughput on this direction. The result also represents the saw-tooth pattern as well as the opposite direction. Moreover, the thing that pcie-bench works with the software memory device demonstrates that the NetTLP platform can prototype one of the PCIe devices in software. Besides, the maximum throughput is approximately 4.7 Gbps. We confirmed that pcie-bench used TLP tag values from 0x00 to 0x17; thus, psmem with LibTLP could utilize the 16 cores in parallel by the tag-based UDP port distribution.

Table 2 shows DMA read latency from the pcie-bench on the adapter host to the psmem on the device host. We measured 100000 DMA reads for each request size. As shown, there are no significant differences by request sizes, unlike the original pcie-bench evaluation in hardware. This result is because the software processing on the device host—receiving and sending UDP packets—is dominant. However, the latency also meets the completion timeout range A.

Table 2: DMA Read latency from the pcie-bench to the psmem (microseconds).

Request size	Min	Median	Max	Stddev
256	14.312	17.268	87.456	1.321
512	12.2	18.764	68.552	1.550
1024	12.256	20.06	52.608	1.685
2048	11.612	18.588	68.224	2.385

6 Use Cases

This section demonstrates three use cases of NetTLP. We (1) observed specific behaviors of a commercial root complex and peripherals by capturing TLPs, (2) implemented a theoretical model of an Ethernet NIC as an actual NIC, and (3) demonstrate memory introspection for physical machines. All observations and demonstrations in this section were conducted on the same machines used in the micro-benchmarks.

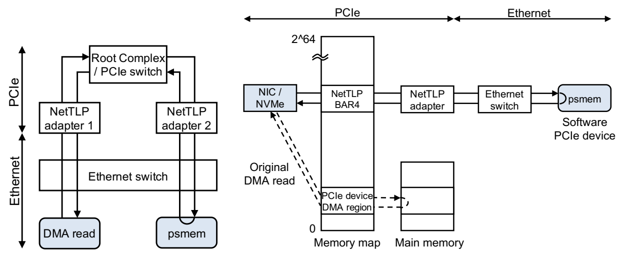
6.1 Capturing TLPs

As the first demonstration, we observe PCIe transactions of a commercial root complex, two Ethernet NICs, and two NVMe SSDs by capturing TLPs. The NetTLP adapter delivers TLPs over Ethernet links; thus, NetTLP enables us to analyze TLPs by using powerful IP network software with UNIX commands, i.e., tcpdump. Besides, the flexibility of PCIe topologies enables us to adapt NetTLP to observe various PCIe transactions issued and processed by different elements.

6.1.1 Root Complex and PCIe Switch

The first observation is to clarify the behavior of root complex. The PCIe specification does not allow PCIe switches to modify PCIe packets during switching. However, root complexes are permitted to split a PCIe packet into small PCIe packets when routing the PCIe packets between PCIe devices. The specification does not describe detailed mechanisms of TLP splitting on peer-to-peer device communication by root complexes. Although TLP splitting may negatively affect performance, its behavior depends on each root complex implementation, and observing the behavior is difficult. As a demonstration, we clarify this point by comparing actual TLPs through a root complex or a PCIe switch captured by NetTLP.

To capture the TLPs, we prepared two NetTLP adapters under the root complex or the PCIe switch on the machine used in the micro-benchmark. Figure 12a shows the topology for this observation. In the test scenario, a DMA read application on the device host sent a 512-byte MRd TLP to psmem through the two NetTLP adapters on the adapter host, and psmem returned CplD TLPs. Moreover, we switched the intermediate element from the PCIe switch to the root complex by changing PCIe slots where the NetTLP adapters were



(a) Root Complex. (b) NIC and NVMe devices.

Figure 12: Two topologies for capturing TLPs. We captured TLPs by port mirroring on the Ethernet switch.

installed. On this topology, we captured TLPs before and after passing through the PCIe switch or root complex by port mirroring on the Ethernet switch.

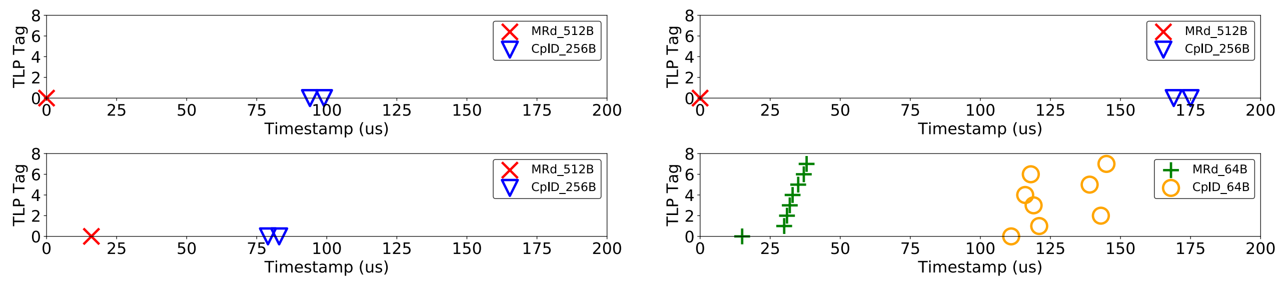
Figure 13 shows the captured TLPs. The x-axis indicates timestamps when a capture machine captured the TLPs from the mirror port. Note that the timestamps were stamped by NIC hardware so that the accuracy was on the nanosecond scale. The y-axis indicates TLP tag values of the TLPs. The TLPs were captured twice: before and behind the PCIe switch or root complex. The graphs on the upper row and lower row show the TLPs captured on the links connected to the NetTLP adapter 1 and adapter 2 depicted in Figure 12a, respectively.

Figure 13a confirms that the PCIe switch does not modify the TLPs as expected. The DMA read application sent a 512-byte MRd TLP, and psmem returned two 256-byte CplD TLPs. By contrast, Figure 13b reveals that the root complex split a 512-byte MRd TLP into eight 64-byte MRd TLPs with different TLP tag values when routing the TLPs between the NetTLP adapters. psmem returned eight 64-byte CplD TLPs, and the root complex rebuilt two 256-byte CplD TLPs from the small CplD TLPs. As a result, the DMA read application received the expected CplD TLPs that are aligned with MPS.

6.1.2 Ethernet NIC and NVMe SSD

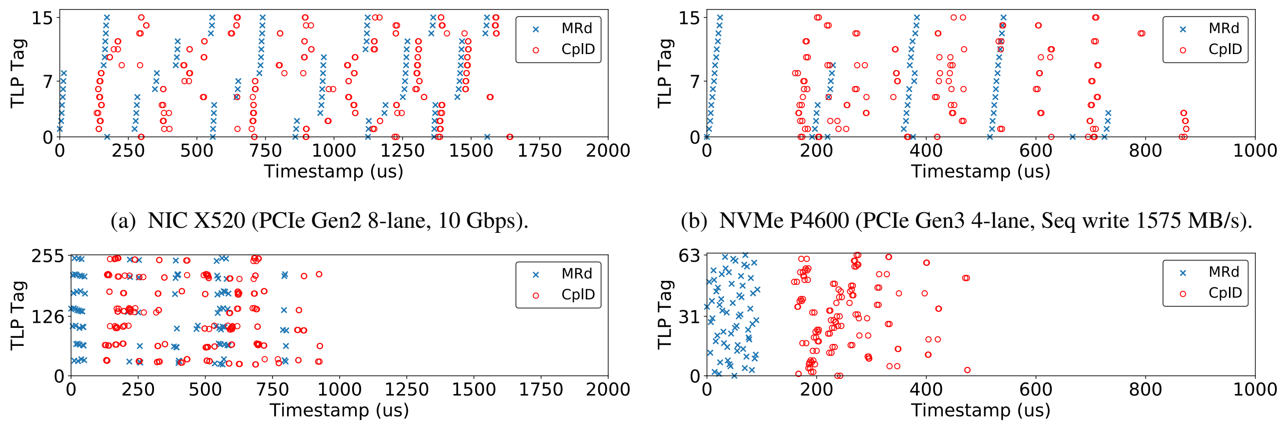
Next, we measured and compared TLPs generated by commercial NIC and NVMe devices. Knowledge of how product devices use TLPs would be a useful guideline for developing PCIe devices with high performance. General peripheral devices communicate with the CPU by DMA to the main memory. To capture the TLPs from the devices, we used modified netmap drivers [39] for Ethernet NICs and a modified UNVMe [32] for NVMe SSDs to change the DMA address from main memory to the BAR4 of the NetTLP adapter. As a result, NetTLP enables capturing the TLPs sent from the devices on the Ethernet link connected to the NetTLP adapter.

For observing various behaviors of PCIe devices, we prepared different types and speeds of devices: Intel X520 and XL710 NICs, and Intel P4600 and Samsung PM1725a NVMe SSDs. Throughput of the devices are as follows: Intel X520 is



(a) A 512-byte memory read via the PCIe switch. (b) A 512-byte memory read via the root complex.

Figure 13: Comparison of captured TLPs of DMA read across the PCIe switch or the root complex. The graphs on the lower row indicate the captured TLPs behind the PCIe switch or the root complex.



(a) NIC X520 (PCIe Gen2 8-lane, 10 Gbps). (b) NVMe P4600 (PCIe Gen3 4-lane, Seq write 1575 MB/s).

(c) NIC XL710 (PCIe Gen3 8-lane, 40 Gbps). (d) NVMe PM1725a (PCIe Gen3 8-lane, Seq write 2600 MB/s).

Figure 14: Comparison of tag field usage of the NIC and NVMe devices.

a 10 Gbps Ethernet NIC, Intel XL710 is a 40 Gbps Ethernet NIC, the sequential write speed of the Intel P4600 NVMe device is 1575 MB/s, and the sequential write speed of the Samsung PM1725 is 2600 MB/s. Figure 12b shows the experimental setup of this observation. In this setup, NIC or NVMe and the NetTLP adapter were installed in PCIe slots under the same PCIe switch. The devices sent MRd TLPs for sending packets or writing data to the NVMe SSDs, and the MRd TLPs were delivered to psmem. psmem then returned CplD TLPs with Ethernet frames prepared in advance for the NIC scenario or zero-filled data for the NVMe scenario. For the NIC scenario, the NICs sent 32 1500-byte packets, and for the NVMe scenario, the NVMe SSDs wrote 32-MB data to the SSDs. Note that the block size of the Intel P4600 is 512 bytes and that of the Samsung PM1725a is 4096 bytes; therefore, we adjusted the number of NVMe write commands to write 32-MB data. To capture the TLPs, we used port mirroring on the Ethernet switch between the NetTLP adapter and the device host where psmem runs as well as the last experiment.

Figure 14 shows the result of captured TLPs of the NIC and NVMe devices. The result reveals that each PCIe device uses the TLP tag differently. X520 and P4600 use tag values from 0 to 15, PM1725a uses values from 0 to 63, and XL710 uses values from 24 to 249. The PCIe link speeds have been improved along with generations of PCIe; however, MPS has hardly improved. As a result, these PCIe devices improve data transfer throughput by sending memory requests continuously by leveraging TLP tags. The numbers of used tag values increase along with the desired throughput of the devices. According to the latency measurement in pcie-bench [34], the latency of a 512-byte DMA read is approximately 580 nanoseconds. The calculated throughput from this latency is about 7 Gbps when not using the tag field. Therefore, exploiting the tag field well is an important matter to achieve the desired throughput as this observation revealed.

6.2 Prototyping an Ethernet NIC

To confirm that NetTLP can prototype PCIe devices in software, we implemented an Ethernet NIC as a proof-of-concept on the NetTLP platform. The target NIC we implemented is simple NIC introduced by pcie-bench [34]. The original

```

(b) TLPs for receiving a 98-byte ICMP reply packet.

Figure 15: tcpdump output of captured TLPs of the simple NIC implementation. `len` indicates length of data payload in DWORD.

simple NIC is a theoretical model of a simplistic Ethernet NIC, which does not have any performance optimizations such as DMA batching, for understanding PCIe interactions and calculating bandwidth. This nonexistent NIC model was a good target for demonstrating the productivity of NetTLP. NetTLP enables us to prototype such models of PCIe devices in software and confirm whether the models actually work with existent hardware root complexes.

The detailed interactions between a host and a simple NIC device are described in the model's implementation [2]. On the TX side, (1) the host updates a 4-byte TX queue tail pointer, (2) the device reads a 16-byte TX descriptor on the host memory, (3) the device reads the packet content and transmits the packet, and (4) the device generates 4-byte interrupt. On the RX side, (1) the host updates a 4-byte RX queue tail pointer, (2) the device reads a 16-byte RX descriptor on the host memory, (3) the device writes a received packet to the host memory, (4) the device generates 4-byte RX interrupt.

Our simple NIC implementation on the NetTLP platform performs an actual NIC with a physical root complex on the adapter host following the model's PCIe interaction. The implementation consists of two parts: a device driver for the NetTLP adapter and a software simple NIC device implementation using LibTLP. The device driver based on the basic driver treats the NetTLP adapter as an Ethernet NIC as well as usual drivers for hardware NICs. The software simple NIC creates a tap interface on the device host and uses the tap interface as its Ethernet port. The Ethernet frames transmitted to the NetTLP adapter are transferred to the device host as TLPs over the PCIe links and Ethernet links, and the Ethernet frames are transmitted to the tap interface. The software simple NIC implementation is about 400 lines of C codes, and it actually performs an Ethernet NIC.

TLPs of the simple NIC generated by the root complex and LibTLP can be observed on the Ethernet link. Figure 15a shows TLPs captured by the modified tcpdump when sending an ICMP echo packet through the simple NIC. The driver writes a TX queue pointer on the BAR4 of the NetTLP adapter (1st TLP), the simple NIC reads the TX descriptor and the packet content on 0x3bb26800 (2nd to 5th TLPs), and the simple NIC generates interrupt to 0xfee1a000 pointed by the MSI-X table after sending the packet to the tap interface (6th TLP). On the RX side shown in Figure 15b, the interaction starts from writing the received ICMP reply packet to the host memory (1st TLP) because the driver told the RX buffer to the simple NIC before receiving new packets. Afterward, the simple NIC updates the RX descriptor (2nd TLP) and generates an interrupt (3rd TLP). After the host consumes the received packet, the driver sends the buffer back to the simple NIC by updating the RX queue tail pointer (4th TLP), and the simple NIC reads the RX descriptor (5th and 6th TLPs). In this manner, the NetTLP enables implementing PCIe devices in software with hardware root complexes. Moreover, the interactions can be observed by the IP networking technique.

6.3 Physical Memory Introspection

The NetTLP provides flexible programmability for TLP interactions between hardware and software. This characteristic offers adaption of NetTLP to other use cases, for example, memory introspection. Methods for monitoring and injecting data on memory have been investigated for both physical [3,12,29,41,46] and virtual [17,49] environments. NetTLP also provides accesses to host memory via PCIe, which is similar to previous studies. However, the NetTLP adapter is a channel to manipulate the host memory remotely; therefore, researchers can implement their introspection and detection methods on top of LibTLP and IP network stack without implementing dedicated hardware or virtual machine monitors.

As the third use case, we demonstrate the possibility of adopting NetTLP into remote memory introspection through two naive applications. The first application is process-list command similar to an example of LibVMI [27]. The process-list collects process information on the Linux host equipped with a NetTLP adapter. Figure 16a shows an example usage of the process-list. When the process-list is executed, it finds

```
$ ./process-list -r 192.168.10.1 -b 1b:00 -s System.map

(b) codedump to obtain the code area of a specified process.

Figure 16: Two example applications for physical memory introspection by NetTLP. Both applications are executed on the device host and read the physical memory of the adapter host.

an address of `task_struct` representing the first process from the specified System.map of the adapter host. Next, the process-list starts to walk through `task_struct` structures of the adapter host using `dma_read()`.

Next, let us focus on a single process. codedump obtains a binary of a running process from the adapter host. Figure 16b shows an example usage of this command. The codedump finds `task_struct` for the specified process ID by using the same methods of the process-list and obtains `mm_struct` representing the virtual memory of the process. The codedump then converts process-specific addresses for the code area into corresponding physical addresses by walking through the page table. Lastly, the dumped code area by DMA reads from LibTLP can be treated as a usual binary object file that can even be reassembled by objdump command. In these manners, researchers and developers can easily implement their memory introspection methods on the NetTLP platform.

7 Related Work

Future Interconnect: Some next-generation interconnect specifications are designed by extending the functionality of PCIe. CCIX [13] and CXL [14] introduce cache coherency between processors and peripherals to their interconnects. CCIX uses the PCIe data link layer and defines its transaction layer, and CLX defines CLX extensions on the PCIe data link layer and transaction layer. OpenCAPI [36] and Gen-Z [18] support IEEE 802.3 Ethernet and the PCIe physical layer. These interconnects require hardware extensions for both peripherals and host chipsets. Although such next-generation interconnects introduce new features, they are still packet-based data communications. NetTLP delivers TLPs over Ethernet by exploiting the packet-based communications. Thus, we believe that the NetTLP design can be applied to future interconnects as long as they adopt the layering model and packet-based communications.

Difference between NetTLP and RDMA: As with NetTLP, Remote DMA (RDMA) protocols also achieve DMA from distant hosts over Ethernet and IP networks for high speed interconnect. RoCEv2 encapsulates the Infiniband header and payload with Ethernet, IP, and UDP headers [8]. iWARP uses Ethernet, IP, and TCP headers [38]. In contrast to their purposes, NetTLP aims to provide the observability of PCIe transactions; therefore, it adopts directly encapsulating TLPs in IP and Ethernet. RDMA protocols need to convert the PCIe protocol into RDMA protocol in RDMA adapters. Thus, they lack observability of PCIe protocols that we demonstrated through the use cases.

Device drivers for software PCIe devices: NetTLP has made PCIe prototyping easier, but it has not contributed to the productivity of device drivers. Developing device drivers still requires certain effort. For improving the productivity of device drivers in the NetTLP platform, there are two approaches: the first approach is to use frameworks that automatically generate device drivers from templates related to protocol specifications and device characteristics [42,43]. Another approach is to write device drivers in userspace as with DPDK [20] while using some assists [19].

8 Conclusion

In this paper, we have proposed NetTLP that enables developing software PCIe devices that can interact with hardware root complexes. The key technique to achieve the platform is to separate the PCIe transaction layer into software and then connect the software transaction layer and the hardware data link layer by delivering TLPs over Ethernet and IP networks. Researchers and developers can prototype their own PCIe devices in software and observe actual TLPs by the IP networking techniques such as tcpdump. The use cases in this paper showed the observation of the TLP-level behaviors of the root complex and the product NICs and NVMe SSDs, the 400 LoC software Ethernet NIC implementation interacting with the hardware root complex, and physical memory introspection. We believe that the high productivity and observability on the NetTLP platform demonstrated through the use cases contribute to current and future PCIe development on both research and industrial communities.

Near-Optimal Latency Versus Cost Tradeoffs in Geo-Distributed Storage

Muhammed Uluyol, Anthony Huang, Ayush Goel, Mosharaf Chowdhury, and Harsha V. Madhyastha
University of Michigan

Abstract— **By replicating data across sites in multiple geographic regions, web services can maximize availability and minimize latency for their users. However, when sacrificing data consistency is not an option, we show that service providers have to today incur significantly higher cost to meet desired latency goals than the lowest cost theoretically feasible. We show that the key to addressing this sub-optimality is to 1) allow for erasure coding, not just replication, of data across data centers, and 2) mitigate the resultant increase in read and write latencies by rethinking how to enable consensus across the wide-area network. Our extensive evaluation mimicking web service deployments on the Azure cloud service shows that we enable near-optimal latency versus cost tradeoffs.**

1 Introduction

Replicating data across data centers is important for a web service to tolerate the unavailability of some data centers [1] and to serve users with low latency [5]. A front-end web server close to a user can serve the user's requests by accessing nearby copies of relevant data (see Figure 1). Even in collaborative services such as Google Docs and ShareLaTeX, accessing a majority of replicas suffices for a front-end to read or update shared data while preserving consistency.

However, it is challenging to keep data spread across the globe strongly consistent as no single design can simultaneously minimize read latency, write latency, and cost.

- To preserve consistency, *any* subset of sites which are accessed to serve a read must overlap with *all* subsets used for writes. Therefore, allowing a front-end to read from nearby data sites forces other front-ends to write to distant data sites, thus increasing write latency.
- Similarly, providing low read latency requires having at least one data site near each front-end, thereby increasing the total number of data sites. This inflates expenses incurred both for storage and for data transfers to synchronize data sites.

Given these tradeoffs, service providers must determine how to meet their desired latency goals at minimum cost. Or, correspondingly, how to minimize read and write latencies given a cost budget? In this paper, we make the following contributions towards addressing these questions.

1. We show that existing solutions for enabling strongly consistent distributed storage are far from optimal in trading off latency versus cost. The cost necessary to satisfy bounds on read and write latencies is often significantly higher than the lowest cost theoretically feasible. For example, across a range of access patterns and latency bounds, the state-of-the-art geo-replication protocol EPaxos [51] imposes on average 30% higher storage cost than is optimal (§5.1.2). This sub-optimality also inflates the minimum latency bounds satisfiable within a cost budget.

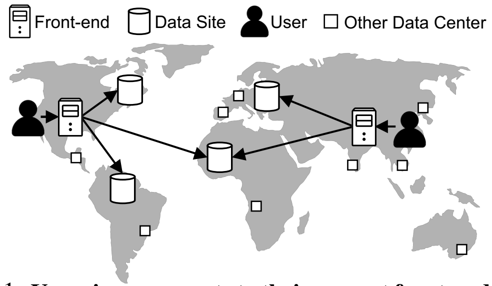

Figure 1: **Users issue requests to their nearest front-end servers which in turn access geo-distributed storage.**

2. We demonstrate the feasibility of achieving near-optimal latency versus cost tradeoffs in strongly consistent geo-distributed storage. In other words, we do not merely improve upon the status quo, but show that there remains little room for improvement over the tradeoffs enabled by PANDO, our new approach for consensus across the wide-area network. PANDO exploits the property that, from any data center's perspective, some data centers are more proximate than others in a geo-distributed deployment. Therefore, beyond reducing the *number of round-trips* of wide-area communication when executing reads and writes (as has typically been the goal in prior work [49, 42, 51]), it is equally important to reduce the *magnitude of delay incurred on every round-trip*. We apply this principle in two ways.

2a. We show how to erasure-code objects across data sites without reads incurring higher wide-area latencies compared to replicated data. By splitting each object's data and storing one split (instead of one replica) per data site, a service can use its cost budget to spread each object's data across more data centers than is feasible with replication. To leverage this increased geographic spread for minimizing latencies, PANDO separates out two typically intertwined aspects of consensus: discovering whether the last write completed, and determining how to resolve any associated uncertainty. Since writes seldom fail in typical web service deployments, we enable a client to read an object by first communicating with a small subset of nearby data sites; only in the rare case when it is uncertain whether the last write completed does the client incur a latency penalty to discover how to resolve the uncertainty.

2b. In the wide-area setting, we show how to reach consensus in two rounds, yet approximate a one-round protocol's latency. Executing writes in two rounds simplifies compatibility with erasure-coded data, and we ensure that this approach has little impact on latency. First, PANDO requires clients to contact a smaller, more proximate subset of data sites in the first round than in the second round. Second, after a client initiates the first round, it delegates initiation of the second round to a more central data center, which receives all responses from the first round. By combining these two measures, messaging delays incurred in the first phase of a write help reduce the latency incurred in the second phase, instead of adding to it.

3. We compare PANDO to state-of-the-art consensus protocols via extensive measurement-driven analyses and in deployments on Azure. In the latency–cost tradeoff space, we find that PANDO reduces by 88% the median gap between achievable tradeoffs and the best theoretically feasible tradeoffs. Moreover, PANDO can cut dollar costs to meet the same latency goals by 46% and lower 95^{th} percentile read latency by up to 62% at the same storage overhead.

2 Setting and Motivation

We begin by describing our target setting, the approach we use for enabling globally consistent reads and writes, and the shortcomings of existing solutions that use this approach.

2.1 System model, goals, and assumptions

We seek to meet the storage needs of globally deployed applications, such as Google Docs [4] and ShareLaTeX [8], in which low latency and high availability are critical, yet weak data consistency (such as eventual or causal) is not an option. In particular, we focus on enabling a geo-distributed object/key-value store which a service's front-end servers read from and write to when serving requests from users. We aim to support GETs and conditional-PUTs on any individual key; we defer support for multi-key transactions to future work. In contrast to PUTs (which blindly overwrite the value for a key), conditional-PUTs attempt to write to a specific version of a key and can succeed only if that version does not already have a committed value. This is essential in services such as Google Docs and ShareLaTeX to ensure that a client cannot overwrite an update that it has not seen.

In enabling such a geo-distributed key-value store, we are guided by the following objectives:

- **Strong consistency:** Ensure all reads and writes on any key are linearizable; i.e., all writes are totally ordered and every read returns the last successful write.
- **Low latency:** Satisfy service provider's SLOs[1] (service-level objectives) for bounds on read and write latencies, so as to ensure a minimum quality-of-service for all users. We focus on the wide-area latency incurred when serving reads or writes, assuming appropriate capacity planning and load balancing to bound queuing delays.
- **Low cost:** Minimize cost (sum of dollar costs for storage, data transfers, storage operations, and compute) necessary to satisfy latency goals. Since cost for storage operations and data transfers grows with more copies stored, in parts of the paper, we use storage overhead (i.e., number of copies stored of every data item) as a proxy for cost. This frees us from making any assumptions about pricing policy or the workload (e.g., read-to-write ratio).
- **Fault-tolerance:** Serve requests on any key as long as fewer than f data centers are unavailable.

[1]Unlike SLAs, violations of SLOs are acceptable, but need to be minimized.

We focus on satisfying input latency bounds in the absence of conflicts and failures—both of which occur rarely in practice [11, 2, 48, 29]—but seek to minimize performance degradation when they do occur (§3.5 and §5.1.2). In addition, we build upon state-of-the-art cloud services which offer low latency variance between their data centers [34] and within their intra-data center storage services (e.g., Azure's CosmosDB provides a 10 ms tail read latency SLA [12]).

Note that, in order to satisfy desired latency SLOs at minimum cost (or to minimize latencies given a cost budget), a service cannot select the data sites for an object at random. Instead, as we describe later in Section 4, any service must utilize its knowledge of an object's workload (e.g., locations of the users among whom the object is shared) in doing so.

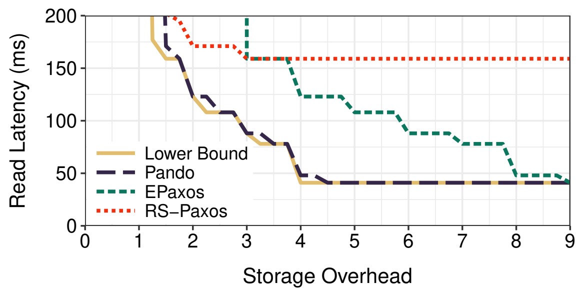
2.2 Approach

One can ensure linearizability in distributed storage by serializing all writes through a leader and rely on it for reads, e.g., primary-backup [18], chain replication [68], and Raft [57]. A single leader, however, cannot be close to all front-ends across the globe. Front-ends which are distant from the leader will have to suffer high latencies.

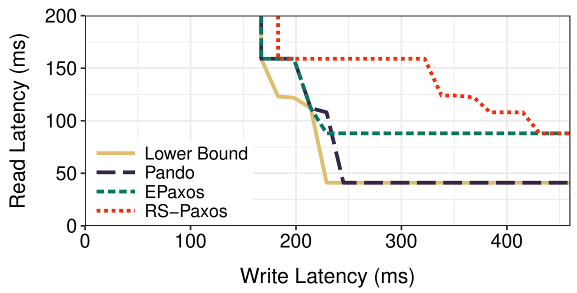
To reduce the need to contact a distant leader, one could use read leases [21, 52] and migrate the leader based on the current workload, e.g., choose as the leader the replica closest to the front-end currently issuing reads and writes. However, unless the workload exhibits very high locality, tail latency will be dominated by the latency overheads incurred during leader migration and lease acquisition.

To keep read and write latencies within specified bounds irrespective of the level of locality, we pursue a leaderless approach. Among the leaderless protocols which allow every front-end to read and write data from a subset of nearby data sites (a read or write quorum), we consider those based on Paxos because it enables consensus. Other quorum-based approaches [20] which only enable atomic register semantics (i.e., PUT and GET) are incapable of supporting conditional updates [35]. While there exist many variants of Paxos, in all cases, we can optimize latencies in two ways.

First, instead of executing Paxos, a front-end can read an object by simply fetching the object's data from a read quorum. To enable this, a successful writer asynchronously marks the version it wrote as committed at all data sites. In the common case, when there are no failures or conflicts, a read is complete in one round trip if the highest version seen across a read quorum is marked as committed [44].



(a) Write latency ≤ 300 ms



(b) Storage overhead $\leq 6\times$

Figure 2: **Slices of the three-dimensional tradeoff space where we compare latency estimates for replication-based EPaxos [51], erasure coding-based RS-Paxos [53], and our solution PANDO against a lower bound. Front-ends are in Azure's Australia East, Central India, East Asia, East US, and Korea South data centers, whereas data sites are chosen from all Azure data centers.**

Second, instead of every front-end itself executing reads and writes, we allow for it to relay its operations through a delegate in another data center. The flexibility of utilizing a delegate can be leveraged to reduce latency when, compared to the front-end, that delegate is more centrally placed relative to the data sites of the object being accessed.

2.3 Sub-optimality of existing solutions

The state-of-the-art Paxos variant for geo-replicated data is EPaxos [51], as we show in Section 5. For typical replication factors (i.e., 3 or 5), EPaxos enables any front-end to read/write with one round of wide-area communication with the nearest majority of replicas. If lower read latencies than feasible with $2f+1$ replicas are desired, then one can use a higher replication factor N, set the size R of read quorums to be $\geq f+1$ (to ensure overlap with write quorums even in the face of f failures) and set the size W of write quorums to $N-R+1$ (to preserve consistency).

Figure 2 shows the tradeoffs enabled by EPaxos for an example access pattern. For each read latency bound, these graphs respectively plot the minimum storage overhead and write latency bounds that are satisfiable. As we discuss later in the paper, we compute these bounds by solving protocol-specific mixed integer programs (§4) which take as input the expected access pattern and latency measurements between all pairs of data centers (§5.1). We show two two-dimensional slices of the three-dimensional read latency–write latency–storage overhead tradeoff space.

To gauge the optimality of the tradeoffs achievable with EPaxos, we compare it against a lower bound. Given a bound on read latency, the minimum storage overhead necessary and the minimum write latency bound that can be satisfied cannot be lower than those determined by our lower bound. Though the lower bound may be unachievable by any existing consensus protocol, we compute it by solving a mixed integer program which assumes that reads and writes can be executed in a single round and enforces the following properties that *any* quorum-based approach must respect:

- *Tolerate unavailability of $\leq f$ data centers:* All data sites in at least one read and one write quorum must be available in the event that $\leq f$ data centers fail.
- *Prevent data loss:* At least one copy of data must remain in any write quorum when any f data sites are unavailable.
- *Serve reads:* The data sites in any read quorum must collectively contain at least one copy of the object.
- *Preserve strong consistency:* All read–write and write–write quorum pairs must have a non-empty intersection.

Equally important are constraints that we do *not* impose: all read quorums (same for write quorums) need not be of the same size, and an arbitrary fraction of an object's data can be stored at any data site.

Figure 2 shows that EPaxos is sub-optimal in two ways. First, to meet any particular bound on read latency, EPaxos imposes a significant cost overhead; in Figure 2(a), EPaxos requires at least 9 replicas to satisfy the lowest feasible read latency bound (40 ms), whereas the lower bound storage overhead is 4x. Recall that, greater the number of copies of data stored, higher the data transfer costs when reading and writing. Second, given a cost budget, the read latencies achievable with EPaxos are significantly higher than the lower bound; in Figure 2(b), where storage overhead is capped at 6x, we see that the minimum read latency achievable with EPaxos (80 ms) is twice the lower bound (40 ms).

Of course, a lower bound is just that; some of the tradeoffs that it deems feasible may potentially be unachievable. However, for the example in Figure 2 and across a wide range of configurations in Section 5, we show that PANDO comes close to matching the lower bound. We describe how next.

3 Design

The fundamental source of EPaxos's sub-optimality in trading off cost and latency is its reliance on replication. Replication-based approaches inflate the cost necessary to meet read latency goals because spreading an object's data across more sites entails storing an additional *full copy* at each of these sites. To enable latency versus cost tradeoffs that are closer to optimal, the key is to store a *portion* of an object's data at each data site, like in the lower bound.

Therefore, we leverage erasure coding, a data-agnostic approach which enables such flexible data placement while matching replication's fault-tolerance at lower cost [69]. For example, to tolerate $f = 1$ failures, instead of requiring at least $2f + 1 = 3$ replicas, one could use Reed-Solomon coding [60] to partition an object into $k = 2$ splits, generate $r = 2$ parity splits, and store one split each at $k + r = 4$ sites; any k splits suffice to reconstruct the object's data. Compared to replication, this reduces storage overhead to $2\times$, thus also reducing the number of copies of data transferred over the wide-area when reading or writing.

State-of-the-art implementations of erasure coding [9] require only hundreds of nanoseconds to encode or decode kilobyte-sized objects. This latency is negligible compared to wide-area latencies, which range from tens to hundreds of milliseconds. Moreover, the computational costs for encoding and decoding pale in comparison to costs for data transfers and storage operations (§ 5.1.3).

3.1 Impact of erasure coding on wide-area latency

While there exist a number of protocols which preserve linearizability on erasure-coded data [15, 24], they largely focus on supporting PUT/GET semantics. To support conditional updates, we consider how to enable consensus on erasure-coded data with a leaderless approach such as Paxos. We have one of two options.

One approach would be to extend one of several one-round variants of Paxos to work on erasure-coded data. However, most of these protocols require large quorums (e.g., a write would have to be applied to a super-majority [42] or even all [49] data sites), rendering them significantly worse than the lower bound. Whereas, extending EPaxos [51], which requires small quorums despite needing a single round, to be compatible with erasure-coded data is far from trivial given the complex mechanisms that it employs for failure recovery.

Therefore, we build upon the classic two-phase version of Paxos [40] and address associated latency overheads. In either phase, a writer (a front-end or its delegate) communicates with all the data sites of an object and waits for responses from a write quorum. In Phase 1, the writer discovers whether there already is a value for the version it is attempting to write and attempts to elect itself leader for this version. In Phase 2, it sends its write to all data sites. A write to a version succeeds only if, prior to its completion of both phases, no other writer has been elected the leader. If the leader fails during Phase 2 but the write succeeds at a quorum of data sites, subsequent leaders will adopt the existing value and use it as part of their Phase 2, ensuring that the value for any specific version never changes once chosen.

This natural application of Paxos on erasure-coded data, called RS-Paxos [53], is inefficient in three ways.

- **Two rounds of wide-area communication.** Any reduction in read latency achieved by enabling every front-end to read from a more proximate read quorum has twice the adverse effect on write latency. In Figure 2(b), we see that when the read latency bound is stringent (e.g., $\leq$ 100 ms), the minimum write latency bound satisfiable with RS-Paxos is twice that achievable with EPaxos. When the read latency bound is loose (e.g., $\geq$ 150 ms), write latency inflation with RS-Paxos is lower because the data sites are close to each other and front-ends benefit from delegation.

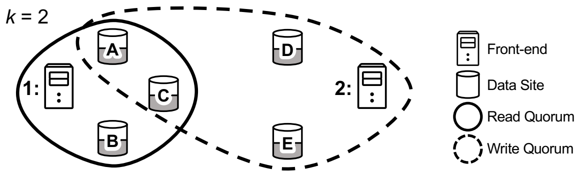


Figure 3: **Example execution of RS-Paxos on an erasure-coded object, whose data is partitioned into $k = 2$ splits. For all readers and writers to be able to reconstruct the last successful write, any write quorum must have an overlap of k or more data sites with every read and every write quorum.**

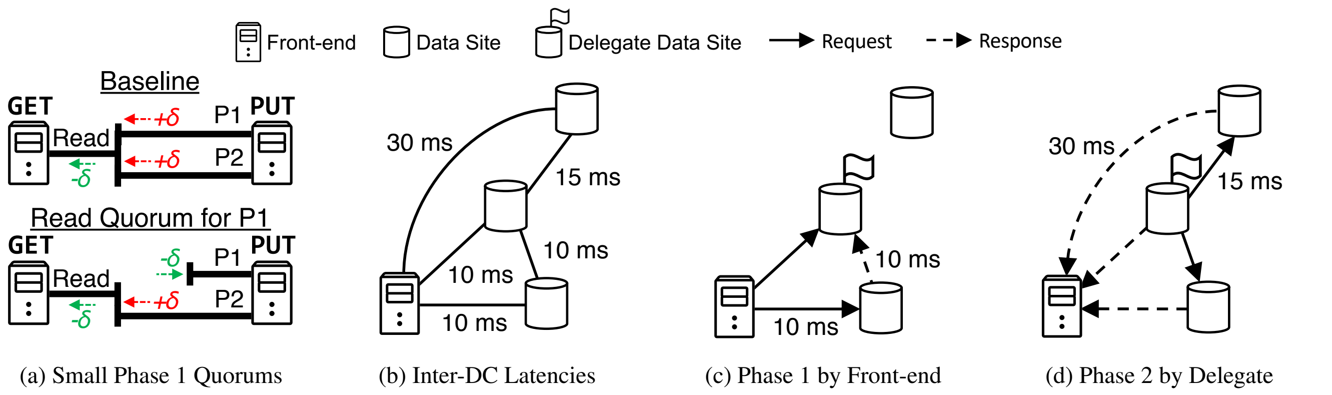
- **Increased impact of conflicts.** Executing writes in two rounds makes them more prone to performance degradation when conflicts arise. When multiple writes to the same key execute concurrently, none of the writes may succeed within two rounds. Either round of each write may fail at more than a quorum of data sites if other writes complete one of their rounds at those sites.
- **Larger intersections between quorums.** As we see in Figure 2(a), at storage overheads of 4x or more, the minimum read latency bound satisfiable with RS-Paxos is significantly higher than that achievable with EPaxos. This arises because, when an object's data is partitioned into k splits, every read quorum must have an overlap of at least k sites with every write quorum (see Figure 3). Thus, erasure coding's utility in helping spread an object's data across more sites (than feasible with replication for the same storage overhead) is nullified.

3.2 Overview of PANDO

What if these inefficiencies did not exist when executing Paxos on erasure-coded data? To identify the latency versus cost tradeoffs that would be achievable in this case, we consider a hypothetical ideal execution of Paxos on erasure-coded data: one which requires a single round of communication and can make do with an overlap of only one site between read–write and write–write quorum pairs. For the example used in Figure 2, this hypothetical ideal (not shown in the figure) comes close to matching the lower bound.

Encouraged by this promising result, we design PANDO to approximate this ideal execution of Paxos on erasure-coded data. First, we describe how to execute Paxos in two rounds on geo-distributed data, yet come close to matching the messaging delays incurred with one-round protocols. Second, leveraging the rarity of conflicts and failures in typical web service workloads, we describe how to make do with a single data site overlap between quorums in the common case. Finally, we discuss how to minimize performance degradation when conflicts do arise. In our description, we assume an object's data is partitioned into k splits.



(a) Small Phase 1 Quorums (b) Inter-DC Latencies (c) Phase 1 by Front-end (d) Phase 2 by Delegate

Figure 4: **(a) Reusing read quorums in Phase 1 of writes enables reduction in read latency without impacting (Phase 1 + Phase 2) latency for writes. (b) Example deployment with one-way delays between relevant pairs of data centers shown. Phase 1 quorum size is 2 and Phase 2 quorum size is 3. If same (Phase 2) quorum were used in both phases of a write, like in RS-Paxos, write latency would be 120 ms. (c) and (d) By directing Phase 1 responses to a delegate and having it initiate Phase 2, Pando reduces write latency to 65 ms (20 ms in Phase 1 + 45 ms in Phase 2), close to the 60 ms latency feasible with one-round writes.**

3.3 Mitigating write latency

We reduce the latency overhead of executing Paxos in two rounds by revisiting the idea of delegation (§ 2.2): a front-end sends its write request to a stateless delegate, which executes Paxos and returns the response. When data sites are spread out (to enable low read latencies), two round-trips to a write quorum incurs comparable delay from the front-end versus from the delegate. The round-trip from the front-end to the delegate proves to be an overhead.

To mitigate this overhead, what if 1) transmission of the message from the front-end to the delegate overlaps with Phase 1 of Paxos, and 2) transmission of the response back overlaps with Phase 2? The latency for a front-end to execute the two-phase version of Paxos would then be roughly equivalent to one round-trip between the front-end and the delegate, thus matching the latency feasible with a one-round protocol. We show how to make this feasible in two steps.

3.3.1 Shrinking Phase 1 quorums

First, we revisit the property of classic Paxos that a writer needs responses from the same number of data sites in both phases of Paxos: the size of a write quorum. To ensure that a writer discovers any previously committed value, Paxos only requires that any Phase 1 quorum intersect with every Phase 2 quorum; Phase 1 quorums need not overlap [37]. In Pando, we take advantage of this freedom to use a smaller quorum in the first phase of Paxos than in the second phase.

We observe that the intersection requirements imposed on Phase 1 and Phase 2 quorums are precisely the properties required of read and write quorums: any read quorum must intersect with every write quorum, whereas no overlap between read quorums is required. Therefore, when executing Phase 1 of Paxos to write to an object, it suffices to get responses from a read quorum, thus allowing improvements in read latency to also benefit leader election. A writer (a front-end or its delegate) needs responses from a write quorum only when executing Phase 2.

Figure 4(a) illustrates the corresponding improvements in write latency. When a quorum of the same size is used in both phases of a write, a reduction of δ in the read latency bound results in a 2δ increase in the minimum satisfiable write latency bound (because of the need for read and write quorums to overlap). In contrast, our reuse of read quorums in the Phase 1 of writes ensures that spreading out data sites to enable lower read latencies has (roughly speaking) no impact on write latency; when read quorums are shrunk to reduce the read latency bound by δ, the increase of δ in Phase 2 latency (to preserve overlap between quorums) is offset by the decrease of δ in Phase 1 latency.

3.3.2 Partially delegating write logic

While our reuse of read quorums in Phase 1 of a write helps reduce write latency, Phase 2 latency remains comparable to a one-round write protocol. Therefore, the total write latency remains significantly higher than that feasible with one-round protocols.

Pando addresses this problem via *partial* use of delegation. Rather than having a front-end executing a write either do all the work of executing Paxos itself or offload all of this work to a delegate, we offload *some* of it to a delegate.

Figures 4(c–d) show how this works in Pando. A front-end initiates Phase 1 of Paxos by sending requests to data sites of the object it is writing to, asking them to send their responses to a chosen delegate. In parallel, the front-end sends the value it wants to write directly to the delegate. Once the delegate receives enough responses (i.e., the size of a read quorum), it will either inform the front-end that Phase 1 failed (the rare case) or initiate Phase 2 (the common case), sending the value to be written to all data sites for the object. Those data sites in turn send their responses directly back to the front-end, which considers the write complete once it receives responses from a write quorum.

Note that partial delegation preserves Paxos's fault tolerance guarantees. To see why, consider the case where a end-user's client sends the same request to two front-ends—perhaps due to suspecting that the first front-end has failed—and both front-ends execute the request. Paxos guarantees that at most one of these writes will succeed. Similarly, with partial delegation, in the rare case when the front-end suspects that the delegate is unavailable, it can simply re-execute both phases on its own. Paxos will resolve any conflicts and at most one of the two writes (one executed via the delegate and the other executed by the front-end) will succeed.

Thanks to the heterogeneity of latencies across different pairs of data centers, the use of small Phase 1 quorums combined with the delegation of Phase 2 eliminates most of the latency overhead of two-phase writes. In Figure 4(b-d), the two techniques reduce write latency down from 120 ms with classic Paxos to 65 ms with PANDO, only 5 ms higher than what can be achieved with a one-round protocol. The remaining overhead results from the fact that there still has to be some point of convergence between the two phases.

3.4 Enabling smaller quorums

The techniques we have described thus far lower the minimum write latency SLO that is satisfiable given an SLO for read latency. However, as we have seen in Figure 2(a), erasure coding inflates the minimum read latency SLO achievable given a cost budget (e.g., a bound on storage overhead). As discussed earlier in Section 3.1, this is due to the need for larger intersections between quorums when data is erasure-coded, as compared to when replicated.

Recall that the need for an intersection of k data sites between any pair of read and write quorums exists so that any read on an object will be able to reconstruct the last value written; at least k splits written during the last successful write will be part of any read quorum. Thus, linearizability is preserved even in the worst case when a write completes at the minimum number of data sites necessary to be successful: a write quorum. However, since concurrent writes are uncommon [48, 29] and data sites are rarely unavailable in typical cloud deployments [11, 2], most writes will be applied to all data sites. Therefore, in the common case, all data sites in any read quorum will reflect the latest write.

In PANDO, we leverage this distinction between the common case and the worst case to optimize read latency (and equivalently any write's Phase 1 latency, given that PANDO uses the same quorum size in both cases) as follows.

Read from smaller quorum in the common case. After issuing read requests to all data sites, a reader initially waits for responses from a subset which is 1) at least of size k and 2) has an intersection of at least one site with every write quorum; we refer to this as a Phase 1a quorum. In the common case, all k splits have the same version and at least one of them is marked committed; the read is complete in this case. An overlap of only one site with every write quorum

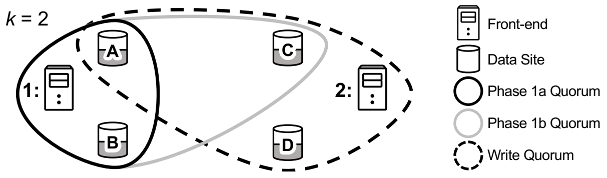


Figure 5: **For an object partitioned into $k = 2$ splits, PANDO requires an overlap of only one site between any Phase 1a and Phase 2 quorum. Responses from the larger Phase 1b quorum are needed only in the case of failure or conflict.**

suffices for the reader to discover the latest version of the object; at least one of the splits received so far by the reader will be one written by the last successful write to this object.

Read from larger quorum if failure or conflict. At this juncture, if the last successful write has not yet been applied to all data sites, the reader may only know the latest version of the object but not the value of that version. To reconstruct that value, the reader must wait for responses from more data sites until the subset it has heard from has an overlap of k sites or more with every write quorum; this is a Phase 1b quorum. As a result, a reader must incur the latency penalty of waiting for responses from farther data sites only if the last successful write was executed when either some data sites were unavailable or a conflicting write was in progress.

In the example in Figure 5, Front-end 1 can complete reading based on responses from sites A and B in the common case since two splits suffice to reconstruct the object. If the last write was from Front-end 2 and this write completed only at a subset of sites, there are two cases to consider:

- If Front-end 2's write has been applied to a write quorum (say A, C, and D), then the response from site A will help Front-end 1 discover the existence of this write. Front-end 1 needs an additional response from C in this case to be able to reconstruct the value written by Front-end 2.
- If Front-end 2's write has been applied to less than a write quorum (say, A and D), then Front-end 1 may be unable to find k splits for this version even from a Phase 1b quorum (A, B, and C). In this case, that value could not have been committed to *any* Phase 2 quorum. Therefore, the reader falls back to the previous version. PANDO garbage collects the value for a version only once a value has been committed for the next version (§4). The overhead of storing multiple versions of a key will be short-lived in our target setting where failures and write conflicts are rare.

Phase 1a and 1b quorums can also be used as described above during the first round of a write. The only difference in the case of writes is that responses from data sites can be potentially directed to a delegate at a different data center than the one which initiates Phase 1.

To preserve correctness of both reads and writes, the minimum size of Phase 1a quorums must be $\max(k, f+1)$, and Phase 1b and Phase 2 quorums must contain at least $f+k$ data sites. These quorum sizes are inter-dependent because any Phase 1a quorum must have a non-empty overlap with every Phase 2 quorum and any Phase 1b or Phase 2 quorum must have an overlap of at least k sites with every Phase 2 quorum. For each of the three quorum types, all quorums of that type are of the same size and any subset of data sites of that size represent a valid quorum of that type.

Note that, if further reductions in common-case read latency are desired, one could use timed read leases as follows [21, 52]. Instead of using the normal read path, a front-end that holds a lease for a key could cache the value or fetch it from k nearby data sites to avoid the latency of communicating with a complete Phase 1a quorum. However, this approach would not benefit tail latency for reads and may increase latency for writes.

3.5 Reducing impact of conflicting writes

Lastly, we discuss how PANDO mitigates performance degradation when conflicts arise. As mentioned before (§2), since conflicts rarely occur in practice [48, 29], we allow for violations of input latency bounds when multiple writes to a key execute concurrently. However, we ensure that the latency of concurrent writes is not arbitrarily degraded.

Our high-level idea is to select one of every key's data sites as the leader and to make use of this leader *only when conflicts arise*. PANDO's leaderless approach helps satisfy lower latency bounds by eliminating the need for any front-end to contact a potentially distant leader. However, when a front-end's attempted write fails and it is uncertain whether a value has already been committed for this version, the front-end forwards its write to the leader. In contrast to the front-end retrying the write on its own, relying on the leader can ensure that the write completes within at most two rounds.

To make this work, we ensure that any write executed by a key's leader always supersedes writes to that key being attempted in parallel by front-ends. For this, we exploit the fact that front-ends always retry writes via the leader, i.e., any front-end will attempt to directly execute a write at most once. Therefore, when executing Paxos, we permit any front-end to use proposal numbers of the form (0, front-end's ID) but only allow the leader to set the first component to values greater than or equal to 1, so that its writes take precedence at every data site.

Note that, since we consider it okay to violate the write latency bound in the rare cases when conflicts occur, we do not require the leader to be close to any specific front-end. Therefore, leader election can happen in the background (using any of a number of approaches [23, 14]) whenever the current one fails. If conflicting writes are attempted precisely when the leader is unavailable, these writes will block until a new leader is elected. Like prior work [51, 40], PANDO cannot bound worst-case write latency when conflicts *and* data center failures occur simultaneously.

A proof of PANDO's correctness and a TLA+ specification are in Appendices A and B.

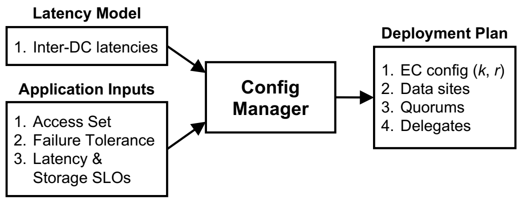

Figure 6: **Selecting a deployment plan with ConfigManager.**

4 Implementation

To empirically compare the manner in which different consensus approaches trade off read latency against write latency and cost, we implemented a key-value store which optimizes the selection of data sites for an object based on knowledge of how the object will be accessed.

ConfigManager. Central to this key-value store is the ConfigManager, which sits off the data path (thus not blocking reads and writes) and identifies *deployment plans*, one per access pattern. As shown in Figure 6, a deployment plan determines the number of splits k that the key's value is partitioned into, the number of redundant splits r, and the $k + r$ data sites at which these splits are stored; $k = 1$ corresponds to replication, and Reed-Solomon coding [60] is used when $k > 1$. The deployment plan also specifies the sizes of different quorum types and the choice of delegates (if any).

To make this determination, in addition to the application's latency, cost, and fault-tolerance goals, ConfigManager relies on the application to specify every key's *access set*: data centers from which front-ends are expected to issue requests for the key. An application can determine an object's access set based on its knowledge of the set of users who will access that object, e.g., in Google Docs, the access set for a document is the set of data centers from which the service will serve users sharing the document. When uncertain (e.g., for a public document), the access set can be specified as comprising all data centers hosting its front-ends; this uncertainty will translate to higher latencies and cost.

The ConfigManager selects deployment plans by solving a mixed integer program, which accounts for the particular consensus approach being used. For example, PANDO's ConfigManager selects a delegate and preferred quorums per front-end, using RTT measurements to predict latencies incurred. Given bounds on any two dimensions of the trade-off space, the ConfigManager can optimize the third (e.g. minimize max read latency across front-ends given write latency and storage cost SLOs). Given the stability of latencies observed between data centers in the cloud both in prior work [34] and in our measurements,[2] and since our current implementation assumes an object's access set is unchanged after it is created, we defer reconfiguration of an object's data sites [19] to future work.

[2]In six months of latency measurements between all pairs of Azure data centers, we observe less than 6% change in median latency from month to month for any data center pair and less than 10% difference between 90th percentile and median latency within each month for most pairs.

Executing reads and writes. Unlike typical applications of Paxos, our use of erasure coding prevents servers from processing the contents of Paxos logs. Instead of separating application and Paxos state, we maintain one Paxos log for every key and aggressively prune old log entries. In order to execute a write request, a Proxy VM initiates Phase 1 of Paxos and waits for the delegate to run Phase 2. If the operation times out, the Proxy VM assumes the delegate has failed and executes both phases itself. Once Phase 2 successfully completes, the Proxy VM notifies the client and asynchronously informs learners so that they may commit their local state and garbage collect old log entries. The read path is simpler: a Proxy VM fetches the associated Paxos state and reconstructs the latest value before returning to the client. If the latest state happens to be uncommitted, then the Proxy VM issues a write-back to guarantee consistency.

5 Evaluation

We evaluate PANDO in two parts. First, in a measurement-based analysis, we estimate PANDO's benefits over prior solutions for enabling strongly consistent distributed storage. We quantify these benefits not only with respect to latency and cost separately, but also the extent to which PANDO helps bridge the gap to the lower bound in the latency–cost tradeoff space (§2). Second, we deploy our prototype key-value store and compare latency and throughput characteristics under microbenchmarks and an application workload. The primary takeaways from our evaluation are:

- Compared to the union of the best available replication- and erasure coding-based approaches, PANDO reduces the median gap to the lower bound by 88% in the read latency–write latency–storage overhead tradeoff space.
- Compared to EPaxos, given bounds on any two of storage overhead, read latency, and write latency, PANDO can improve read latency by 12–31% and reduce dollar costs (for storage, compute, and data transfers) by 6–46%, while degrading write latency by at most 3%.
- In a geo-distributed deployment on Azure, PANDO offers 18–62% lower read latencies than EPaxos and can reduce 95th percentile latency for two GitLab operations by 19–60% over EPaxos and RS-Paxos.

5.1 Measurement-based analysis

Setup. Our analysis uses network latencies between all pairs of 25 Microsoft Azure data centers. We categorize access sets (the subset of data centers from which an object is accessed) into four types: North America (NA), North America & Europe (NA-EU), North America & Asia (NA-AS), and Global (GL). For NA and NA-EU, we use 200 access sets chosen randomly. For NA-AS and GL, we first filter front-end data centers so that they are at least 20 ms apart, and then sample 200 random access sets. In all cases, we consider all 25 Azure data centers as potential data sites.

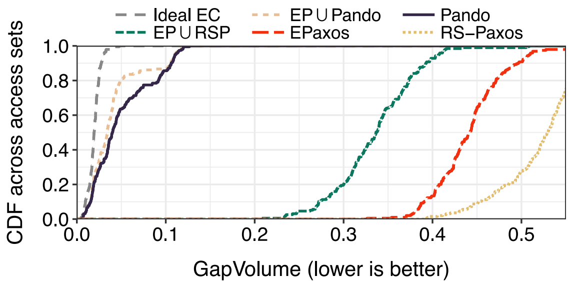

Figure 7: **For NA-AS access sets, comparison of GapVolume with PANDO to EPaxos and RS-Paxos individually and their union (EP ∪ RSP). In addition, we evaluate EP ∪ PANDO (the union of EPaxos and PANDO) and Ideal EC (a hypothetical Paxos variant that supports erasure coding, one-round writes, and 1-split intersection across quorums).**

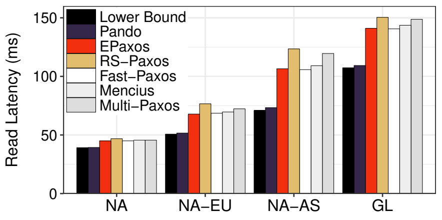
We compare PANDO to four replication-based approaches (EPaxos [51], Fast Paxos [42], Mencius [49], and Multi-Paxos [40]) and the only prior approach which can enable conditional updates on erasure-coded data (RS-Paxos [53]). We refer to the union of EPaxos and RS-Paxos (i.e., use either approach to satisfy the desired SLOs) as EP ∪ RSP.

Metrics. Our analysis looks at three types of metrics: 1) read and write latency (in either case, we estimate the max latency seen by any front-end in the access set) and storage overhead (size of the data stored divided by size of user data); 2) *GapVolume*, a metric which captures the gap in the three-dimensional read latency–write latency–storage overhead tradeoff space between the lower bound (described in §2) and the approach in question; and 3) total dollar cost as the sum of compute, storage, data transfer, and operation costs necessary to support reads and writes.

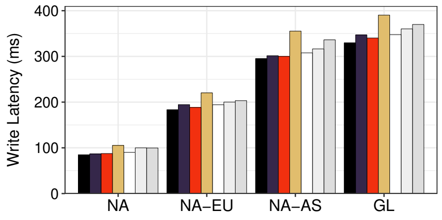
5.1.1 Impact on Achievable Tradeoffs

We use GapVolume to evaluate how close each approach is to the lower bound (§2.3). For any access set, we compute GapVolume with a specific consensus approach as the gap in the (read, write, storage) tradeoff space between the surfaces represented by the lower bound and by tradeoffs achievable with this consensus approach. We normalize this gap relative to the volume of the entire theoretically feasible tradeoff space, i.e., the portion of the tradeoff space above the lower bound surface. For every access set, we cap read and write latencies at values that are achievable with all approaches, and we limit storage overhead to a maximum of 7 as higher values are unlikely to be tenable in practice.

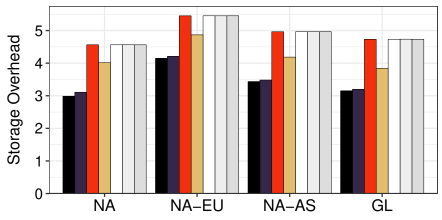
Proximity to lower bound. Figure 7 shows that PANDO significantly reduces GapVolume compared to EPaxos and RS-Paxos for access sets of type NA-AS. We do not show results for other replication-based approaches because they are subsumed by EPaxos, i.e., every combination of SLOs that is achievable with Mencius, Fast Paxos, and Multi-Paxos is also achievable with EPaxos. PANDO lowers median GapVolume to 4%, compared to 53% with RS-Paxos and 44% with EPaxos. Even with EP ∪ RSP (i.e., use two



(a) Read Latency



(b) Write Latency



(c) Storage Overhead

Figure 9: **Average performance across different metrics. Lower is better in all plots. For each metric, we pick SLO combinations for the other two metrics that are achievable with all approaches. For each such SLO pair, we estimate the minimum value of the metric achievable with each approach. We then take the geometric mean across all access sets and SLO pairs.**

GapVolume	NA	NA-EU	NA-AS	GL
PANDO	0.06	0.07	0.04	0.07
EP ∪ RSP	0.37	0.40	0.34	0.34
EPaxos	0.44	0.48	0.44	0.49
RS-Paxos	0.52	0.59	0.53	0.48

Table 1: **GapVolume for median access set of various types. Lower values are better; imply closer to the lower bound.**

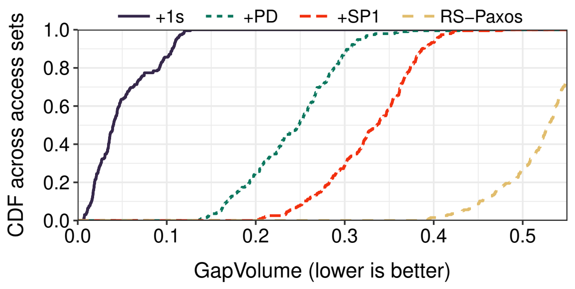


Figure 8: **For access sets of type NA-AS, contributions of each of PANDO's techniques in reducing GapVolume. SP1 = small Phase 1, PD = partial delegation, 1s = 1-split overlap.**

significantly different designs to realize different tradeoffs), median GapVolume remains at 34%. Table 1 shows similar benefits for NA, NA-EU, and GL access sets.

Moreover, EP ∪ PANDO (i.e., SLO combinations achievable with any of EPaxos or PANDO) is only marginally closer to the lower bound (i.e., has lower GapVolume) than PANDO, and that too only for some access sets. The few SLO combinations that EPaxos can achieve but not PANDO all have low write latency SLOs, in which case no choice of delegate can help PANDO overcome the overheads of two-round writes.

Utility of individual techniques. Figure 8 shows that each of the techniques used in PANDO contribute to the GapVolume reductions. For the median access set, using small Phase 1 quorums reduces GapVolume over RS-Paxos by 36%, adding partial delegation reduces GapVolume by a further 16%, and finally incorporating 1-split intersection reduces GapVolume by an additional 39%. When examining the improvements for each access set, we observe that both small Phase 1 quorums and 1-split intersection help across all access sets by reducing quorum size requirements. Similarly, we find that partial delegation typically improves GapVolume, indicating that some data sites are often closer to Phase 1 and Phase 2 quorums than the front-end.

Obstacles to matching the lower bound. From the gap between PANDO and Ideal EC in Figure 7, we surmise that most of the remaining gap between PANDO and the lower bound could be closed if one-round writes on erasure-coded data were feasible. Addressing any potential sub-optimality thereafter likely requires realizing the lower bound's flexibility with regards to varying the fraction of an object's data across sites (e.g., by using a different erasure coding strategy than Reed-Solomon coding) and varying quorum sizes across front-ends.

5.1.2 Latency and Storage Improvements

Figure 9 examines improvements in each of read latency, write latency, and storage overhead independently. To do this for read latency, we first identify all (write, storage) SLO pairs that are achievable by all candidate approaches. For each such pair, we then estimate the lowest read latency bound that is satisfiable with each approach. We take the geometric mean [31] across all feasible (write, storage) SLO pairs for all access sets to compare PANDO's performance relative to other approaches. We perform similar computations for write latency and storage overhead.

We find that PANDO achieves 12–31% lower read latency, 0–3% higher write latency, and 22–32% lower storage overhead than EPaxos across all types of access sets. Although PANDO executes writes in two phases, the use of small Phase 1 quorums plus partial delegation provides similar write latency as EPaxos. In all cases, EPaxos outperforms Fast Paxos, Mencius, and Multi-Paxos. Compared to RS-Paxos, PANDO reduces read latency by 15–40%, write latency by 11–17%, and storage overhead by 13–22%.

Latency under failures. Figure 10 compares the read latency bounds satisfiable with PANDO and EPaxos when any one data center is unavailable. During failures, a front-end may need to contact more distant data sites in order to read or write data. In this case, for the median access set, we observe that PANDO supports a read latency bound which is 110 ms lower than EPaxos. Since erasure coding spreads data more widely than replication for the same storage overhead, there are more nearby sites to fall back on when a failure occurs.

However, erasure coding is not universally helpful in failure scenarios. Upon detecting the loss of its write delegate, a PANDO front-end will locally identify a new one that min-

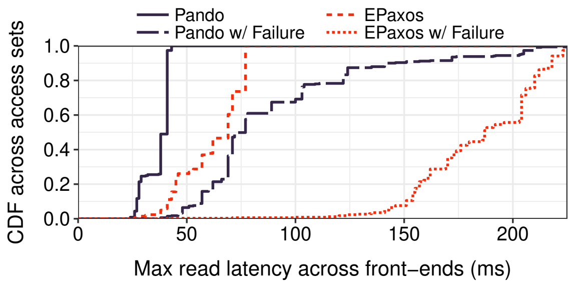

Figure 10: **For access sets of type NA-AS, impact of data center failures on read latency for PANDO and EPaxos (300 ms write SLO, 5× overhead storage SLO).**

imizes latency at the front-end. Still, across NA-AS access sets, median write latency with PANDO is 10% higher than EPaxos when any one data site is unavailable, despite the two approaches having similar latency in the failure-free case. In addition, under permanently data loss, bringing up a replacement data site requires decoding the data of k separate sites instead of fetching the same volume of data from one replica.

5.1.3 Cost

Beyond storage, public cloud providers also charge users for wide-area data transfers, PUT/GET requests to storage, and for virtual machines used to execute RPCs and encode/decode data. These overheads have driven production systems to adopt two key optimizations. First, replication-based systems execute reads by fetching version numbers from remote sites, not data. Second, Paxos-based systems issue writes only to a quorum (or for PANDO, a superset of a write quorum that intersects with all Phase 1a quorums likely to be used). Taking these optimizations into consideration, we now account for these other sources of cost and evaluate PANDO's utility in reducing total cost.

We considered 200 access sets of type NA-AS and set latency SLOs that both RS-Paxos and EPaxos are capable of meeting: 100 ms for read latency and 375 ms for write latency. We derived the CPU cost of Proxy VMs by measuring the throughput achieved in deployments of our prototype system. Using pricing data from Azure CosmosDB [3], we estimated the cost necessary to store 10 TB of data and issue 600M requests, averaged across all access sets; these parameters are based on a popular web service's workload [7] and a poll of typical MySQL deployment sizes [10].

Across several values for mean object size and read-to-write ratio, Figure 11 shows that PANDO reduces overall costs by 6–46% over EPaxos and 35–40% over RS-Paxos. When objects are large, PANDO's cost savings primarily stem from the reduction in the data transferred over the wide-area network. Note that even though EPaxos uses replication, it still requires reading remote data when a copy is not stored at the front-end data center. Whereas, when objects are small, storage fees dominate and PANDO reduces cost primarily due to the lower storage overhead that it imposes. Though erasure coding increases the number of requests

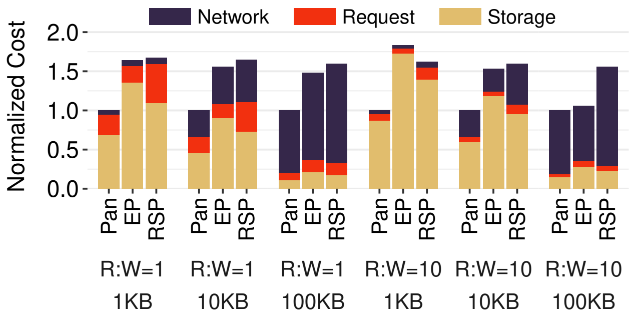

Figure 11: **Comparison of cost for a month in NA-AS to store 10 TB of data and execute 600M requests/month. In all cases, the costs of Proxy VMs (not shown) were negligible, and read and write latency SLOs were set to 100 ms and 375 ms.**

to storage compared to replication, ConfigManager opts to erasure-code data only when the corresponding decrease in storage and data transfer costs help reduce overall cost. Unlike write requests, which have to first write metadata to storage before transferring and writing the data itself, read requests only issue storage operations to fetch data. This leads to greater cost reductions for read-dominated workloads.

5.2 Prototype deployment

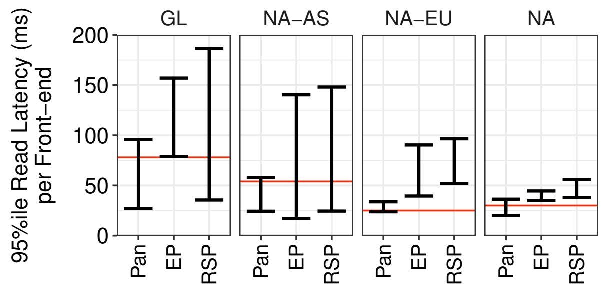
Next, via deployments on Azure, we experimentally compare PANDO versus EPaxos and RS-Paxos. We use our implementations of PANDO and RS-Paxos and the open-source implementation of EPaxos [50]. This experimental comparison helps account for factors missing from our analysis, such as latency variance and contention between requests. We consider one access set of each of our 4 types:

- NA: Central US, East US, North Central US, West US
- NA-EU: Canada East, Central US, North Europe, West Europe
- NA-AS: Central US, Japan West, Korea South
- GL: Australia East, North Europe, SE Asia, West US

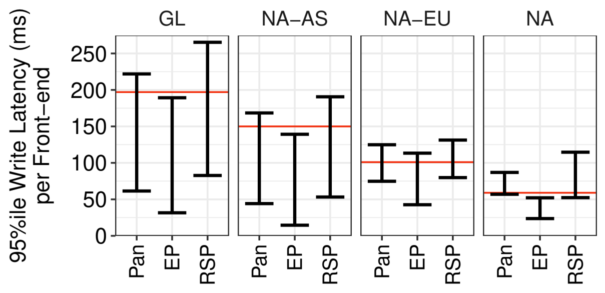
Informed by prior studies of production web service workloads [29, 22], we read and write objects between 1–100 KB in size. Unless stated otherwise, we use A1v2 (1 CPU, 2 GB memory) virtual machines and issue requests using YCSB [28]—a key-value store benchmark.

5.2.1 Microbenchmarks

Tail latency across front-ends. Figure 12 shows 95th percentile read and write latencies for each of the four access sets when running a low contention (zipfian coefficient = 0.1) workload with 1 KB values and a read:write ratio of 1. In all cases, when using PANDO, we observe that the slowest front-end performs similarly to the read latency SLO deemed feasible by ConfigManager. This confirms the low latency variance in the CosmosDB instance at each data center and on the network paths between them. While all approaches achieve sub-55 ms read latency in NA, only PANDO can provide sub-100 ms latency in all regions. In GL, NA-AS, and



(a) Read Latency when Write SLO = 300, 300, 150, and 100 ms for GL, NA-AS, NA-EU, and NA, respectively



(b) Write Latency when Read SLO = 200, 150, 125, and 75 ms for GL, NA-AS, NA-EU, and NA, respectively

Figure 12: **Latency comparison with a low contention workload under a storage SLO of 3× overhead. Red lines represent the lowest latency SLO that ConfigManager identifies as feasible with PANDO. With every approach, in each access set, we measure 95th %ile latency at every front-end and plot the min and max of this value across front-ends. Pan = Pando, EP = EPaxos, and RSP = RS-Paxos.**

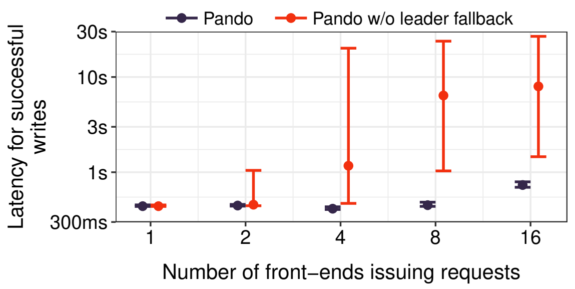


Figure 13: **Write latency comparison under contention using a fully leaderless approach and the leader-based fallback (§3.5). 5th percentile, median, and 95th percentile across 1000 writes are shown. Note logscale on y-axis.**

NA-EU, PANDO improves read latency for the slowest front-end by 39–62% compared to EPaxos. PANDO falls short of the write latency offered by EPaxos but comes close.

Latency under high conflict rates. Although our focus is on workloads with few write conflicts, we seek to bound performance degradation when conflicts occur. To evaluate this, we setup front-ends in 16 Azure data centers spread across five continents. We mimic conflicts by synchronizing a subset of front-ends (assuming low clock skew) to issue writes on the same key and version simultaneously. We show latency for successful conditional writes since other writes will learn the committed value and terminate shortly afterward.

Figure 13 shows that PANDO is effective at bounding latency for writes in the presence of conflicts. Without a leader-based fallback, writes in PANDO may need to be tried many times before succeeding, resulting in unbounded latency growth, e.g., with four concurrent writers, we observe more than 15 proposals for particular (key, version) pairs. In contrast, falling back to a leader ensures that a write succeeds within two write attempts.

Read and write throughput. While erasure coding can decrease bandwidth usage compared to replication, it requires additional computation in the form of coding/decoding and messaging overhead. We quantify the inflection point at which CPU overheads dominate by deploying PANDO in a single data center and measuring the achievable throughput

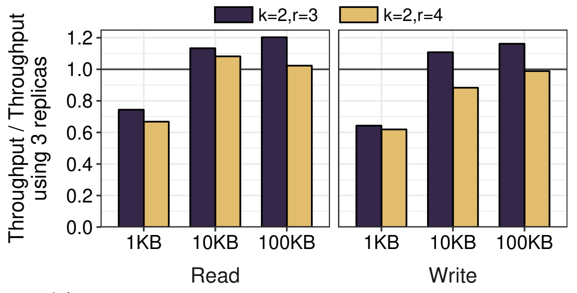

Figure 14: **Per-machine throughput of different erasure coding configurations compared to using 3 replicas.**

with all data in memory. Each server, which stored 1 split or 1 replica, had two Xeon Silver 4114 processors and 192 GB of memory. All servers were connected over a 10 Gbps network with full bisection bandwidth. Across multiple value sizes, we measured the per-server throughput of filling the system with over 20 GB of data and reading it back.

Figure 14 compares the per-machine throughput achieved with 3 replicas to two erasure coding configurations, one with the same storage overhead and another with lower storage overhead. When objects are 10 KB or larger, we find that bandwidth is the primary bottleneck. Because it has identical bandwidth demands as replication, the $(k = 2, r = 4)$ configuration achieves similar read throughput and 0.9–1× the write throughput of replication for objects larger than 10 KB. Whereas, due to its lower bandwidth consumption, the $(k = 2, r = 3)$ configuration offers 1.1-1.2× the throughput of replication for 10 KB–100 KB sized objects. All configurations are CPU-bound with value sizes of 1 KB or smaller. Since replication requires exchanging fewer messages per request than erasure coding, it has lower CPU overhead and can thus achieve higher throughput.

5.2.2 Application Workload

Lastly, we evaluate the utility of PANDO on a geo-distributed deployment of GitLab [6], a software development application that provides source code management, issue tracking, and continuous integration.

Operations and setup. We evaluate the performance of two GitLab operations: listing issues targeting a devel-

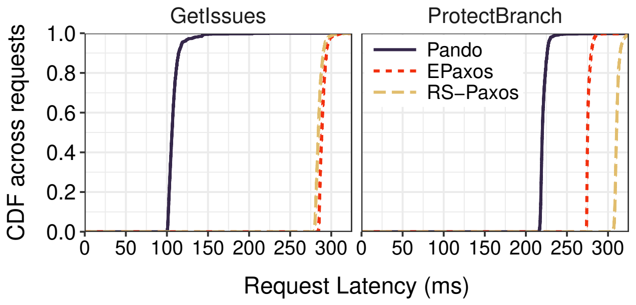

Figure 15: **Latencies for GitLab requests in Central US.**

opment milestone (GetIssues) and (un-)protecting a branch from changes (ProtectBranch). GetIssues fetches a list of issues for the requested milestone and then fetches 20 issues in parallel to display on a page. ProtectBranch reads the current branch metadata then updates its protection status.

We deployed front-ends and storage backends in the NA-AS access set on A2v2 (2 CPU, 4 GB memory) virtual machines, and preloaded the system with 100 projects, each with 20 branches, 10 milestones, and 100 issues. We used a $3\times$ bound on storage overhead and set the write latency SLO to 175 ms. Every front-end executed 1000 GetIssues and ProtectBranch requests in an open loop and selected items using a uniform key distribution.

Performance. Figure 15 shows the latency distribution observed for both operations by the front-end in Central US. PANDO reduces 95th percentile GetIssues latency by over 59% compared to both EPaxos and RS-Paxos. Because ProtectBranch consists of a write in addition to a read operation, it incurs higher latency compared to GetIssues, which consists solely of read operations. Despite this, PANDO is able to lower 95th percentile ProtectBranch latency by 19% over EPaxos and 28% over RS-Paxos.

6 Related work

Geo-distributed storage. While some prior geo-distributed storage systems [46, 45, 47, 66] weaken consistency semantics to minimize latencies and unavailability, PANDO follows others [29, 64, 71, 21] in serving the needs of applications that cannot make do with weak consistency. Compared to efforts focused solely on minimizing latency with any specific replication factor [51, 49, 42], PANDO aims to also minimize the cost necessary to meet latency goals. Unlike systems [13, 70] which focus only on judiciously placing data to minimize cost, we also leverage erasure coding and rethink how to enable consensus on erasure-coded data.

Partial delegation in PANDO is akin to the chaining of RPCs [63] to eliminate wide-area delays. We show that combining this technique with the use of smaller quorums in Phase 1 of Paxos helps a two-round execution approximate the latencies achievable with one-round protocols in a geo-distributed setting.

Erasure-coded storage. Erasure coding has been widely used for protecting data from failures [69], most notably in RAID [58]. While PANDO leverages Reed Solomon codes [60] for storage across data centers, other codes have been used to correct errors in DRAM [33], transmit data over networks [62], and efficiently reconstruct data in cloud storage [67, 38, 61]. In contrast to the typical use of erasure coding for immutable and/or cold data [54, 32, 59, 55, 27], PANDO supports the storage of hot, mutable objects.

Previous protocols [15, 24] that support strong consistency with erasure-coded data provide only atomic register semantics or require two rounds of communication [53]. We show how to enable consensus on geo-distributed erasure-coded data without sacrificing latency. Some systems [26, 27] support strong consistency by erasure coding data but replicating metadata. We chose to not pursue this route to avoid the complexity of keeping the two in sync, as well as to minimize latency and metadata overhead.

Paxos variants. Many variants of Paxos [40] have been proposed over the years [53, 37, 43, 41], including several [51, 42, 49] which enable low latency geo-distributed storage. Compared to Paxos variants that reduce the number of wide-area round trips [51, 49, 42], PANDO lowers latency by reducing the magnitude of delay in each round trip.

Flexible Paxos [37] was the first to observe that Paxos only requires overlap between every Phase 1–Phase 2 quorum pair, and others [16, 56] have leveraged this observation since. All of these approaches make *Phase 2 quorums smaller*, so as to improve throughput and common case latency in settings with high spatial locality. In PANDO, we instead *reduce the size of Phase 1 quorums and reuse these quorums for reads*, thereby enabling previously unachievable tradeoffs between read and write latency bounds in a workload-agnostic manner.

Compression. Data compression is often used to lower the cost of storing data [36, 65, 25] or transferring it over a network [30]. In contrast to erasure coding, the effectiveness of compression depends on both the choice of compression algorithm used as well as the input data [17]. Compression and erasure coding are complementary as data can be compressed and then erasure-coded or vice-versa.

7 Conclusion

Today, geo-distributed storage systems take for granted that data must be replicated across data centers. In this paper, we showed that it is possible to leverage erasure coding to significantly reduce costs while successfully mitigating the associated overheads in wide-area latency incurred for preserving consistency. The key is to rethink how consensus is achieved across the wide-area. Importantly, we showed that the latency versus cost tradeoffs achievable with our approach for enabling consensus, PANDO, are close to optimal.

A The PANDO write protocol: specification and proof of correctness

In this section, we focus on how PANDO achieves consensus on a *single value* and prove that it matches the guarantees provided by Paxos. Other functionality used in our paper is layered on top of this base as follows:

- **Mutating values.** As with Multi-Paxos, we build a distributed log of values and run PANDO on each entry of the log. We only ever attempt a write for version i if we know that $i-1$ has already been chosen. This invariant ensures that the log is contiguous, and that all but possibly the latest version have been decided.
- **Partial delegation of writes.** One of the key optimizations used in PANDO is to execute Phase 1 and Phase 2 on different nodes (§3.3.2). We achieve this without sacrificing fault tolerance as follows. Each proposer is assigned an id (used for Lamport clocks), but we additionally assign a proposer id to each (proposer, delegate) pair. When executing a write using partial delegation, we simply direct responses accordingly, and have the proposer inform the delegate about which value to propose (unless one was recovered, in which case the delegate has to inform the proposer about the change). In case the delegate fails, a proposer can always choose to execute a write operation normally, and because it uses a different proposer id in this case, it will look as though the write from the proposer and the write from the (proposer, delegate) pair are writes from two separate nodes. We already prove (§A.1) that PANDO maintains consistency in this case.
- **One round reads.** As with other consensus protocols, we support (common-case) one-round reads by adding a third, asynchronous phase to writes that broadcasts which value was chosen and caches this information at each acceptor. Upon executing a read at a Phase 1a quorum, we check to see if any acceptor knows whether a value has already been chosen. If we find such a value, we try to reconstruct it and fall back on the larger Phase 1b quorum in case there are not enough splits present in the Phase 1a quorum. Otherwise, we follow the write path, but propose a value only if we were able to recover one (else none have been chosen). We maintain linearizability with this approach because the task of resolving uncertainty is done via the write path.
- **Fallback to leader.** In PANDO, front-ends directly execute writes unless a conflict is observed, in which case they defer the request to a leader (§3.5). From the perspective of the consensus protocol, the leader is just another proposer, so no consistency issues may arise even if multiple leaders exist. However, PANDO prevents non-leader front-ends from attempting writes more than once which can lead to unavailability if the leader fails. It is up to the leader election mechanism to quickly elect a new leader when the the current one fails.

$A.ppn$	Promised proposal no. stored at acceptor A
$A.apn$	Accepted proposal no. stored at acceptor A
$A.vid$	Accepted value id stored at acceptor A
$A.vlen$	Accepted value length stored at acceptor A
$A.vsplit$	Accepted value split stored at acceptor A
vid_v	Unique id for v, typically a hash or random number
$vlen_v$	Length of v (to remove padding)
$\text{Split}(v, A)$	(Computed on proposers) The erasure-coded split associated with acceptor A

Figure 16: Summary of notation.

PANDO's consistency and liveness properties rely on certain quorum constraints being met. We describe the constraints below under the assumption that data is partitioned into k splits (Constraint 3 needed only if Phase 1a quorums are used for reads):

1. The intersection of any Phase 1a and Phase 2 quorums contains at least 1 split.
2. The intersection of any Phase 1b and Phase 2 quorums contains at least k splits.
3. A Phase 1a quorum must contain at least k splits.
4. After f nodes fail, at least one Phase 1b and Phase 2 quorum must consist of nodes that are available.

Below is pseudocode for the PANDO write protocol.

Phase 1 (Prepare-Promise)

```
Proposer $P$ initiates a write for value $v$:
  1. Select a unique proposal number $p$ (typically done using Lamport clocks).
  2. Broadcast $\text{Prepare}(p)$ messages to all acceptors.

Acceptor $A$, upon receiving $\text{Prepare}(p)$ message from Proposer $P$:
  3. If $p > A.ppn$ then set $A.ppn \leftarrow p$ and reply $\text{Promise}(A.apn, A.vid, A.vlen, A.vsplit)$.
  4. Else reply NACK.

Proposer $P$, upon receiving Promise messages from a Phase 1a quorum:
  5. If the values in all Promise responses are NULL, then skip to Phase 2 with $v' \leftarrow v$.

Proposer $P$, upon receiving Promise messages from a Phase 1b quorum:
```

6. Iterate over all Promise responses sorted in decreasing order of their apn.
   (a) If there are at least k splits for value w associated with apn, recover the value w (using the associated $vlen$ and $vsplit$s) and continue to Phase 2 with $v' \leftarrow w$.
7. If no value was recovered, continue to Phase 2 with $v' \leftarrow v$.

<u>*Phase 2 (Propose-Accept)*</u>

Proposer P, initiating Phase 2 to write value v' with proposal number p:

8. If no value was recovered in Phase 1, set $vid_{v'} = hash(v)$ (or some other unique number, see Figure 16). If a value was recovered, use the existing $vid_{v'}$.
9. Broadcast $\text{Propose}(p, vid_{v'}, vlen_{v'}, \text{Split}(v', A))$ messages to all acceptors.

Acceptor A, upon receiving $\text{Propose}(p, vid, vlen, vsplit)$ **from a Proposer P:**

10. If $p < A.ppn$ reply NACK
11. $A.ppn \leftarrow p$
12. $A.apn \leftarrow p$
13. $A.vid \leftarrow vid$
14. $A.vlen \leftarrow vlen$
15. $A.vsplit \leftarrow vsplit$
16. Reply $\text{Accept}(p)$

Proposer P, upon receiving $\text{Accept}(p)$ **messages from a Phase 2 quorum:**

17. P now knows that v' was chosen, and can check whether the chosen value v' differs from the initial value v or not.

A.1 Proof of correctness

Definitions. We let $\mathcal{A}$ refer to the set of all acceptors and use $\mathcal{Q}_a$, $\mathcal{Q}_b$, and $\mathcal{Q}_2$ refer to the sets of Phase 1a, Phase 1b, and Phase 2 quorums, respectively. Using this notation, we restate our quorum assumptions:

$$Q \subseteq \mathcal{A} \qquad \forall Q \in \mathcal{Q}_a \cup \mathcal{Q}_b \cup \mathcal{Q}_2 \qquad (1)$$
$$|Q_a \cap Q_2| \geq 1 \qquad \forall Q_a \in \mathcal{Q}_a, Q_2 \in \mathcal{Q}_2 \qquad (2)$$
$$|Q_b \cap Q_2| \geq k \qquad \forall Q_b \in \mathcal{Q}_b, Q_2 \in \mathcal{Q}_2 \qquad (3)$$

Definition 1. *A value is* ***chosen*** *if there exists a Phase 2 quorum of acceptors that all agree on the identity of the value and store splits corresponding to that value.*

We now show that the PANDO write protocol provides the same guarantees as Paxos:

- **Nontriviality.** Any chosen value must have been proposed by a proposer.
- **Liveness.** A value will eventually be chosen provided that RPCs complete before timing out and all acceptors in at least one Phase 1b and Phase 2 quorum are available.
- **Consistency.** At most one value can be chosen.
- **Stability.** Once a value is chosen, no other value may be chosen.

Theorem 1. *(Nontriviality)* PANDO *will only choose values that have been proposed.*

Proof. By definition, a value can only be chosen if it is present at a Phase 2 quorum of acceptors. Values are only stored at acceptors in response to Propose messages initiated by proposers. □

Theorem 2. *(Liveness)* PANDO *will choose a a value provided that RPCs complete before timing out and all acceptors in at least one Phase 1b and Phase 2 quorum are available.*

Proof. Let t refer to the (maximum) network and execution latency for an RPC. Since PANDO has two rounds of execution, a write can complete within $2t$ as long as a requested is uncontended. If all proposers retry RPCs using randomized exponential backoff, a time window of length $\geq 2t$ will eventually open where only a Proposer P is executing. Since no other proposer is sending any RPCs during this time, both Phase 1 and Phase 2 will succeed for Proposer P. □

Following the precedence of [37], we will show that PANDO provides both consistency and stability by proving that it provides a stronger guarantee.

Lemma 1. *If a value v is chosen with proposal number p, then for any proposal with proposal number $p' > p$ and value v', $v' = v$.*

Proof. Recall that PANDO proposers use globally unique proposal numbers (Line 1); this makes it impossible for two different proposals to share a proposal number p. Therefore, if two proposals are both chosen, they must have different proposal numbers. If $v' = v$ then we trivially have the desired property. Therefore, assume $v' \neq v$.

Without loss of generality, we will consider the smallest p' such that $p' > p$ and $v' \neq v$ (*minimality assumption*). We will show that this case always results in a contradiction: either the Prepare messages for p' will fail (and thus no Propose messages will ever be sent) or the proposer will adopt and re-propose value v.

Let $Q_{2,p}$ be the Phase 2 quorum used for proposal number p, and $Q_{a,p'}$ be the Phase 1a quorum used for p'. By Quorum Property 2, we know that $|Q_{2,p} \cap Q_{a,p'}|$ is non-empty. We will now look at the possible ordering of events at each acceptor A in the intersection of these two quorums ($Q_{2,p}$ and $Q_{a,p'}$):

- Case 1: A receives $\text{Prepare}(p')$ before $\text{Propose}(p, \ldots)$.

  The highest proposal number at A would be $p' > p$ by the time $\text{Propose}(p, \ldots)$ was processed, and so A would reject $\text{Propose}(p, \ldots)$. However, we know that this is not the case since $A \in Q_{2,p}$, so this is a contradiction.

- Case 2: A receives $\text{Propose}(p, \ldots)$ before $\text{Prepare}(p')$.

  The last promised proposal number at A is q such that $p \leq q < p'$ ($q > p'$ would be a contradiction since $\text{Prepare}(p')$ would fail even though $A \in Q_{a,p'}$). By our minimality assumption, we know that all proposals z such that $p \leq z < p'$ fail or re-propose v. Therefore, the acceptor A responds with $\text{Promise}(q, vid_v, \ldots)$.

At this point, the proposer has received at least one Promise message with a non-empty value. Therefore, it does not take the Phase 1 fast path and waits until it has heard from a Phase 1b quorum (denoted $Q_{b,p'}$). Using the same logic as above, the proposer for p' will receive a minimum of k Promise messages each referencing value v since there are k acceptors in $Q_{b,p'} \cap Q_{2,p}$ (Quorum Property 3). Since the proposer has a minimum of k responses for v, it can reconstruct value v. Let q denote the highest proposal number among all k responses.

Besides those in $Q_{b,p'} \cap Q_{2,p}$, other acceptors in $Q_{b,p'}$ may return values that differ from v. We consider the proposal number q' for each of these accepted values:

- Case 1: $q' < q$. The proposer for p' will ignore the value for q' since it uses the highest proposal number for which it has k splits.

- Case 2: $p' < q'$. Not possible since $\text{Prepare}(p')$ would have failed.

- Case 3: $p < q' < p'$. This implies that a $\text{Propose}(q', v'')$ was issued where $v'' \neq v$. This violates our minimality assumption.

Therefore, the proposer will adopt value v since it can reconstruct it (the proposer has k splits from the acceptors in $Q_{b,p'} \cap Q_{2,p}$ alone) and the highest returned proposal number references it. This contradicts our assumption that $v' \neq v$. □

Theorem 3. *(Consistency)* PANDO *will choose at most one value.*

Proof. Assume that two different proposals with proposal numbers p and q are chosen. Since proposers use globally unique proposal numbers, $p \neq q$. This implies that one of the proposal numbers is greater than the other, assume that $q > p$. By Lemma 1, the two proposals write the same value. □

Theorem 4. *(Stability) Once a value is chosen by* PANDO, *no other value may be chosen.*

Proof. The proposal numbers used for any two chosen proposals will not be equal. Thus, with the additional assumption that acceptors store their state in durable storage, this follows immediately from Lemma 1. □

B TLA+ specification for Pando reads and writes

In addition to our proof of correctness for Pando's write path, we have model checked Pando's correctness using TLA+ [39]. The purpose of this exercise was to *mechanically verify* Pando's safety guarantees under a number of scenarios.

We checked the following invariants: consistency and stability for writes, that any value marked chosen at an acceptor was indeed chosen, and that successful reads only ever returned chosen values. The configurations modeled used 2–3 proposers (and readers) that could write (read) 2–3 values to (from) 4–6 acceptors when splitting the data into 2–4 splits. We set up 2–3 quorums of each type (Phase 1a, Phase 1b, and Phase 2).

The TLA+ model checker considers all possible histories including those with message reordering and arbitrary (or infinite) delay in delivering messages. When run on the specification for Pando (below) and the configurations listed earlier, no invariant violations were found.

Abstract

Modern networks enforce rich and dynamic policies (e.g., dynamic service chaining and path pinning) over a number of complex and stateful NFs (e.g., stateful firewall and load balancer). Verifying if those policies are correctly implemented is important to ensure the network's availability, safety, and security. Unfortunately, theoretical results suggest that verifying even simple policies (e.g., A cannot talk to B) in stateful networks is undecidable. Consequently, any approach for stateful network verification has to fundamentally make some relaxations; e.g., either on policies supported, or the network behaviors it can capture, or in terms of the soundness/completeness guarantees. In this paper, we identify practical opportunities for relaxations in order to develop an efficient verification tool. First, we identify key domain-specific insights to develop a more compact network semantic model which is equivalent to a general semantic model for checking a wide range of policies under practical conditions. Second, we identify a restrictive-yet-expressive policy language to support a wide range of policies including dynamic service chaining and path pinning while enable efficient verification. Third, we develop customized symbolic model checking algorithms as our model and policy specification allows us to succinctly encode network states using existential first-order logic, which enables efficient checking algorithms. We prove the correctness of our approach for a subset of policies and show that our tool, NetSMC, achieves orders of magnitude speedup compared to existing approaches.

1 Introduction

Today's computer networks deploy a large number and variety of complex *stateful* functions [44], ranging from stateful firewalls, NATs, to proxies, and load balancers. Network operators configure those network functions (NFs) to enforce *rich and dynamic policies*, such as dynamic service chaining (e.g., all packets should traverse IPS, while only malicious packets detected by IPS should be sent to FW) [18, 19] and path pinning (e.g., if packets from A to B traverse NF f_1 and then f_2, the reverse packets from B to A should traverse f_2 and then f_1). Formally verifying if the network correctly implements the policies is critical to ensure the availability, security, and safety of the network.

Checking whether policies are correctly enforced, however, is challenging on stateful networks (networks with stateful NFs). Even checking simple policies such as isolation policies (packets from A cannot be delivered to B), an efficiently solvable problem on stateless networks [23, 25–27, 31], is undecidable on stateful networks [47]. In practice, policies enforced on stateful networks will be more complex (see §2).

As such, making practical progress requires non-trivial trade-offs on the supported network behavior, expressiveness of policies, and the soundness/completeness guarantees. For example, recent work VMN [41] simplifies the behavior of a stateful network by assuming that each NF can buffer multiple packets in an out-of-order way, which makes the problem decidable for checking a restrictive set of policies. To verify policies, VMN encodes the network and the policy using first-order logical formulas which are solved by a general-purpose SMT solver. However, it is inefficient to even check the isolation policy due to its high complexity (i.e., EXPSPACE-complete [47]).

In this work, we revisit the stateful network verification problem and explore a different set of relaxation trade-offs in order to achieve more efficient verification for practical scenarios based on the following domain-specific insights:

One-packet at a time network model: Instead of dealing with multiple packets, we adopt a simpler model where only one packet exists in every network state. This model is motivated by the fact that packets inducing conflict behavior on a network are often processed by the network in an *order-preserving* way. For example, connection-based NFs often process packets in a connection in order. Thus, each packet would be processed by the network exactly in the same way when traversing the network with other packets as when traversing alone. Therefore, we can consider only one packet at a time in each network state. While this model simplifies the behavior of a network (e.g., we cannot find violations appearing only under packet interleaving. See §8), we show that the verification result of a wide range of policies (e.g., isolation) based on this model is correct w.r.t. the more complex model in previous work [41] for order-preserving networks (details in §4).

Customized policy and verification algorithm: We design a restricted-yet-expressive policy language based on a subset of linear temporal logic and verification algorithms based on symbolic model checking (SMC) to achieve further speedup of the verification. While our model of network behavior reduces the state space of the problem, checking simple policies (e.g., isolation) efficiently is still hard. Naive approaches based on reducing the problem to constraint solving using general-purpose solvers is not particularly efficient since it would not benefit from the simpler model (see §7).

There are two key challenges to apply the SMC framework to stateful networks: 1) how to succinctly encode a large number of network states and 2) how to efficiently support the computation required in SMC. To this end, we leverage the customized policy structure to use simple existential first order logic (EFO) formulas to succinctly encode a large number of network states. Furthermore, we develop efficient algorithms required in the SMC framework by leveraging the simple network model and extending classic algorithms in other domains (e.g., query containment in database theory).

Based on the key insights discussed above, we implement NetSMC, a symbolic model checker for stateful networks. We prove the correctness of our algorithms w.r.t. a general network semantic model for a subset of policies (e.g., isolation properties). For other policies requiring reasoning about packet interleaving, NetSMC is a sound-but-incomplete bug finding tool that is very efficient. We show the effectiveness of NetSMC via several use cases using real-world NFs such as pfSense [3] and HAProxy [2] running in Cloudlab [43]. We evaluate NetSMC on various network topologies and policies and show that NetSMC scales to networks with hundreds of stateful NFs and is $>$ 200X faster than the state-of-the-art stateful network verification tool VMN [41] on typical fattree-topology networks.

2 Motivation

We motivate the stateful network verification problem by describing several practical policies, followed by the key challenges of the verification problem.

2.1 Stateful Network Verification Examples

Isolation. Consider a network (Fig. 1a) with a stateful firewall to protect the Department from the Internet. Network operators may enforce the isolation policy: traffic from untrusted hosts in the Internet cannot be sent to the Department.
Conditional reachability. Continuing the example above, the network operators may additionally enforce the policy to allow all traffic from the Department and to allow traffic from those trusted hosts in the Internet that have a connection already established from a host in Department.
Flow affinity. Consider a load balancer that distributes traffic among n servers as shown in Fig. 1b. To keep the service provisioning undisrupted, the network operator wants to enforce the following flow affinity policy: if a packet from a host Client is load balanced to a server, then all future packets in the same flow should always be sent to the same server.
Dynamic service chaining. Fig. 1c shows a multi-stage intrusion prevention system (IPS) consisting of a light IPS and a heavy IPS. Each device in the network is configured such that all traffic from the Department is sent to the light IPS, which performs basic detection such as counting the number of bad connections for each host. If a host is detected suspicious by light IPS (e.g. issuing more than 10 bad connections), all future packets from the host should be directed to the heavy IPS for further processing; otherwise its traffic is directly sent to the Internet.
Path pinning. Often a network needs to deploy multiple instances of the same middlebox function for better throughput.

	Buzz & Symnet	VMN	**NetSMC**
Model	One-packet	Out-of-order	One-packet
Policy lang.	Assertion	LTL-based	LTL-based
Correctness	Sound	Sound, Complete	Sound, Cond. complete

Table 1: Comparison with network verification tools.

Consider the network shown in Fig. 1d which is configured to forward traffic between the Department and the Internet to one of the firewalls. An interesting path pinning policy is: if a packet from H1 in the Department to H2 in the Internet goes through the i-th firewall, then all future packets from H2 to H1 should traverse the same firewall.

2.2 Challenges

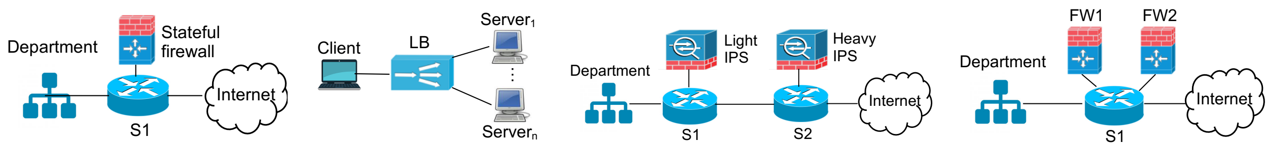
Stateful network verification is more challenging compared to stateless verification. In general, this problem has been shown to be undecidable even for simple isolation policies (see Theorem 1 in [47]). As such, any practical progress needs to make practical relaxations on at least one of the following dimensions: the supported network behavior, the expressiveness of policies, and the correctness guarantees.

As an example, VMN [41] recovers the decidability of the problem by assuming that an NF buffers packets in an out-of-order fashion instead of FIFO. VMN reduces the verification problem to encoding network configurations and policies as first-order logical constraints which can be solved by an SMT solver. Since solving general first-order constraints is undecidable, VMN targets policies in the form of "if packet p reaches node B then p must not satisfy some property P in the past", so that the encoded constraints fall in a decidable fragment. Even with the above simplification the verification problem induces high complexity (i.e., EXPSPACE-hard [47]). Thus, VMN is not scalable to large-size networks even for checking simple isolation policies as shown in §7.

3 Overview

The undecidability result [47] means that *any* approach in this space has to seek some relaxations or tradeoffs in order to make the problem tractable. One of our contributions is identifying and exploring a different point in this space of practical relaxation choices in order to develop an efficient verification tool in practical network scenarios. Table 1 summarizes key difference of our trade-offs compared with existing work.

More specifically, our trade-off is based on the following two key domain-specific insights: First, the key challenge to stateful network verification is to handle interleaving among multiple packets in the network (e.g., packet p_1 is processed by NF A before packet p_2, but p_2 is processed by NF B before p_1). In practice, however, networks often exhibit intrinsic *order-preserving* property in several scenarios, where packets that induce conflict network behavior are processed in the same order. For example, a syn packet is often processed by the network before a synack packet is sent into and processed by the network. Motivated by this observation, we



(a) Stateful firewall. (b) Load balancing. (c) Multi-stage IPS. (d) Multiple stateful firewalls.

Figure 1: Examples

adopt a semantic model that only allows one packet being considered at each network state. In effect, we consider a sequential execution model of networks, similar to the ones considered in stateful network testing tools [18, 45]. Second, even with this simple model verifying simple isolation policies is still hard (i.e. PSAPCE-hard) and naively employing a general-purpose tool is not efficient for large-size networks (see §7). Motivated by recent success in customized stateless network verification tools (e.g., HSA [26], VeriFlow [27]), we design a customized policy language and verification technique for stateful networks based on the symbolic model checking (SMC) framework. We are able to identify efficient symbolic representations for network states and develop efficient SMC algorithms.

Next, we discuss our key design choices before delving into more detailed algorithmic designs in the following sections.

Network model (§4). To model the behavior of a stateful network, we need two key components, an NF model that can capture various NF behavior and the modeling of packets traversing the network as we discussed above.

We need an expressive yet restrictive model that can model various NF behavior while supporting efficient verification. On one end of the spectrum, we could use a general purpose language (e.g., C in Buzz [18]), but that leads to highly inefficient verification. Motivated by existing NF models [7, 52], a stateful NF can be modeled as: 1) a set of state tables indexed by packet header fields, and 2) a set of rules that modify those state tables based on packet matching and table testing results of the incoming packet. Such restricted formalization enables efficient checking algorithms in SMC as we show in §6.

Policy specification language (§5). As shown in §2, stateful network policies have temporal properties, so a temporal specification language such as linear temporal logic (LTL) [42] is a natural choice for specifying such policies. While it is expressive enough for a wide set of network policies, the full set of LTL is computationally difficult to handle.

Our insight is that the set of network policies of interest fall into the intersection of LTL and computational tree logic (CTL) which has more efficient verification algorithms [13]. Therefore, we identify a subset of LTL that is intuitive and expressive to specify a wide range of policies while using efficient verification algorithms based on CTL. As we show in §6, reasoning about policies in this set of policies also enables us to use succinct symbolic encoding of network states and efficient checking algorithms required in SMC.

Efficient verification algorithm (§6). We design customized verification techniques based on classic SMC framework for efficiency. Algorithms for the symbolic model checking framework are well known. However, there are a set of challenges to instantiate the framework in the context of stateful network verification. First, we need a succinct symbolic representation for a large set of network states, particularly for the internal state (e.g., connection state tables) of NFs. Second, the symbolic model checking algorithm requires computing the pre-image of a symbolic state (i.e., the set of states that can transition to this state in one step), and the termination of the symbolic model checking framework requires efficient computation to check containment of two sets of states in the symbolic representation. How to efficiently support the computations remains another challenge. While classic data structures such as BDD are widely used in other contexts, it is not suitable in the context of stateful networks due to the large state space. For example, a stateful firewall maintains state for each flow and thus the number of states is as large as 2^F where F, the maximal number of flows a firewall tracks, can be in the order of thousands. Our design of the network model and policies allows us to address those two challenges. First, we succinctly encode a large set of states into a fragment of existential first-order logic (EFO). As an example for a stateful firewall, we may use $\exists x, y. Trust[x, y] = 1$ to represent all network states where there is a legitimate flow (a src-dst pair for simplicity) recorded by the connection table *Trust*. Our choice of the policy language ensures that any symbolic state emerged during the computation of SMC can be encoded in EFO. Second, our simple NF model allows us to efficient compute the pre-image of a symbolic state . Moreover, using EFO, we identify the connection between containment checking of sets of states in EFO and conjunctive query containment problem in the database community [11, 29]. We adapt the query containment checking algorithm to efficiently check the containment of two sets of network states.

4 Stateful Network Model

We present our stateful network model, including the NFs and semantic rules. We illustrate the expressiveness of our NF model via example encodings of common network functions.

4.1 NF Model

We summarize the syntax in Fig. 2. Inspired by prior work [7, 52], each NF includes local state which are key-value maps and a set of rules for processing packets and updating local state. NFs' computations are restricted to state checking, simple counting, and non-deterministic value choice. This model is more expressive than the one used by the verification

Figure 2: Syntax of stateful network model.

tool VMN [41] and is efficient (§6).

Basics. We write *pkt* to denote packets, which are records of packet fields (notation $\{\overrightarrow{t_i}\}$ is a shorthand for $\{t_1, \cdots, t_n\}$). Packet field names, denoted f, are drawn from a set of predefined names, including common field names such as `srcip`, `dstip`, `srcport` and user-defined application specific field names. We use Loc to denote the set of all locations (e.g., interfaces at a switch) in the network, including two special ones: Drop (denoting that packets are dropped) and Exit (denoting that packets exit the network). A located packet, denoted *lp*, is a pair of a location and a packet.

NF. We model all the network devices as *network functions*, denoted *NF*, which is a tuple consisting of a set of locations $\overrightarrow{l}$ (i.e. interfaces), a set of tables $\overrightarrow{T}$ for storing internal state (e.g. a stateful firewall may use state tables to store connection state), and a list of rules R that process packets and update its state. Stateless devices' state tables are empty.

A rule r consists of a list of tests on packet fields and state tables, denoted t, and a sequence of commands, denoted c, for updating the state and generating the outgoing packet. For instance, a stateful firewall may drop or forward the packet (captured by c) depending on the result of testing the packet headers and the internal state (captured by t). A rule r is fired, i.e., its commands are executed, when the current packet and state tables pass the tests in r.

We allow the following atomic tests: trivial tests that return true; tests that check the current location of the incoming packet; tests that check whether a field value or the value of a state table entry is in a specified finite domain D (e.g., an interval). Common features such as longest prefix matching for IP addresses can be modeled using $f \in D$. A command c is a sequence of updates to state tables, denoted u and actions applied to packets, denoted a.

We write e to denote expressions that can be used by rules of NFs, which include constants, packet field values indexed by field names, values picked (nondeterministically) from a domain D (**pickFrom**(D)), and values stored in state tables. Each state table is a finite key-value map, where we write $T[\overrightarrow{e_i}]$ to denote the value in an entry indexed by the key $\overrightarrow{e_i}$.

A state table can be updated. The update $T[\overrightarrow{e_i}] := e$ updates the entry indexed by the key $\overrightarrow{e_i}$ to the value of e. We allow simple counting operations to model IDS/IPS. $\mathbf{inc}(T[\overrightarrow{e_i}], v)$ increments the value in the table entry by a constant v; $\mathbf{dec}(T[\overrightarrow{e_i}], v)$ performs decrementing similarly. We consider the following actions for incoming packets: forwarding, dropping, and modifying the value of a packet field. We do not model multicasting or broadcasting in this paper.

Upon receiving a packet *pkt* at a location l, an NF attempts to match the located packet $lp = (l, pkt)$ with all of its rules. The matching succeeds if all atomic tests in the rule are true given *lp* and the current state tables. For an atomic test that involves a field name f (e.g., $f \in D$), that field name evaluates to the value of the field f in the packet *pkt*. As an example, an atomic test `Trust[`**`dst,src`**`]=1` first evaluates **`src`** and **`dst`** to be the source and destination addresses of the incoming packet *pkt*, then uses the concrete values as the key to look up the entry in the table `Trust`, and finally checks if the corresponding entry is `1`. If the matching succeeds, all actions and updates of the rule are applied sequentially. Without loss of generality, we assume that exactly one rule can match an incoming packet. It is straightforward to translate other models such as the one based on first-match into this model.

4.2 NF Examples

To demonstrate the expressiveness of our model, we show example encodings of several stateful network functions. Writing a NF model is a one-time effort, and can be automated (c.f. [48]), which is out of the scope of this work.

Stateful firewall. A stateful firewall protects an internal network by restricting accesses from external hosts. Fig. 3 shows the code snippet of a stateful firewall. Here, we assume that the internal network is connected to location 0 of the stateful firewall, and the outside network is connected to location 1. The stateful firewall uses a state table `Trust` to keep track of the flows that are established by the internal network. Initially, all entries in `Trust` have value 0. When a packet comes from the internal network, the firewall forwards it directly to the outside, and updates the state table entry for that flow to 1 (the 1st rule). When a packet comes from outside (location 1), the firewall first checks the state table to see whether a packet in the reverse direction has been seen (i.e., the table entry is 1); if so, the packet is forwarded (the 2nd rule); otherwise the packet is dropped (the 3rd rule).

Load balancer. A load balancer forwards packets destined for a virtual destination of a service (e.g., online searching) to one of the backend servers that implement the service. Fig. 4 shows a load balancer for a service with virtual IP address

```
loc=0 => Trust[src,dst]:= 1, fwd(1);
loc=1, Trust[dst,src]=1 => fwd(0);
loc=1, Trust[dst,src]=0 => drop;
```

Figure 3: Stateful firewall.

VIP, where we assume that servers are connected to location 1 and clients are connected to location 0. The load balancer maintains two state tables, `Connected` for storing whether a client has been assigned to a server and `Server` for storing the address of the server assigned to each client. Initially all table entries have value 0, indicating that no server has been assigned to any client. The first rule corresponds to the case where a client was assigned to a server (i.e. `Connect[src]=1`), and the load balancer needs to modify the destination address of the packet to the address of the assigned server as stored in the `Server` table. Similarly, the second rule accounts for the case where the client has not been assigned to any servers (i.e., `Connect[src]=0`). In this case, the load balancer picks a server from all the backend servers `D`, updates the state tables, and modifies the packet destination accordingly. Note that the use of `pickFrom(D)` abstracts away the concrete mechanism of choosing the server for a client. For packets not destined to the service, the load balancer may drop the packets as shown in the third rule. Last, for traffic going from servers to clients, the load balancer simply modify the source address of the packet to the virtual address, as indicated by the last rule.

```
loc=0, dst=VIP, Connected[src]=1 =>
  modify(dst, Server[src]), fwd(1);
loc=0, dst=VIP, Connected[src]=0 =>
  Server[src]:=pickFrom(D), Connected[src]:=1,
  modify(dst, Server[src]), fwd(1);
loc=0, dst!=VIP => drop;
loc=1 => modify(src, VIP), fwd(0);
```

Figure 4: Load balancer.

4.3 Network Semantic Model

Network configuration. We consider a network configuration N as a set of links, denoted *topo*, together with a set of NFs in the network. We model the execution of a stateful network as a state transition system, where each state corresponds to a snapshot of the network (referred to network state) and a transition between two network states denotes an atomic step of feasible network execution. In each network state, we need to consider the valuation of state tables of each NF as well as the packets in the network. We use a function Δ, which maps each state table T to a function δ_T, to denote the valuation of all NF state tables.

Packet processing in the network. To model packets in the network, a general approach is to associate each NF interface with *an infinite* FIFO queue buffering packets to be processed. As mentioned in §1, unfortunately, policy checking in such models is undecidable. Recent progress [41] relaxes this model by assuming packets are buffered in an out-of-order way. While this out-of-order model recovers decidability for some policies, it still incurs high computational complexity.

For efficient verification, we consider a model where only one packet exists in any network state. We model a network state as a pair (lp,Δ), where lp is a located packet being processed and Δ is a table valuation. Our model has three types of transitions: (1) At a network state (lp,Δ), the packet is received by a *NF* and *NF* modifies the located packet to lp' and updates the state tables to Δ', and the network evolves to state (lp',Δ'); (2) When a packet pkt is moved from one end l of a link to the other end l', a network state $((l,pkt),\Delta)$ can evolve to $((l',pkt),\Delta)$; (3) When the current packet pkt is dropped or exits the network, a new packet at an ingress location is brought into the network.That is, $((O,pkt),\Delta)$ can evolve to $((I,pkt'),\Delta)$, where O is Drop or Exit, I denotes an ingress location, and pkt' is an arbitrary packet. We write $E = s_0 \xrightarrow{lp_0/lp_1} \cdots \xrightarrow{lp_{n-1}/lp_n} s_n$ to denote execution traces, where s_i is a network state, lp_{i-1}/lp_i denotes the processed located packet and the resulting located packet in step i respectively. We assume no indefinite loops for any packet; transient loops are allowed. Detailed rules are in Appendix A.

Connecting to packet-interleaving model. Our one-packet model excludes packet interleaving behaviors, and thus cannot find all policy violations. To answer the question: *when can packet interleaving be safely ignored*, we first formalize when do the two models agree and what do they agree on.

Let us write $\mathsf{E}^{\infty}(N)$ to denote the set of all closed (i.e., both the initial and final states have only packets at locations Drop or Exit) finite execution traces of the network N under the packet interleaving semantics; similarly, we write $\mathsf{E}^{\mathsf{one}}(N)$ to denote the set of all finite closed network execution traces under the one-packet model. We assume that each packet has an unique ID, that is not modified by any NFs. Given a network execution trace $E = s_0 \xrightarrow{lp_0/lp_1} \cdots \xrightarrow{lp_{n-1}/lp_n} s_n \in \mathsf{E}^{\mathsf{one}}$ of a network N and a packet ID id, we define *per-packet trace* for a packet with ID id, denoted $E|_{id}$, as the sequence $[lp_{i_1}/lp_{i_1+1} \dots lp_{i_k}/lp_{i_k+1}]$ obtained by keeping only those lp_i/lp_{i+1} pairs whose packet ID is id. Per-packet trace for $E \in \mathsf{E}^{\infty}$ can be defined similarly.

It turns out that most network policies are checkable on per-packet traces. For example, checking the policy "packets from N1 cannot reach N2" can be achieved by examining packet-traces for every packet in the network. Then, when are the per-packet traces of the one-packet model the same as the per-packet traces of the packet interleaving model?

Our key insight is that a wide range of network scenarios are intrinsically *order-preserving*, where packets whose interleaving matters (i.e., swapping their process orders induces divergent network behavior) are processed in the same order by all NFs in the network. For example, the state update of connection-based stateful NFs is triggered by control packets of a connection, which are often sent to and processed by the network in order (e.g., a syn packet is processed before a synack packet). Thus, a network with connection-based stateful NFs is order-preserving. As another example, modern network devices often integrate a pipeline of NFs where packets traverse them in order. Networks with such stateful devices on the edge of the network such that any packet only traverses one of them is also an order-preserving network. The formal definitions are in Appendix C. We can show that for order-preserving networks, the packet interleaving model and the one-packet model agree on per-packet traces. Formally:

Lemma 1 *Given an order-preserving network N, $\forall E \in \mathsf{E}^{\infty}(N)$, $\exists E' \in \mathsf{E}^{\mathsf{one}}(N)$, s.t. $\forall id$, $E|_{id} = E'|_{id}$.*

The above lemma is the building block for proving the conditional soundness and completeness results of our algorithm.

5 Network Policies

To strike a reasonable balance between efficiency and expressiveness, we use a subset of the linear temporal logic (LTL) as our specification language. This language is expressive enough to specify a wide range of policies as we show in §7 and also is more efficient for policy checking compared to the full set of LTL formulas. Policies in this language can be translated to equivalent ones in the computational tree logic (CTL), thus allowing more efficient checking algorithms of CTL to be used [14]. Further, a simple fragment of first order logic can be used to reason about network states (details in §6). We envision tools could be used to build policy templates (e.g., [41]) or GUI (e.g., [18]), to ease the policy specification process. We provide a high-level overview of our policy specification language with details in Appendix B. We show an example policy specification from §2. We end by a theorem stating that the one-packet and packet interleaving model agree on checking several practical policies.

Syntax. The syntax of our specification language is shown below. Predicates, denoted θ, include equality checks between a packet field value, the current location of the packet, and a state table value and a variable (a symbolic value).

Predicate	θ	::=	$f = x \mid \mathtt{loc} = x \mid T[\overrightarrow{e_i}] = x$
Basic formula	γ	::=	$\theta \mid \neg\gamma \mid \gamma_1 \wedge \gamma_2 \mid \gamma_1 \vee \gamma_2$
Temporal formula	ρ	::=	$\gamma \mid \mathtt{F}\,\gamma \mid \mathtt{f}\,\gamma \mid \mathtt{X}\,(\gamma \to \rho)$
			$\mid \mathtt{G}\,(\gamma \to \rho) \mid \mathtt{g}\,(\gamma \to \rho)$
Policy	P	::=	$\overrightarrow{\forall x_i \in D_i}.\rho$

We write γ to denote basic formulas, which include predicates and propositional connectives. A temporal formula is denoted ρ, whose semantics is defined on an execution trace E, assuming the first state of E is the current state. An execution trace E satisfies $\mathtt{F}\gamma$ if γ is true on some future network state in E. We do not have the $\mathtt{U}$ operator in LTL but introduce two special operators $\mathtt{f}$ and $\mathtt{g}$ to specify properties that should hold during the traversal of the current packet in the network. More concretely, $\mathtt{f}\gamma$ is the short-hand for $(\mathtt{loc} \neq \mathsf{Drop} \wedge \mathtt{loc} \neq \mathsf{Exit})\,\mathtt{U}\gamma$. E satisfies $\mathtt{f}\gamma$ if γ holds on some future network state in the current packet's traversal. $\mathtt{g}\gamma$ is the short-hand for $\gamma\mathtt{U}(\mathtt{loc} = \mathsf{Drop} \vee \mathtt{loc} = \mathsf{Exit})$. It is true on E if γ is true on every network state in the current packet's traverse. Nested temporal formulas is only allowed in the restricted forms: $\mathtt{X}(\gamma \to \rho)$, $\mathtt{G}(\gamma \to \rho)$ and $\mathtt{g}(\gamma \to \rho)$, where $\mathtt{X}(\gamma \to \rho)$ states that starting on the next state γ is true entails ρ is true, and $\mathtt{G}(\gamma \to \rho)$ ($\mathtt{g}(\gamma \to \rho)$, resp.) intuitively asserts that whenever γ holds (during the traversal of the current packet, resp.) ρ should also hold. A network policy is a closed temporal formula, universally quantified at the outermost layer. A network N satisfies a policy P, denoted $N \models P$ iff for all execution E starting from an initial network state of N, E satisfies P. Formally definitions are in Appendix B.

The predicates here are customized to one-packet model in that a packet field name uniquely identifies the packet in the network state. By prefixing each packet field with a packet ID (i.e., $id.f$), we can express (equivalent) policies for networks with packet interleaving.

An example. We show the specification of the dynamic service chaining policy in §2. More examples can be found in §7. For space constraint, we consider a sub-policy of the dynamic service chaining policy: if a host is detected suspicious by Light IPS then all of its future packets should be directed to Heavy IPS. Suppose Light IPS keeps an internal state table named *susp* which counts bad connection numbers from each host, and a host is suspicious when the count is larger than 10. The top-level structure of the policy is $\forall x.\mathtt{G}(\gamma(x) \to \rho(x))$, which specifies that for all host x whenever $\gamma(x)$ holds $\rho(x)$ should also hold. Here, $\gamma(x) = (\mathtt{src} = x \wedge susp[x] > 10)$ specifies that the *susp* count of x is larger than 10 and the current packet is from x; $\rho(x)$ specifies that whenever a packet is sent from x, it will eventually reach H (i.e. the location of Heavy IPS) before being dropped or exiting the network. We can specify this policy as follows.

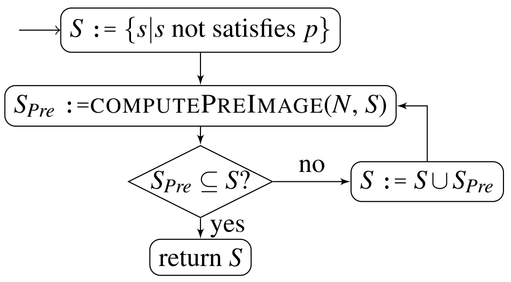
$$\forall x \in Dept. \quad \mathtt{G}(\mathtt{src} = x \wedge susp[x] > 10 \to \\ \mathtt{G}(\mathtt{src} = x \to \mathtt{f}(\mathtt{loc} = H)))$$

Model equivalence. We write $N \models^{\infty} P$ to denote that a network N satisfies policy P in the packet interleaving model; we use $N \models^{one} P$ to denote that N satisfies P in the one-packet model. A policy P^{one} specified for the one-packet model can be translated to a policy for the packet-interleaving model, denoted P^{∞}. For example, the translated isolation polity in Appendix F is $\forall id.\mathtt{G}(id.loc = A \to ((id.loc \neq B)\mathtt{U}(id.loc = \mathsf{Drop} \vee id.loc = \mathsf{Exit}))$. We prove the following theorem stating that checking a number of policies is not affected by ignoring the packet interleaving (Appendix D).

Corollary 2 *For all order-preserving networks N, $N \models^{\infty} P^{\infty}$ if and only if $N \models^{one} P^{one}$, if P is the isolation, tag preservation, or tag-based isolation policy.*

6 NetSMC Checking Algorithms

We view the verification of policies on a network as a model checking problem. Our choice of the policy language in the



$S := \{s | s \text{ not satisfies } p\}$
S_{Pre} :=COMPUTEPREIMAGE(N, S)
$S_{Pre} \subseteq S$?
no
$S := S \cup S_{Pre}$
yes
return S

Figure 5: Generic SMC algorithm workflow to check G p

restricted LTL form allows us to use the more efficient CTL model checking algorithm. In addition, to handle the large state space we adopt the symbolic model checking (SMC) framework for CTL. In this section, we first provide some background of SMC to highlight key challenges in implementing an SMC tool, and then discuss our approaches to address those challenges.

6.1 Background on SMC

Symbolic model checking is a verification technique that has been proven to be effective and efficient in many domains [14, 35]. Given a system model N and a policy P to be checked, a generic SMC framework computes the set of system states S that violates P (i.e. the set of states satisfying $\neg P$). Then the algorithm checks whether an initial state is in the set S. If so, a violation of the policy P is found; otherwise, P is verified.

To compute the set of states S satisfying $\neg P$, an SMC algorithm computes the set of states that satisfies each sub-formula of $\neg P$ bottom-up, following the structure of $\neg P$. As an example, Figure 5 shows the generic SMC algorithm to compute the set of states that violates G p, i.e., from those states there exists an execution trace of the system that violates p.

Initially, the algorithm computes the set of states violating the sub-formula p. Then it repeatedly adds states that can reach some state violating p. In each iteration of the loop, the algorithm computes the set of states S_{Pre} that can transition to a state in S in one step (i.e., $S_{Pre} = \{s | \exists s' \in S.s \rightarrow s'\}$, called the pre-image of S). The algorithm converges when every state in S_{Pre} is contained in S, and then returns the desired set.

To enable efficient SMC, we need a succinct symbolic encoding for a large set of states (e.g. S and S_{Pre}) while supporting efficient computation over them as shown in pre-image computation and subset checking. In the following, we present key components of our algorithm to address these challenges.

6.2 Symbolic Network States in EFO

To illustrate the intuition of our symbolic encodings, consider the firewall example in Fig. 3, where we are interested in checking whether packets from external networks can reach the internal network. Based on the firewall model, a packet from the outside is only allowed to go through if the tests in the second rule return true. The tests return true for all network states where an entry with value 1 exists in the table `Trust`. That is, the network states of interest can be encoded as $\exists x, y.Trust[x,y] = 1$. Thanks to our policy specification, any set of states generated in the checking of (violation of) a policy can be encoded in such an existential form (see details later in this section). Therefore, we can use the following fragment of existential first-order logic (EFO) as our symbolic state encoding. The existential quantifications are only at the outermost level (we thus omit quantifiers) and we operate on the inner formulas without quantifiers.

Atomic Predicates	α	$::=$	$x \in D \mid x \neq y$
		$\mid$	$loc = x \mid f = x \mid T[\overrightarrow{x_i}] = y$
Clauses	β	$::=$	$\bigwedge_i \alpha_i$
State Formulas	ϕ	$::=$	$\bigvee_i \beta_i$

A set of network states is encoded using a state formula, written ϕ, in a DNF form. We say that a network state (lp, Δ) is encoded by ϕ, if there exists a substitution of concrete values for all free variables in ϕ such that (lp, Δ) satisfies ϕ under that substitution. We write $Sat(\phi)$ to denote the set of network states encoded by ϕ. The atomic predicates, α, include membership predicate, inequality check, and test for fields, location and state tables. For the firewall example above, the state formula ϕ is $(Trust[x,y] = 1)$, encoding all network states where the firewall has an entry in *Trust* with value 1. As we show in the following, the encoding of EFO enables efficient computation of key components in SMC.

6.3 Computing Pre-Image

Next, we describe how to compute the state formula of the pre-image of a symbolic state S, denoted $Pre(S)$, (i.e. COMPUTEPREIMAGE). That is, given a state formula ϕ, we need to compute the state formula ϕ_{Pre}, such that $Sat(\phi_{Pre}) = Pre(Sat(\phi))$. We develop an algorithm that directly generates ϕ_{Pre} by transforming ϕ based on the network model.

Notation. Before explaining the algorithm, we define some auxiliary notations. Without loss of generality, we assume that for each clause β in ϕ, each field f appears at most once (any formula can be rewritten to this form). We write $var(f, \beta)$ to denote the variable being compared to f in β. That is, $var(f, \beta) = x$ if $f = x$ appears in β. If f does not appear in β, $var(f, \beta)$ returns a fresh variable. We write $\beta \backslash_\alpha$ to denote the formula resulted from removing the clause α from β.

Top-level algorithm. Our pre-image computing algorithm (shown in Alg. 1) considers all three types of network transitions (c.f. §4). The top-level function COMPUTEPREIMAGE takes as inputs the network model and the state formula ϕ and returns ϕ_{Pre}. The loop (lines 2-5) goes over every rule in every network function to generate a pre-image that could reach ϕ using that rule. Function COMPUTEPRERULE accounts for the network transitions under NF processing; Function COMPUTELINK on line 6 computes the pre-image for link traversal; Function COMPUTELASTPKT on line 7 computes the pre-image when ϕ represents the state where a new packet

17: function COMPUTECLS($u$, $\beta$, $[(g_{e_i}, x_{e_i})]$, $(g_e, x_e)$)
18:     let tList be the list of state tests $T(\overrightarrow{x}) = y$ in $\beta$
19:     match tList with
20:         | nil $\Rightarrow$ return $\beta$
21:         | $h$::$hs \Rightarrow \phi_0 =$ COMPUTECLS($u$, $\beta \backslash_h$)
22:             T[$\overrightarrow{e_i}$]:=$e \leftarrow u$, $(T(\overrightarrow{x}) = y) \leftarrow h$
23:             $\beta_0 := (\overrightarrow{x} = \overrightarrow{x_{e_i}}) \wedge (y = x_e)$
24:             $\beta_j := h \wedge (x_j \neq x_{e_j})$ for $j = 1, .., m$
25:             return $\bigvee_{\beta' \in \phi_0} ((\beta_0 \wedge \beta') \vee \bigvee_j (\beta_j \wedge \beta'))$
```

enters the network. The algorithm returns the disjunction of all formulas for each possible transition. Note that the returned state formula is still in EFO, which enables us to only consider EFOs for state containment. Next, we describe two key functions. We omit the third as it is similar.

Packet transitions. Function COMPUTELASTPKT computes the pre-image when a new packet comes to the network. It computes the pre-image of each clause β in ϕ, and returns the disjunction of all computed pre-images. If a network state $((l', pkt'), \Delta)$ is the result of the transition, then the state before this transition has the same state tables but a different packet. Therefore, all constraints on packet fields and locations are removed from β (line 22-24) as they do not apply to the packet in the pre-image. Furthermore, the location of the packet in the pre-image must be either Drop or Exit, and l' must be an ingress location. Thus, constraints $\texttt{loc} = \text{Drop}$, $\texttt{loc} = \text{Exit}$ are added, the same for $var(loc, \beta) = l$ for each ingress location l (line 26, 27).

NF transitions. The function COMPUTEPRERULE iteratively computes the pre-image ϕ_c under the actions and updates in r (line 9 in Alg. 1). The pre-image under rule r is obtained by adding constraints of the tests t in r using the helper function *trans* (not shown due to space) which translates each atomic test into a clause. Key sub-routines are summarized in Alg. 2.

Function COMPUTEPREACTION computes the pre-image of an action a. Consider the case where a is **modify**(f, e). The semantics of **modify** require the value of field f be modified to the value of e. Thus, the algorithm first considers the value returned by the expression e using the helper function F, which returns a clause g_e together with a variable x_e given expression e. The intuitive meaning is that if g_e is satisfied, then the value of e is equal to x_e (F's formal definitions is omitted). As an example for $e = (T[\texttt{src}, \texttt{dst}])$, $g_e = (\texttt{src} = y_1 \wedge \texttt{dst} = y_2 \wedge T[y_1, y_2] = y_3)$, and $x_e = y_3$. Then the algorithm adds the constraint g_e and $var(f, \beta) = x_e$. Furthermore, since the value for f is modified, the constraints associated with f from β can be removed as they do not apply to the pre-image.

Function COMPUTEPREUPDATE computes the pre-image under an update $T[\overrightarrow{e_i}] := e$; **inc** and **dec** are similar. The function computes the pre-images for each clause β using the sub-procedure COMPUTECLS, and returns the union of them. Function COMPUTECLS recursively enumerates all possible effects of u to β to compute its pre-image. More concretely, the function considers two cases that u may impact a constraint $T(\overrightarrow{x}) = y$ in β: 1) $T(\overrightarrow{x}) = y$ is updated by u, and 2) $T(\overrightarrow{x}) = y$ is not updated by u. In the first case, it must be the cases that $\overrightarrow{x} = \overrightarrow{x_{e_i}}$ and $y = x_e$, where x_{e_i} denotes the value read from e_i (β_0 shown in line 23). In the second case, $x_i \neq x_{e_i}$ for at least one x_i (line 24). We obtain the pre-image of β as a disjunction of the two case shown in line 25.

6.4 Containment of Network States

As shown in Figure 5, we need an efficient approach to check the containment of two sets of network states. Given two state formulas ϕ_1 and ϕ_2, we need to check if $Sat(\phi_1) \subseteq Sat(\phi_2)$. This is equivalent to checking $\exists \overrightarrow{x}.\phi_1 \Rightarrow \exists \overrightarrow{y}.\phi_2$, where $\overrightarrow{x}$ ($\overrightarrow{y}$, resp.) denotes all free variables in ϕ_1 (ϕ_2, resp.). While this can be solved using a general-purpose SMT solver, as we show in the evaluation section, this is quite inefficient.

Instead, we observe that the state containment problem of EFO is a variant of the *query containment* problem well-studied in database theory [11]. In short, query containment aims to determine if the result of a database query q_1 is contained in that of q_2 for all database instances I. To make the connection clearer, consider the state formula $\phi_1 = (\texttt{src} = x \wedge \texttt{dst} = y \wedge Trust[y,x] = 1)$. This formula can be viewed as the following (conjunctive) query on a database with three tables: *src*, *dst* and *Trust*. $q_1(x,y) : -src(x), dst(y), Trust(y,x)$

Each concrete network state can be viewed as a database instance with the schema defined by packet fields and state tables. Furthermore, each state formula ϕ is a union of conjunctive queries, where each clause β in ϕ is a conjunctive query with inequalities between variables.

In database theory, to determine whether a conjunctive query q_1 is contained in another conjunctive query q_2, it is equivalent to checking whether there is a *homomorphism* from q_2 to q_1, i.e. a function h that maps variables in q_2 to variables and constants in q_1, such that for all $R(x_1,x_2,..)$ in q_2, there is an $R(h(x_1),h(x_2),..)$ in q_1 [11].

However, there are still a few challenges in applying the algorithm to our problem. First, as shown in [29], when there are inequalities, there may not exist a homomorphism even when ϕ_1 is contained in ϕ_2. For example, $\phi_1 = (x_1 \neq x_3 \wedge T[x_1,x_2] = 1 \wedge T[x_2,x_3] = 1)$ is contained in $\phi_2 = (y_1 \neq y_2 \wedge T[y_1,y_2] = 1)$, but there is not homomorphism from ϕ_2 to ϕ_1. Second, in query containment problem a variable ranges over a continuous domain (e.g. rational numbers) [29], while in network verification a variable can only take discrete values such as IP addresses. As a result again, there may not exist a homomorphism, even if a set of states encoded in ϕ_1 is contained in the set of states encoded in ϕ_2, E.g., $\phi_1 = (x \in \{0\} \wedge y \in \{0\} \wedge T_1[x] = 1 \wedge T_1[y] = 0)$ is contained in $\phi_2 = (T_2[z] = 0)$ since no states are encoded by ϕ_1, but no homomorphism exists.

To address the first challenge, we break each clause in ϕ_1 into *atomic clauses*, which has been shown to handle inequalities [29]. We call a clause β an atomic clause w.r.t. a state formula ϕ_2, if all variables in β are distinct, and for all variables x in β and y in ϕ_2, the domain of x is either contained in or disjointed with the domain of y. For the first example above, ϕ_1 can be break into the following three atomic clauses, namely, $\beta_1 = (x_1 \neq x_2 \wedge x_2 \neq x_3 \wedge x_1 \neq x_3 \wedge T[x_1,x_2] = 1 \wedge T[x_2,x_3] = 1)$, $\beta_2 = (x_1 \neq x_2 \wedge T[x_1,x_2] = 1 \wedge T[x_2,x_2] = 1)$, and $\beta_3 = (x_1 \neq x_3 \wedge T[x_1,x_1] = 1 \wedge T[x_1,x_3] = 1)$. We see that there is a homomorphism from ϕ_2 to β_3. For the second challenge, we check for emptiness of clauses, and show that given a state formula ϕ_2 and an atomic clause β w.r.t. ϕ_2, $Sat(\beta) \subseteq Sat(\phi_2)$ if and only if there is a homomorphism from some $\beta' \in \phi_2$ to β, or $Sat(\beta)$ is empty. Now we can verify the containment in the second example above. We obtain our algorithm of checking containment by putting these two pieces together (Alg. 3).

Algorithm 3 Checking containment

```
1: function CHECKCMT($\phi_1$, $\phi_2$)
2:     for all $\beta$ in $\phi_1$ do
3:         let $[\beta_0,..,\beta_k]$ be the set of atomic clauses w.r.t. $\phi_2$ obtained from $\beta$
4:         for all $i = 0$ to $k$ do
5:             if ISEMPTY($\beta_i$) then continue
6:             if there is no homomorphism from $\beta'$ to $\beta_i$ for all $\beta' \in \phi_2$ then
7:                 return False
8:     return True
```

We prove the correctness of our algorithm w.r.t. the one-packet semantics: if NetSMC says policy verified, then all possible executions of the network satisfy the policy; and if NetSMC says policy violated, then there exists an execution that violates the policy. Formally:

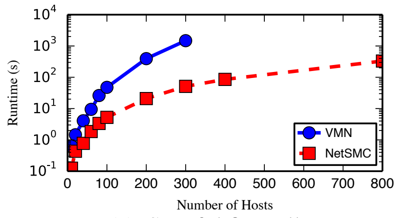
Theorem 3 (Correctness) *Given a stateful network N and a policy P, NetSMC returns True if and only if N satisfies the policy P under the one-packet model.*

The above theorem uses our one-packet semantics. Combined with theorems like Lemma 1 , the verification results of our tool on a large set of practical scenarios are correct w.r.t. the general packet interleaving semantic model as well.

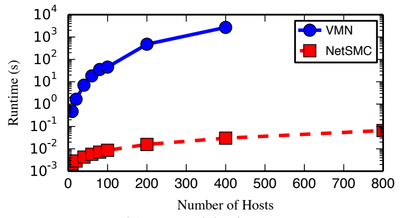
7 Evaluation

We implement a prototype tool NetSMC in Python based on the algorithms above. We evaluate NetSMC and show that:

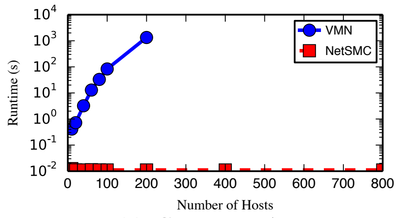
- NetSMC can scale to large-size networks and is orders of magnitude more efficient than existing approaches (§7.1);
- Our custom algorithm on containment checking in NetSMC is effective and is 42 times more efficient than naive approaches based on general-purpose solvers (§7.1);
- NetSMC can check a wide range of network policies in various practical network scenarios, which can not be easily supported in alternative tools (§7.2).



(a) Stateful firewall

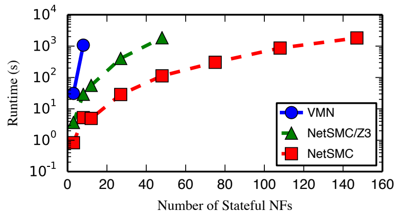


(b) Load balancer

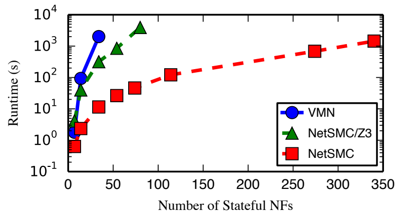


(c) Content cache

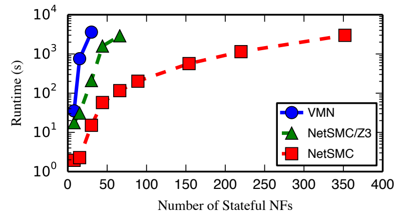
Figure 6: Scalability with NF complexity



(a) Fattree



(b) Ai3



(c) Sprint

Figure 7: Scalability with network complexity.

Evaluation setup: We ran NetSMC on a server with 20 cores (2.8GHz) and 128GB RAM. We first evaluate NetSMC's scalability by varying the complexity of NFs, topologies, and policies (§7.1). For comparison, we use the open-source implementation of VMN [41], a state-of-the-art stateful network verification tool. We also demonstrate the effectiveness and expressiveness in a range of network scenarios using real NFs based on emulation in Cloudlab [43] (§7.2). We use pfSense [3] as stateful firewalls and NATs, HAProxy [2] as load balancers. For the case study that required dynamic rule installation (e.g., path pinning), we used the Mininet-based emulation with POX [34] as the SDN controller. We ensure high-fidelity of NetSMC NF models using Alembic [38], which can automatically synthesize NF models from NF implementations. For NFs that are not readily available from Alembic (e.g., POX programs), we manually translate NF programs into equivalent NetSMC models.

7.1 Scalability

NF complexity. Stateful NFs may implement complex functionalities using multiple configuration rules. To evaluate the scalability of NetSMC w.r.t. the complexity of NFs, we consider three types of stateful NFs: (1) a stateful firewall, (2) a load balancer, and (3) a content cache. To create NF configurations with varying complexity, we connect n hosts and n servers to each NF, and for each pair of hosts and servers, we add a rule to the NF. For example, for the stateful firewall, we add rules to limit access from servers to hosts.

Fig. 6 shows the runtime on verifying isolation of a server to a host. NetSMC is orders of magnitude faster than VMN on all tested NFs. Particularly, for the stateful firewall experiment, VMN takes 1477 seconds to verify the policy with 300 hosts, while NetSMC only takes 51 seconds (28×). In the load balancer experiment, VMN takes 2693 seconds with 400 hosts while NetSMC only takes 0.03 seconds. We observe similar speedup in the cache experiment.

Topology complexity. We consider the fattree [4] topology and Ai3 and Sprint, from Topology Zoo [30]. For fattree, we create a range of topologies by varying the number of ports per switch. For Ai3 and Sprint, we systematically extend each switch with multiple switches to generate topologies with varying size. For each topology with n switches, we add additional $2n/3$ stateful NFs where each switch is attached to at most one stateful NF. We use each tool to verify the isolation policy of two hosts in each network. Since VMN critically relies on the slicing technique, we slice the flowspace of all tested networks before applying both tools.

Fig. 7 shows the runtime of verification tools w.r.t. the number of *stateful* NFs in the network. We make the following observations. First, NetSMC is at least two orders of magnitude faster than VMN. Specifically, VMN spends 1072 seconds on the fattree network with 8 stateful NFs, while NetSMC only uses 5 seconds (200× faster). Furthermore, VMN cannot scale to larger networks within 12 hours, while NetSMC can successfully verify the desired policy for networks with 147 stateful NFs in half an hour. For Ai3 and Sprint network, we see similar performance speedup. For example, VMN uses 2011 seconds on the Ai3 network with 34 stateful NFs while NetSMC only uses 11 seconds (175×).

Effectiveness of customized algorithm. To evaluate the benefit of our custom algorithms, we consider an alternative approach by using Z3 to solve the containment problem of network states in NetSMC (shown as NetSMC/Z3 in Fig. 7). We observe that our custom algorithm on containment checking significantly improves the scalability. When using Z3 to check containment, the tool uses 1844 seconds to verify the policy for the fattree network with 48 stateful NFs, which is 16× slower than our custom approach. On Ai3 and Sprint, we measured 42× and 25× speedup respectively.

Policy complexity. To evaluate the scalability of NetSMC w.r.t. the complexity of the policy to be checked, we use NetSMC to check a range of service chaining policies with varied number of NFs on the chain. Since VMN's implementation does not support this type of policy, we consider the variant of NetSMC that uses Z3 for containment checking for comparison. Fig. 8 plots the results. First, we observe that NetSMC can scale up to reasonably large policies. Particularly, NetSMC can check the service chaining policy with 20 NFs in 20 minutes. Second, we observe again that our custom algorithm on containment checking significantly improves the performance: on 12 NFs, our custom model checking algorithm is 23× faster than the Z3 variant.

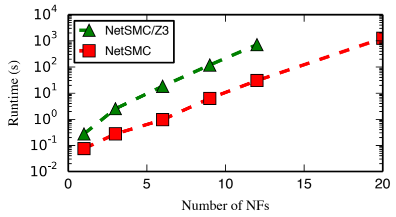


Figure 8: Scalability with policy complexity.

Comparison with general-purpose model checkers. To evaluate the benefit of our custom symbolic model checking algorithm, we further compare NetSMC with a classical BDD-based symbolic model checker NuSMV [12] and a SMT-based model checker Cubicle [15]. Since NuSMV cannot effectively model the state tables using small BDD structures, we model state tables with fixed sizes in NuSMV. We repeat the stateful firewall experiment as described above. With table size 16, NuSMV takes 1163 seconds on verify the reachability policy, while NetSMC only uses 0.015 seconds without size constraint on the state tables. NetSMC is 750X faster than Cubicle. The result confirms that our encoding of symbolic states and custom algorithms for stateful networks are more efficient than general-purpose encodings and tools.

7.2 Effectiveness and Expressiveness

Red-blue team exercise: To validate the effectiveness of NetSMC, we conduct a red-blue team exercise in a range of network scenarios using real NFs. In each scenario, the red team (Author 2 and Author 3) set up a network with intended policies in CloudLab and then delele/modify NF rules (which are kept secret from the blue team) to introduce misconfiguration. The blue team (Author 1) uses NetSMC to check intended policies on the network, so as to identify and fix the misconfiguration.

• **Blocking hosts behind NAT [19]:** The red team sets up a network with two subnetworks (N1 and N2) and two NFs using pfSense with the intended policy to block a host h1 in N1 from reaching another host h2 in N2. However, using NetSMC, the blue team identifies a violation that packets from h1 can still reach h2. The root cause is that the red team mistakenly adds a NAT rule in the first NF such that h1's address is translated and bypassing the firewall rule installed on the second NF blocking h1's address. The blue team fixes this misconfiguration by adding the firewall rule on the first NF and NetSMC verifies the policy.

Policy & network scenario	Time: Verification	Time: Bug find
Conditional reach.: A stateful firewall with ACL rules.	0.06s	0.03s
Data isol. [41]: A content cache with a client and a server.	2.23s	0.0007s
Pipeline [41]: A stateful firewall with two hosts and servers.	0.001s	0.0006s
Flow affinity: As described in Fig. 1b.	0.19s	0.04s
Dynamic service chaining: As described in Fig. 1c.	0.1s	0.008s
Reachability: Two cascaded NATs [1] (Outside can reach the inside server).	0.001s	0.005s
Tag-based isol.: Network as in Fig. 1c. (A packet labeled by a specific tag should not pass a specific MB).	0.04s	0.94s
Tag preservation: Network as in Fig. 1c. (A packet's tag labeled by a MB should be not be modified).	0.03s	0.98s
NAT consistency: If a NAT modifies a packet's port then all future packets in the flow should have the same port.	0.09s	0.078s

Table 2: Example policies supported by NetSMC.

• **Opposite rules in firewalls:** The red team sets up a network with two subnetworks (N1 and N2) and two stateful firewalls in each subnetwork (fw1 in N1 and fw2 in N2) to protect the subnetworks. The intended policy is to allow N1's packet to reach N2. The blue team uses NetSMC to check this policy and find a violation that packets from N1 is allowed by fw1 but denied at fw2. The blue team fixes the misconfiguration by removing the rule blocking N1 on fw2. Using the new model after the fix, NetSMC successfully verifies the policy.

• **Consistent load balancing:** The red team configures HAProxy to enforce the policy that packets from the same host should always be load balanced to the same server. Using NetSMC, the blue team finds a violation where one flow is sent to server 1 while another is sent to server 2. Checking the configuration, the blue team identifies that HAProxy is misconfigured in the "round robin" mode thus violating the policy. The blue team then reconfigures the LB in the "Source" mode. NetSMC successfully verifies the desired policy.

• **Path pinning:** The red team sets up the network scenario in Fig. 1d with two hosts for the Department and Internet. To enforce the path pinning policy, the red team uses a POX controller to program the forwarding rules on s1. The blue team uses NetSMC to check the path pinning policy, which finds a violation where the first packet from Department is sent to FW1 but the return packet is sent to FW2. The root cause is that the controller mistakenly installed a wrong rule on the switch for the return packets. The blue team fixes the problem by using consistent rules on the controller. Then, NetSMC then successfully verifies the policy.

Policy expressiveness. We show a wide range of policies that can be specified and checked using NetSMC, summarized in Table 2. For each case, we simulate networks in NetSMC as described in the table and introduce misconfiguration by deleting/modifying rules in NFs. NetSMC identifies the misconfiguration in all cases and can verify all policies after fixing the bugs. We report the time of verifying the policy or finding bugs. We can see that NetSMC significantly expands the scope of efficiently verifiable network policies. Today's stateless verification tools cannot model any network scenarios considered in the table, and existing stateful network verification tools [5, 41] cannot specify some of the policies (summarized in Appendix D).

8 Limitation and Discussion

One-packet model: NetSMC is built on top of the one-packet model, and thus may not find violations caused by packet interleaving. For instance, in the second example of the red-blue team exercise, if fw1 drops all packets from N1 once receiving packets from N2, while fw2 allows packets from N1 to reach N2 after seeing packets from N2 to N1, then NetSMC declares packets from N1 cannot reach N2. However, the following violating trace is missed by the one-packet model: first, a packet p1 from N1 passes fw1, then fw2 processes packet p2 from N2 to N1. Next, fw2 allows p1 to reach N2.

NF Model: NetSMC only supports header matching, state table checking, and simple counting; more complex operations, such as computing average values, are not supported.

Policy: Our policy language cannot express policies needing arbitrary quantification, nesting of temporal operators, or generic until path formulas. For instance, the policy that "at some time in the future, a packet from h1 to h2 is delivered", $\texttt{F}(loc = h1 \rightarrow \texttt{f}(loc = h2))$, is beyond our scope.

Network failures: Currently NetSMC does not model network failures directly and can only check policies in the presence of failure by enumerating each failure scenario and run NetSMC in each case, which may not be efficient.

9 Related Work

Our stateful network model is motivated by existing work on network modeling and programming languages [6, 7, 21, 28, 36, 37, 52]. Our NF model shares key characteristics with the models in NetEgg [52] and SNAP [7].

There is a rich body of work for testing and verifying forwarding behaviors in stateless networks [23, 25–27, 31, 32, 46, 49, 50, 53, 53, 54]. While those work can efficiently check a number of policies such as reachability and loop freedom, it is nontrivial to extend those work to support stateful data planes, which are the target of our work.

For example, Header Space Analysis (HSA) [26] models each packet as a point in the high-dimension space of packet headers and each switch as a transfer function from a subspace into another. Based on symbolic reasoning of the transfer functions, HSA can efficiently verify policies such as reachability and loop freedom. Adapting HSA for stateful network verification would need to introduce some notion of state to the transfer function, which would require a complete redesign of the verification algorithm.

Veriflow [27] uses an alternative "trie" like encoding and focuses on checking policies incrementally when network configurations change. Whenever a rule change occurs on a switch, Veriflow computes the packet space that is influenced by the change, and only applies verification to the delta part. Again, adding state to the trie structure and its associated algorithms is non-trivial.

NoD [31] is based on a generic Datalog framework to check reachability policies, where both networks and policies are encoded in Datalog. NoD can potentially be extended to model stateful network functions. However, Datalog is limited in its expressive power in terms of network policies; temporal properties such as flow affinity and dynamic service chaining cannot be easily specified. It is also unclear if such a stateful extension (if exists) scales.

Our work is closely related to recent efforts on stateful data plane testing and verification. Buzz [18] and SymNet [45] generate test cases for stateful networks based on symbolic execution. VMN [41] verifies isolation properties based on SMT encodings. Alpernas et al. present abstractions to check isolation properties [5]. Those projects, except VMN, only support a subset of our policies. We cannot express generic policies involving past operations; while VMN cannot express some policies NetSMC supports. Our approach is also different in the network model and we build a highly custom symbolic model checker to improve the efficiency.

There are several complementary proposals on verifying control planes: Batfish [20], ERA [17], ARC [22] and Minesweeper [9] analyze routing control planes. NICE [10], VeriCon [8], SDNRacer [16], FlowLog [39] and Kuai [33] target SDN controllers. Work on verifying firewalls [24, 40, 51, 55] can handle statefulness in firewalls, but it is not clear whether those techniques can generalize to handle more expressive network functions and policies.

10 Conclusions

This paper explores a different design space in building efficient verification tools for stateful networks. We identify key domain-specific insights to define a compact model of stateful networks, customize policy specifications, and develop efficient custom symbolic model checking algorithms for verification. We implement NetSMC and show that it achieves orders of magnitude speedup compared to alternative approaches, while supporting a wide range of policies.

Appendix

A Semantics of Stateful Network Model

The top-level transition rules are of the form: $s \rightarrow s'$. We use a number of auxiliary transitions summarized below:

$[\![e]\!]_{lp;\Delta} = v$	Expression evaluation
$[\![at]\!]_{lp;\Delta} = b$	Atomic test evaluation
$[\![t]\!]_{lp;\Delta} = b$	Test evaluation
$c; lp; \Delta \rightarrow lp'; \Delta'$	Command evaluation
$r; lp; \Delta \rightarrow lp'; \Delta'$	Rule evaluation
$\texttt{NF}; lp; \Delta \rightarrow lp'; \Delta'$	NF evaluation

The semantic rules of our stateful network model are summarized in Figure 10, Figure 11, and Figure 9.

$\boxed{s \rightarrow s'}$

$$\textsc{Net-Trans-NF}\quad \frac{NF = (L,\_,\_) \qquad l \in L \qquad lp = (l, pkt) \qquad NF;(l,pkt);\Delta \rightarrow (l',pkt');\Delta'}{(lp,\Delta) \rightarrow ((l',pkt'),\Delta')}$$

$$\frac{topo(l) = l'}{((l,pkt),\Delta) \rightarrow ((l',pkt),\Delta)}\ \textsc{Net-Link}$$

$$\frac{l = \mathsf{Drop/Exit} \qquad l' \in IngressLocs}{((l,\_),\Delta) \rightarrow ((l',pkt),\Delta)}\ \textsc{Net-Packet}$$

Figure 9: One-packet semantics of network execution.

$\boxed{[\![e]\!]_{lp;\Delta} = v}$

PICKFROM
$$\frac{v \in D}{[\![\mathbf{pickFrom}(D)]\!]_{lp;\Delta} = v}$$

FIELD
$$\frac{lp = (\_, pkt) \qquad pkt.f = v}{[\![f]\!]_{lp;\Delta} = v}$$

STATE-TABLE
$$\frac{\forall i, [\![e_i]\!]_{lp;\Delta} = v_i \qquad \delta_T = \Delta(T) \qquad \delta_T(\overrightarrow{v_i}) = v}{[\![T[\overrightarrow{i = e_i}]]\!]_{lp;\Delta} = v}$$

$\boxed{[\![at]\!]_{lp;\Delta} = b}$

TEST-LOC-TRUE
$$\frac{lp = (l, \_)}{[\![\mathtt{loc} = l]\!]_{lp;\Delta} = \mathsf{True}}$$

TEST-LOC-FALSE
$$\frac{lp = (l', \_) \qquad l \neq l'}{[\![\mathtt{loc} = l]\!]_{lp;\Delta} = \mathsf{False}}$$

TEST-FIELD-TRUE
$$\frac{[\![f]\!]_{lp,\Delta} \in D}{[\![f \in D]\!]_{lp;\Delta} = \mathsf{True}}$$

TEST-FIELD-FALSE
$$\frac{[\![f]\!]_{lp,\Delta} \notin D}{[\![f \in D]\!]_{lp;\Delta} = \mathsf{False}}$$

TEST-TABLE-TRUE
$$\frac{[\![T[\overrightarrow{i = e_i}]]\!]_{lp;\Delta} = v}{[\![T[\overrightarrow{i = e_i}] = v]\!]_{lp;\Delta} = \mathsf{True}}$$

TEST-TABLE-FALSE
$$\frac{[\![T[\overrightarrow{i = e_i}]]\!]_{lp;\Delta} = u \qquad u \neq v}{[\![T[\overrightarrow{i = e_i}] = v]\!]_{lp;\Delta} = \mathsf{False}}$$

TEST-NEG
$$\frac{}{[\![\neg at]\!]_{lp;\Delta} = \neg[\![at]\!]_{lp;\Delta}}$$

$\boxed{[\![t]\!]_{lp;\Delta} = b}$

TEST-SEQUENCE-TRUE
$$\frac{[\![t_1]\!]_{lp;\Delta} = \mathsf{True}}{[\![t_1, t_2]\!]_{lp;\Delta} = [\![t_2]\!]_{lp;\Delta}}$$

TEST-SEQUENCE-TRUE
$$\frac{[\![t_1]\!]_{lp;\Delta} = \mathsf{False}}{[\![t_1, t_2]\!]_{lp;\Delta} = \mathsf{False}}$$

Figure 11: Semantics of network function (cont.).

B Policy Semantics

We define the semantics of open formulas ρ over a tuple $(\mathtt{V}, E, N)$ (Figure 2), where $\mathtt{V}$ is the valuation function of all free variables appearing in ρ, E is an infinite network execution trace (i.e., a sequence of network states), and N is the network configuration. We write E_i to denote the i-th state in E and $E[i..]$ as the suffix of E starting at the i-th state, Similar to the semantic rules, we omit the network configuration N for simplicity of presentation. $(\mathtt{V}, E)$ satisfying ρ, written $(\mathtt{V}, E), \models \rho$ is formally defined below.

- $(\mathtt{V}, E) \models \gamma$ iff $E_0 \models \gamma$ in the standard way.
- $(\mathtt{V}, E) \models \mathtt{G}\rho$ iff $(\mathtt{V}, E[i..]) \models \rho$ for all $i \geq 0$
- $(\mathtt{V}, E) \models \mathtt{g}\rho$ iff there is an $i \geq 0$ where $E_i = (lp, \Delta)$, s.t. 1) $lp = (\mathsf{Drop}, \_)$ or $lp = (\mathsf{Exit}, \_)$ and 2) for all $j < i$, $(\mathtt{V}, E[j..]) \models \rho$.
- $(\mathtt{V}, E) \models \mathtt{F}\gamma$ iff $(\mathtt{V}, E[i..]) \models \gamma$ for some i
- $(\mathtt{V}, E) \models \mathtt{f}\gamma$ iff there is an $i \geq 0$ s.t. 1) $E_i \models \gamma$ and 2) for all $j < i$ where $E[j] = (lp, \Delta)$, $lp \neq (\mathsf{Drop}, \_)$ and $lp \neq (\mathsf{Exit}, \_)$
- $(\mathtt{V}, E) \models \mathtt{X}\rho$ iff $(\mathtt{V}, E[1..]) \models \rho$.

C One packet vs. packet interleaving model

We identify sufficient conditions under which our one packet model is equivalent to the interleaving model considered in [41] w.r.t. a set of policies. First, we give the formal semantics of the interleaving model; then we show sufficient conditions under which our one packet model is equivalent to the interleaving model, followed by our proofs establishing the equivalence.

Executions in packet interleaving network model: A network state in the packet interleaving model is a pair $(\mathtt{Q},\Delta)$, where $\mathtt{Q}$ is the set of packets buffered at each network location and Δ is the valuation function of state tables as usual. The network state of the one-packet model is a special case where $|\mathtt{Q}| = 1$. We use $ID(p)$ to denote the ID of packet p and $ID(lp)$ has its natural meaning. The top-level transition rules of the packet interleaving model are given in Fig. 12, where the three rules generalized the corresponding rules in the one packet model. Each transition in the transition system of the packet-interleaving model is of the form of $s \xrightarrow{lp/lp'}_{NF} s'$, where lp/lp' denote the (located) packet that is processed by the transition and lp (lp', resp.) denote the packet before (after, resp.) the transition, NF denotes the NF that processes that packet or *null* (which we typically ignore) if the packet is transmitted by a link or injected into the network.

A network execution trace E is a sequence of transitions $s_0 \Rightarrow s_1 \Rightarrow \cdots \Rightarrow s_n$. A *closed network execution trace* is a finite network execution where the both initial state s_0 and the final state s_n contain no packets buffered at any location except for Drop and Exit. We use $\mathsf{E}^\infty(N)$ to denote the set of all closed network execution traces of a given network N under the packet interleaving semantics; similarly, we use $\mathsf{E}^{\mathsf{one}}(N)$ to denote the set of all closed network execution traces under the one-packet model. We assume that there is no indefinite loops for any packet traversal; transient loops are allowed to appear.

Formalization of processing-order preserving: We give necessary definitions first before we formalize the processing-order preserving condition.

Definition 4 (Non-conflict) *Given NF, lp_1, lp_2, we say that lp_1 is non-conflicting with lp_2 at NF if $\forall \Delta_0, \Delta_1, \Delta_2, lp'_1, lp'_2$ s.t. $NF; lp_1; \Delta_0 \to lp'_1; \Delta_1$ and $NF; lp_2; \Delta_1 \to lp'_2; \Delta_2$, $\exists \Delta'_1$ s.t. $NF; lp_2; \Delta_0 \to lp'_2; \Delta'_1$ and $NF; lp_1; \Delta'_1 \to lp'_1; \Delta_2$.*

We define processing-order preserving based on packet orders. Particularly, given a set of packets, a packet order $\prec$ is a strict total order on the IDs of the packets. Given two located packets lp_1 and lp_2, we denote $lp_1 \prec lp_2$ if $ID(lp_1) \prec ID(lp_2)$.

Definition 5 (Processing-order preserving trace) *Given a network N, a network execution trace $E = s_0 \Rightarrow \ldots \Rightarrow s_n$ (under the packet interleaving model) in $\mathsf{E}^\infty(N)$, a packet order $\prec$, E is* processing-order preserving *(or order-preserving in short) under $\prec$ if $\forall lp_1, lp_2, NF$ such that $lp_2 \prec lp_1$ and lp_1 is conflicting with lp_2 at NF, there do not exist transitions $s_j \xrightarrow{lp_1/lp'_1}_{NF} s_{j+1}$ and $s_k \xrightarrow{lp_2/lp'_2}_{NF} s_{k+1}$ in E where $k \geq j+1$.*

$$\boxed{(\mathtt{Q},\Delta) \xrightarrow{lp/lp'}_{NF} (\mathtt{Q},\Delta')}$$

NET-TRANS-NF

$$\frac{\begin{array}{c} NF = (L,\_,\_) \\ l \in L \qquad pkt \in \mathtt{Q}(l) \qquad NF;(l,pkt);\Delta \to (l',pkt');\Delta' \\ \mathtt{Q}' = \mathtt{Q}[l' \mapsto (\mathtt{Q}(l') \cup \{pkt'\})][l \mapsto (\mathtt{Q}(l) \setminus \{pkt\})] \end{array}}{(\mathtt{Q},\Delta) \xrightarrow{(l,pkt)/(l',pkt')}_{NF} (\mathtt{Q}',\Delta')}$$

NET-LINK

$$\frac{\begin{array}{c} topo(l) = l' \qquad pkt \in \mathtt{Q}(l) \\ \mathtt{Q}' = \mathtt{Q}[l' \mapsto (\mathtt{Q}(l') \cup \{pkt\})][l \mapsto (\mathtt{Q}(l) \setminus \{pkt\})] \end{array}}{(\mathtt{Q},\Delta) \xrightarrow{(l,pkt)/(l',pkt')}_{null} (\mathtt{Q}',\Delta)}$$

NET-TRANS-IN

$$\frac{l \in \mathsf{IngressLocs} \qquad \mathtt{Q}' = \mathtt{Q}[l \mapsto (\mathtt{Q}(l) \cup \{pkt\})]}{(\mathtt{Q},\Delta) \xrightarrow{-/(l,pkt)}_{null} (\mathtt{Q}',\Delta)}$$

Figure 12: Semantics of packet interleaving execution.

We call a network N *processing-order preserving* if there is a packet order $\prec$ such that for all $E \in \mathsf{E}^\infty(N)$, E is order preserving under $\prec$. Some example processing-order preserving networks includes: (1) a network with no stateful NFs; (2) a network where any single packet only traverses one stateful NF; (3) a network with connection-based NFs where packets in a connection are delivered in order.

Equivalence between one packet model and packet interleaving model: Given a closed network execution trace $E = s_0 \xrightarrow{lp_1/lp_2} \cdots \xrightarrow{lp_{n-1}/lp_n} s_n$ in $\mathsf{E}^\infty(N)$ of a network N and an ID id, we call the per-packet trace of id, denoted $E|_{id}$, as the sequence $[lp_{i_1}/lp_{i_1+1} \ldots lp_{i_k}/lp_{i_k+1}]$ obtained by projecting all lp_i/lp_{i+1} pairs (except for the first pair corresponding to the NET-TRANS-IN rule) with the ID id from the sequence $[lp_1/lp_2 \ldots lp_{n-1}/lp_n]$. We define the per-packet trace for executions in the one-packet model similarly.

Lemma 1 *Given an order-preserving network N, $\forall E \in \mathsf{E}^\infty(N)$, $\exists E' \in \mathsf{E}^{\mathsf{one}}(N)$, s.t. $\forall id$, $E|_{id} = E'|_{id}$.*

PROOF. Let $\prec$ be the packet order satisfying the order-preserving of N. Suppose $E = s_0 \xrightarrow{lp_0/lp'_0} s_1 \xrightarrow{lp_1/lp'_1}, \ldots, \xrightarrow{lp_{n-1}/lp'_{n-1}} s_n$. We define the out-of-order index I of E as number of disordered transitions w.r.t. $\prec$. Formally $I(E,\prec) = \sum_{i<n} |\{j | j < i, lp_i \prec lp_j\}|$.

We prove this lemma by induction over the out-of-order index of E.

Base case: Since $I(E,\prec) = 0$, we know that $lp_i \not\prec lp_{i-1}$ for all

$i \geq 1$, i.e., $ID(lp_{i-1}) = ID(lp_i)$ or $ID(lp_{i-1}) \prec ID(lp_i)$. Since E is closed, there is an execution trace $(lp_0, \Delta_0) \to (lp_1, \Delta_1) \to \ldots \to (lp_n, \Delta_n)$ (if some lp_i is empty, simply ignore that state) in the one-packet model where Δ_i is the table valuation in s_i, and the per-packet trace for all packets are the same.

Inductive case: We have the inductive hypothesis: For all $E \in \mathsf{E}^\infty(N)$ where $I(E, \prec) \leq k$, there is an execution trace $E' \in \mathsf{E}^{\mathsf{one}}(N)$ s.t. $E|_{id} = E'|_{id}$. Now consider the case where $I(E, \prec) = k+1$. Since $I(E, \prec) > 0$, there exists $i > 0$ such that $s_{i-1} \xRightarrow{lp_{i-1}/lp'_{i-1}} s_i \xRightarrow{lp_i/lp'_i} s_{i+1}$ and $lp_i \prec lp_{i-1}$. We claim that there must exists a network state s'_i such that $s_{i-1} \xRightarrow{lp_i/lp'_i} s'_i \xRightarrow{lp_{i-1}/lp'_{i-1}} s_{i+1}$. This is easy to see when the transition $s_i \xRightarrow{lp_i/lp'_i} s_{i+1}$ is obtained from rule NET-LINK or NET-TRANS-IN. Suppose the transition is from NET-TRANS-NF and the NF that processes lp_i on s_i is NF. If transition $s_{i-1} \xRightarrow{lp_{i-1}/lp'_{i-1}} s_i$ is not from NET-TRANS-NF or does not correspond to the processing NF NF, the claim is also obvious. When both transitions correspond to the process of the packets on NF, from the processing-order preserving definition, lp_i must be non-conflicting with lp_{i-1} at NF. Thus from Lemma 6 the claim is still true. By swapping the processing of lp_{i-1} and lp_i we obtain an order-preserving execution trace E'' from E such that $E''|_{id} = E|_{id}$ for all id and $I(E'', \prec) = k$. From the inductive hypothesis, there is an execution trace $E' \in \mathsf{E}^{\mathsf{one}}(N)$ s.t. $E'|_{id} = E''|_{id} = E|_{id}$ for all id. □

Lemma 6 *For all network N, located packets lp_1, lp'_1, lp_2, lp'_2, $NF \in N$, and network states s_1, s_2, s_3 of N, if $s_1 \xRightarrow{lp_1/lp'_1}_{NF} s_2 \xRightarrow{lp_2/lp'_2}_{NF} s_3$ and lp_1 is non-conflicting with lp_2 at NF, then $\exists s'_2$ s.t. $s_1 \xRightarrow{lp_2/lp_2}_{NF} s'_2 \xRightarrow{lp_1/lp'_1}_{NF} s_3$.*

PROOF. Immediate from definition of non-conflicting.

D Soundness and Completeness of Checking Per-Packet-Trace Policies

From Lemma 1, we can show that checking a range of policies involving per-packet traces is equivalent between the packet interleaving network model and the one packet model provided that network is processing-order preserving.

Per-packet-trace policies. We define per-packet-trace policies (for the one-packet model) as follows.

$$\varphi^{one} \ ::= \forall \overrightarrow{x_i \in D_i}.\mathtt{G}\,(\gamma_1 \to \mathtt{g}\gamma_2) \,|\, \forall \overrightarrow{x_i \in D_i}.\mathtt{G}\,(\gamma_1 \to \gamma_2)$$

A translation function, denoted $\langle \cdot \rangle$, turns a formula for the one-packet model to a corresponding formula for the packet-interleaving model. It is defined as follows, which essentially introduces a packet ID into the formula. We only show selected rules and the rest are inductively defined over the structure of the formula.

$$\begin{aligned}
&\langle \forall \overrightarrow{x_i \in D_i}.\mathtt{G}\,(\gamma_1 \to \mathtt{g}\gamma_2) \rangle = \\
&\quad \forall id. \forall \overrightarrow{x_i \in D_i}.\mathtt{G}\,(\langle \gamma_1 \rangle_{id} \to \\
&\qquad \langle \gamma_2 \rangle_{id}\, \mathtt{U}\,(id.\mathtt{loc} = \mathsf{Drop} \vee id.\mathtt{loc} = \mathsf{Exit})) \\
&\langle f = x \rangle_{id} = id.f = x \\
&\langle \mathtt{loc} = x \rangle_{id} = id.\mathtt{loc} = x \\
&\langle f \rangle_{id} = id.f \quad \langle x \rangle_{id} = x \quad \langle v \rangle_{id} = v
\end{aligned}$$

We can prove the following theorem.

Theorem 7 *For all order-preserving network N, $N \models^{one} \varphi^{one}$ if and only if $N \models^\infty \langle \varphi^{one} \rangle$.*

PROOF. We only prove the case for the first form of φ^{one}. Proofs for the second is very similar. Let $\varphi^{one} = \forall \overrightarrow{x_i \in D_i}.\mathtt{G}\,(\gamma_1 \to \mathtt{g}\gamma_2)$.

($\leftarrow$) Suppose $N \not\models^{one} \varphi^{one}$. By the definition of the policy, there exists $\overrightarrow{v_i}$ for $\overrightarrow{x_i}$ and an execution trace $E = (lp_0, \Delta_0) \to \ldots \to (lp_n, \Delta_n) \in \mathsf{E}^{\mathsf{one}}(N)$, and some i, j, such that $0 \leq i \leq j \leq n$, $(V, E[i..]) \models \gamma_1$, and $(V, E[j..]) \not\models \gamma_2$, where $V = [\overrightarrow{x_i \mapsto v_i}]$. and for all k, l_k s.t. $i < k < j$ and $lp_k = (l_k, \_)$, $l_k \notin \{\mathsf{Drop}, \mathsf{Exit}\}$.

By the semantics of one-packet model, $\forall m$ s.t. $i < m < j$, $ID(lp_m) = ID(lp_i) = ID(lp_j) = pid$.

We can then construct an execution trace $E' \in \mathsf{E}^\infty(N)$ by injecting one packet at a time to simulate E, and the only trivial difference between E and E' is that incoming packets takes an extra step, rather than being enqueued right after the previous packet exits.

It's straightforward to show that $(V[id \mapsto pid], E'[i..]) \models \langle \gamma_1 \rangle_{id}$ and $(V[id \mapsto pid], E'[j..]) \not\models \langle \gamma_2 \rangle_{id}$, and $i < k < j$ and $(V[id \mapsto pid], E'[k..]) \models id.\mathtt{loc} \neq \mathsf{Drop} \wedge id.\mathtt{loc} \neq \mathsf{Exit}$, since there is only one packet with ID pid in the packet queue.

By the formula semantics, $(V[id \mapsto pid], E'[i..]) \not\models \langle \mathtt{g}\,\gamma_2 \rangle_{id}$. It follows that $(\emptyset, E') \not\models \langle \varphi^{one} \rangle$, so $N \not\models^\infty \langle \varphi^{one} \rangle$, which contradicts with our assumption.

($\rightarrow$) Suppose $N \not\models^\infty \langle \varphi^{one} \rangle$. By the definition of the policy, there exists $\overrightarrow{v_i}$ for $\overrightarrow{x_i}$, pid for id and an execution trace $E = s_0 \Rightarrow \ldots \Rightarrow s_n \in \mathsf{E}^\infty(N)$, and some i, j, such that $0 \leq i \leq j \leq n$, $(V, E[i..]) \models \langle \gamma_1 \rangle_{id}$, and $(V, E[j..]) \not\models \langle \gamma_2 \rangle_{id}$, where $V = [\overrightarrow{x_i \mapsto v_i}, id \mapsto pid]$. And for all k s.t. $i < k < j$, $(V, E[k..]) \models id.\mathtt{loc} \neq \mathsf{Drop} \wedge id.\mathtt{loc} \neq \mathsf{Exit}$.

By the network semantics, the located packet with ID pid in E_i must have entered the queue at some point. Let $i' \leq i$ be the index of the first such state in E, such that $E = \cdots \xRightarrow{lp_{i'}/lp'_{i'}} s_{i'} \cdots$. Similarly, we identify $j' \leq j$ such that j' is the first state where the located packet in E_j has arrived at the packet queue. W.o.l.g. $E = \cdots \xRightarrow{lp_{i'}/lp'_{i'}} s_{i'} \cdots \xRightarrow{lp_{j'}/lp'_{j'}} s_{j'} \cdots$. It is straightforward that for all k s.t. $i' < k < j'$, $(V, E[k..]) \models id.\mathtt{loc} \neq \mathsf{Drop} \wedge id.\mathtt{loc} \neq \mathsf{Exit}$ (Dropped or Exited packets cannot come back with the same pid). Note that $ID(lp'_{i'}) = ID(lp'_{j'}) = pid$.

By Lemma 1, there is an execution trace $E' \in \mathsf{E}^{\mathsf{one}}(N)$ where $E'|_{pid} = E|_{pid}$. By the semantics of the one packet model, $E' = \cdots E'' \cdots$, where $E''|_{pid} = E|_{pid}$ and E'' contains processing of only packets with ID pid. So, $(V\backslash id, E') \not\models \gamma_1 \rightarrow \mathtt{g}\,\gamma_2$.

It follows that $N \not\models^{one} \varphi^{one}$, which contradicts with our assumption. □

Corollary 8 *NetSMC is sound and complete w.r.t. the packet interleaving model when checking isolation, tag preservation, tag-based isolation policies.*

This follows from Theorem 7 and Theorem 3.

Comparison with VMN: VMN accepts policies of the form: $\forall n, p : G\neg(rcv(d,n,p) \wedge predicate(p))$ (see Appendix B.2 in [41]) where $predicate(p)$ may include past events. We can express all the policies in VMN that do not have past events in $predicate(p)$ (i.e., a basic formula). Isolation, tag-based isolation, and tag preservation fall into this category. Further, in the three cases. NetSMC is sound and complete w.r.t. VMN.

The conditional isolation in VMN cannot be expressed in our policy language, since it involves past events and requires a generic until operator, which we do not support. On the other hand, NAT consistency, conditional reachability, flow affinity, double NAT, and dynamic service chaining cannot be expressed in VMN. In these cases, NetSMC is sound and conditional complete w.r.t. the one-packet model.

E Policy Translation to CTL

Our choice of the policy language as a subset of LTL allows us to translate policies to equivalent forms in CTL. Thus we can use the model checking algorithm of CTL to check those policies. To simplify our notation in the proof, we write $(V,s) \models \rho$ to denote that $\forall E$ s.t. $E_0 = s$, $(V,E) \models \rho$.

Theorem 9 *For all network N and policy P, $N \models P$ if and only if $N \models P_{CTL}$.*

PROOF. Suppose $P = \forall \overrightarrow{x_i \in D_i}.\rho$ and thus $P_{CTL} = \forall \overrightarrow{x_i \in D_i}.\rho_{CTL}$. (If) Since $N \models P_{CTL}$, by the definition over the structure of ρ $\forall V, s$ s.t. $V[x_i] \in D_i$ and s is an initial state of N, $(V,s) \models \rho_{CTL}$. By Lemma 10, $(V,s) \models \rho$. Thus $N \models P$. (Only if) Since $N \models P$, by the definition, $\forall V, s$ s.t. $V[x_i] \in D_i$ and s is an initial state of N, $(V,s) \models \rho$. By Lemma 10, $(V,s) \models \rho_{CTL}$. Thus $N \models P_{CTL}$. □

Lemma 10 *For all network N, temporal formula ρ, valuation function V for variables appeared in ρ, state s in N, $(V,s) \models \rho$ if and only if $(V,s) \models \rho_{CTL}$.*

PROOF. Proof by induction over the structure of ρ.
Case 1 $\rho = \gamma$: This is immediate from the definition.
Case 2 $\rho = \mathtt{F}\gamma$: (If) Since $(V,s) \models \mathtt{AF}\gamma$, for all execution trace E where $E_0 = s$, there is some $i \geq 0$ s.t. $E_i \models \gamma$. Thus, $(V,s) \models \mathtt{F}\gamma$. (Only if) Since $(V,s) \models \mathtt{F}\gamma$, for all execution trace E where $E_0 = s$, there is some $i \geq 0$ s.t. $E_i \models \gamma$. Thus, $(V,s) \models \mathtt{AF}\gamma$.
Case 3 $\rho = \mathtt{f}\gamma$: (If) Since $(V,s) \models \mathtt{A}((\mathtt{loc} \neq \mathsf{Drop} \wedge \mathtt{loc} \neq \mathsf{Exit})\mathtt{U}\gamma)$, for all execution trace E where $E_0 = s$, there is some $i \geq 0$ s.t. $E_i \models \gamma$ and for all $j < i$, the location of E_j is not Drop nor Exit. Thus, $(V,E) \models \mathtt{f}\gamma$. Thus, $(V,s) \models \mathtt{f}\gamma$. (Only if) Since $(V,s) \models \mathtt{f}\gamma$, for all execution trace E where $E_0 = s$, there is some $i \geq 0$ s.t. $E_i \models \gamma$ and for all $j < i$ the location of E_j is not Drop nor Exit. Thus, $(V,s) \models \mathtt{A}((\mathtt{loc} \neq \mathsf{Drop} \wedge \mathtt{loc} \neq \mathsf{Exit})\mathtt{U}\gamma)$.
Case 4 $\rho = \mathtt{G}(\gamma \rightarrow \rho')$: From Lemma 12, we only need to show for all s', $(V,s') \models \gamma \rightarrow \rho'$ if and only if $(V,s') \models \gamma \rightarrow \rho_{CTL}$. First, when $(V,s') \not\models \gamma$, we have $(V,s') \models \gamma \rightarrow \rho'$ and $(V,s') \models \gamma \rightarrow \rho_{CTL}$. Second, when $(V,s') \models \gamma$, from the inductive hypothesis, $(V,s') \models \rho'$ if and only if $(V,s') \models \rho_{CTL}$.
Case 5 $\rho = \mathtt{g}(\gamma \rightarrow \rho_1)$: Similar to the proof of Case 4 and use Lemma 11.
Case 6 $\rho = \mathtt{X}(\gamma \rightarrow \rho_1)$: Similar to the proof of Case 4 and use Lemma 12. □

Note that the ρ in the following two lemmas are generic temporal formulas, not confined to our policy syntax.

Lemma 11 *For all network N, temporal formula ρ, valuation function V for variables appeared in ρ, if for all state s, $(V,s) \models \rho$ is equivalent to $(V,s) \models \rho_{CTL}$, then for all state s', $(V,s') \models \mathtt{g}\rho$ is equivalent to $(V,s') \models \mathtt{A}((\rho_{CTL})\mathtt{U}(\mathit{loc} = \mathsf{Drop} \vee \mathit{loc} = \mathsf{Exit}))$.*

PROOF. (If) By the definition of $(V,s') \models \mathtt{A}((\rho_{CTL})\mathtt{U}(\mathsf{Drop} \vee \mathsf{Exit}))$, for all execution trace E where $E_0 = s'$ and $i \geq 0$ where the location of E_i is Drop or Exit, $(V,E_j) \models \rho_{CTL}$ for all $j < i$. By the assumption, $(V,E_j) \models \rho$. Thus, $(V,E[j..]) \models \rho$. Therefore, $(V,E) \models \mathtt{g}\rho$. Thus, $(V,s') \models \mathtt{g}\rho$.
(Only if) Suppose $(V,s') \not\models \mathtt{A}((\rho_{CTL})\mathtt{U}(\mathtt{loc} = \mathsf{Drop} \vee \mathtt{loc} = \mathsf{Exit}))$. By its definition, there is a execution trace E and $i \geq 0$ such that $E_0 = s'$ and $(V,E_i) \not\models \rho_{CTL}$ and for all $j \leq i$, the location of E_j is not Drop nor Exit. Since $(V,E_i) \not\models \rho_{CTL}$, we have $(V,E_i) \not\models \rho$; i.e. there is a execution trace E' where $E'_0 = E_i$ such that $(V,E') \not\models \rho$. Consider the execution trace $E'' = E[0..i-1] + +E'$. Note that $E''[i..] = E'$, thus $(V,E''[i..]) \not\models \rho$. In addition, for all $j \leq i$, the location of E''_j is not Drop nor Exit. Thus $(V,E'') \not\models \mathtt{g}\rho$, which contradicts to that $(V,s') \models \mathtt{g}\rho$. □

Lemma 12 *For all network N, temporal formula ρ, valuation function V for variables appeared in ρ, if for all state s, $(V,s) \models \rho$ is equivalent to $(V,s) \models \rho_{CTL}$, then for all state s', $(V,s') \models \mathtt{G}\rho$ is equivalent to $(V,s') \models \mathtt{AG}(\rho_{CTL})$ and $(V,s') \models \mathtt{X}\rho$ is equivalent to $(V,s') \models \mathtt{AX}(\rho_{CTL})$.*

PROOF. Similar to above. □

F Formal Specification of Example Policies

Isolation: Packets sent from host A can never reach host B:

$$\mathtt{G}(\mathtt{loc} = A \rightarrow \mathtt{g}(\mathtt{loc} \neq B))$$

Tag-based isolation: Packets tagged with T cannot reach the middlebox MB.

$$\mathtt{G}(\mathtt{tag} = T \rightarrow \mathtt{g}(\mathtt{loc} \neq MB))$$

Tag preservation: The tag T should not be modified by NFs.

$$\mathtt{G}(\mathtt{tag} = T \rightarrow \mathtt{g}(\mathtt{tag} = T))$$

NAT consistency: If a NAT modifies a packet's port then all future packets in the flow should have the same port.

$$\begin{aligned} \forall i.\quad & \mathtt{G}(\mathtt{flow} = i \wedge \mathtt{loc} = NAT\_IN \rightarrow \\ & \quad \mathtt{X}(\mathtt{srcport} = p \wedge \mathtt{loc} = NAT\_OUT \rightarrow \\ & \quad\quad \mathtt{G}(\mathtt{flow} = i \wedge \mathtt{loc} = NAT\_IN \rightarrow \\ & \quad\quad\quad \mathtt{X}(\mathtt{srcport} = p)))) \end{aligned}$$

Conditional reachability: Whenever a packet sent from a host A reaches host B, all packets sent from host B afterwards can reach A.

$$\mathtt{G}(\mathtt{loc} = A \rightarrow g(\mathtt{loc} = B \rightarrow \mathtt{G}(\mathtt{loc} = B \rightarrow f(\mathtt{loc} = A))))$$

Flow affinity: Packets in the same flow should be load-balanced ot the same server.

$$\begin{aligned} \forall i.\quad & \mathtt{G}(\mathtt{flow} = i \wedge \mathtt{loc} = S_1 \rightarrow \\ & \quad \mathtt{G}(\mathtt{loc} = C \wedge \mathtt{flow} = i \rightarrow \\ & \quad\quad \mathtt{f}(\mathtt{loc} = S_1))) \end{aligned}$$

Double NAT: Packets from the outside can always reach the inside (despite two NATs).

$$\mathtt{G}(\mathtt{loc} = OUT \rightarrow \mathtt{f}(\mathtt{loc} = IN))$$

Dynamic service chaining: After a host from *Dept* has sent more than 10 suspicious packets, all of its packets should pass heavy IPS H.

$$\begin{aligned} \forall x \in Dept.\quad & \mathtt{G}(\mathtt{src} = x \wedge susp[x] > 10 \rightarrow \\ & \quad \mathtt{G}(\mathtt{src} = x \rightarrow \mathtt{f}(\mathtt{loc} = H))) \end{aligned}$$

Tiramisu: Fast Multilayer Network Verification

Anubhavnidhi Abhashkumar*, Aaron Gember-Jacobson†, Aditya Akella*
University of Wisconsin - Madison, Colgate University†*

Abstract: Today's distributed network control planes are highly sophisticated, with multiple interacting protocols operating at layers 2 and 3. The complexity makes network configurations highly complex and bug-prone. State-of-the-art tools that check if control plane bugs can lead to violations of key properties are either too slow, or do not model common network features. We develop a new, general multilayer graph control plane model that enables using fast, property-customized verification algorithms. Our tool, Tiramisu can verify if policies hold under failures for various real-world and synthetic configurations in $<$ 0.08s in small networks and $<$ 2.2s in large networks. Tiramisu is 2-600X faster than state-of-the-art without losing generality.

1 Introduction

Many networks employ complex topologies and distributed control planes to realize sophisticated network objectives. At the topology level, networks employ techniques to virtualize multiple links into logically isolated broadcast domains (e.g., VLANs) [8]. Control planes employ a variety of routing protocols (e.g., OSPF, eBGP, iBGP) which are configured to exchange routing information with each other in intricate ways [9, 21]. Techniques to virtualize the control plane (e.g., virtual routing and forwarding (VRF)) are also common [8].

Bugs can easily creep into such networks through errors in the detailed configurations that the protocols need [9, 21]. In many cases, bugs are triggered when a failure causes the control plane to reconverge to new paths. Such bugs can lead to a variety of catastrophic outcomes: the network may suffer from reachability blackholes [5]; services with restricted access may be rendered wide open [4]; and, expensive paths may be selected over inexpensive highly-preferred ones [4].

A variety of tools attempt to verify if networks could violate important policies. In particular, *control plane analyzers* [6, 12–14, 23, 29] proactively verify if the network satisfies policies against various environments, e.g., potential failures or external advertisements. State-of-the-art examples include: graph-algorithm based tools, such as ARC [14] which models all paths that may manifest in a network as a series of weighted digraphs; satisfiability modulo theory (SMT) based tools, such as Minesweeper [6] which models control planes by encoding routing information exchange, route selection, and failures using logical constraints/variables; and, explicit-state model checking (ESMC) based tools, such as Plankton [23][1] which models routing protocols in a custom language, such that an explicit state model checker can explore the many possible data plane states resulting from the control plane's execution.

Unfortunately, these modern control plane tools still fall short because they make a hard trade-off between performance and generality (§2). ARC abstracts many low level control plane details which allows it to leverage polynomial time graph algorithms for verification, offering the best performance of all tools. But the abstraction ignores many network design constructs, including commonly-used BGP attributes, and iBGP. While these are accounted for by the other classes of tools [6, 23] that model control plane behavior at a much lower level, the tools' detailed encoding renders verification performance extremely poor, especially when exploring failures (§8). Finally, all existing tools ignore VLANs, and VRFs.

This paper seeks a fast general control plane verification tool that also accounts for layer 2.5 protocols, like VLANs.

We note that today's trade-off between performance and generality is somewhat artificial, and arises from an unnatural coupling between the control plane encoding and the verification algorithm used. For example, in existing graph-based tools, graph algorithms are used to verify the weighted digraph control plane model. In SMT-based tools, the detailed constraint-based control plane encoding requires a general constraint solver to be used to verify any policy. ESMC-based tools' encoding forces a search over the many possible data plane states, mirroring software verification techniques that exhaustively explore the execution paths of a general program.

The key insight in our framework, Tiramisu, is to decouple encoding from verification algorithms. Tiramisu leverages a *new, rich encoding* for the network that models various control plane features and network design constructs. The encoding allows Tiramisu to use different *custom verification algorithms* for different *categories of policies* that substantially improve performance over the state-of-the-art.

Tiramisu's network model uses graphs as the basis, similar to ARC. However, the graph model is multi-layered and uses multi-attribute edge weights, thereby capturing dependencies among protocols (e.g., iBGP depending on OSPF-provided paths) and among virtual and physical links, and accounting for filters, tags, and protocol costs/preferences.

For custom verification, Tiramisu notes that most policies studied in the literature can be grouped into three categories (Table 1): (i) policies that require the actual path that manifests in the network under a given failure; (ii) policies that care about certain quantitative properties of paths that may manifest (e.g., maximum path length); and, finally, (iii) policies that merely care about whether a path exists. Tiramisu leverages the underlying model's graph structure to develop performant verification algorithms for each category.

To verify category (i) policies, Tiramisu efficiently solves the stable paths problem [15] using the *Tiramisu Path Vector Protocol* (*TPVP*). *TPVP* simulates control plane computa-

[1]Plankton was developed contemporaneously with our system

tions across multiple devices and interdependent protocols by operating on the Tiramisu network model. *TPVP*'s domain-specific path computation is faster than the general search strategies used in SMT solvers, making Tiramisu orders of magnitude faster in verifying category (i) policies. *TPVP* also outperforms ESMC-based tools, because *TPVP*'s use of routing algebra [16, 25] atop the Tiramisu rich graph allows it to compute paths in one shot, whereas ESMC-based tools emulate protocols, and explore their state, one at a time in order to account for inter-protocol dependencies.

For category (ii), Tiramisu's insight is to use integer linear program (ILP) formulations that only model the variables that are relevant to the policy being verified. Tiramisu significantly outperforms SMT- and ESMC-based tools, whose computation of specific paths requires them to (needlessly) explore a much larger variable search space.

For category (iii), Tiramisu uses a novel graph traversal algorithm to check path existence. The algorithm invokes canonical depth-first search on multiple Tiramisu subgraphs, to account for tags (e.g., BGP communities) whose use on a path controls the path's existence. For such policies, Tiramisu matches ARC's performance for simple control planes; but Tiramisu is much more general.

Finally, for many of the policies in categories (i) and (ii), Tiramisu leverages the underlying model's graph structure to develop a graph algorithm-based accelerator for further verification speed-up. We show how to use a variant of a dynamic programming-based algorithm for the k shortest paths problem [31] to curtail needlessly exploring paths that manifest under many not-so-relevant failure scenarios.

We implemented Tiramisu in Java [2] and evaluated it with many real and synthetic configurations, spanning campus, ISP, and data center networks. We find that Tiramisu significantly outperforms the state-of-the-art, and is more general—some of the networks have layer-2/3 features that Minesweeper and Plankton don't model. Using category-specific algorithms on complex networks, Tiramisu verified category i, ii, and iii policies in *60*, *80* and *3ms*, respectively. Compared to Minesweeper, Tiramisu is *80X*, *50X*, and *600X* faster for category i, ii, and iii policies, respectively. On iBGP networks, Tiramisu outperforms Plankton by up to *300X* under failures. Tiramisu's *TYEN* acceleration improves performance by *1.3-3.8X*. Tiramisu scales well, providing verification results in $\sim$100ms per traffic class for networks with $\sim$160 routers.

2 Motivation

In this section, we provide an overview of state-of-the-art control plane verifiers. We then identify their key drawbacks that motivate Tiramisu's design.

2.1 Existing control plane verifiers

State-of-the-art control plane verifiers are based on three different techniques: graph algorithms [14], symbolic model checking [6,12,29], and explicit-state model checking [13,23]. We review the most advanced verifier in each category.

Graph algorithms: ARC [14] models a network's control plane using a set of directed graphs. Each graph encodes the network's forwarding behavior for a specific traffic class–i.e., packets with specific source and destination subnets. In the graphs, vertices represent routing processes (i.e. instances of routing protocols running on specific devices); directed edges represent possible network hops enabled by the exchange of advertisements between processes; edge weights encode OSPF costs or AS path lengths. ARC verifies a policy by checking a simple graph property: e.g, *src* and *dst* are always blocked if they are in separate components. By leveraging graph algorithms, ARC offers orders-of-magnitude better performance [14] than simulation-based verifiers [13]. However, ARC's simple graph model does not cover: widely used layer-3 protocols (e.g., iBGP), any layer-2 primitives (e.g., VLANs), and many protocol attributes (e.g., BGP community).

Symbolic model checking: Minesweeper [6] verifies a network's policy compliance by formulating and solving a satisfiability modulo theory (SMT) problem. The SMT constraints encode the behavior of the network's control and data planes (M) as well as the negation of a target policy ($\neg P$). If the SMT constraints ($M \wedge \neg P$) are unsatisfiable, then the policy is satisfied. To provide extensive network design coverage, Minesweeper uses many variables, which results in a large search space. Minesweeper verifies all policies on this large general SMT model. To verify for k failures, Minesweeper's SMT solver may, in the worst case, enumerate all possible combinations of k-link failures.

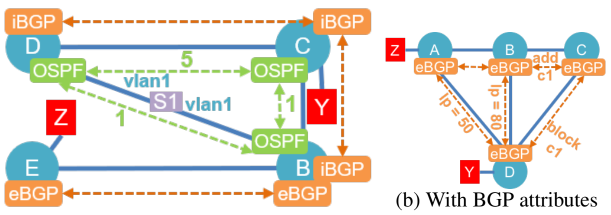
Explicit-state model checking: Plankton [23] models different control plane protocols (e.g., OSPF, BGP) using the Path Vector Protocol (PVP) [15] in a modeling language (Promela). It tracks dependencies among protocols defined in a network's control plane based on packet equivalence classes (PECs). It then uses an explicit state model checker, SPIN, to search on the overall state space of this model and find a state that violates a policy. To speedup verification, Plankton runs multiple independent SPIN instances in parallel. Plankton uses other optimizations including device equivalence to reduce the failure scenarios to explore. Despite these optimizations, Plankton still enumerates the state space of many failure scenarios, and checks them sequentially (§8).

2.2 Challenges

We now identify three high-level challenges that affect existing verifiers' performance and/or correctness.

Cross-layer dependencies. Consider the network in Figure 1a. Router B is an eBGP peer of router E, and router C is an iBGP peer of routers B and D. B and D are connected to switch $S1$ on VLAN 1. All routers except E belong to the same OSPF domain; the cost of link C–D is 5 and others is 1.

In this network, C learns a route to E through its iBGP neighbor B; the route's next hop is the IP address of B's loopback interface. In order for C to route traffic through B,



(a) With protocol dependencies (b) With BGP attributes

Figure 1: Example networks

C must compute a route to *B* using OSPF. The computed path depends on the network's failure state. In the absence of failures, *OSPF* prefers path $C \rightarrow B$ (cost 1). When the link *B–C* fails, *OSPF* prefers a different path: $C \rightarrow D \rightarrow B$ (cost 6). Unfortunately, traffic for *E* is dropped at *D*, because *D* never learns a route to *E*; *E* is not in the same OSPF domain, and routes learned (by *C*) via iBGP are not forwarded. If *B* and *D* were iBGP peers, or *B* redistributed its *eBGP*-learned routes to *OSPF*, then this blackhole would be avoided.

ARC's simplistic graph abstraction cannot model iBGP and thus cannot model iBGP-OSPF dependencies. Hence, ARC cannot be used to verify policies in this network. Minesweeper can model iBGP, but its encoding is inefficient. To model iBGP, Minesweeper creates *n* additional copies of the network where *n* represents number of routers running iBGP. Each copy models forwarding towards the next-hop address associated with each iBGP router. This increases Minesweeper's SMT model size by *n*X, which significantly degrades its performance. In Plankton, the iBGP-OSPF dependency is encoded as a dependency between PECs, which prevents Plankton from fully parallelizing its SPIN instances. Hence, Plankton loses the performance benefits of parallelism.

Cross-layer dependencies also impact other network scenarios. Assume the $B - S1$ link in Figure 1a was assigned to VLAN 2. Now *B* and *D* are connected to the same switch $S1$ on different VLANs; internally, $S1$ runs two *virtual switches*, one for each VLAN. Hence, traffic between *B* and *D* cannot flow through switch $S1$. By default, ARC, Minesweeper, and Plankton, assume layer-2 connectivity. Thus, according to these verifiers, *B* and *D* are reachable and traffic can flow between them, which is incorrect.

The overall theme is that protocols "depend" on each other—e.g., iBGP depends on OSPF, BGP and OSPF depend on VLANs, etc.—and these dependencies must be *fully*, *correctly* and *efficiently* modeled.

Protocol attributes. Consider the network in Figure 1b. All routers (*A–D*) run eBGP. *B* adds community "c1" to the advertisements it sends to *C*, and *D* blocks all advertisements from *C* with community "c1". Additionally, *D* prefers routes learned from *B* over *A* by assigning local preference (lp) values 80 and 50, respectively.

The path that *D* uses to reach *A* depends on communities and local preference. There are three physical paths from *D* to *A*: (*i*) $D \rightarrow A$, (*ii*) $D \rightarrow B \rightarrow A$, and, (*iii*) $D \rightarrow C \rightarrow B \rightarrow A$. However, since router *B* adds community "c1" to routes advertised to *C*, and *D* blocks advertisements from *C* with this community, path *iii* is unusable. Furthermore, path *ii* is preferred over the shorter path *i* due to local preference.

Since ARC uses Dijkstra's algorithm to compute paths, it can only model additive path metrics like OSPF cost and AS-path length; it cannot model non-additive properties such as local preference, communities, etc. Hence, ARC incorrectly concludes that path *iii* is valid and (shortest) path *i* is preferred. Although Minesweeper and Plankton can model these attributes, they suffer from other drawbacks mentioned earlier.

Failures. Assume there are no communities in the network in Figure 1b, and routers *A* and *D* are configured to run OSPF in addition to eBGP. This network can tolerate a single link failure without losing connectivity.

According to ARC, traffic from *D* to *A* can flow through four paths: $D_{bgp} \rightarrow C_{bgp} \rightarrow B_{bgp} \rightarrow A_{bgp}$, $D_{bgp} \rightarrow B_{bgp} \rightarrow A_{bgp}$, $D_{bgp} \rightarrow A_{bgp}$, and $D_{ospf} \rightarrow A_{ospf}$. To evaluate the network's failure resilience, ARC calculates the *min-cut* of this graph, which is 3, and concludes that it can withstand two arbitrary, simultaneous link failures. This is incorrect because edges $D_{ospf} \rightarrow A_{ospf}$ and $D_{bgp} \rightarrow A_{bgp}$ are both unusable when the physical link *D–A* fails.

As mentioned in §2.1, Minesweeper and Plankton enumerate multiple failure scenarios and this makes them very slow to verify for failures. For example, in this 5-link network, to *verify reachability with 1 failure*, Minesweeper (and Plankton without optimization) may explore 5 failure scenarios before establishing reachability.

An overall issue is that irrespective of the policy, Minesweeper and Plankton need to compute the actual path taken in the network. ARC, on the other hand, represents policies as graph properties, e.g. mincut, connectivity, etc. It then uses fast polynomial time algorithms to compute these properties. However, ARC's simplistic graph abstraction cannot model all network features. Our goal is to create a tool that combines the network coverage of Minesweeper and Plankton, with the performance benefits of ARC.

3 Overview

Motivated by the inefficiencies and coverage limitations of existing network verifiers (§2), we introduce a new network verification tool called Tiramisu.Tiramisu is rooted in a rich graph-based network model that captures forwarding and failure dependencies across multiple routing and switching layers (e.g., BGP, OSPF, and VLANs). Since routing protocols are generally designed to operate on graphs and their constituent paths, graphs offer a natural way to express the route propagation, filtering, and selection behaviors encoded in device configurations and control logic. Moreover, graphs admit efficient analyses that allow Tiramisu to quickly reason about important network policies—including reachability, path lengths, and path preferences—in the context of multi-link failures. In this section, we highlight how Tiramisu's graph-based model and verification algorithms address the challenges discussed in §2. Detailed descriptions, algorithms, and proofs of cor-

Category	Policy	Meaning	Comments
i: compute path with *TPVP*	PREF	Path Preference	Can use *TYEN*
	MC	Multipath Consistency	
ii: compute actual numeric graph property with ILP	KFAIL	Reachability < K failures	Can use *TYEN*
	BOUND	All paths have length < K	
	EB	All paths have equal length	
iii: identify connectivity wth *TDFS*	BLOCK	Always Blocked	
	WAYPT	Always Waypointing	
	CW	Always Chain of Waypoints	
	BH	No Blackhole

rectness, are presented in later sections.

3.1 Graph-based network model

To accurately and efficiently model cross-layer dependencies, Tiramisu constructs two inter-related types of graphs: *routing adjacencies graphs* (RAGs) and *traffic propagation graphs* (TPGs). The former allows Tiramisu to determine which routing processes may learn routes to specific destinations. The latter models more detail, especially, all the prerequisites for such learning to occur—e.g., OSPF must compute a route to an iBGP neighbor in order for the neighbor to receive BGP updates. Our verification algorithms run on the TPGs.

Routing adjacencies graph. A RAG (e.g, Figure 2a) encodes routing *adjacencies*. Two routing processes are adjacent if they are configured as neighbors (e.g., BGP) or configured to operate on interfaces in the same layer-2 broadcast domain (e.g., OSPF). A RAG contains a vertex for each routing process, and a pair of directed edges for each routing adjacency. Tiramisu runs a domain-specific "tainting" algorithm on the RAG to determine which routing processes may learn routes for a given prefix p.

Traffic propagation graph. In addition to routing adjacencies, propagation of traffic requires: (*i*) a route to the destination, (*ii*) layer-2 and, in the case of BGP, layer-3 routes to adjacent processes, and (*iii*) physical connectivity. A TPG (e.g., Figure 2b) encodes these *dependencies*. Vertices are created for each VLAN on each device and each routing process. Directed edges model the aforementioned dependencies as follows: (*i*) a VLAN vertex is connected to an OSPF/BGP vertex associated with the same router if, according to the RAG, the process may learn a route to a given subnet; (*ii*) an OSPF vertex is connected to the vertices for the VLANs on which it operates, and a BGP vertex is connected to an OSPF and/or VLAN vertex associated with the same router; (*iii*) a VLAN vertex is connected to a vertex for the same VLAN on another device if the devices are physical connected. Additionally, multi-attribute edge labels are assigned to edges to encode filters and "costs" associated with a route. With this structure, Tiramisu is able to correctly model a much wider range of networks than state-of-the-art graph-based models [14]. All verification procedures operate on the TPG.

3.2 Verification algorithms

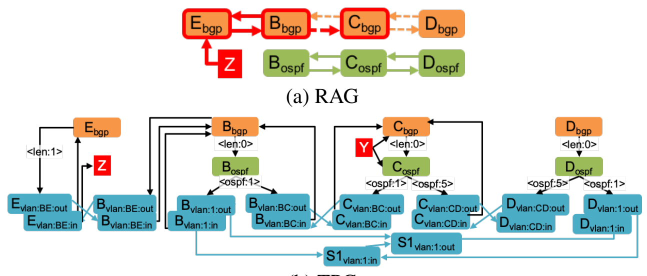
Tiramisu's verification process is rooted in the observation that network policies explored in practice and in academic research (Table 1) fall into three categories: (*i*) policies concerned with the actual path taken under specific failures—e.g., path preference (PREF); (*ii*) policies concerned with quantitative path metrics—e.g., how many paths are present (KFAIL) and bounds on path length (BOUND); and (*iii*) policies concerned with the existence of a path—e.g., blocking (BLOCK) and waypointing (WAYPT). Verifying policies in the first category requires high fidelity modeling of the control plane's output—namely, enumeration/computation of precise forwarding paths—whereas verifying policies in the last category requires low fidelity modeling of the control plane's output—namely, evidence of a single plausible path. For optimal efficiency, Tiramisu's core insight is to introduce category-specific verification algorithms that operate with the minimal level of fidelity required for accurate verification.

TPVP. To verify category *i* policies, Tiramisu efficiently solves the stable paths problem [15] using the *Tiramisu Path Vector Protocol* (*TPVP*). *TPVP* extends Griffin's "simple path vector protocol" (SPVP) [15]. In TPVP, each TPG node consumes the multi-dimensional attributes of outgoing edges, and uses simple arithmetic operations (based on a routing algebra [26]) to select among multiple available paths. In simple networks (that use a single routing protocol) *TPVP* devolves to a distance vector protocol, which computes paths under failures in polynomial time. For such networks, TPVP is comparable to ESMC tools [23], but is faster than general SMT-based tools [6]. For general networks with dependent control plane protocols, TPVP is faster than SMT-based tools, because it uses a domain-specific approach to computing paths, compared to an SMT-based general search strategy. TPVP also beats ESMC tools by emulating the control plane in one shot as opposed to emulating the constituent protocols and exploring their state space one at a time to account for inter-protocol dependencies.

ILP. For category *ii* policies, Tiramisu leverages general integer linear program (ILP) encodings that compute network flows through the TPG, rather than precise paths. The ILPs only consider protocol attributes that impact whether paths can materialize (e.g., BGP communities), and they avoid path computation. Thus, Tiramisu is much faster than state-of-the-art approaches that always consider all attributes (e.g., BGP local preferences) and enumerate actual paths [6, 23] (§8).

TDFS. Finally, *Tiramisu depth-first search* (*TDFS*) is a novel polynomial-time graph traversal algorithm to check for the existence of paths and verify category *iii* policies. *TDFS* makes a constant number of calls to the canonical DFS algorithm. Each call is to a subgraph of the TPG that models the interaction between tag-based (e.g., BGP-community-based) route filters along a path that control if a path can materialize.

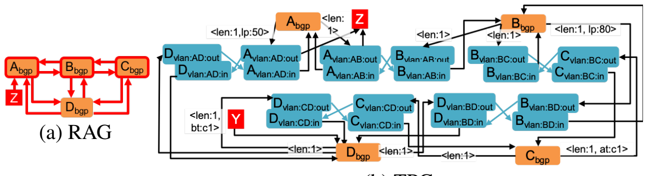
Tiramisu further improves over state-of-the-art verifiers for some category *i* and *ii* policies by avoiding unnecessary path computation. Specifically, we note that some category *i* and *ii* properties require knowing *when* certain paths are taken (i.e., after how many link failures, or after how many more-preferred paths have failed). For such properties, ex-



(a) RAG

(b) TPG

Figure 2: Graphs for network in Figure 1a



(a) RAG

(b) TPG

Figure 3: Graphs for network in Figure 1b

haustively exploring all failures by running *TPVP* for each scenario, while sufficient, is overkill. To avoid enumerating not-so-useful failure scenarios, Tiramisu leverages the graph structure of the network model to run a variant of Yen's dynamic programming based algorithm for k-shortest paths [31], to directly compute a preference order of paths that manifest under arbitrary failures. Our variant, *TYEN*, invokes *TPVP* in a limited fashion from within Yen's execution, minimizing path exploration. For PREF over k paths, we simply use *TYEN* to compute the top-k paths over the TPG. Likewise, we use *TYEN* to accelerate KFAIL, a category *ii* policy. Note that *TYEN* can only be applied to networks whose path metrics are monotonic [16].

4 Tiramisu Graph Abstraction

In this section, we describe in detail the two types of graphs used in Tiramisu: *routing adjacencies graphs* (RAGs) and *traffic propagation graphs* (TPGs). TPGs are partially based on RAGs, and both are based on a network's configurations and physical topology.

4.1 Routing adjacencies graphs

RAGs encode routing adjacencies to allow Tiramisu to determine which routing processes may learn routes to specific IP subnets. Tiramisu constructs a RAG for each of a network's subnets. For example, Figures 2a, and 3a show the RAGs for subnet Z for the networks in Figure 1.

Vertices. A RAG has a vertex for each routing process. For example, B_{bgp} and B_{ospf} in Figure 2a represent the BGP and OSPF processes on router B in Figure 1a. A RAG also has a vertex for each device with static routes for the RAG's subnet.

Edges. A RAG contains an edge for each routing adjacency. Two BGP processes are adjacent if they are explicitly configured as neighbors. Two OSPF process are adjacent if they are configured to operate on router interfaces in the same Layer 2 (L2) broadcast domain (which can be determined from the topology and VLAN configurations). These adjacencies are represented using pairs of directed edges—e.g., $E_{bgp} \leftrightarrows B_{bgp}$ and $B_{ospf} \leftrightarrows C_{ospf}$—since routes can flow between these processes in either direction. However, if two processes are iBGP neighbors then a special pair of directional edges are used—e.g., $B_{bgp} \overset{\leftarrow}{\underset{\dashrightarrow}{}} C_{bgp}$—because iBGP processes do not forward routes learned from other iBGP processes. A routing adjacency is also formed when one process (the redistributor) distributes routes from another process on the same device (the redistributee). This is encoded with a unidirectional edge from redistributee to redistributor. Vertices representing static routes may be redistributees, but will not have any other edges.

Taints. To determine which routing processes may learn routes to specific destinations, Tiramisu runs a "tainting" algorithm on the RAG. All nodes that originate a route for the subnet associated with the RAG (including vertices corresponding to static routes) are tainted. Then taints propagate freely across edges to other vertices, with one exception: when taints traverse an iBGP edge they cannot immediately traverse another iBGP edge. For example, in Figure 2a, E_{bgp} is tainted, because it originates a route for Z. Then taints propagate from E_{bgp} to B_{bgp} to C_{bgp}, but not to D_{bgp}. No OSPF vertices are tainted, because no OSPF processes originate a route for Z and no processes are configured to redistribute routes.

The tainting algorithm assumes all configured adjacencies are active and no routes are filtered. However, for an adjacency to be active in the real network, certain conditions must be satisfied: e.g., B_{ospf} must compute a route to C's loopback interface and vice versa in order for B_{bgp} to exchange routes with C_{bgp}. These dependencies are encoded in TPGs.

4.2 Traffic propagation graph

A process P on router R can advertise a route for subnet S to an adjacent routing process P' on router R' if all of the following dependencies are satisfied: (*i*) P learns a route for S from an adjacent process, or P is configured to originate a route for S; (*ii*) neither P or P' filters the advertisement; (*iii*) another process/switch on R learns a route to R', or R is connected to the same subnet/layer-2 domain as R'; and (*iv*) R is physically connected to R' through a sequence of one or more links. TPGs encode these dependencies. Tiramisu constructs a TPG for every pair of a network's IP subnets. Figures 2b and 3b show the TPGs that model how traffic from subnet Y is propagated to subnet Z for the networks in Figure 1.

Vertices. A TPG's vertices represent the routing information bases (RIBs) present on each router and the (logical) traffic ingress/egress points on each router/switch. Each routing process maintains its own RIB, so the TPG contains a vertex for each process: e.g., B_{bgp} and B_{ospf} in Figure 2b correspond to the BGP and OSPF processes on router B in Figure 1a.

Traffic propagates between routers and switches over VLANs. Consequently, the TPG contains a pair of ingress/egress vertices for each of a device's VLANs: e.g., $S1_{v1:in}$ and $S1_{v1:out}$ in Figure 2b correspond to the VLAN on switch $S1$ in Figure 1a. Tiramisu creates implicit VLANs for pairs of directly connected interfaces: e.g., $B_{vlan:BE:in}$,

$B_{vlan:BE:out}$, $E_{vlan:BE:in}$, and $E_{vlan:BE:out}$ in Figure 2b correspond to the directly connected interfaces on routers B and E in Figure 1a.

The TPG also includes vertices for the source and destination (target) of the traffic being propagated: e.g., Y and Z, respectively, in Figure 2b.

Edges. A TPG's edges reflect the virtual and physical "hops" the traffic may take. Edges model dependencies as follows:

- **Layers 1 & 2:** For each VLAN V on device D, the egress vertex for V on D is connected to the ingress vertex for V on device D' if an interface on D participating in V has a direct physical link to an interface on D' participating in V: e.g., $B_{vlan1:out} \rightarrow S1_{vlan1:in}$ in Figure 2b corresponds to the physical link between B and $S1$ in Figure 1a. Also, the ingress vertex for V on D is connected to the egress vertex for V on D to model L2 flooding: e.g., $S1_{vlan1:in} \rightarrow S1_{vlan1:out}$.
- **OSPF's dependence on L2:** The vertex for OSPF process P on router R is connected to the egress vertex for VLAN V on R if P is configured to operate on V: e.g., $D_{ospf} \rightarrow D_{vlan:CD:out}$ and $D_{ospf} \rightarrow D_{vlan:1:out}$ in Figure 2b model OSPF operating on router D's VLANs in Figure 1a.
- **BGP's dependence on connected and OSPF routes:** For each peer N of the BGP process P on router R, an edge is created from the vertex for P to the egress vertex for VLAN V on R if N's IP address falls within the subnet assigned to V: e.g., $E_{bgp:B} \rightarrow E_{vlan:BE:out}$ in Figure 2b models the BGP process on router E communicating with the adjacent process on directly connected router B in Figure 1a. If no such V exists, then the vertex for P is connected to the vertex for OSPF process P' on R: e.g., $B_{bgp} \rightarrow B_{ospf}$ models the BGP process on B communicating with the adjacent process on router C (which operates on a loopback interface) via an OSPF-computed path.
- **Routes to the destination:** Every VLAN ingress vertex on router R is connected to the vertex for process P on R if the vertex for P in the RAG is tainted: e.g., $B_{vlan:BC:in} \rightarrow B_{bgp}$ in Figure 2b is created due to the taint on B_{bgp} in Figure 2a, which models that fact that the BGP process on B may learn a route to subnet Z from the adjacent process on E. If the destination subnet T is connected to R and at least one routing process on R originates T, then every VLAN ingress vertex on R is connected to the vertex for T: e.g., $E_{vlan:BE:in} \rightarrow Z$ in Figure 2b. If the source subnet S is connected to R and the vertex for process P on R is tainted in the RAG, then the vertex for S is connected to the vertex for P: e.g., $Y \rightarrow C_{bgp}$ in Figure 2b.

Filters. As mentioned in §4.1, a RAG may overestimate which processes learn a route to a subnet due to route and packet filters not being encoded in the RAG. A TPG models filters using two approaches: edge pruning and edge attributes.

Tiramisu uses edge pruning to model prefix- or neighbor-based filters. A BGP process P may filter routes imported from a neighbor P' (or P' may filter routes exported to P) based on the advertised prefix or neighbor from (to) whom the route is forwarded. Tiramisu models such a filter by removing from the vertex associated with P, the outgoing edge that corresponds to P'. For example, if router B in Figure 1a had an import filter, or router E had an export filter, that block routes for Z, then edge $B_{bgp} \rightarrow B_{vlan:BE:out}$ would be removed from Figure 2a. Note that import and export filters are both modeled by removing an outgoing edge from the vertex associated with the importing process. OSPF is limited to filtering incoming routes based on the advertised prefix. Tiramisu models such route filters by removing all outgoing edges from the vertex associated with the OSPF process where the filter is deployed. Lastly, packets sent (received) on VLAN V can be filtered based on source/destination prefix. Tiramisu models such packet filters by removing the outgoing (incoming) edge that represents the physical link connecting V to its neighbor.

Tiramisu uses edge attributes to model tag- (e.g., BGP community- or ASN-) based filters. If a BGP process P filters routes imported from a neighor P' (or P' filters routes exported to P) based on tags, then Tiramisu adds a "blocked tags" attribute to the outgoing edge from the vertex associated with P that corresponds to P'. For example, the edge $D_{bgp} \rightarrow D_{vlan:CD:out}$ in Figure 3b is annotated with $bt = \{c1\}$ to encode the import filter router D applies to routes from C in Figure 1b. Edges can also include "added tags" and "removed tags" attributes: e.g., $C_{bgp} \rightarrow C_{vlan:BC:out}$ is annotated with $at = \{c1\}$ to encode the export filter router B applies to routes advertised to C. Notice that tag actions defined in import and export filters are both added to an outgoing edge from the vertex associated with the importing process.

Costs/preferences. Each routing protocol uses a different set of *metrics* to express link and path costs/preferences. For example, OSPF uses link costs, and BGP uses AS-path length, local preference (lp), etc. Similarly, administrative distance (*AD*) allows routers to choose routes from different protocols. Hence a single edge weight cannot model the route selection decisions of all protocols. Tiramisu annotates the outgoing edges of OSPF, BGP, and VLAN ingress vertices with a *vector of metrics*. Depending on the edge, certain metrics will be null: e.g., OSPF cost is null for edges from BGP vertices.

5 Category (i) Policies

We now describe how Tiramisu verifies policies that require knowing the actual path taken in the network under a given failure (§3.2). One such policy is path preference (PREF). For example, $P_{pref} = p1 \gg p2 \gg p3$, states when path $p1$ fails, $p2$ (if available) should be taken; and when $p1$ and $p2$ both fail, $p3$ (if available) should be taken. A path can become unavailable if a link or device along the path fails. We model such failures by removing edges (between egress and ingress VLAN vertices) or vertices from the TPG. To verify PREF, we need to know what alternate paths materialize, and whether a materialized path is indeed the path meant to be taken according to preference order. Similar requirements arise for verifying multipath consistency (MC).

In this section, we introduce an algorithm, *TPVP*, to compute the actual path taken in the network. *TPVP* can be used to exhaustively explore failures to verify category (i) policies, but it is slow. We show how to accelerate verification using a dynamic-programming based graph algorithm.

5.1 Tiramisu Path Vector Protocol

Griffin et al. observed that BGP attempts to solve the *stable paths problem* and proposed the Simple Path Vector Protocol (SPVP) for solving this problem in a distributed manner [15]. Subsequently, Sobrinho proposed routing algebras for modeling the route computation and selection algorithms of *any* routing protocol in the context of a path vector protocol [25]. Griffin and Sobrinho then extended these algebras to model routing across administrative boundaries—e.g., routing within (using OSPF) and across (using BGP) ASes [16]. However, they did not consider the dependencies between protocols within the same administrative region—e.g., iBGP's dependence on an OSPF. Recently, Plankton addressed these dependencies by solving multiple stable paths problems, and proposed the Restricted Path Vector Protocol (RPVP) for solving these problems in a centralized manner [23].

Below, we explain how the *Tiramisu Path Vector Protocol* (*TPVP*) leverages routing algebras and extends SPVP to compute paths using our graph abstraction. Since SPVP was designed for Layer 3 protocols, *TPVP* works atop a simplified TPG called the Layer 3 TPG (L3TPG). Tiramisu uses path contraction to replace L2 paths with an L3 edge connecting L3 nodes, to model the fact that advertisements can flow between routing processes as long as there is at least one L2 path that connects them. Recall that the incoming edges of VLAN egress vertices and the outgoing edges of VLAN ingress vertices include (non-overlapping) edge labels (§4.2); these are combined and applied to the L3 edge(s) that replace the L2 path(s) containing these L2 edges.

Routing algebras. Routing algebras [16, 25] model routing protocols' path cost computations and path selection algorithms. An algebra is a tuple $(\Sigma, \preceq, L, \oplus, O)$ where:

- Σ is a set of *signatures* representing the multiple metrics (e.g., AS-path length, local pref, ...) associated with a path.
- $\preceq$ is the *preference* relation over signatures. It models route selection, ranking paths by comparing multiple metrics of multiple path signatures in a predefined order (e.g., first compare local pref, then AS-path length, ...)
- L is set of *labels* representing multi-attribute edge-weight.
- $\oplus$ is a function $L \times \Sigma \rightarrow \Sigma$, capturing how labels and signatures combine to form a new signature; i.e., $\oplus$ models path cost computations. $\oplus$ has multiple operators, each computing on certain metrics.[2]
- O is the signature attached to paths at origination.

In Tiramisu, path signatures contain metrics from all possible protocols (e.g., OSPF cost, AS-path length, AD, ...), but $\preceq$ and $\oplus$ are defined on a per-protocol basis and only operate on the metrics associated with that protocol. For example, $\oplus_{BGP}$ sets local pref and adds AS-path lengths from a label ($\lambda \in L$), but copies the OSPF cost and AD directly from the input signature ($\sigma \in \Sigma$) to the output signature ($\sigma' \in \Sigma$). Similarly, $\preceq_{BGP}$ compares local pref, AS-path lengths, and OSPF link costs[3] but does not compare AD.

TPVP. *TPVP* (Algorithm 1) is derived from SPVP [15]. For each vertex in the L3TPG, *TPVP* computes and selects a most-preferred path to *dst* based on the (signatures of) paths selected by adjacent vertices. However, *TPVP* extends *SPVP* in two fundamental ways: (*i*) it uses a shared memory model instead of message passing, akin to *RPVP* [23]; and (*ii*) it models multiple protocols in tandem by computing path signatures and selecting paths using routing algebra operations corresponding to different protocols: e.g., $\oplus_{BGP}$ and $\preceq_{BGP}$ are applied at vertices corresponding to BGP processes.

For each peer v of each vertex u (v is a peer of u if $u \rightarrow v \in$ L3TPG) *TPVP* uses variables $p_u(v)$ and $\sigma_u(v)$ to track the most preferred path to reach *dst* through v and the path's signature, respectively. Likewise, variables p_u and σ_u represent the most preferred path and its signature to reach *dst* from u.

In the initial state, *TPVP* sets the *path* and *sign* values of all nodes except *dst* to null (line 2). p_{dst} is set to ε and σ_{dst} is set to O, since it "originates" the advertisement (line 3). Similar to *SPVP*, there are three steps in each iteration. First, for each node u, *TPVP* computes all its $p_u(*)$ and $\sigma_u(*)$ values based on the path signatures of its neighbors and outgoing edge labels $\lambda_{u \rightarrow *}$ (lines 7–10). It calculates the best path based on the preference relation (line 11). If the current p_u changes from previous iteration, then the network has not converged and the process repeats (lines 12–13).

Theorem 1. *If the network control plane converges,* TPVP *always finds the exact path taken in the network under any given failure scenario.*

We prove Theorem 1 is in Appendix C.1. The proof shows that *TPVP* and the TPG correctly model the permitted paths and ranking function to solve the stable paths problem.

Plankton [23] leverages basic SPVP to model the network. But because basic SPVP cannot directly model iBGP, to verify networks that use iBGP, Plankton runs multiple SPVP instances. As mentioned in §2.1, BGP routing depends on the outcome of OSPF routing. Hence, Plankton runs SPVP multiple times: first for multiple OSPF instances, and then for dependent BGP instances. In contrast, because Tiramisu's *TPVP* is built using routing algebra atop a network model with rich edge attributes, we can bring different dependent routing protocols into one common fold of route computation. Thus, we can analyze iBGP networks, and, generally, dependent protocols, "in one shot" by running a single *TPVP* instance.

[2]For example, *ADD* operator adds OSPF link costs and AS-path lengths. *LP* operator sets local pref, *TAGS* operator prohibits paths with a tag, etc.

[3]OSPF cost is used as a tie-breaker in BGP path selection [10].

Algorithm 1 Tiramisu Path Vector Protocol

```
1:  procedure $TPVP(L3TPG)$
2:      $\forall i \in \{V - dst\} : p_i = \varnothing, \sigma_i = \phi$
3:      $p_{dst} = [dst], \sigma_{dst} = O$                ▷ $dst$ originates the route
4:      $converged = false$
5:      while $\neg converged$ do
6:          $converged = true$
7:          for each $u \in L3TPG$ do
8:              for each $v \in peers(u)$ do
9:                  $p_u(v) = edge_{u \to v} \circ p_v$            ▷ add edge to path
10:                 $\sigma_u(v) = \lambda_{u \to v} \oplus_{type(u)} \sigma_v$
11:                 compute $p_u$ and $\sigma_u$ using $\preceq$ over $\sigma_u(*)$
12:                 if $p_u$ has changed then
13:                     $converged = false$
```

In Appendix D, we show that *TPVP* can verify other policies, like "Multipath Consistency (MC)", that requires materialization of certain paths.

5.2 Tiramisu Yen's algorithm

To verify PREF, Tiramisu runs *TPVP* multiple times to compute paths for different failure scenarios. For example, while verifying P_{pref}, Tiramisu runs *TPVP* for all possible failures (edge removals) that render paths $p1$ and $p2$ unavailable. Then, it checks if *TPVP* always computes $p3$ (if available). While correct, this is tedious and slow overall.

We can accelerate the verification of this policy by leveraging the graph structure of the L3TPG and developing a graph algorithm that avoids unnecessary path explorations/computations. Specifically, we observed that there are similarities between analyzing PREF and finding the k shortest paths in a graph [31]. This is because, in the k shortest paths problem, the k^{th} shortest path is taken only when $k-1$ paths have failed. To avoid enumerating all possible failures of all $k-1$ shorter paths, Yen [31] introduced an efficient algorithm for this problem that uses dynamic programming to avoid failure enumeration. Yen uses the intuition that the k^{th} shortest path will be a small perturbation of the previous $k-1$ shortest paths. Instead of searching over the set of all paths, which is exponential, Yen constructs a polynomial candidate set from the previous $k-1$ paths, in which the k^{th} path will be present.

To accelerate PREF, our *TYEN* algorithm makes two simple modifications to Yen. Yen uses Dijkstra to compute the shortest path. We replace Dijkstra with *TPVP*. Next, we add a condition to check that during the i^{th} iteration, the i^{th} computed path follows the preference order specified in PREF. The detailed description of Yen and *TYEN* are in Appendix A. Note that Yenand hence TYEN, assumes the path-cost composition function is strictly monotonic. Hence, TYEN acceleration can be leveraged only on monotonic networks.

6 Category (ii) Policies

We now describe how Tiramisu verifies policies pertaining to quantitative path metrics, e.g., KFAIL and BOUND. For such policies, Tiramisu uses property-specific ILPs. These ILPs run fast because they abstract the underlying TPG and only model protocol attributes that impact whether paths can materialize (e.g., communities).

6.1 Tiramisu Min-cut

KFAIL states that *src* can reach *dst* as long as there are $< K$ link failures. ARC [14] verifies this policy by computing the min-cut of a graph; if min-cut is $\geq K$, then KFAIL is satisfied.

However, standard min-cut algorithms do not consider how route tags (e.g., BGP communities) impact the existence of paths. For example, in Figure 3b, any path that includes $D_{bgp:c} \to D_{vlan:CD:out}$ followed by $C_{bgp:b} \to C_{vlan:BC:out}$ is prohibited due to the addition and filtering of tags on routers B and D, respectively. In this manner, tags prohibit paths with certain combinations of edges in the TPG, making the TPG a "correlated network". It is well known that finding the min-cut of a correlated network is NP-Hard [30]. Note that traffic flows in the direction opposite to route advertisements. Hence, the prohibited paths have tag-blocking edges followed by tag-adding edges.

We propose an ILP which accounts for route tags, but ignores irrelevant edge attributes (e.g., edge costs), to compute the min-cut of a TPG For brevity, we explain the constraints at a high-level, leaving precise definitions to Appendix B.1. Equation numbers below refer to equations in Appendix B.1.

The objective of the ILP is to minimize the number of physical link failures (F_i) to disconnect *src* from *dst*.

$$\textbf{Objective:} \qquad \texttt{minimize} \sum_{i \in pEdges} F_i \qquad (1)$$

Traffic constraints. We first define constraints on reachability. The base constraint states that *src* originates the traffic (Eqn 2). To disconnect the graph, the next constraint states that the traffic must not reach *dst* (Eqn 3). For other nodes, the constraint is that traffic can reach a node if it gets *propagated* on any of its incoming edges (Eqn 4).

Now we define constraints on traffic propagation. Traffic can propagate through an edge e if: it reaches the start node of that edge; the traffic does not carry a tag that is blocked on that edge; and, if the edge represents an inter-device edge, the underlying physical link has not failed. This is represented as shown in Eqn 5.

Tags. We now add constraints to model route tags. The base constraints state that each edge that blocks on a tag forwards that tag, and each edge that removes that tag does not forward it further (Eqn 6 and Eqn 7). For other edges, we add the constraint that edge e forwards a tag t iff the start node of edge e receives traffic with that tag (Eqn 8). Finally, we add the constraint that an edge e carries a blocked tag iff that blocked tag can be added by edge e (Eqn 9).

We prove the correctness of this ILP in Appendix C.2 based on the correctness of Tiramisu's modeling of permitted paths.

Using TYEN for KFAIL with ACLs. This ILP is not accurate when packet filters (ACLs) are in use. ACLs do not influence advertisements. Hence, routers can advertise routes for traffic that get blocked by ACLs. Recall that during graph creation, Tiramisu removes edges that are blocked by ACLs §4.2. This leads to an incorrect min-cut computation as shown below:

Assume *src* and *dst* are connected by three paths $P1$, $P2$ and $P3$ in decreasing order of path-preference. Also assume these paths are edge disjoint and path $P2$ has a data plane ACL on it. If a link failure removes $P1$, then the control plane would select path $P2$. However, all packets from *src* will be dropped at the ACL on $P2$. In this case, a single link failure (that took down $P1$) is sufficient to disconnect *src* and *dst*. Hence the true min-cut is 1. On the other hand, Tiramisu would remove the offending ACL edge from the graph. The graph will now have paths $P1$ and $P3$, and the ILP would conclude that the min-cut is 2, which is incorrect.

We address this issue as follows. Nodes can become unreachable when failures either disconnect the graph or lead to a path with an ACL. We compute two quantities: (1) N: Minimum failures that disconnects the graph, and, (2) L: Minimum failures that cause the control plane to pick a path blocked by an ACL. The true min-cut value is $min(N, L)$.

First we use our min-cut ILP to compute N. To compute L, in theory, we could simply run TPVP to exhaustively explore k-link failures for $k = 1, 2, ..$, and determine the smallest failure set that causes the path between *src* and *dst* to traverse an ACL. However, this is expensive.

We can accelerate this process by leveraging *TYEN*, similar to our approach for PREF. We first construct a TPG without removing edges for ACLs. Then, we run *TYEN* until we find the first path with a dropping ACL on it. Say this was the M^{th} preferred path. Then, we remove all edges from the graph that do not exist in any of the previous $M-1$ paths. Next, we use our min-cut ILP to compute the minimal failures L to disconnect this graph. This represents the minimal failures to disconnect previous $M-1$ paths and pick the ACL-blocked path. If $min(L, N) \geq K$ then KFAIL is satisfied.

Overall, to compute KFAIL, the above requires Tiramisu to run (a) *TYEN* to compute M paths; and (b) two min-cut ILPs to compute N and L respectively. Note that to verify KFAIL, Minesweeper will explore all combinations of k link failures.

6.2 Tiramisu Longest path

Always bounded length policy (BOUND) states that for a given K, BOUND is true if under every failure scenario, traffic from *src* to *dst* never traverses a path longer than K hops. Enumerating all possible paths and finding their length is infeasible.

However, this policy can be verified efficiently by viewing it as a variation of computing a quantitative path property, namely the *longest path problem*: for a given K, BOUND is true if the longest path between *src* and *dst* is $\leq K$.

Finding the longest path between two nodes in a graph is also NP hard [19]. To verify BOUND, we thus propose another ILP whose objective is to maximize the number of inter device edges (*dEdges*) traversed by traffic (A_i).

$$\textbf{Objective:} \quad \texttt{maximize} \sum_{i \in dEdges} A_i \qquad (2)$$

We present detailed constraints and a proof of correctness in Appendices B.2 and C.2, respectively.

Constraints. We first add constraints to ensure that traffic flows on one path, *src* sends traffic, and *dst* receives it (Eqn 11 and Eqn 12). For other nodes, we add the flow conservation property, i.e., the sum of incoming flows is equal to the sum of outgoing flows (Eqn 13). Finally, we add constraints on traffic propagation: traffic will be blocked on edge e if it satisfies the tag constraints (Eqn 14).

In Appendix D, we show that a similar ILP can be used to verify other policies of interest—e.g., all paths between *src* and *dst* have equal length (EB).

7 Category (iii) Policies

Finally, we describe how Tiramisu verifies policies that only require us to check for just the existence of a path, e.g., "always blocked" (BLOCK). For these policies, we use a new simple graph traversal algorithm. Tiramisu's performance is fastest when checking for such policies (§8).

Standard graph traversal algorithms, like *DFS*, also do not account for tags. DFS will identify the prohibited path from Figure 3b ($D_{bgp:c} \rightarrow D_{vlan:CD:out}$ followed by $C_{bgp:b} \rightarrow C_{vlan:BC:out}$) as valid, which is incorrect. To support tags, we propose *TDFS*, Tiramisu Depth First Search (Algorithm 2). *TDFS* makes multiple calls to *DFS* to account for tags.

TDFS. As mentioned in §4, edges can add, remove or block on tags. In presence of such edges, the order in which these edges are traversed in a path determines if *dst* is reachable.

TDFS first checks if *dst* is unreachable from *src* according to *DFS* (line 3, 4). If they are reachable, then *TDFS* checks if all paths that connect *src* to *dst* (i) have an edge (say X) that blocks route advertisements and hence traffic (for *dst*) with a tag (line 5 to 6), (ii) followed by an edge (say Y) that adds the tag to the advertisements for *dst* (line 7 to 8), and (iii) has no edge between X and Y that removes the tag (line 9 to 10). If all these conditions are satisfied, then *src* and *dst* are unreachable. If any of these conditions are violated, the nodes are reachable.

We prove the correctness of *TDFS* in Appendix C.3.

The above algorithm naturally applies to verifying BLOCK. It can similarly be used to verify WAYPT ("always waypointing"): after removing the waypoint, if *src* can reach *dst*, then there is a path that can reach *dst* without traversing the waypoint. *TDFS* can also verify "always chain of waypoints (WAYPT)" and "no blackholes (BH)" (Appendix D).

8 Evaluation

We implemented Tiramisu in Java (≈ 7K lines of code) [2]. We use Batfish [13] to parse router configurations and Gurobi [3] to solve our ILPs. We evaluate Tiramisu on a variety of issues:

- How quickly can Tiramisu verify different policies?
- How does Tiramisu perform compared to state-of-the-art?

Algorithm 2 Always blocked with tags

```
1:  procedure $TDFS(G, src, dst)$
2:      $tA, tR, tB \leftarrow$ edges that add, remove, or block on tag (respectively)
3:      if $dst$ is unreachable by $DFS$ (G, $src$) then
4:          return true (nodes are already unreachable)
5:      if $dst$ is reachable by $DFS$ (G-$tB$, $src$) then
6:          return false ($\exists$ path $src \rightsquigarrow dst$ where tagged-routes are not blocked)
7:      if $\exists e_b \in tB$ s.t. $dst$ is reachable by $DFS$ (G-$tA$, $e_b$) then
8:          return false (tag-blocking edges can get ads for $dst$ without tags)
9:      if $\forall e_b \in tB, e_a \in tA$: $e_a$ is unreachable by $DFS$ (G-$tR$, $e_b$) then
10:         return false (tags always removed before reaching blocking edges)
11:     return true
```

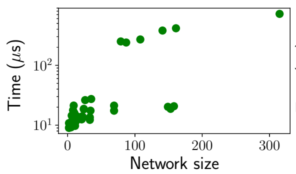


Figure 4: Graph generation time (all networks)

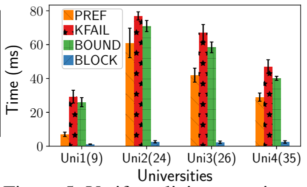

Figure 5: Verify policies on university configs

• How does Tiramisu's performance scale with network size? Our experiments were performed on machines with dual 10-core 2.2 GHz Intel Xeon Processors and 192 GB RAM.

8.1 Network Characteristics

In our evaluation, we use configurations from (a) 4 real university networks, (b) 34 real datacenter networks operated by a large online service provider, (c) 7 networks from the topology zoo dataset [20], and (d) 5 networks from the Rocketfuel dataset [27]. The university networks have 9 to 35 devices and are the richest in terms of configuration constructs. They include eBGP, iBGP, OSPF, static routes, packet/route filters, BGP communities, local preferences, VRFs and VLANs. The datacenter networks have 2 to 24 devices and do not employ local preference or VLANs. The topology zoo networks have 33 to 158 devices, and the Rocketfuel networks have 79 to 315 devices. The configs for topology zoo and Rocketfuel were synthetically generated for random reachability policies [11, 23] and do not contain static routes, packet filters, VRFs or VLANs. Details on the TPGs for these networks are in Appendix E. The main insight is that the number of routing processes and adjacencies per device varies. Hence, the number of nodes and edges in the TPG do not monotonically increase with network size.

Policies. We consider five polices: (PREF) path preference, (KFAIL) always reachable with $< K$ failures, (BOUND) always bounded length, (WAYPT) always waypointing, and (BLOCK) always unreachable. Recall that: PREF is *category i* and is accelerated by *TYEN* calling *TPVP* from within; KFAIL and BOUND are *category ii* and use ILPs; BLOCK and WAYPT are *category iii* and use *TDFS*.

8.2 Verification Efficiency

We examine how efficiently Tiramisu can construct and verify these TPGs. First, we evaluate the time required to generate the TPGs. We use configurations from all the networks. Figure 4 shows the time taken to generate a *traffic class-specific TPG* for all networks. Tiramisu can generate these graphs, even for large networks, in ≈ 1 *ms*.

Next, we examine how efficiently Tiramisu verifies various policies. Since the university networks are the richest in terms of configuration constructs, we use them in this experiment. Because of VRF/VLAN, Minesweeper, Plankton and ARC cannot model these networks. Figure 5 shows the time taken to verify PREF, KFAIL, BOUND, and BLOCK. Since WAYPT uses *TDFS*, it is verified in a similar order-of-magnitude time as BLOCK. Hence for brevity, we do not show their results. In this and all the remaining experiments, the values shown are the median taken over *100 runs* for *100 different traffic classes*. Error bars represent the std. deviation.

We observe that BLOCK can be verified in less than **3 ms**. Since it uses a simple graph traversal algorithm (*TDFS*), it is the fastest to verify among all policies. In fact, for BLOCK, our numbers are comparable to ARC [14]. The time taken to verify PREF is higher than BLOCK, because *TPVP* and *TYEN* algorithms are more complex, as they run our path vector protocol to convergence to find paths (and in *TYEN*'s case, *TPVP* is invoked several times). Finally, KFAIL and BOUND, both use an ILP and are the slowest to verify. However, they can still be verified in $\approx$ **80 ms** per traffic class.

Although $Uni2$ and $Uni3$ have fewer devices than $Uni4$, their TPGs are larger (§E), so it takes longer to verify policies.

8.3 Comparison with Other tools

Next, to put our performance results in perspective, we compare Tiramisu with other state-of-art verification tools.

Minesweeper [6] In this experiment we use datacenter networks and consider policies PREF, BOUND, WAYPT, and BLOCK. Minesweeper takes the number of failures (K) as input and checks if the policy holds as long as there are $\leq K$ failures. To verify a property under all failure scenarios, we set the value of K to one less than the number of physical links in the network. Figure 6 shows the time taken by Tiramisu and Minesweeper to verify these policies, and Figure 7 shows the speedup provided by Tiramisu.

PREF is the only policy where speedup does not increases with network size. This is because larger networks have longer path lengths and more possible candidate paths, both of which affect the complexity of the *TYEN* algorithm. The number of times *TYEN* invokes *TPVP* increases significantly with network size. Hence the speedup for PREF is relatively less, especially at larger network sizes. For BOUND, the speedup is as high as $50X$. For policies that use *TDFS* (BLOCK and WAYPT), Tiramisu's speedup is as high as 600-800X.

Next, we compare the performance of Tiramisu and Minesweeper for the same policies but without failures, e.g. "currently reachable" instead of "always reachable". Tiramisu verifies these policies by generating the actual path using *TPVP*. Figure 8 (a, b, c, and d) shows the speedup provided by Tiramisu for each of these policies. Even for *no failures*,

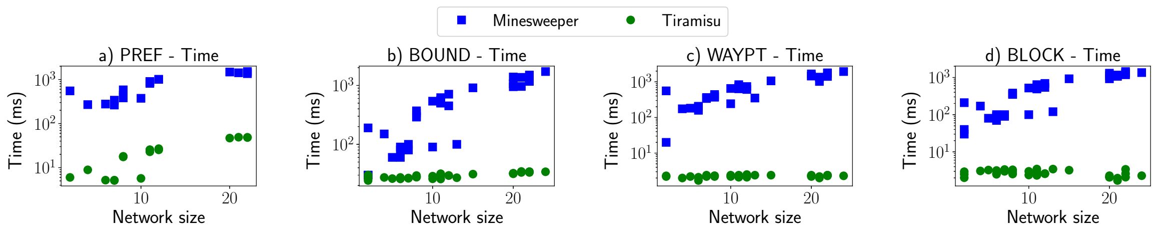

Figure 6: Performance under all failures: Tiramisu vs Minesweeper (datacenter networks)

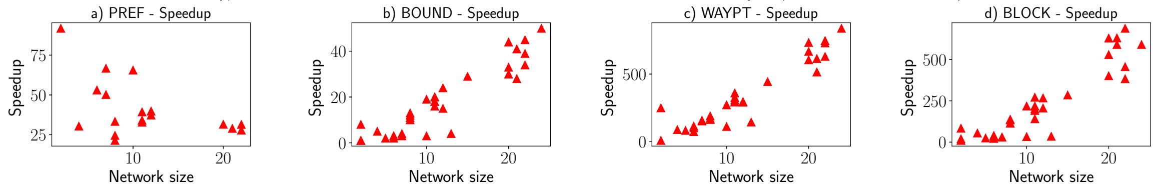

Figure 7: Speedup under all failures: Tiramisu vs Minesweeper (datacenter networks)

Tiramisu significantly outperforms Minesweeper across all policies. Minesweeper has to invoke the SMT solver to find a satisfying solution even in this simple case.

To shed further light on Tiramisu's benefits w.r.t. Minesweeper, we compare the number of variables used by Minesweeper's SMT encoding and Tiramisu's ILP encoding to verify KFAIL and BOUND. We observed that Tiramisu uses 10-100X fewer variables than Minesweeper. For Tiramisu, we also found that BOUND uses fewer variables than KFAIL.

Plankton [23] Next, we compare Tiramisu against Plankton using the Rocketfuel topologies. We generate two sets of configurations: one with only OSPF and one with iBGP and OSPF. We run Plankton with 32 cores to verify reachability with one failure, i.e. k=1 in KFAIL. Figure 9(a) shows the time taken by Plankton (SPVP on 32 cores) and Tiramisu (ILP on 1 core) to verify this policy. Due to dependencies, Plankton (P-iBGP) performs poorly for iBGP networks. It gave an out-of-memory error for large networks. For small networks, Tiramisu (T-iBGP) outperforms Plankton by 100-300X. On networks that run only OSPF, Plankton (P-OSPF) performed better on a single network with 108 routers. Communication with the authors revealed that Plankton may have gotten lucky by quickly trying a link failure that violated the policy. Disregarding that anomaly, Tiramisu (T-OSPF) outperforms Plankton by 2-50X on the OSPF-only networks.

Batfish [13] Data-plane verifiers, like Batfish, generate data planes and verify policies on each generated data plane. ARC [14] showed that Batfish is impractical to use even for small failures. Here, we show that even without failures, Tiramisu outperforms Batfish. We run Batfish with all its optimization, on the datacenter networks to verify reachability without failures. As mentioned earlier, Tiramisu verifies this policy using *TPVP*. Figure 9(b) shows that it outperforms Batfish by 70-100X.

Bonsai Bonsai [7] introduced a compression algorithm to improve scalability of configuration verifiers like Minesweeper, to verify certain policies exclusively under **no failures**. We repeat the previous experiment to evaluate Bonsai (built on Minesweeper). Figure 9(b) shows that Tiramisu still outperforms Bonsai, and can provide speedup as high as 9X.

8.4 Scalability

Here, we evaluate Tiramisu's performance to verify PREF, KFAIL, BOUND, and, BLOCK, on large networks from the topology zoo. Figure 10 shows the time taken to verify these policies. Tiramisu can verify these policies in $<$ **0.12 s**.

For large networks, time to verify PREF (*TYEN*) is as high as BOUND. Again, this is due to larger networks having longer and more candidate paths. Large networks also have high diversity in terms of path lengths. Hence, we see more variance in the time to verify PREF compared to other policies.

For large networks, the time to verify KFAIL is significantly higher than other policies. This happens because KFAIL's ILP formulation becomes more complex, in terms of number of variables, for such large networks. As expected, verifying BLOCK is significantly faster than all other policies, and it is very fast across all network sizes.

Impact of *TYEN* acceleration. In our analysis of PREF and KFAIL, we invoke *TYEN*'s acceleration. To evaluate how much acceleration *TYEN* provided, we now measure the time taken to verify PREF on the Rocketfuel and datacenter networks, with and without *TYEN*'s optimization. Our main conclusions are (i) on small networks (< 20 devices), *TYEN* provides a acceleration as high as 1.4X, and (ii) on large networks (> 100 devices), *TYEN* provides acceleration as high as 3.8X.

Evaluation Summary. By decoupling the encoding from algorithms, Tiramisu uses custom property-specific algorithms with graph-based acceleration to achieve high performance.

9 Extensions and limitations

Although we describe Tiramisu's graphs in the context of BGP and OSPF, the same structure can be used to model other popular protocols (e.g., RIP and EIGRP). Additionally, virtual routing and forwarding (VRFs) can be modeled by replicating routing process vertices for each VRF in which the process participates. To verify policies for different traffic classes, Tiramisu generates a TPG per traffic class. To reduce the number of TPGs, we can compute non-overlapping packet equivalence classes (PEC) [17, 23] and create a TPG per PEC.

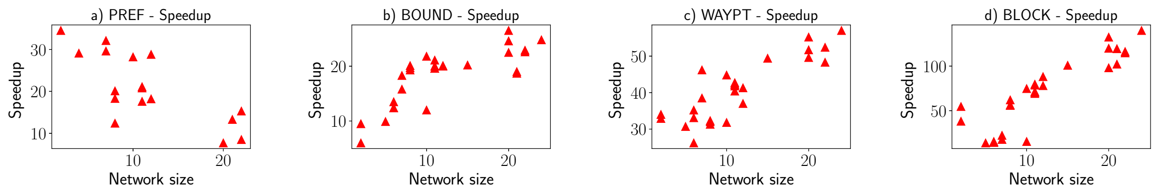

Figure 8: Speedup under no failures: Tiramisu vs Minesweeper (datacenter networks)

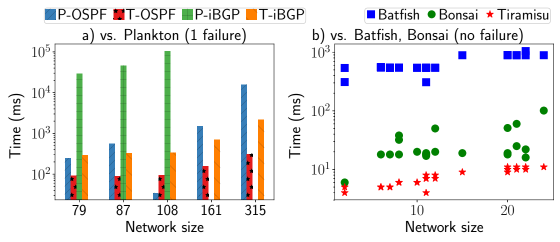

Figure 9: Comparisons with Plankton, Batfish, and Bonsai

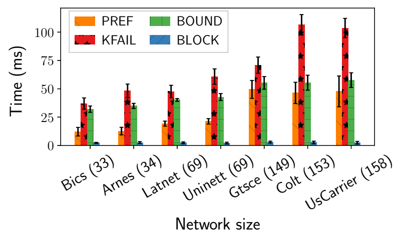

Figure 10: Performance on scale (topology zoo)

Unlike SMT-based tools, Tiramisu does not symbolically model advertisements. Consequently, Tiramisu cannot determine if there exists some external advertisement that could lead to a policy violation; Tiramisu can only exhaustively explore link failures. Tiramisu must be provided concrete instantiations of external advertisements; in such a case, Tiramisu can analyze the network under the given advertisement(s) and determine if any policies can be violated. A related issue is that Tiramisu cannot verify control plane equivalence: two control planes are equivalent, if the behavior of the control planes (paths computed) is the same under all advertisements and all failure scenarios. In essence, while Tiramisu can replace Minesweeper for a vast number of policies, it is not a universal replacement. Minesweeper's SMT-encoding is useful to explore advertisements. Additionally, Tiramisu cannot check quantitative advertisement policies—e.g., does an ISP limit the number of prefixes accepted from a peer.

Tiramisu's modeling of packet filters in the TPG only considers IP-based filtering. Consequently, in networks with protocol- or port-based packet filters, Tiramisu may over- or under-estimate reachability for packets using particular ports or protocols. Additionally, Tiramisu does not account for packet filters that impact route advertisements—e.g., filtering packets destined for a particular BGP neighbor—or route filters where multiple tags affect the same destination—e.g., community groups, AS-path filters, etc. We plan to extend Tiramisu in the future to address these limitations.

Finally, Tiramisu cannot correctly model a control plane where (1) iBGP routes lead to route deflection, and (2) an iBGP process assigns preferences (lp) or tag-based filters to routes received from its iBGP neighbors (Appendix C).

10 Related Work

We surveyed various related works in detail in earlier sections. Here, we survey others that were not covered earlier.

ERA [12] is another control plane verification tool. It symbolically represents advertisements which it propagates through a network and transforms it based on how routers are configured. ERA can verify reachability against arbitrary external advertisements, but it does not have the full coverage of control plane constructs as Tiramisu to analyze a range of policies. Bagpipe [29] is similar in spirit to Minesweeper and Tiramisu, but it only applies to a network that only runs BGP. FSR [28] focuses on encoding BGP path preferences.

Batfish [13] and C-BGP [24] are control plane simulators. They analyze the control plane's path computation as a function of a given environment, e.g., a given failure or an incoming advertisement, by conducting low level message exchanges, emulating convergence, and creating a concrete data plane. Tiramisu also conducts simulations of the control plane; but, for certain policies, Tiramisu can explore multiple paths at once via graph traversal and avoid protocol simulation. For other policies, Tiramisu only simulates a path vector protocol. Although P-Rex [18] is modeled for fast verification under failures, it focuses solely on MPLS.

11 Conclusion

While existing graph-based control plane abstractions are fast, they are not as general. Symbolic and explicit-state model checkers are general, but not fast. In this paper, we showed that graphs can be used as the basis for general and fast network verification. Our insight is that, rich, multi-layered graphs, coupled with algorithmic choices that are customized per policy can achieve the best of both worlds. Our evaluation of a prototype [2] shows that we offer 2-600X better speed than state-of-the-art, scale gracefully with network size, and model key features found in network configurations in the wild.

Acknowledgments. We thank the anonymous reviewers for their insightful comments. We also thank the network engineers that provided us real university and datacenter configurations. This work is supported by the National Science Foundation grants CNS-1637516 and CNS-1763512.

A Yen's and *TYEN* Algorithm

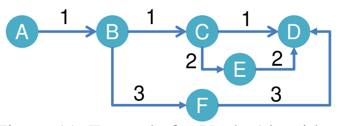

Figure 11: Example for Yen's Algorithm

Yen's algorithm. We use the graph in Figure 11 to explain this algorithm. Although line numbers below refer to *TYEN*, those lines of code also apply to the original Yen's algorithm.

Yen uses two lists: *listA* (to keep track of the shortest path seen so far) and *listB* (to keep track of candidates for the next shortest path). At the start, Yen finds the first shortest path (line 2) from *src* to *dst* using any shortest path algorithm (e.g. Dijkstra's). In Figure 11, it is $A \to B \to C \to D$. Let this path be P. Yen adds P to *listA*.

During each iteration of k, Yen takes every node n in path P (line 13, 14), and finds the *rootPath* and *spurPath* of that node. The *rootPath* of n is the subpath of P from *src* to node n (line 15). The *spurPath* is the shortest path from node n to *dst* (line 20) after making the following changes to the graph: i) to avoid loops, Yen removes all *rootPath* node except n from the graph, ii) to avoid recomputation, Yen removes all outgoing edges e from n, where e is part of any path P_A from *listA* having the same *rootPath* (line 17, 18). For example, if P_A is $A \to B \to C \to D$ and B is n, then $A \to B$ is the *rootPath* and e is $edge_{B \to C}$. By condition (i), Yen removes A and $edge_{A \to B}$. By condition (ii), it removes $edge_{B \to C}$. Then, it computes *spurPath* as $B \to F \to D$. Yen combines the *rootPath* and *spurPath* to form a new path P' (line 21) that is not blocked by tags. P' is added to *listB* if it doesn't already exist in *listA* or *listB* (line 23).

After traversing each node n in path P, Yen picks the shortest path from *listB* and reruns the previous steps with this path as the new P. This continues till Yen finds k paths.

Tiramisu Yen. To verify PREF, we make two simple modifications to Yen (*TYEN*). First, we replace Dijkstra with *TPVP*. Next, we add a condition to check that during each i^{th} iteration of k, the i^{th} path follows the preference order specified in PREF. To achieve this, *TYEN* associates each path with a variable, *eRemoved*. *eRemoved* keeps track (line 22) of edges that were removed from L3TPG (line 17-19) to compute that path. During each iteration of P, *TYEN* identifies the most preferred path specified in PREF that did not have an edge in *P.eRemoved* (line 8). If it varies from P, then preference is violated (line 9, 10).

Algorithm 3 Tiramisu Yen

```
Input:
  $G$ is the graph
  $src$, $dst$ are source and destination nodes
  $K$ is no. of path specified in path-preference policy
  PREF, a map of preference level and path
1: procedure TYEN ($G, src, dst, K$)
2:   $P \leftarrow$ path from src to dst returned by TPVP
3:   $pathsSeen \leftarrow 0$
4:   $P.eRemoved \leftarrow$ [], as best path requires no edge removal
5:   $listA \leftarrow$ [], tracks paths already considered as $P$
6:   $listB \leftarrow$ [], tracks paths not yet considered
7:   while $pathsSeen < K$ do
8:     $mostPref \leftarrow$ most preferred path in PREF whose edges don't overlap with $P.eRemoved$
9:     if $P \neq mostPref$ then
10:      return false, since path preference is violated
11:    $pathsSeen \leftarrow pathsSeen + 1$
12:    add $P$ to $listA$
13:    for i $\leftarrow$ 0 to P.length - 1 do
14:      $sNode \leftarrow i^{th}$ node of P
15:      $rootPath \leftarrow$ subpath of P from $src$ to $sNode$
16:      for each $sp \in listA$ do                ▷ paths in $listA$
17:        if $sp$ has same $rootPath$ at $sNode$ then
18:          remove out edge of $sNode$ in $sp$, so path $sp$ is not considered
19:      remove all nodes and edges of $rootPath$ except $sNode$ to avoid loops
20:      $spurPath \leftarrow$ path from $sNode$ to $dst$ returned by TPVP
21:      $P' \leftarrow rootPath + spurPath$
22:      $eRemoved \leftarrow$ all edges removed in this iteration
23:      add $P'$ to end of $listB$ if $P'$ is valid and $P' \notin [listA, listB]$
24:      append $P'.eRemoved$ to include $eRemoved$
25:      add back all nodes and edges to the graph
26:    P $\leftarrow$ remove first path from $listB$
27:  return true, since loop didn't find preference violation
```

B Tiramisu ILPs

Table 2 lists the boolean indicator variables and functions used in the ILPs.

B.1 Tiramisu Min-cut

We now present the complete ILP for KFAIL (§6.1). We repeat the description of the constraints to ensure ease of reading.

The objective is to minimize the number of physical link

	Name	Description
Variable	F_e	set as 1 if edge e fails
	A_e	set as 1 if traffic propagates on edge e
	R_n	set as 1 if traffic reaches node n
	B_e	set as 1 if edge e carries blocked tag
	$T_{n,t}$	set as 1 if node n forwards tag t
Function	$nodes$	returns all nodes of graph
	$edges$	returns all edges of graph
	$dEdges$	returns all inter-device edges of graph
	$pEdges$	returns all physical edges of the network
	$oNodes$	returns all nodes except src and dst
	$iE(n)$	returns incoming edges of node n
	$oE(n)$	returns outgoing edges of node n
	$iN(n)$	returns start nodes of all incoming edges of node n
	$at(e)$	returns tags added by edge e
	$rt(e)$	returns tags removed by edge e
	$bt(e)$	returns tags blocked on edge e
	$ot(e)$	returns tags $\notin [at(e), rt(e)]$
	$start(e)$	returns start node of edge e
	$end(e)$	returns end node of edge e
	$phy(e)$	returns physical edge associated with edge e

Table 2: *Variables and Functions*

failures required to disconnect *src* from *dst*.

$$\textbf{Objective:} \qquad \texttt{minimize} \sum_{i \in pEdges} F_i \tag{1}$$

Forwarding constraints. We first discuss the constraints added to represent *traffic forwarding*. The base constraint states that *src* originates the traffic. To disconnect the graph, the next constraint states that the traffic must not reach *dst*.

$$R_{src} = 1 \tag{2}$$

$$R_{dst} = 0 \tag{3}$$

For other nodes, the constraint is that traffic can reach a node n if it gets *propagated* (A_e) on any incoming edge e.

$$\forall n \in oNodes, R_n = \bigvee_{e \in iE(n)} A_e \tag{4}$$

(Logical AND/OR can be expressed as ILP constraints.)
Traffic can propagate through an edge e: if it reaches the start node of e ($start(e)$); if the traffic does not carry a tag that is blocked on e ($\neg B_e$); and if e represents an inter-device edge, the underlying physical link does not fail ($\neg F_{phy(e)}$). This is represented as

$$\forall n \in oNodes, \forall e \in iE(n) :$$
$$A_e = R_{start(e)} \wedge \neg B_e \wedge \neg F_{phy(e)} \tag{5}$$

Tag Constraints. We now add constraints to model route tags. Route tags propagate in route advertisements from processes that add tags to processes that remove tags or block advertisements based on tags. However, the TPG models traffic propagation, which occurs in the opposite direction of route propagation. Hence, instead of modeling the flow of tags from the nodes that add them to the nodes that block/remove them, we model the flow of *blocked tags* from the nodes that block them to the nodes that remove/add them. The base constraints state that each edge that blocks on the tag "forwards" the blocked tag, and each edge that removes the blocked tag does not forward it.

$$\forall e \in edges, \forall t \in bt(e) :$$
$$T_{e,t} = 1 \tag{6}$$

$$\forall e \in edges, \forall t \in rt(e) :$$
$$T_{e,t} = 0 \tag{7}$$

For other edges, we add the constraint that edge e forwards a blocked tag t iff the start node of e ($start(e)$) receives traffic with t.

$$\forall e \in edges, \forall t \in ot(e) :$$
$$T_{e,t} = \bigvee_{i \in iE(start(e))} T_{i,t} \tag{8}$$

Finally, we add the constraint that an edge e carries blocked traffic iff e receives a tag that is added by e.

$$\forall e \in edges :$$
$$B_e = \bigvee_{t \in at(e)} T_{e,t} \tag{9}$$

B.2 Tiramisu Longest Path

We now present the complete ILP for BOUND (§6.2). For ease of reading, we repeat our description of the constraints.

Recall that our objective is to maximize the number of inter device edges ($dEdges$) traversed by traffic (A_i).:

$$\textbf{Objective:} \qquad \texttt{maximize} \sum_{i \in dEdges} A_i \tag{10}$$

Path constraints. To ensure traffic flows on only one path, *src* sends traffic, and *dst* receives traffic, we add the following constraints:

$$\sum_{out \in oE(src)} A_{out} = 1 \tag{11}$$

$$\sum_{in \in iE(dst)} A_{in} = 1 \tag{12}$$

For other nodes, we add the flow conservation property, i.e. the sum of incoming flows is equal to the outgoing flows.

$$\forall n \in oNodes : \sum_{in \in iE(n)} A_{in} = \sum_{out \in oE(n)} A_{out} \tag{13}$$

Traffic constraints. Next, we add constraints on traffic propagation. Traffic will be blocked on edge e if it satisfies the tag (B_e) constraints. This is similar to Eqn 9.

$$\forall e \in edges : A_e \leq \neg B_e \tag{14}$$

C Proofs

We first prove the correctness of *TPVP* (§C.1). This theorem is then used to prove the correctness of our ILPs(§C.2) and *TDFS* (§C.3).

C.1 *TPVP*

In this section, we prove that we correctly model and solve the stable paths problem. Griffin *et al* [15] showed that *an instance of the stable paths problems is a graph together with the permitted paths $\mathcal{P}$ at each node and the ranking functions for each node.* Hence, we first need to prove that we correctly model the permitted paths $\mathcal{P}$ and the ranking function. We will use the following lemmas to prove them. Finally, we will prove that as long as the network converges, *TPVP* finds the exact path taken in the network and hence the solution to the stable path problem.

Lemma 2. *All permitted paths $p \in \mathcal{P}$ that a routing process $v \in V$ may take in the actual network to reach the destination, exists in the TPG ($p \in TPG$).*

Proof: Consider the path $v_i \rightarrow v_{i+1} ... \rightarrow v_n$, where v represents a node in the graph. We will inductively prove that for any path $p \in \mathcal{P}$, a node v_i has a path to the *dst* node in the TPG, if there is an equivalent path that traverses the same routing processes (i.e. the traffic matches the RIB entries of these routing processes) and vlan-interfaces on the real network.

When $i = n$, then the node v_i represents the destination (*dst*) of traffic.

Assume there is a path from node v_{i+1} to v_n and this is modeled correctly. We will now prove that v_i is connected to v_{i+1} in the TPG if v_i can use v_{i+1} to reach the next-hop router (in its path towards the destination node). Node v_i can be one of the following types of nodes

Case (i): node v_i is an OSPF node According to §4.2, node v_{i+1} will be a VLAN-egress node. TPG connects v_i and v_{i+1} if *OSPF* is configured to operate on that *VLAN* interface. OSPF uses its configured interfaces [22] to (a) receive link-state advertisement from its neighbors, and (b) forward/send traffic towards its neighbors. Hence, OSPF will use the VLAN-egress node to forward traffic to its neighbors/next-hop router. Hence case (i) is modeled correctly.

Case (ii): node v_i is an BGP node According to §4.2, node v_{i+1} will be either an OSPF node or an VLAN-egress node. These instances represent BGP using either an OSPF-computed route or a connected subnet to reach the next hop router. Assume v_{i+1} is an *OSPF* node. BGP process is allowed to communicate with its neighboring adjacent process through an OSPF-computed path. Hence these nodes can be connected in the actual network. Assume v_{i+1} is a VLAN-egress node for VLAN interface V. TPG connects them if BGP's next-hop IP address falls within the subnet assigned to VLAN interface V. Similar to case (i), this interface is use to receive advertisements and send traffic to the next-hop router. Hence case (ii) is modeled correctly.

Case (iii): node v_i is a VLAN-ingress node According to §4.2, node v_{i+1} will be either an OSPF/BGP node representing the processes running on the same router, or an egress node for the same VLAN on that router. Assume v_{i+1} is an OSPF/BGP node. In the TPG, all traffic enters a router through a VLAN-ingress node. In the actual network, all incoming traffic looks up the global RIB of the router to move to the next-hop router. A router's global RIB contains entries from all the RIBs of all of its routing processes. The TPG connects the VLAN-ingress node to an OSPF/BGP node if that node is tainted in the RAG. Since only those processes that have a RIB entry for the *dst* are tainted, this is modeled correctly. Assume v_{i+1} is an VLAN-egress node. TPG connects them iff the underlying device is a switch. Since flooding occurs at Layer-2, this is modeled correctly.

Case (iv): node v_i is a VLAN-egress node According to §4.2, node v_{i+1} will be a VLAN-ingress node. TPG connects them if they belong to the same VLAN and their underlying routers are connected in the physical topology. This models basic physical connectivity in the real network. Hence, case (iv) is modeled correctly.

Case (v): node v_i is the *src* node According to §4.2, node v_{i+1} will be either an OSPF node or a BGP node. The *src* node is like any other VLAN-ingress node, with the difference being that the *src* originates the traffic. Hence, using similar arguments as case (iii), case (v) is modeled correctly.

Lemma 3. TPVP *will not choose a path $p \notin \mathcal{P}$ from a routing process $v \in V$ to the destination, that the routing process v cannot choose in the actual network.*

Proof: A TPG is partially based on the physical topology. In the TPG, the only inter-device edge is the edge between the VLAN-egress node of a device and the VLAN-ingress node of its neighboring device. Hence, the TPG will not have any path that does not exist in the actual physical network topology.

In the TPG, *OSPF* and *BGP* nodes are connected to a VLAN-egress node if they processes is configured to operate on that VLAN. Additionally, a VLAN-ingress node is connected to *OSPF* and *BGP* nodes if those processes are tainted in the RAG. Hence, the TPG will correctly connect the interfaces with its associated routing process, and won't have any path due to incorrect route adjacency.

Next, we prove that Tiramisu correctly models prefix/neighbor-based and tag-based filters. The TPG models prefix/neighbor-based filters by removing edges from the node associated with the process that uses those filters. Hence, the TPG will not have any path that is blocked due to prefix/neighbor-based filters in the actual network.

The only path that may exist in the TPG and not in the network is the path blocked by tags. *TPVP* uses routing algebra [16, 25] to model route computation and route selection operations. [16] showed that routing algebra can model and filter routes based on tags. Routing algebra uses "tag" attributes in their edge labels and path signatures. Their

$\oplus$ (operation) function models both addition of tags and blocking routes based on tags. Hence *TPVP* will not choose a path that is blocked by tags.
Hence *TPVP* will not choose a path p that cannot be chosen in the actual network.

Lemma 4. *L3TPG has the same set of layer 3 paths as the actual network and has no path that cannot exist in the actual network.*

Proof: Since advertisements can flow between layer 3 nodes as long as there is at least one layer 2 path that connects them, Tiramisu uses path contraction to replace layer 2 paths with a layer 3 edge.
Assume there is a layer 3 path P^* in the L3TPG that does not exist in the network. Since path contraction replaces subpaths with edges and does not add paths, P^* with (layer 2 nodes inbetween) must exist in the original TPG. I.e. If nodes are connected in the layer-3 graph, then they have to be connected even before path contraction. This contradicts Lemma 3.
Assume there is a layer 3 path $P^{\#}$ in the network that does not exist in the L3TPG. Since path contraction replaces subpaths with edges and does not eliminate paths, $P^{\#}$ with (layer 2 nodes inbetween) must not exist in the original TPG. This contradicts Lemma 2.

In the following lemmas, we operate on the contracted L3TPG.

Lemma 5. *For all routing process $v \in V$, given a set of paths $\mathcal{P}$, $best(\mathcal{P}, v)$ matches the path that v would choose when paths $\mathcal{P}$ are given as choices in the actual network.*

Proof: *TPVP* uses routing algebras to model the ranking behavior of actual protocols (*OSPF* and *BGP*). Routing algebras model route selection/path ranking using a $\preceq$ preference relation over path signatures. This correctly models the route selection algorithm in the underlying network. Hence the path chosen by $best(\mathcal{P}, v)$ for each routing process $v \in V$ matches the path chosen in the actual network.

Lemma 6. *For all routing process $v \in V$, the set of paths $\mathcal{P}$ considered by* TPVP *matches the paths that v can choose from in the actual network.*

Proof: Our networks may run either (i) only *OSPF* processes, (ii) only *BGP* processes, or (iii) both *OSPF* and *BGP* processes. We leverage Lemma 5 to prove the correctness for each scenario.

Case (i): OSPF-only network In the L3TPG, we have only *OSPF* nodes. From Lemma 5, we know that *OSPF* nodes will make the same choice as the actual OSPF processes. Hence case (i) is modeled correctly.

Case (ii): BGP-only network In the L3TPG, we have only *BGP* nodes. From Lemma 5, we know that *BGP* nodes will make the same choice as the actual *BGP* processes. Hence case (ii) is modeled correctly.

Case (iii): OSPF+BGP network In the layer 3 TPG, we have both *BGP* and *OSPF* nodes. Here choices made by *OSPF* or *BGP* nodes may depend on the opposite protocol's choices.

Case (iii-a): both node v_i and v_{i+1} are BGP nodes. This is similar to case (ii). Hence it is modeled correctly.
The next three cases represent instances where *BGP* uses an *OSPF* computed path to reach its next hop.

Case (iii-b): node v_i is a BGP node, node v_{i+1} is an OSPF node, and v_{i+1} is connected to a single BGP node. Since *OSPF* has only one choice, it will select the *BGP* process as its next hop and case (iii-b) is modeled correctly.

Case (iii-c): node v_i is a BGP node, node v_{i+1} is an OSPF node, and v_{i+1} is connected to multiple BGP nodes having equal preference (same cost). Since BGP *processes* are equally preferred, OSPF cost is used to select the best path/route [1]. Case (i) showed that given a set of OSPF-costs, the *OSPF* node will make the right choice. Hence, this case (iii-c) is modeled correctly.

Case (iii-d): node v_i is a BGP node, node v_{i+1} is an OSPF node and v_{i+1} is connected to multiple BGP nodes having different preferences. Since an *OSPF* node cannot make a decision using *BGP* preferences, Tiramisu cannot model this scenario. In the real network, this scenario arises when an iBGP process assigns preferences (lp) or tag-based filters to routes received from its iBGP neighbors.

Case (iii-e): node v_i is a BGP node, node v_{i+1} is an OSPF node and v_{i+1} is connected to one or multiple OSPF nodes. This scenario can only happen if *BGP* and *OSPF* have route redistribution. In this scenario, v_{i+1} makes the choice for intra-domain routing and v_i makes the choice for inter-domain routing. Using similar arguments as case (i) and case (ii), choices made by v_{i+1} and v_i will be correct.

Case (iii-f): node v_i is an OSPF node. Assume node v_{i+1} is an *OSPF* node. This is similar to case (i). Hence it is modeled correctly. Assume node v_{i+1} is a BGP node. This will lead to similar scenarios as case (iii-c) to case (iii-e). Hence, using similar arguments, case (iii-f) is modeled correctly as long as iBGP processes do not assign preferences to routes received from its iBGP neighbors.

Theorem 1. *If the network control plane converges,* TPVP *always finds the exact path taken in the network under any given failure scenario.*

Proof: Lemma 2 and 3 showed that we correctly model permitted paths $\mathcal{P}$. Lemma 5 and 6 showed that we correctly model path selection/ranking function. Now, we need to prove that under convergence, *TPVP* is equivalent to PVP.

The body of the loop code of *TPVP* (line 7 to 11) is equivalent to the *PVP* code that runs at each node [26]. The termination conditions of *PVP* and *TPVP* (line 12 to 13) are also similar. Both of them establish convergence when there are no new messages in the distributed and shared buffers respectively. And finally, both of them are executed after removing edges to represent failures.

The main difference between *PVP* [15, 26] and *TPVP* is the following: In PVP, there is no restriction on the order in which messages are processed by different routers. As long as the network converges and there exists a stable path, *PVP* will find it irrespective of the order in which messages are sent and processed. In *TPVP*, we process and send messages in a fixed round-robin order (line 5). Since any ordering of messages in *PVP* leads to a valid solution, a fixed ordering of messages should also lead to a valid solution. Hence if the network converges, *TPVP* finds the exact path.[4]

C.2 ILP

We will first use two lemmas to prove that *TPVP* and the min-cut ILP consider the same set of paths. Recall that the min-cut ILP can be applied directly only on a TPG with no ACLs; in §6.1, we showed how it deals with ACLs.

Lemma 7. *The min-cut ILP only considers paths computed by TPVP.*

Proof: Assume the min-cut ILP considered a path that was not computed by *TPVP*. This implies the path was ignored by *TPVP* but not the ILP. This is not possible because (i) according to Lemma 2 and 3, *TPVP* correctly models permitted paths, and (ii) the ILP and *TPVP* exclude the same set of paths, i.e. both of them exclude paths based on tags. The ILP constraints on tags (Eqn 6 and 14) ensure that all paths blocked by tags are ignored by the ILP.

Lemma 8. *The min-cut ILP considers all paths computed by TPVP.*

Proof: Assume the min-cut ILP did not consider a path computed by *TPVP*. This implies the path was ignored by the ILP but not by *TPVP*. Similar to Lemma 7, this is not possible because (i) the ILP correctly models permitted paths (Lemma 2 and 3), and (ii) the ILP and *TPVP* exclude the same set of paths.

Theorem 9. *In the absence of ACLs, the min-cut ILP computes the minimal failures to disconnect the src and dst in the TPG.*

Proof: By Lemma 7 and 8, the ILP considers the same set of paths as *TPVP*. Next, we will show that this ILP computes a valid cut. Then, we will show that the cut is minimum.

Assume the ILP does not compute a valid cut. This means there is a path where all its edges A_e are equal to 1. However that also means that by Eqn 4, one of $R_{start(e)}$ is R_{dst} and R_{dst} is equal to 1. This contradicts Eqn 3.

Assume the ILP computes an invalid cut. This means there is still a path where all its edges A_e are equal to 1. Using the same argument, this will again contradict Eqn 4 with Eqn 3.

Assume the cut computed by ILP is not the minimum. This will contradict the objective function (Eqn 1) which minimizes the number of edge failures (removals) to disconnect the graph.

Next, we prove the correctness of the longest-path ILP.

Theorem 10. *The longest-path ILP computes the length of the longest inter-device path between src and dst in the TPG.*

Proof: Note that the longest-path ILP is modeled for the same TPG as the min-cut ILP. Although the ILPs are different, the constraints used to block based on tags are the same. Using similar arguments as min-cut ILP, we can prove the following two lemmas

Lemma 11. *The longest-path ILP only considers paths computed by TPVP.*

Proof: Similar to Lemma 7

Lemma 12. *The longest-path ILP considers all paths computed by TPVP.*

Proof: Similar to Lemma 8

Hence, by Lemma 11 and 12, this ILP also considers the same set of paths as *TPVP*. Next, we will show that this ILP computes a valid path. Then, we will show that this path is the longest.

Assume, the ILP finds an invalid path. This means there is some node which has an outgoing flow without any incoming flow. This contradicts the flow conservation constraint (Eqn 13). Assume, the ILP misses a valid path. This means there is some node which does not have an outgoing flow but has an incoming flow. This also contradicts Eqn 13.

Assume the path computed by ILP is not the longest. This will contradict the objective function (Eqn 10) which maximizes the number of edges traversed to reach the destination.

C.3 TDFS

Theorem 13. TDFS *identifies a src-dst pair as always unreachable iff there never exists a path from src to dst under all possible failures*

Proof: Assume there existed some path in the network that *TDFS* did not consider. This implies the path was ignored by TDFS and not *TPVP*. We will now prove by contradiction why this is not possible.

There are four types of paths that can exist in the network to establish reachability. We will show that *TDFS* will capture each of those paths.

Case (a): assume a path p_1 exists from *src* to *dst* which does not traverse any edge with tags. Assume this path is ignored by *TDFS*. Line 5 of *TDFS* runs *DFS* after removing edges that block on tags. In this case, no edges are removed. Since p_1 connects *src* to *dst*, *DFS* will return true and *TDFS* will say *dst* is reachable from *src*. This contradicts our assumption.

Case (b): assume a path p_2 exists from *src* to *dst* which does not traverse any edge that blocks on a tag. Assume this path is ignored by *TDFS*. Line 5 of *TDFS* runs *DFS* after removing edges that block on tags. Since p_2 connects *src* to *dst* without traversing any of these removed edges, *DFS* will return true and *TDFS* will say *dst* is reachable. This again contradicts our assumption.

Case (c): assume a path p_3 exists from *src* to *dst* that traverses an edge that blocks on tags but does not traverse any edge which adds tags to an advertisement. Assume this path is ignored by *TDFS*. Line 7 of *TDFS* runs *DFS* after (i) establishing that all paths go through edges that block on tags, and, (ii) removing edges that add tags. Because of (i), we know all

[4]Note that Tiramisu assumes network convergence. The routing algebra that models *TPVP* will have all the algebraic properties required for convergence.

p_3 will traverse a tag blocking edge. Since p_3 connects *src* to *dst* (and hence a tag-blocking edge to *dst*) without traversing the removed edges, *DFS* will return true and *TDFS* will say *dst* is reachable. This again contradicts our assumption.

Case (d): assume a path p_4 exists from *src* to *dst* which traverses an edge that blocks on tags, followed by an edge that removes that tag and an edge that adds that tag. Assume *TDFS* ignores this path. Line 9 of *TDFS* runs *DFS* after (i) establishing that all paths go through both edges that block on a tag and add that tag, and (ii) removing edges that remove that tag.

TDFS will return false if *DFS* states that the tag-blocking edge cannot reach the tag-adding edge. This can happen in two scenarios. In the first scenario, the tag-blocking edge could not reach the tag-adding edge even before node removal. In the second scenario, the tag-blocking edge could reach the tag-adding edge, but the removal of the tag-removing edge disconnected them. p_3 already captures the first scenario. And p_4 represents the second scenario. *TDFS* captures both these scenarios. Hence, this again contradicts our assumption.

Assume there exists some path $P^{\#}$ that is considered by *TDFS* as a valid path but does not exist in the network. As mentioned in Lemma 3, the only path that exists in the TPG and not in the network is the path blocked by tags. Hence, $P^{\#}$ must be blocked by tags. However, Line 11 of *TDFS* returns true if all paths that connect *src* to *dst* traverses a tag-blocking edge X, followed by a tag-adding edge Y, and no tag removing edge between X and Y. Hence, *TDFS* correctly identifies and ignores paths based on tags. This again contradicts our assumption.

D Other Policies

Some of the other policies that Tiramisu can verify are listed below:

Always Chain of Waypoints (CW)**.** Similar to waypointing, we remove nodes associated with each waypoint, one at a time. Using *TDFS*, we check if nodes associated with one of the preceding waypoints in the chain can reach nodes associated with one of the following waypoints in the chain.

Equal Bound (EB)**.** This policy checks that all paths from *src* to *dst* are of the same length. The objective of the ILP in §6.2 can be changed to find the shortest path length. If the longest and shortest path length varies, then this policy is violated.

Multipath Consistency (MC)**.** Multipath consistency is violated when traffic is dropped along one path but blocked by an ACL on another. To support multipath in *TPVP*, we change the p_* variable to keep track of multiple most preferred path signatures to reach *dst*. Using *TPVP*, Tiramisu can identify the number of best paths to reach *dst*. We run *TPVP* on graphs with and without removing edges for ACLs. If the number of paths varies with and without ACLs, then the policy is violated.

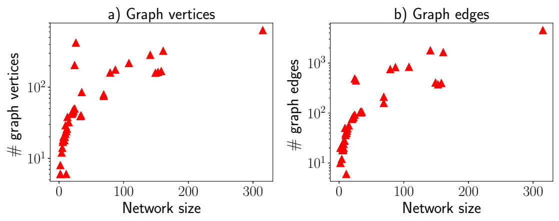

Figure 12: Size of multilayer graphs of all networks

Always no black holes (BH)**.** Black holes occur when traffic gets forwarded to a router that does not have a valid forwarding entry. Blackholes are caused by i) ACLs: routers advertises routes for traffic that is blocked by their ACLs; ii) static routes: the next-hop router of a static route cannot reach *dst*. Tiramisu uses *TDFS* to check these conditions. For (i) Tiramisu first creates the graph without removing edges for ACLs. Let R be the router with a blocking ACL. If *src* can reach router R and R can reach *dst* (using *TDFS*), then traffic will reach router R under some failure, and then get dropped because of the ACL. For (ii) if *src* can reach the router with the static route and the next-hop router *cannot reach dst*, then the traffic gets dropped.

E Protocols/Modifiers in Network

We used university, datacenter, topology zoo, and Rocketfuel configurations in our evaluation §8. Table 3 shows what percentage of networks in these datasets support each network protocol/modifier.

	% of Networks			
Protocols/Modifiers	University	Datacenter	Topology Zoo	Rocketfuel
eBGP	100%	100%	100%	100%
iBGP	100%	0%	100%	100%
OSPF	100%	97%	100%	100%
Static routes	100%	100%	0%	0%
ACLs	100%	100%	0%	0%
Route Filters	100%	97%	100%	0%
Local Prefs	50%	0%	100%	0%
VRF	100%	0%	0%	0%
VLAN	100%	0%	0%	0%
Community	100%	100%	100%	0%

Table 3: Configuration constructs used in networks

Figure 12 characterizes the size of the TPGs generated by Tiramisu for these networks. It shows the number of nodes and edges used to represent the graph. We observe two outliers in both Figure 12a and Figure 12b. These occur for networks *Uni*2 (24 devices) and *Uni*3 (26 devices), from the university dataset. These networks have multiple VRFs and VLANs, and Tiramisu creates multiple nodes (and edges between these nodes) for different VRFs, routing processes and VLAN interfaces. Note also that for the other networks, the number of routing processes per device varies. Hence, the number of nodes and edges do not monotonically increase with network size.

Automated Verification of Customizable Middlebox Properties with Gravel

Abstract

Building a formally-verified software middlebox is attractive for network reliability. In this paper, we explore the feasibility of verifying "almost unmodified" software middleboxes. Our key observation is that software middleboxes are already designed and implemented in a modular way (e.g., Click). Further, to achieve high performance, the number of operations each element or module performs is finite and small. These two characteristics place them within reach of automated verification through symbolic execution.

We perform a systematic study to test how many existing Click elements can be automatically verified using symbolic execution. We show that 45% of the elements can be automatically verified and an additional 33% of Click elements can be automatically verified with slight code modifications. To allow automated verification, we build Gravel, a software middlebox verification framework. Gravel allows developers to specify high-level middlebox properties and checks correctness in the implementation without requiring manual proofs. We then use Gravel to specify and verify middlebox-specific properties for several Click-based middleboxes. Our evaluation shows that Gravel avoids bugs that are found in today's middleboxes with minimal code changes and that the code modifications needed for proof automation do not affect middlebox performance.

1 Introduction

Middleboxes (e.g., NATs, firewalls, and load balancers) play a critical role in modern networks. Yet, building functionally correct middleboxes remains challenging. Critical bugs have routinely been found in middlebox implementations. Many of these bugs [8–12] directly lead to system failure or information leaks. Worse still, malformed packets can trigger some of these bugs and expose severe security vulnerabilities.

Given the importance of building functionally correct middleboxes, researchers have turned to formal verification and have made significant progress [14, 40]. Crucially, these efforts tackle real middlebox implementations rather than abstract middlebox models and verify non-trivial program properties. However, just as with using software verification in other areas of computer systems, this can incur a non-trivial amount of proof effort (e.g., 10:1 proof to code ratio in VigNAT [40]). At the same time, the excessive proof effort prevents researchers from exploring verification of high-level middlebox-specific properties (e.g., a middlebox rejects unsolicited external connection). As a consequence, recent verification efforts focus either entirely on low-level code properties (e.g., free of crashes, memory safety) [14] or on proving equivalence to pseudocode-like low-level specifications [39, 40].

In this paper, we ask whether it is possible to make software middlebox verification completely automated with minimal proof effort. In particular, our goal is two-fold. First, we want verification to work on real-world "almost unmodified" middlebox implementations without requiring manual proofs. Second, we want developers to be able to express and verify high-level properties directly translated from RFCs (e.g., RFC5382 [29] for NAT) without writing manual proofs towards each of these properties. To deliver on these goals, we seek to replicate the automated reasoning approach used in some recent verification projects that focus on file systems and OS system calls [30, 34]. Specifically, we would like to use symbolic execution to automatically encode a middlebox implementation and its high-level specification using satisfiability modulo theories (SMT) and then use solvers to verify that the implementation is consistent with the specification.

Our key observation regarding the suitability of this approach is that many existing middleboxes are already designed and implemented in a modular way (e.g., Click [23]) for reusability. As they aim for high performance, the number of operations they perform on each packet is finite and small. Both characteristics place these middleboxes within reach of automated verification through symbolic execution. Thus, one goal of this paper is to identify domain-specific analyses that enable symbolic execution to exploit these characteristics and distill SMT encodings for middlebox implementations.

We begin by studying whether we can use automated verification on existing software middleboxes. We perform a systematic study on all 290 Click elements and 56 Click configurations (≈60K lines of code) in Click's official repository to test whether they are suitable for automated verification. We find that a baseline symbolic executor can derive symbolic expressions for 45% of the elements and 16% of the configurations. We then introduce a set of domain-specific static analyses and code modifications (such as replacing element state by SMT-encoded abstract data types) to enable the symbolic execution of a more substantial fraction of Click elements. These techniques allow us to symbolically execute an additional 33% and 50% of elements and configurations, respectively.

Encouraged by the results of the empirical study, we designed and implemented Gravel, a framework for automated software verification of middleboxes written using Click [23]. Gravel provides developers with programming interfaces to specify high-level trace-based properties in Python. Gravel symbolically executes the LLVM intermediate representation compiled from an element's C++ implementation. Gravel then uses Z3 [38] to verify the correctness of the middlebox without the burden of manual proofs.

We then evaluate Gravel by porting five Click middleboxes: MazuNAT, a load balancer, a stateful firewall, a web proxy, and a learning switch. We verify their correctness against high-level specifications derived from RFCs and other sources. Only 133 out of 1687, 63 out of 1151, 63 out of 1447, 50 out of 953, and 0 out of 594 lines of code need to be modified to make them automatically verifiable. The high-level specification of the middlebox-specific properties can be expressed concisely in Gravel, using only 177, 70, 68, 39, and 91 lines of code. Our evaluation shows that Gravel can avoid bugs similar to those found in existing unverified middleboxes. Finally, we show that the code modifications do not degrade the performance of the ported middleboxes.

2 Encoding Existing Software Middleboxes

To understand the feasibility of applying automated verification to existing software middleboxes, we perform an empirical study of all the 290 Click elements and 56 Click configurations[1] in Click's official repository [23]. In this section, we first explain what is automated verification and then describe ways to enhance the effectiveness of automated verification for middleboxes. Finally, we show that 78% of Click elements and 66% of Click configurations are amenable to automated verification after some limited modifications to the code.

2.1 Automating verification using symbolic execution

A well-established approach to software verification is deductive verification. In this style, a developer generates a collection of proof obligations from the software and its specifications. Proof assistants, such as Coq [7], Isabelle [32], and Dafny [24], are highly expressive, allowing mathematical reasoning in high-order logic. However, the verification process is mostly manual, requiring significant effort from the developer to convey his/her knowledge of why the software is correct to the verification system. For example, when applied to a NAT, VigNAT [40] shows a 10:1 proof-to-code ratio.

Recently, researchers have started exploring the feasibility of automating the verification process through exhaustive symbolic execution, which encodes the middlebox implementation into a symbolic expression that can be checked against a high-level specification. This style of software verification reduces the developers' manual proof effort and has already been used successfully to verify file systems [34] and operating systems [30]. However, this style is more limited than deductive verification, putting restrictions on the programming model. For example, Hyperkernel requires loops in its system call handlers to have compile-time bounds on their iteration counts.

[1]Our empirical study focuses on the Click elements and configurations that process packets in a run-to-completion model.

```
class CntSrc : public Element {
    // omitting constructor and destructor
    Packet *process_packet(Packet *pkt) {
        if (pkt->ip_header->saddr == target_src_)
            cnt_++;
        return pkt;
    }
    IPAddress target_src_;
    uint64_t cnt_;
}
```

Figure 1: A C++ implementation of a simple packet counter.

To see an example of symbolic execution based verification, Figure 1 shows a simple packet counter. This code increments a counter when the source IP address of a packet matches a signature (i.e., `target_src_`). Here we model this `process_packet` function as $f : \mathbb{S} \times \mathbb{P} \mapsto \mathbb{S} \times \mathbb{P}$, where $\mathbb{S}$ is the set of all possible internal states (`target_src_` and `cnt_`) and $\mathbb{P}$ denotes the set of all possible packets. For simplicity, this formulation assumes that at most one outgoing packet is generated for each incoming packet. Symbolically executing this code snippet generates the following symbolic expression:

$$\begin{aligned}
&\forall s,\ s' \in \mathbb{S}, \forall p,\ p' \in \mathbb{P},\ f(s,p) = (s',p') \Rightarrow \\
&\qquad (p' = p) \wedge (s'.target\_src = s.target\_src) \\
&\qquad \wedge (p.saddr = s.target\_src \Rightarrow s'.cnt = s.cnt + 1) \\
&\qquad \wedge (p.saddr \neq s.target\_src \Rightarrow s'.cnt = s.cnt))
\end{aligned}$$

This symbolic expression says that for all possible inputs, outputs and state transitions: (1) the input packet should be the same as the output packet; (2) the `target_src_` should not change; (3) if the packet's source IP address matches `target_src_`, the `cnt_` in the new state should be the `cnt_` in the old state plus 1; (4) if the packet's source IP address does not match `target_src_`, the `cnt_` should not change.

Symbolic execution alone is not enough for automated verification; it only ensures that we can automatically generate the above expression. To ensure automated verification, when the developer verifies the above expression against a specification using an off-the-shelf theorem solver (such as Z3 [38]), the solver needs to be able to solve it efficiently.

A program is suitable for **automated verification** if:

1. Symbolic execution of the program halts and yields a symbolic expression.
2. The resulting symbolic expression is restricted to an effectively decidable fragment of first-order logic.

Condition 1 means the program has to halt on every possible input. Condition 2 depends on which fragment of first-order logic a solver can solve efficiently. This fragment changes as solver technologies improve over time. Empirically, we know that if we can restrict the symbolic expression to only bit vectors and equality with uninterpreted functions, a solver can tackle the expression efficiently [30].

2.2 Baseline effectiveness of symbolic execution

We now study the feasibility of automating verification by examining middleboxes written using Click. We perform an empirical study on both Click elements and Click configurations, which are datagraphs formed by composing Click elements. This study allows us to measure both the fraction of Click code and the fraction of automatically verifiable Click programs. To perform this empirical analysis, we implement a baseline symbolic executor to analyze whether an element or a configuration satisfies the conditions mentioned above. Since elements are C++ classes, the symbolic executor first analyzes all the member fields to determine whether the state could be encoded with SMT (Condition 2). It then performs symbolic execution over the compiled LLVM byte code[2] of the element to check if Condition 1 is met. However, since both conditions are undecidable, we choose to use the following two conservative criteria. (In fact, we describe in the subsequent section how we augment our baseline symbolic executor with domain-specific extensions.)

Absence of pointers in element state. When the symbolic executor analyzes each of an element's members, it checks whether the element state can be expressed solely by bit vectors and uninterpreted functions. Though one could use bit vectors to encode the entire memory into a symbolic state, it would be difficult to efficiently solve expressions containing such a symbolic state due to the sheer size of the search space. Therefore, we choose a conservative criterion, the absence of pointers in element states, as it is easy to see that elements without pointers always have bounded state. Each element in Click can only have a finite number of member variables, and each non-pointer variable can only consume a finite amount of memory. Thus, the state space of a Click element without pointers can always be expressed by constant size bit vectors. Of course, such criteria introduce false negatives, for example, using pointers to access a bounded data structure (e.g., fixed-size array).

Absence of loops and recursions. To determine whether Click elements' execution is bounded (Condition 1), the symbolic executor invokes the packet processing code using a symbolic element state and a symbolic packet content. The symbolic executor detects potential unbounded execution by searching for loops and recursive function calls and only performs execution on those elements that do not contain them. The symbolic executor performs the check by comparing each jump/call target with the history of executed instructions.

Table 1 shows the results of running this baseline symbolic executor. We found that 130 of the existing Click elements (45%) are suitable for automated verification. Among the ones that failed our test, 143 elements failed because of pointers, and 78 elements failed because of unbounded execution. 61 of the elements have both pointers and unbounded execution. A Click configuration is amenable to automated verification if and only if all the Click elements in the configuration can be automatically verified. Among the 56 configurations in the official Click repository, only 9 out of the 56 Click configurations (16%) are suitable for automated verification.

[2]We chose to use LLVM byte code rather than C++ abstract syntax tree as the former makes it easier to reason about the control flow by eliminating C++ related complexities (e.g., function overloading and interface dispatching).

2.3 Enhancing symbolic execution

We now augment our baseline executor with additional techniques that aid symbolic execution. We also examine the impact of performing a small number of code modifications to make the middleboxes amenable to automated verification. Some of the techniques described below are broadly applicable but are likely more effective for middlebox programs that operate on packet data with well-defined protocol specifications. The remaining techniques are domain-specific analyses that are suitable only for packet processing code.

Code unrolling. When detecting a backward jump, the symbolic executor unrolls the loop and executes its loop body. The executor keeps count of how many times it executes the backward jump instruction and raises an error if the number goes beyond a pre-defined threshold. This technique is useful when the source code has loops with a static number of iterations or loops whose iteration count is a small symbolic value, as would be the case for code that processes protocol fields of known size.

Pointer analysis to detect immutable pointers and static arrays. In general, we can classify the use of pointers into three categories: pointers to singleton objects, pointers corresponding to arrays, and pointers used to build recursive data structures. These use cases introduce two distinct challenges in the symbolic execution of Click code with pointers. First, the symbolic executor needs to determine whether two pointers point to overlapping memory regions and update the symbolic state of elements correctly irrespective of which pointer is used for the update. Second, when pointers are used to implement recursive data structures, such as linked list or tree, the data structure access often involves loops whose iteration counts depend on the symbolic state of the elements. Our symbolic executor first identifies how pointers are used and then uses the appropriate technique for symbolic execution.

We first use an analysis pass to identify immutable pointers by checking which of the pointer fields in a Click element remain unmodified after allocation. At the same time, we determine which of the other program variables serve as possible aliases for a given pointer field. Further, for pointers pointing to an array of data items, the symbolic executor also performs a static bounds check on accesses performed using the pointers to ensure that all accesses are within allocated regions. By doing so, the symbolic executor can prove an invariant that accesses performed using the array pointer do not touch other memory regions.

After performing these analyses, the symbolic executor limits itself to handling accesses through immutable and unaliased pointers that refer to either singleton objects or arrays. For each pointer referring to a singleton object, the executor associates a corresponding symbolic value. For each pointer referring to an array of data, the symbolic executor uses an uninterpreted function in SMT to represent the contents of the array. The symbolic executor uses uninterpreted functions that map array index (64-bit integer) to bytes (8-bit integer) to model the content of the array. We choose to use this offset-to-bytes mapping as the unified representation for both array and packet content since reinterpreting a sequence of bytes in memory as a different type is a common practice in packet processing (e.g., parsing packet header, endianness conversion). We record updates to the array as a sequence of (possibly symbolic) index/value pairs. Since the functions are "uninterpreted", they model all possible values of the array data. Compared with bit vectors, representing states with uninterpreted functions makes symbolic execution scale to larger state size [6, 34].

Our symbolic executor does not handle pointers that are used to build a recursive data structure, such as a linked list, except in the case of certain abstract data types for which we are able to provide SMT encodings (as discussed next).

SMT encodings of commonly used abstract data types. Our next technique avoids the symbolic execution of the data structure implementation by hiding the implementation under a well-defined data structure interface. This technique allows us to integrate implementations that may contain unbounded loops or recursive data structures into our analysis. When performing the symbolic execution, we can simply provide an encoding in SMT for common data structures, such as `HashSet`. Note that not all data structures can have their interfaces encoded in SMT. The key challenge here is to prevent the explosion of the state space; the size of the encoding should not depend on the actual size of the data structure. We managed to encode three commonly used data structures in Click, `Vector`, `HashSet`, `HashMap`, into SMT. (See Appendix A.)

Replace element state with abstract data types. With the SMT encoding of common data types, another technique we could apply is to modify the element implementation by replacing its states with the data types mentioned above. This process requires the developer to inspect how the packet processing code uses a specific element state. If all the accesses performed on the state can be modeled using the interface of a data type with SMT encoding, we could replace the state with the SMT-encoded counterpart and run the symbolic execution on the modified implementation instead.

Consider the `CheckIPAddress` element (Figure 2). This element serves as a source IP packet filter. Before our proposed modifications, `CheckIPAddress` stores a list of bad IP addresses (`bad_src_`). A packet is dropped if the source IP address of the packet is listed in the bad IP address list. In

```
class CheckIPAddress : public Element {
    // omitting constructor and destructor
    Packet *process_packet(Packet *pkt) {
        auto saddr = pkt->ip_header->saddr;
-       for (size_t i = 0; i < num_bad_src_; i++)
-           if (bad_src_[i] == saddr)
+       if (bad_src_.find(saddr) != bad_src_.end())
                return NULL;
        return pkt;
    }
-    IPAddress *bad_src_;
-    size_t num_bad_src_;
+   HashSet<IPAddress> bad_src_;
}
```

Figure 2: Modification of `CheckIPAddress`'s implementation to remove the usage of pointers and loops.

this element, `bad_src_` and `num_bad_src_` together represents a fixed size array containing the bad IP addresses. To check whether the source IP address of a received packet matches any address in the array, `CheckIPAddress` uses a "for" loop to go through this array. `CheckIPAddress` is not suitable for automated verification: (1) The size of the array that `bad_src_` is pointing to is not known by the symbolic executor; thus, it may flag out-of-bound memory access. (2) If the executor tries to unroll the loop, it faces a path explosion problem as the number of iterations in the loop can be large.

To make this element meet the conditions for automated verification, we can modify its implementation, as shown in Figure 2. This change is based on the observation that the way `bad_src_` and `num_bad_src_` are used complies with the `HashSet` interface. The change replaces the pointer-size pair `bad_src_` and `num_bad_src_` with a `HashSet`. Besides that, the "for" loop to check whether the source IP is in the bad IP address list is also replaced with a `find` method call. The code changes remove both the use of pointers and unbounded loops. Since the semantics of `HashSet` and its `find` interface is modeled with SMT, we can symbolically execute the element.

Concretization of control flow structures. Middleboxes perform packet classification based on the value of specific fields in the packet header. Packet classification is implemented using finite-state machines, and it is often optimized by statically compiling the classification rules into a state machine model that is stored in memory. When processing an incoming packet, the classifier performs state transitions using the rules until the state machine reaches one of the end states. If the values of the state transition table are abstract, then the classification process would appear to be unbounded.

We address this issue and enable the symbolic execution of the classification tasks. We load the Click configuration containing concrete classification rules and run the state machine creation code of the classification element. We then ingest the raw bytes representing the transition rules into symbols with concrete values. We use symbolic execution to verify that the

Technique	# Elements	# Conf.
Unmodified	130 (45 %)	9 (16 %)
Code unrolling	138 (48 %)	9 (16 %)
Fix-sized array detection	185 (63 %)	9 (16 %)
SMT-encoded abstract datatype	218 (75 %)	13 (23 %)
Replacing with abstract datatype	222 (77 %)	15 (27 %)
Concretization	226 (78 %)	37 (66 %)

Table 1: Number of Click elements and configuration that can be symbolically executed.

contents of the memory region representing the state transition table remain unchanged during program execution. We then symbolically execute the packet classification code but replace the symbolic transition rules with the concrete values identified in the first step. The executor can thus process the packet classification code within a statically bounded number of steps.

2.4 Overall effectiveness of symbolic execution

We now repeat our analysis of Click elements and configurations after enhancing our symbolic executor with these additional techniques. Table 1 shows the result. Our techniques improve the fraction of elements that can be symbolically executed from 45% to 78%. The fraction of Click configurations that are suitable for automated verification improves from 16% to 66%.

Our symbolic executor cannot handle 22% of the Click elements. Among the 64 unsupported elements, 19 of them could not be symbolically executed because there are loops that traverse the payload of the packets (e.g., `AES` element for encryption). Another 26 elements use customized data structures that contain pointers that can not be modeled with SMT. One such example is `LookupIP6Route` element that uses a match table with longest prefix matching as opposed to a traditional exact match hash table. 11 elements contain loops whose number of iterations is based on the current (symbolic) element state. For example, the `AggregateFilter` element, which aggregates incoming packets according to their header values, has to loop over a queue to determine which aggregation group a packet should belong to. 8 elements have pointer accesses that are deeply coupled with the rest of the code that replacing with abstract data types is not feasible. For example, `IP6NDSolicitor` uses a set of linked lists to handle the response messages of the neighbor discovery protocol.

Three approaches can potentially improve Gravel's ability to verify more Click elements automatically. The first approach is to model more data structures using SMT. Currently, Gravel only supports `HashMap`, `HashSet`, and `Vector`. The second approach is to allow developers to write annotations to rule out part of the implementation that is not relevant to the specification. For example, if the developers only want to prove that the `AES` element does not change the TCP header of the packet, the symbolic executor can skip over the loop that traverses the packet payload. The third approach is to use an interactive theorem prover (e.g., Coq [7], Dafny [24]) to verify the correctness of element-level implementations. These interactive theorem provers can verify higher-order logic than what SMT can verify. For example, more sophisticated data structures such as priority queues or an LRU cache could be more easily verified with the help of an interactive prover.

3 The Gravel Framework

Gravel is a framework for specifying and verifying Click [23]-based software middleboxes. It aims to verify high-level properties, such as a load balancer's connection persistency, against a low-level C++ implementation. Gravel uses symbolic execution to translate the C++ implementation into a symbolic expression automatically, and it uses the techniques described in the previous section to enhance the effectiveness of symbolic execution. In this section, we describe how Gravel allows developers to specify the desired high-level properties using Python code and a domain-specific library containing verification primitives. In Section 4, we describe how we check whether the symbolic expression derived from the implementation provides the desired properties.

3.1 Overview

Figure 3 shows the workflow of Gravel. Gravel expects three inputs from middlebox developers:

1. Click configuration, which is a directed graph of elements.
2. A set of high-level middlebox specifications.
3. Element-level specifications for all Click elements used in the configuration.[3]

[3]Gravel provides specifications for commonly used elements.

Like building a normal Click middlebox, Gravel first takes as input a directed graph of Click elements. In Click, a middlebox is decomposed into smaller packet processing "elements". Each element keeps private state that is accessible only to itself and has a set of handlers for events such as incoming packet or timer events. Elements can also have many input and output ports through which elements can be connected with others and transfer packets. The directed graph from a Click configuration connects Click elements together to form the dataplane for packet processing. The topology of the directed graph remains unchanged during the execution of the middlebox.

Gravel then requires a formalization of the high-level middlebox properties. To check properties automatically with an SMT solver, they need to be expressed using first-order logic. In Gravel, properties are formalized as predicates over a trace of events. Gravel includes a Python library for developers to specify middlebox-specific properties.

Gravel also requires a specification for each Click element. The element-level specification describes each element's private state and packet processing behavior. The element-level specification provides a simplified description of an element's behavior and omits low-level details such as performance optimizations. Gravel again provides a Python library for developers to write element-level specifications.

With these three inputs, Gravel verifies the correctness of the middlebox in two steps. First, Gravel checks whether a Click configuration composed using Click elements satisfies the desired high-level properties of the middlebox. A high-level property is expressed as a symbolic trace of the middlebox's behavior (in Python). Gravel verifies the high-level property by symbolically executing the datagraph of elements using element-level specifications (in Python). Then, Gravel verifies that the low-level C++ implementation of each element has equivalent behavior as the element-level specification. Gravel compiles the low-level C++ implementation into LLVM intermediate representation (LLVM IR) and then symbolically executes the LLVM IR to obtain a symbolic expression of the element. Gravel then checks whether the element-level specification holds in the element's symbolic expression. If there is any bug in the Click configuration or the implementation of the elements, Gravel outputs a counterexample that contains element states and an incoming packet that makes the middlebox violate its specification.

3.2 A Sample Application: ToyLB

The rest of this section describes the Gravel framework in the context of a simple running example corresponding to a Layer-3 load balancer, ToyLB. ToyLB receives packets on its incoming interface and forwards them to a pool of servers in a round-robin fashion. It steers traffic by rewriting the destination IP on the packet. ToyLB resembles popular Layer-3 load balancer designs used by large cloud providers [16, 19].

The ToyLB middlebox is decomposed into five elements, as shown in Figure 4. When there is an incoming packet, it first goes through two header-checking elements, `CheckIPHeader` and `CheckTCPHeader`. These two elements act like filters and discard any packet that is not a TCP packet. Then, the `FlowTable` element checks whether the packet belongs to a TCP flow that has been seen by ToyLB earlier. If so, `FlowTable` rewrites the packet with the corresponding backend server's IP address stored in the FlowTable and sends the packet to the destination server. Otherwise, the `FlowTable` consults a `RoundRobinSwitch` scheduler element to decide which backend server should the new connection bind to. After the `RoundRobinSwitch` decides which backend server to forward the packet to, `RoundRobinSwitch` notifies the `FlowTable` of the decision. The `FlowTable` stores the decision into its internal state and also rewrites the destination address of the packet into the destination server. For further simplicity, low-level functionalities such as ARP lookup are omitted in ToyLB.

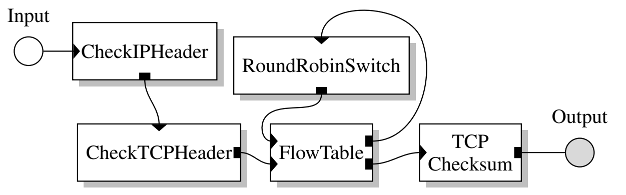

Figure 4: Breakdown of ToyLB's functionalities into packet-processing elements.

We next describe how Gravel can be used to model high-level specifications of middleboxes such as ToyLB and then outline how the element-level properties are specified. Later, in §4, we show how Gravel performs verification.

3.3 High-level Specifications

Gravel models the execution of a middlebox as a state machine. State transitions can occur in response to external events such as incoming packets or passage of time. The time event can be used to implement garbage collection for middlebox states. For each state transition, the middlebox may also send packets out.

Gravel provides a specification programming interface, embedded in Python, for developers to specify high-level properties. Developers can use the interface to describe middlebox behavior over a symbolic event sequence. (See Appendix A.)

Packets in Gravel's high-level specification are expressed using key-value map abstraction, where the keys are the name of header fields and values are the content of the fields. This abstraction makes the specification concise and hides the implementation details that are less related to high-level properties (e.g., the position of IP addresses in the packet header).

Gravel provides three kinds of core interfaces (see Appendix A) in its high-level specification: (1) a set of `sym_*` functions that allow developers to create symbolic representations of different types of states such as IP address, packet, or middlebox state; (2) middlebox's event-handling functions, like handle_packet(state, pkt), handle_time(state, timestamp), that takes as input the current state of the middlebox and the incoming packet/time event, and returns an (optional) output packet and the resulting middlebox state after a state transition; and (3) the verify(formula) function call that first encodes the given logical formula in SMT and invokes the SMT solver to check if formula is always true. Besides that, Gravel also provides some helper functions for developers to encode high-level middlebox properties.

To make this concrete, we next describe how to encode two high-level properties of ToyLB using this specification programming interface. We describe how to encode two load balancer properties: (1) liveness and (2) connection persistence. We first consider the liveness guarantee.

Property 1 (ToyLB liveness)**.** For every TCP packet received, ToyLB always produces an encapsulated packet.

In Gravel, this can be specified as:

```
def toylb_liveness():
    # create symbolic packet and symbolic ToyLB state
    p, s0 = sym_pkt(), sym_state()
    # get the output packet after processing packet p
    o, s1 = handle_packet(s0, p)
    verify(Implies(is_tcp(p), Not(is_none(o))))
```

In this liveness formulation, we first construct a symbolic packet p and the symbolic state of the middlebox s0. Then, we let the middlebox with state s0 process the packet p by invoking the handle_packet function. After that, the state of the middlebox changes to s1, and the output from the middlebox is o. If o is None, the middlebox has not generated an outgoing packet. This high-level specification says that, if the incoming packet is a TCP packet, the middlebox has an outgoing packet.

Note that the formulation of liveness property is abstract, given that it does not say anything about the states of the middlebox. We don't even formulate the set of data structures used by ToyLB. This brevity is indeed the benefit of using high-level specifications. These formulations are concise and are directly related to the desired middlebox properties.

Now, we move to a more complex load balancer property—connection persistency. This property is crucial to a load balancer as it ensures that packets from the same TCP connection are always forwarded to the same backend server.

Property 2 (ToyLB persistency)**.** If ToyLB forwards a TCP packet to a backend b at time t, subsequent packets of the same TCP connection received by ToyLB before time $t + WINDOW$, where $WINDOW$ is a pre-defined constant, will also be forwarded to b.

Formulation of Property 2 is more complex than the liveness property because it requires a forwarding requirement (i.e., the forwarding of packets of a certain TCP connection to b) to hold over all possible event sequences between time t and time $t + WINDOW$. This complexity means that we cannot formulate connection persistency with traces containing only a single event, but rather, we need to use induction to verify that the property holds on event traces of unbounded length.

Gravel allows us to specify Property 2 as an inductive invariant. First, we formulate the forwarding condition that should be held during the time window. The steer_to function defined below determines whether a packet received at time t will be forwarded to the backend server with address dst_ip. The code snippet first lets the middlebox handle a time event with timestamp t, followed by the handling of pkt. We ascertain whether the packet is forwarded to dst_ip by checking that the output from the packet processing is not None and that the resulting packet's destination address is dst_ip.

```
def steer_to(state, pkt, dst_ip, t):
    o0, s_n = handle_time(state, t)
    o1, s_n2 = handle_packet(s_n, pkt)
    return And(Not(is_none(o1)),
               o1.ip4.dst == dst_ip,
               payload_eq(o1, pkt))
```

Then, for the base case of induction, we specify that once ToyLB forwards a packet of a particular TCP connection to a backend, subsequent packets from the same connection received within a period *WINDOW* will be forwarded to the same backend. Similar to the formulation of the liveness property, the following code snippet first creates two symbolic packets and a symbolic middlebox state, then invokes handle_packet to obtain the output packet as well as the new state after packet processing. After that, the code requires the verifier to prove that if p0 is forwarded to dst_ip, then a packet, p1, in the same connection received any time before the expiration time ddl is also forwarded to dst_ip, assuming that the middlebox state hasn't changed from state s1.

```
def base_case():
    p0, p1, s0 = sym_pkt(), sym_pkt(), sym_state()
    o, s1 = handle_packet(s0, p0)
    dst_ip, t0 = sym_ip(), s0.curr_time()
    t = sym_time()
    ddl = t0 + WINDOW
    verify(Implies(And(Not(is_none(o)),
                       o.ip4.dst == dst_ip,
                       from_same_flow(p0, p1)),
              ForAll([t], Implies(t <= ddl,
                      steer_to(s1, p1, dst_ip, t)))))
```

In addition to the base case invariant, the specification includes two inductive cases showing that processing an additional event (e.g., a packet from a different connection or time event) does not change the forwarding behavior. The two inductive cases specify that the invariant steer_to(...) holds on the middlebox states when processing packets or time events if the timestamp is before the expiration time.

```
def step_packet():
    dst_ip, p0, p1 = sym_ip(), sym_pkt(), sym_pkt()
    s0, t0, p_other = sym_state(), sym_time(), sym_pkt()
    o, s1 = handle_packet(s0, p_other)
    verify(Implies(And(steer_to(s0, p0, dst_ip, t0),
                       from_same_flow(p0, p1)),
                   steer_to(s1, p1, dst_ip, t0)))
```

```
def step_time():
    dst_ip, p0, p1 = sym_ip(), sym_pkt(), sym_pkt()
    s0, t0, t1 = sym_state(), sym_time(), sym_time()
    _, s1 = handle_time(s0, t1)
    verify(Implies(And(steer_to(s0, p0, dst_ip, t0),
                       t1 < t0, from_same_flow(p0, p1)),
                   steer_to(s1, p1, dst_ip, t0)))
```

3.4 Element-level Specifications

Verifying high-level specifications directly from low-level C++ implementations is hard because of the gap in their semantics. Similar to all the seminal work [20, 30, 34] in software verification, we break down the verification process using refinement. Gravel requires the developer to give specifications of each element. As long as the element-level specifications capture the behavior of their corresponding elements' implementation, we can simply use the element-level specifications to prove the high-level specifications. Compared to deductive verification, this incurs a lower verification effort because element-level specifications are short (§5). Element-level specifications can be reused across different middleboxes. The element-level specification in Gravel consists of two parts: the definition of abstract states that will be used by the element during execution, and a set of event handling behaviors in response to incoming packets and time events.

Element states. Specification of a Gravel element starts with a declaration of the state associated with the element. To ensure efficient encoding with SMT, Gravel requires the state to be bounded. More specifically, elements' state in Gravel may contain: (1) fixed-size variables including bit vectors; (2) maps from one finite set to another (e.g., a map from IP address space to 64-bit integer). For example, in ToyLB, the state of FlowTable is defined as:

```
class FlowTable(Element):
    num_in_ports = 2
    num_out_ports = 2

    decisions = Map([AddrT, PortT, AddrT, PortT], AddrT)
    timestamps = Map([AddrT, PortT, AddrT, PortT], TimeT)
    curr_time = TimeT
    ...
```

This part of element-level specifications defines three components of FlowTable's state:

- decisions maps from a TCP connection to a backend server address. FlowTable identifies a TCP connection by the tuple of source and destination addresses and port numbers. This map is used to store the results from the Selector element.
- timestamps stores the latest times at which packets were received for each TCP flow stored in decision.
- curr_time stores the current time.

Here the types such as AddrT and TimeT are pre-defined integers of different bit widths. Besides the state, the code also informs Gravel as to how many input/output ports the FlowTable element has through num_in_ports/num_out_ports.

```
def flowtable_process_packet(s, p, in_port):
    flow = p.ip4.saddr, p.tcp.sport, \
           p.ip4.daddr, p.tcp.dport
    # the case when flowtable has record of the flow
    known_flow = And(
        # packet is received from the network
        in_port == IN_TCP_FILTER,
        # flowtable has record of the flow
        flow in s.decisions)
    # construct the encapsulated packet
    fwd_pkt = p.copy()
    fwd_pkt.ip4.dst = s.decisions[flow]
    # update the timestamp of the flow with current time
    after_fwd = s.copy()
    after_fwd.timestamps[flow] = s.curr_time
    known_flow_action =
        Action(known_flow,
               {PORT_TO_EXT: fwd_pkt}, after_fwd)
```

Figure 5: Example of an element-level action.

Event handlers. Gravel requires each element to have a handler function for packets received from its input ports. This packet handler needs to be specified in the element-level specification. The specification of the packet handler describes the operations the element performs when handling packets. Besides that, an optional time event handler can also be specified. In Gravel, the two event handlers are defined as functions with the following signatures:

```
flowtable_process_packet(state, pkt, in_port) → actions
flowtable_process_time(state, timestamp) → actions
```

The return value of each event handler (actions) is a list of *condition-action pairs*. Each entry in the list describes the action an element should take under certain conditions. In the python code, developers can write:

```
Action(cond, { port_i : pkt_i }, new_state)
```

to denote an action that sends pkt_i to output port port_i while also updating the element state to new_state. This action will be taken when condition cond holds. To make it concrete, let us consider the packet handler of FlowTable. Upon receiving a packet, FlowTable does one of the followings:

- If the packet is from the CheckTCPHeader element, and the decisions map contains a record for the connection, FlowTable rewrites the destination address and sends the packet to TCP Checksum element, as shown in Figure 5.
- If the FlowTable does not have a record for a packet, the packet is sent to RoundRobinSwitch element.
- If the packet is sent from RoundRobinSwitch, FlowTable records the destination decided by RoundRobinSwitch and forwards the packet to TCP Checksum.

Similarly, FlowTable's behavior in response to time changes is also specified as *condition-actions*:

```
def flowtable_process_time(self, s, time):
    new = s.copy()
    # update the "curr_time" state
    new.curr_time = time
    # records with older timestamps should expire
    def should_expire(k, v):
        return And(s.timestamps.has_key(k),
                   time >= WINDOW + s.timestamps[k])

    new.decisions = new.decisions.filter(should_expire)
    new.timestamps = new.timestamps.filter(should_expire)
    return Action(True, {}, new)
```

When `FlowTable` is notified of a time change, it updates its `curr_time` to the given time value. Gravel offers a `filter` interface for its map object, which takes a predicate, `should_expire`, and deletes all the entries that satisfy the predicate. `FlowTable` uses this to remove all the records that were inactive for a period longer than a constant `WINDOW` value. ToyLB's complete element-level specifications are in Appendix B.

Summary: Overall, we presented an example of (1) how to specify high-level trace-based middlebox properties, and (2) how to write element-level specifications to make verification modular. We provide a framework for developers to articulate complex trace-based properties. These high-level properties are implementation-independent. Element-level specifications decouple verification problem into two orthogonal problems: that element-level specifications conform to the high-level properties and that elements' implementations comply with their element-level specifications.

4 Verifier Implementation

Gravel proves the middlebox properties with two theorems:

THEOREM 1 (Graph Composition). *The element-level specifications, when composed using the given Click configuration, complies with the high-level specification of the middlebox.*

THEOREM 2 (Element Refinement). *The C++ implementation of Click is a refinement of that element's specification. That is, every possible state transition and packet processing action of the C++ implementation must have an equivalent counterpart in the element-level specification.*

Theorem 1 verifies that the composition of element-level specifications meets the requirement in the high-level specifications. Theorem 2 verifies that Click's C++ implementation of each element meets its element-level specification.

4.1 Graph Composition

Gravel verifies the Graph Composition theorem (Theorem 1) in two steps. First, Gravel symbolically executes the event sequence specified in high-level specifications. Second, Gravel checks whether the high-level specifications hold on the resulting state and outgoing packets from symbolic execution.

Gravel performs symbolic execution on the directed graph. Before the symbolic execution, Gravel creates a symbolic state of the entire middlebox, which is a composition of the symbolic states of all elements in the middlebox. Remember that the high-level specification describes required middlebox behavior on an event sequence. The goal of the symbolic execution is to reproduce the sequence symbolically. For example, if the high-level specification contains an incoming packet, Gravel generates a symbolic packet at the source element of the directed graph. This symbolic packet, when processed by the first element of the graph, can trigger handlers of other downstream elements, which are symbolically executed as well. If the element-level specification contains a branch (e.g., depending on the packet header, a packet can be forward to one of the two downstream elements), Gravel performs symbolic execution in a breadth-first search manner.

After performing symbolic execution for each event type, Gravel records the updated state of each element as well as the packet produced by each output element. Gravel provides this information as the return value of the `handle_*` functions in the high-level specification. Gravel then invokes the functions defined in the high-level specification. Once the `verify` function is invoked, Gravel encodes the high-level specifications into SMT form and uses a solver to see if they always hold.

Loops in the graph. Gravel allows the directed graph of elements to contain loops in order to support bi-directional communications between elements, such as `FlowTable` and `RoundRobinSwitch` in ToyLB (§3). However, loops may introduce non-halting execution when we symbolically execute the datagraph. Gravel addresses this issue by setting a limit on the number of elements traversed by the symbolic executor. When the symbolic execution hits this limit, Gravel raises an alert and fails the verification. For example, in ToyLB, the `FlowTable` is hit at most twice: when `FlowTable` cannot find a record for a certain packet, the packet is sent to `RoundRobinSwitch`, which will later send the packet back to `FlowTable`; upon receiving packets from `RoundRobinSwitch`, `FlowTable` records the selected backend server into its own records and does not send the packet back to `RoundRobinSwitch`. Thus, the maximum number of elements traversed during the symbolic execution is 6, and developers can safely set 6 as the limit for ToyLB.

The graph composition verifier is implemented with 1981 lines of Python. It exposes a similar set of interfaces as Click configuration language so that developers could port existing code into the verifier. The verifier uses the Python binding of Z3 to generate symbolic packets and element states.

4.2 Element Refinement

Gravel verifies the Element Refinement theorem (Theorem 2) in two steps. First, a symbolic expression of the element is generated for each event handler's compiled LLVM intermediate representation. Second, Gravel checks if the element's specification holds on the symbolic expression.

Before performing the symbolic execution, Gravel first uses the LLVM library to extract the memory layout of the C++ class of the element, along with the types of each of its member variables. The verifier can later use this information to determine which field is accessed when it encounters memory access in LLVM bytecode. As mentioned in §2.3, to bound the symbolic execution step and state size, abstract data structures are executed by using their abstract SMT model instead of actual code. A complete list of the data structures and interfaces replaced is given in Appendix A.

For packet content access and modification, Gravel's symbolic executor is compatible with Click's `Packet` interface. In the LLVM bytecode, packet content accesses are compiled into memory operations over a memory buffer. To establish the relation between packet header fields and memory offsets, Gravel needs to extract the symbolic header field value for each output packet after the symbolic execution. Gravel first computes offsets for each header field. Note that these offsets are also symbolic values as they depend on the content of other packet fields. After that, Gravel extracts the value of each header field from the memory buffer of the packet. Each extracted value is then encoded into an SMT formula and compared against fields from the abstract packet using an SMT solver. Gravel concludes that the packet and the memory buffer are equivalent when values of all fields are equivalent.

At the end of symbolic execution, the verifier gets a list of ending states, along with the packets sent out at each output port and the path conditions under which it can be reached. For each entry in the list, Gravel uses Z3 to find an equivalent counterpart in the element specification. If such a counterpart exists for all entries, the refinement of the element is proved.

Gravel's element refinement verifier is implemented in C++ using the LLVM library. The verifier invokes LLVM library's IR parser and reader to load and symbolically execute the compiled LLVM bytecode of each Click element. Besides the SMT encoding of all LLVM instructions used in the compiled Click elements, the verifier also has the SMT encoding of the abstract data types as described in §2. The refinement verifier and the symbolic executor consists of 10396 lines of C++.

4.3 Trusted Computing Base

The trusted computing base (TCB) of Gravel includes the verifier (used for proving Theorem 1 and Theorem 2), the high-level specifications, the tools it depends on (i.e., the Python interpreter, the LLVM compiler framework, and the Z3 solver), and Click runtime. Note that the specification of each element is not trusted.

5 Evaluation

This section aims to answer the following questions:

- How much effort is needed to port existing Click applications? Can Gravel scale to verify the Click applications?
- Can Gravel's verification framework prevent bugs?
- How much run-time overhead does the code modification introduce to middleboxes in order for them to be automatically verifiable by Gravel?

5.1 Case Studies

To evaluate whether Gravel can work for existing Click applications, we port five Click applications to Gravel. For each application, we choose a set of high-level middlebox-specific properties either by formalizing them directly or extracting them from existing RFCs. We use Gravel to verify that these properties hold. Gravel also verifies the low-level properties, such as memory safety and bounded execution.

		LOC	Verif. Time (s)	LOC changed
MazuNAT	Impl	1687	–	133
	Spec (element)	443	64.60	–

Switch	Impl	594	–	0
	Spec (element)	131	27.73	–
	Spec (high-level)	91	1.61	–

Table 2: Development effort and verification time of using Gravel on five Click-based middleboxes.

MazuNAT: MazuNAT is a NAT that has been used by Mazu Networks. MazuNAT consists of 33 Click elements. (See Appendix C.) MazuNAT forwards traffic between two network address spaces, the internal network, and the external network. It mainly performs two types of packet rewriting:

1. For a packet whose destination address is the NAT, the NAT rewrites its destination IP address and port with the corresponding endpoint in the internal network.
2. For a packet going from the internal to the external network, NAT assigns an externally visible source IP address and port to the connection. The NAT also needs to keep track of assigned addresses and ports to guarantee persistent address rewriting for packets in the same connection.

One common property we verified for all five middleboxes is that the middlebox does not change the packets' payload:

PROPERTY 3 (Payload Preservation)**.** For any packet that is processed by the middlebox, the middlebox never modifies the payload of the packet.

For NAT-specific properties, we verified that MazuNAT meets the requirements proposed in RFC5382 [29].[4] These requirements are proposed to make NATs transparent to applications running behind them [17].

PROPERTY 4 (Endpoint-Independent Mapping)**.** For packets p_1 and p_2 from the same internal IP, port $(X : x)$, where

[4]We omit the set of requirements related to ICMP becuase MazuNAT does not support ICMP.

- p_1 targets external endpoint $(Y_1 : y_1)$ and gets its source address and port translated to $(X'_1 : x'_1)$
- p_2 targets external endpoint $(Y_2 : y_2)$ and gets its source address and port translated to $(X'_2 : x'_2)$

the NAT should guarantee that $(X'_1 : x'_1) = (X'_2 : x'_2)$.

PROPERTY 5 (Endpoint-Independent Filtering)**.** Consider external endpoints $(Y_1 : y_1)$ and $(Y_2 : y_2)$. If the NAT allows connections from $(Y_1 : y_1)$, then it should also allow connections from $(Y_2 : y_2)$ to pass through.

PROPERTY 6 (Hairpinning)**.** If the NAT currently maps internal address and port $(X_1 : x_1)$ to $(X'_1 : x'_1)$, a packet p originated from the internal network whose destination is $(X'_1 : x'_1)$ should be forwarded to the internal endpoint $(X_1 : x_1)$. Furthermore, the NAT also needs to create an address mapping for p's source address and rewrite its source address accordingly.

These properties are essential to ensure the transparency of the NAT and are required for TCP hole punching in peer-to-peer communications.

We also prove that the MazuNAT preserves the address mapping for a constant amount of time:

PROPERTY 7 (Connection Memorization)**.** If at time t, the NAT forwards a packet from a certain connection c, then for all states s' reachable before time $t + THRESHOLD$, where *THRESHOLD* is a predefined constant value, packets in c are still forwarded to the same destination.

Property 7 guarantees that the NAT can translate the address of all packets from a TCP connection consistently. The constant *THRESHOLD* defines a time window where the TCP connection should be memorized by the NAT. The NAT has the freedom to recycle the resources used for storing connection information after the time window expires.

Load Balancer: Besides the round-robin load balancer mentioned in §3, we also verified a load balancer using Maglev's hashing algorithm [16]. Its element graph looks exactly the same as in Figure 4. The only difference is that the `RoundRobinSwitch` element is replaced by a hashing element that uses consistent hashing. The load balancer steers packets by rewriting the destination IP address.

We verified connection persistency for both of the load balancers. The goal of connection persistency is to make load-balancing transparent to the clients.

PROPERTY 8 (Load Balance Persistence)**.** For all packets p_1 and p_2 from connection c, if the load balancer steers p_1 to a backend server, then the load balancer steers p_2 to the same backend server before c is closed.

Stateful Firewall: The stateful firewall is adapted from the firewall example in the Click paper [23]. Besides performing static traffic filtering, it also keeps track of connection states between the internal network and the external network. The firewall updates connection states when processing TCP control packets (e.g., *SYN*, *RST*, and *FIN* packets), and removes records for connections that are finished or disconnected.

We prove that the stateful firewall can prevent packets from unsolicited connections [28]. Also, the firewall should garbage collect finished connections.

PROPERTY 9 (Firewall Blocks Unsolicited Connection)**.** For any connection c, no packet in c from the external network is allowed until a *SYN* packet has been sent out for c.

PROPERTY 10 (Firewall Garbage-collects Records)**.** For any connection c, no packet in c from the external network is allowed after the firewall sees a *FIN* or *RST* packet for c.

Web Proxy: The Web proxy transparently forwards all web requests to a dedicated proxy server. When the middlebox receives a packet, it first identifies if it is a web request by checking the TCP destination port. For web request packets, the proxy rewrites the packet header to redirect them to the proxy server. The proxy also memorizes the sender of the web request to forward the reply messages back to the sender.

We prove that the web proxy middlebox forwards packets in both directions.

PROPERTY 11 (Web Proxy Bi-directional)**.** For a web request packet p with 5-tuple `(SA,SP,DA,DP,PROTO)`, if the middlebox forwards p to the proxy server and rewrites the 5-tuple to `(SA',SP',DA',DP',PROTO)`, then a packet from the reply flow with 5-tuple `(DA',DP',SA',SP',PROTO)` should be forwarded back to the sender.

Learning Switch: The Learning switch implements the basic functionality of forwarding Ethernet frames and MAC learning. The switch learns how to send to an Ethernet address A by watching which interface packets with source Ethernet address A arrives. If the switch has not learned how to send to an Ethernet address, it broadcasts the packet to all its interfaces.

We prove the following properties about the switch.

PROPERTY 12 (Forwarding Non-interference)**.** For any Ethernet address A, the behavior of how the switch forwards packets targeting A is not be affected by packets whose source Ethernet address is not A.

PROPERTY 13 (Broadcasting until Learnt)**.** For any address A, if the switch broadcasts packets targeting A, it keeps broadcasting until a packet from A is received by the switch.

5.2 Verification Cost

To understand the cost of middlebox verification on Gravel, we evaluate the amount of development effort and the verification time. Table 2 shows the result.

Development effort. We find that porting existing Click applications to Gravel requires little effort and that writing specifications with Gravel are also easy. We only modified 133 lines of code in MazuNAT to make it compatible with Gravel. The firewall and load balancer required only 63 lines

Middlebox	Bug ID	Description	Can be prevented?	Why/Why not?
Load Balancer	bug #12	Packet corruption	✓	high-level specification
	bug #11	Counter value underflow	✓	element refinement
	bug #10	Hash function not balanced	✗	not formalized in specification
	bug #6	throughput not balanced	✗	not formalized in specification
Firewall	bug #822	Counter value underflow	✓	element refinement
	bug #691	segfault by uninitialized pointer	✓	element refinement
	bug #1085	Malformed configuration leading crash	✗	Gravel assumes correct init
NAT	bug #658	Invalid packet can bypass NAT	✓	element refinement
	bug #227	Stale entries may not expire	✓	high-level specification
	bug #148	Infinite loop	✓	element refinement

Table 3: Bugs from real-world software middleboxes.

of code modifications. Our proxy required 50 lines of code to be changed, and the switch requires no modification. Most of the required code changes come from the `IPRewriter` element. We had to remove the priority queue that is used for flow expiration and instead use a linear scan to expire old mappings. Other code changes include removing pointers to other elements in `FTPPortMapper`, replacing `ARPTable` in `ARPQuerier` with hashmaps, and the change of `CheckIPHeader` mentioned in §2. The specifications are concise. The high-level specification is below 200 lines of code and the element-level specifications are less than 450 lines of code for all five middleboxes. The associated developer effort is also small. For the web proxy and learning switch, it took less than one person-day for both the high-level properties and the element specifications. The load balancer and the stateful firewall each required a full day's effort in order to port them to Gravel and verify their correctness. The most complicated middlebox in our case study, MazuNAT, took about 5 person-days to port and specify. Five elements (`Classifier`, `IPClassifier`, `IPRewriter`, `CheckIPHeader`, and `EtherEncap`) are reused across these middleboxes, and thus we reuse their element-level specifications.

Verification time. With Gravel's two-step verification process, Gravel's verifier can efficiently prove that the middlebox applications provide the desired properties. Most of the verification time is spent on proving the equivalence of the C++ implementation of each element and its element-level specification. Verification of the high-level specifications from the element-level specifications took less than 4 seconds for the different applications. Overall, even for MazuNAT, the overall verification time is just over a minute.

5.3 Bug prevention

When verifying MazuNAT with Gravel, we found that the original MazuNAT implementation did not possess the endpoint independent mapping property (Property 4). MazuNAT uses a 5-tuple as the key to memorize rewritten flows. This means that when MazuNAT forwards a packet coming from the external network, the packet's source IP address and source port affects the forwarding behavior, violating Property 4. To fix this, we changed the `IPRewriter` element to use only a part of the 5-tuple when memorizing flows.

To evaluate the effectiveness of Gravel at a broader scope, we manually analyze bugs from several open-source middlebox implementations. We wanted to understand whether these bugs can happen if the middlebox is built using Gravel. We examine bug trackers of software middleboxes with similar functionalities as those in our case studies (i.e., NAT, load balancer, firewall) and search the CVE list for related vulnerabilities. We inspect bug reports from the NAT and firewall of the netfilter project [31], and the Balance load balancer [3]. Since the netfilter project contains components other than the NAT and the firewall, we use the bug tracker's search functionality to find bugs relevant only to its NAT and firewall components. We inspect the most recent 10 bugs for all three kinds of middleboxes and list the result in Table 3.

Of the 30 bugs we inspected, we exclude 10 bugs for features that are not supported in our middlebox implementations, 3 bugs related to documentation issues, 5 bugs on command-line interface, and 2 bugs on performance.

From the remaining 10 bugs, Gravel's verifier is able to catch 7 of them. Among these bugs, *Bug #12* in the load balancer and *bug #227* in the NAT can be captured by the verification of the high-level specification as they lead to the violation of Property 3 and Property 7 respectively. Other bugs involving integer underflow or invalid memory access can be captured by the C verifier. Note that there are still three bugs Gravel cannot capture, such as incorrect initialization of the system and properties that are not in our high-level specifications (e.g., unbalanced hashing).

5.4 Run-time Performance

To examine the run-time overhead introduced by the code modifications we made, we compare the performance of the middleboxes before and after the code modifications. We run these Click middleboxes on DPDK [13].

Our testbed consists of two machines each with Intel Xeon E5-2680 (12 physical cores, 2.5 GHz), running Linux (v4.4) and has a 40 Gbps Mellanox ConnectX-3 NIC. The two machines are directly connected via a 40 Gbps link. We run the

		Throughput (Gbps)	Latency (μs)
NAT	Unverified	37.39 ($\pm$ 0.03)	14.43 ($\pm$ 0.19)
	Gravel	37.41 ($\pm$ 0.04)	15.14 ($\pm$ 0.22)
LB	Unverified	37.38 ($\pm$ 0.04)	14.82 ($\pm$ 0.23)
	Gravel	37.37 ($\pm$ 0.04)	14.86 ($\pm$ 0.20)
Firewall	Unverified	37.37 ($\pm$ 0.05)	15.21 ($\pm$ 0.20)
	Gravel	37.38 ($\pm$ 0.04)	15.11 ($\pm$ 0.24)
Proxy	Unverified	37.36 ($\pm$ 0.05)	14.54 ($\pm$ 0.19)
	Gravel	37.35 ($\pm$ 0.06)	14.35 ($\pm$ 0.18)
Switch	Unverified	37.36 ($\pm$ 0.05)	15.02 ($\pm$ 0.19)
	Gravel	37.39 ($\pm$ 0.07)	14.96 ($\pm$ 0.29)

Table 4: Performance of verified middleboxes, compared to their unmodified counterparts.

middlebox application with DPDK on one machine and use the other machine as both the client and the server.

The code modification to make these Click applications compatible with Gravel has minimal run-time overhead. We measure the throughput of 5 concurrent TCP connections using *iperf*, and use *NPtcp* for measuring latency (round trip time of a 200-byte TCP message). Table 4 shows the results. The code modifications introduce negligible overheads in terms of throughput and latency.

6 Related Work

Middlebox verification. Verifying the correctness of middleboxes is not a new idea. Software dataplane verification [14] uses symbolic execution to catch low-level programming errors in existing Click elements [23]. Our work is also based on Click, but we target high-level middlebox-specific properties, such as load balancer's connection persistency. In addition, we show that 78% of existing Click elements are amenable for automated verification with slight code modifications. VigNAT [40] proves a NAT with a low-level pseudocode specification. Vigor [39] generalizes VigNAT to a broader class of middleboxes and verifies the underlying OS network stack and the packet-processing framework. We believe it is non-trivial to extend VigNAT and Vigor to specify and verify the set of high-level trace-based NAT properties (e.g., hairpinning, endpoint-independence) Gravel can verify.

We note though that specifying the correctness of programs is a fundamentally hard problem. Gravel chooses to let developers specify high-level specifications on a symbolic trace of packets. We find specifications using Gravel's specification interface to be more abstract than psuedo-code like NAT specification in VigNAT [40]. However, even with Gravel, writing specifications is still hard. For example, specifying the connection persistency property for ToyLB requires the usage of induction (§3.3). Empirically, we find that a trace-based specification is flexible enough to express the correctness of middleboxes in the RFCs we examined.

Network verification. In the broader scope of network verification, most existing work [1, 2, 4, 15, 21, 22, 26, 27, 33, 37] targets verifying network-wide objectives (e.g., no routing loop) assuming an abstract network operation model. Gravel, along with other middlebox verification work [14, 39, 40], aims to verify the low-level C++ implementation of a single middlebox's implementation. As switches become programmable [5], researchers have built tools to debug [36], verify [18, 25] P4 programs. Similar to Gravel, this line of work relies heavily on symbolic execution. Our work targets "almost unmodified" middleboxes written in C++.

Currently, Gravel only supports verification of middleboxes implemented with Click. However, since our key observation on Click middleboxes, that the number of operations performed processing each packet is finite and small, may also hold on non-Click middleboxes, we believe that Gravel's verification techniques can also be applied on other middleboxes. For example, the eXpress Data Path (XDP) in the Linux kernel also constrains the packet processing code to be loop-free. It also only allows a limited set of data structures for maintaining global states. These properties make it seem plausible that one could apply Gravel's verification techniques to it.

SMT-based automated verification. Automated software verification using symbolic execution has recently become popular. This technique has been used to successfully verify file systems [34], operating systems [30], and information flow control systems [35]. However, this technique usually requires a complete re-implementation of the target application because of the restricted programming model. We conduct a systematic study on (§2) whether unmodified Click-based software middleboxes can be automatically verified.

7 Conclusion

Verifying middlebox implementations has long been an attractive approach to obtain network reliability. We explore the feasibility of verifying "almost unmodified" software middleboxes. Our empirical study on existing Click-based middleboxes shows that existing Click-based middleboxes, with small modifications, are suitable for automated verification using symbolic execution. Based on this, we have designed and implemented a software middlebox verification framework, Gravel. Gravel allows verifying high-level trace-based middlebox properties of "almost unmodified" Click applications. We ported five Click applications to Gravel. Our evaluation shows that Gravel can avoid bugs found in existing middleboxes with small proof effort. Our evaluation also shows that the modifications required for automated verification incur negligible performance overheads. Gravel's source code is available at https://github.com/Kaiyuan-Zhang/Gravel-public.

A Gravel Programming Interface

A.1 High-level Specification Interface

Table 5 gives a list of the interfaces Gravel offers to the developers. The core interfaces of Gravel includes:

- Functions that generates symbolic value (bitvectors) of different sizes (the `sym_*` API).
- Functions that performs graph composition and returns the result of packet or event processing (`handle_*`)
- The `verify` function which informs Gravel's verifier the verification task to perform.

Besides the core interfaces, Gravel also provides a set of helper functions to ease the formalization effort. These functions include functions that access header fields and functions that checks whether two packets are from the same TCP flow. Table 5 also lists some examples of helper functions.

A.2 Modeling Abstract Data Structure

As discussed in §4, Gravel masks the actual C++ implementation of several data structures and replace them with an SMT encoding during the symbolic execution in order to generate SMT expressions that could be efficiently reasoned about by SMT solvers. Table 6 lists all the interfaces that Gravel's symbolic executor masks during the verification process. This section gives more details on how Gravel generates SMT encoding for these data structure interfaces in a way that the resulting formular can be effciently solved.

Unlike bounded data such as the content of a network packet or an integer field in element state, which can be encoded as a symbolic byte sequence using the bitvector theory of SMT, these data structures have a large state space. This means that encoding them with bitvectors does not results in practically solvable expression. For example, the state of a `HashMap<IPAddress, IPAddress>` could grow up to $2^{64}-1$ bytes. This sheer size makes it infeasible to be encoded using bitvectors.

Gravel's symbolic executor choose to use a different approach and represents data structures as a set of uninterpreted functions. In the aforementioned `HashMap` example, Gravel represents the map as two functions:

$$f_{contain} : \{0,1\}^{32} \mapsto \{\perp, \top\}$$
$$f_{value} : \{0,1\}^{32} \mapsto \{0,1\}^{32}$$

$f_{contain}$ maps from the key space $\{0,1\}^{32}$ to boolean space and represents whether certain key is present in the `HashMap`. Similarly, f_{value} represents the mapping between hashmap keys and the corresponding values.

Each of the data structure interfaces is also modeled by Gravel as operations performed on uninterpreted functions. For the `find(K k)` interface of `HashMap`, Gravel first gets the symbolic value representing whether the key is in the map

Function name	Description
`Core Interfaces:`	
`sym_*()` $\rightarrow$ `SymValT`	Create a symbolic value of corresponding type
`handle_packet(s, pkt, in_port)` $\rightarrow$ `o1, ⋯, on, ns`	Handle the packet and returns the outputs and new state
`handle_time(s, timestamp)` $\rightarrow$ `o1, ⋯, on, ns`	Handle time event, return value is same as `handle_packet`
`verify(formula)`	Encode given formula and verify that a formula always holds
`Helper Functions:`	
`is_none(output)` $\rightarrow$ `Bool`	Check if an output is `None`
`payload_eq(p1, p2)` $\rightarrow$ `Bool`	Determine if two packets have the same payload
`from_same_flow(p1, p2)` $\rightarrow$ `Bool`	Determine if two packets are from the same TCP connection
`is_tcp(pkt)` $\rightarrow$ `Bool`	Check if a packet is TCP packet

Table 5: Gravel's specification programming interface.

by computing $f_{contain}(k)$. Based on the result, Gravel takes different actions:

$$\text{If } f_{contain}(k) = \top, \texttt{find(k)} = f_{value}(k)$$
$$\text{If } f_{contain}(k) = \bot, \texttt{find(k)} = \bot$$

In the actual implementation, $\bot$ is represented as `HashMap::end()`.

The `intert(K k, V v)` interface performs update on the content of the `HashMap`. In Gravel, this is modeled as creating a new set of uninterpreted functions, $f'_{contain}$ and f'_{value} such that:

$$\begin{aligned}&\forall k' \in \{0,1\}^{32} \cdot \\ &\quad f'_{contain}(k') = (f_{contain}(k') \vee (k = k')) \\ &\wedge (k \neq k') \Rightarrow f'_{value}(k') = f_{value}(k') \\ &\wedge f'_{value}(k) = v\end{aligned}$$

Similarly, `erase(K k)` replaces $f_{contain}$ with a new function $f'_{contain}$ such that:

$$\forall k' \in \{0,1\}^{32} \cdot f'_{contain}(k') = f_{contain}(k') \wedge (k \neq k')$$

Besides modeling interfaces from existing Click code base, Gravel also adds a set of iteration interfaces that corresponds to commonly used data structure traverse paradigms. These interfaces could be used to abstract away loops in the Click implementation and making more elements feasible for automated verification.

Gravel currently provides two interfaces for `HashMap`, `map` and `filter`. for `map` interface, Gravel takes as parameter a function g and replace f_{value} with a function f'_{value} where:

$$\forall k \in \{0,1\}^{32} \cdot f'_{value}(k) = g(k, f_{value})$$

Similarly, `filter` takes a predicate p and create a function $f'_{contain}$ such that:

$$\forall k \in \{0,1\}^{32} \cdot f'_{contain}(k) = p(k, f_{value})$$

The modeling of interfaces of `Vector` and `HashSet` are similar to the modeling of `HashMap` mentioned above. The main difference are that `HashSet` only uses $f_{contain}$ function, where as `Vector` uses a symbolic integer to denote the size of the vector and does not have a $f_{contain}$ function.

B ToyLB's Element-level Specification

This section gives a detailed description of the element-level specification of ToyLB. As mentioned in §3, element-level specification in Gravel is given as a list of "condition-action" pairs. In Gravel, developers write python functions that generates the list of possible actions for an element. For example, The `CheckIPHeader` element only forwards packets that are both IP packets and are not from a known "bad" address:

```
def checkipheader_process_packet(s, p, in_port):
    is_bad_src = p.ip.src in s.bad_src
    return [Action(And(p.ether.ether_type == 0x0800,
                       Not(is_bad_src)),
                   {0: p},
                   s)]
```

Remember that the `Action` is used to create a *condition-action* entry, which denotes an action that the element takes under certain condition (§3).

Similarly, `CheckTCPHeader` filters all packets that are not TCP packets.

```
def checktcpheader_process_packet(s, p, in_port):
    return [Action(p.ip.proto == 6,
                   {0: p},
                   s)]
```

`RoundRobinSwitch` not only performs address rewriting for incoming packets, it also updates packet header fields and its own state:

```
def roundrobinswitch_process_packet(s, p, in_port):
    ns, np = s.copy(), p.copy()
    dst_ip = s.addr_map[s.cnt]
    ns.cnt = (s.cnt + 1) % s.num_backend
    np.ip4.dst = dst_ip
    return [Action(True, {0: np}, ns)]
```

The FlowTable element have a more complex specification as it takes one of three actions based on both the content of the incoming packet and its own state:

```
def flowtable_process_packet(s, p, in_port):
    flow = p.ip4.saddr, p.tcp.sport, \
           p.ip4.daddr, p.tcp.dport
    # the case when flowtable has record of the flow
    known_flow = And(
        # packet is received from the network
        in_port == IN_TCP_FILTER,
        # flowtable has record of the flow
        flow in s.decisions)
    # construct the encapsulated packet
    fwd_pkt = p.copy()
    fwd_pkt.ip4.dst = s.decisions[flow]
    # update the timestamp of the flow with current time
    after_fwd = s.copy()
    after_fwd.timestamps[flow] = s.curr_time

    known_flow_action =
        Action(known_flow,
               {PORT_TO_EXT: fwd_pkt}, after_fwd)

    # the case when flowtable does not know the flow
    consult_sched = And(
        in_port == INPORT_NET,
        Not(flow in s.decisions))
    unknown_flow_action =
        Action(consult_sched, {PORT_TO_SCHED: p}, s)

    # packet from the Scheduler
    register_new_flow = in_port == IN_SCHED
    # extract the new_flow
    new_flow = p.inner_ip.saddr, p.tcp.sport, \
               p.inner_ip.daddr, p.tcp.dport
    # add the record of the new_flow to FlowTable
    after_register = s.copy()
    after_register.decisions[new_flow] = p.ip4.daddr
    after_register.timestamps[new_flow] = s.curr_time
    register_action =
        Action(register_new_flow, {PORT_TO_EXT: p},
               after_register)

    return [known_flow_action,
            unknown_flow_action,
            register_action]
```

C Verifying Properties of MazuNAT

The MazuNAT middlebox is the most complicated application Gravel verifies in the case study (§5.1). Figure 6 shows the directed graph of Click elements extracted from its configuration file.

The three properties of MazuNAT proved by Gravel are extracted from RFC [29]. They are important to provide transparency guarantees for application running inside the network. Here we give the formalization of them in Gravel using Gravel's Python interface.

Payload Preservation (Property 3). The specification of Property 3 simply says that the payload of any packet forwarded by the middlebox remains the same. Note that this is a general property that can be verified on multiple middleboxes.

```
def test_payload_unchanged(self):
    p, s = sym_pkt(), sym_state()
    for source in sources:
        ps, _ = handle_packet(s, source, p)
        for sink in sinks:
            verify(Implies(Not(ps[sink].is_empty()),
                           ps[sink].payload == p.payload))
```

Endpointer Independent Mapping (Property 4. For Property 4, the specification starts by creating two symbolic packets, p1 and p2. It then invoke the process_packet on both packets (using the same symbolic state s). After that, it asks the verifier to check if the rewritten packets sending to the external network have the same source address.

```
def to_external(p, s):
    return p.ip.dst != s.public_ip

def same_src(p1, p2):
    return And(is_tcp_or_udp(p1), is_tcp_or_udp(p2),
               p1.ip.src == p2.ip.src,
               src_port(p1) == src_port(p2))

def test_ep_independent_map(self):
    p1, p2, s = sym_pkt(), sym_pkt(), sym_state()

    out1, _ = handle_packet(s, 'from_intern', p1)
    out2, _ = handle_packet(s, 'from_intern', p2)
    o1 = out1['to_extern']
    o2 = out2['to_extern']
    verify(Implies(And(to_external(p1, s),
                       to_external(p2, s),
                       same_src(p1, p2)),
                   same_src(o1, o2)))
```

Endpoint Independent Filtering (Property 5). The high-level specification of Property 5 starts with creating symbolic packet p1 and symbolic state s. Then it creates a new packet p2 by replace only the source address and port with fresh symbolic values. After that the specification uses process_packet to get the resulting packets from processing p1 and p2. Finally, we ask the verifier to check whether the resulting packets (o1 and o2 in the code snippet below) are sent to the same destination.

```
def test_ep_independent_filter(self):
    p1, s = sym_pkt(), sym_state()
    ps1, _ = handle_packet(s, 'from_extern', p1)
    p2 = p1.copy()
    p2.ip.src = sym_ip()
    p2.tcp.src = sym_port()
    p2.udp.src = sym_port()
    ps2, _ = handle_packet(s, 'from_extern', p2)
    for sink in sinks:
        o1 = ps1[sink]
        o2 = ps2[sink]
        verify(Implies(Not(o1.is_empty()),
                       And(Not(o2.is_empty()),
                           o1.ip.dst == o2.ip.dst,
                           dst_port(o1) == dst_port(o2))))
```

Hairpinning (Property 6). As shown below, rather than inspecting the state of elements in MazuNAT to determine whether a address mapping is established. Gravel uses the packet forwarding behavior as the indicator. The specification says that if a packet p1 from external network is forwarded

Function name	Description
`Vector<T>:`	
`const T& get(unsigned int)`	Get value by index
`void set(unsigned int i, T v)`	Set i-th value of vector to `v`
`void map(void(*)(T) f)`	Apply function `f` for all value in vector
`HashMap<K, V>:`	
`V &find(K k)`	Lookup by key `k`
`void insert(K k, V v)`	Insert key-value pair `k, v` into the hashmap
`void erase(K k)`	Delete key `k` from the hashmap
`void map(void(*)(K k, V v) f`	Apply function `f` to all key-value pair in hashmap
`void filter(bool(*)(K k, V v) p)`	Filter key-value pairs in the hashmap with predicate `p`
`HashSet<T>:`	
`T &find(T v)`	Check if `v` is present in hashset
`void insert(T v)`	Insert `v` into the hashset
`void erase(T v)`	Delete `v` from the hashset
`void filter(bool(*)(T v) p)`	Filter with predicate `p`

Table 6: Data structure interfaces supported by Gravel.

to internal network. any packet p2 with the same destination address and port received from internal network is also forwarded to the same destination in the internal network.

```
def test_hairpinning(self):
    p1, p2, s = sym_pkt(), sym_pkt(), sym_state()
    out1, _ = handle_packet(s, 'from_extern', p1)
    out2, _ = handle_packet(s, 'from_intern', p2)
    o1 = out1['to_intern']
    o2 = out2['to_intern']
    verify(Implies(And(p1.ip.dst == p2.ip.dst,
                       p1.ip.proto == p2.ip.proto,
                       dst_port(p1) == dst_port(p2),
                       o1.not_empty()),
                   And(o2.not_empty(),
                       o1.ip.dst == o2.ip.dst,
                       o1.tcp.dst == o2.tcp.dst)))
```

Connection memorization (Property 7). The formalization of Property 7 uses the same inductive approach as in the ToyLB example. As shown below, the specification is decomposed into a base case and two inductive cases. The base case states that when a packet from internal network is forwarded to external world by MazuNAT, the translation will be still effective within the time window THRESHOLD.

```
def test_memorize_init(self):
    p0, p1, s0 = sym_pkt(), sym_pkt(), sym_state()
    o, s1 = handle_packet(s0, 'from_intern', p0)
    ext_port = o['to_extern'].tcp.src
    t = s0['rw'].curr_time
    ddl = t + THRESHOLD
    verify(Implies(is_tcp(p0),
                   steer_to(c, s1, p0, ext_port, ddl)))
```

Then, the two inductive cases show that processing a packet from other flows or any time event before the end of the time window do not effect existing translation mappings.

```
def test_memorize_step_pkt(self):
    p0, p1, s0 = sym_pkt(), sym_pkt(), sym_state()
    t = sym_time()

    p_diff = sym_pkt()
    ext_port = sym_port()
    _, s1 = handle_packet(s0, 'from_intern', p_diff)
    verify(Implies(And(steer_to(c, s0, p0, ext_port, t),
                       from_same_flow(p0, p1)),
                   steer_to(c, s1, p0, ext_port, t)))

def test_memorize_step_time(self):
    ext_port = fresh_bv('port', 16)
    p0, p1, s0 = sym_pkt(), sym_pkt(), sym_state()
    t0, t1 = sym_time(), sym_time()
    _, s1 = handle_time(s0, 'rw', t1)
    verify(Implies(And(steer_to(c, s0, p0, ext_port, t0),
                       z3.ULT(t1, t0),
                       from_same_flow(p0, p1)),
                   steer_to(c, s1, p1, ext_port, t0)))
```

APKeep: Realtime Network Verification for Real Networks

Peng Zhang*, Xu Liu*, Hongkun Yang†, Ning Kang*, Zhengchang Gu*, and Hao Li*
*Xi'an Jiaotong University, †Google

Abstract

Realtime network verification ensures the correctness of network by incrementally checking data plane updates in real time (e.g., $<$ 1ms per rule update). Even state-of-the-art methods can already achieve sub-millisecond verification time, such speed is achieved mostly for pure IP forwarding devices, and is unrealistic for real-world networks, due to two reasons. (1) Their network models cannot express the forwarding behavior of real devices, which have various functions including IP forwarding, ACL, NAT, policy-based routing, etc. (2) Their update algorithms do not scale in space and/or time: multi-field rules (e.g., ACL rules) can make these tools run out of memory and/or incur long verification time. To scale realtime verification to real networks, we propose APKeep based on a new modular network model that is expressive for real devices, and propose new algorithms that can achieve low memory cost and fast update speed at the same time. Our experiments show that for real-world update traces consisting of IP forwarding rules and ACL rules, existing methods either run out of memory or incur a prohibitively long verification time, while APKeep still achieves a sub-millisecond verification time. We also show that APKeep can verify an update of NAT rule mostly in less than 1 millisecond.

1 Introduction

Computer networks are prone to faults due to protocol misconfigurations, software bugs, and hardware failures [7,17,26,35]. Manually troubleshooting the faults often costs a network downtime up to several hours [7]. How to prevent network faults by ensuring network correctness becomes a fundamental problem posed to network operators and researchers.

Network verification seeks to automatically check network correctness at both control plane [9, 12, 13, 16, 18, 19, 30] and data plane [10, 15, 20, 22–24, 27, 36–40]. Compared to control plane verification which focuses on detecting protocol misconfigurations, data plane verification directly checks the data plane, which is closer to the actual forwarding behaviors of packets, and thus can catch a broader range of faults due to switch software bugs and hardware failures.

More recently, *realtime data plane verification* allows operators to check the correctness of data plane as it updates in realtime [20, 22, 24, 37–39]. To achieve this, realtime data plane verifiers often partition packets into *equivalence classes (ECs)*, and maintain a model of forwarding behavior for these ECs. When the data plane updates, they *incrementally* update the model, and check the updated model against correctness properties.

State-of-the-art realtime data plane verifiers have already achieved sub-millisecond verification time [20, 24]. However, such speed is mostly achieved for pure forwarding devices. For real devices consisting of various functions other than forwarding, these verifiers exhibit two fundamental limitations.

Network model is *not expressive* for real devices. Apart from IP forwarding, real devices have many other functions including access control list (ACL), network address translation (NAT), etc., which are composed in specific orders to implement various processing logic. For example, inside a typical router, multiple ACLs can be chained and applied at multiple ports to filter inbound and/or outbound packets [1]. Some routers may perform NAT on packets matching an ACL. Tools like VeriFlow [24] and Delta-net [20] assume simple models which only express forwarding functions. Models of NetPlumber [22] and AP Verifier [38, 39] can express more functions, but are hard to extend. For example, most vendors provide variants of policy-based routing [8], and adding such a feature requires heavy modification of their models. Even for the same set of functions, different devices may also have different pipelines, and writing a model for each of them is clearly not scalable.

Verification algorithms are *not scalable* for real devices. Range EC-based methods like VeriFlow and Delta-net represent each EC as a range of packet headers, thereby achieving a fast verification speed for IP forwarding rules. For example, Delta-net can check an update of IP forwarding rule in tens of microseconds on average. However, when there are multi-field rules, e.g., ACL rules, range EC-based methods may suffer from the problem of *EC explosion*, where the number of ECs grows exponentially with the number of multi-field rules. We find that for a real-world dataset consisting of only 686 ACL rules, an open-source version of VeriFlow and our multi-field extension of Delta-net can create up to 15 million ECs, causing either prohibitively long verification times or memory overflows.

AP Verifier computes the minimum number of ECs with respect to the network behavior. The downside, however, is that the update of ECs is more difficult, and can cost up to 10 milliseconds [37].

To overcome the above limitations and bring realtime network verification closer to the real world, this paper presents APKeep, a new realtime data plane verifier.

APKeep builds on a new network model that is modular and expressive. It models networks in a granularity of logical functions instead of physical devices. Each function, e.g., forwarding, filtering, rewriting, is modeled as a logically-independent *element*, which holds a set of logical *ports* corresponding to different actions on packets. APKeep views packets forwarded to the same port (i.e., undergoing the same actions) at each element as an EC, and encodes each EC with a logical *predicate*. The modularity of our model makes it easy to support common functions and vendor-specific compositions of functions in real devices. In addition, it also reduces the update scope and makes the update more efficient.

APKeep uses novel algorithms to compute and maintain the minimum number of ECs in realtime. A key reason for EC explosion of existing methods is that they create ECs based on the match fields of rules, resulting in a lot of unnecessary ECs with the same forwarding behavior. In addition, they cannot compress these ECs after creation. APKeep significantly reduces the number of ECs based on two principles. *(1) Creating ECs only when necessary.* APKeep creates ECs only when it needs more ECs to express new forwarding behaviors. *(2) Merging ECs when possible.* APKeep tracks the forwarding behavior of each EC, and merges multiple ECs with the same forwarding behavior. *We proved that by applying the above principles, APKeep always maintains the minimum number of ECs during update.*

In summary, our contribution is three-fold:

- We introduce a new network model that is modular and expressive for modeling real network devices.
- We design APKeep, which uses novel algorithms to fast update the network model for realtime verification.
- We show APKeep achieves a sub-millisecond verification time for update traces consisting of IP forwarding rules, ACL rules, and NAT rules.

Roadmap. We present the design overview (§ 2) and details (§ 3) of APKeep, followed by a case study (§ 4). Then, we show the experiment results (§ 5). After discussing related work (§ 6) and potential issues (§ 7), we conclude (§ 8).

2 Design Overview

This section overviews the design of APKeep. We will first introduce the network model that APKeep builds on, and then show how APKeep can fast update the model.

2.1 The Modular Network Model

To achieve realtime network verification for real networks, the network model should satisfy three key requirements: (1) *expressive* for common functions in real devices, e.g., IP forwarding, ACL, NAT, policy-based routing, etc.; (2) *extensible* for different devices with different vendor-specific implementations of these functions; (3) *efficient* to update for achieving realtime verification.

We propose *Port-Predicate Map (PPM)*, a new network model that meets all the above requirements. To demonstrate how PPM works, we use the example network shown at the top-left corner of Figure 1. In this network, switch *C* has four functions or modules (two ACLs, one forwarding, and one NAT), each having its own rules. If packets arrive at *port*1, two ACLs *ACL1* and *ACL2* are applied in sequence; if they arrive at *port*2, only *ACL1* is applied. Then, the packets will be sent to an output port according to the forwarding rules. If the output port is *port*5, packets will go through an NAT.

As an alternative, we could model a device as a monolithic box. This approach has the following drawbacks. First, it will be difficult to extend the model for new functionalities. For example, a device from another vendor may have a different chaining of modules (e.g., NAT before IP forwarding), or a new function (e.g., overriding IP forwarding with user policies). Then, we need to compose another device model. In addition, it will also make the update inefficient. For example, suppose a rule is inserted into *ACL1*, then we need to update the ECs allowed by the two input ports.

Element. Instead of modeling a network as a set of devices, PPM models at a granularity of *element*, defined as a logically-independent function (e.g., IP forwarding, ACL, or NAT). Each element has its own set of *rules*, and holds a set of logical *ports*. Different from physical ports, i.e., interfaces, logical ports represent generic actions including "output to VLAN 10", "permit SSH traffic", "rewrite dstIP to 10.0.0.1". This allows elements to express a broad range of functions other than IP forwarding. In specific, an element holds one port for each distinct action of rules in the element, and a special port for the default action is reserved for packets not matching any rules. When a packet arrives at an element, it will be "forwarded to" to exactly one port of the element, i.e., taking the actions of that port. Currently, PPM supports three types of elements, and more types can be added in the future.

- A **forwarding element** has rules that match IP prefixes and whose actions are "output packets to a specific set of interfaces". A forwarding element holds one port for

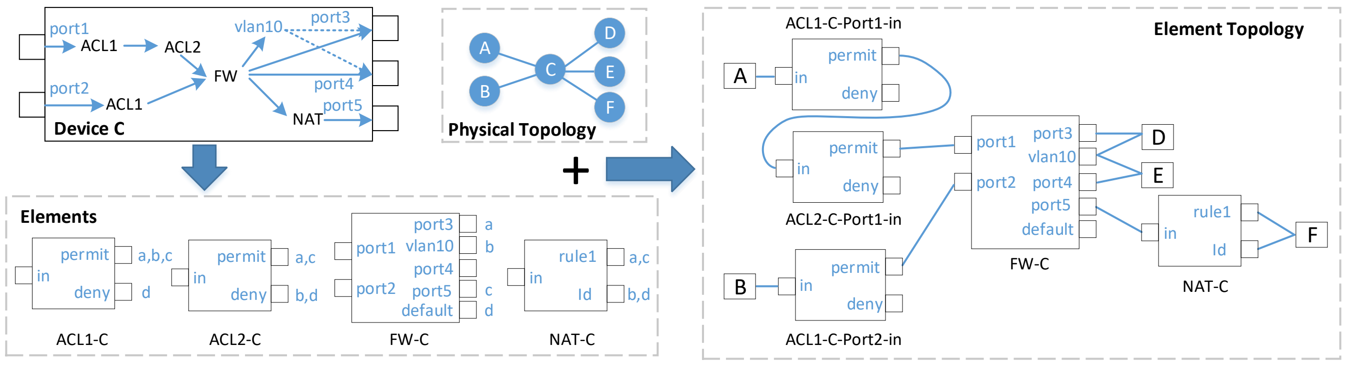

Figure 1: An example showing how APKeep divides devices into elements.

each distinct set of interfaces, and a *default* port for the default action, e.g., dropping packets.

- A **filtering element** has rules that match 5-tuples and whose actions are either "permit" or "deny". A filtering element holds exactly two ports: *permit* and *deny*.
- A **rewriting element** has rules which match 5-tuples and whose actions are "rewrite a specific header field to a specific value". A rewriting element holds one port for each distinct rewriting action, and an *id* port corresponding to no packet rewrite.

When a device has multiple functions, we break it into multiple elements. As shown in the left bottom of Figure 1, device C breaks into a forwarding element `FW-C`, two filtering elements `ACL1-C`, `ACL2-C`, and a rewriting element `NAT-C`.

Equivalence Class. Let $\mathcal{E}$ be the set of all elements in the network, and $\mathcal{H}$ be the set of all packet headers. For each header $h \in \mathcal{H}$ and element $e \in \mathcal{E}$, let $Port_e(h)$ be the port that h would be "forwarded to", assuming h has been received by e. Then, we have the following definition for equivalence class (EC).

Definition 1. *We say $\mathcal{C} = \{c_1, c_2, \dots, c_n\}$ is a set of equivalence classes (ECs) with respect to element set $\mathcal{E}$ and header set $\mathcal{H}$ if: (1) $c_i \wedge c_j = \emptyset, i \neq j$; (2) $\vee_{i=1}^{n} c_i = \mathcal{H}$; (3) $\forall h_1, h_2 \in \mathcal{H}$, $h_1 \neq h_2$: $\exists c \in \mathcal{C}$, $h_1, h_2 \in c \Rightarrow \forall e \in \mathcal{E}, Port_e(h_1) = Port_e(h_2)$ [1]. We say $\mathcal{C}$ is the minimum set of ECs if it is the smallest set satisfying the above conditions.*

APKeep encodes an EC with a logical *predicate*, i.e., Boolean formula. The reason to use predicate instead of range as in [20, 24] is that a predicate can encode an arbitrary set of packet headers, such that multiple range-based ECs having the same forwarding behavior can be represented as a single predicate. This allows APKeep to merge ECs with the same forwarding behavior, thereby avoiding explosion of ECs (§ 2.2).

Port-Predicate Map. For each predicate c and each element e, let $Port_e(c) = Port_e(h), \forall h \in c$. Suppose $p = Port_e(c)$, then we say port p *holds* predicate c. Define the *predicate set* of port p as: $Pred(p) = \{c \in \mathcal{C} | Port_e(c) = p, e \in \mathcal{E}\}$. We can see that $Pred$ is a map from port to predicates, which encodes the network forwarding behavior: given a packet h at element e, suppose it belongs to predicate c, then h will be forwarded by e to the port p satisfying $c \in Pred(p)$.

Element Topology. PPM uses the *element topology* to describe how elements are chained to process packets in the network. The right of Figure 1 shows the element topology of the example. First, each node represents an "application" of the corresponding element. For example, since `ACL1-C` is applied to *port*1 and *port*2, there are two nodes `ACL1-C-Port1-in` and `ACL1-C-Port2-in`. The forwarding element `FW-C` is applied once, and thus it corresponds to a single node. Creating a separate node for each application allows elements to be agnostic of input ports where packets are received. Second, each node has a set of ports, each holding a set of predicates, in the same way as its corresponding element. Thus, we only need to update a single element rather than all its nodes. For example, when a rule is inserted into $ACL1$, we only update the element `ACL1`, rather than its two nodes. Third, nodes are connected based on the physical topology, and how the elements are applied inside devices. For example, a port of A is connected to *port*1 of C in the network topology. Then, in the element topology, the port of A connects to the *in* port of `ACL1-C-Port1-in`, whose *permit* port connects to the *in* port of `ACL2-C-Port1-in`, and its *permit* port connects to the *port*1 of `FW-C`. The element topology will be used to construct forwarding graphs for verification (§ 3.3).

As shown above, PPM achieves modularity by breaking the composite functions inside a device into logically-independent elements. This brings the following benefits.

Expressiveness. Using the three types of elements as building blocks, PPM can express the forwarding, ACL, and NAT functions. Besides that, we will show how PPM can express the policy-based routing function offered by a major device vendor (§ 4).

Extensibility. Even most devices share roughly the same set of functions, the implementations and compositions of these functions are often vendor-specific. Writing a model for each

[1] Condition (3) says that for each h_1 and h_2 in $\mathcal{H}$ such that $h_1 \neq h_2$, we have: if there exists an c in $\mathcal{C}$ such that h_1 and h_2 both belong to c, then for each element e in $\mathcal{E}$, $Port_e(h_1) = Port_e(h_2)$

different device wastes time and effort. PPM models each device at the function level with elements, therefore it is relatively easy to model devices with vendor-specific compositions of functions by properly chaining the elements.

Reduced update scope. First, updates of multiple elements are decoupled, and when a rule is updated, we only need to update the element where the rule is updated, without affecting other elements. For example, multiple ACLs may be chained and applied to an interface. If a rule is inserted to one ACL, we only need to update the element of that ACL. Secondly, the application of elements is decoupled away from the elements themselves. For example, an ACL can be applied to multiple interfaces, and we only need to update the element of the ACL once, instead of updating all these interfaces. As another example, an operator may activate/deactivate an existing ACL on a port, or even migrate an ACL from a port to another [33]. In this case, we do not need to update the element of the ACL, as the forwarding behavior of the element is not affected.

2.2 The Update of Network Model

In the following, we show how APKeep updates the network model using a simple example in Figure 2. As shown in (a), the device has an ACL applied to its input port, followed by a forwarding module. For simplicity, we assume there are two match fields: *dstIP* represented with 2 bits x_1, x_2, and *dstPort* represented with 2 bits y_1, y_2. The forwarding module matches only *dstIP* with longest prefix match, and the ACL matches both *dstIP* and *dstPort* according to priorities (larger number means higher priority). We assume that by default, the ACL denies all packets and the forwarding module forwards all packets to *port*1. Initially, we have one EC *a*, which appears at the port *port*1 of element `FW`, and the port *deny* of element `ACL`. We will insert two ACL rules $R1$ and $R2$ shown in (b), and two forwarding rules $R3$ and $R4$ shown in (c).

First, we insert an ACL rule $R1$, whose match fields are $x_1x_2 = 0*, y_1y_2 = 00$, as shown at the top of (d). APKeep analyzes how $R1$ will affect the behaviors of element `ACL`. Specifically, APKeep finds $R1$ overrides the default deny rule in the red dashed rectangle. However, since $R1$ also has a deny action, packets in the rectangle will not change. Thus, APKeep does not update the EC *a*, which still appears at *port*1 of `FW` and *deny* of `ACL`, as shown at the bottom of (d). In contrast, if we create range-based ECs based on match fields, we will split EC *a* into three ECs, each of which is a rectangle in the header space.

Suppose another ACL rule $R2$ is inserted. Since $R2$ has a lower priority than $R1$, APKeep finds $R2$ can match only the shaded area, where it overrides default deny rule. As a result, packets matching the shaded area will change their behavior from deny to permit. To reflect that change, APKeep decides to transfer those packets from port *deny* to port *permit*. Since the packets are a portion of EC *a*, it splits *a* into two ECs, i.e., *b* for the shaded area, and another one by subtracting *b* from *a*. Then, APKeep transfers *b* to port *permit*, as shown at the bottom of (e). The reason that the EC *b* can be a non-rectangle area is that ECs are encoded with predicates. Specifically, the match fields of $R1$ and $R2$ can be represented as predicates $\bar{x}_1\bar{y}_1\bar{y}_2$ and $\bar{y}_1$, respectively. Then, *b* can be calculated by logical operations as $b = \bar{y}_1 \wedge \neg(\bar{x}_1\bar{y}_1\bar{y}_2) = (\bar{y}_1x_1) \vee (\bar{y}_1y_2)$.

Suppose a forwarding rule $R3$ is inserted. $R3$ overrides the default rule in the red dashed rectangle, which changes its port from *port*1 to *port*2. APKeep creates two new EC *c* and *d* by splitting *a* and *b*, respectively, and transfers them to *port*2, as shown in (f). The insertion of another forwarding rule $R4$ is similar and shown in (g). At this time, APKeep finds two ECs *d* and *f* appear at the same port at both elements, meaning that they have the same forwarding behavior – permitted by the ACL and forwarded to *port*2. Thus, APKeep merges *d* and *f* into a single EC. Similarly, APKeep merges *c* and *e* into a single EC, as shown in (h). The merging of ECs translates into logical disjunction of predicates. For example, *d* and *f* are merged into an EC represented by $(\bar{x}_1\bar{x}_2\bar{y}_1y_2) \vee (x_1\bar{x}_2\bar{y}_1)$.

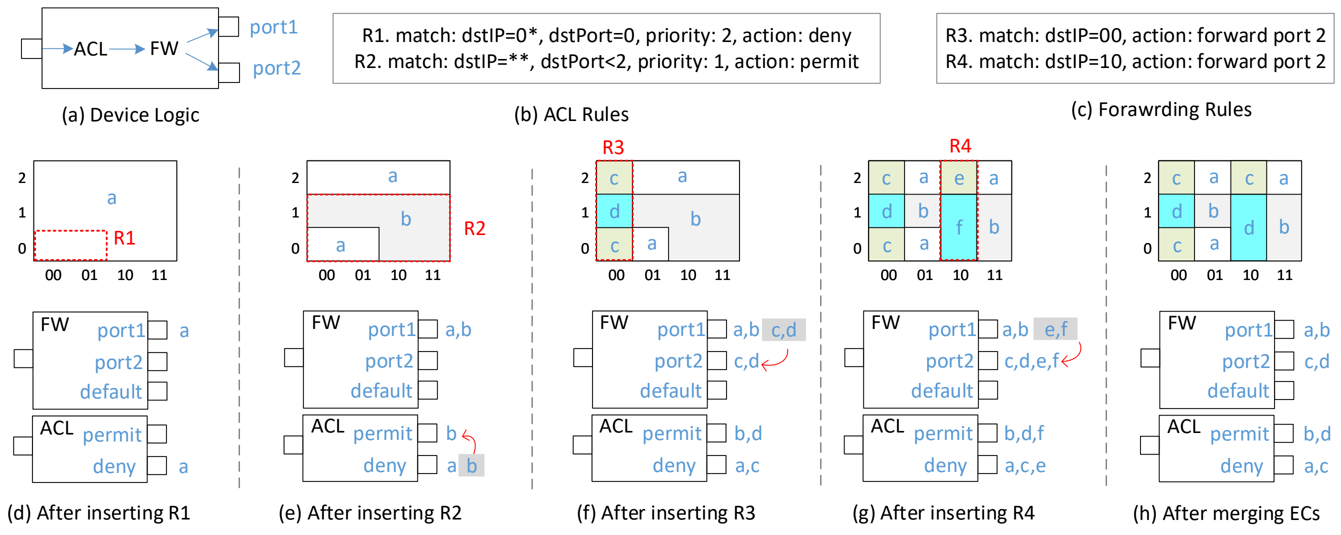
Finally, after inserting $R1$ through $R4$, APKeep creates 4 ECs. In contrast, if we create range-based ECs based on match fields, we will need 10 ECs, one for each rectangle of (h). The above is just an over-simplified example with only two fields which have 3-4 values. In real scenarios, the reduction rate can be as high as 99.99% (see Table 3). Actually, we prove that APKeep always maintains the minimum number of ECs during update (see Theorem 1).

The reason that APKeep can update such a small number of ECs is two-fold: *(1) Creating new ECs only when necessary.* APKeep creates a new EC only when part of an existing EC changes its forwarding behavior and the EC needs to be split into two ECs. In contrast, creating new ECs whenever the match fields of the new rule split some existing ECs will result in many redundant ECs. *(2) Merging ECs whenever possible.* APKeep tracks the forwarding behaviors of ECs, and merges multiple ECs if they have the same forwarding behavior. In contrast, range-based EC presentation mostly does not allow ECs to be merged.

The update of ECs in APKeep is much faster compared to AP Verifier due to the following reason. APKeep can quickly identify the changes of forwarding behaviors, and incrementally update predicates instead of re-computing them (§ 3.2). In contrast, AP Verifier maintains a port predicate for each device port, and computes atomic predicates (minimum number of ECs) based on all port predicates. When a rule is updated, it needs to first update the port predicates, and if new port predicates are created, it re-computes the atomic predicates based on the updated port predicates. We observe an up to 200× speedup in our experiments.

3 Design Details

This section presents the design of APKeep. Figure 3 shows the architecture of APKeep, which consists of three layers:



ACL
FW
port1
port2
(a) Device Logic
R1. match: dstIP=0*, dstPort=0, priority: 2, action: deny
R2. match: dstIP=**, dstPort<2, priority: 1, action: permit
(b) ACL Rules
R3. match: dstIP=00, action: forward port 2
R4. match: dstIP=10, action: forward port 2
(c) Forawrding Rules
R1
R2
R3
R4
default
permit
deny
(d) After inserting R1
(e) After inserting R2
(f) After inserting R3
(g) After inserting R4
(h) After merging ECs

Figure 2: An example of incremental update for rule insertion.

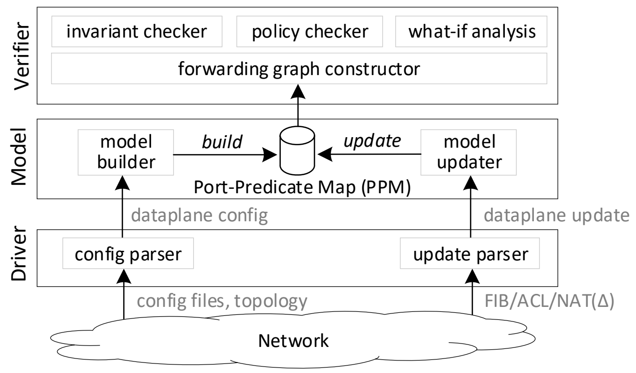


Figure 3: The architecture of APKeep.

The driver layer serves as the interface between network data plane and the model layer. In the bootstrap stage, the *config parser* reads in the network topology and configuration files, and generates the vendor-neutral *data plane config*, describing the configuration of interfaces, VLANs, ACLs, etc. for each device. The *update parser* fetches the FIB/ACL/NAT (changes) from each device and generates *data plane updates*, including insertion/deletion/modification of rules.

The model layer is the core of APKeep system. The *model builder* constructs PPM model by creating all the elements based on the data plane config. The *model updater* continuously updates the PPM model by processing each data plane update in sequence.

The verifier layer hosts verification applications on top of the model layer. The *forwarding graph constructor* generates forwarding graphs based on the PPM model, and on top of the graphs, various applications can be deployed to check network invariants, operator policies, or conduct what-if analysis.

In the following, we show how APKeep builds and updates the PPM model, and performs verification. Then, we show how APKeep supports packet rewrites, and present some optimization techniques.

3.1 Building PPM

For each device, APKeep constructs a device model based on its configuration of interfaces, ACLs, NAT, etc., and decomposes the device model into a set of elements. Currently, APKeep offers three types of elements, i.e., forwarding element, filtering element, and rewriting element. Initially without any rules, a forwarding element has a $default$ port; a filtering element has a *permit* port and a *deny* port; a rewriting element has an *id* port. For forwarding and rewriting elements, more ports can be created on-the-fly during rule insertions.

After creating elements, APKeep constructs the *element topology* by augmenting the physical topology with intra-device element connections, based on how elements are composed inside the device. For example, if an ACL $ACL1$ is declared to filter inbound traffic at port $port1$, then there is a connection from the *permit* port of $ACL1$ to the $port1$ port of the forwarding element.

Initially there is only one `True` predicate, standing for the set of all possible packets. For each element, the `True` predicate is held by its $default$, *deny*, or *id* port, depending on the element type. APKeep initializes the predicate set $Pred(p)$ (§ 2.1) to {`True`} if p is $default$, *deny*, or *id* port, and to empty set otherwise.

3.2 Updating PPM

For each rule update, APKeep updates the PPM using three steps: (1) encoding the match fields of the rule, (2) identifying the changes of forwarding behavior, and (3) updating the predicates and the map from port to predicates. The following only shows the case for rule insertion, and rule deletion differs only slightly in Step (2). Rule modification can be seen as a pair of rule deletion and insertion.

Let r be the rule to be inserted, specified as a 3-tuple $(priority, match, action)$, and let e be the element where r

Algorithm 1: `IdentifyChangesInsert`(r, $\mathcal{R}$)

```
Input: r: the newly inserted rule; R: the list of existing rules,
       sorted by decreasing priorities.
Output: C: the set of changes due to the insertion of rule r.
1  $C \leftarrow \{\}$;
2  $r.hit \leftarrow r.match$;
3  foreach $r' \in \mathcal{R}$ do
4      if $r'.prio > r.prio$ and $r'.hit \wedge r.hit \neq \emptyset$ then
5          $r.hit \leftarrow r.hit \wedge \neg r'.hit$;
6      if $r'.prio < r.prio$ and $r'.hit \wedge r.hit \neq \emptyset$ then
7          if $r'.port \neq r.port$ then
8              $C \leftarrow C \vee \{(r.hit \wedge r'.hit, r'.port, r.port)\}$;
9          $r'.hit \leftarrow r'.hit \wedge \neg r.hit$;
10 Insert $r$ into $\mathcal{R}$;
11 return $C$;
```

is inserted.

Step 1. Encoding match fields. Assume each packet header has h bits, each of which can be represented as a Boolean variable. Then, the match field of a rule corresponds to a set of packet headers, and can be represented as Boolean formula of h variables. For example, an IP match field of 128.0.0.∗ can be represented as $x_1 \wedge \bar{x}_2 \wedge \cdots \wedge \bar{x}_{24}$. We adopt the methods of [37] to encode the Boolean formulas of match fields based on Binary Decision Diagram (BDD [11]). BDD is a data structure that can canonically represent Boolean formulas, and it allows efficient logical operations including conjunction ($\wedge$), disjunction ($\vee$), and negation ($\neg$). By encoding the match fields with BDDs, we can efficiently compute and update predicates leveraging these logical operations. We use *r.match* to denote the match fields of r, encoded with BDD.

Step 2. Identifying changes. This step identifies the changes of forwarding behavior at element e, by analyzing how the insertion of r affects existing rules of e. Here, a behavior change takes the form of $(\delta, from, to)$, meaning packets satisfying predicate δ, which are originally forwarded to port $from$, will now be forwarded to port to. Note that this step is locally performed at e.

Before introducing the algorithm, we define the *hit* and *port* fields for each rule. First, note that multiple rules may have overlapping match fields, and packets will take the action of the rule with the highest priority. Thus, some headers in *r.match* may not "hit" rule r due to the presence of some higher-priority rules. To represent the headers that actually "hit" a rule, we define the *hit field* for each rule r as:

$$r.hit \triangleq \neg(\vee_{r'.prio > r.prio} r'.match) \wedge r.match \qquad (1)$$

If $h \in r.hit$, we know that h will take the action of r. Initially when there is only one default rule, the hit field of the default rule is equal to its match field, i.e., `True`. Second, recall that each element has a port corresponding to each distinct action of rules in the element. We use $r.port$ to denote the port corresponding to the action field of r. As an example, if r is a forwarding rule whose action field is "output to interface eth0/0", then $r.port = eth0/0$.

Algorithm 1 summarizes the procedure to identify the set of all behavior changes when a rule is inserted. It calculates the hit field *r.hit* by subtracting the match fields of higher-priority rules from *r.match* (Line 3-5), and identifies all behavior changes by analyzing how *r.hit* "overrides" lower-priority rules with different ports (Line 6-9). The algorithm for rule deletion differs only slightly and is not given here.

Step 3. Updating predicates. In this stage, APKeep takes the set of behavior changes caused by the inserted rule, denoted by C, and computes the set of transferred predicates, denoted by D. The process is summarized in Algorithm 2. In order to track which ports hold a given predicate, the algorithm maintains a map *Port* from each predicate c to the set of ports holding c, defined as $Port(c) = \{Port_e(c) | e \in \mathcal{E}\}$. We term $Port(c)$ as the *port set* of predicate c.

Initially, the set of transferred predicates D is set to empty (Line 1). For each change $(\delta, from, to)$, we iterate over each predicate p in the predicate set of $from$, and check whether p overlaps with δ (Lines 2-4). If so, we further perform the following three steps (Lines 5-10).

(1) Splitting predicates. In this step, we check whether p belongs to δ (Line 5). If not so, we need to split p into two new predicates $p \wedge \delta$ and $p \wedge \neg\delta$. by invoking the `Split` function (Line 6). As shown in Lines 11-17, the function `Split`$(p, p1, p2)$ first updates the predicate set of each *port* in $Port(p)$, by replacing p with $p1$ and $p2$ (Lines 12-13). Then, it initializes the port set of $p1$ and $p2$ with that of p (Lines 14-15). Finally, it updates the set of transferred predicates if needed (Lines 16-17).

(2) Transferring predicates. This step transfers the predicate $p \wedge \delta$ from port $from$ to port to by invoking the `Transfer` function (Line 7), as shown in Lines 18-22.

(3) Merging predicates. This step checks whether each predicate p' held by port to has the same port set with p (Line 8). If so, p' and p have the same forwarding behavior, and we merge them into a new predicate $p \vee p'$, by invoking the `Merge` function (Line 9), as shown in Lines 23-28.

After the above three steps, we update δ by subtracting p from it, and proceed to the next predicate of port $from$ (Line 10).

Theorem 1. *APKeep maintains the minimum set of equivalence classes after each rule update.*

The proof is given in Appendix A.

3.3 Verification

Checking Invariants. APKeep can check network invariants including loop-freedom and blackhole-freedom, which are defined as follows.

Algorithm 2: `Update`(C)

```
Input: $C$: the set of changes identified in the first stage.
Output: $D$: the set of transferred predicates.
1  $D \leftarrow \{\}$;
2  foreach $(\delta, from, to) \in C$ do
3      foreach $p \in Pred(from)$ do
4          if $p \wedge \delta \neq \emptyset$ then
5              if $p \wedge \delta \neq p$ then
6                  Split($p, p \wedge \delta, p \wedge \neg\delta$);
7              Transfer($p \wedge \delta, from, to$);
8              if $\exists p' \neq p, Port(p') = Port(p)$ then
9                  Merge($p, p', p \vee p'$);
10             $\delta \leftarrow \delta \wedge \neg p$;
11 Function Split($p, p1, p2$):
12     foreach $port \in Port(p)$ do
13         $Pred(port) \leftarrow Pred(port) \cup \{p1, p2\} \setminus \{p\}$;
14     $Port(p1) \leftarrow Port(p)$;
15     $Port(p2) \leftarrow Port(p)$;
16     if $p \in D$ then
17         $D \leftarrow D \cup \{p1, p2\} \setminus \{p\}$;
18 Function Transfer($p, from, to$):
19     $Pred(from) \leftarrow Pred(from) \setminus \{p\}$;
20     $Pred(to) \leftarrow Pred(to) \cup \{p\}$;
21     $Port(p) \leftarrow Port(p) \cup \{to\} \setminus \{from\}$;
22     $D \leftarrow D \cup \{p\}$;
23 Function Merge($p1, p2, p$):
24     foreach $port \in Port(p1)$ do
25         $Pred(port) \leftarrow Pred(port) \cup \{p\} \setminus \{p1, p2\}$;
26     $Port(p) \leftarrow Port(p1)$;
27     if $p1 \in D$ or $p2 \in D$ then
28         $D \leftarrow D \cup \{p\} \setminus \{p1, p2\}$;
29 return $D$;
```

- **Loop.** A packet traverses the same device for the second time, without being modified.
- **Blackhole.** A packet arrives at a device but does not match any forwarding rule.

Similar to Delta-net, APKeep checks invariants by constructing and traversing a *delta forwarding graph (DFG)*, a graph with each edge labeled with the ECs allowed on the edge. The difference is that APKeep updates the PPM model rather than DFG, and only constructs DFG based on the PPM model when checking invariants. Specifically, given a set of transferred predicates, APKeep constructs the DFG by adding the transferred predicates and the corresponding edges on the element topology. Then, APKeep traverses the DFG with a set of predicates P, which is initialized to the transferred predicates. When an edge is visited, P is intersected with the set of predicates on that edge. The traversal terminates when P becomes empty, reaching an edge with no next hop (blackhole detected), or the same node is visited twice (loop detected). The construction and traversal algorithms of DFG are given in Appendix B.

Checking policies. Operators may need to check user-defined policies such as hosts in a specific prefix can or cannot access a web server, traffic from subnet1 to subnet2 should pass the firewall, etc. We show how APKeep can support this task. Here, we define a policy as a pair of *match condition* and *path constraint*, where the match condition can be specified by header fields (e.g., 5-tuple), and a path constraint can be specified by a regular expression. Given a policy, APKeep can convert its match condition into a *policy predicate*, i.e., a BDD denoted as q, and its path constraint into an automata denoted as A. APKeep can check whether the policy is satisfied after an update as follows.

Let D be the transferred predicates after an update. APKeep computes a new set of predicates $D_q \leftarrow \{\delta \in D | \delta \wedge q \neq false\}$, and constructs the DFG G_q based on D_q. Then, APKeep traverses G_q while updating an instance of automata A for each $p_i \in D_q$, denoted as A_i. Specifically, APKeep updates the automata A_i if the predicate p_i visits a new node in DFG. The policy is satisfied if after traversal, all the automata enter the absorbing states; otherwise, the policy is violated. Note here multiple policies can be checked in parallel, and for each policy, the updating of each automata can also be parallelized.

What-if analysis. Operators can use APKeep to conduct "what-if analysis", e.g., will the invariants break if a specific link fails? APKeep answers such a query by retrieving all the predicates traversing the link, constructing a DFG using these predicates, and traversing the DFG to check invariants. The time to answer such a query heavily depends on the total number of ECs. We will show APKeep achieves a much shorter running time than Delta-net (§ 5.4).

3.4 Supporting Packet Rewrites

APKeep supports packet rewrites with *rewriting elements*. A rewriting element consists of a list $\mathcal{T}$ of rewrite rules, where each $T \in \mathcal{T}$ matches on 5-tuples, and rewrites the header to a specific value. APKeep creates a port for each rule in the rewriting element.

Based on the match fields of rewrite rules, we can compute predicates, and assign them to each port of the rewriting element, just as the forwarding and filtering element. The different part is: (1) how to encode packet rewrites using logical operations; (2) how to update predicates in the presence of rewrites.

Encoding packet rewrites. we adopt the methods in [39] to encode packet rewrites with logical operations as follows. First, it uses the existential quantification on predicate. Let p be a predicate, and x be one of the Boolean variables that p is defined on. The existential quantification of x is defined as:

$$\exists x.p = p|_{x=true} \wedge p|_{x=false} \tag{2}$$

, where $p|_{x=true}$ sets the value of variable x in p as `true`. Suppose the header has two bits x_1, x_2, then an NAT rule T that rewrites it to $x_1 = 1, x_2 = 0$ can be encoded as a logical function:

$$T(p) = (\exists x_1 \exists x_2 . p) \wedge (x_1 \wedge \bar{x}_2) \tag{3}$$

The existential quantification operation is supported by BDD.

Updating predicates in the presence of rewrites. Recall that for verification, we need to traverse a DFG which is constructed based on PPM. When there are only forwarding and filtering elements, we only need to perform intersections on predicate sets during traversal. However, when there are rewriting elements, predicates need to be transformed, and we need to ensure two conditions:

(1) Each predicate should be unambiguously transformed, i.e., the transformation should be defined for each predicate in PPM. For example, suppose p is split into $p1$ and $p2$, we should know how to transform each of them; otherwise, when traversing with only $p1$ or $p2$ in the predicate set, the rewriting element does not know how to transform it.

(2) The result of transformation should be represented by a set of predicates in PPM such that the traversal can proceed. For example, suppose a predicate p is held by the port of rewrite rule T, and $T(p) = p'$. If p' cannot be represented by a set of predicates in PPM, the traversal cannot continue since p' is not "recognized" by other elements.

In order to satisfy these two conditions, we apply the following two operations: (1) when a predicate p of a rewriting port is split into $p1$ and $p2$, we compute $p1' = T(p1)$ and $p2' = T(p2)$, and apply operation (2). (2) if the transformation result p cannot be represented as a set of predicates, we create new predicates to represent p. Note that this may split a predicate of some rewriting port and trigger operation (1).

Algorithm 3 summarizes how APKeep handles rule updates for rewriting elements. First, it updates the predicates with Algorithm 2 (Line 1). The difference lies in that the algorithm also maintains a *rewrite table*, where for each entry (k, v), k is a predicate before rewrite, and v is a set of predicates after rewrite. After transferring one predicate p to the port of another rule r', we need to apply the rewrite rule r' on p, and ensure the values in the rewrite table are still predicates (Lines 2-12).

Algorithm 3: `UpdateRewrite`$(C, \mathcal{RT})$

```
Input: $C$: the set of changes identified in the first stage; $\mathcal{RT}$:
       the rewrite table.
Output: $D$: the set of transferred predicates.
1  $D \leftarrow$ UpdateRW($C$);
2  while $true$ do
3      $updated \leftarrow false$;
4      foreach $(k,v) \in \mathcal{RT}$ do
5          foreach $p \in v$ do
6              if $p \notin \mathcal{P}$ then
7                  foreach $p' \in \mathcal{P}$ do
8                      if $p' \wedge p \neq false$ and $p' \wedge \neg p \neq false$
                       then
9                          SplitRW ($p', p' \wedge p, p' \wedge \neg p$);
10                 $updated \leftarrow true$;
11     if $updated = false$ then
12         break;
13 Function SplitRW($p, p1, p2$):
14     Split($p, p1, p2$);
15     foreach $(k,v) \in \mathcal{RT}$ do
16         if $p \in v$ then
17             $v \leftarrow v \cup \{p1, p2\} \setminus \{p\}$;
18     $\mathcal{RT}.remove(p)$;
19     $\mathcal{RT}.add(p1, \{T(p1)\})$;
20     $\mathcal{RT}.add(p2, \{T(p2)\})$;
21 return $D$;
```

3.5 Optimization

Delayed predicate merging. In Algorithm 2, APKeep merges two predicates instantly if they have the same port set. However, for some datasets, we find that some predicates are repeatedly merged and split, resulting in a waste of time. Thus, we adopt a delayed predicate merging: when a predicate can be merged, we record it, and when the total number of predicates exceeds a threshold (500 by default), we merge all the recorded predicates. To fast determine whether a predicate can be merged, we maintain a hash table where the key is an ordered list of ports, and the value is a set of predicates that appear at all these ports.

Separate update for different types of elements. Updating both forwarding rules and ACL rules may result in a large number of predicates. For example, suppose there are n ECs generated by forwarding rules, and an ACL rule matching a destination port range will create n new ECs. AP Verifier [37] proposed to compute the atomic predicates for forwarding and ACL rules, separately. We adopt this approach and update two sets of predicates, one for forwarding elements, and one for ACL elements. When traversing the forwarding graph, we need to carry two sets of predicates, and set intersection only happen between the same set of predicates. Different from [37], our algorithm avoids false positives when verifying invariants. For example, when a node is visited twice, we evaluate whether there exist two predicates, one from each set, that have non-empty conjunction. If so, the loop exists; otherwise, the loop is a false positive.

4 Case Study

We study the expressiveness of our PPM model by showing how to model a vendor-specific function with the three built-in

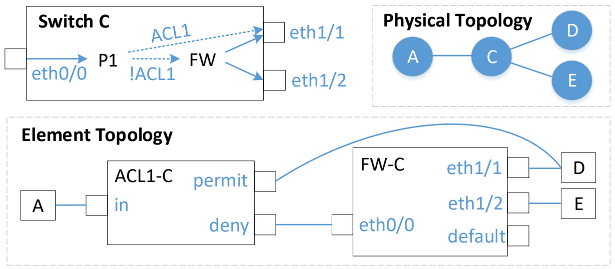

Figure 4: Modeling traffic policy in APKeep.

element types.

Policy-Based Routing (PBR) is a function commonly available in many routers and switches. It allows operators to override the IP forwarding rules such that packets are forwarded based on criteria other than destination IP address. Different vendors may implement their own version of PBR, and here we study one such implementation offered by a large device vendor.

The vendor offers a function named *traffic policy*, defined as a set of classifier-behavior pairs. The following shows a traffic policy `p1` applied to inbound traffic of interface `eth0/0` at switch *C*. `p1` is defined by a classifier `c1` and a behavior `b1`, meaning that packets satisfying `c1` will be forwarded according to `b1`. `c1` is defined using an ACL `ACL1`, and the behavior is redirecting traffic to interface `eth1/1`. The top-left and top-right of Figure 4 show the processing logic of switch *C* and the network topology, respectively.

```
interface eth0/0
traffic-policy p1 inbound
#
traffic policy p1 match-order config
classifier c1 behavior b1
#
traffic classifier c1 operator or precedence 5
if-match acl ACL1
#
traffic behavior b1
permit
redirect interface eth1/1
```

In our PPM model, the above traffic policy can be easily modeled by creating an ACL element `ACL1-C`, and properly chaining it into the forwarding graph, as shown in the bottom of Figure 4: (1) connecting its `in` port to the upstream port originally connected to `eth0/0`, (2) connecting its `permit` port to the downstream port originally connected to `eth1/1`, (3) connecting its `deny` port to the `eth0/0` port of `FW-C`.

The above is just the simplest form of traffic policy, and in a more general case, a policy can contain multiple classifier-behavior pairs, and each classifier can contain multiple ACLs. Then, we need to create multiple elements, one for each ACL, and cascade them together.

In addition to 5-tuples, a traffic policy also matches various information including VLAN ID, layer-3 packet length, time ranges, etc. Since the predicate-based EC representation has no restriction on the match fields, we can encode these match conditions by adding more fields. For example, we can add a 16-bit field to encode the packet length from 0 to 65535, and a 5-bit field to encode the hour-level time range. Note since PPM models the packet forwarding behaviors of symbolic packets, the fields to add do not have to be packet headers.

Apart from PBR, the traffic policy function also supports other behaviors including traffic statistics, flow mirroring, etc., which do not change the forwarding behaviors, and rate limiting, congestion avoidance, which selectively drop packets. As all previous data plane verifiers, PPM cannot model these features.

Table 1: Dataset statistics.

Network	Nodes	Links	Forwarding rules	ACL rules	Updates
Airtel1	68	260	6.89×10^4	0	1.42×10^7
Airtel2	68	260	9.84×10^4	0	5.05×10^8
4Switch	12	16	1.12×10^6	0	1.12×10^6
Internet2	9	56	1.26×10^5	0	2.52×10^5
Stanford*	16	74	3.84×10^3	0	7.68×10^3
Purdue*	1,646	3,094	3.52×10^6	0	7.04×10^6
Stanford	124	182	3.84×10^3	686	9.05×10^3
Purdue	2,159	3,607	3.52×10^6	2,707	7.05×10^6

5 Evaluation

5.1 Setup

Implementation. We implemented APKeep with around 5K lines of Java code. Currently, we have implemented config parsers for three different vendors, which translate vendor-specific configuration files into a unified representation in JSON format. We also implemented an update parser for one vendor, whose devices support fetching data plane state including FIBs and ACLs. For verification, we implemented an invariant checker that can detect loop and blackhole, and a what-if analyzer that can reason about the possible impact of link failures. For BDD operations, we use JDD, a BDD library for Java [34].

Dataset. Table 1 shows the datasets we use. The first six consist of updates of IPv4 forwarding rules, and the last two consist of updates of both IPv4 forwarding rules and ACL rules. The first three datasets are generated by Delta-net [20] using the ONOS SDN-IP application [6], and the Internet2 dataset is from [5]. The Stanford dataset [2] consists of both IPv4 forwarding rules and ACL rules, and the original Purdue dataset [32] consists of only ACL rules. We generate forwarding rules for the Purdue dataset, using shortest path routing. Finally, we remove the ACL rules from these two datasets, and obtain another two pure-IP datasets Stanford* and Purdue*. Since the last five datasets are snapshots of rules, we generate a sequence of updates from each of them as follows. First, we add all the ACL rules (if any), one rule per ACL each time, and then all the forwarding rules, one rule per device each time. After that we delete these rules in the reverse order as they are inserted.

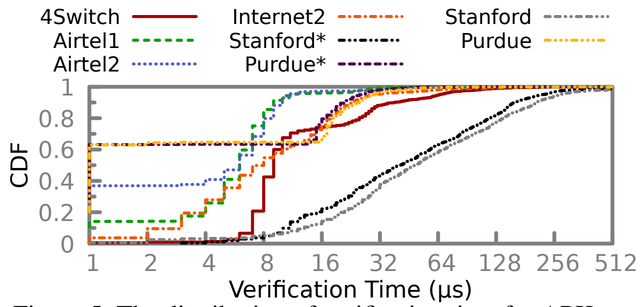

Figure 5: The distribution of verification time for APKeep.

Methods to compare. We compare APKeep with four data plane verification tools.

AP Verifier [37]. We use its open-source implementation in Java [4], and also the authors' implementation of incremental update algorithms [3]. We modify it to process our rule updates, and implement an incremental loop checker for it.

Delta-net [20]. We implement an extended version of Delta-net using C++, referred to as **Delta-net$^{\mathbf{MF}}$**. It handles single-field IP forwarding rules in the same way as Delta-net, and handles multi-field ACL rules using a multi-layered tree approach as in VeriFlow. Note, Delta-net^{MF} may not be the best approach for extending Delta-net so that it can apply to multiple fields.

VeriFlow [24]. We use its open-source implementation in C. Since VeriFlow only supports match fields expressed with prefixes, an ACL rule matching port ranges may be split into multiple ones which match prefixes.

NetPlumber [22]. We use its open-source implementation in C++ [2]. Since NetPlumber takes transfer function (TF) rule as input, we translate our rule updates into equivalent TF rule updates. Prior to update, we insert all the default rules created by NetPlumber since the insertion and deletion of them take a long time, as confirmed by the paper. We attach one source node to each device for NetPlumber to inject “flows” in the network model.

Apart from the above four methods, we also consider **APKeep^{-}**, standing for APKeep without merging predicates. For benchmark purpose, we let each method check loops after each update. All the experiments run on a Linux desktop with a 3.0GHz Intel Core i5 CPU and 32GB RAM.

5.2 Verification Time

Figure 5 shows the verification time of APKeep. We can see for all datasets, the verification time is less than 250μs for 90% of updates. Table 2 compares the average running time of APKeep with the other methods. For datasets with only IP forwarding rules, the running time of APKeep is comparable to Delta-net^{MF}, and much shorter than the other methods. For the 4Switch dataset, APKeep is 253×, 128×, and 937× faster than AP Verifier and VeriFlow, and NetPlumber, respectively. Note that NetPlumber is relatively slow since it models each rule as a node, and computes all the flows through these rules. Thus, its model is more fine-grained than APKeep, but incurs a relatively high cost. Surprisingly, APKeep^{-} is even faster than APKeep on some datasets. The reason is that these datasets have a rather small number of ECs (see Table 3), and therefore merging ECs incurs additional overhead without paying off. However, for the 4Switch dataset, APKeep^{-} is much slower as it has 271,793 ECs, while APKeep has only 557 ECs. For datasets with multiple match fields, all other methods including APKeep^{-} either incur a prohibitively long running time or run out of memory. For the Purdue dataset, only APKeep runs to completion, with an average running time of 13μs; all other methods either time out or run out of memory. This demonstrates existing methods can hardly meet the realtime requirement when the rules to update match multiple fields.

5.3 Number of Equivalence Classes

We observe that the number of ECs heavily impacts the running time of realtime data plane verifiers. To confirm this, we report the number of ECs maintained by APKeep, APKeep^{-}, and Delta-net^{MF} in Table 3.

We can see that when there is a single match field, APKeep^{-} computes slightly fewer ECs than Delta-net^{MF}. The reduction is due to the fact that predicates can encode arbitrary packet sets, rather than ranges. By merging predicates, APKeep computes much fewer ECs than APKeep^{-}. This indicates that using predicates alone cannot efficiently reduce the number of ECs.

The number of ECs computed by Delta-net^{MF} grows from 2283 to 15 million after only 686 ACL rules are inserted in the Stanford dataset, and reaches over 100 million after 2,707 ACL rules are inserted in the Purdue dataset. Note that Delta-net^{MF} actually does not run to completion for Stanford and Purdue datasets, and the numbers are counted by running only the functions related to the creation of ECs. In contrast, APKeep computes only 515 and 4,160 ECs for these two datasets, a 99.99% reduction compared with Delta-net^{MF}.

The above results show that range-based EC representation easily leads to an explosion of ECs when there are only a small number of rules with multiple match fields. On the other hand, by representing ECs with predicates, and updating the minimum number predicates, APKeep can dramatically reduce the total number of ECs, thereby achieving a fast verification speed with small memory footprint.

Figure 6 shows the number of ECs maintained by APKeep and Delta-net^{MF} during the updates. The Airtel1 dataset consists of rule insertions and deletions which are generated to react to link failures. Thus, the number of rules is small during update, and the total number of ECs is also quite small. The 4Switch dataset only has rule insertions; and the last three datasets insert all rules and remove them later. Thus, for Internet2 and Stanford, APKeep finally has only one and two predicates, respectively. For the Purdue dataset, since both

Table 2: Average verification time of different methods (D^{MF} is shorthand for Delta-net^{MF}). TO means timeout ($>$ 24h), and MO means memory overflow ($>$ 32GB).

Network	Average verification time (μs)						Percentage $< 250\mu$s					
	AP Verifier	VeriFlow	NetPlumber	D^{MF}	APKeep$^-$	**APKeep**	AP Verifier	VeriFlow	NetPlumber	D^{MF}	APKeep$^-$	**APKeep**

Purdue*	1,176	939	267	77.4%
Stanford	15,100,968	842,734	515	99.99%
Purdue	>104,743,229	>168,891	4,160	99.99%

Table 4: Verification time for "what if" queries. The results for Delta-net were from paper [20], whose experiments ran on a 3.47GHz Intel Xeon CPU.

Network	# Rules	Average query time (ms)		+Loops (ms)	
		Delta-net	APKeep	Delta-net	APKeep
Airtel	38,100	0.04	0.02	2.3	0.13
4Switch	1,120,000	21.1	0.48	128.1	1.37

Delta-net^{MF} and APKeep$^-$ cannot run to completion, we only show the number for the first 3000 updates.

5.4 Answering "What if" Queries

We evaluate the running time for APKeep to answer "what if" queries. In particular, we consider the query "what is the fate of packets that use a link if the link fails?". To answer this query, Delta-net constructs a forwarding graph using those ECs on that link, and is reported to be 10× faster than VeriFlow. Thus, we only compare our results to those of Delta-net. In Table 4, Columns 3-4 show the average query time, and Columns 5-6 show the average query time if we additionally check loops. We can see that APKeep is 17× and 93× faster than Delta-net in overall query time for the Airtel and 4Switch datasets, respectively. The reason is that the number of ECs in APKeep is much smaller than that in Delta-net.

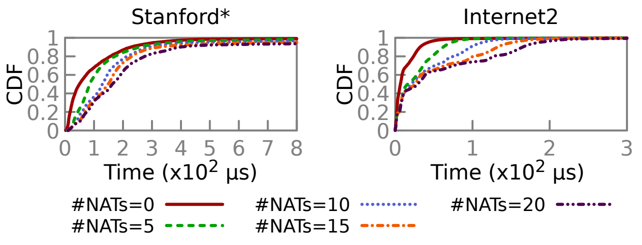

Figure 7: The cumulative distribution of verification time when different number of NATs are added.

5.5 Updating Rewrite Rules

We evaluate the time for APKeep to handle updates of rewrite rules. We use the Stanford* and Purdue* dataset, and add NAT rules into the network as follows. First, for each dataset, we find all the edge ports: an edge port holds a non-empty set of predicates, and is not connected to any other switches. Then, for each edge port, we randomly select a predicate associated with it, and compute an IP prefix that satisfies the predicate. Finally, for each IP prefix, we generate 25 NAT rules, each of which translates an IP address to another address belonging to a different IP prefix. We place the updates of NAT rules after the updates of forwarding rules.

Figure 7 shows the running time of APKeep for different numbers of NATs ranging from 0 to 20. Since each NAT has 25 rules, the number of NAT rules ranges from 0 to 1000. We can see that the running time of APKeep is mostly less than 1ms, and scales well with the number of NAT rules.

6 Related Work

Offline data plane verification was originally studied by Xie et al. [36], and later advanced by FlowChecker [10], Anteater [27], HSA [23], and NoD [25]. These tools take a snapshot of the data plane state, and check whether it satisfies network invariants like blackhole-freedom, loop-freedom, etc. AP Verifier [37–39] uses Binary Decision Diagraph (BDD) to compute a predicate for each port, and uses all port predicates to generate atomic predicates, which are the minimum set of ECs. APKeep differs in that it builds on a modular element-level model that is much more expressive than the monolithic model used by AP Verifier. In addition, APKeep incrementally updates the ECs instead of re-computing them from scratch, thereby achieving up to 200× speedup compared to the incremental version of AP Verifier (Table 2). To scale verification to large networks, Libra [40] uses MapReduce to parallelize verification. Plotkin et al. [29] propose to transform large networks into smaller ones for scalable verification, based on network surgery and symmetry. APKeep can leverage this technique to reduce network size, thereby scaling to larger networks. RCDC [15] decomposes data plane verification into the validation of local contracts. However, RCDC assumes structured datacenter networks so as to track the topology and address locality, while APKeep targets general networks. SymNet [31] and VMN [28] focus on verifying stateful data planes with middleboxes.

Realtime data plane verification incrementally checks the network data plane for each update in real time. NetPlumber [22] builds on the plumbing graph model, where each node is a rule and a flow is a set of packets traversing the same sequence of rules. Thus, the model has a finer grain than PPM, while the downside is that updating the model is relatively slow (Table 2). VeriFlow [24] achieves a smaller verification time ($<$ 1ms) by computing the equivalence classes (ECs) affected by an update, and checking the forwarding graph of each affected EC. Delta-net [20] further reduces the verification time by incrementally maintaining a single EC-labelled graph, rather than constructing multiple graphs for each update. VeriFlow and Delta-net can achieve sub-millisecond verification time for updates of single-field IP forwarding rules. Howerver, they may suffer from the problem of EC explosion when there are multi-field rules, and cannot handle updates of rewriting rules.

Representation of ECs. Bjørner et al. propose ddNF [14], a new data structure for representing ECs, and show it outperforms BDD on datasets consisting of forwarding rules. However, the set of ECs represented using ddNF may not be minimal. #PEC [21] introduces a new lattice-theoretic method which can construct the minimum number of ECs, faster than using BDD. #PEC may serve as a better foundation for multi-field extension of Delta-net, and it would also be interesting to study how to leverage #PEC to further speed up APKeep.

Control plane verification checks whether protocol configurations are correct [9, 12, 13, 16, 18, 19, 30]. They are orthogonal to APKeep, while tools like Batfish [18] may use APKeep to speed up the verification of generated data planes.

7 Discussion

Model modularity vs. number of ECs. Modeling the network at a fine granularity can make the update more efficient, while may also increase the number of ECs. The reason is that the model may have more different forwarding behaviors, which need to be represented with more ECs. For example, even two packets behave the same at a device level, their behaviors may differ in the intra-device processing, and thus should be represented with different ECs. Thus, there is a tradeoff between the model granularity and the number of ECs. It will be interesting to further navigate such tradeoff in the future.

Fetching data plane state. APKeep fetches the whole data plane state only once in the bootstrap stage, and only fetches data plane updates afterwards, whose cost can be much less compared to fetching the whole data plane. To ensure timeliness, APKeep needs to fetch the updates from devices at a sufficient frequency. We are aware some new devices have already provided APIs for fetching FIB updates, and we expect this feature will be supported by more devices in the future.

Ensuring update consistency. Since the data plane state is in continuous transition, a violation can be falsely triggered by a transient state. APKeep can be made robust to such inconsistency as follows. If an update fails the verification of an invariant, APKeep flags it as suspicious without raising an alarm. After a configured time window, APKeep checks the invariant again to confirm whether the update is a true violation. Detailed design is left as one of our future work.

Why microsecond-level verification. One major purpose of speeding up incremental verification is to ensure the network model, which verification is based on, can keep up with fast network updates. For example, in a large datacenter with 1k devices, a 1ms model update time only allows the verifier to keep up with an average network update rate of 1 update per device every second. Thus, further speeding up data plane verifiers can scale the verification to larger network size and higher data plane update rate.

8 Conclusion

This paper presented APKeep, a new realtime data plane verifier. APKeep builds atop PPM, a modular network model that is expressive for real devices, and incrementally maintains the minimum number of equivalence classes in realtime. We showed that for real updates consisting of both forwarding and ACL rules, all other methods either ran out of memory or incurred a prohibitively long verification time, while APKeep still achieved a sub-millisecond verification time.

A Proof of Theorem 1

Proof. According to Definition 1, it is easy to see that a set of ECs is minimum if the other direction of condition (3) also holds, i.e., if two packets are forwarded to the same port at each element, then they must belong to the same EC. Therefore, define (3)' by replacing "$\Rightarrow$" with "$\Leftrightarrow$" in (3), and we need to prove that conditions (1)(2)(3)' hold for all predicates in the PPM model.

Clearly, these conditions hold initially when there are no updates: each element has a single default rule, and there is only one `True` predicate, which is assigned to the default/deny/id port depending on element type. We prove the theorem by induction: if the conditions hold before an update, then they still hold after the update.

Let e be the element whose rule is updated. For condition (1)(2), it is clear that `transfer` operations do not modify predicates, and thus have no effect on these conditions. Also, since `split` and `merge` only move part of one predicate into another one, they will not break these conditions, either. In the following, we show both directions of (3)' hold.

$\Rightarrow$: Suppose $h_1, h_2 \in c$ after update, we show they appear in the same set of ports. There are two cases. (1) h_1 and h_2 belong to the same predicate before update. Then, we know $Port_s(h_1) = Port_s(h_2), \forall s$, and the update only changes $Port_e(h_1)$ and $Port_e(h_2)$. Then, we only need to show $Port_e(h_1) = Port_e(h_2)$ after update. Clearly this holds if neither h_1 or h_2 changes its port at e. Suppose at least one of them changes its port at e, and let $Port_e(h_1) = Port_e(h_2) = p_a$ before update. Without loss of generality, suppose h_1 changes its port to $p_b \neq p_a$, we prove by contradiction that h_2 must have also changed its port to p_b. Assume h_2 either keeps its port unchanged or changes its port to $p_c \neq p_b$. Suppose $h_1 \in c_1$ and $h_2 \in c_2$ after transferring predicates, then c_1 appears at port p_b, and c_2 appears at port p_a or p_c. Since c_1 and c_2 appear in different ports at e, they cannot be merged, contradicting our assumption that $h_1, h_2 \in c$ after update. (2) h_1 and h_2 belong to different predicates before update. Let $h_1 \in c_1$ and $h_2 \in c_2$ before update, then c_1 and c_2 must have been merged into c. That is, c_1 and/or c_2 must have been transferred to the same port after update, which implies that h_1 and h_2 must have changed their ports to the same one at e.

$\Leftarrow$: Suppose $Port_s(h_1) = Port_s(h_2), \forall s$ after update, there are two cases. (1) $h_1, h_2 \in c'$ before update. Then, $Port_s(h_1) = Port_s(h_2), \forall s$ before update, implying that both h_1 and h_2 do not change their ports or change to the same port. If they do not change their ports, then they will still belong to the same predicate (either c' if c' is not split or $c' \wedge \neg\delta$ if c is split). If they change their ports, then a predicate including h_1, h_2 (either c' if c' is not split or $c' \wedge \delta$ if c' is split) will be transferred to a new port, and they will still belong to the same predicate, no matter whether the transferred predicate is merged or not. (2) $h_1 \in c_1, h_2 \in c_2$ before update, then we know $Port_e(h_1) \neq Port_e(h_2)$ before update, and thus at least one of them must have changed its port. Without loss of generality, suppose h_1 has changed its port such that $Port_s(h_1) = Port_s(h_2)$ after the change, and let c' be the transferred predicate satisfying $h_1 \in c'$. This will trigger our algorithm to merge c' and c_2. $\square$

Algorithm 4: `ConstructDeltaForwardingGraph`(D)

```
Input: D: the set of transferred predicates.
Output: G: the forwarding graph used for invariant checking.
$V \leftarrow \{\}, E \leftarrow \{\}, A \leftarrow \perp$;
foreach $\delta \in D$ do
    foreach $port \in Port(\delta)$ do
        $s1 \leftarrow$ the node holding $port$;
        if $s1 \notin V$ then
            $V \leftarrow V \cup \{s1\}$;
        $s2 \leftarrow$ the node connected to $port$;
        if $s2 \notin V$ then
            $V \leftarrow V \cup \{s2\}$;
        if $(s1, s2) \notin E$ then
            $A(s1, s2) \leftarrow \{\}$;
            $E \leftarrow E \cup \{(s1, s2)\}$;
        $A(s1, s2) \leftarrow A(s1, s2) \cup \{\delta\}$;
return $G(V, E, A)$;
```

B Algorithms for Constructing Delta Forwarding Graphs and Checking Invariants

Constructing delta forwarding graphs. Algorithm 4 summarizes the process of constructing delta forwarding graphs. It takes the set of transferred predicates, denoted as D, computed by Algorithm 2, and returns a delta forwarding graph, denoted as $G(V,E,A)$. Here, V is the set of nodes, E is the set of edges, and $A: E \rightarrow 2^{\mathcal{C}}$ is a map from each edge to the set of predicates allowed on that edge ($\mathcal{C}$ denotes the set of all predicates). That is, $A(s1,s2)$ is the set of predicates that can be sent from switch $s1$ to switch $s2$. First, V, E, and A are initialized (Line 1). For each predicate δ in D, APKeep iterates over each *port* in the port set of δ (Lines 2-3). If the node $s1$ holding *port* is not in the node set V, then $s1$ is added into V (Lines 4-6). Similarly, if the node directly connected to *port* is not in V, then $s2$ is also added into V (Lines 7-9). Note here if the *port* is “default”, we assume it is connected to a virtual node named “default”. If the edge $(s1,s2)$ is not in the edge set E, then it is added into E, and the mapping $A(s1,s2)$ is initialized to empty set (Lines 10-12). Finally, the transferred predicate δ is added into the set $A(s1,s2)$ (Line 13).

Checking invariants. With the delta forwarding graph G, operators can check network invariants by traversing G. Algorithm 5 shows an example program for checking blackhole-freedom and loop-freedom (defined in § 3.3). The algorithm starts the traversal from each node $s \in V$. Here V includes all nodes corresponding to the element where the rule is updated. Before each traversal, the algorithm initializes *pset*, the current set of predicates, to D, and *history*, the nodes that have been visited, to empty set (Lines 2-3). The traversal stops when *pset* becomes empty (Line 6-7) or the visited node is already in *history* (Line 8-10), meaning a loop is detected, or the next hop is *default* (Line 12-14), meaning packets in *pset* match no forwarding rule in the corresponding device, i.e., a blackhole is detected. Otherwise, the algorithm updates *pset* and *history* and traverses the next hop (Line 15).

Algorithm 5: `CheckInvariants`(G, D, V)

```
Input: G: the forwarding graph used for invariant checking, D:
       the set of transferred predicates, V: the set of nodes to
       start check.
foreach $s \in V$ do
    $pset \leftarrow D$;
    $history \leftarrow \{\}$;
    Traverse ($s, predicates, history$);
Function Traverse($s, pset, history$):
    if $pset = \emptyset$ then
        return;
    if $s \in history$ then
        Alter('loop');
        return;
    foreach $(s, s') \in E$ do
        if $s' = default$ then
            Alter('backhole');
            return;
        Traverse ($s', pset \wedge A(s, s'), history \cup \{s\}$);
    return;
```

Table 5: Memory cost. TO means timeout (> 24h), and MO means memory overflow (> 32GB).

Network	Memory cost (MB)				
	AP Verifier	VeriFlow	NetPlumber	Delta-net^{MF}	APKeep
Airtel1	417	508	4,283	61	180
Airtel2	5170	16,049	TO	74	193
4Switch	7,722	2,520	1,749	785	936
Internet2	360	206	613	44	87
Stanford*	6	16	4,971	25	3
Purdue*	1,465	1,414	MO	3,414	648
Stanford	6	98	8,607	MO	3
Purdue	TO	TO	MO	MO	744

C Memory Cost

We compare the memory cost of APKeep with the other four methods. Not surprisingly, for single-field datasets, the memory cost of APKeep is comparable to Delta-net^{MF}, and both of them have smaller memory footprint than others. For the multi-field Stanford dataset, Delta-net^{MF} runs out of 32GB memory. For the multi-field Purdue dataset, AP Verifier and VeriFlow do not run to completion within 24 hours; NetPlumber and Delta-net^{MF} run out of 32GB memory. APKeep still maintains a small memory footprint for these two multi-field datasets.

Liveness Verification of Stateful Network Functions

Abstract

Network verification tools focus almost exclusively on various safety properties such as "reachability" invariants, *e.g.,* is there a path from host A to host B? Thus, they are inapplicable to providing strong correctness guarantees for modern programmable networks that increasingly rely on stateful *network functions*. Correct operations of such networks depend on the validity of a larger set of properties, in particular *liveness* properties. For instance, a stateful firewall that only allows solicited external traffic works correctly if it *eventually* detects and blocks malicious connections, *e.g.,* if it eventually blocks an external host E that tries to reach the internal host I before receiving a request from I.

Alas, verifying liveness properties is computationally expensive and, in some cases, undecidable. Existing verification techniques do not scale to verify such properties. In this work, we provide a compositional programming abstraction, model the programs expressed in this abstraction using compact Boolean formulas, and show that verification of complex properties is fast on these formulas, *e.g.,* for a 100-host network, these formulas result in 8× speedup in the verification of key properties of a UDP flood mitigation function compared to a naive baseline. We also provide a compiler that translates the programs written using our abstraction to P4 programs.

1 Introduction

In recent years, network verification has emerged as a crucial framework to check if networks satisfy important properties. While there are a variety of tools that differ in their focus (*e.g.,* verifying current data plane snapshot vs. verifying a network's control plane under failures), they all share a common attribute: they focus mainly on verifying various flavors of reachability invariants: Is a point in the network reachable from another point [33, 34, 42, 43]? Is there a loop-free path between them [33, 34, 42, 43]? Is the path congested [27,29,38]? Does it traverse a waypoint [41,58]? Is the reachability preserved under link failures or external messages [10, 26]? Are all datacenter shortest paths available for routing [30]? *etc.* Crucially, these tools leave out a richer set of properties that depend on networks guaranteeing *liveness*.

Networks today increasingly deploy complex and stateful network functions such as intrusion detection/prevention systems (IDPS) that monitor traffic for malicious activity and policy violations, and they prevent such activities. To rely on such networks, operators need to verify if "something good (a desired property) eventually happens" [47]—i.e., liveness. As a concrete example, consider a stateful firewall with the policy that a host E external to an enterprise is only allowed to send traffic to an internal host I if I sends a request to E first. The liveness property here is "will a host E that should be allowed to send traffic to I (*i.e., E* was first contacted by I) eventually get whitelisted?", or more precisely that "the event of I sending traffic to E leads to the firewall's whitelisting of E" (§3). Existing reachability-centric tools cannot verify this property: the existence of paths from I to E does not show whether any packet has actually traversed that path; similarly, the reachability of I from E does not give any guarantees whether it was established before or after I sent traffic to E.

Recent work has shown that reachability verification can be made efficient by operating on *Equivalence Classes* (ECs), *i.e.,* groups of packets that experience the same forwarding behavior [33, 34, 43] on a *static* snapshot of the network state. However, verifying liveness is not amenable to such techniques as liveness properties reason about progress and concern the succession of events in dynamic systems. They cannot be verified on a static snapshot of the system.

A dynamic network, in which the state changes, can be modeled as a state machine and, conceptually, existing static verification approaches [35] could be extended to reason about properties of the states and transitions of this machine (§3). However, this naive approach results in state explosion as the network size increases and is therefore impractical (§3, §4).

In this paper, we argue that the goal of verifying liveness properties is achievable using a top-down *function-oriented* strategy that rethinks network abstractions with the efficiency

[*]Work done during an internship at Johns Hopkins University.

of verification in mind. To realize this vision: (a) we provide network programmers with a simple, familiar *abstraction* of one big switch to express their intent. This abstraction enforces the logical separation of different network functions (§2). (b) We then *model* the program as a compact "packet-less" data structure that, unlike the common approach of modeling the forwarding behavior for classes of packets [33,34,42,43], abstracts away the explicit notion of packets and focuses instead on the entities responsible for implementing functions: packet handling rules. (c) We build and evaluate a prototype of our system.

Abstraction: We provide a unified abstraction of one big switch for both control and data planes that conceptually handles all packets. This abstraction closely resembles the simple, familiar data plane abstraction of one big switch directly connecting all hosts [36, 49]. In contrast to the data plane one-big-switch, our abstraction does not require a separate control plane to program it. To reduce verification time, we enforce a *functional decomposition* by requiring the user to implement each function using a separate logical flow table.

Modeling and verification: For verifying properties, similar to prior work [28], we focus exclusively on network behaviors *visible* to users. This enables us to model the system behavior using a compact "packet-less" data structure that abstracts away any details invisible to users, such as the hop-by-hop journey of the packet inside the network [33,34,42,43,52] or even the explicit notion of packets or classes of packets (§3). The packet-less structure models changes in the forwarding behavior as Boolean transitions. We demonstrate the verification efficiency of the packet-less model experimentally (§4), *e.g.,* for a UDP flood mitigation function, within a 1,000*sec.* time-bound, it enables verifying a key liveness property (*host A is eventually blocked*) for networks that are $3.5\times$ larger than those verifiable with the aforementioned naive approach (extending static verification to deal with network states and dynamic transitions).

Implementation and evaluation: We develop a prototype of our design that exposes two interfaces (to express functions on the one-big-switch abstraction and specify verification properties) and a P4 compiler that converts such functions to programs executable on today's programmable devices. Our evaluations show the expressiveness of our interfaces, their low overhead, and the efficiency of our verification design, *e.g.,* for a 100-host network, the packet-less model verifies key liveness properties of a UDP flood mitigation function $8\times$ faster than a packet-based baseline—a gap that increases with the network scale (§4).

2 A Unified Switch Abstraction

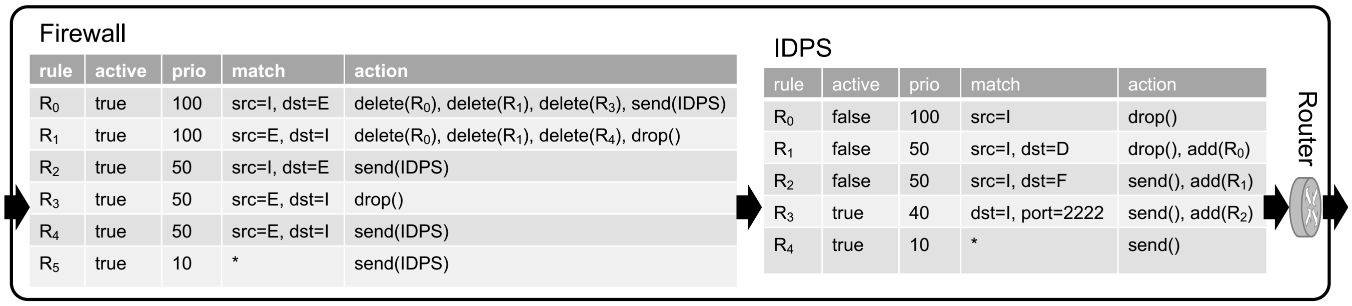
To simplify programming and relieve network programmers of the burden of writing distributed, multi-tier programs, we provide the abstraction of a single, centralized switch that conceptually handles *every* packet. This approach for simplifying programming by having a single unified abstraction for both the control plane and data plane is inspired by Maple [59] and deployed in Flowlog [46]. In contrast to Maple that allows programmers to use standard programming languages and Flowlog's SQL-like language, we start with the most basic and familiar data plane abstraction in networks: one switch that directly connects all hosts. We then augment this abstraction to make it programmable. Similar to Maple and Flowlog, we proactively compile the programs written on our abstraction to control and data plane programs executable in today's networks (§4). We describe our abstraction, its distinction from the common one-big-switch abstraction, and how several canonical network functions can be programmed on it, in turn.

One-big-switch: A common data plane abstraction in networking is that of one logical switch with multiple flow tables, each containing a set of rules, that directly connects all users' hosts together [5, 32, 36, 44]. A rule generally includes: (a) a match field to match against packet headers and ingress ports, (b) priority to determine the matching precedence of rules, (c) counters that are updated when packets are matched, (d) timers that show the time that the rule will be expired and removed from the switch, and (e) actions that are executed when a packet matches the match field of an unexpired rule that has the highest priority among all unexpired rules. These actions could result in changes in the packet, dropping it, or forwarding it. We use *R*.`match`, *R*.`priority`, *R*.`counter`, *R*.`timer`, and *R*.`action` to denote the match, priority, counter, timer, and action of rule *R*.

Our goal is to provide a similar abstraction to this familiar abstraction while making it programmable and amenable to fast verification. In particular, rather than a static, stateless switch, the programmer should be able to implement *dynamic* functions whose behaviors change over time based on traffic. Plus, she should be able to focus solely on the high-level *functionality* that she wishes her switch to provide (*e.g.,* the firewall policies), and the provider of the abstraction is responsible for handling the low-level, distributed implementation of the functionality including reachability (*e.g.,* ensuring that all required packets are correctly forwarded through the firewall). To further assist the user in developing her desired functions, an ideal framework should also provide modular programming and separate the functionality of a program into independent modules. Towards these goals, we make the following alteration in the one-big-switch abstraction [5, 36]:

Add/delete actions: In addition to the standard SDN actions (forward, drop, *etc.*), we allow the execution of a rule to add or remove rules from the switch. As an example, to program a stateful firewall that allows an external host E to talk to an internal host I only after I sends E a request, the switch needs a rule that, upon receiving a request from I to E, alters its state to allow E to I communication.

Actions `add(`*R*`)` and `delete(`*R*`)` show that the execution of the rule results in, respectively, adding and deleting rule



rule	active	prio	match	action
R_0	true	100	src=I, dst=E	delete(R_0), delete(R_1), delete(R_3), send(IDPS)
R_1	true	100	src=E, dst=I	delete(R_0), delete(R_1), delete(R_4), drop()
R_2	true	50	src=I, dst=E	send(IDPS)
R_3	true	50	src=E, dst=I	drop()
R_4	true	50	src=E, dst=I	send(IDPS)
R_5	true	10	*	send(IDPS)

rule	active	prio	match	action
R_0	false	100	src=I	drop()
R_1	false	50	src=I, dst=D	drop(), add(R_0)
R_2	false	50	src=I, dst=F	send(), add(R_1)
R_3	true	40	dst=I, port=2222	send(), add(R_2)
R_4	true	10	*	send()

Figure 1: One-big-switch implements firewall and IDPS.

R. To each rule R, we add a boolean variable R.`active` to show if the rule is currently active on the switch, *i.e.,* packets are matched against it. As an example, the initial state R_0.`active=true`; R_1.`active=false`; R_0.`action=add`(R_1) shows that, unlike R_0, rule R_1 is not initially active and will be activated as a result of R_0's execution.

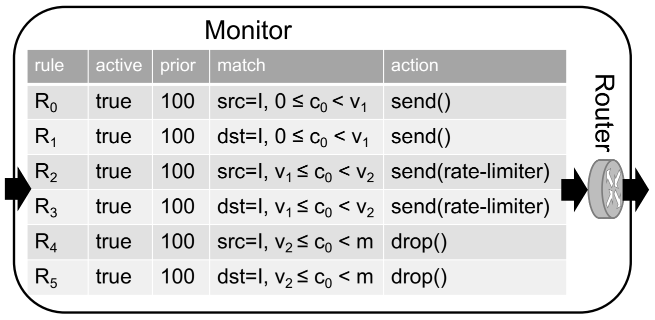
Actionable measurements: For a rule R_i, we allow users to define match fields as predicates not just on packet headers (*e.g., src*=A) but also as conditions in the forms of $l_i \leq c_j < u_i$ on counters, where c_j is the j^{th} counter and l_i and u_i are constants. This condition expresses that for the rule to match a packet, the value of counter c_j should be in the $[l_i, u_i)$ interval.[1] We assume that counters are bounded in the range $[0, m)$. Counters enable the network programmer to easily write critical network functions that depend on traffic statistics such as security applications that detect SYN flood, port scanning, DNS amplification, *etc.* [7, 16, 23] and campus network monitors [35] that block users once their usage exceeds the quota specified by the campus policy. Whenever a rule with a counter is executed on a packet, the counter value is incremented by one. We allow multiple rules to share a counter.

Other optimizations: To improve programmability and verification speed, we also perform the following optimizations: (a) *Functional decomposition:* the user is provided separate tables for each of her network functions, *e.g.,* one table for her firewall, one table for her load balancer, *etc.* If a packet matching a rule R in function F_1 needs to be sent to another function F_2, *e.g.,* an IDPS rule needs to send a packet to the traffic scrubber, this is expressed as R.`action=send`(F_2) in table F_1. (b) *Declarative routing:* Our abstraction provides routing and forwarding as a service, that we call the *router*, to its users. This liberates the user from computing paths and updating them after infrastructure changes, such as changes in policy, topology, and addressing. The user only declares the goal that a packet should reach a destination and delegates the task of figuring out *how* this is done to the provider. Action rules `send`(A) and `send`() simply express the intent of the user to forward a matching packet to the endpoint with ID A and to the packet's destination, respectively. In our prototype, for implementing our declarative routing service, we deploy a basic shortest path forwarding function [1]. (c) *Symbolic rule representation:* the original one-big-switch rules can express a restricted subset of predicates on explicit packet headers, *e.g.,* `src-IP=10.0.0.1` $\wedge$ `dst-IP=10.0.0.2`. Declarative routing enables us to provide a higher-level abstraction to express any general predicate on sets of endpoint identities and header fields, *e.g.,* the programmer can declare a forwarding policy for packets sent to or from a set of hosts called T via a single rule R: R.`match=(src=`T`∨dst=`T`)`, R.`action=send`(), without managing low-level details such as the physical locations and IP addresses of T's hosts.

The changes above turn the data plane one-big-switch abstraction into a unified abstraction that can be efficiently verified: add/delete actions and actionable measurements make the abstraction programmable, and other optimizations accelerate the verification process by reducing the program size (§4). To further assist with efficient verification, our abstraction is designed to have less expressive power than Turing-complete control plane programming languages [46] such as Floodlight [4] and Pyretic [44]. We find experimentally that despite being computationally universal, in practice, control planes perform only a limited set of operations, *e.g.,* adding and deleting rules based on traffic patterns. Our one-big-switch abstraction is designed to be capable of performing similar computations and is therefore expressive enough to program a wide range of network functions. Table 1 lists the functions of a few common control planes and recent network abstractions that we re-wrote on top of our abstraction (implementations in §8). To support the functions that cannot be expressed on top of our abstraction, such as content-based security policies, our framework allows the use of external libraries in conjunction with our abstraction. However, we can only verify the programs expressed on our abstraction.

Examples. Figure 1 shows an illustrative example where the user deploys two tables to implement a chain of two canonical functions: a stateful firewall followed by an IDPS. The first table implements a stateful firewall at the periphery of an enterprise that allows endpoint E (*e.g.,* as an external host) to talk to I (*e.g.,* as an internal host) only if I sends a request to E first. Initially, the table has high priority rules that "watch for" traffic between I and E (R_0 and R_1). If traffic from E to I

[1] If the rule only increases the value of c_j when executed without defining a condition on c_j, we assume l_i=0, and u_i= m, where m is the maximum value supported for counters.



rule	active	prior	match	action
R_0	true	100	src=I, $0 \le c_0 < v_1$	send()
R_1	true	100	dst=I, $0 \le c_0 < v_1$	send()
R_2	true	100	src=I, $v_1 \le c_0 < v_2$	send(rate-limiter)
R_3	true	100	dst=I, $v_1 \le c_0 < v_2$	send(rate-limiter)
R_4	true	100	src=I, $v_2 \le c_0 < m$	drop()
R_5	true	100	dst=I, $v_2 \le c_0 < m$	drop()

Figure 2: One-big-switch implements a monitor.

is observed first, the execution of rule R_1 drops the traffic and changes the state to block E from reaching I. Receiving traffic from I to E first, however, triggers the execution of R_0 which in turn allows bidirectional traffic between I and E to pass through the firewall. Packets not discarded by the firewall are always sent to the next function, the IDPS explained below, for further monitoring. Note that when defining rules in the one-big-switch abstraction, the match fields of the rules must be defined in a way that at least one rule matches each received packet.

The second table implements an IDPS that detects and blocks Trojans. The IDPS determines if the internal host I is infected and needs to be blocked based on a recognizable fingerprint of a backdoor application [16] with the following sequence of operations: (i) I receives a connection on port 2222, (ii) I connects to an FTP server F, and (iii) I tries to connect to the database server D.

Initially, the table contains two active rules: R_3 that matches traffic destined to I on port 2222, and a lower priority rule R_4 that matches all other traffic. Both rules forward the traffic to its destination. The execution of R_3, however, corresponds with the (i) operation above. Once triggered, it activates R_2 that is executed once I tries to reach F (operation (ii)). R_2's execution, in turn, activates R_1, and once I tries to send traffic to D (operation (iii)), it gets blocked (R_1 activates R_0). Once the traffic goes through this pipeline of tables, it is handed to the router to be delivered to its destination.

Figure 2 shows another example for an application that implements a simple campus policy in which an inside-campus host I is allowed to send and receive data before hitting a utilization cap v_1. Once its usage exceeds v_1, but before it reaches v_2, its traffic is routed through a rate limiter. After its usage passes v_2, its access is blocked.[2] A survey of campus network policies shows that universities commonly deploy such usage-based rate-limiting [35]. While for simplicity, we only provide examples of linear chaining of functions in this section (*e.g.,* IDPS after firewall), our abstraction is general enough to express arbitrary dependencies between functions. An example is provided in §8.

[2]In practice, such policies are usually enforced periodically, *e.g.,* the rules (along with their counters set to 0) are re-installed daily.

3 Function Verification

A standard approach for verifying liveness properties of dynamic systems is modeling the behavior of the system as a transition system and expressing its desired properties using temporal logics. The complexity and scalability of this approach depend on the size of the state machine. In this section, we show how we can model stateful dynamic network functions as compact, Boolean "packet-less" transition systems that can be verified efficiently. In §4, we show experimentally that this approach significantly reduces the average verification time for canonical applications compared to a naive packet-based baseline.

3.1 Network as a Transition System

We can model the network as a *transition system*, an analytical framework for reasoning about the behavior of dynamic systems where nodes represent the states of the system (each state corresponds to a valuation of system variables) and edges represent state transitions [8]. Each transition system has a set of initial states as well as a labeling function that maps each node to a set of properties that hold in that state. More formally, a *transition system TS* is a tuple (S, Act, I, AP, L):

- S is a set of states,
- Act is a set of actions,
- $\rightarrow \ \subseteq S \times Act \times S$ is a transition relation,
- $I \subseteq S$ is a set of initial states,
- AP is a set of atomic propositions, and
- $L : S \rightarrow 2^{AP}$ is a labeling function.

For convenience, we write $s \xrightarrow{\alpha} s'$ instead of (s, α, s'). Intuitively, a transition system starts in some initial state $s_0 \in I$ and evolves according to the transition relation $\rightarrow$. That is, if s is the current state, then a transition $s \xrightarrow{\alpha} s'$ is selected nondeterministically and taken, *i.e.,* the action α is performed, and the system evolves from state s into state s'.

In networks, the state of the network at each point is its forwarding state (*e.g.,* rules and counters), and transitions are the events that change the state, *e.g.,* policy updates. We next show the properties that can be expressed on these transition systems, explain what makes liveness verification hard, and demonstrate how we can model the network as a compact "packet-less" transition system.

Atomic propositions: *Atomic propositions* are Boolean-valued propositions that express simple known facts about the state of the system. We define these propositions as (h,a) pairs where h and a are, respectively, an equivalence class of packets, and a list of actions (*e.g.,* `send`(I)). For the network transition system TS, an atomic proposition (h,a) holds in a state $s \in S$ if action a applies to all the packets in h.

Labeling function: A *labeling function L* relates a set $L(s) \in 2^{AP}$ of atomic propositions to any state $s \in S$.[3] In the network transition system TS, L maps each state to the set

[3]Recall that 2^{AP} denotes the power set of atomic propositions.

of atomic propositions that hold in that state. That is, (h,a) exists in $L(s)$ if the list of actions a is applied to all the packets in h in state s.

Properties: An execution of a program can be shown as an infinite sequence of states: $s_0, s_1 \ldots$, where each state s_i results from executing a single action in state s_{i-1}.[4] A program's behavior is the set of all such sequences. A *property* is also defined as a set of such sequences [6]. A property *holds* in a program if the set of sequences defined by the program is contained in the property [6]. A partial execution is a finite sequence of program states.

Temporal logic to express properties: Temporal logic is an extension of ordinary logic that facilitates expressing properties via adding assertions about time. Here, we adopt linear temporal logic (LTL) [19], which can express various liveness and safety properties [37,47]. *Temporal logic assertions* are built up from atomic propositions using the ordinary logical operations $\wedge, \vee$, and $\neg$ and some temporal operators—if P and S are atomic propositions: (1) $\mathtt{G}P$ implies "now and forever" P holds, (2) $\mathtt{F}P$ implies "now or sometime in the future" P holds,[5] (3) $P \rightarrow S$ shows logical implication and implies that if P is true now then S will always be true, (4) $P\mathtt{U}S$ implies P remains true "until" S becomes true, and (5) $\mathtt{O}P$ implies P holds in the "next" state. Using the above temporal operators, we can express various properties, *e.g.,* $\mathtt{F}((\mathtt{src}{=}E \wedge \mathtt{dst}{=}I), \mathtt{send}(I))$ [47] asserts that eventually E-to-I packets are delivered, *i.e.,* E can eventually reach I.

3.2 Liveness vs. Safety

A key categorization of properties in distributed systems is into safety and liveness. The categorization is important as the two groups are proved using different techniques [6]. Informally, a *safety* property stipulates that some "bad thing" (deadlocks, two processes executing in critical sections simultaneously, *etc.*) never happens and *liveness* guarantees that "something good" (termination, starvation freedom, guaranteed service, *etc.*) eventually happens [47]. That is, for a property P to be a safety property, if P does not hold for an execution, then at some point, some irremediable "bad thing" must happen. Most of the properties verified in networks today are safety: if a property—such as reachability invariants (E is always reachable from I) [33, 34, 42, 43], waypoint (a certain class of traffic always traverses an intrusion detection system) [41, 58], congestion-freedom [27, 29, 38], and loop-freedom [33, 34, 42, 43]—is violated, then there is an identifiable point—such as a change in the latest snapshot of the network— at which the "bad thing" happens [6].

A partial execution γ is *live* for a property P if and only if there is a sequence of states β such that P holds in $\gamma\beta$. A property for which *all* partial executions are live is a liveness property. In contrast to safety, for liveness properties, no partial execution is irremediable—it is always possible for the required "good thing" to happen in the future [6]. This makes detecting liveness violations challenging as it fundamentally requires an exhaustive search of the entire state space of the network. In the next section, we discuss our approach to overcoming this challenge by modeling networks with compact transition systems. Some examples of liveness properties in networks are (a) the intrusion detection system *eventually* detects all infected hosts, (b) all hosts *eventually* become reachable, *e.g.,* after routing convergence, and (c) showing a recognizable fingerprint of a backdoor application *leads-to* the host being blocked. More generally, "event A leads-to event B" and "event B eventually happens" are two classes of liveness properties [47] as it is always possible for "something good" (*i.e.,* event B) to happen. An example of a property that includes liveness is *total correctness* which is composed of partial correctness (the program never generates an incorrect output; a safety property) and termination (the program generates an output; a liveness property) [6].

3.3 Packet-less Model

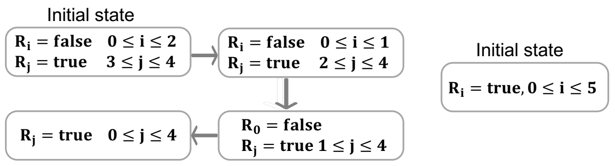
Feasibility of model checking is tied inherently to handling state explosion [19]. To mitigate this problem, we try to provide a compact "packet-less" structure that models only the entities that perform the functions in the network: packet handling rules. Plus, we model rules in the most abstract form: as *Boolean* variables, abstracting away all of the attributes of rules, such as their match fields, actions, and priorities. This is in contrast to pervasive network verification techniques that model the network behavior in terms of packets and equivalence classes of packets (ECs) [34, 35, 43].

Boolean variables and formulas provide a more compact way to represent the state space of a transition system. State-of-the-art model checkers like NuSMV [18] use symbolic techniques, such as Binary Decision Diagrams (BDDs), for efficiently exploring transition systems that have a Boolean representation. Such representations enable model checkers to explore extremely large state spaces efficiently [15]. We next explain how we can encode the behavior of dynamic network functions as packet-less models. We then show in §4 that this approach of packet-less modeling results in a significant reduction in the verification time of canonical network functions compared to a packet-based approach.

Compact, packet-less models: We initially model the network as a transition system TS with a single Boolean variable corresponding to each rule. This variable is true if the rule is active in the network and false otherwise. As a starting point, we abstract away counters, assuming that rules do not depend on them. (We will later refine this model to incorporate counter semantics.) Each node in this structure shows one **state** of the network defined by a valuation of Boolean

[4]Terminating executions are modeled as sequences where the last state reached by the terminating trace repeats infinitely.

[5]Note that $\mathtt{F}$ is the dual of $\mathtt{G}$, *i.e.,* $\mathtt{F}P$ is equivalent to $\neg\mathtt{G}\neg P$, where P is an atomic proposition [47].



Initial state
R_i = false $0 \le i \le 2$
R_j = true $3 \le j \le 4$
R_i = false $0 \le i \le 1$
R_j = true $2 \le j \le 4$
R_0 = false
R_j = true $1 \le j \le 4$
R_j = true $0 \le j \le 4$
Initial state
R_i = true, $0 \le i \le 5$

Figure 3: Packet-less models of the (a) IDPS and (b) monitor.

rule variables. S is the set of all these states. A rule can be *executed* in a state if, for at least one packet that it matches, it is the highest priority rule with value=`true` in that state. **Actions** are the execution of rules that update the forwarding state by adding or deleting rules, and **transitions** show how the state evolves as a result of these actions. If in a network state $s \in S$, rule R_i can be executed and its execution adds or deletes rules, then there is a transition $s \ \xrightarrow{R_i} \ s', s' \in S$, where for each added rule R_j, R_j=`true` in s' and for each deleted rule R_k, R_k=`false` in s'. In the initial state, the value of each R_i is equal to the initial value of R_i.`active` in the original program. Figure 3 shows the packet-less models for the IDPS and the campus monitor functions in Figures 1 and 2 (not including labeling functions).

Despite being more efficient, not explicitly modeling packets causes some key challenges: (1) Abstracting away the notion of packets makes it challenging to incorporate the semantics of traffic statistics such as counters. (2) As §3.1 explains, properties are defined on packets and whether a property holds in a network state depends on the actions of the highest priority rule that matches the packet. Thus, it is challenging to verify properties on a structure that abstracts away any explicit notion of packets, headers, priorities, *etc.* For the IDPS function in Figure 1, for example, the packet-less model has two rules in the initial state that can match packets sent to I with port number 2222, as Figure 3 (a) shows. With each rule modeled as a Boolean variable, it is not possible to determine which matching rule handles a packet (and therefore verify properties). We address these challenges next.

3.3.1 Boolean Formulas of Counters

The first challenge of the Boolean packet-less modeling is preserving the semantics of stateful programs with traffic counters. Recall that in packet-less models, we initially abstracted away counters. We next show how to refine these models to incorporate semantics of counters.

Refining states: To model counters, we observe that if the only variable that changes across a set of network states is a counter value and the value of this counter does not pass counter conditions, then the forwarding behavior remains the same in all those states. In the monitor function, the network behavior is identical for all counter values between 0 and v_1. This allows us to track counter *predicates*, Boolean-valued functions on counters, instead of actual counter values. In the monitor function, we can define the following three predicates: $(0 \le c_0 < v_1)$, $(v_1 \le c_0 < v_2)$, and $(v_2 \le c_0 < m)$. In the initial state, only the first predicate, $(0 \le c_0 < v_1)$, is true.

The fact that the forwarding behavior is determined not by exact counter values but by counters passing thresholds makes counters amenable to *predicate abstraction*, a powerful technique to mitigate the challenges of verifying programs with large base types such as integers [19]. This technique reduces the size of the model by tracking only predicates on data and eliminating invisible data variables.

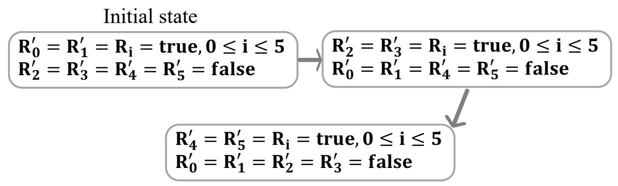
Concretely, counter conditions partition an interval into subintervals that may have distinct forwarding behaviors. Let R_i be a rule that depends on the j^{th} counter, c_j, *i.e.,* it is active if c_j's value is in the $[l_i, u_i)$ range, and $P_j = \text{order}(\cup_i(l_i \cup u_i))$, *i.e.,* an ordered list (in non-decreasing order) of all lower and upper bounds of all rules that depend on c_j. $P_{j,k}$, $l_{j,k}$, and $u_{j,k}$ denote, respectively, the k^{th} subinterval of counter c_j, its lower bound, and its upper bound. In the monitor program, $P_{0,0} = [0, v_1)$ is the first subinterval of the first counter, $l_{0,0} = 0$, and $u_{0,0} = v_1$. When the counter value is in this subinterval, rule R_0 can handle packets as its counter conditions, $(l_0 \le c_0 < u_0)$, are satisfied, *i.e.,* $(l_0 \le l_{0,0}) \wedge (u_{0,0} \le u_0)$ where $l_0 = 0$ and $u_0 = v_1$. R_2, on the other hand, cannot handle packets because its counter conditions are not satisfied in this subinterval, *i.e.,* $(l_2 \not\le l_{0,0}) \wedge (u_{0,0} \not\le u_2)$ where $l_2 = v_1$ and $u_2 = v_2$.

We refine TS by adding a Boolean variable R'_i for every rule R_i. Our goal is to set the value of this variable to `true` in a state s if the counter conditions of R_i are satisfied in s and to `false` otherwise. For any rule R_k that does not depend on counters, R'_k=`true`.[6] The numbers in P_j are the only places where R'_i variables of the rules that depend on c_j can change. In the monitor program, $P_0 = [0, v_1, v_2, m]$ lists the only points in the $[0, m)$ range where the condition of a rule that depends on counter c_0 such as R_0 can transition from `true` to `false` and vice versa.

For each counter c_j in a state in the packet-less model, we partition the state into $|P_j| - 1$ states, where $|P_j|$ is the number of points in P_j, *e.g.,* P_0=4 in the monitor example. Each of these $|P_j| - 1$ states corresponds to one subinterval. Suppose that R_i is a rule that depends on counter c_j, *i.e.,* R_i can handle packets when the value of the counter satisfies its counter conditions: $l_i \le c_j < u_i$. The value of R'_i in each refined state should show whether the counter conditions of rule R_i are satisfied in the corresponding subinterval $P_{j,k}$: $R'_i = ((l_i \le l_{j,k}) \wedge (u_{j,k} \le u_i))$.

In any given state $s \in S$ and for a subinterval of $P_{j,k}$, the network behavior is determined by the rules that (a) are active in that state (*i.e.,* R_i=`true`) and (b) either do not depend on counters or their counter conditions are satisfied in that subinterval (*i.e.,* R'_i=`true`), *e.g.,* in the monitor example's initial state, R_0 and R_1 are active (*i.e.,* R_0=R_1=`true`) and their counter conditions are satisfied in the first subinterval $P_{0,0} = [0, v_1)$ (*i.e.,*

[6]Note that it is possible to avoid defining these variables for the rules that do not depend on counters. We define these variables for all rules here for ease of exposition.



Initial state
$R'_0 = R'_1 = R_i = \mathbf{true}, 0 \le i \le 5$
$R'_2 = R'_3 = R'_4 = R'_5 = \mathbf{false}$
$R'_2 = R'_3 = R_i = \mathbf{true}, 0 \le i \le 5$
$R'_0 = R'_1 = R'_4 = R'_5 = \mathbf{false}$
$R'_4 = R'_5 = R_i = \mathbf{true}, 0 \le i \le 5$
$R'_0 = R'_1 = R'_2 = R'_3 = \mathbf{false}$

Figure 4: The refined structure for the monitor function.

R'_0=R'_1=`true`).

In summary, the set of variables in the packet-less model TS includes a pair of Boolean variables R_i and R'_i for each rule. The values of these variables at any point define the **state** of the packet-less model at that point. In the **initial state**, for every rule R_i, the value of R_i is equal to R_i.`true` in the original program. In the initial state, R'_i=`true` *iff* R_i either does not depend on any counters or if it depends on counter c_j and its counter conditions are satisfied in the first subinterval of c_j, $P_{j,0}$, *i.e.,* $((l_i \le l_{j,0}) \wedge (u_{j,0} \le u_i))$.

In the refined model, a rule R_i can be *executed* in a state if (a) for at least one packet that R_i matches, it is the highest priority rule, (b) R_i is active in that state (*i.e.,* R_i=`true`), and (c) R_i either does not depend on any counters or its counter conditions are satisfied in that subinterval (*i.e.,* R'_i=`true`).

Transitions in the refined model: Let s_k and s_{k+1} be, respectively, the k^{th} and $(k+1)^{\text{th}}$ refined state if state s is refined for counter c_j, *i.e.,* the states representing the Boolean formulas for subintervals k and $k+1$ of P_j. We add a transition from state s_k to state s_{k+1} if there is at least one rule R_i that depends on c_j and can be executed in s_k. The reason is that c_j increases monotonically so if a counter-dependent rule can be executed in s_k, it can result in c_j transitioning to the next subinterval (corresponding to state s_{k+1}). For each transition $s \rightarrow^{\alpha} s'$ in the original packet-less model before refinement, where α is the execution of a rule R_i that adds or deletes rules, there is a transition $s_k \rightarrow^{\alpha} s'_k$ if R_i can be executed in s_k. As before, for each added rule R_j that R_i adds, R_j=`true` in s'_k and for each rule R_k that R_i deletes, R_k=`false` in s'_k. Figure 4 shows the Boolean packet-less states and the transitions for the monitor function in Figure 2 (see Figure 3 (b) for its corresponding pre-refinement packet-less model). There is a transition from the initial partitioned state (in which $R'_0 = R'_1$=`true`) to a state in which $R'_0 = R'_1$=`false`, reflecting the fact that the network state evolves from an initial state that satisfies the counter conditions of these rules to one where the counter conditions of these rules are no longer satisfied. If the program has multiple counters, the state and transition refinements are performed sequentially for each counter.

3.3.2 Boolean Formulas of Properties

We explained earlier how we could express *atomic propositions* in terms of packets and the desired actions on them. Properties are built out of atomic propositions, and in a transition system such as the packet-based model in prior work [35], the atomic proposition (h,a) holds for a state *iff* the list of actions a is applied to all the packets in h in that state. The second challenge of packet-less modeling is evaluating a proposition on Boolean packet-less models. In this part, we explain how an (h,a) proposition can be expressed as a Boolean formula on rules exploiting a priori known rule priorities.

We say that a rule R_i can be *applied* if (a) R_i is active, *i.e.,* R_i=`true` and (b) R_i either does not depend on any counters or its counter conditions are satisfied, *i.e.,* R'_i=`true`. For a rule to be executed, in addition to satisfying the conditions above, for at least one packet that it matches, it should be the highest priority rule.

Let $W_{0,n} = [R_0, R_1, ..., R_n]$ and $W'_{0,n} = [R'_0, R'_1, ..., R'_n]$ be, respectively, the list of rules R_i and the list of variables R'_i, sorted in non-increasing order of the priorities of rules, *i.e.,* R_i.`priority` $\ge R_j$.`priority`, R'_i.`priority` $\ge R'_j$.`priority` if $i < j$. Our goal is to express whether a proposition holds in a state as a Boolean formula on this list. We achieve this with a recursive function: Let $K((h,a), W_{0,n}, W'_{0,n})$ be a function that is true if $W_{0,n}$ and $W'_{0,n}$ satisfy the proposition (h,a) and false otherwise. For the two special cases, where (1) h is empty and (2) h is not empty and the list of rules is empty, we assume that $K((h,a), W_{0,n}, W'_{0,n})$ evaluates to, respectively, `true` and `false` because any condition holds for a non-existing packet (item (1) above, $h = \varnothing$) and an empty set of rules does not satisfy any conditions for packets (item (2) above, $h \neq \varnothing$ and the list of rules=[]). In other conditions, we have the following cases:

Case 1: If the highest priority rule R_0 matches some packets in h, *i.e.,* if $(h \cap R_0.\texttt{pkts}) \neq \varnothing$, where $R_i.\texttt{pkts}$ denotes the set of packets that R_i matches, and its action includes the actions in the proposition, *i.e.,* $a \subset R_0.\texttt{action}$, then for the proposition to hold, one of these two conditions should hold (a) either R_0 can be applied ($R_0 \wedge R'_0$) and for all the packets of h that do not match R_0, the proposition should hold for the next, lower-priority matching rules, *i.e.,* $(R_0 \wedge R'_0) \wedge (K((h - R_0.\texttt{pkts}, a), W_{1,n}, W'_{1,n}))$, or (b) R_0 cannot be applied ($\neg(R_0 \wedge R'_0)$, R_0 either is not installed in the network or its counter conditions are not satisfied), but in this case, for all the packets of h, the proposition should hold for the next, lower-priority matching rules, *i.e.,* $\neg(R_0 \wedge R'_0) \wedge (K((h,a), W_{1,n}, W'_{1,n}))$. In other words, $K((h,a), W_{0,n}, W'_{0,n}) = ((R_0 \wedge R'_0) \wedge (K((h - R_0.\texttt{pkts}, a), W_{1,n}, W'_{1,n}))) \vee (\neg(R_0 \wedge R'_0) \wedge (K((h,a), W_{1,n}, W'_{1,n})))$.

Case 2: If the highest priority rule R_0 matches some packets in h, *i.e.,* if $(h \cap R_0.\texttt{pkts}) \neq \varnothing$, and its action does not include the actions in the proposition, then for the proposition to hold, it should not be possible to apply R_0, *i.e.,* $\neg(R_0 \wedge R'_0)$. Otherwise, it matches the packets but does not apply the intended actions on them. Plus, for all the packets of h, the proposition should hold for the next, lower-priority matching rules, *i.e.,* $K((h,a), W_{0,n}, W'_{0,n}) = \neg(R_0 \wedge$

$R'_0) \wedge (K((h,a),W_{1,n},W'_{1,n}))$.

Case 3: If the highest priority rule R_0 does not match any packets in h, then irrespective of whether R_0 can be applied or not, for all the packets of h, the proposition should hold for the next, lower-priority matching rules, *i.e.,* $K((h,a),W_{0,n},W'_{0,n}) = K((h,a),W_{1,n},W'_{1,n})$.

Applied recursively to the ordered list (according to priority) of all rules in the network, $K((h,a),W_{0,n},W'_{0,n})$ expresses the proposition (h,a) as a Boolean formula on R_i and R_i' variables. As an example, in the IDPS function of Figure 1, the proposition $((\texttt{src=}I,\texttt{dst=}E),\texttt{send()})$ is translated to

$$\begin{aligned}
K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),W_{0,4},W'_{0,4}) &= \\
\neg(R_0 \wedge R'_0) \wedge (K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),W_{1,4},W'_{1,4})) &= \\
\neg(R_0 \wedge R'_0) \wedge K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),W_{2,4},W'_{2,4}) &= \\
\neg(R_0 \wedge R'_0) \wedge K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),W_{3,4},W'_{3,4}) &= \\
\neg(R_0 \wedge R'_0) \wedge K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),W_{4,4},W'_{4,4}) &= \\
\neg(R_0 \wedge R'_0) \wedge & \\
(\,(\,(R_4 \wedge R'_4) \wedge K((\varnothing,\texttt{send()}),[])) \vee & \\
(\neg(R_4 \wedge R'_4) \wedge K(((\texttt{src=}I,\texttt{dst=}E),\texttt{send()}),[]))) &= \\
\neg(R_0 \wedge R'_0) \wedge (R_4 \wedge R'_4). &
\end{aligned}$$

This Boolean formula results from applying the rules specified in cases (2), (3), (3), (3), (1), and the first two special cases, respectively. It has different truth values in different states in Figure 4 depending on the truth values of rules in those states, *e.g.,* it is true in the initial state S_0 where R_0=`false` and R_4=`true`, meaning that the assertion $((\texttt{src=}I,\texttt{dst=}E),\texttt{send()})$ holds (I may talk to E in this state), but is false in the final state (I is blocked), where R_0=`true` and R_4=`true`. Note that R'_i variables are always `true` in this example as the rules do not depend on counters.

In the network transition system TS, **labeling function** L maps each state to the set of atomic propositions that hold in that state. That is, (h,a) exists in $L(s)$ if the list of actions a is applied to all the packets in h in state s, *i.e.,* $K((h,a),W_{0,n},W'_{0,n})$=`true` where $W_{0,n}$ and $W'_{0,n}$ are, respectively, the list of rules R_i and the list of variables R'_i (sorted in non-increasing order of rule priorities) in s.

4 Implementation and Evaluation

To evaluate the performance of our design, we build a prototype that enables network operators to program and verify their functions and a compiler that converts these functions to programs executable on programmable switching ASICs. After a brief overview of our prototype, we show that our network abstraction and specification language are expressive and impose only minimal overhead. We also show that compared to a packet-based baseline, the packet-less model's verification of different properties is faster and more scalable, *e.g.,* for a network with 100 hosts, the packet-less model results in 8$\times$ speedup in the verification of liveness properties of a UDP flood mitigation function compared to the packet-based model.

4.1 Implementation

Interfaces: Our system exposes two interfaces: a *one-big-switch* interface that enables a network operator to program her functions on our abstraction (§2) and a *specification* interface that allows her to express her desired properties (§3). Our *generator* then automatically builds the packet-less model and the Boolean formula representing the specification as explained in §3 and interacts with NuSMV, a state-of-the-art model checker [18], to verify specification properties.

Compiling the abstraction to P4 programs: P4 [14] is a language for expressing the packet processing of programmable data planes. Along with the programmable data plane, the control plane is responsible for populating the tables defined by the P4 program. We build a compiler to compile a one-big-switch program using our abstraction to a P4_16 program for the P4 behavioral model [3], an open-source programmable software switch. Along with the software switch, we develop a control plane which adds and deletes table rules. We describe some of the salient features of the compilation:

(a) Functional decomposition: We map each table in the abstraction to a P4 table, whose match fields and actions are constructed using the rules in the table. Network function traversal policies are implemented using P4 control flow constructs, *e.g.,* to traverse a firewall table `fw` conditionally:

```
    if (meta.visit_fw) == 1)
        fw.apply();
```

where `meta.visit_fw` is a metadata variable used by the tables before the firewall table to ensure the packet goes through the firewall table.

(b) Actionable measurement: We use P4's registers to support incrementing and matching on counters shared across multiple rules. If a table in the abstraction uses counters, we create a separate P4 table which is responsible for updating the shared counters and transferring the counter state to metadata such that the function table can use the value for matching. This helps us confine register accesses to a single table. Thus, packet processing can happen at the line rate [54].

(c) Add/delete actions: Currently, P4 data planes do not support add/delete actions, *i.e.,* rule actions that add or delete other table rules, due to hardware limitations of existing platforms. We support this functionality by cloning the packet [55] to the control plane, acting similar to the PacketIn functionality in OpenFlow [2]. When a rule in the program has an add/delete action, our switch program clones the packet in the data plane and sends it to the switch-local

Function source	Function	One-big-switch LoC	Packets calling controller [%]	P4 LoC	Compilation time[ms]
Pyretic [44]/Kinetic [35]	Simple counter	1	0	144	1.8
	Port knocking	3	6×10^{-3}	133	1.8
	Simple firewall	2	0	128	1.6
	IP rewrite	2	0	134	1.8
	Simple rate limiter	3	0	141	2.1
Floodlight [4]	Firewall/ACL	2	0	132	1.7

Bohatei [23]	Elephant flow detection	3	0	182	2.4
	DNS amplification mitigation	3	7×10^{-3}	135	1.9
	UDP flood mitigation	2	0	148	1.8

Table 1: Applications written on one-big-switch.

control plane; the control plane (which we also generate) then adds/deletes table rules as decided by the add/delete actions in the program. This approach has the overhead of punting some packets (specifically, first packets in a connection matching specific rules) to the local switch CPU—this is a cost we pay for lack of data plane support for add/delete actions.

4.2 Evaluation

Expressiveness: Despite its simplicity, our one-big-switch abstraction enables developers to express a broad range of applications and network functions. Table 1 shows a list of functions that we have developed in our framework. Full descriptions of these programs are provided in §8. Network policies can be succinctly expressed on our one-big-switch abstraction in only a few lines of code (column 3 in Table 1), *e.g.,* a simple stateful firewall policy that allows only the traffic whose connection was initiated by a host in a given department can be expressed in 3 lines of code on the one-big-switch abstraction. The compiled P4 code of the same policy is expressed in 133 lines of code (comprising of 100 lines of boilerplate code for headers and parsers) and ~50 lines of code for the P4 control plane for cloning the packets at the data plane and adding rules from the control plane. Various specification properties, including the most common specification patterns in practice [21], can also be specified in the temporal logic presented in §3.

Limited overhead: Add/delete actions of our abstraction are not directly supported in the switching ASIC today. Our P4 compiler implements these by involving the controller whenever a rule has such actions. To measure the overhead of involving the controller, we deploy the functions listed in Table 1 and replay a packet trace of a university datacenter [12], with over 102K packets and 1,791 IP addresses and measure the frequency of calling the controller. This overhead is modest for all functions, *i.e.,* 0-0.3% (column 4, Table 1).

Verification time: We test the efficiency of bounded-time verification of packet-less and packet-based models at scale to answer questions such as, what functions and properties are verifiable with each approach? How does the verification time scale with respect to the network (and hence the model) size? How does it scale with respect to the property size? To do so, for the functions in Table 1 with per-host policies (*e.g.,* the heavy-hitter detector, port knocking, rate limiter, phishing/spam detector, and UDP flood mitigation function), we define one policy for each host in the network. The heavy hitter detector, for example, deploys a per-source IP counter that is incremented for every new SYN packet and starts dropping packets when the counter exceeds a threshold (Table 4). For the functions that define policies between communicating pairs of hosts or on flows, *e.g.,* FTP monitor and DNS amplification mitigation functions, we run the same datacenter trace as above to find the communicating pairs and matching flows and define one policy for each. For functions that classify hosts into sets, *e.g.,* the firewall function with sets of internal and external hosts, we randomly assign each host to a set. Finally, for counter bounds, we draw random samples from the uniform distribution on the set of possible values.

We measure the verification time for various functions, properties, and network scales for packet-less and packet-based models. Note that increasing the network size in this manner results in larger models. For each experiment, we run 20 repeated trials, each trial with a time budget of 1,000 *sec.*, *i.e.,* we stop the verification process when the verification time exceeds 1,000 *sec*. We give a brief overview of our packet-based baseline below before presenting our results.

Packet-based transition systems as the baseline: A powerful technique for scaling static verification is slicing the network into a set of *equivalence classes* (ECs) of packets [33,34,43]. Each EC is a set of packets that always experience the same forwarding actions throughout the network [43]. As shown in prior work, this approach can be extended to model dynamic networks [35]. To do so, one can detect a program's ECs using verifiers that classify packets into ECs [43].

Rule	Init	Priority	Match	Action
R_0	true	100	(protocol=UDP) & (source IP=A) & ($c_0 < X$)	send()
R_1	true	100	(protocol=UDP) & (source IP=A) & ($X \leq c_0 < m$)	drop()

Table 2: A UDP flood mitigation function.

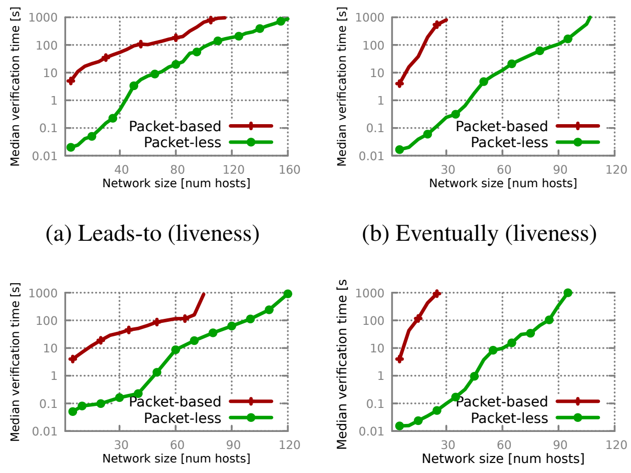
Alternatively, and similar to Kinetic [35], the programmer may be tasked with providing ECs and their transition systems.

In the packet-based transition system, each *node* represents a *state* of the network, *i.e.,* the set of ECs in that state. For instance, for the IDPS in Figure 1, in the initial state, two ECs exist in the network: EC_0 that includes all packets destined to I and with port number 2222 and EC_1 that includes all remaining packets. *Transitions* are the events that change the state of the network, *e.g.,* receiving packets from the ECs whose forwarding actions update the network's forwarding behavior. In the example above, receiving packets from EC_0 transitions the system into another state in which three different ECs exist: EC_2 that includes all packets from I that are destined to F, EC_3 that includes all packets not included in EC_2 that are sent to I with port number 2222, and EC_4 that includes all packets not included in EC_2 and EC_3.

We implement this packet-based model as our baseline. For classifying packets into ECs in this baseline, we use the heuristic developed in VeriFlow [43]. Despite their similarities, the packet-based model and Kinetic [35] have a few key differences: the greater expressiveness of our programming abstraction (*e.g.,* to allow for matching on shared packet counters) increases the difficulty of the verification problem. Plus, in contrast to Kinetic that requires operators to provide the state machine as an input, the packet-based model automatically generates these from the rules written on our one-big-switch abstraction.[7] Thus, despite their conceptual similarities, we refrain from calling our baseline Kinetic.

Our results demonstrate that the packet-less model is faster than the packet-based model for different categories of liveness properties such as "leads-to" (*e.g.,* host A sending traffic to host B leads to A being blocked) and "eventually" (*e.g.,* host A is eventually blocked). Figure 5 (a) and (b) show examples for a UDP flood mitigation function (Table 2) which deploys a per-source IP counter that is incremented for every UDP packet and starts dropping packets when the counter exceeds a threshold. Verifying a leads-to property—host A sending more packets than a threshold leads to it being blocked—in a network with 100 hosts, for example, is 7.8× faster with the packet-less model than the packet-based model (85 vs. 667 *sec.*). In 1,000 *sec.*, the packet-less model verifies a different liveness property, "eventually" (A is eventually blocked), for networks that are 3.5× larger than those verifiable with the packet-based model (105 hosts *vs.* 30). By reducing the size of the state machine, the packet-less model also improves the ver-

[7]In Kinetic, a knowledgeable operator can conceivably provide compact state machines, smaller than the packet-based model, and hence experience lower verification times.



(a) Leads-to (liveness)

(b) Eventually (liveness)

(c) Absence (safety)

(d) Universality (safety)

Figure 5: Packet-less verification reduces the verification time of different properties for a flood mitigation function.

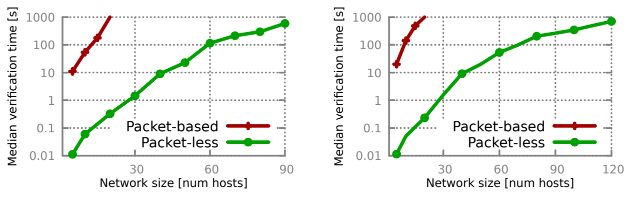
ification time for safety properties. Figure 5 (c) and (d) show examples for an "absence" property (host A is never reachable) and "universality" (A is always reachable), respectively. Similarly, verifying the same liveness and safety properties, *e.g.,* "eventually" and "universality", in a stateful firewall (Table 13) is, respectively, 3.3× and 4.9× faster with the packet-less model than the packet-based model in a 30-host network (figures not shown).

We observe that greater degrees of state sharing across rules (*e.g.,* counters shared by multiple rules) result in slower verification for both approaches, but the performance degradation is more pronounced for the packet-based model, *e.g.,* for a rate limiter (Table 5), in 1,000 *sec.*, we can verify an "eventually" property in networks with up to 90 hosts with the packet-less model (*v.s.* 105-host networks for the UDP flood detection application above), and for networks with at most 15 hosts with the packet-based model (*v.s.* 30 hosts for the UDP flood detection application above). Figure 6 shows the results for a liveness and a safety property for this function. The packet-less model can verify them for network 6× larger than the packet-based model, and even for small-scale networks, it is at least two orders of magnitude faster.

In addition to testing the scalability with respect to the network (and consequently the model) size, we also scale properties. Verification time is a function of the size of the transition system and the property formula, *e.g.,* there exists an LTL model-checking algorithm whose running time depends linearly on the size of the transition system and exponentially

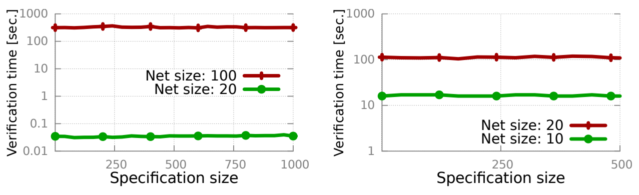
Property	LTL specification [17,21]	Meaning and example
Leads-to (a.k.a Response)	$\mathtt{G}(P \rightarrow \mathtt{F}S)$	*P* must always be followed by *S*, a host showing a malicious activity must always be followed by the IDPS blocking the host.
Universality	$\mathtt{G}P$	*P* always holds, *e.g., A* is always blocked.
Absence	$\mathtt{G}\neg P$	*P* never holds, *e.g., A* can never send traffic to *B*.
Eventually (a.k.a Existence)	$\mathtt{F}P$	*P* eventually happens, *e.g., A* can eventually reach *B*.
Precedence	$\mathtt{F}P \rightarrow (\neg P \mathtt{U}(S \wedge \neg P))$	*P* must always be proceeded by *S*, *e.g.,* blocking a host must always be proceeded by the host exhibiting some malicious activity.

Table 3: List of properties verified.



(a) Eventually (b) Universality

Figure 6: Verification times for a rate limiter.



(a) Packet-less (b) Packet-based

Figure 7: The property size does not impact the verification time.

on the length of the LTL formula [20]. Although in practice, the structure size is usually the dominant factor in determining the verification time, in our approach, the size of property formulas can potentially be large and increase the verification time.[8] To test the sensitivity of the verification time to the property size, we first construct atomic propositions for reachability of randomly selected (with replacement) hosts, *e.g.,* ($\mathtt{dst}$=A,$\mathtt{send}(A)$). Then, we use logical operations to build formulas of various sizes out of these atomic propositions, as explained in §3, *e.g.,* $(\mathtt{dst}{=}A,\mathtt{send}(A))\wedge(\mathtt{dst}{=}B,\mathtt{send}(B))$ for a property with size 2. Finally, we use these assertions to construct the liveness and safety properties listed in Table 3. We observe that scaling the property size does not affect the verification time of either approach. For the same UDP flood mitigation function as above, in a network with 200 hosts, changing the property size from 1 to 200, results in a standard deviation of less than 7.2. This holds even for smaller networks where the relative impact of the property size is expected to be greater. Figure 7 shows two examples for verifying $\mathtt{F}(\wedge_{h\in S}(\mathtt{dst}{=}h,\mathtt{send}(h))$, *i.e.,* eventually, all the hosts in the set *S* will become reachable, for small networks with 10, 20, and 100 hosts.

[8]Recall that in a packet-less model, we also need to express properties in terms of Boolean formulas on rules (§3.3.2).

5 Related Work

Static network verifiers [33,34,39,42,43,61] verify various aspects of reachability invariants such as loop-freedom and lack of blackholes on a snapshot of the network. More recently, reachability verification and enforcement techniques are extended to incorporate degrees of dynamism [10,22,26,40,48, 60], *e.g.,* with failures and policy changes [26,27,29,31,38, 52], with mutable data planes [48], and with focusing on controllers instead of snapshots of the data plane [10,11,22,60]. However, the targeted properties in all these proposals are safety invariants such as reachability and loop-freedom. Our focus on verifying a computationally more complex category of properties (liveness) drives our novel packet-less model, which is distinct from prior models. Plus, some of the assumptions in prior work restrict the set of network functions that they can verify. VMN, for example, models network functions in which (a) flows are independent, and (b) forwarding is not affected by transaction orderings. We find that many crucial network functions such as IDPS and Trojans detectors [16] do not possess those properties.

We share the goal of designing verifiable programming languages with VeriCon [9], FlowLog [46], and Kinetic [35], but since our programs are compiled to P4 programs (instead of the OpenFlow rules that VeriCon's CSDN language, FlowLog, and Kinetic programs are compiled to), we are able to express programs that these frameworks cannot, *e.g.,* programs with multiple rules that share counters. Plus, VeriCon's use of first-order logic makes it infeasible to specify dynamic properties such as liveness. Finally, VeriCon, FlowLog, and Kinetic are packet-based. Kinetic, for example, extends the Pyretic controller [44] to add support for the verification of dynamic networks based on packet equivalent classes [35]. In Kinetic, the programmer needs to specify "located packet equivalence classes" (LPECs), maximal regions of the flow space (*e.g.,* packets with a given source IP) that experience the same forwarding behavior in each state, and their associated finite state machines (FSMs) that encode the handling of LPECs. We show experimentally and theoretically that compared to packet-based approaches deployed in these proposals, our packet-less approach results in faster verification.

Many recent projects in network verification leverage classical concepts of model checking to control the state explo-

Table 5: A simple rate limiter.

sion challenge in verifying dynamic systems such as slicing [48, 50], symbolic execution [48, 57, 63], and abstraction refinement [53]. Our work shares similarities with these in terms of the high-level techniques for scaling verification (*e.g.,* we also use symbolic modeling and abstraction). As our targeted properties (liveness vs. safety invariants) are different, however, our application of these techniques diverges from existing works, *e.g.,* we deploy symbolic representation not to abstract packet header fields (as NoD does for verifying reachability invariants in dynamic networks [40]), but to abstract away packets altogether. Works on verifying networks via testing [24] and simulations [25, 51] are complementary to our approach. Via applying model checking, we strive to provide a fully *automatic* verifier that, unlike testing and simulation, searches the state space of our abstraction *exhaustively*.

6 Limitations and Future Work

The focus of our work is on functional correctness; this leaves out large sets of functions and properties, including those focused on path and traffic engineering properties (is a path congested? is the load balanced across multi-paths? *etc.*). Our one-big-switch abstraction is not suited for programming such functions. Plus, while a familiar abstraction to operators, the one-big-switch abstraction is relatively low-level. An interesting direction for future research is developing higher-level abstractions amenable to efficient liveness verification.

Our verifier is not a "full-stack" one; it is not designed to verify low-level properties such as memory safety and crash freedom that tools such as Vigor [62] and VigNAT [63][9] can verify and does not verify the compiled P4 code. Consequently, tools such as compiler verifiers (such as p4v [39]), P4 debuggers (*e.g.,* Vera [56])), and testers are still essential to guarantee the faithful implementation of our verified abstractions, *e.g.,* to detect and debug switch firmware and P4 compiler bugs. Finally, while our packet-less modeling improves the verification time compared to a packet-based model and enables the verification of complex properties such as liveness ones, the absolute verification times remain high for large-scale networks (note the logarithmic scale in figures). Further reducing the verification complexity of stateful functions remains an open challenge.

7 Conclusion

Modern networks rely on a variety of stateful network functions to implement rich policies. Correct operation of such networks relies on ensuring that they support key liveness properties. Unfortunately, despite exciting recent work on network verification, no existing approach is practical for, or applicable to, validating liveness. We take a top-down approach to this problem by first designing a new programming model built with verification in mind. It offers natural extensions to the convenient one-big-switch abstraction and allows decomposition of different network functions. We develop a novel encoding of these programs under dynamic events such as network state changes using Boolean formulas that can capture rich semantics (*e.g.,* counters) while also ensuring that the encoding remains bounded-size and amenable to fast liveness verification. We develop a compiler that translates our programs into those runnable on modern hardware. Our evaluation shows that the programming model can succinctly express a variety of functions, our compilation is fast, our encoding is compact and orders of magnitude more scalable to verify than naive encodings, *i.e.,* it results in substantial verification speedup.

[9]VigNAT [63] partitions programs into stateful and stateless components. While the stateless component is verified automatically via applying symbolic model checking, the verification of the stateful part is done via theorem proving and requires human assistance. In Vigor [62], the function code that cannot be symbolically executed is stored in a specialized library and verified by experts using theorem proving (*i.e.,* writing proofs).

8 Appendix

Table 1 lists the functions that can be represented in our language. Below we write these functions on our one-big-switch abstraction.

Simple counter: A packet counter for every source, destination IP address pair (Table 6).

Port knocking: Open a certain port *O* by attempting to open a connection on a prespecified closed port *K* (Table 7).

Simple firewall: Allows traffic between certain source, destination MAC addresses (Table 8).

IP rewrite: Rewrite IP address of all traffic coming from and directed to a particular IP address (Table 9).

Simple rate limiter: There are multiple implementations of this function. The first example (Table 5) assumes different ports are capable of sending traffic at different rates. It uses per-source IP counters to decide the traffic rate.

The second example (Table 10) uses counters on subsets of traffic to decide what traffic will be forwarded normally, redirected to a rate limiter, or dropped.

Firewall/ACL: Allows or Blocks traffic based on certain packet fields (Table 11).

Phishing/Spam detection: A per-MTA (Mail Transfer Agent) counter to detect MTAs that send a large amount of mail (Table 12).

Simple stateful firewall: A firewall that allows only the traffic whose connection was initiated by a host in *I*, where *I* is the set of departmental addresses (Table 13).

FTP monitor: Allows traffic on data port only if it received a signal on the control port (Table 14).

Heavy-hitter detection: A per-source IP counter that is incremented for every new SYN. It starts dropping packets when the counter exceeds a threshold value (Table 4).

Super spreader detection: Similar to heavy-hitter detection, the counter is incremented for every SYN. But it is also decremented for every FIN.

Sampling based on the flow size: This can be done using two tables. The first table (Table 15) uses counters to classify the flow size into three categories - small, medium, and large. It adds this metadata information into the packet (*e.g.,* using the QoS field). The second table (Table 16) samples packets based on its flow size, using its own counters.

Elephant flow detection: This is similar to sampling based on flow size, where flows of large size are elephant flows.

DNS amplification mitigation: Allows DNS reply (source port=53) to a particular IP only if it receives a DNS request/query from that IP (Table 17).

UDP flood mitigation: A per-source IP counter that is incremented for every UDP packet. It starts dropping packets when the counter exceeds a threshold value (Table 2).

Application chaining: Our language can represent non-linear chaining of applications. For example, consider a system that wants to rate-limit phishing and heavy-hitter traffic. This can be represented in our language using three tables.

University of Michigan

Abstract

The popularity of big data and AI has led to many optimizations at different layers of distributed computation stacks. Despite – or perhaps, because of – its role as the narrow waist of such software stacks, the design of the execution engine, which is in charge of executing every single task of a job, has mostly remained unchanged. As a result, the execution engines available today are ones primarily designed for low latency and high bandwidth datacenter networks. When either or both of the network assumptions do not hold, CPUs are significantly underutilized.

In this paper, we take a first-principles approach toward developing an execution engine that can adapt to diverse network conditions. Sol, our *federated execution engine architecture*, flips the status quo in two respects. First, to mitigate the impact of high latency, Sol proactively assigns tasks, but does so judiciously to be resilient to uncertainties. Second, to improve the overall resource utilization, Sol decouples communication from computation internally instead of committing resources to both aspects of a task simultaneously. Our evaluations on EC2 show that, compared to Apache Spark in resource-constrained networks, Sol improves SQL and machine learning jobs by 16.4× and 4.2× on average.

1 Introduction

Execution engines form the narrow waist of modern data processing software stacks (Figure 1). Given a user-level intent and corresponding input for a job – be it running a SQL query on a commodity cluster [9], scientific simulations on an HPC environment [52], realtime stream processing [12], or training an AI/ML algorithm across many GPUs [7] – an execution engine orchestrates the execution of tasks across many distributed workers until the job runs to completion even in the presence of failures and stragglers.

Modern execution engines have primarily targeted datacenters with low latency and high bandwidth networks. The absence of noticeable network latency has popularized the *late-binding* task execution model in the control plane [10, 36, 43, 48] – pick the worker which will run a task only when the worker is ready to execute the task – which maximizes flexibility. At the same time, the impact of the network on task execution time is decreasing with increasing network bandwidth; most datacenter-scale applications today are compute- or memory-bound [7, 42]. The availability of high bandwidth has led to *tight coupling* of a task's roles to hide design complexity in the data plane, whereby the same task reads remote input and computes on it too. Late-binding before execution and tight coupling during execution work well together when the network is well-provisioned.

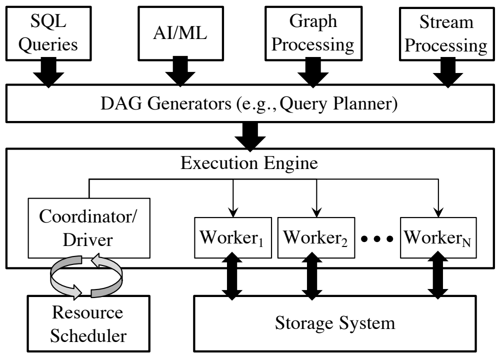

Figure 1: ***Execution engine forms the narrow waist between diverse applications and resources.***

Many emerging workloads, however, have to run on networks with high latency, low bandwidth, or both. Large organizations often perform interactive SQL and iterative machine learning between on- and off-premise storage [4, 16, 24, 27]. For example, Google uses federated model training on globally distributed data subject to privacy regulations [11, 58]; telecommunications companies perform performance analysis of radio-access networks (RAN) [30, 31]; while others troubleshoot their appliances deployed in remote client sites [39]. Although these workloads are similar to those running within a datacenter, the underlying network can be significantly constrained in bandwidth and/or latency (§2). In this paper, *we investigate the impact of low bandwidth and high latency on latency-sensitive interactive and iterative workloads.*

While recent works have proposed solutions for bandwidth-sensitive workloads, the impact of network constraints on latency-sensitive workloads has largely been overlooked. Even for bandwidth-sensitive workloads, despite many resource schedulers [28, 56], query planners [45, 50], or application-level algorithms [24, 57], the underlying execution engines of existing solutions are still primarily the ones designed for datacenters. For example, Iridium [45], Tetrium [28], and Pixida [33] rely on the execution engine of Apache Spark [54], while many others (e.g., Clarinet [50], Geode [51]) are built atop the execution engine of Apache Tez [47].

Unfortunately, under-provisioned networks can lead to large CPU underutilization in today's execution engines. First, in a high-latency network, late-binding suffers significant coordination overhead, because workers will be blocked on receiving updates from the coordinator; this leads to wasted CPU cycles and inflated completion times of latency-sensitive tasks. Indeed, late-binding of tasks to workers over the WAN can slow down the job by 8.5×–30× than running it within the local-area network (LAN). Moreover, for bandwidth-intensive tasks, coupling the provisioning of communication and computation resources at the beginning of a task's execution leads to head-of-line (HOL) blocking: bandwidth-sensitive jobs hog CPUs even though they bottleneck on data transfers, which leads to noticeable queuing delays for the rest.

By accounting for network conditions, we present a federated execution engine, Sol, which is API-compatible with Apache Spark [54]. Our design of Sol, which can transparently run existing jobs and WAN-aware optimizations in other layers of the stack, is based on two high-level insights to achieve better job performance and resource utilization.

First, we advocate *early-binding control plane decisions over the WAN* to save expensive round-trip coordinations, while continuing to late-bind workers to tasks within the LAN for the flexibility of decision making. By promoting early-binding in the control plane, we can pipeline different execution phases of the task. In task scheduling, we subscribe tasks for remote workers in advance, which creates a tradeoff: binding tasks to a remote site too early may lead to sub-optimal placement due to insufficient knowledge, but deferring new task assignments until prior tasks complete leaves workers waiting for work to do, thus underutilizing them. Our solution deliberately balances efficiency and flexibility in scheduling latency-bound tasks, while retaining high-quality scheduling for latency-insensitive tasks even under uncertainties.

Second, *decoupling the provisioning of resources for communication and computation within data plane task executions* is crucial to achieving high utilization. By introducing dedicated communication tasks for data reads, Sol decouples computation from communication and can dynamically scale down a task's CPU requirement to match its available bandwidth for bandwidth-intensive communications; the remaining CPUs can be redistributed to other jobs with pending computation.

Our evaluations show that Sol can automatically adapt to diverse network conditions while largely improving application-level job performance and cluster-level resource utilization. Using representative industry benchmarks on a 40-machine EC2 cluster across 10 regions, we show that Sol speeds up SQL and machine learning jobs by 4.9× and 16.4× on average in offline and online settings, respectively, compared to Apache Spark in resource-constrained networks. Even in datacenter environments, Sol outperforms Spark by 1.3× to 3.9×. Sol offers these benefits while effectively handling uncertainties and gracefully recovering from failures.

Figure 2: ***While execution engines are widely deployed on cloud platforms, the underlying network conditions can be diverse in latency and bandwidth.***

2 Background and Motivation

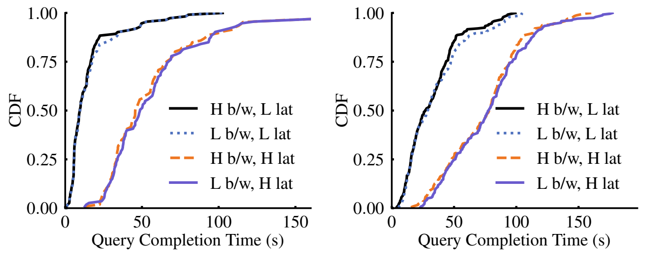
2.1 Execution Engines

The execution engine takes a graph of *tasks* – often a directed acyclic graph (DAG) – from the higher-level scheduler as its primary input. Tasks performing the same computation function on different data are often organized into *stages*, with dependencies between the stages represented by the edges of the execution DAG. Typically, a central *coordinator* in the execution engine – often referred to as the driver program of a job – interacts with the cluster resource manager to receive required resources and spawns *workers* across one or more machines to execute runnable tasks.[1] As workers complete tasks, they notify the coordinator to receive new runnable tasks to execute.

Design space. The design of an execution engine should be guided by how the environment and workload characteristics affect delays in the *control plane* (i.e., coordinations between the coordinator and workers as well as amongst the workers) and in the *data plane* (i.e., processing of data by workers). Specifically, a task's lifespan consists of four key components:

- *Coordination time* (t_{coord}) represents the time for orchestrating task executions across workers. This is affected by two factors: network latency, which can vary widely between different pairs of sites (Figure 2(a)), and the inherent computation overhead in making decisions. While the latter can be reduced by techniques like reusing schedules [37,49], the former is determined by the environment.
- *Communication time* (t_{comm}) represents the time spent in reading input and writing output of a task over the network and to the local storage.[2] For the same amount of data, time spent in communication can also vary widely based on Virtual Machine (VM) instance types and LAN-vs-WAN (Figure 2(b)).
- *Computation time* (t_{comp}) represents the time spent in running every task's computation.
- *Queuing time* (t_{queue}) represents the time spent waiting

[1]A task becomes runnable whenever its dependencies have been met.
[2]Most transfers after the input-reading stages happen over the network.



(a) Apache Spark (b) Apache Tez

Figure 3: ***TPC query completion times in different network settings using different execution engines (scale factor is set to 100).***

for resource availability before execution. Given a fixed amount of resources, tasks of one job may have to wait for tasks of other jobs to complete.

We first take into account t_{comp}, t_{coord}, and t_{comm} in characterizing the design of execution engines for a single task. By assuming $t_{comp} \gg t_{coord}, t_{comm}$ (i.e., by focusing on the execution of *compute-bound* workloads such as HPC [21], AI training [7] and in many cases within datacenters), existing execution engines have largely ignored two settings in the design space.

First, the performance of jobs can be dominated by the coordination time (i.e., $t_{coord} \gg t_{comm}, t_{comp}$), and more time is spent in the control plane than the data plane. An example of such a scenario within a datacenter would be stream processing using mini-batches, where scheduling overhead in the coordinator is the bottleneck [49]. As $t_{coord} \to O(100)$ ms over the WAN, coordination starts to play a bigger role even when scheduler throughput is not an issue. As $\frac{t_{comp}}{t_{coord}}$ and $\frac{t_{comm}}{t_{coord}}$ decrease, e.g., in interactive analytics [30, 31] and federated learning [11], coordination time starts to dominate the end-to-end completion time of each task.

Second, in *bandwidth-bound* workloads, more time is likely to be spent in communication than computation (i.e., $t_{comm} > t_{coord}, t_{comp}$). Examples of such a scenario include big data jobs in resource-constrained private clusters [36] or across globally distributed clouds [24, 45, 50, 51], and data/video analytics in a smart city [25].

In the presence of multiple jobs, inefficiency in one job's execution engine can lead to inflated t_{queue} for other jobs' tasks. For latency-sensitive jobs waiting behind bandwidth-sensitive ones, t_{queue} can quickly become non-negligible.

2.2 Inefficiencies in Constrained Network Conditions

While there is a large body of work reasoning about the performance of existing engines in high-bandwidth, low-latency datacenters [41, 42], the rest of the design space remains unexplored. We show that existing execution engines suffer significant resource underutilization and performance loss in other settings.

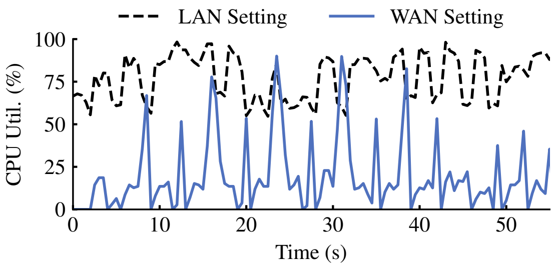


Figure 4: ***CPU utilization throughout a machine learning job.***

Performance degradation due to high latency. To quantify the impact of high latency on job performance, we analyzed the individual query completion times of 110 queries on two industrial benchmarks: TPC-DS and TPC-H. We use two popular execution engines – Apache Spark [54] and Apache Tez [47] – on a 10-site deployment; each site has 4 machines, each with 16 CPU cores and 64 GB of memory. We consider four network settings, each differing from the rest in terms of either bandwidth or latency as follows: [3]

- *Bandwidth:* Each VM has a 10 Gbps NIC in the high-bandwidth and 1 Gbps in the low-bandwidth setting.
- *Latency:* Latency across machines is <1 ms in the low-latency setting, while latencies across sites vary from $O(10)$–400 ms in the high-latency setting.

Figure 3 shows the distributions of average query completion times of Spark and Tez, where we use a dataset of scale factor 100.[4] We found that the availability of more bandwidth has little impact on query completion times; different query plans and task placement decisions in Spark and Tez did not improve the situation either. However, job completion times in the high-latency setting are significantly inflated – up to 20.6× – than those in the low-latency setting. Moreover, we observe high network latency can lead to inefficient use of CPUs for a latency-bound machine learning job (Figure 4).

The root cause behind this phenomenon is the *late-binding* of tasks to workers in the control plane. In existing execution engines, decision making in the control plane, such as task scheduling [50] and straggler mitigation [8], often requires realtime information from data plane executions, whereas data processing is initiated by control plane decisions. With high coordination latency, this leads to wasted CPU cycles as each blocks on acquiring updates from the other.

CPU underutilization due to low bandwidth. To understand the impact of low bandwidth on resource efficiency, we analyzed bandwidth-sensitive workloads using a scale factor of 1000 on the same experimental settings as above.

Figure 5 reports both the CPU and network utilizations throughout the execution of a representative query (query-

[3]We use the latency profile of 10 sites on EC2 and set a large TCP window size to reach the network capacity [34]. For the high-bandwidth setting and the low-bandwidth one, we refer to the available LAN bandwidth on *m4.10xlarge* and *m4.2xlarge* instances, respectively.

[4]A scale factor of X means a X GB dataset.

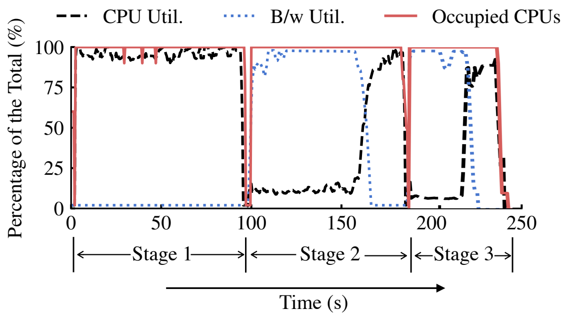

Figure 5: ***Resource utilization over a bandwidth-bound query's lifespan (scale factor is set to 1000).***

25 from the TPC-DS benchmark), which involves two large shuffles (in stage 2 and stage 3) over the network. During task executions, large data reads over the network are communication-intensive, while computations on the fetched data are CPU-intensive. We observe that, when tasks are bandwidth-constrained, their overall CPU utilization plummets even though they continue to take up all the available CPUs. This is due to the coupling of communication with computation in tasks. In other words, the number of CPUs involved in communication is independent of the available bandwidth. The end result is head-of-line (HOL) blocking of both latency- and bandwidth-sensitive jobs (not shown) by bandwidth-bound underutilized CPUs of large jobs.

Shortcomings of existing works. Existing works on WAN-aware query planning and task placement [28, 45, 50, 51] cannot address the aforementioned issues because they focus on managing and/or minimizing bandwidth usage during task execution, not on the impact of latency before execution starts or CPU usage during task execution.

3 Sol: A Federated Execution Engine

To address the aforementioned limitations, we present Sol, a *federated execution engine* which is aware of the underlying network's characteristics (Figure 6). It is primarily designed to facilitate efficient execution of emerging distributed workloads across a set of machines which span multiple sites (thus, have high latency between them) and/or are interconnected by a low bandwidth network. Sol assumes that machines within the same site are connected over a low-latency network. As such, it can perform comparably to existing execution engines when deployed within a datacenter.

Design goals. In designing Sol, we target a solution with the following properties:

- *High-latency coordinations should be pipelined.* Coordinations between control and data planes should not stall task executions. As such, Sol should avoid synchronous coordination (e.g., workers blocking to receive tasks) to reduce overall t_{coord} for latency-bound tasks. This leads to early-binding of tasks over high-latency networks.
- *Underutilized resources should be released.* Sol should release unused resources to the scheduler, which can be repurposed to optimize t_{queue} for pending tasks. This calls for decoupling communication from computation in the execution of bandwidth-intensive tasks without inflating their t_{comm} and t_{comp}.
- *Sol should adapt to diverse environments automatically.* The network conditions for distributed computation can vary at different points of the design space. Sol should, therefore, adapt to different deployment scenarios with built-in runtime controls to avoid reinventing the design.

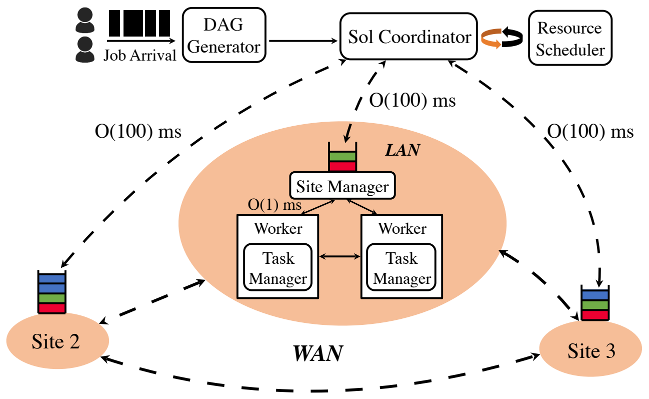

Figure 6: ***Sol components and their interactions. Low-latency sites synchronously coordinate within themselves and asynchronously coordinates across high-latency links.***

System components. At its core, Sol has three primary components:

- *Central Coordinator:* Sol consists of a logically centralized coordinator that orchestrates the input job's execution across many remote compute sites. It can be located at any of the sites; each application has its own coordinator or driver program. Similar to existing coordinators, it interacts with a resource manager for resource allocations.
- *Site Manager:* Site managers in Sol coordinate local workers within the same site. Each site manager has a shared queue, where it enqueues tasks assigned by the central coordinator to the workers in this site. This allows for late-binding of tasks to workers within the site and ensures high resource utilization, wherein decision making can inherit existing designs for intra-datacenter systems. The site manager also detects and tackles failures and stragglers that are contained within the site.
- *Task Manager:* At a high level, the task manager is the same as today: it resides at individual workers and manages tasks. However, it manages compute and communication resources independently.

Figure 7 shows a high-level overview explaining the interaction among these components throughout our design in the control plane (§4) and the data plane (§5).

4 Sol Control Plane

Modern execution engines primarily target datacenters with low latency networks [7, 12, 47, 54], wherein late-binding of

```

```

Figure 7: ***The interaction between the central coordinator, site manager and task manager.***

tasks to workers maximizes flexibility. For example, the coordinator assigns new tasks to a worker after it is notified of new resource availability (e.g., due to task completion) from that worker. Moreover, a variety of on-demand communication primitives, such as variable broadcasts and data shuffles, are also initiated lazily by the coordinator and workers. In the presence of high latency, however, late-binding results in expensive coordination overhead (§2.2).

In this section, we describe how Sol pushes tasks to sites to hide the expensive coordination latency (§4.1), the potential benefits of push-based execution (§4.2) as well as how we address the challenges in making it practical; i.e., how to determine the right number of tasks to push to each site (§4.3), how to handle dependencies between tasks (§4.4), and how to perform well under failures and uncertainties (§4.5).

4.1 Early-Binding to Avoid High-Latency Coordination

Our core idea to hide coordination latency (t_{coord}) over high-latency links is early-binding tasks to sites. Specifically, Sol optimizes t_{coord} between the central coordinator and remote workers (i) by *pushing* and queuing up tasks in each site; and (ii) by *pipelining* task scheduling and execution across tasks.

Figure 8 compares the control flow in traditional designs

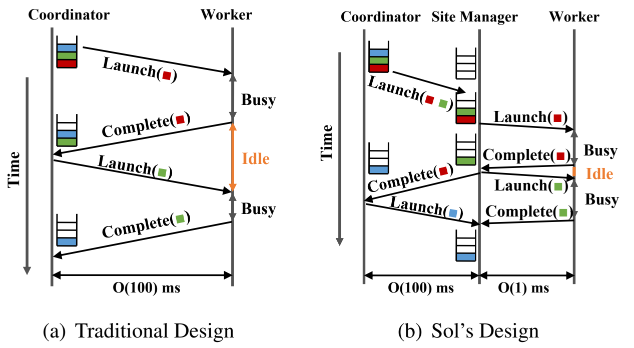

Figure 8: ***Task execution control flows in traditional designs vs. Sol. In Sol, tasks (denoted by colored rectangles) are queued at a site manager co-located with workers.***

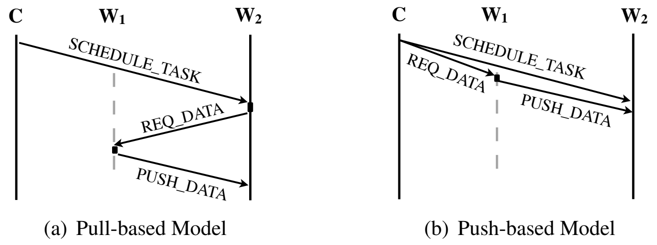

Figure 9: ***Sol adopts the push-based model to pipeline task scheduling and data fetch.***

with that in Sol. In case of late-binding, workers have to wait for new task assignments from the remote coordinator. In contrast, the site manager in Sol directly dispatches a task already queued up in its local queue and asynchronously notifies the coordinator of task completions as well as the resource status of the site. The coordinator makes new task placement decisions and queues up tasks in site managers asynchronously, while workers in that site are occupied with task executions.

Furthermore, this execution model enables us to pipeline t_{coord} and t_{comm} for each individual task's execution. When the coordinator assigns a task to a site, it notifies the corresponding upstream tasks (i.e., tasks in the previous stage) of this assignment. As such, when upstream tasks complete, they can proactively push their latency-bound output partitions directly to the site where their downstream tasks will execute, even though the control messages containing task placements may still be on-the-fly. As shown in Figure 9, pull-based data fetches experience three sequential phases of communication; in contrast, the scheduling of downstream tasks and their remote data reads are pipelined in the push-based model, improving their completion times.

4.2 Why Does Early-Binding Help?

Assume that the coordinator continuously allocates tasks to a remote site's k CPUs. For each task completion, the pull-based model takes one RTT for the coordinator to receive the task completion notification and then send the next task assignment; during this period, the task is queued up in the coordinator for scheduling. Hence, on average, $\frac{i-1}{k}$ RTTs are

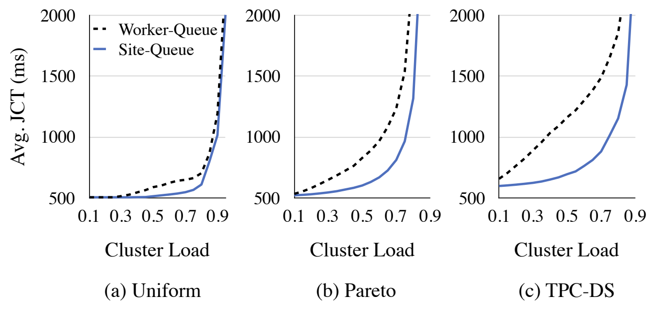

Figure 10: ***Job performance with Site- and Worker-Queue approaches. Variance in task durations increases from (a) to (c).***

wasted before the i^{th} task runs. The push-based model can save up to $\frac{i-1}{k}$ RTTs for the i^{th} task by pipelining inter-task assignments and executions. Our analysis over 44 datacenters using the measured inter-site latencies shows that, compared to late-binding, the push-based model can achieve an average improvement of 153 ms for the data fetch of every downstream task (more details in Appendix A). Such gaps become magnified at scale with a large number of small tasks, e.g., a large fan-out, latency-sensitive job.

One may consider pulling multiple tasks for individual workers at a time, but the push model provides more flexibility. Pushing from the coordinator can react to online scheduling better. When tasks arrive in an online manner, multiple tasks may not be available for pulling at a time. e.g., when a new task keeps arriving right after serving a pull request, pulling multiple tasks degenerates into pulling one by one.

Moreover, by late-binding task assignments within the site, our site-manager approach enables more flexibility than pushing tasks to individual workers (i.e., maintaining one queue per worker). To evaluate this, we ran three workloads across 10 EC2 sites, where all workloads have the same average task duration from TPC-DS benchmarks but differ in their distributions of task durations. Figure 10 shows that the site-manager approach achieves superior job performance owing to better work balance, particularly when task durations are skewed.

4.3 How to Push the Right Number of Tasks?

Determining the number of queued-up tasks for site managers is crucial for balancing worker utilization versus job completion times. On the one hand, queuing up too few tasks leads to underutilization, inflating t_{queue} due to lower system throughput. On the other hand, queuing up too many leads to sub-optimal work assignments because of insufficient knowledge when early-binding, which inflates job completion times as well (see Appendix B for more details).

Our target: Intuitively, as long as a worker is not waiting to receive work, queuing more tasks does not provide additional benefit for improving utilization. To fully utilize the resource, we expect the total execution time of the queued-up tasks will occupy the CPU before the next task assignment arrives, which is the key to strike the balance between utilization and job performance.

Our solution: When every task's duration is known, the number of queued-up tasks can adapt to the instantaneous load such that the total required execution time of the queued-up tasks keeps all the workers in a site busy, but not pushing any more to retain maximum flexibility for scheduling across sites. However, individual task durations are often highly skewed in practice [8], while the overall distribution of task durations is often stable over a short period [20, 44].

Even without presuming task-specific characteristics or distributions, we can still approximate the ideal queue length at every site dynamically for a given resource utilization target. We model the total available cycles in each scheduling round as our target, and the duration of each queued-up task is a random variable. This can be mapped into a packing problem, where we have to figure out how many random variables to sum up to achieve the targeted sum.

When the individual task duration is not available, we extend Hoeffding's inequality, and inject the utilization target into our model to determine the desired queue length (Appendix C for a formal result and performance analysis). Hoeffding's inequality is known to characterize how the sum of random variables deviates from its expected value with the minimum, the average, and the maximum of variables [23]. We extend it but filter out the outliers in tasks, wherein we rely on three statistics – 5th percentile, average, and 95th percentile (which are often stable) – of the task duration by monitoring the tasks over a period. As the execution proceeds, the coordinator in Sol inquires the model to generate the target queue size, whereby it dynamically pushes tasks to each site to satisfy the specified utilization. Note that when the network latency becomes negligible, our model outputs zero queue length as one would expect.

4.4 How to Push Tasks with Dependencies?

In the presence of task dependencies, where tasks may depend on those in their parent stage(s), pushing tasks is challenging, since it creates a tradeoff between the efficiency and quality of pipelining. For latency-sensitive tasks, we may want to push downstream tasks to save round-trip coordinations even before the upstream output is available. However, for bandwidth-intensive tasks, pushing their downstream tasks will not bring many benefits; this may even miss optimal task placements due to insufficient knowledge about the outputs from all upstream tasks [45, 50]. Sol, therefore, has to reconcile between latency- and bandwidth-sensitive tasks at runtime without presuming task properties.

To achieve desired pipelining efficiency for latency-bound tasks, Sol speculates the best placements for downstream tasks. Our straw-man heuristic is first pushing the downstream task to the site with the least work, with an aim to minimize the queueing time on the site. Moreover, Sol can refine its speculation by learning from historical trends (e.g., recurring jobs) or the iterative nature of many jobs. For example, in stream processing and machine learning, the output partitions

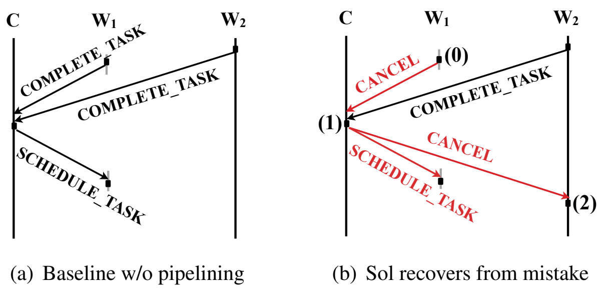

Figure 12: ***(b) The recovery process is shown in red. (0) W_1 detects large output, and sends CANCEL message to the coordinator C for task rescheduling. (1) Upon receiving the update, C waits until it gathers required information, then reschedules task, and (3) cancels task in W_2.***

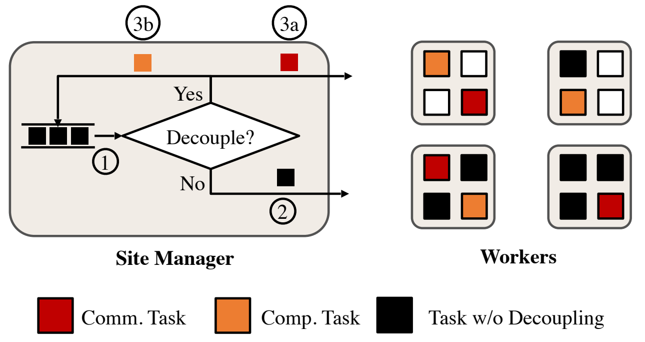

Figure 13: ***High-level overview of data plane decoupling.***

computed for every batch are largely similar [55], so are their task placements [49]. As such, Sol can reuse the placement decisions in the past run.

However, even when a bandwidth-intensive task is pushed to a suboptimal site, Sol can gracefully retain the scheduling quality via worker-initiated re-scheduling. Figure 12 shows the control flow of the recovery process in Sol and the baseline. In Figure 12(b), we push upstream tasks to workers W_1 and W_2, and downstream tasks are pushed only to W_2. As the upstream task in W_1 proceeds, the task manager detects large output is being generated, which indicates we are in the regime of bandwidth-intensive tasks. (0) Then W_1 notifies the coordinator C of task completion and a CANCEL message to initiate rescheduling for the downstream task. (1) Upon receiving the CANCEL message, the coordinator will wait until it collects output metadata from W_1 and W_2. The coordinator then reschedules the downstream task, and (2) notifies W_2 to cancel the pending downstream task scheduled previously. Note that the computation of a downstream task will not be activated unless it has gathered the upstream output.

As such, even when tasks are misclassified, Sol performs no worse than the baseline (Figure 12(a)). First, the recovery process does not introduce more round-trip coordinations due to rescheduling, so it does not waste time. Moreover, even in the worst case, where all upstream tasks have preemptively pushed data to the downstream task by mistake, the total amount of data transfers is capped by the input size of the downstream. However, note that the output is pushed only if it is latency-sensitive, so the amount of wasted bandwidth is also negligible as the amount of data transfers is latency-bound.

4.5 How to Handle Failures and Uncertainties?

Fault tolerance and straggler mitigation are enforced by the local site manager and the global coordinator. Site managers in Sol try to restart a failed task on other local workers; failures of long tasks or persistent failures of short tasks are handled via coordination with the remote coordinator. Similarly, site managers track the progress of running tasks and selectively duplicate small tasks when their execution lags behind. Sol can gracefully tolerate site manager failures by redirecting workers' control messages to the central coordinator, while a secondary site manager takes over (§7.5).

Moreover, Sol can guarantee a bounded performance loss due to early-binding even under uncertainties. To ensure a task at the site manager will not experience arbitrarily large queueing delay, the site manager can withdraw the task assignment when the task queueing delay on this site exceeds Δ. As such, the total performance loss due to early-binding is (Δ + RTT), since it takes one RTT to push and reclaim the task.

5 Decoupling in the Data Plane

In existing execution engines, the amount of CPU allocated to a task when it is reading data is the same as when it later processes the data. This tight coupling between resources leads to resource underutilization (§2.2). In this section, we introduce how to improve t_{queue} by mitigating HOL blocking.

5.1 How to Decouple the Provisioning of Resource?

To remove the coupling in resource provisioning, Sol introduces dedicated communication tasks,[5] which fetch task input from remote worker(s) and deserialize the fetched data, and computation tasks, which perform the computation on data. The primary goal of decoupling is to scale down the CPU requirements when multiple tasks have to fetch data over low-bandwidth links.

Communication and computation tasks are internally managed by Sol without user intervention. As shown in Figure 13, ① when a task is scheduled for execution, the site manager checks its required input for execution and reserves the provisioned resource on the scheduled worker. ② Bandwidth-insensitive tasks will be dispatched directly to the worker to execute. (3a) However, for tasks that need large volumes of remote data, the site manager will notify the task manager on the scheduled worker to set up communication tasks for data preparation. (3b) At the same time, the corresponding computation tasks be marked as inactive and do not start their execution right away. Once input data is ready for computation, the site manager will activate corresponding computation tasks to perform computation on the fetched data.

[5]Each communication task takes one CPU core by default in our design.

Although decoupling the provisioning of computation and communication resource will not speed up individual tasks, it can greatly improve overall resource utilization. When the input for a task's computation is being fetched by the communication task, by oversubscribing multiple computation tasks' communication to fewer communication tasks, Sol can release unused CPUs and repurpose them for other tasks. In practice, even the decoupled job can benefit from its own decoupling; e.g., when tasks in different stages can run in parallel, which is often true for jobs with complicated DAGs, computation tasks can take up the released CPUs from other stages in decoupling.

5.2 How Many Communication Tasks to Create?

Although decoupling is beneficial, we must avoid hurting the performance of decoupled jobs while freeing up CPUs. A key challenge in doing so is to create the right number of communication tasks to fully utilize the available bandwidth. Creating too many communication tasks will hog CPUs, while creating too few will slow down the decoupled job.

We use a simple model to characterize the number of required communication tasks. There are two major operations that communication tasks account for: (i) fetch data with CPU cost $C_{I/O}$ every time unit; (ii) deserialize the fetched data simultaneously with CPU cost C_{deser} in unit time. When the decoupling proceeds with I/O bandwidth B, the total requirement of communication tasks N can be determined based on the available bandwidth ($N = B \times (C_{I/O} + C_{deser})$).

Referring to the network throughput control, we use an adaptive tuning algorithm. When a new task is scheduled for decoupling, the task manager first tries to hold the provisioned CPUs to avoid resource shortage in creating communication tasks. However, the task manager will opportunistically cancel the launched communication task after its current fetch request completes, and reclaim its CPUs if launching more communication tasks does not improve bandwidth utilization any more.[6] During data transfers, the task manager monitors the available bandwidth using an exponentially weighted moving average (EWMA).[7] As such, the task manager can determine the number of communication tasks required currently: $N_{current} = \lceil \frac{B_{current}}{B_{old}} \times N_{old} \rceil$. Therefore, it will launch more communication tasks when more bandwidth is available and the opposite when bandwidth decreases. Note that the number of communication tasks is limited by the total provisioned CPUs for that job to avoid performance interference.

5.3 How to Recover CPUs for Computation?

Sol must also ensure that the end-to-end completion time on computation experiences negligible inflation. This is because when the fetched data is ready for computation, the decoupled job may starve if continuously arriving computation tasks take up its released computation resources.

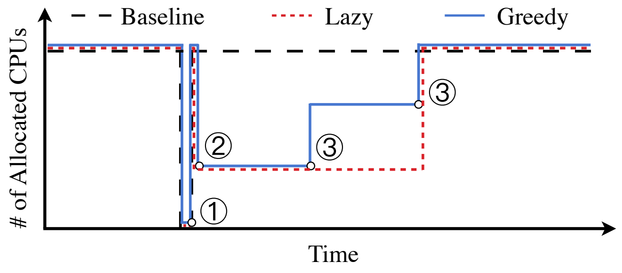

Figure 14: ***Three strategies to manage decoupled jobs. We adopt the Greedy strategy: ① when the downstream tasks start, they hold the reserved CPUs. ② But the task manager will reclaim the unused CPUs, and ③ activate the computation task once its input data is ready. The first trough marks the stage boundary.***

We refer to not decoupling as the *baseline* strategy, while waiting for the entire communication stage to finish as the *lazy* strategy. The former wastes resources, while the latter can hurt the decoupled job. Figure 14 depicts both.

Instead, Sol uses a *greedy* strategy, whereby as soon as some input data becomes ready (from upstream tasks), the site manager will prioritize the computation task corresponding to that data over other jobs and schedule it. As such, we can gradually increase its CPU allocation instead of trying to acquire all at once or holding onto all of them throughout.

5.4 Who Gets the Freed up CPUs?

Freed up CPUs from the decoupled jobs introduce an additional degree of freedom in scheduling. Resource schedulers can assign them in a FIFO or fair manner. As the duration of communication tasks can be estimated by the remaining data fetches and the available bandwidth, the scheduler can plan for the extra resources into the future, e.g., similar to [19].

6 Implementation

While our design criteria are not married to specific execution engines, we have implemented Sol in a way that keeps it API compatible with Apache Spark [2] in order to preserve existing contributions in the big data stack.

Control and Data Plane To implement our federated architecture, we add site manager modules to Spark, wherein each site manager keeps a state store for necessary metadata in task executions, and the metadata is shared across tasks to avoid redundant requests to the remote coordinator. The central coordinator coordinates with the site manager by heartbeat as well as the piggyback information in task updates. During executions, the coordinator monitors the network latency using EWMA in a one second period. This ensures that we are stable despite transient latency spikes. When the coordinator schedules a task to the site, it assigns a dummy worker for the pipelining of dependent tasks (e.g., latency-bound output will be pushed to the dummy worker). Similar to delay scheduling, we set the queueing delay bound Δ to 3 seconds [56]. Upon receiving the completion of upstream tasks, the site manager

[6] This introduces little overhead, since the data fetch is in a streaming manner, wherein the individual block is small.

[7] $B_{current} = \alpha\, B_{measured} + (1-\alpha)\, B_{old}$, where α is the smoothing factor ($\alpha = 0.2$ by default) and B denotes the available bandwidth over a period.

can schedule the downstream task more intelligently with late-binding. Meanwhile, the output information from upstream tasks is backed up in the state store until their completions.

Support for Extensions Our modifications are to the core of Apache Spark, so users can enjoy existing Spark-based frameworks on Sol without migrations of their codebase. Moreover, for recent efforts on WAN-aware optimizations, Sol can support those more educated resource schedulers or location-conscious job schedulers by replacing the default, but further performance analysis of higher-layer optimizations is out of the scope of this paper. To the best of our knowledge, Sol is the first execution engine that can optimize the execution layer across the design space.

7 Evaluation

In this section, we empirically evaluate Sol through a series of experiments using micro and industrial benchmarks. Our key results are as follows:

- Sol improves performance of individual SQL and machine learning jobs by 4.9×–11.5× w.r.t. Spark and Tez execution engines in WAN settings. It also improves streaming throughput by 1.35×–3.68× w.r.t. Drizzle (§7.2).
- In online experiments, Sol improves the average job performance by 16.4× while achieving 1.8× higher utilization (§7.3).
- Even in high bandwidth-low latency (LAN) setting, Sol improves the average job performance by 1.3× w.r.t. Spark; its improvement in low bandwidth-low latency setting is 3.9× (§7.4).
- Sol can recover from failures faster than its counterparts, while effectively handling uncertainties (§7.5).

7.1 Methodology

Deployment Setup We first deploy Sol in EC2 to evaluate individual job performance using instances distributed over 10 regions.[8] Our cluster allocates 4 *m4.4xlarge* instances in each region. Each has 16 vCPUs and 64GB of memory. To investigate Sol performance on multiple jobs in diverse network settings, we set up a 40-node cluster following our EC2 setting, and use *Linux Traffic Control* to perform network traffic shaping to match our collected profile from 10 EC2 regions.

Workloads We use three types of workloads in evaluations:

1. *SQL*: we evaluate 110 industry queries in TPC-DS/TPC-H benchmarks [5, 6]. Performance on them is a good demonstration of how good Sol would perform in real-world applications handling jobs with complicated DAGs.
2. *Machine learning*: we train three popular federated learning applications: linear regression, logistic regression, and k-means, from Intel's industry benchmark [26]. Each training data consists of 10M samples, and the training time of each iteration is dominated by computation.
3. *Stream processing*: we evaluate the maximum throughput that an execution design can sustain for *WordCount* and *TopKCount* while keeping the end-to-end latency by a given target. We define the end-to-end latency as the time from when records are sent to the system to when results incorporating them appear.

Baselines We compare Sol to the following baselines:

1. *Apache Spark* [54] and *Apache Tez* [47]: the mainstream execution engines for generic workloads in datacenter and wide-area environments.
2. *Drizzle* [49]: a recent engine tailored for streaming applications, optimizing the scheduling overhead.

Metrics Our primary metrics to quantify performance are the overarching user-centric and operator-centric objectives, including *job completion time (JCT)* and *resource utilization*.

7.2 Performance Across Diverse Workloads in EC2

In this section, we evaluate Sol's performance on individual jobs in EC2, with query processing, machine learning, and streaming benchmarks.

Sol outperforms existing engines Figure 15 shows the distribution of query completion times of 110 TPC queries individually on (10, 100, 1000) scale factor datasets. As expected, Sol and Spark outperform Tez by leveraging their in-memory executions. Meanwhile, Sol speeds up individual queries by 4.9× (11.5×) on average and 8.6× (23.3×) at the 95th percentile over Spark (Tez) for the dataset with scale factor 10. While these queries become more bandwidth- and computation- intensive as we scale up the dataset, Sol can still offer a noticeable improvement of 3.4× and 1.97× on average compared to Spark on datasets with scale factors 100 and 1000, respectively. More importantly, Sol outperforms the baselines across all queries.

Sol also benefits machine learning and stream processing. For such predictable workloads, Sol pipelines the scheduling and data communication further down their task dependencies. Figure 16 reports the average duration across 100 iterations in machine learning benchmarks, where Sol improves the performance by 2.64×-3.01× w.r.t. Spark.

Moreover, Sol outperforms Drizzle [49] in streaming workloads. Figure 17 shows that Sol achieves 1.35×–3.68× higher throughput than Drizzle. This is because Sol follows a *push-based* model in both control plane coordinations and data plane communications to pipeline round-trips for inter-site coordinations, while Drizzle optimizes the coordination overhead between the coordinator and workers. Allowing a larger target latency improves the throughout, because the fraction of computation time throughout the task lifespan increases, and thus the benefits from Sol become less relevant.

Sol is close to the upper bound performance To explore how far Sol is from the optimal, we compare Sol's perfor-

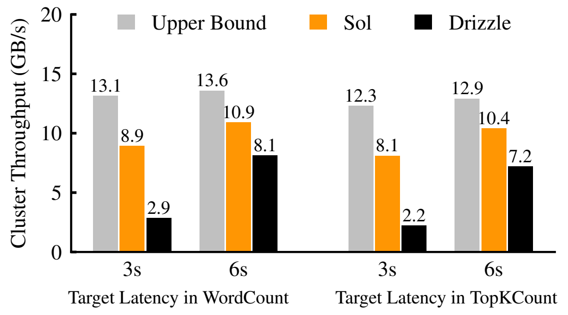

Figure 17: ***Performance on stream processing. Higher is better.***

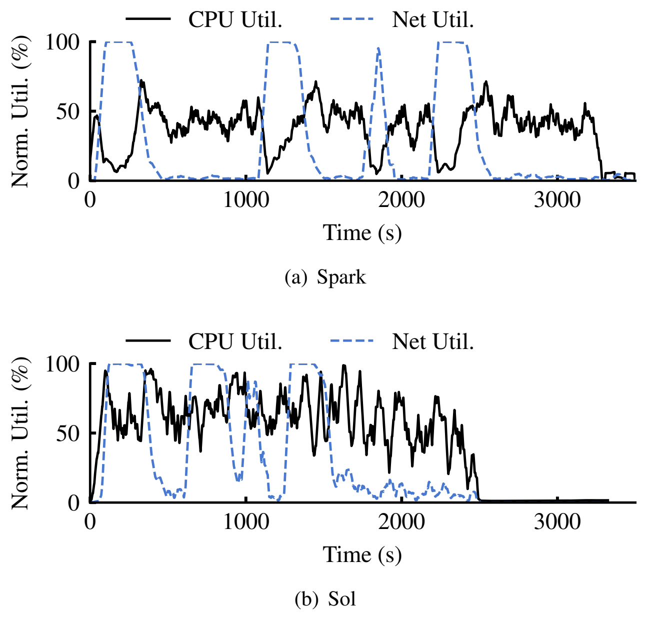

Figure 18: ***Resource utilization over time.***

mance in the high latency setting against Sol in a hypothetical latency-free setting [9], which is a straightforward upper bound on its performance. While high latencies lead to an order-of-magnitude performance degradation on Spark, Sol is effectively approaching the optimal. As shown in Figure 15 and Figure 16, Sol's performance is within 3.5× away from the upper bound. As expected in Figure 15(c), this performance gap narrows down as Sol has enough work to queue-up for hiding the coordination delay.

7.3 Online Performance Breakdown

So far we have evaluated Sol in the offline setting with individual jobs. Here we move on to evaluate Sol with diverse workloads running concurrently and arriving in an online fashion with our cluster. Specifically, we evaluate Sol in an online setting, where we run 160 TPC queries – randomly drawn from the (10, 100)-scale TPC benchmarks – run as foreground, interactive jobs, and bandwidth-intensive CloudSort jobs [3] – each has 200 GB or 1 TB GB input – in the background. The TPC queries are submitted following a Poisson process with an average inter-arrival time of 10 seconds, while the CloudSort jobs are submitted every 300 seconds.

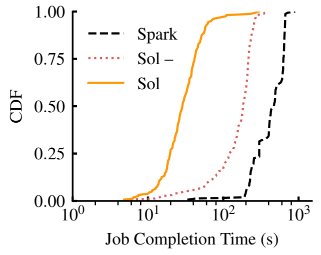
We evaluate Sol and Spark using two job schedulers:

1. *FIFO*: Jobs are scheduled in the order of their arrivals, thus easily resulting in Head-of-Line (HOL) blocking;
2. *Fair sharing*: Jobs get an equal share of resources, but the execution of early submitted jobs will be prolonged.

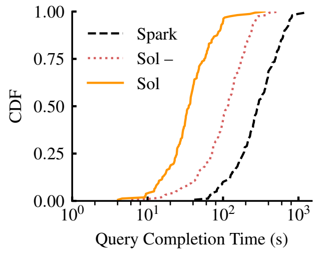
These two schedulers are prevalent in real deployments [1,22], especially when job arrivals and durations are unpredictable.

Improvement of resource utilization Figure 18 shows a timeline of normalized resource usage for both network bandwidth and total CPUs with the FIFO scheduler. A groove in CPU utilization and a peak in network utilization dictate the execution of bandwidth-intensive background jobs. Similarly, a low network utilization but high CPU utilization implicate

[9]We create a 40-node cluster in a single EC2 region.



(a) FIFO Scheduler



(b) Fair Scheduler

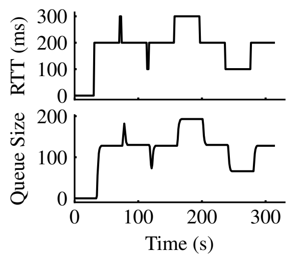
(b) Low Latency and Low B/w

Figure 20: ***Sol performance in other design space.***



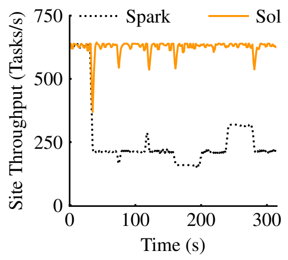


Figure 21: ***Sol performance under latency variations.***

the execution of foreground jobs. We observe Sol improves the CPU utilization by 1.8× over Spark. The source of this improvement comes from both control and data planes: (i) Sol pipelines high-latency coordinations, and thus workers are busy in running tasks all the time. (ii) Sol flexibly repurposes the idle CPU resources in the presence of bandwidth-intensive jobs, thus achieving higher utilizations by orchestrating all jobs. Note that the CPU resource is not always fully saturated in this evaluation, because the cluster is not extremely heavy-loaded given the arrival rate. Therefore, we believe Sol can provide even better performance with heavy workloads, wherein the underutilized resource can be repurposed for more jobs with decoupling. Results were similar for the fair scheduler too.

Improvement of JCTs Figure 19(a) and Figure 19(b) report the distribution of job completion times with FIFO and fair schedulers respectively. The key takeaways are the following. First, simply applying different job schedulers is far from optimal. With the FIFO scheduler, when CloudSort jobs are running, all the frontend jobs are blocked as background jobs hog all the available resources. While the fair scheduler mitigates such job starvation by sharing resource across jobs, it results in a long tail as background jobs are short of resources.

Instead, Sol achieves better job performance by improving both the intra-job and inter-job completions in the task execution level: (i) Early-binding in the control plane improves small jobs, whereby the cluster can finish more jobs in a given time. Hence, even the simple pipelining can achieve an average improvement of 2.6× with the FIFO scheduler and 2.5× with the fair scheduler. (ii) With data plane decoupling, the latency-sensitive jobs can temporarily enjoy under-utilized resource without impacting the bandwidth-intensive jobs. We observe the performance loss of bandwidth-intensive job is less than 0.5%. As the latency-sensitive jobs complete faster, bandwidth-intensive jobs can take up more resource. As such, Sol further improves the average JCTs w.r.t. Spark with both FIFO (average 16.4×) and fair schedulers (average 8.3×).

7.4 Sol's Performance Across the Design Space

We next rerun the prior online experiment to investigate Sol's performance in different network conditions with our cluster.

High bandwidth-low latency network In this evaluation, each machine has 10 Gbps bandwidth, and the latency across machines is <1 ms. Figure 20 shows the distribution of JCTs. The benefits of data plane decoupling depend on the time spent on data exchanges over the network. Although jobs are prone to finishing faster in this favorable environments, Sol can still improve over Spark by 1.3× on average by mitigating the HOL blocking with the decoupling in task executions.

Low bandwidth-low latency network In practice, users may deploy cheap VMs to perform time-insensitive jobs due to budgetary constraints. We now report the JCT distribution in such a setting, where each machine has 1 Gbps low bandwidth and negligible latency. As shown in Figure 20(b), Sol largely outperforms Spark by 3.9×. This gain is again due to the presence of HOL blocking in Spark, where bandwidth-intensive jobs hog their CPUs when tasks are reading large output partitions over the low-bandwidth network.

Note that the high latency-high bandwidth setting rarely exists. As such, Sol can match or achieve noticeable improvement over existing engines across all practical design space.

7.5 Sol's Performance Under Uncertainties

As a network-aware execution engine, Sol can tolerate different uncertainties with its federated design.

Uncertainties in network latency While Sol pushes tasks to site managers with early-binding under high network latency, its performance is robust to latency jitters. We evaluate Sol by continuously feeding our cluster with inference jobs; each scans a 30 GB dataset and the duration of each task is around 100 ms. We snapshot a single site experiencing tran-

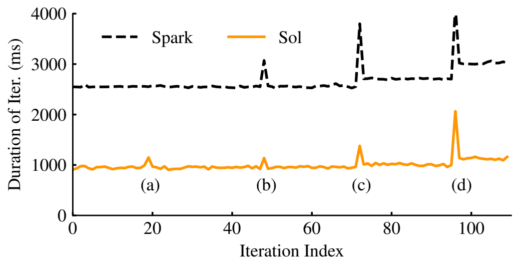

Figure 22: ***Impact of different failures on iteration duration for Sol and Spark: (a) Sol site manager failure, (b) task failure, (c) node failure , and (d) site-wide failure.***

sient or lasting latency variations. As shown in Figure 21, Sol proceeds more tasks than Spark with early-binding of tasks. Moreover, Sol can efficiently react to RTT variations by adaptively tuning its queue size.

Uncertainties in failure Figure 22 compares Sol's performance with Spark under different failures. In this evaluation, we train a long running linear regression in our 10-site deployment, and each iteration performs two stages: training on the data and the aggregation of updates. When the site manager fails (a), Sol restarts the site manager on other local machines, and reschedules the missing queued-up tasks. The recovery of site managers is pipelined with task executions, experiencing little overhead in job performance. Task failures (b) and machine failures (c) in Spark require a tight coordination with the remote coordinator, but Sol handles such failures by coordinating the site manager. Upon detecting task failures, the site manager restarts the task on other locally available machines with its metadata, while asynchronously notifying the coordinator. As such, Sol suffers little overhead by hiding the failures silently. Although the coordinator needs to take charge of rescheduling in both Sol and Spark under site-wide failures (d), tasks in Sol complete faster.

8 Discussion and Future Work

Fine-grained queue management. By capturing the range of task durations, Sol pushes the right number of tasks to site managers at runtime. However, Hoeffding's inequality can be suboptimal, especially when the variance of task durations becomes much greater than their average [23]. Further investigations on the queue management of site managers are needed. To this end, one possible approach is to build a context-aware machine learning model (e.g., reinforcement learning) to decide the optimal queue length [13].

Performance analysis of geo-aware efforts. As the first federated execution engine for diverse network conditions, Sol can serve a large body of existing efforts for geo-distributed data analytics [28, 45, 50]. Although these works do not target latency-bound tasks, for which Sol shows encouraging improvements with control plane optimizations, it would be interesting to investigate Sol's improvement for bandwidth-intensive workloads after applying techniques from existing geo-distributed frameworks.

9 Related Work

Geo-distributed storage and data analytics Numerous efforts strive to build frameworks operating on geo-distributed data. Recent examples include geo-distributed data storage [35, 53] and data analytics frameworks [4, 24]. Geode [51] aims at generating query plans that minimize data transfers over the WAN, while Clarinet [50] and Iridium [45] develop the WAN-aware query optimizer to optimize query response time subject to heterogeneous WAN bandwidth. These optimizations for data analytics lie on the scheduler layer and could transparently leverage Sol for further gains (§6).

Data Processing Engines The explosion of data volumes has fostered the world of MapReduce-based parallel computations [18]. Naiad [40] and Flink [12] express data processing as pipelined fault-tolerant data flows, while the batch processing on them performs similar to Spark [54]. The need for expressive user-defined optimizations motivates Dryad [29] and Apache Tez [47] to enable runtime optimizations on execution plans. These paradigms are designed for well-provisioned networks. Other complementary efforts focus on reasoning about system performance [41, 42], or decoupling communication from computation to further optimize data shuffles [14, 15]. Our work bears some resemblance, but our focus is on designing a network-aware execution engine.

Speeding up data-parallel frameworks Although Nimbus [37] and Drizzle [49] try to speed up execution engines, they focus on amortizing the computation overhead of scheduling for iterative jobs. Hydra [17] democratizes the resource management for jobs across multiple groups. While Yaq-c [46] discusses the tradeoff between utilization and job performance in queue management, its solution is bound to specific task durations without dependencies. Moreover, we optimize task performance inside execution engines.

10 Conclusion

As modern data processing expands due to changing workloads and deployment scenarios, existing execution engines fall short in meeting the requirements of diverse design space. In this paper, we explored the possible designs beyond those for datacenter networks and presented Sol, a federated execution engine that emphasizes an early-binding design in the control plane and decoupling in the data plane. In comparison to the state-of-the-art, Sol can match or achieve noticeable improvements in job performance and resource utilization across all practical points in the design space.

Acknowledgments

Special thanks go to the entire CloudLab team for making Sol experiments possible. We would also like to thank the anonymous reviewers, our shepherd, Ramachandran Ramjee, and SymbioticLab members for their insightful feedback. A Benefits of Pipelining

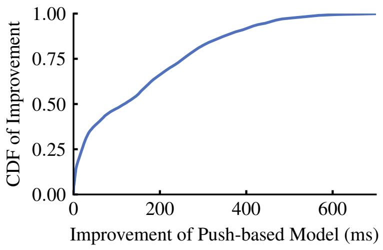

Figure 23: ***Improvement of Push-based Model in (§4.2) .***

To investigate the benefit of pipelining the scheduling and data fetch of a downstream task, we assume zero queuing time and emulate the inter-site coordinations with our measured latency across 44 datacenters on AWS, Azure and Google Cloud. We define the improvement as the difference between the duration of the pull-based model and that of our proposed push-based model for every data fetch (Figure 9). Our results in Figure 23 report we can achieve an average improvement of 153 ms.

Understandably, such benefit is more promising in consideration of the task queuing time, as pushing the remote data is even pipelined with the task spin-wait for scheduling.

B Impact of Queue Length

We quantify the impact of queue size with the aforementioned three workloads (in (§4.2)). In this experiment, we analyze three distinct sites, where the network latency from Site A, B and C to the centralized coordinator is 130 ms, 236 ms and 398 ms, respectively. As shown in Figure 24, queuing up too many or too few tasks can hurt job performance.

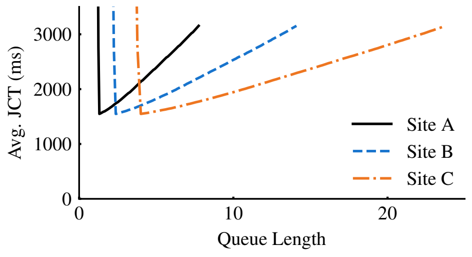
C Determining the Queue Length

Lemma 1. *For a given utilization level* δ *and confidence interval* α *(i.e.,* $\Pr[Util. > \delta] > \alpha$*), the queue length* K *for* S *working slots satisfies:*

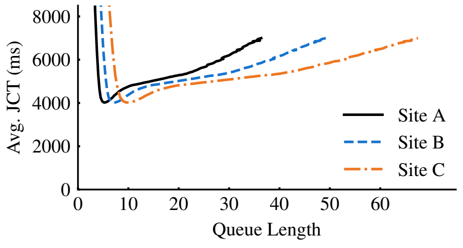
$$K \geq M - \frac{C}{2} + \frac{1}{2D_{avg}}\sqrt{(CD_{avg})^2 - 4MCD_{avg}} \qquad (1)$$

where D_{5th} *and* D_{95th} *denote the 5th and 95th percentile of task durations respectively, and* D_{avg} *denotes the average task duration.* $M = \frac{\delta RTT \times S}{D_{avg}}$, $C = \frac{1}{2}\left(\frac{D_{95th}-D_{5th}}{D_{avg}}\right)^2 \cdot \log\alpha$. *The first term* M *depicts the expectation, while the rest capture the skewness of distributions and confidence.*

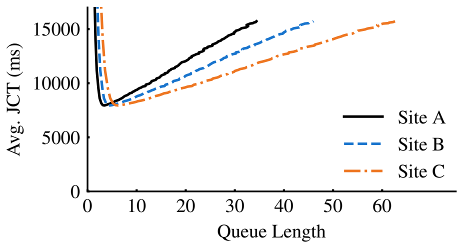
This is true for any distribution of task durations. Unfortunately, we omit the proof for brevity. D_{avg}, D_{5th} and D_{95th} are often stable in a large cluster, and thus available from the historical data. α is the configurable confidence level, which is often set to 99% [32, 38], and δ is set to $\geq$ 100% to guarantee full utilization. Note that from Eq. 1, when task durations follow the uniform distribution, our model ends up with the expectation M. Similarly, when the RTT becomes negligible, this outputs zero queue length.



(a) Uniform Distribution



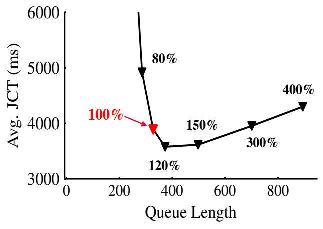
(b) Pareto Distribution



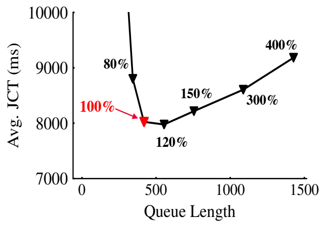
(c) TPC-DS Trace

Figure 24: ***Impact of Queue Size on Job Completion Time (JCT).***

Our evaluations show this model can provide encouraging performance, wherein we reran the prior experiments with the workloads mentioned above (§4.3). We provide the results for workloads with Pareto and TPC-DS distributions by injecting different utilizations in theory, since results for the Uniform distribution are concentrated on a single point (i.e., the expectation M). As shown in Figure 25, the queue length with 100% utilization target locates in the sweet spot of JCTs.



(a) Pareto Distribution



(b) TPC-DS Trace

Figure 25: ***JCT performance with different utilization targets.***

Note that when more task information is available, one can refine this range better; e.g., the bound of Eq. (1) can be improved with Chernoff's inequality when the distribution of task durations is provided.

THEMIS: Fair and Efficient GPU Cluster Scheduling

Kshiteej Mahajan[*], Arjun Balasubramanian[*], Arjun Singhvi[*], Shivaram Venkataraman[*]

Abstract: Modern distributed machine learning (ML) training workloads benefit significantly from leveraging GPUs. However, significant contention ensues when multiple such workloads are run atop a shared cluster of GPUs. A key question is how to fairly apportion GPUs across workloads. We find that established cluster scheduling disciplines are a poor fit because of ML workloads' unique attributes: ML jobs have long-running tasks that need to be gang-scheduled, and their performance is sensitive to tasks' relative placement.

We propose THEMIS, a new scheduling framework for ML training workloads. It's GPU allocation policy enforces that ML workloads complete in *a finish-time fair* manner, a new notion we introduce. To capture placement sensitivity and ensure efficiency, THEMIS uses a two-level scheduling architecture where ML workloads bid on available resources that are offered in an *auction* run by a central arbiter. Our auction design allocates GPUs to winning bids by trading off fairness for efficiency in the short term, but ensuring finish-time fairness in the long term. Our evaluation on a production trace shows that THEMIS can improve fairness by more than $2.25X$ and is ~5% to 250% more cluster efficient in comparison to state-of-the-art schedulers.

1 Introduction

With the widespread success of machine learning (ML) for tasks such as object detection, speech recognition, and machine translation, a number of enterprises are now incorporating ML models into their products. Training individual ML models is time- and resource-intensive with each training job typically executing in parallel on a number of GPUs.

With different groups in the same organization training ML models, it is beneficial to consolidate GPU resources into a shared cluster. Similar to existing clusters used for large scale data analytics, shared GPU clusters for ML have a number of operational advantages, e.g., reduced development overheads, lower costs for maintaining GPUs, etc. However, today, there are no ML workload-specific mechanisms to share a GPU cluster in a *fair* manner.

Our conversations with cluster operators indicate that fairness is crucial; specifically, that sharing an ML cluster becomes attractive to users only if they have the appropriate *sharing incentive*. That is, if there are a total N users sharing a cluster C, every user's performance should be no worse than using a private cluster of size $\frac{C}{N}$. Absent such incentive, users are either forced to sacrifice performance and suffer long wait times for getting their ML jobs scheduled, or abandon shared clusters and deploy their own expensive hardware.

Providing sharing incentive through fair scheduling mechanisms has been widely studied in prior cluster scheduling frameworks, e.g., Quincy [18], DRF [8], and Carbyne [11]. However, these techniques were designed for big data workloads, and while they are used widely to manage GPU clusters today, they are far from effective.

The key reason is that ML workloads have unique characteristics that make existing "fair" allocation schemes actually *unfair*. First, unlike batch analytics workloads, ML jobs have *long running tasks* that need to be scheduled together, i.e., gang-scheduled. Second, each task in a job often runs for a number of iterations while synchronizing model updates at the end of each iteration. This frequent communication means that jobs are *placement-sensitive*, i.e., placing all the tasks for a job on the same machine or the same rack can lead to significant speedups. Equally importantly, as we show, ML jobs differ in their placement-sensitivity (Section 3.1.2).

In Section 3, we show that having long-running tasks means that established schemes such as DRF – which aims to equally allocate the GPUs released upon task completions – can arbitrarily violate sharing incentive. We show that even if GPU resources were released/reallocated on fine time-scales [13], placement sensitivity means that jobs with same aggregate resources could have widely different performance, violating sharing incentive. Finally, heterogeneity in placement sensitivity means that existing scheduling schemes *also violate* Pareto efficiency and envy-freedom, two other properties that are central to fairness [34].

Our scheduler, THEMIS, address these challenges, and supports sharing incentive, Pareto efficiency, and envy-freedom for ML workloads. It multiplexes a GPU cluster across *ML applications* (Section 2), or apps for short, where every app consists of one or more related ML jobs, each running with different hyper-parameters, to train an accurate model for a given task. To capture the effect of long running tasks and placement sensitivity, THEMIS uses a new long-term fairness metric, *finish-time fairness*, which is the ratio of the running time in a shared cluster with N apps to running alone in a $\frac{1}{N}$ cluster. THEMIS's goal is thus to minimize the maximum finish time fairness across all ML apps while efficiently utilizing cluster GPUs. We achieve this goal using two key ideas.

First, we propose to widen the API between ML apps and the scheduler to allow apps to specify placement preferences. We do this by introducing the notion of a round-by-round auction. THEMIS uses leases to account for long-running ML tasks, and auction rounds start when leases expire. At the start of a round, our scheduler requests apps for their finish-time fairness metrics, and makes all available GPUs visible to a fraction of apps that are currently farthest in terms of their fairness metric. Each such app has the opportunity to *bid* for subsets of these GPUs as a part of an auction; bid values reflect the app's new (placement sensitive) finish time fairness metric from acquiring different GPU subsets. A central arbiter determines the global winning bids to maximize the aggregate improvement in the finish time fair metrics across all bidding apps. Using auctions means that we need to ensure that apps are truthful when they bid for GPUs. Thus, we use a *partial allocation* auction that incentivizes truth telling, and ensures Pareto-efficiency and envy-freeness by design.

While a far-from-fair app may lose an auction round, perhaps because it is placed less ideally than another app, its bid values for subsequent auctions naturally increase (because a losing app's finish time fairness worsens), thereby improving the odds of it winning future rounds. Thus, our approach converges to fair allocations over the long term, while staying efficient and placement-sensitive in the short term.

Second, we present a two-level scheduling design that contains a centralized inter-app scheduler at the bottom level, and a narrow API to integrate with existing hyper-parameter tuning frameworks at the top level. A number of existing frameworks such as Hyperdrive [29] and HyperOpt [3] can intelligently apportion GPU resources between various jobs in a single app, and in some cases also terminate a job early if its progress is not promising. Our design allows apps to directly use such existing hyper parameter tuning frameworks. We describe how THEMIS accommodates various hyper-parameter tuning systems and how its API is exercised in extracting relevant inputs from apps when running auctions.

We implement THEMIS atop Apache YARN 3.2.0, and evaluate by replaying workloads from a large enterprise trace. Our results show that THEMIS is at least 2.25X more fair (finish-time fair) than state-of-the-art schedulers while also improving cluster efficiency by ~5% to 250%. To further understand our scheduling decisions, we perform an event-driven simulation using the same trace, and our results show that THEMIS offers greater benefits when we increase the fraction of network intensive apps, and the cluster contention.

2 Motivation

We start by defining the terminology used in the rest of the paper. We then study the unique properties of ML workload traces from a ML training GPU cluster at Microsoft. We end by stating our goals based on our trace analysis and conversations with the cluster operators.

2.1 Preliminaries

We define an ML app, or simply an "app", as a collection of one or more ML model *training* jobs. Each app corresponds to a user training an ML model for a high-level goal, such as speech recognition or object detection. Users train these models knowing the appropriate hyper-parameters (in which case there is just a single job in the app), or they train a closely related set of models (n jobs) that explore hyper-parameters such as learning rate, momentum etc. [21, 29] to identify and train the best target model for the activity at hand.

Each job's constituent work is performed by a number of parallel *tasks*. At any given time, all of a job's tasks collectively process a *mini-batch* of training data; we assume that the size of the batch is fixed for the duration of a job. Each task typically processes a subset of the batch, and, starting from an initial version of the model, executes multiple iterations of the underlying learning algorithm to improve the model. We assume all jobs use the popular synchronous SGD [4].

We consider the finish time of an app to be when the best model and relevant hyper-parameters have been identified. Along the course of identifying such a model, the app may decide to terminate some of its constituent jobs early [3, 29]; such jobs may be exploring hyper-parameters that are clearly sub-optimal (the jobs' validation accuracy improvement over iterations is significantly worse than other jobs in the same app). For apps that contain a single job, finish time is the time taken to train this model to a target accuracy or maximum number of iterations.

2.2 Characterizing Production ML Apps

We perform an analysis of the properties of GPU-based ML training workloads by analyzing workload traces obtained from Microsoft. The GPU cluster we study supports over 5000 unique users. We restrict our analysis to a subset of the trace that contains 85 ML training apps submitted using a hyper-parameter tuning framework.

GPU clusters are known to be heavily contented [19], and we find this also holds true in the subset of the trace of ML apps we consider (Figure 1). For instance, we see that GPU demand is bursty and the average GPU demand is ~50 GPUs.

We also use the trace to provide a first-of-a-kind view into the characteristics of ML apps. As mentioned in Section 2.1, apps may either train a single model to reach a target accuracy (1 job) or may use the cluster to explore various hyper-parameters for a given model (n jobs). Figure 2 shows that ~10% of the apps have 1 job, and around ~90% of the apps perform hyper-parameter exploration with as many as 100 jobs (median of 75 jobs). Interestingly, there is also a significant variation in the number of hyper-parameters explored ranging from a few tens to about a hundred (not shown).

We also measure the *GPU time* of all ML apps in the trace. If an app uses 2 jobs with 2 GPUs each for a period of 10 minutes, then the GPU time for — the tasks would be 10 minutes each, the jobs would be 20 minutes each, and the app would be 40 GPU minutes. Figure 3 and Figure 4 show the long running nature of ML apps: the median app takes 11.5 GPU days and the median task takes 3.75 GPU hours. There is a wide diversity with a significant fraction of jobs and apps that are more than 10X shorter and many that are more than 10X longer.

From our analysis we see that ML apps are heterogeneous in terms of resource usage, and number of jobs submitted.

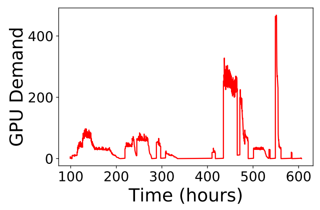

Figure 1: Aggregate GPU demand of ML apps over time

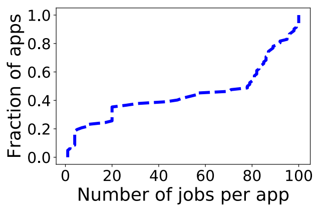

Figure 2: Job count distribution across different apps

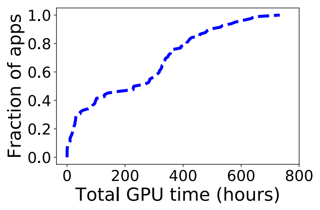

Figure 3: ML app time (= total GPU time across all jobs in app) distribution

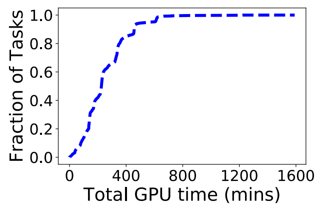

Figure 4: Distribution of Task GPU times

Running times are also heterogeneous, but at the same time much longer than, e.g., running times of big data analytics jobs (typically a few hours [12]). Handling such heterogeneity can be challenging for scheduling frameworks, and the long running nature may make controlling app performance particularly difficult in a shared setting with high contention.

We next discuss how some of these challenges manifest in practice from both cluster user and cluster operator perspectives, and how that leads to our design goals for THEMIS.

2.3 Our Goal

Our many conversations with operators of GPU clusters revealed a common sentiment, reflected in the following quote:

" We were scheduling with a balanced approach ... with guidance to 'play nice'. Without firm guard rails, however, there were always individuals who would ignore the rules and dominate the capacity. "

— An operator of a large GPU cluster at Microsoft

With long app durations, users who dominate capacity impose high waiting times on many other users. Some such users are forced to "quit" the cluster as reflected in this quote:

"Even with existing fair sharing schemes, we do find users frustrated with the inability to get their work done in a timely way... The frustration frequently reaches the point where groups attempt or succeed at buying their own hardware tailored to their needs. "

— An operator of a large GPU cluster at Microsoft

While it is important to design a cluster scheduler that ensures efficient use of highly contended GPU resources, the above indicates that it is perhaps equally, if not more important, for the scheduler to allocate GPU resources in a fair manner across many diverse ML apps; in other words, roughly speaking, the scheduler's goal should be to allow all apps to execute their work in a "timely way".

In what follows, we explain using examples, measurements, and analysis, why existing fair sharing approaches when applied to ML clusters fall short of the above goal, which we formalize next. We identify the need both for a new fairness metric, and for a new scheduler architecture and API that supports resource division according to the metric.

3 Finish-Time Fair Allocation

We present additional unique attributes of ML apps and discuss how they, and the above attributes, affect existing fair sharing schemes.

3.1 Fair Sharing Concerns for ML Apps

The central question is - given R GPUs in a cluster C and N ML apps, what is a *fair way* to divide the GPUs.

As mentioned above, cluster operators indicate that the primary concern for users sharing an ML cluster is performance isolation that results in "timely completion". We formalize this as: if N ML Apps are sharing a cluster then an app should not run slower on the shared cluster compared to a dedicated cluster with $\frac{1}{N}$ of the resources. Similar to prior work [8], we refer to this property as *sharing incentive* (SI). Ensuring sharing incentive for ML apps is our primary design goal.

In addition, resource allocation mechanisms must satisfy two other basic properties that are central to fairness [34]: Pareto Efficiency (PE) and Envy-Freeness (EF) [1]

While prior systems like Quincy [18], DRF [8] etc. aim at providing SI, PE and EF, we find that they are ineffective for ML clusters as they fail to consider *the long durations of ML tasks* and *placement preferences of ML apps*.

3.1.1 ML Task Durations

We empirically study task durations in ML apps and show how they affect the applicability of existing fair sharing schemes.

Figure 4 shows the distribution of task durations for ML apps in a large GPU cluster at Microsoft. We note that the tasks are, in general, very long, with the median task roughly 3.75 hours long. This is in stark contrast with, e.g., big data analytics jobs, where tasks are typically much shorter in duration [26].

State of the art fair allocation schemes such as DRF [8] provide instantaneous resource fairness. Whenever resources become available, they are allocated to the task from an app with the least current share. For big data analytics, where task durations are short, this approximates instantaneous resource fairness, as frequent task completions serve as opportunities to redistribute resources. However, blindly applying such schemes to ML apps can be disastrous: running the much longer-duration ML tasks to completion could lead to newly arriving jobs waiting inordinately long for resources. This leads to violation of SI for late-arriving jobs.

Recent "attained-service" based schemes address this problem with DRF. In [13], for example, GPUs are leased for a certain duration, and when leases expire, available GPUs are given to the job that received the least GPU time thus far;

[1]Informally, a Pareto Efficient allocation is one where no app's allocation can be improved without hurting some other app. And, envy-freeness means that no app should prefer the resource allocation of an other app.

	VGG16	Inception-v3
4 P100 GPUs on 1 server	103.6 images/sec	242 images/sec
4 P100 GPUs across 2 servers	80.4 images/sec	243 images/sec

Table 1: Effect of GPU resource allocation on job throughput. VGG16 has a machine-local task placement preference while Inception-v3 does not.

this is the "least attained service", or LAS allocation policy. While this scheme avoids the starvation problem above for late-arriving jobs, it still violates all key fairness properties because it is placement-unaware, an issue we discuss next.

3.1.2 Placement Preferences

Next, we empirically study placement preferences of ML apps. We use examples to show how ignoring these preferences in fair sharing schemes violates key properties of fairness.

Many apps, many preference patterns: ML cluster users today train a variety of ML apps across domains like computer vision, NLP and speech recognition. These models have significantly different model architectures, and more importantly, different placement preferences arising from different computation, communication needs. For example, as shown in Table 1, VGG16 has a strict machine-local task placement preference while Inception-v3 does not. This preference inherently stems from the fact that VGG-like architectures have very large number of parameters and incur greater overheads for updating gradients over the network.

We use examples to show the effect of placement on DRF's allocation strategy. Similar examples and conclusions apply for the LAS allocation scheme.

Ignoring placement affects SI: example: Consider the Instance 1 in Figure 5. In this example, there are two placement sensitive ML apps - A_1 and A_2, both training VGG16. Each ML app has just one job in it with 4 tasks and the cluster has two 4 GPU machines. As shown above, given the same number of GPUs both apps prefer GPUs to be in the same server than spread across servers.

For this example, DRF [8] equalizes the dominant resource share of both the apps under resource constraints and allocates 4 GPUs to each ML app. In Instance 1 of Figure 5 we show an example of a valid DRF allocation. Both apps get the same type of placement with GPUs spread across servers. This allocation violates SI for both apps as their performance would be better if each app just had its own dedicated server.

Ignoring placement affects PE, EF: example: Consider Instance 2 in Figure 5 with two apps - A_1 (Inception-v3) which is not placement sensitive and A_2 (VGG16) which is placement sensitive. Each app has one job with four tasks and the cluster has two machines: one 4 GPU and two 2 GPU.

Now consider the allocation in Instance 2, where A_1 is allocated on the 4 GPU machine whereas A_2 is allocated across the 2 GPU machines. This allocation violates EF, because A_2 would prefer A_1's allocation. It also violates PE because swapping the two apps' allocation would improve A_2's performance without hurting A_1.

In fact, we can formally show that:

Theorem 3.1. Existing fair schemes (DRF, LAS) ignore placement preferences and violate SI, PE, EF for ML apps.

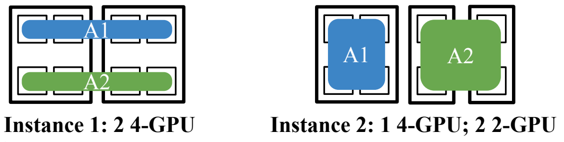

Figure 5: By ignoring placement preference, DRF violates sharing incentive.

$\vec{G}$	$[0,0]$	$[1,0] = [1,0]$	$[1,1]$
ρ	ρ_{old}	$\frac{200}{400} = \frac{1}{2}$	$\frac{100}{400} = \frac{1}{4}$

Table 2: Example table of bids sent from apps to the scheduler

Proof Refer to Appendix.

In summary, existing schemes fail to provide fair sharing guarantees as they are unaware of ML app characteristics. Instantaneous fair schemes such as DRF fail to account for long task durations. While least-attained service schemes overcome that limitation, neither approach's input encodes placement preferences. Correspondingly, the fairness metrics used - i.e., dominant resource share (DRF) or attained service (LAS) - do not capture placement preferences.

This motivates the need for a new placement-aware fairness metric, and corresponding scheduling discipline. Our observations about ML task durations imply that, like LAS, our fair allocation discipline should not depend on rapid task completions, but instead should operate over longer time scales.

3.2 Metric: Finish-Time Fairness

We propose a new metric called as finish-time fairness, ρ. $\rho = \frac{T_{sh}}{T_{id}}$.

T_{id} is the *independent finish-time* and T_{sh} is the *shared finish-time*. T_{sh} is the finish-time of the app in the shared cluster and it encompasses the slowdown due to the placement and any queuing delays that an app experiences in getting scheduled in the shared cluster. The worse the placement, the higher is the value of T_{sh}. T_{id}, is the finish-time of the ML app in its own independent and exclusive $\frac{1}{N}$ share of the cluster. Given the above definition, sharing incentive for an ML app can be attained if $\rho \leq 1$. [2]

To ensure this, it is necessary for the allocation mechanism to estimate the values of ρ for different GPU allocations. Given the difficulty in predicting how various apps will react to different allocations, it is intractable for the scheduling engine to predict or determine the values of ρ.

Thus, we propose a new wider interface between the app and the scheduling engine that can allow the app to express a *preference* for each allocation. We propose that apps can encode this information as a table. In Table 2, each column has a permutation of a potential GPU allocation and the estimate of ρ on receiving this allocation. We next describe how the scheduling engine can use this to provide fair allocations.

3.3 Mechanism: Partial Allocation Auctions

The finish-time fairness $\rho_i(.)$ for an ML app A_i is a function of the GPU allocation $\vec{G_i}$ that it receives. The allocation policy

[2]Note, sharing incentive criteria of $\rho \leq 1$ assumes the presence of an admission control mechanism to limit contention for GPU resources. An admission control mechanism that rejects any app if the aggregate number of GPUs requested crosses a certain threshold is a reasonable choice.

Pseudocode 1 Finish-Time Fair Policy

```
 1: Applications $\{A_i\}$                                   ▷ set of apps
 2: Bids $\{\rho_i(.)\}$                        ▷ valuation function for each app $i$
 3: Resources $\overrightarrow{R}$                    ▷ resource set available for auction
 4: Resource Allocations $\{\overrightarrow{G}_i\}$        ▷ resource allocation for each app $i$

 5: procedure AUCTION($\{A_i\}$, $\{\rho_i(.)\}$, $\overrightarrow{R}$)
 6:     $\overrightarrow{G}_{i,pf} = \arg\max \prod_i 1/\rho_i(\overrightarrow{G_i})$   ▷ proportional fair (pf) allocation per app $i$
 7:     $\overrightarrow{G}^{-i}_{j,pf} = \arg\max \prod_{j!=i} 1/\rho_j(\overrightarrow{G_j})$   ▷ pf allocation per app $j$ without app $i$
 8:     $c_i = \frac{\prod_{j!=i} 1/\rho_j(\overrightarrow{G}_{j,pf})}{\prod_{j!=i} 1/\rho_j(\overrightarrow{G}^{-i}_{j,pf})}$
 9:     $\overrightarrow{G_i} = c_i * \overrightarrow{G}_{i,pf}$                        ▷ allocation per app $i$
10:     $\overrightarrow{L} = \sum_i 1 - c_i * \overrightarrow{G}_{i,pf}$              ▷ aggregate leftover resource
11:     return $\{\overrightarrow{G_i}\}$, $\overrightarrow{L}$
12: end procedure
13: procedure ROUNDBYROUNDAUCTIONS($\{A_i\}$, $\{\rho_i(.)\}$)
14:     while True do
15:         ONRESOURCEAVAILABLEEVENT $\vec{R'}$:
16:         $\{A_i^{sort}\}$ = SORT($\{A_i\}$) on $\rho_i^{current}$
17:         $\{A_i^{filter}\}$ = get top $1 - f$ fraction of apps from $\{A_{sort}\}$
18:         $\{\rho_i^{filter}(.)\}$ = get updated $\rho(.)$ from apps in $\{A_i^{filter}\}$
19:         $\{\overrightarrow{G_i^{filter}}\}$, $\overrightarrow{L}$ = AUCTION($\{A_i^{filter}\}$, $\{\rho_i^{filter}(.)\}$, $\vec{R'}$)
20:         $\{A_i^{unfilter}\} = \{A_i\} - \{A_i^{filter}\}$
21:         allocate $\overrightarrow{L}$ to $\{A_i^{unfilter}\}$ at random
22:     end while
23: end procedure
```

takes these $\rho_i(.)$'s as inputs and outputs allocations $\vec{G_i}$.

A straw-man policy that sorts apps based on their reported ρ_i values and allocates GPUs in that order reduces the maximum value of ρ but has one key issue. An app can submit *false information* about their ρ values. This greedy behavior can boost their chance of winning allocations. Our conversations with cluster operators indicate that apps request for more resources than required and they require manual monitoring ("*We also monitor the usage. If they don't use it, we reclaim it and pass it on to the next approved project*"). Thus, this simple straw-man fails to incentivize truth-telling and violates another key property, namely, *strategy proofness* (SP).

To address this challenge, we propose to use *auctions* in THEMIS. We begin by describing a simple mechanism that runs a single-round auction and then extend to a round-by-round mechanism that also considers online updates.

3.3.1 One-Shot Auction

Details of the inputs necessary to run the auction are given first, followed by how the auction works given these inputs.

Inputs: Resources and Bids. $\vec{R}$ represents the total GPU resources to be auctioned, where each element is 1 and the number of dimensions is the number of GPUs to be auctioned.

Each ML app bids for these resources. The bid for each ML app consists of the estimated finish-time fair metric (ρ_i) values for several different GPU allocations ($\vec{G_i}$). Each element in $\vec{G_i}$ can be $\{0,1\}$. A set bit implies that GPU is allocated to the app. Example of a bid can be seen in Table 2.

Auction Overview. To ensure that the auction can provide strategy proofness, we propose using a *partial allocation* auction (PA) mechanism [5]. Partial allocation auctions have been shown to incentivize truth telling and are an appropriate fit for modeling subsets of indivisible goods to be auctioned across apps. Pseudocode 1, line 5 shows the PA mechanism. There are two aspects to auctions that are described next.

1. Initial allocation. PA starts by calculating an intrinsically proportionally-fair allocation $\overrightarrow{G_{i,pf}}$ for each app A_i by maximizing the product of the valuation functions i.e., the finish-time fair metric values for all apps (Pseudocode 1, line 6). Such an allocation ensures that it is not possible to increase the allocation of an app without decreasing the allocation of at least another app (satisfying PE [5]).

2. Incentivizing Truth Telling. To induce truthful reporting of the bids, the PA mechanism allocates app A_i only a fraction $c_i < 1$ of A_i's proportional fair allocation $\overrightarrow{G_{i,pf}}$, and takes $1 - c_i$ as a *hidden payment* (Pseudocode 1, line 10). The c_i is directly proportional to the decrease in the collective valuation of the other bidding apps in a market with and without app A_i (Pseudocode 1, line 8). This yields the final allocation $\vec{G_i}$ for app A_i (Pseudocode 1, line 9).

Note that the final result, $\vec{G_i}$ is not a market-clearing allocation and there could be unallocated GPUs $\vec{L}$ that are leftover from hidden payments. Hence, PA is not work-conserving. Thus, while the one-shot auction provides a number of properties related to fair sharing it does not ensure SI is met.

Theorem 3.2. The one-shot partial allocation auction guarantees SP, PE and EF, but does not provide SI.

Proof Refer to Appendix. The intuitive reason for this is that, with unallocated GPUs as hidden payments, PA does not guarantee $\rho \leq 1$ for all apps. To address this we next look at multi-round auctions that can maximize SI for ML apps. We design a mechanism that is based on PA and preserves its properties, but offers slightly weaker guarantee, namely min max ρ. We describe this next. It runs in multiple rounds. Empirically, we find that it gets $\rho \leq 1$ for most apps, even without admission control.

3.3.2 Multi-round auctions

To maximize sharing incentive and to ensure work conservation, our goal is to ensure $\rho \leq 1$ for as many apps as possible. We do this using three key ideas described below.

Round-by-Round Auctions: With round-by-round auctions, the outcome of an allocation from an auction is binding only for a *lease* duration. At the end of this lease, the freed GPUs are re-auctioned. This also handles the online case as any auction is triggered on a *resource available event*. This takes care of app failures and arrivals, as well as cluster reconfigurations.

At the beginning of each round of auction, the policy solicits updated valuation functions $\rho(.)$ from the apps. The estimated work and the placement preferences for the case of ML apps are typically time varying. This also makes our policy adaptive to such changes.

Round-by-Round Filtering: To maximize the number of apps with $\rho \leq 1$, at the beginning of each round of auctions we filter the $1 - f$ fraction of total active apps with the greatest values of current estimate of their finish-time fair metric ρ. Here, $f \in (0,1)$ is a system-wide parameter.

This has the effect of restricting the auctions to the apps that are at risk of not meeting SI. Also, this restricts the auction to a smaller set of apps which reduces contention for resources and hence results in smaller hidden payments. It also makes the auction computationally tractable.

Over the course of many rounds, filtering maximizes the number of apps that have SI. Consider a far-from-fair app i that lost an auction round. It will appear in future rounds with much greater likelihood relative to another less far-from-fair app k that won the auction round. This is because, the winning app k was allocated resources; as a result, it will see its ρ improve over time; thus, it will eventually not appear in the fraction $1-f$ of not-so-fairly-treated apps that participate in future rounds. In contrast, i's ρ will increase due to the waiting time, and thus it will continue to appear in future rounds. Further an app that loses multiple rounds will eventually lose its lease on all resources and make no further progress, causing its ρ to become unbounded. The next auction round the app participates in will likely see the app's bid winning, because any non-zero GPU allocation to that app will lead to a huge improvement in the app's valuation.

As $f \rightarrow 1$, our policy provides greater guarantee on SI. However, this increase in SI comes at the cost of efficiency. This is because $f \rightarrow 1$ restricts the set of apps to which available GPUs will be allocated; with $f \rightarrow 0$ available GPUs can be allocated to apps that benefit most from better placement, which improves efficiency at the risk of violating SI.

Leftover Allocation: At the end of each round we have leftover GPUs due to hidden payments. We allocate these GPUs at random to the apps that did not participate in the auction in this round. Thus our overall scheme is work-conserving.

Overall, we prove that:

Theorem 3.3. Round-by-round auctions preserve the PE, EF and SP properties of partial auctions and maximize SI.

*P*roof. Refer to Appendix.

To summarize, in THEMIS we propose a new finish-time fairness metric that captures fairness for long-running, placement sensitive ML apps. To perform allocations, we propose using a multi-round partial allocation auction that incentivizes truth telling and provides Pareto efficient, envy free allocations. By filtering the apps considered in the auction, we maximize sharing incentive and hence satisfy all the properties necessary for fair sharing among ML applications.

4 System Design

We first list design requirements for an ML cluster scheduler taking into account the fairness metric and auction mechanism described in Section 3, and the implications for the THEMIS scheduler architecture. Then, we discuss the *API* between the scheduler and the hyper-parameter optimizers.

4.1 Design Requirements

Separation of visibility and allocation of resources. Core to our partial allocation mechanism is the abstraction of making available resources visible to a number of apps but allocating each resource exclusively to a single app. As we argue below, existing scheduling architectures couple these concerns and thus necessitate the design of a new scheduler.

Integration with hyper-parameter tuning systems. Hyper-parameter optimization systems such as Hyperband [21], Hyperdrive [29] have their own schedulers that decide the resource allocation and execution schedule for the jobs within those apps. We refer to these as app-schedulers. One of our goals in THEMIS is to integrate with these systems with minimal modifications to app-schedulers.

These two requirements guide our design of a new *two-level semi-optimistic* scheduler and a set of corresponding abstractions to support hyper-parameter tuning systems.

4.2 THEMIS Scheduler Architecture

Existing scheduler architectures are either pessimistic or fully optimistic and both these approaches are not suitable for realizing multi-round auctions. We first describe their shortcomings and then describe our proposed architecture.

4.2.1 Need for a new scheduling architecture

Two-level pessimistic schedulers like Mesos [17] enforce pessimistic concurrency control. This means that visibility and allocation go hand-in-hand at the granularity of a single app. There is restricted single-app visibility as available resources are partitioned by a mechanism internal to the lower-level (i.e., cross-app) scheduler and offered only to a single app at a time. The tight coupling of visibility and allocation makes it infeasible to realize round-by-round auctions where resources need to be visible to many apps but allocated to just one app.

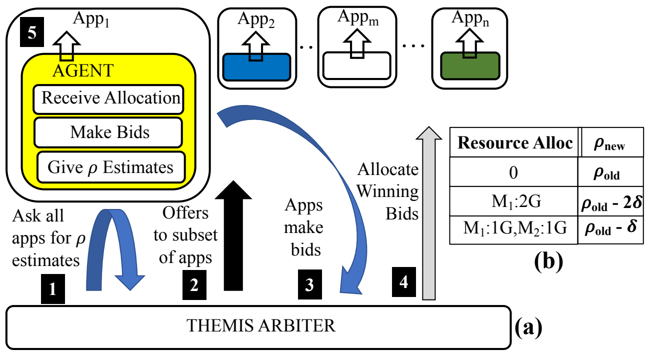
Shared-state fully optimistic schedulers like Omega [30] enforce fully optimistic concurrency control. This means that visibility and allocation go hand-in-hand at the granularity of multiple apps. There is full multi-app visibility as all cluster resources and their state is made visible to all apps. Also, all apps contend for resources and resource allocation decisions are made by multiple apps at the same time using transactions. This coupling of visibility and allocation in a lock-free manner makes it hard to realize a global policy like finish-time fairness and also leads to expensive conflict resolution (needed when multiple apps contend for the same resource) when the cluster is highly contented, which is typically the case in shared GPU clusters.

Thus, the properties required by multi-round auctions, i.e., multi-app resource visibility and single-app resource allocation granularity, makes existing architectures ineffective.

4.2.2 Two-Level Semi-Optimistic Scheduling

The two-levels in our scheduling architecture comprise of multiple app-schedulers and a cross-app scheduler that we call the ARBITER. The ARBITER has our scheduling logic. The top level per-app schedulers are minimally modified to interact with the ARBITER. Figure 6 shows our architecture.

Each GPU in a THEMIS-managed cluster has a lease associated with it. The lease decides the duration of ownership of the GPU for an app. When a lease expires, the resource is made



Resource Alloc	ρ_{new}
0	ρ_{old}
M$_1$:2G	ρ_{old} - 2δ
M$_1$:1G,M$_2$:1G	ρ_{old} - δ

Figure 6: THEMIS Design. (a) Sequence of events in THEMIS - starts with a resource available event and ends with resource allocations. (b) Shows a typical bid valuation table an App submits to ARBITER. Each row has a subset of the complete resource allocation and the improved value of ρ_{new}.

available for allocation. THEMIS's ARBITER pools available resources and runs a round of the auctions described earlier. During each such round, the resource allocation proceeds in 5 steps spanning 2 phases (shown in Figure 6):

The first phase, called the *visibility phase*, spans steps 1–3.

1 The ARBITER asks all apps for current finish-time fair metric estimates. **2** The ARBITER initiates auctions, and makes the same non-binding resource-offer of the available resources to a fraction $f \in [0,1]$ of ML apps with worst finish-time fair metrics (according to round-by-round filtering described earlier). To minimize changes in the ML app scheduler to participate in auctions, THEMIS introduces an AGENT that is co-located with each ML app scheduler. The AGENT serves as an intermediary between the ML app and the ARBITER. **3** The apps examine the resource offer in parallel. Each app's AGENT then replies with a single bid that contains preferences for desired resource allocations.

The second phase, *allocation phase*, spans steps 4–5. **4** The ARBITER, upon receiving all the bids for this round, picks winning bids according to previously described partial allocation algorithm and leftover allocation scheme. It then notifies each AGENT of its winning allocation (if any). **5** The AGENT propagates the allocation to the ML app scheduler, which can then decide the allocation among constituent jobs.

In sum, the two phase resource allocation means that our scheduler enforces *semi-optimistic concurrency control*. Similar to fully optimistic concurrency control, there is multi-app visibility as the cross-app scheduler offers resources to multiple apps concurrently. At the same time, similar to pessimistic concurrency control, the resource allocations are conflict-free guaranteeing exclusive access of a resource to every app.

To enable preparation of bids in step **3**, THEMIS implements a narrow API from the ML app scheduler to the AGENT that enables propagation of app-specific information. An AGENT's bid contains a *valuation function* ($\rho(.)$) that provides, for each resource subset, an estimate of the finish-time fair metric the app will achieve with the allocation of the resource subset. We describe how this is calculated next.

4.3 AGENT and AppScheduler Interaction

An AGENT co-resides with an app to aid participation in auctions. We now describe how AGENTs prepare bids based on inputs provided by apps, the API between an AGENT and its app, and how AGENTs integrate with current hyper-parameter optimization schedulers.

4.3.1 Single-Job ML Apps

For ease of explanation, we first start with the simple case of an ML app that has just one ML training job which can use at most job_demand_{max} GPUs. We first look at calculation of the finish-time fair metric, ρ. We then look at a multi-job app example so as to better understand the various steps and interfaces in our system involved in a multi-round auction.

Calculating $\rho(\vec{G})$. Equation 1 shows the steps for calculating ρ for a single job given a GPU allocation of $\vec{G}$ in a cluster C with R_C GPUs. When calculating ρ we assume that the allocation $\vec{G}$ is binding till job completion.

$$\begin{aligned}
\rho(\vec{G}) &= T_{sh}(\vec{G})/T_{id} \\
T_{sh} &= T_{current} - T_{start} + \\
&\quad iter\_left * iter\_time(\vec{G}) \\
T_{id} &= T_{cluster} * N_{avg} \\
iter\_time(\vec{G}) &= \frac{iter\_time\_serial * \mathcal{S}(\vec{G})}{min(||\vec{G}||_1, job\_demand_{max})} \\
T_{cluster} &= \frac{iter\_total * iter\_serial\_time}{min(R_C, job\_demand_{max})}
\end{aligned} \tag{1}$$

T_{sh} is the shared finish-time and is a function of the allocation $\vec{G}$ that the job receives. For the single job case, it has two terms. First, is the time elapsed ($= T_{current} - T_{start}$). Time elapsed also captures any queuing delays or starvation time. Second, is the time to execute remaining iterations which is the product of the number of iterations left ($iter\_left$) and the iteration time ($iter\_time(\vec{G})$). $iter\_time(\vec{G})$ depends on the allocation received. Here, we consider the common-case of the ML training job executing synchronous SGD. In synchronous SGD, the work in an iteration can be parallelized across multiple workers. Assuming linear speedup, this means that the iteration time is the serial iteration time ($iter\_time\_serial$) reduced by a factor of the number of GPUs in the allocation, $||\vec{G}||_1$ or job_demand_{max} whichever is lesser. However, the linear speedup assumption is not true in the common case as network overheads are involved. We capture this via a slowdown penalty, $\mathcal{S}(\vec{G})$, which depends on the placement of the GPUs in the allocation. Values for $\mathcal{S}(\vec{G})$ can typically be obtained by profiling the job offline for a few iterations. [3] The slowdown is captured as a multiplicative factor, $\mathcal{S}(\vec{G}) \geq 1$, by which T_{sh} is increased.

[3] $\mathcal{S}(\vec{G})$ can also be calculated in an online fashion. First, we use crude placement preference estimates to begin with for single machine (=1), cross-machine (=1.1), cross-rack (=1.3) placement. These are replaced with accurate estimates by profiling iteration times when the ARBITER allocates

T_{id} is the estimated finish-time in an independent $\frac{1}{N_{avg}}$ cluster. N_{avg} is the average contention in the cluster and is the weighted average of the number of apps in the system during the lifetime of the app. We approximate this as the finish-time of the app in the whole cluster, $T_{cluster}$ multiplied by the average contention. $T_{cluster}$ assumes linear speedup when the app executes with all the cluster resources R_C or maximum app demand whichever is lesser. It also assumes no slowdown. Thus, it is approximated as $\frac{iter\_total*iter\_serial\_time}{min(R_C, job\_demand_{max})}$.

4.3.2 Generalizing to Multiple-Job ML Apps

ML app schedulers for hyper-parameter optimization systems typically go from aggressive exploration of hyper-parameters to aggressive exploitation of best hyper-parameters. While there are a number of different algorithms for choosing the best hyper-parameters [3, 21] to run, we focus on early stopping criteria as this affects the finish time of ML apps.

As described in prior work [9], automatic stopping algorithms can be divided into two categories: Successive Halving and Performance Curve Stopping. We next discuss how to compute T_{sh} for each case.

Successive Halving refers to schemes which start with a total time or iteration budget B and apportion that budget by periodically stopping jobs that are not promising. For example, if we start with n hyper parameter options, then each one is submitted as a job with a demand of 1 GPU for a fixed number of iterations I. After I iterations, only the best $\frac{n}{2}$ ML training jobs are retained and assigned a maximum demand of 2 GPUs for the same number of iterations I. This continues until we are left with 1 job with a maximum demand of n GPUs. Thus there are a total of $log_2 n$ *phases* in Successive Halving. This scheme is used in Hyperband [21] and Google Vizier [9].

We next describe how to compute T_{sh} and T_{id} for successive halving. We assume that the given allocation $\overrightarrow{G}$ lasts till app completion and the total time can be computed by adding up the time the app spends for each phase. Consider the case of phase i which has $J = \frac{n}{2^{i-1}}$ jobs. Equation 2 shows the calculation of $T_{sh(i)}$, the shared finish time of the phase. We assume a separation of concerns where the hyper-parameter optimizer can determine the optimal allocation of GPUs *within a phase* and thus estimate the value of $\mathcal{S}(\overrightarrow{G_j})$. Along with *iter_left*, *serial_iter_time*, the AGENT can now estimate $T_{sh(j)}$ for each job in the phase. We mark the phase as finished when the slowest or last job in the app finishes the phase (max_j). Then the shared finish time for the app is the sum of the finish times of all constituent phases.

To estimate the ideal finish-time we compute the total time to execute the app on the full cluster. We estimate this using the budget B which represents the aggregate work to be done and, as before, we assume linear speedup to the maximum number of GPUs the app can use app_demand_{max}.

unseen placements. The multi-round nature of allocations means that errors in early estimates do not have a significant effect.

$$
\begin{aligned}
T_{sh(i)} &= max_j\{T(\overrightarrow{G_j})\}\\
T_{sh} &= \sum_i T_{sh(i)}\\
T_{cluster} &= \frac{B}{min(R_C, app\_demand_{max})}\\
T_{id} &= T_{cluster} * N_{avg}
\end{aligned}
\tag{2}
$$

The AGENT generates ρ using the above procedure for all possible subsets of $\{\overrightarrow{G}\}$ and produces a bid table similar to the one shown in Table 2 before. The API between the AGENT and hyper-parameter optimizer is shown in Figure 7 and captures the functions that need to implemented by the hyper-parameter optimizer.

Performance Curve Stopping refers to schemes where the convergence curve of a job is extrapolated to determine which jobs are more promising. This scheme is used by Hyperdrive [29] and Google Vizier [9]. Computing T_{sh} proceeds by calculating the finish time for each job that is currently running by estimating the iteration at which the job will be terminated (thus T_{sh} is determined by the job that finishes last). As before, we assume that the given allocation $\overrightarrow{G}$ lasts till app completion. Since the estimations are usually probabilistic, i.e., the iterations at which the job will converge has an error bar, we over-estimate and use the most optimistic convergence curve that results in the maximum forecasted completion time for that job. As the job progresses, the estimates of the convergence curve get more accurate and improves the accuracy of the estimated finish time T_{sh}. The API implemented by the hyper-parameter optimizer is simpler and only involves getting a list of running jobs as shown in Figure 7.

We next present an end-to-end example of a multi-job app showing our mechanism in action.

4.3.3 End-to-end Example.

We now run through a simple example that exercises the various aspects of our API and the interfaces involved.

Consider a 16 GPU cluster and an ML app that has 4 ML jobs and uses successive halving, running along with 3 other ML apps in the same cluster. Each job in the app is tuning a different hyper-parameter and the serial time taken per iteration for the jobs are $80, 100, 100, 120$ seconds respectively.[4] The total budget for the app is $10,000$ seconds of GPU time and we assume the job_demand_{max} is 8 GPUs and $\mathcal{S}(\overrightarrow{G}) = 1$.

Given we start with 4 ML jobs, the hyper-parameter optimizer divides this into 3 phases each having $4, 2, 1$ jobs, respectively. To evenly divide the budget across the phases, the hyper-parameter optimizer budgets $\approx 8, 16, 36$ iterations in each phase. First we calculate the T_{id} by considering the budget, total cluster size, and cluster contention as: $\frac{10000\times4}{16} =$ 2500s.

Next, we consider the computation of T_{sh} assuming that 16

[4]The time per iteration depends on the nature of the hyper-parameter being tuned. Some hyper-parameters like batch size or quantization used affect the iteration time while others like learning rate don't.

```
class JobInfo(int itersRemaining,
              float avgTimePerIter,
              float localitySensitivity);
// Successive Halving
List<JobInfo> getJobsInPhase(int phase,
                             List<Int> gpuAlloc);
int getNumPhases();
// Performance Curve
List<JobInfo> getJobsRemaining(List<Int> gpuAlloc);
```

Figure 7: API between AGENT and hyperparameter optimizer

$\|\|\vec{G}\|\|_1$	0	1	2	4	8	16
ρ	ρ_{old}	4	2	1	0.5	0.34

Table 3: Example of bids submitted by AGENT

GPUs are offered by the ARBITER. The AGENT now computes the bid for each subset of GPUs offered. Consider the case with 2 GPUs. In this case in the first phase we have 4 jobs which are serialized to run 2 at a time. This leads to $T_{sh(1)} = (120 \times 8) + (80 \times 8) = 1600$ seconds. (Assume two 100s jobs run serially on one GPU, and the 80 and 120s jobs run serially on the other. T_{sh} is the time when the last job finishes.)

When we consider the next stage the hyper-parameter optimizer currently does not know which jobs will be chosen for termination. We use the *median* job (in terms of per-iteration time) to estimate $T_{sh(i)}$ for future phases. Thus, in the second phase we have 2 jobs so we run one job on each GPU each of which we assume to take the median 100 seconds per iteration leading to $T_{sh(2)} = (100 \times 16) = 1600$ seconds. Finally for the last phase we have 1 job that uses 2 GPUs and runs for 36 iterations leading to $T_{sh(3)} = \frac{(100\times36)}{2} = 1800$ (again, the "median" jobs takes 100s per iteration). Thus $T_{sh} = 1600 + 1600 + 1800 = 5000$ seconds, making $\rho = \frac{5000}{2500} = 2$. Note that since placement did not matter here we considered any 2 GPUs being used. Similarly ignoring placement, the bids for the other allocations are shown in Table 3.

We highlight a few more points about our example above. If the jobs that are chosen for the next phase do not match the median iteration time then the estimates are revised in the next round of the auction. For example, if the jobs that are chosen for the next round have iteration time 120, 100 then the above bid will be updated with $T_{sh(2)} = (120 \times 16) = 3200$[5] and $T_{sh(3)} = \frac{(120\times36)}{2} = 2160$. Further, we also see that the $job\_demand_{max} = 8$ means that the ρ value for 16 GPUs does not linearly decrease from that of 8 GPUs.

5 Implementation

We implement THEMIS on top of a recent release of Apache Hadoop YARN [1] (version 3.2.0) which includes, Submarine [2], a new framework for running ML training jobs atop YARN. We modify the Submarine client to support submitting a group of ML training jobs as required by hyper-parameter exploration apps. Once an app is submitted, it is managed by a Submarine Application Master (AM) and we make changes to the Submarine AM to implement the ML app scheduler (we use Hyperband [21]) and our AGENT.

To prepare accurate bids, we implement a profiler in the AM that parses TensorFlow logs, and tracks iteration times and loss values for all the jobs in an app. The allocation of a job changes over time and iteration times are used to accurately estimate the placement preference ($\mathcal{S}$) for different GPU placements. Loss values are used in our Hyperband implementation to determine early stopping. THEMIS's ARBITER is implemented as a separate module in YARN RM. We add gRPC-based interfaces between the AGENT and the ARBITER to enable offers, bids, and final winning allocations. Further, the ARBITER tracks GPU leases to offer reclaimed GPUs as a part of the offers.

All the jobs we use in our evaluation are TensorFlow programs with configurable hyper-parameters. To handle allocation changes at runtime, the programs checkpoint model parameters to HDFS every few iterations. After a change in allocation, they resume from the most recent checkpoint.

[5]Because the two jobs run on one GPU each, and the 120s-per-iteration job is the last to finish in the phase

6 Evaluation

We evaluate THEMIS on a 64 GPU cluster and also use a event-driven simulator to model a larger 256 GPU cluster. We compare against other state-of-the-art ML schedulers. Our evaluation shows the following key highlights -

- THEMIS is better than other schemes on finish-time fairness while also offering better cluster efficiency (Figure 9-10-11-12).
- THEMIS's benefits compared to other schemes improve with increasing fraction of placement sensitive apps and increasing contention in the cluster, and these improvements hold even with errors – random and strategic – in finish-time fair metric estimations (Figure 14-18).
- THEMIS enables a trade-off between finish-time fairness in the long-term and placement efficiency in the short-term. Sensitivity analysis (Figure 19) using simulations show that $f = 0.8$ and a lease time of 10 minutes gives maximum fairness while also utilizing the cluster efficiently.

6.1 Experimental Setup

Testbed Setup. Our testbed is a 64 GPU, 20 machine cluster on Microsoft Azure [23]. We use NC-series instances. We have 8 NC12-series instances each with 2 Tesla K80 GPUs and 12 NC24-series instances each with 4 Tesla K80 GPUs.

Simulator. We develop an event-based simulator to evaluate THEMIS at large scale. The simulator assumes that estimates of the loss function curves for jobs are known ahead of time so as to predict the total number of iterations for the job. Unless stated otherwise, all simulations are done on a heterogeneous 256 GPU cluster. Our simulator assumes a 4-level hierarchical locality model for GPU placements. Individual GPUs fit onto

slots on *machines* occupying different cluster *racks*.[6]

Workload. We experiment with 2 different traces that have different workload characteristics in both the simulator and the testbed - **(i) Workload 1.** A publicly available trace of DNN training workloads at Microsoft [19,24]. We scale-down the trace, using a two week snapshot and focus on subset of jobs from the trace that correspond to hyper-parameter exploration jobs triggered by Hyperdrive. **(ii) Workload 2.** We use the app arrival times from Workload 1, generate jobs per app using the successive halving pattern characteristic of the Hyperband algorithm [21], and increase the number of tasks per job compared to Workload 1. The distribution of number of tasks per job and number of jobs per app for the two workloads is shown in Figure 8.

The traces comprise of models from three categories - computer vision (CV - 10%), natural language processing (NLP - 60%) and speech (Speech - 30%). We use the same mix of models for each category as outlined in Gandiva [39]. We summarize the models in Table 4.

Baselines. We compare THEMIS against four state-of-the-art ML schedulers - Gandiva [39], Tiresias [13], Optimus [27], SLAQ [42]; these represent the best possible baselines for maximizing efficiency, fairness, aggregate throughput, and aggregate model quality, respectively. We also compare against two scheduling disciplines - shortest remaining time first (SRTF) and shortest remaining service first (SRSF) [13]; these represent baselines for minimizing average job completion time (JCT) with efficiency as secondary concern and minimizing average JCT with fairness as secondary concern, respectively. We implement these baselines in our testbed as well as the simulator as described below:

Ideal Efficiency Baseline - Gandiva. Gandiva improves cluster utilization by packing jobs on as few machines as possible. In our implementation, Gandiva introspectively profiles ML job execution to infer placement preferences and migrates jobs to better meet these placement preferences. On any resource availability, all apps report their placement preferences and we allocate resources in a greedy highest preference first manner which has the effect of maximizing the average placement preference across apps. We do not model time-slicing and packing of GPUs as these system-level techniques can be integrated with THEMIS as well and would benefit Gandiva and THEMIS to equal extents.

Ideal Fairness Baseline - Tiresias. Tiresias defines a new service metric for ML jobs – the aggregate GPU-time allocated to each job – and allocates resources using the Least Attained Service (LAS) policy so that all jobs obtain equal service over time. In our implementation, on any resource availability, all apps report their service metric and we allocate the resource to apps that have the least GPU service.

Ideal Aggregate Throughput Baseline - Optimus. Optimus proposes a throughput scaling metric for ML jobs – the ratio of new job throughput to old job throughput with and without an additional GPU allocation. On any resource availability, all apps report their throughput scaling and we allocate resources in order of highest throughput scaling metric first.

Ideal Aggregate Model Quality - SLAQ. SLAQ proposes a greedy scheme for improving aggregate model quality across all jobs. In our implementation, on any resource availability event, all apps report the decrease in loss value with allocations from the available resources and we allocate these resources in a greedy highest loss first manner.

Ideal Average App Completion Time - SRTF, SRSF. For SRTF, on any resource availability, all apps report their remaining time with allocations from the available resource and we allocate these resources using SRTF policy. Efficiency is a secondary concern with SRTF as better packing of GPUs leads to shorter remaining times.

SRSF is a service-based metric and approximates gittins index policy from Tiresias. In our implementation, we assume accurate knowledge of remaining service and all apps report their remaining service and we allocate one GPU at a time using SRSF policy. Fairness is a secondary concern as shorter service apps are preferred first as longer apps are more amenable to make up for lost progress due to short-term unfair allocations.

Metrics. We use a variety of metrics to evaluate THEMIS.

(i) Finish-time fairness: We evaluate the fairness of schemes by looking at the finish-time fair metric (ρ) distribution and the maximum value across apps. A tighter distribution and a lower value of maximum value of ρ across apps

[6]The heterogeneous cluster consists of 16 8-GPU machines (4 slots and 2 GPUs per slot), 6 4-GPU machines (4 slots and 1 GPU per slot), and 16 1-GPU machines

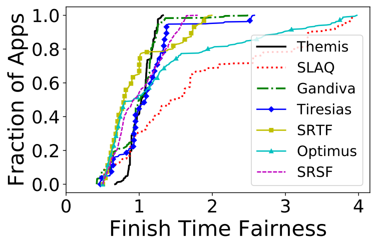

Figure 9: [TESTBED] Comparison of finish-time fairness across schedulers with Workload 1

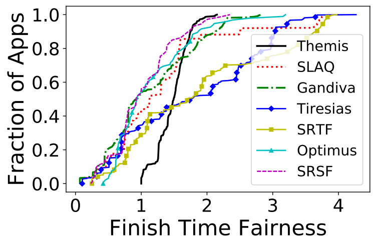

Figure 10: [TESTBED] Comparison of finish-time fairness across schedulers with Workload 2

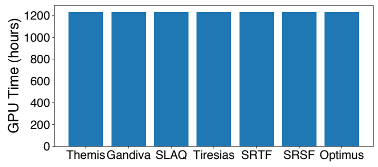

Figure 11: [TESTBED] Comparison of total GPU times across schemes with Workload 1. Lower GPU time indicates better utilization of the GPU cluster

indicate higher fairness. **(ii) GPU Time:** We use *GPU Time* as a measure of how efficiently the cluster is utilized. For two scheduling schemes S_1 and S_2 that have GPU times G_1 and G_2 for executing the same amount of work, S_1 utilizes the cluster more efficiently than S_2 if $G_1 < G_2$. **(iii) Placement Score:** We give each allocation a placement score (≤ 1). This is inversely proportional to slowdown, $\mathcal{S}$, that app experiences due to this allocation. The slowdown is dependent on the ML app properties and the network interconnects between the allocated GPUs. A placement score of 1.0 is desirable for as many apps as possible.

6.2 Macrobenchmarks

In our testbed, we evaluate THEMIS against all baselines on all the workloads. We set the fairness knob value f as 0.8 and lease as 10 minutes, which is informed by our sensitivity analysis results in Section 6.4.

Figure 9-10 shows the distribution of finish-time fairness metric, ρ, across apps for THEMIS and all the baselines. We see that THEMIS has a narrower distribution for the ρ values which means that THEMIS comes closest to giving all jobs an equal sharing incentive. Also, THEMIS gives 2.2X to 3.25X better (smaller) maximum ρ values compared to all baselines.

Figure 11-12 shows a comparison of the efficiency in terms of the aggregate GPU time to execute the complete workload. Workload 1 has similar efficiency across THEMIS and the baselines as all jobs are either 1 or 2 GPU jobs and almost all allocations, irrespective of the scheme, end up as efficient. With workload 2, THEMIS betters Gandiva by ~4.8% and outperforms SLAQ by ~250%. THEMIS is better because global visibility of app placement preferences due to the auction abstraction enables globally optimal decisions. Gandiva in contrast takes greedy locally optimal packing decisions.

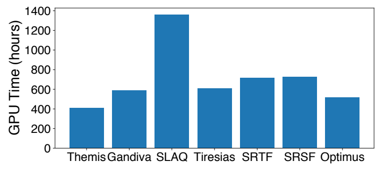

Figure 12: [TESTBED] Comparison of total GPU times across schemes with Workload 2. Lower GPU time indicates better utilization of the GPU cluster

Job Type	GPU Time	# GPUs	ρ_{THEMIS}	$\rho_{Tiresias}$
Long Job	~580 mins	4	~1	~0.9
Short Job	~83 mins	2	~1.2	~1.9

Table 5: [TESTBED] Details of 2 jobs to understand the benefits of THEMIS

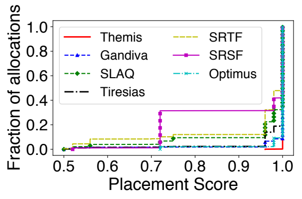

Figure 13: [TESTBED] CDF of placement scores across schemes

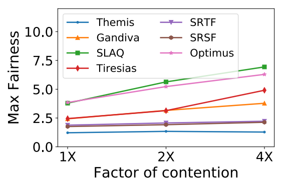

Figure 14: [TESTBED] Impact of contention on finish-time fairness

6.2.1 Sources of Improvement

In this section, we deep-dive into the reasons behind the wins in fairness and cluster efficiency in THEMIS.

Table 5 compares the finish-time fair metric value for a pair of short- and long-lived apps from our testbed run for THEMIS and Tiresias. THEMIS offers better sharing incentive for both the short and long apps. THEMIS induces altruistic behavior in long apps. We attribute this to our choice of ρ metric. With less than ideal allocations, even though long apps see an increase in T_{sh}, their ρ values do not increase drastically because of a higher T_{id} value in the denominator. Whereas, shorter apps see a much more drastic degradation, and our round-by-round filtering of farthest-from-finish-time fairness apps causes shorter apps to participate in auctions more often. Tiresias offers poor sharing incentive for short apps as it treats short- and long-apps as the same. This only worsens the sharing incentive for short apps.

Figure 13 shows the distribution of placement scores for all the schedulers. THEMIS gives the best placement scores (closer to 1.0 is better) in workload 2, with Gandiva and Optimus coming closest. Workload 1 has jobs with very low GPU demand and almost all allocations have a placement score of 1 irrespective of the scheme. Other schemes are poor as they do not account for placement preferences. Gandiva does greedy local packing and Optimus does greedy throughput scaling and are not as efficient because they are not globally optimal.

6.2.2 Effect of Contention

In this section, we analyze the effect of contention on finish-time fairness. We decrease the size of the cluster to half and quarter the original size to induce a contention of $2X$ and $4X$ respectively. Figure 14 shows the change in max value of ρ as the contention changes with workload 1. THEMIS is the only scheme that maintains *sharing incentive* even in high contention scenarios. SRSF comes close as it preferably allocates resources to shorter service apps. This behavior is similar to that in THEMIS. THEMIS induces altruistic shedding of resources by longer apps (Section 6.2.1), giving shorter apps a preference in allocations during higher contention.

6.2.3 Systems Overheads

From our profiling of the experiments above, we find that each AGENT spends 29 (334) milliseconds to compute bids at the median (95-%). The 95 percentile is high because enumeration of possible bids needs to traverse a larger search space when the number of resources up for auction is high.

The ARBITER uses Gurobi [14] to compute partial allocation of resources to apps based on bids. This computation takes 354 (1398) milliseconds at the median (95-%ile). The high tail is once again observed when both the number of offered resources and the number of apps bidding are high. However, the time is small relative to lease time. The network overhead for communication between the ARBITER and individual apps is negligible since we use the existing mechanisms used by Apache YARN.

Upon receiving new resource allocations, the AGENT changes (adds/removes) the number of GPU containers available to its app. This change takes about 35 (50) seconds at the median (95-%ile), i.e., an overhead of 0.2% (2%) of the app duration at the median (95-%ile). Prior to relinquishing control over its resources, each application must checkpoint its set of parameters. We find that that this is model dependent but takes about 5-10 seconds on an average and is driven largely by the overhead of check-pointing to HDFS.

6.3 Microbenchmarks

Placement Preferences: We analyze the impact on finish-time fairness and cluster efficiency as the fraction of network-intensive apps in our workload increases. We synthetically construct 6 workloads and vary the percentage of network-intensive apps in these workloads from 0%-100%.

From Figure 15, we notice that *sharing incentive* degrades most when there is a heterogeneous mix of compute and network intensive apps (at 40% and 60%). THEMIS has a max ρ value closest to 1 across all scenarios and is the only scheme to ensure sharing incentive. When the workload consists solely of network-intensive apps, THEMIS performs ~1.24 to 1.77X better than existing baselines on max fairness.

Figure 16 captures the impact on cluster efficiency. With only compute-intensive apps, all scheduling schemes utilize the cluster equally efficiently. As the percentage of network intensive apps increases, THEMIS has lower GPU times to execute the same workload. This means that THEMIS utilizes the cluster more efficiently than other schemes. In the workload with 100% network-intensive apps, THEMIS performs ~8.1% better than Gandiva (state-of-the-art for cluster efficiency).

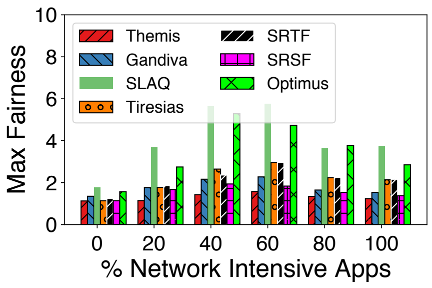

Figure 15: [SIMULATOR] Impact of placement preferences for varying mix of compute- and network-intensive apps on max ρ

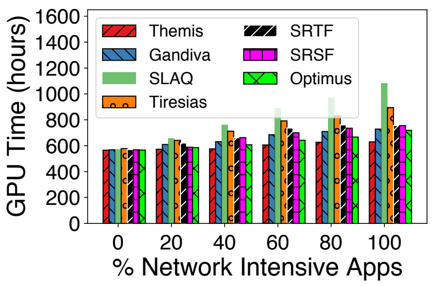

Figure 16: [SIMULATOR] Impact of placement preferences for varying mix of compute- and network-intensive apps on GPU Time

Error Analysis: Here, we evaluate the ability of THEMIS to handle errors in estimation of number of iterations and the slowdown ($\mathcal{S}$). For this experiment, we assume that all apps are equally susceptible to making errors in estimation. The percentage error is sampled at random from [-X, X] range for each app. Figure 17 shows the changes in max finish-time fairness as we vary X. Even with $X = 20\%$, the change in max finish-time fairness is just 10.76% and is not significant.

Truth-Telling: To evaluate strategy-proofness, we use simulations. We use a cluster of 64 GPUs with 8 identical apps with equivalent placement preferences. The cluster has a single 8 GPU machine and the others are all 2 GPU machines. The most preferred allocation in this cluster is the 8 GPU machine. We assume that there is a single strategically lying app and 7 truthful apps. In every round of auction it participates in, the lying app over-reports the slowdown with staggered machine placement or under-reports the slowdown with dense machine placement by $X\%$. Such a strategy would ensure higher likelihood of winning the 8 GPU machine. We vary the value of X in the range $[0, 100]$ and analyze the lying app's completion time and the average app completion time of the truthful apps in Figure 18. We see that at first the lying app does not experience any decrease in its own app completion time. On the other hand, we see that the truthful apps do better on their average app completion time. This is because the hidden payment from the partial allocation mechanism in each round of the auction for the lying app remains the same while

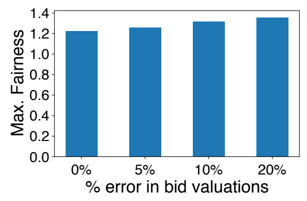

Figure 17: [SIMULATOR] Impact of error in bid values on max fairness

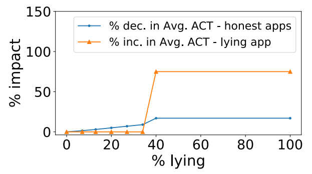

Figure 18: [SIMULATOR] Strategic lying is detrimental

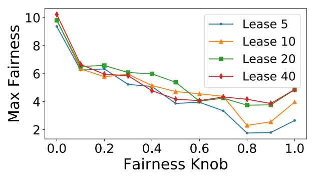
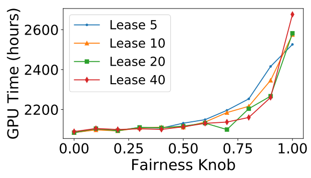


(a) Impact on Max Fairness



(b) Impact on GPU Time

Figure 19: [SIMULATOR] Sensitivity of fairness knob and lease time.

the payment from the rest of the apps keeps decreasing. We also observe that there is a sudden tipping point at $X > 34\%$. At this point, there is a sudden increase in the hidden payment for the lying app and it loses a big chunk of resources to other apps. In essence, THEMIS incentivizes truth-telling.

6.4 Sensitivity Analysis

We use simulations to study THEMIS's sensitivity to fairness knob f and the lease time. Figure 19 (a) shows the impact on max ρ as we vary the fairness knob f. We observe that filtering $(1-f)$ fraction of apps helps with ensuring better *sharing incentive*. As f increases from 0 to 0.8, we observe that fairness improves. Beyond $f = 0.8$, max fairness worsens by around a factor of $1.5X$. We see that the quality of sharing incentive, captured by max ρ, degrades at $f = 1$ because we observe that only a single app with highest ρ value participates in the auction. This app is forced sub-optimal allocations because of poor placement of available resources with respect to the already allocated resources in this app. We also observe that smaller lease times promote better fairness since frequently filtering apps reduces the time that queued apps wait for an allocation.

Figure 19 (b) shows the impact on the efficiency of cluster usage as we vary the fairness knob f. We observe that the efficiency decreases as the value of f increases. This is because the number of apps that can bid for an offer reduces as we increase f leading to fewer opportunities for the ARBITER to pack jobs efficiently. Lower lease values mean than models need to be check-pointed more often (GPUs are released on lease expiry) and hence higher lease values are more efficient.

Thus we choose $f = 0.8$ and *lease* $= 10$ minutes.

7 Related Work

Cluster scheduling for ML workloads has been targeted by a number of recent works including SLAQ [42], Gandiva [39], Tiresias [13] and Optimus [27]. These systems target different objectives and we compare against them in Section 6.

We build on rich literature on cluster scheduling disciplines [8, 10–12] and two level schedulers [17, 30, 36]. While those disciplines/schedulers don't apply to our problem, we build upon some of their ideas, e.g., resource offers in [17]. Sharing incentive was outlined by DRF [8], but we focus on long term fairness with our finish-time metric. Tetris [10] proposes resource-aware packing with an option to trade-off for fairness using multi-dimensional bin-packing as the mechanism for achieving that. In THEMIS, we instead focus on fairness with an option to trade-off for placement-aware packing, and use auctions as our mechanism.

Some earlier schemes [11, 12] also attempted to emulate the long term effects of fair allocation. Around occasional barriers, unused resources are re-allocated across jobs. THEMIS differs in many respects: First, earlier systems focus on batch analytics. Second, earlier schemes rely on instantaneous resource-fairness (akin to DRF), which has issues with placement-preference unawareness and not accounting for long tasks. Third, in the ML context there are no occasional barriers. While barriers do arise due to synchronization of parameters in ML jobs, they happen at *every* iteration. Also, resources unilaterally given up by a job may not be usable by another job due to placement preferences.

8 Conclusion

In this paper we presented THEMIS, a fair scheduling framework for ML training workloads. We showed how existing fair allocation schemes are insufficient to handle long-running tasks and placement preferences of ML workloads. To address these challenges we proposed a new long term fairness objective in finish-time fairness. We then presented a two-level semi-optimistic scheduling architecture where ML apps can bid on resources offered in an auction. Our experiments show that THEMIS can improve fairness *and* efficiency compared to state of the art schedulers.

A Appendix

PROOF OF THEOREM 3.1. Examples in Figure 5 and Section 3.1.2 shows that DRF violates SI, EF, and PE. Same examples hold true for LAS policy in Tiresias. The service metric i.e. the GPU in Instance 1 and Instance 2 is the same for A1 and A2 in terms of LAS and is deemed a fair allocation over time. However, Instance 1 violates SI as A1 (VGG16) and A2 (VGG16) would prefer there own independent GPUs and Instance 2 violates EF and PE as A2 (VGG16) prefers the allocation of A1 (Inception-v3) and PE as the optimal allocation after taking into account placement preferences would interchange the allocation of A1 and A2. □

PROOF OF THEOREM 3.2. We first show that the valuation function, $\rho(.)$, for the case of ML jobs is homogeneous. This means that $\rho(.)$ has the following property: $\rho(m * \overrightarrow{G}) = m * \rho\overrightarrow{G}$.

Consider a job with GPUs spread across a set of some M machines. If we keep this set of machines the same, and increase the number of GPUs allocated on these same set of machines by a certain factor then the shared running time (T_{sh}) of this job decreases proportionally by the same factor. This is so because the slowdown, $\mathcal{S}$ remains the same. Slowdown is determined by the slowest network interconnect between the machines. The increased allocation does not change the set of machines M. The independent running time (T_{id}) remains the same. This means that ρ also proportionally changes by the same factor.

Given, homogeneous valuation functions, the PA mechanism guarantees SP, PE and EF [5]. However, PA violates SI due to the presence of hidden payments. This also make PA not work-conserving. □

PROOF OF THEOREM 3.3. With multi-round auctions we ensure truth-telling of ρ estimates in the visibility phase. This is done by the AGENT by using the cached $\rho(.)$ estimates from the last auction the app participated in. In case an app gets leftover allocations from the leftover allocation mechanism, the AGENT updates the ρ estimate again by using the cached $\rho(.)$ table. In this way we guarantee SP with multi-round auctions.

As we saw in Theorem 3.2, an auction ensures PE and EF. In each round, we allocate all available resources using auctions. This ensures end-to-end PE and EF.

For maximizing sharing incentive, we always take a fraction $1 - f$ of apps in each round. A wise choice of f ensures that we filter in all the apps with $\rho > 1$ that have poor sharing incentive. We only auction the resources to such apps which maximizes sharing incentive. □

Fine-Grained Replicated State Machines for a Cluster Storage System

Abstract

We describe the design and implementation of a consistent and fault-tolerant metadata index for a scalable block storage system. The block storage system supports the virtualized execution of legacy applications inside enterprise clusters by automatically distributing the stored blocks across the cluster's storage resources. To support the availability and scalability needs of the block storage system, we develop a distributed index that provides a replicated and consistent key-value storage abstraction.

The key idea underlying our design is the use of fine-grained replicated state machines, wherein every key-value pair in the index is treated as a separate replicated state machine. This approach has many advantages over a traditional coarse-grained approach that represents an entire shard of data as a state machine: it enables effective use of multiple storage devices and cores, it is more robust to both short- and long-term skews in key access rates, and it can tolerate variations in key-value access latencies. The use of fine-grained replicated state machines, however, raises new challenges, which we address by co-designing the consensus protocol with the data store and streamlining the operation of the per-key replicated state machines. We demonstrate that fine-grained replicated state machines can provide significant performance benefits, characterize the performance of the system in the wild, and report on our experiences in building and deploying the system.

1 Introduction

Enterprise clusters often rely on the abstraction of a block storage volume to support the virtualized execution of applications. Block storage volumes appear as local disks to virtual machines running legacy applications, even as the storage service distributes volume data across the cluster. The storage system provides ubiquitous access to volumes from any node in the cluster and ensures durability and availability through replication.

Our work is in the context of a commercial enterprise cluster product built by Nutanix, a software company that specializes in building private clouds for enterprises. VMs deployed in these clusters rely on a cluster block storage system, called Stargate. As with other block storage systems [8,10,27,29,31], Stargate provides a virtual disk abstraction on which applications/VMs can instantiate any file system. However, unlike most other block storage systems, Stargate co-locates both computing and storage on the same set of cluster nodes. This approach provides cost, latency, and scalability benefits: it avoids needing to provision separate resources for computing and storage, it allows for local access to storage, and it lets both storage and compute scale with the cluster size.

A key component of such a system is the metadata index, which maps the logical blocks associated with a virtual disk to its actual physical locations. Just like the overall system, this mapping layer should provide high performance and strong consistency guarantees in the presence of failures. These requirements suggest a design with the following elements: (a) achieve high throughput and scalability by distributing the index as key-value pairs and utilizing all the cluster nodes, (b) ensure availability and consistency by replicating key-value pairs and using a consensus algorithm, such as Paxos [16] or Viewstamped Replication [25], to implement replicated state machines (RSMs), and (c) ensure durability of a node's shard of key-value state by employing a node-level durable data structure such as the log-structured merge tree (LSM).

This traditional approach to building a distributed index has drawbacks in our specific context where: (a) all operations, including metadata operations, have to be made durable before they are acknowledged, (b) there is significant variation in operation execution latency, and (c) the distributed index service has to share compute and storage with the rest of Stargate and application VMs. In particular, the use of a per-shard consensus operation log, which records the order of issued commands, introduces inefficiencies, such as short- and long-term load imbalances on storage devices, sub-optimal batching of storage operations, and head-of-line blocking caused by more expensive operations.

To address these issues, we develop a design that uses *fine-grained replicated state machine (fRSMs)*, where each key-value pair is represented as a separate RSM and can operate independently. This approach allows for flexible and dynamic scheduling of operations on the metadata service and enables effective use of the storage and compute resources. To efficiently realize this approach, we use a combination of techniques to streamline the state associated with the object radically. In particular, our approach uses no operation logs and maintains only a small amount of consensus state along with the perceived value of a key. We also address performance and consistency issues by co-designing the consensus protocol and the local node storage, providing strong guarantees on operation orderings, and optimizing failure recovery by enhancing the LSM data structure to handle the typical failure scenarios efficiently. It is worth noting that our innovation is not in the consensus protocol (as we merely borrow elements from Paxos and Viewstamped Replication), but in exploring

[*]University of Washington
[†]University of Michigan
[‡]Nutanix

an extreme operating point that is appropriate for balancing load across storage and compute resources in a managed environment with low downtimes.

We present experimental evaluations of our implementation both in a controlled testbed as well as in production deployments. Compared with traditional coarse-grained RSMs, fRSMs achieve 5.6× and 2.3× higher throughput for skewed and uniform scenarios in controlled testbeds. The resulting implementation is part of a commercial storage product that we have deployed on thousands of clusters over the past eight years. To date, we have not had a data loss event at any of these deployed production sites. We have also been able to leverage the metadata store for other applications such as write-ahead logs and distributed hypervisor management.

2 Motivation

We begin with a description of our setting and our goals. We then describe a baseline approach and discuss its shortcomings that motivate our work.

2.1 Metadata Storage Overview

Setting. Our work targets clusters that are typically used by enterprises as private clouds to perform on-premise computing. Customers instantiate virtual machines (VMs) that run legacy applications. The cluster management software then determines which node to run each VM on, migrating them as necessary to deal with faults and load imbalances.

Our Stargate storage system provides a virtual disk abstraction to these VMs. VMs perform reads and writes on the virtual disk blocks, and Stargate translates them to the appropriate accesses on physical disks that store the corresponding blocks. Stargate stores the blocks corresponding to virtual disks on any one of the cluster nodes on which user VMs are executed, thus realizing a *hyper-converged cluster infrastructure* that co-locates compute and storage. An alternate approach would be to use a separate cluster of storage nodes (as is the case with solutions such as SAN) and provide the virtual disk abstraction over the network. Nutanix employs co-location as it reduces infrastructure costs and allows the storage system to flexibly migrate data blocks accessed by a VM to the node on which the VM is currently hosted, thereby providing low latency access and lowering network traffic.

Metadata storage. In this paper, we focus on how Stargate stores the metadata index that maps virtual disk blocks to physical locations across the cluster. One can implement the virtual disk abstraction by maintaining a map for each virtual disk (vDisk) that tracks the physical disk location for every block in that vDisk. Our design, outlined below, introduces additional levels of indirection to support features such as deduplication, cloning and snapshotting. It also separates *physical maps* from *logical maps* to allow for decoupled updates to these maps.

A virtual disk is a sequence of *extents*, each of which is identified by an *ExtentID*. An extent can be shared across virtual disks either because of the deduplication of disk blocks

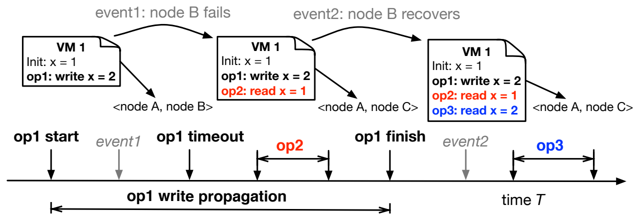

Figure 1: Example timeline that satisfies linearizability but complicates reasoning about failures. The notation <node A, node B> means that the VM is on node A and the leader of the replica group maintaining key *X* is on node B. The value of key *x* is 1 at the start of the timeline. A VM, initially running on node A, issues a write to *x*, partially performs it on node B, and suffers a timeout due to B's failure. After another node C becomes the leader, the VM reads 1 from *x* and expects to continue to see *x* set to 1, barring new writes issued subsequently. If the old leader were to recover, it could propagate its updated copy of *x* and interfere with the VM's logic.

or snapshotting/cloning of virtual disks. Extents are grouped into units called extent groups, each of which has an associated *ExtentGroupID*, and each extent group is stored as a contiguous unit on a storage device. Given this structure, the storage system uses the *vDisk Block Map* to map portions of a vDisk to ExtentIDs, the *ExtentID Map* to map extents to ExtentGroupIDs, and the *ExtentGroupID Map* to map ExtentGroupIDs to physical disk locations. These maps are shared between VMs and the cluster storage management system, which might move, compress, deduplicate, and garbage-collect storage blocks. All accesses to a given vDisk are serialized through a vDisk controller hosted on one of the cluster nodes. Stargate migrates vDisk controllers and VMs upon node failures.

Goals. In determining how to store Stargate's metadata index, apart from maximizing availability and efficiency, we have the following goals:

- ***Durability:*** To minimize the probability of data loss, any update to the metadata must be committed to stable storage on multiple nodes in the cluster before Stargate acknowledges the write as complete to the client. Note that our system should maintain consistent metadata even when the entire cluster comes down (e.g., due to a correlated failure).
- ***Consistency:*** Operations on the metadata index should be linearizable, i.e., all updates to a block's metadata should be totally ordered, and any read should return the last completed write. This guarantee provides strong consistency semantics to client VMs and various background services that operate on the metadata.
- ***Reasoning about failures:*** Under linearizability, even if a read issued after a failure does not reflect a write issued before the failure, this does not mean that the write failed; the update could have been arbitrarily delayed and might get applied later, causing subsequent reads to observe the updated value (see Figure 1). The system should provide stronger guarantees to client VMs so that they can reason about operation failures. In particular, any subsequent read

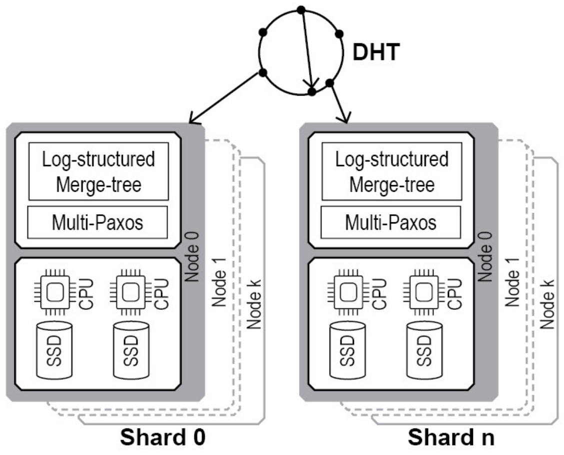

Figure 2: Baseline system architecture representing a coarse-grained replicated state machine built using LSM and Paxos.

of the metadata after an operation timeout must confirm whether the prior operation succeeded or not, and successive reads of a piece of metadata should return the same value as long as there are no concurrent updates initiated by other agents in the system.

2.2 Baseline Design

Let us now consider a baseline approach for realizing the above-mentioned goals. This baseline takes the traditional approach of (a) sharding the metadata index across multiple nodes and multiple cores or SSDs on a given node, (b) using a consensus protocol for ordering operations on any given shard, and (c) executing operations on a durable data structure such as a log-structured merge tree.

In the baseline, all nodes in the cluster participate in implementing a distributed key-value store. We partition keys into shards, use consistent hashing to map shards to replica sets, and consider a leader-based consensus protocol wherein each node serves as the leader for one or more shards in the system. Leader-less designs (such as EPaxos [23]) can lower the communication costs as they eliminate the coordination overheads for the leader, but provide limited benefits in our setting. First, when storage and compute are co-located, there is limited value in moving communication costs from the leader to a client that is sharing network resources with a different server in the cluster. Second, as we will demonstrate later, storage and compute resources are bigger bottlenecks in our setting than the network. Due to our design choice of co-locating compute and storage, the metadata service shares resources with client VMs, which have a higher priority.

We consider a layered design wherein the lower layer corresponds to a consensus protocol, and the upper layer corresponds to a state machine implementing a durable data structure such as a log-structured merge tree. The timeline for processing a request proceeds as follows.

Consensus layer processing. For every shard, one of the replicas of the shard becomes the leader by sending "prepare" messages to a quorum of replicas. When the leader receives a mutating command such as a write, it sequences and propagates this command to all replicas (including itself) using a consensus protocol such as Paxos [16], Viewstamped Replication [25], or Raft [26]. Each shard that a node is assigned to is associated with a specific core and a specific SSD on that node; the core is responsible for sequencing updates to the shard, and the corresponding operation log is stored on the SSD. The system maximizes efficiency by committing commands to the SSD in batches, with every node batching updates destined to one of its SSDs until the prior write to that SSD is complete. Once a batched write is completed, all operations in that batch are considered "accepted". After the leader receives a quorum number of accepts for a command, it can then execute the command locally and send "learn" messages to all followers, indicating that the command has been "chosen." The chosen status does not have to be recorded in stable storage as it can be recreated upon failures. A centralized approach with primary-backup replication [3] can eliminate the use of a consensus protocol and simplify the system design. Such a design, however, limits both the operational scale and performance, and wouldn't satisfy the system requirements that we had outlined above.

LSM layer processing. At every node, the LSM layer processes all chosen commands in the order determined by the consensus layer. LSM processing is streamlined to include just the in-memory Memtable and the stable SSTables. In particular, this is a slightly customized version of a traditional LSM implementation as the commit log, which is available from the consensus layer, can be eliminated from the LSM code. The Memtable access and compaction operations need to be synchronized with other concurrent operations to support multi-core operations. The leader acknowledges a command as complete to the client after a quorum of nodes has recorded the command, and the leader has executed the command in its chosen order because the success of some commands (e.g., compare-and-swap) can be determined only when they are executed after all previously accepted commands have been applied. Leases enable the leader to serve reads on the LSM without any communication with other nodes. However, the leader must synchronize every read on a key with ongoing updates to the same key.

Ordering guarantees. RSMs built using consensus protocols provide linearizability. Further, an RSM can guarantee in-order execution of operations issued by a client. This helps the client reason about the execution status of its operations that have timed out – if the result of a later operation implies that an earlier operation has not been performed, the client can not only deduce that the prior operation has not yet completed but also get the guarantee that the service will never perform the operation. This guarantee can be provided even after RSM reconfigurations. Upon leadership and view changes, protocols such as Viewstamped Replication ensure that operations partially performed in a previous view are not completed in sub-

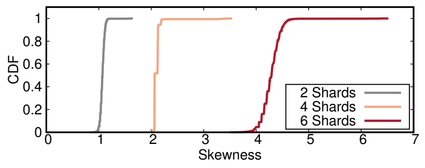

Figure 3: CDF of access skewness with 2/4/6 data shards. ***skewness*** **at any instant is defined as the ratio of the maximum to the average of outstanding IOs per shard.**

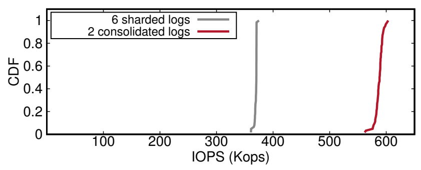

Figure 4: CDF of aggregate SSD throughput when 6 commit logs (3 per SSD) are used compared to when 2 commit logs (one per SSD) are used.

sequent views. These guarantees provide clients with some capability to infer the completion status of their operations.

2.3 Performance Implications of Baseline Design

This baseline design, however, results in several sources of inefficiency. We quantify them with micro-benchmarks using the same computing setup as our evaluations (see Section 4.1).

- ***Load imbalance due to skew:*** The skew in load across shards can lead to an imbalance across SSDs and CPU cores. For instance, differences in popularity across keys can result in long-term skew, whereas random Poisson arrival of requests can cause short-term skew. Figure 3 quantifies the skews across shards for random Poisson arrival.
- ***Sub-optimal batching:*** If there are n nodes in a replica set, each with m SSDs, the number of shards into which commands would be accumulated would be the least common multiple of m and n. (This ensures that the assignment of shard storage to SSDs and the assignment of shard leadership to nodes are statically balanced.) Batching updates independently on each of these shards can result in less than optimal latency amortization. Figure 4 shows that batching across multiple data shards can achieve 1.6× higher bandwidth than a traditional per-shard log design.
- ***High tail latency:*** Tail latency or even average latency of operations could be high due to multiple reasons. First, since the RSM abstraction requires that all replicas execute all updates in the same order, if one of the replicas for a shard is missing a command in its commit log, subsequent operations on that shard will block until this replica catches up. Second, since LSM operations vary in terms of their execution costs (shown in Figure 5), a heavyweight operation can delay the execution of lightweight operations even if processor cores are available to execute the operations.

Sub-dividing the shards into even smaller shards would mitigate the load imbalance issue. However, it suffers from three drawbacks. First, it doesn't address the request head-of-line blocking issue. Requests still have to commit and execute in sequence, as specified in the log order. Second, it further reduces batching efficiency for storage devices. Third, it doesn't provide the benefit of fast node recovery, as a recovering node cannot immediately participate in the protocol. As a result, we instead adopt a shard-less design to overcome all of these issues, as we describe next.

3 System Design

We now present the design of Stargate's metadata storage system, which provides the desired efficiency, availability, durability, and consistency properties. We use the same high-level approach as the baseline: consistent hashing to distribute metadata across replica sets, log-structured merge trees to store and access large, durable datasets, and a consensus protocol to ensure consistency of operations on replicated data.

Our approach differs in one fundamental aspect: it uses fine-grained replicated state machines (fRSMs), wherein each replicated key is modeled as a separate RSM. This approach provides the flexibility needed to effectively manage multiple storage devices and CPU cores on a server, reduces load imbalances, and enables flexible scheduling of key-value operations. However, the use of fine-grained state machines raises both performance and consistency issues, and we address them by carefully co-designing the consensus protocol, the data store, and the client stubs that interact with the storage layer.

3.1 Overview and Design Roadmap

Replicating every key-value pair as a separate RSM, though conceptually straightforward, could impose significant overheads because RSMs are rather heavyweight. For example, a typical RSM contains an operation log and consensus state for each entry in the operation log. The operation log is used to catch up replicas that are lagging behind and/or have missing entries; each operation in the log has to be propagated to laggards to get their state up-to-date.

Lightweight RSMs. Fortunately, the RSM state can be vastly streamlined for simple state machines, such as the key-value objects we use in our system.

- For normal read/write and synchronizing operations such as compare-and-swap, the next state of a key-value pair is a function of its current state and any argument that is provided along with the operator. For such operations, one can eliminate the need for an operation log; it suffices to maintain just the last mutating operation that has been performed on the object and any in-progress operations being performed on the object. We use an API that is simple and yet sufficiently powerful to support the metadata operations of a cluster storage system. (See Section 3.2.)
- The consensus state for operations on a key (e.g., promised and accepted proposal numbers) is stored along with the

key-value state in the LSM as opposed to requiring a separate data structure for maintaining this information. (See Section 3.3.1.)

- A consensus protocol typically stores accepted but not yet committed values along with its committed state and commits an accepted value when consensus has been reached. Instead, our system speculatively executes the operations, stores the resulting value in a node's LSM, and relies on the consensus protocol to update this to the consensus value for the key in the case of conflicts. This further reduces the RSM state associated with each key. It also eliminates the need for explicit learn messages.[1] (See Section 3.3.2.)
- Similar to the Vertical Paxos approach [18], leader election is performed on a per key-range granularity using a separate service (e.g., Zookeeper [13] in our case).

Enabled optimizations. We co-design the consensus protocol and the LSM layer implementing the key-value store to realize per-key RSMs.[2] This enables many optimizations.

- *Consolidated LSM:* All the key-values replicated on a given node can be stored in a single LSM tree as opposed to the canonical sharded implementation that would require a separate LSM tree for each shard. The commit log of the unified LSM tree can be striped across the different storage devices, thus leading to more effective batching of I/O requests to the commit log.
- *Load balancing:* Per-key RSMs enable flexible and late binding of operation processing to CPU cores; a key-value operation can be processed on any core (as long as there is per-key in-memory synchronization to deal with concurrency) and durable updates can be performed on any SSD, leading to more balanced utilization of cores and SSDs.
- *Minimizing stalls:* By requiring ordering of operations only per-key, rather than per-shard, we can eliminate head-of-line blocking. Message loss and high-latency LSM operations do not impact the performance of ongoing operations on other keys, thus improving the tail latency of operations.
- *Low-overhead replication:* Each operation can be applied to just a quorum of replicas (e.g., two nodes in a replica set of three), thus increasing the overall throughput that the system can support. With coarse-grained RSMs, this optimization would result in a period of unavailability whenever a node fails, because new operations on a shard can only be served after stale nodes catch up on all previous operations on the shard. With fRSMs, lagging nodes can be updated on a per-key basis and can be immediately used as part of a quorum.

Challenges. The per-key RSM approach, however, comes with certain performance and consistency implications that we outline below.

- *Overhead of per-key consensus messages:* A coarse-grained RSM can elect a leader for a given shard and avoid the use of prepare messages for mutating operations performed on any key in the shard. In contrast, with per-key RSMs, a node would have to transmit a per-key prepare message if it had not performed the previous mutating operation on that key. Fortunately, node downtimes are low in managed environments such as ours, and a designated home node coordinates most operations on a key. We quantify the overhead associated with this using failure data collected from real deployments.
- *Reasoning about the completion status of old operations:* As discussed earlier, a coarse-grained consensus protocol such as Viewstamped Replication can discard operations initiated but not completed within a view. With fRSMs, one could perform such a view change on a per-key basis, but this would imply additional overheads even for non-mutating operations. We limit these overheads to only when a key might have outstanding incomplete operations initiated by a previous leader. (See Section 3.3.3.)

3.2 Operation API and Consistency Semantics

Operations supported: Our key-value store provides the following operations: *Create* key-value pair, *Read* value associated with a key, *Compare-and-Swap (CAS)* the value associated with a key, and *Delete* key. The *CAS* primitive is atomic: provided a key k, current value v, and a new value v', the key-value storage system would atomically overwrite the current value v with new value v'. If the current value of key k is not v, then the atomic *CAS* operation fails. Note that *Create* and *Delete* can also be expressed as *CAS* operations with a special value to indicate null objects.

We note that the *CAS* operation has a consensus number of infinity according to Herlihy's *impossibility and universality hierarchy* [12]; it means that objects supporting *CAS* can be used to solve the traditional consensus problem for an unbounded number of threads and that realizing *CAS* is as hard as solving consensus. Further, Herlihy's work shows that objects supporting *CAS* are more powerful than objects that support just reads and writes (e.g., shared registers [1]) or certain read-modify-write operations like fetch-and-increment.

We do not support blind writes, i.e., operations that merely update a key's value without providing the current value. Since all of our operations are *CAS*-like, we can provide at-most-once execution semantics without requiring any explicit per-client state as in RIFL [19]. Further, most of our updates are read-modify-write updates, so it is straightforward to express them as *CAS* operations.

Consistency model: Apart from linearizability, we aim to provide two consistency properties to simplify reasoning about operation timeouts and failures.

[1]It is worth noting that the optimization of piggybacking learn messages with subsequent commands is difficult to realize in fine-grained RSMs as a subsequent operation on the same key might not be immediate.

[2]Since we integrate the RSM consensus state into each key-value pair, we can reuse LSM APIs as well as its minor/major compaction mechanisms.

- *Session ordering:* Client operations on a given key are performed in the order in which the client issues them. This property lets a client reason about the execution status of its outstanding operations.
- *Bounded delays:* Client operations are delivered to the metadata service within a bounded delay. This property lets other clients reason about the execution status of operations issued by a failed client.

Sections 3.3.2 and 3.3.3 describe how we implement linearizable *CAS* and *read* operations using a leader-based protocol. We provide session ordering using two mechanisms: (a) leaders process operations on a given key in the order in which they were received from a client, and (b) the *read* processing logic either commits or explicitly fails outstanding operations initiated by previous leaders (see Section 3.3.3). Section 3.4 describes how coarse-grained delay guarantees from the transport layer can help clients reason about the storage state of failed clients.

Our metadata service exposes single-key operation ordering semantics as opposed to supporting transactional semantics involving multiple keys. To support multi-key operations, one can implement a client-side transaction layer that includes a two-phase commit protocol and opportunistic locking [14, 32]. This is similar to what is required of a coarse-grained RSM system to support cross-shard multi-key transactions.

3.3 Operation Processing Logic

3.3.1 Consensus State

Associated with each key is a *clock attribute* that stores information regarding logical timestamps and per-key state that is used for providing consistent updates. The clock attribute is stored along with a key-value pair in the various data structures (e.g., commit log, Memtable, and SSTables), and it comprises of the following fields.

- *epoch number* represents the generation for the key and is updated every time the key is deleted and re-created.
- *timestamp* within an epoch is initialized when the key is created and is advanced whenever the key's value is updated. The epoch number and the timestamp together represent a Paxos instance number (i.e., the sequence number of a command performed on a key-value object).
- *promised proposal number* and *accepted proposal number* associated with the key's value maintained by a given node; these represent consensus protocol state.
- *chosen bit* indicates whether the value stored along with the key represents the consensus value for the given epoch number and timestamp.

The clock attribute is a concise representation of the value associated with the key, and it is used instead of the value in quorum operations (e.g., quorum reads discussed in Section 3.3.3). Since they are frequently accessed, the clock attributes alone are maintained in an in-memory *clock cache* to minimize SSTable lookups and optimize reads/updates.

3.3.2 CAS Processing

For implementing *CAS* operations, we use a variant of the traditional Multi-Paxos algorithm, wherein we co-design different parts of the system and customize the consensus protocol for our key-value store. First, we integrate the processing associated with the consensus algorithm and the key-value store. As an example of a co-designed approach, *accept* messages will be rejected both when the promise is insufficient and when there is a *CAS error*. Second, the nodes do not maintain per-key or per-shard operation logs, but instead, skip over missed operations and directly determine and apply the accepted value with the highest associated proposal number (with a possibly much higher timestamp). Third, the processing logic speculatively updates the LSM tree and relies on subsequent operations to fix speculation errors.

Client CAS updates are built using the clock obtained via the key read previously. With each read, a client also receives the current epoch (e) and timestamp (t) for the value. The client CAS update for the key would then contain the new value along with epoch e and timestamp $t+1$. This is a logical CAS where the client specifies the new value for timestamp $t+1$ after having read the value previously at timestamp t. The request is routed to the leader of the replica group responsible for the key. It then performs the following steps.

1. **Retrieve key's consensus state:** The leader reads its local state for key k and retrieves the key's local clock. The clock provides the following values: the proposal number for a promise (p_p) and the proposal number for the currently accepted value (p_a).
2. **Prepare request:** If p_p is for a prepare issued by a different node, then the leader generates a higher proposal number, sends prepare messages to other nodes, and repeats this process until it obtains promises from a quorum of nodes. The leader skips this step if p_p and p_a are the same and refer to proposals made by the leader.

   Prepare handler: Each of the replicas, including the leader, acknowledges a *prepare* message with a promise to not accept lower numbered proposals if it is the highest prepare proposal number received thus far for the key. The replicas durably store the prepare proposal number as part of the key's clock attribute (i.e., in the commit log as well as the Memtable).
3. **Accept request:** The leader sends an *accept* message with the client-specified timestamp, i.e., $t+1$, the current epoch, and the proposal number associated with a successful prepare.

   Accept handler: At each of the replicas, including the leader, the *accept* message is processed if the current timestamp associated with the key is still t and the proposal number is greater than or equal to the local promised proposal number. If so, the key's value and the corresponding clock are recorded in the commit log and Memtable at each node. An *accept* request is rejected at one of the nodes if it has issued a promise to a higher proposal number or if the timestamp associated with the object is greater than t. In both cases, the replica returns its current value and the proposal number attached to it.

4. **Accept response processing:** The leader processes the accept responses in one of the following ways.
   - If a quorum of successful accept responses is received at the leader, the leader considers the operation to be completed and records a chosen bit on its Memtable entry for the key-value pair. It then reports success back to the client.
   - If the accept requests are rejected because the promise is not valid, then the leader performs an additional round of prepare and accept messages.
   - If the request is rejected because the (epoch, timestamp) tuple at a replica is greater than or equal to the client-supplied epoch and timestamp, then a *CAS error* is sent to the client. Further, *accept* messages are initiated to commit the newly learned value and timestamps at a quorum of nodes.

The protocol described above is faithful to the traditional consensus protocols, but it is customized for our key-value application and the use of fine-grained RSMs. In our system, a client needs to wait for a previous write to complete before issuing a subsequent write. We discuss the equivalence with coarse-grained RSM in Appendix A.4.

3.3.3 Read Processing

A read operation has to ensure the following properties upon completion: (a) the value returned should be the most recent chosen value for a given key, and (b) other previously accepted values with higher <epoch, timestamp> than the returned value are not chosen. The former requires the completion of in-progress *CAS* operations that are currently visible to the leader; this property is required for linearizability. The latter ensures that any other *CAS* operations that are in-progress but aren't visible will not be committed in the future; this is akin to a view change in the Viewstamped Replication protocol where operations that are not deemed complete at the end of a view are prevented from committing in a subsequent view.

To meet these requirements, read operations are processed in one of three different modes: *leader-only reads*, *quorum reads*, and *mutating quorum reads*. When the operation is routed to the leader, the leader checks whether it is operating in the *leader-only mode*, where all of its key-value pairs are up-to-date as a consequence of obtaining the chosen values for every key in the shard through a shard-level scan (described in Section 5.1). If the check is successful, then the leader will serve the request from its Memtable or one of the SSTables. If the leader is not operating in the *leader-only mode*, then it has to poll the replica set for a quorum and identify the most recent accepted value for a key (i.e., perform a *quorum read*). If this value is not available on a quorum of nodes, the leader has to propagate the value to a quorum of nodes (i.e., perform a *mutating quorum read*). Further, if there is an unreachable replica that might have a more recent accepted value, then the *mutating quorum read* performs an additional quorum-wide update to just the timestamp to prevent such a value from being chosen. Note that the consensus state can help determine the possibility of an update languishing in a failed/partitioned node; at least one node in a quorum set of nodes should have an outstanding promise to the failed/partitioned node, and the *read* protocol can detect this condition using a quorum operation.

We now provide additional details regarding *quorum reads* and *mutating quorum reads*. A leader not operating in *leader-only mode* satisfies a *read* request using the following steps.

1. **Quorum read request:** The leader sends the *read* request to other nodes in the replica set. Each node responds with the clock attribute associated with its local version of the key-value pair.
2. **Quorum read response:** The leader then examines the received clock attributes and checks whether any of them have a <higher epoch, timestamp> compared to the leader's clock and whether a quorum of nodes is reporting the most recent value. If the leader does not have the value associated with the highest epoch and timestamp, it obtains the value from one of the nodes reporting the most recent value. If a quorum of nodes reports not having this value, the leader propagates this value to other nodes in the quorum.
3. **Check for outstanding accepted values:** The leader then examines the received clock attributes and checks whether any of them contain a promise that satisfies the following two conditions: (1) the promise is greater than or equal to the highest proposal number associated with an accepted value, and (2) the promise is made to a node that did not respond with a clock attribute.
4. **Update timestamp to quench outstanding accepts:** If such a promise exists, then the read will perform an additional round of updates to a quorum. Let p_p be the promise associated with an unreachable node, and let v, e, and t be the value, epoch, and timestamp associated with the highest accepted proposal. The leader issues prepare commands to the replica nodes to obtain a promise greater than p_p, and then sends accept commands to the replica nodes to update their value, epoch, and timestamp fields to v, e, and $t+1$, respectively. The higher timestamp value prevents older *CAS* operations from succeeding.

The different modes for satisfying a read operation have progressively higher execution costs. In the common case, the *leader-only reads* can satisfy a read operation using local information and without communicating with the other replicas. The *quorum reads* are performed when the leader is not operating in *leader-only mode* immediately after a failover. In this case, the leader has to communicate with the other replica nodes in order to process the read request. If the most recent accepted value is not available on a quorum or if there is evidence of an unreachable node with an outstanding promise, then we resort to *mutating quorum reads* that not only incurs additional communication rounds to the replicas but also pays the overhead of writes to stable storage in order to record the updated value and timestamp. Fortunately, a *mutating quorum read* is needed only after failover and when there is an unreachable node that has obtained a promise to update the given key-value pair. Further, this is invoked only for the very first operation on the key after the failover; subsequent reads can be processed locally by the leader. This escalation of operating modes means that we incur the additional overheads associated with our use of fine-grained RSMs (e.g., per-key prepare messages and per-key timestamp updates) only in a limited number of cases.

3.4 Bounded Transport Processing

The logic outlined above allows reads to either commit or explicitly fail outstanding operations that have been received and processed by any member of the replica group. We now enhance our system to provide time bounds on the delay for propagating a command from the client to a replica node. This allows clients to also reason about the execution status of commands recently initiated by some other client in the system (e.g., the previous instance of a VM that failed unexpectedly).

CAS operations are tagged with the time at which they are initiated by the Stargate code. The leader ensures that it finishes processing the *CAS* operation within a bounded time of T seconds. If the time bound expires and the leader had failed to initiate any accept messages to process and propagate the new value, then it simply drops the request and returns a timeout message. As a consequence of this time bound, a *read* operation that is issued T seconds after an update will encounter one of the following cases: the prior update has been committed; the prior update was accepted at a subset of the nodes, in which case the read will commit it; or prior update is not at any of the responsive replicas, in which case the read will prevent the prior update from committing. The *read* can thus determine the execution status of the prior update, and repeated reads will return the same consistent value in the absence of other concurrent updates.

This bounded-time guarantee assists in handling failover of application code, migration of virtual disks across Stargate instances, and other tasks. For example, the cluster management software can delay the failover of applications until the time bound has expired to ensure that they are not affected by spurious races. For the Stargate systems code, such as that of virtual disk migration logic where stalls are not appropriate, clients directly invoke *mutating quorum read* to abort any in-flight operations from the old site until the time bound has expired.

The use of time bounds is similar in spirit to that of leases in a distributed system, and the concerns associated with the use of an implicit global clock being mitigated by the following two considerations. First, the clients of the key-value store are the block storage management services that run on the same set of nodes as the distributed key-value store and thereby share the same set of local clocks on each node. Second, in a local area enterprise cluster, time synchronization protocols such as NTP/PTP can achieve sub-millisecond time synchronization accuracy, whereas the time bounds that we provide are in the order of seconds (which is consistent with the disk timeout values in operating systems/file systems).

4 Evaluation and Deployment Measurements

Our evaluations comprise of four parts. First, we characterize the metadata service using representative traces from customer clusters. Second, we show the performance benefits of using fine-grained RSMs by comparing it with an implementation of a coarse-grained RSM (i.e., **cRSM**) approach described in Section 2. We perform these evaluations in a controlled testbed setting that runs just the metadata service and not the rest of the cluster block storage system. Note that the controlled environment has the same failure rate, request read/write ratio, and key popularity distribution that we observed in practice. Third, we present the performance of our metadata service as part of complete system evaluations. We configure a cluster with client VMs and workload generators, measure the performance of our metadata service, and characterize the performance benefits of optimizations. Finally, we report performance numbers from real-world deployments.

4.1 Experiment Setup

Our evaluations are performed on typical enterprise on-premises clusters. Specifically, our controlled testbed is a 4-node cluster, where each node is a Supermicro 1U/2U server, enclosing E5-2680 v3/E5-2620 v4 processors, 64GB/128GB DDR4 memory, two Intel DC P3600 NVMe SSDs, and a dual-port 10Gbps Intel X710 NIC. We perform the remaining evaluations on similar hardware, but at a larger scale across a large number of customer clusters. Appendix B.1 presents details of the LSM configurations that we use in practice. The replication factor for a key is three in all experiments.

4.2 Metadata Workload Characterization

We present metadata measurements from 980 customer clusters (Figure 20 in Appendix B.2). Generally, each cluster contains 3 to 30 nodes and uses 24.7TB block storage on average. The three metadata components (vDisk block, ExtentGroupID, and ExtentId) have sizes that are 0.04%, 0.12%, and 0.02% of the logical storage, respectively. Note that the size of metadata will increase when deduplication and compression are enabled due to more consolidated block storage.

Next, we characterize the metadata workload in terms of read/write ratio, value size distribution, and key access popularity by taking continuous snapshots from three custom clusters, where each cluster has at most 16 nodes. We make the following observations. First, unlike other previous key-value

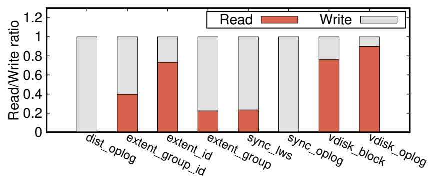

Figure 6: Read/write ratio for 8 frequently accessed metadata tables.

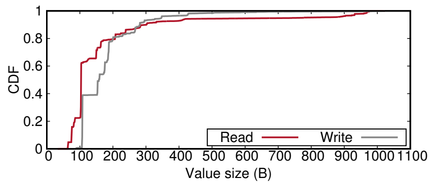

Figure 7: Value size distribution of read/write requests. Key size is less than 100 bytes.

	Cluster1	Cluster2	Cluster3
vdisk block	0.99	0.99	0.99
extent id	0.80	0.80	0.85
extent group id	0.60	0.55	0.50
extent phy_state	Uniform	Uniform	Uniform

Table 1: Key access popularity of four different metadata tables for three customer clusters. The first three types of metadata are Zipf; we show their skewness factors.

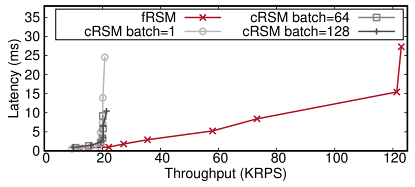

Figure 8: Latency v.s. throughput under the skewed workload for multiple shards.

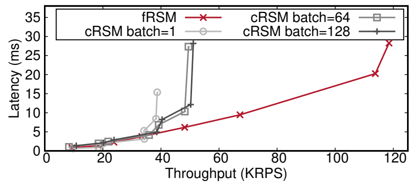

Figure 9: Latency v.s. throughput under the uniform workload for multiple shards.

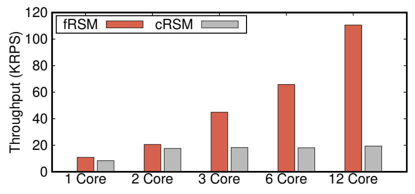

Figure 10: Maximum throu. for the skewed workload as we increase the number of cores.

store workload profiles studied under social networks/web settings [21,24], our metadata service presents various read/write ratios ranging from write-only loads for various system logs to read/write intensive ones for various filesystem metadata items (see Figure 6). Second, the read/write requests are dominated by small values, say less than 512B (see Figure 7). In fact, about 80% of reads and writes involve values that are less than 200 bytes in size. Further, requests that involve more than 1KB value sizes are about 1.0% of the reads/writes. Finally, there exist various access patterns in our metadata service. As shown in Table 1, some metadata shows highly skewed key/value accesses, while others have low skewness or even present uniform access patterns.

4.3 Benefits of Fine-grained RSMs

We now evaluate the performance benefits of fRSMs using streamlined deployments that run just the metadata service on physical nodes (as opposed to client VMs). No client workloads are executing on service nodes. We use a workload generator and configure it to issue a similar request pattern as our most frequently accessed metadata that has 43% reads and 57% writes, value size of 512B, and a Zipf distribution with skewness factor of 0.99. We also consider a uniform access case (i.e., random access pattern) as an additional workload. We inject faults into the leader using failure rate observed in the wild (Section 4.5). We evaluate fRSM and cRSM in terms of both latency and throughput.

Higher throughput. We set up a three-node replica group with twelve data shards, running across two SSDs and twelve CPU cores. In the case of cRSM, each node is a leader for four shards, each shard allocated a separate core, and six shards share each SSD. In the case of fRSM, there is a consolidated commit log striped across the two SSDs, and each operation is dynamically scheduled to a CPU core. We consider cRSM configured to perform batched commit using different batch sizes. fRSM achieves 5.6× and 2.3× higher throughputs over cRSM (with batch size of 128) for skewed and random cases, respectively (see Figures 8 and 9). This is because fRSM (1) allows requests accessing different keys to be reordered and committed as soon as they complete; (2) eliminates the computation cost associated with scanning the RSM log to identify and retry uncommitted entries; (3) avoids unnecessary head-of-line blocking caused by other requests; (4) achieves better load balance across SSDs and cores even in skewed workloads. The first three benefits can be observed even in the single shard case (Figures 11 and 12), while the next experiment further examines the load balance benefits.

Better load balancing. To examine the load-balancing benefits of fRSM , we again consider a three-node replication group with twelve data shards but vary the number of CPU cores used to process the workload. We consider the skewed workload, and we configure cRSM to use a batch size of 64. We then measured the maximum throughputs achieved and the average/p99 latency of operations when we achieve the maximum throughput (see Figures 10 and 13). fRSM provides a 1.9×, 4.1×, 6.1×, 11.0× throughput improvement and 1.9×, 2.4×, 3.3×, 5.3× (1.3×, 2.5×, 3.3×, 4.9×) avg(p99) latency reduction as we increase the number of cores from 1 core to 2, 4, 6, and 12 cores, respectively. The performance of cRSM, on the other hand, does not improve with more than two provisioned cores. Under load skews, fRSM allows balanced and timely execution of operations on different key-based RSMs, while cRSM has to commit requests in the RSM log sequentially and is subject to skews and head-of-line blocking.

4.4 Performance of Commercial Offering

We now evaluate the fRSM approach when implemented inside a commercial product providing a cluster-wide storage abstraction. This introduces many additional overheads as the metadata service is executed inside a controller virtual

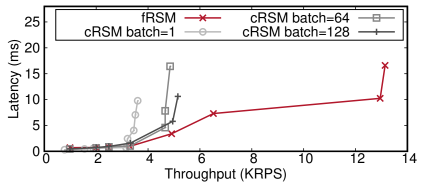

Figure 11: Latency v.s. throughput under the skewed workload for a single shard.

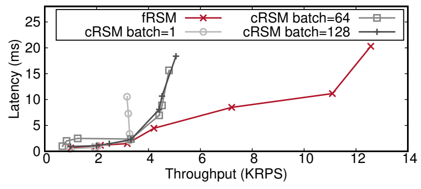

Figure 12: Latency v.s. throughput under the uniform workload for a single shard.

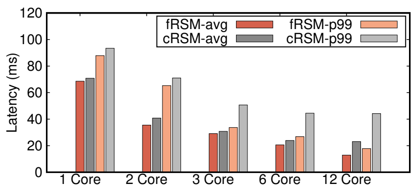

Figure 13: Average/p99 latency for the skewed workload as we increase the number of cores.

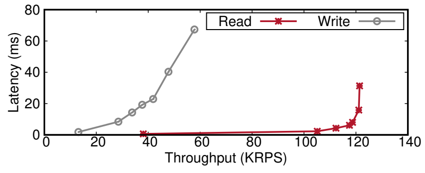

Figure 14: Latency versus throughput for reads and writes inside a Stargate cluster.

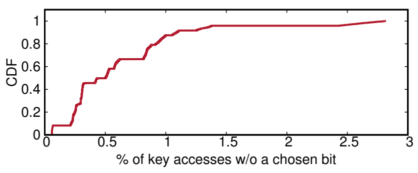

Figure 15: Operations requiring a multi-phase protocol when the leader has no chosen value.

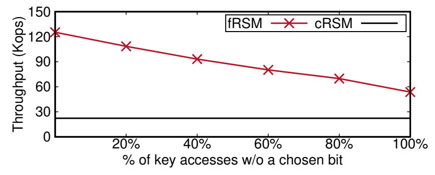

Figure 16: Throughput for the skewed workload varying the fraction of multi-phase operations.

machine, there is virtualized access to the network, and storage/CPU resources are shared with the rest of the cluster management system as well as client VMs.

We use an internal three-node cluster and an in-house workload generator that mimics various types of client VM behavior. Figure 14 reports the performance. The node is able to support peak throughputs of 121.4KRPS and 57.8KRPS for reads and writes, respectively. Under a low to medium request load, the average latency of reads and writes is 0.63ms and 1.83ms, respectively. In the appendix, we provide additional measurements of the internal cluster that quantify the benefits of using a gradation of read execution modes and utilizing the appropriate read variant for a given key. Overall, the throughput performance of fRSM inside the commercial offering is in the same ballpark as the stand-alone evaluation, but the access latency is significantly higher due to various queueing delays and interference with other storage operations that are concurrently performed by the VMs and the cluster management software.

4.5 Measurements from Real-world Deployments

High availability. We collect failure data over a two-week period (from 2018/09/12 to 2018/09/25) from about 2K customer clusters. On average, there are 70 software detached events (due to unanswered heartbeat messages) and 26 hardware failures (e.g., disk failures) per day, respectively. Crucially, our measurements show that a recovering node is able to integrate itself into the service within 30 seconds irrespective of the number of key-value operations that might have been performed when it was down. Appendix B.4 reports detailed failure handling performance. The reason for this fast recovery is that a recovering node only replays the operations in its commit log before it can participate in the consensus protocols. Each key accessed subsequently would allow the recovering node to update just that particular key-value state given the fine-grained nature of the RSMs in our system. The node can also lazily update the remaining key-value state in the background, and we observe that our system does so in about 630secs on average. In other words, the fRSM approach speeds up node integration significantly by more than 20x.

Multi-phase operations. The primary overhead associated with fRSM is the need for one or more additional rounds of protocol messages when a leader invokes an operation on a key that was previously mutated through a different leader. cRSM also incurs leadership change overheads, but they are at a shard-level, whereas fRSM incurs the overheads on a per-key basis. We quantify how often this happens in practice by measuring the fraction of instances where a leader does not have the chosen bit set and has to perform additional protocol phases. Figure 15 shows that fRSM incurs additional overheads for less than 1% of the key accesses in more than 90% of the cluster snapshots. We then performed an analysis of how the fRSM throughput degrades as we vary the number of accesses requiring multi-phase operations given the skewed workload discussed earlier. Figure 16 shows that, even though the throughput of fRSM degrades in our controlled testbed, fRSM's throughput is still higher than that of cRSM's even when 100% of the operations require multiple phases.

Cluster throughputs. We report the node/cluster throughput of the metadata layer from real deployments. Figure 17 shows the cluster throughput, where (1) every point represents a cluster data point; (2) the left y-axis represents both the throughput as well as the number of Paxos state machines that are executing per second (since every operation corresponds to a Paxos instance of a key-value pair); (3) the right y-axis is the number of nodes in the cluster. It varies from 3 nodes to a maximum of 33 nodes in the cluster; (4) the red line represents the throughput measurements per node. We can observe that our metadata layer can scale from a few thousand state machine invocations to about 393K state machine invocations per second across the cluster. The cluster with the maximum number of cluster-level operations had eight nodes,

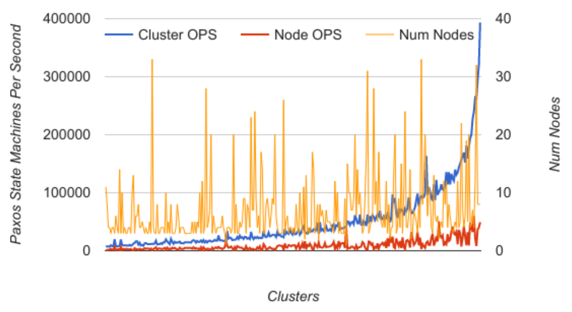

Figure 17: Cluster-level and node-level throughput for the metadata layer in the custom cluster.

and the per-node throughput is ∼59K operations per second, which is consistent with the stress tests performed on the internal cluster. Note that the peak system throughput for the other clusters could be higher, as the observed throughput is a function of the offered load.

5 Deployment-based Experience

From our experience developing the system and troubleshooting issues, we have not only improved the robustness of the system but also have learned a number of non-obvious lessons.

5.1 Fault Tolerance

Stargate provides highly-available block storage, and we describe how the metadata layer handles various cluster failures.

Transient failure. This is a typical failure scenario where the failed node recovers within a short period, e.g., a node taken offline for upgrades. When the node is the leader of a replica group, one of the other replicas will elect itself as the leader. The new leader initially processes reads and writes using quorum operations instead of transiting into *leader-only mode* (since *scan* is an expensive operation). The system keeps track of newly created SSTables on the leader and ensures these newly created SSTables are not compacted with older ones. This guarantees that new updates are segregated from older ones. When the failed node recovers, it elects itself as the leader of the replica group, provided it is the natural leader of the shard. We then transfer the newly created SSTables to the recovered node to enable it to catch up on lost updates and enter *leader-only mode* after it does so. If a significant period of time has elapsed without the failed node recovering (e.g., 30 minutes in our current system), the current leader attempts to transition to *leader-only* mode. For this, it has to *scan* the entire keyspace, by performing batched quorum reads or mutating quorum reads as necessary, to discover the up-to-date state for all keys in its shard.

Correlated or group failure. Generally, this is an uncommon event but will happen when (1) the rack UPS (uninterruptible power supply) or rack networking switch goes down; (2) the cluster undergoes planned maintenance. We apply a rack-aware cluster manager, where Stargate creates different location independent failure domains during the cluster creation and upgrade phases. Upon metadata replication, based on the replication factor (or fault tolerance level), we place replicas across different failure domains to minimize the probability that the entire metadata service is unavailable.

Optimization. It is worth noting that the choice of the LSM tree as a node's local data storage is beneficial in optimizing the handling of failures. With appropriate modifications to the LSM tree, we are able to keep the newly created data segregated. It also helps optimize the transfer of state to new nodes that are added to the replica set (to restore the replication factor in the case of persistent failures) by enabling the bulk transfer of SSTable state to the new nodes. Further, our system has a background process that periodically checks the integrity of stored data and re-replicates if necessary. This accelerates the recovery process. If a node goes down for a while, the system starts a dynamic healing approach that proactively copies metadata to avoid a two-node failure and unavailability.

5.2 Addition/Removal of Nodes

Recall that, in Stargate's metadata store, keys are spread across nodes using consistent hashing. Since we apply every update for a key to only a quorum of the key's replicas to maximize system throughput, the addition of nodes to the cluster must be handled carefully. For example, consider the addition of node A (in between Z and B) to a four-node cluster with nodes Z, B, C, and D. Say a key in the range (Z, A] has previously been written to only B and D, i.e., two out of the key's three replicas B, C, and D. Now, a read for that key could potentially return no value since two of the key's three new replicas (A, B, and C) have no record of it.

To prevent such issues, we introduce a new node by temporarily increasing the replication factor for the keys assigned to it, until the node is caught up. Having a new node catch up by issuing Paxos reads for all of its keys is, however, terribly slow; this process has taken as long as 18+ hours at one of our customers! So, we also had to develop a protocol that enables a new node to directly receive a copy of relevant portions of other nodes' SSTables. Since a new node starts serving new operations while receiving LSM state in the background, we disable caching until the new node is caught up, so as to prevent inconsistency between in-memory and on-disk state. This bulk copy method is also used during the node removal process. Besides that, we place the removed node into a *forwarding state* such that replication requests won't be accepted, but local requests will be forwarded to another node. After affected token ranges are scanned, and a quorum of the remaining nodes can respond to the request, the removed node is excised from the DHT ring.

5.3 Deletion of Keys

Consensus protocols such as Paxos are silent on the issue of deletion; it is assumed that Paxos state must be kept around forever. Therefore, when a key is deleted, correctly removing that key's Paxos state from all replicas proved to be tricky to get right for several reasons. (We describe our delete protocol in Appendix A.2.) Even after all replicas commit to their LSMs, a tombstone record indicating a key's deletion, we found that the key's old value could resurface for multiple reasons. Example causes include faulty SSDs failing to write an update to stable storage despite acknowledging having done so, or misbehaving clients issuing mutating reads with an epoch number lower than the key's epoch value when it was deleted, causing the old value to be re-propagated to all replicas. To avoid such scenarios, apart from using high-quality SSDs, we set a key's tombstone record in the LSM to be deleted only 24 hours after the third record was created. Since we use the current time to pick epoch numbers, 24 hours is sufficiently large that clock skew cannot prevent epoch numbers from monotonically increasing.

6 Related Work

Our work is related to recent research efforts in consensus protocols, consistent storage systems, metadata management, relaxed consistency, and cluster storage.

Consensus protocols: To provide consistency in the presence of node faults, we use a consensus protocol that is an extension of protocols such as Multi-Paxos [16], Viewstamped Replication [25], and Raft [26]. The crucial difference is that we integrate request processing (which in our case is read/CAS/delete operations of a key-value store) with the consensus protocol logic. This approach allows us to realize fine-grained replicated state machines that enable effective use of storage and compute units in a setting where they are scarce (since client VMs are co-located with the storage service).

Many replication protocols reduce coordination by identifying operations that can be performed independently (e.g., Generalized Paxos [17], EPaxos [23]). We employ a similar technique but use it to optimize the use of storage and computing on a server node. Our work is related to foundational algorithmic work on atomic distributed registers [1,9], but we support synchronization operations that have an unbounded consensus number (such as *CAS*).

Consistent storage systems: Our work is also related to recent work on various types of consistent key-value storage systems. Unlike Spanner [5], RIFL [19], FaRM [7], and TAPIR [35], our key-value store does not directly support transactions but rather limits itself to single key operations. Instead, it provides the atomic *CAS* primitive, which is used by the block storage management layer to make mutating updates and limited types of transactional operations. Our key-value store, however, provides bounded time operations and stronger ordering constraints that are required by legacy applications in virtualized settings. Its node-local data structures are based on those of BigTable [4] and HBase [11], and we make some modifications to aid in fast failure recovery. Our consistent storage system is also related to MegaStore [2], which provides per-row transactional updates using Paxos. Our approach integrates the Paxos algorithm with the key-value store logic in order to both enhance performance as well as provide stronger operation ordering guarantees.

Metadata management in P2P systems: Traditional DHT-based P2P storage systems (like DHash [6], Pastry [28], OceanStore [15], Antiquity [33], Ceph [34]) provide a management layer that maps physical blocks to node locations. Such metadata is a read-only caching layer that only changes when nodes join/leave. However, our metadata service maintains mappings between physical and virtual blocks, which could frequently change under VM migration. Hence, our system has a stronger consistency requirement.

Relaxed consistency: Researchers have proposed a couple of relaxed consistency models to reduce request execution latency, especially for geo-replicated key-value storage. For example, Walter [30] supports parallel snapshot isolation and conducts asynchronous replication. Within each site, it uses multi-version concurrency control and can quickly commit transactions that write objects at their preferred sites. COPS [22] is a geo-replicated key-value store that applies causal consistency across the wide area. RedBlue [20] defines two types of requests: blue operations execute locally and lazily replicate in eventually consistency manner; red operations serialize with respect to each other and require cross-site coordination. The metadata layer of our enterprise cloud storage has a linearizable requirement.

7 Conclusion

Enterprise clusters today rely on virtualized storage to support their applications. In this paper, we presented the design and implementation of a consistent metadata index that is required to provide a virtual disk abstraction. Our approach is based on using a distributed key-value store that is spread across the cluster nodes and is kept consistent using consensus algorithms. However, unlike other systems, our design uses fine-grained RSMs with every key-value pair represented by a separate RSM. Our design is motivated by the effective use of storage and computing on clusters that is achieved by flexible scheduling of unrelated operations. Our work tackles a range of challenges in realizing fine-grained RSMs and provides useful ordering guarantees for clients to reason about failures. We build and evaluate our system, compare it with coarse-grained RSMs in controlled testbed settings, and provide measurements from live customer clusters.

A More Details of fRSM

In this appendix, we present additional details regarding the design of our system.

A.1 Read and CAS Algorithmic Description

Algorithm 1 READ procedure

```
procedure READ_LEADER($key$)
    if $leader\_only = 1$ then                    ▷ In leader-only read mode
        $< val_{local}, CLOCK_{local} > \leftarrow lsm\_read(key)$
        if $CLOCK_{local}.chosen$ then
            return $send\_client\_reply(key, val_{local})$
        end if
    end if
    ▷ Do a quorum read.
    for $N$ in $Replica_{group}$ do
        $send\_read(key, N)$
    end for
end procedure

procedure PROCESS_READ_REPLY_AT_LEADER($req$, $msg$)
    if $msg_{type} = SUCCESS$ then
        $++num\_responses$
    else
        $++num\_errors$
    end if
    if $CLOCK_{msg} > CLOCK_{local}$ then
        ▷ Replica has a newer value. Perform mutating quorum read.
        $write\_result \leftarrow$
            $CAS\_LEADER(key_{req}, val_{local}, CLOCK_{local}.epoch, CLOCK_{local}.ts)$
        if $write\_result = CAS_{success}$ then
            return $send\_client\_reply(key_{req}, val_{local})$
        else
            return $send\_client\_reply(key_{req}, READ_{error})$
        end if
    else if $CLOCK_{msg} = CLOCK_{local}$ then
        $++num\_responses\_with\_same\_clock$
    end if
    if $CLOCK_{msg}.P_p = CLOCK_{local}.P_p$ then
        ▷ Local leader holds promise on the replica.
        $++num\_promise\_to\_local\_leader$
    end if
    if $num\_responses\_with\_same\_clock \geq QUORUM$ then
        if $num\_promise\_to\_local\_leader \geq QUORUM$ then
            return $send\_client\_reply(key_{req}, val_{local})$
        else if $num\_responses = Replica_{group}.count$ then
            return $send\_client\_reply(key_{req}, val_{local})$
        end if
    end if
    if $num\_responses + num\_errors = Replica_{group}.count$ then
        ▷ Local leader doesn't hold promise on quorum nodes and some replicas
          didn't reply. Some of these replica nodes may have a value with higher
          timestamp, do a mutating quorum read.

Algorithm 1 and 2 presents how read/CAS requests are handled at the leader and followers. They follow our protocol description in Sections 3.3.3 and 3.3.2.

A.2 Delete Processing

The key-value store also supports a delete operation, which is used by the block storage system to remove index map entries that are no longer necessary (e.g., when a virtual disk snapshot is deleted). A delete request from a client is similar to a regular *CAS* update where the client provides the epoch e and timestamp $t+1$. The leader processes a delete operation by first getting a quorum of nodes to update the value associated with the key to a special *DeleteForCell* value for epoch e and timestamp $t+1$. If the *DeleteForCell* value was not accepted by all replicas but only by a quorum, then a *DeletedCellTombstoned* message is sent to ensure replicas keep the key-value pair until the next deletion attempt. As far as the client is concerned, quorum nodes accepting a *DeleteForCell* is considered as a successful *CAS* update.

Periodically, the leader attempts to complete a two-phase deletion process to delete the value completely. When it has gotten all replicas to accept the delete request, the first phase is considered complete. It then sends a second message to instruct replica nodes to schedule the key for deletion and to remove all state associated with it. This request is recorded in *Memtable/SSTable* individually on every replica. The next major compaction on a replica will remove the state. Until then the deletion record persists at each replica with its associated clock containing epoch e and timestamp $t+1$.

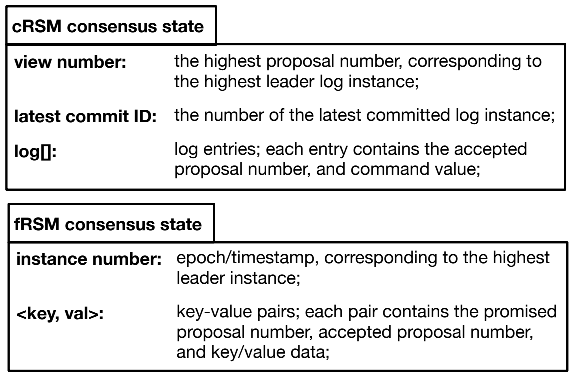
Once the key deletion is successful (quorum nodes have accepted the deletion request), any new CAS updates with epoch $\leq e$ are rejected as *CAS errors*. New client updates for the key (i.e., key creation) must use a new (higher) epoch with timestamp 0.

A.3 fRSM Operation Summary

Table 2 summarizes read/write operations under various cases in terms of request latency, message count, and metadata storage operation count.

A.4 The Relationship between cRSM and fRSM

Note that fRSM works exactly the same as cRSM but in a fine-grained way. In terms of the consensus state (Figure 18 in the appendix), cRSM maintains a per-shard view number, the latest commit ID, and a log of RSM instances (where each instance has an accepted proposal number and the command value). fRSM essentially maintains information only for the most recent instance and directly encodes the promised/accepted proposal number along with the key/value pair. As a result, it doesn't require the latest commit ID. In terms of the way they handle the leader change event, cRSM uses a full two-round consensus protocol to synchronize the latest commit ID, preparing for all future commands. fRSM also takes a full two-phase consensus protocol to synchronize the consensus state for each key. In the example shown



cRSM consensus state
view number:
the highest proposal number, corresponding to the highest leader log instance;
latest commit ID:
the number of the latest committed log instance;
log[]:
log entries; each entry contains the accepted proposal number, and command value;

B More Real-world Evaluation

B.1 LSM Configuration

Table 3 shows key LSM parameters. They are configured based on the physical storage media, cluster setup, and metadata characteristics. The table presents the default values.

B.2 Deployment Scale

Figure 20 presents the deployment scale in terms of node number, storage size, and metadata size.

B.3 Internal Cluster Measurements

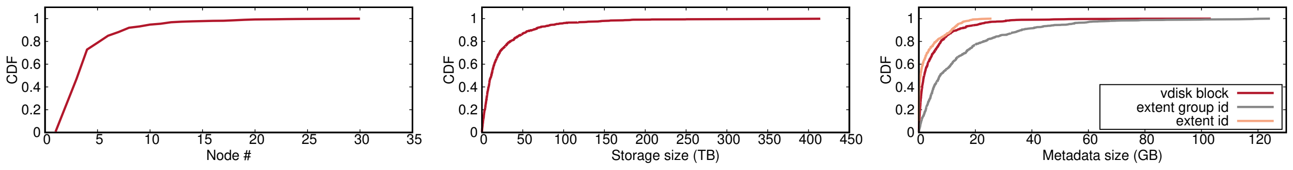
We consider again the internal cluster running the complete storage and virtualization system along with client VMs invoking stress tests on the metadata and storage layer (as discussed earlier in). We report the average/p99 latency distribution of read/write requests (Figure 21), showing comparable end-to-end performance for read and write operations. We also evaluate the performance of leader-only reads. Leader-only mode significantly reduces the number of protocol messages and storage accesses, enabling fast metadata access. Figures 22 and 23 show that leader-only mode results in benefits across different value sizes. On average, across various sizes,

Operations	Latency (RTT)	Message #	Leader LSM RD. #	Leader LSM WR. #	Follower LSM RD. #	Follower LSM WR. #
Cold CAS	2	$4\lceil n/2 \rceil$	1	2	2	2
Warm CAS	1	$2\lceil n/2 \rceil$	1	1	1	1
Leader-only Read	0	0	1	0	0	0
Quorum Read	1	$2n$	1	0	1	0
Mutating Quorum Read	3	$2n+4\lceil n/2 \rceil$	2	2	3	2

Table 2: Message RTTs and LSM read/write counts with no cache for the leader and the follower under different settings. *n* is the number of replicas. *cold CAS* refers to the case that the proposal of a key is issued by another node so that the leader has to invoke the two round Paxos. *warm CAS* means that the leader is able to skip the 1st round of prepares.

Parameter	Description	Default value
max_heap_size	Maximum heap size of the metadata store	2∼4GB
flush_largest_memtables	Heap usage threshold when flushing the largest memtable	0.9
default_memtable_lifetime	Life time in minutes for any memtable	30
min_flush_largest_memtable	Minimum memtable size forced flush when heap usage is high	20MB
max_commit_log_size_on_disk	Maximum disk usage by commit logs before triggering a cleanup task	1GB
commitlog_rotation_threshold	Maximum size of an individual commit log file	64MB
number_of_compaction_threads	Number of threads to perform minor/major compaction	2
compaction_throughput_limit	Maximum disk throughput consumed by compaction on a disk	64MB

Table 3: LSM performance-sensitive parameters.



(a) Node #. (b) Storage size. (c) Metadata size.

Figure 20: Node #, storage size, and metadata size CDF across 980 custom clusters.

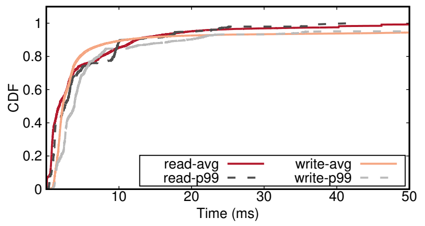


Figure 21: Average/p99 read/write latency CDF inside a Stargate cluster.

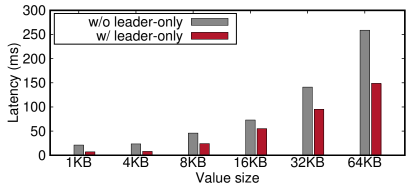

Figure 22: Latency versus value size, compared between with and without leader-only mode.

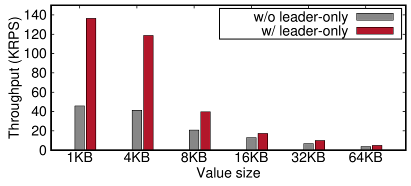

Figure 23: Throughput versus value size, compared between with and without leader-only modes.

leader-only mode halves the latency and more than doubles the throughput. This underscores the benefits of using a gradation of read execution modes and utilizing the appropriate read variant for a given key.

B.4 Failure and Recovery Measurements

We provide additional details on the failure and recovery measurements from our customer clusters. Figure 24 shows the number of software detached events and fatal hardware errors across the measurement period across all of the 2K clusters. Both of them are detected by the DHT health manager. Under software failures, our system will quickly restart the metadata service and rejoin the DHT ring, consuming 2.7s on average. Upon fatal hardware errors, we reboot the server box and then walk through some device checks (e.g., storage media and network). Figure 27 presents our observed server downtime distribution. After node failure, the system follows a 3-phase node handling failure to recover to the leader-only mode, i.e., regaining leadership (*T1*), performing local recovery (*T2*), and performing a leader scan (*T3*). Based on our collected traces, we observe that *T1* consumes 1.0ms. During *T2* phase, the node reads the commit log and executes missing requests. Figures 25 and 26 present the CDF of local node recovery (*T2*) and the number of recovered operation records (from the committed log) for 4 clusters, respective. Note that our cluster node is able to serve client requests starting from *T2* in a non-leader-only mode and enters the leader only mode after the scan finishes (*T3*).

The duration of the *T3* phase depends on scan performance. To enable leader-only reads, the new leader must scan through its owned range to learn the latest values. In some cases, Paxos writes must be done, and this imposes additional la-

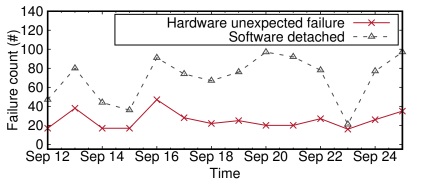

Figure 24: Failure rate among 2K custom VMs (Year 2018).

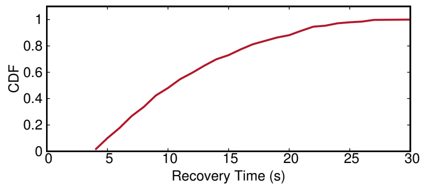

Figure 25: CDF of node recovery time inside a Stargate cluster.

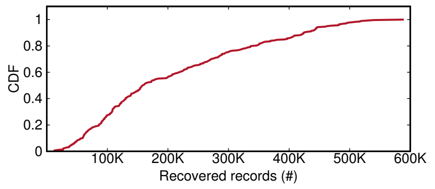

Figure 26: CDF of recovered records inside a Stargate cluster.

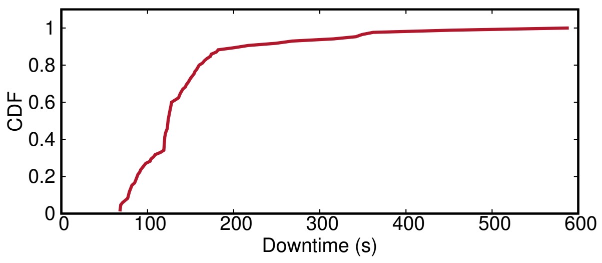

Figure 27: Node downtime CDF (after the hardware failure).

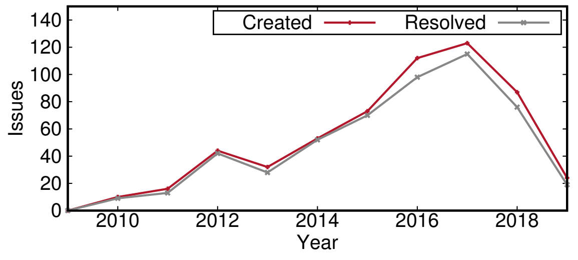

Figure 28: Metadata service corruption report over years.

tency costs for the scanning process. The worst-case repair time occurs when Paxos operations must be performed for every key. Conversely, the best-case scan time occurs when no consensus operations need to performed (i.e., the node has all of the latest data). Figure 29 provides the time associated with scans when the nodes are loaded with data comprising of 32-byte keys and 8KB values. When repairs need to run for every value, the total scan time is about 6× long. These measurements show the quick integration of recovering nodes into the metadata service.

B.5 Metadata Corruption Reports

Figure 28 shows the number of cases that have been reported by our QA based that have caused data unavailability or corrupt data being returned to the client based on the tests. We have not culled for duplicate issues, where the single cause manifested in multiple ways. The broad category of failures has changed over the years. Initially, it was the interaction with the local filesystems (fsyncs, o_directs), persistent media corruption, cluster misconfiguration. In recent years, it has been due to the addition of new features like leader-only reads, fast range migrations, balancing with no node downtimes. There have been a handful of protocol implementation issues that were weeded out fairly quickly.

C Testing Framework

Our testing strategy and framework has evolved over the years. Based on experience, we have found white box testing to be one of the key ways to identify implementation issues in new features and avoid regressions. We have instrumented code to simulate various scenarios and probabilistic error conditions like replica packet drops, timeouts, and erroneous key states. Whenever a bug is discovered in the field or in black box testing, we add a white box test to simulate the same condition

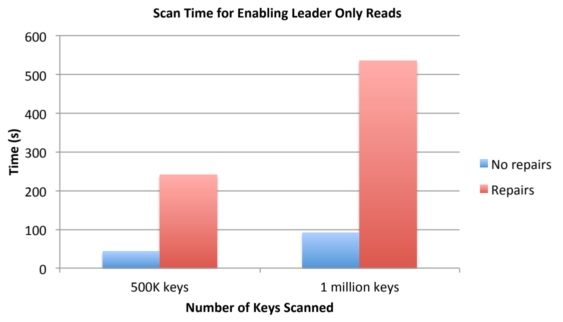

Figure 29: Time to perform a scan in order to enable leader-only reads.

along with making the fix.

We also have multiple test clusters that do end-to-end black box testing with error injections. Errors can be in the form of service restarts, service down, corruption over the network, timeouts, replays, and corruption of persistent store. As an example, we use a test devised specifically for fRSM that performs atomic increments on value(s) stored in key(s) *n* times (where each of the atomic increment is a CAS update) and, at the end, when all clients are done, check whether the final value of each key is *n* times the number of clients. While these clients are incrementing values using CAS, we randomly kill replica/leader nodes, insert failures, randomly drop messages between leader/replica nodes, add a delay in replying to messages, etc. Apart from incrementing values in the keys, we also delete keys in the middle of the test to go through the delete workflow and re-insert the key(s) with the value(s) seen just before the deletes, so the clients can continue incrementing the values. We also add/remove replicas to the metadata service while this test is underway to test add/remove node scenarios and different read variants. These type of tests can be performed within a developer environment and have aided in building a robust system.

It is non-trivial to pinpoint performance bottlenecks due to the complexity of our system. We instrument our logic across the metadata read/write execution path and report runtime statistics at multiple places, such as the number of outstanding requests at the Paxos leader, the hit rate of the key clock attribute, read/write/scan latency at leader and follower of one key-range, etc. This instrumentation has been helpful in identifying various performance issues.

Scalog: Seamless Reconfiguration and Total Order in a Scalable Shared Log

Cong Ding David Chu Evan Zhao Xiang Li[†] Lorenzo Alvisi Robbert van Renesse
Cornell University [†]*Alibaba Group*

Abstract

The *shared log paradigm* is at the heart of modern distributed applications in the growing cloud computing industry. Often, application logs must be stored durably for analytics, regulations, or failure recovery, and their smooth operation depends closely on how the log is implemented. *Scalog* is a new implementation of the shared log abstraction that offers an unprecedented combination of features for continuous smooth delivery of service: Scalog allows applications to customize data placement, supports reconfiguration with no loss in availability, and recovers quickly from failures. At the same time, Scalog provides high throughput and total order.

The paper describes the design and implementation of Scalog and presents examples of applications running upon it. To evaluate Scalog at scale, we use a combination of real experiments and emulation. Using 4KB records, a 10 Gbps infrastructure, and SSDs, Scalog can totally order up to 52 million records per second.

1 Introduction

A shared log[1] offers a simple and powerful abstraction: a sequence of ordered records that can be accessed and appended to by multiple clients. This combination of power and simplicity makes them a popular building block for many modern datacenter applications. All cloud providers offer a shared log service (e.g., AlibabaMQ [2], Amazon Kinesis [3], Google Pub/Sub [8], IBM MQ [10], Microsoft Event Hubs [13], and Oracle Messaging Cloud Service [14]), which is also available through multiple open source implementations (e.g, Apache Kafka [36], Corfu [21], and FuzzyLog [41]).

Shared logs are used to (1) record and analyze web accesses for recommendations, ad placement, intrusion detection, performance debugging, etc. [11, 31, 36, 50]; (2) prepare a transport between stages in a processing pipeline that may be replayed for failure recovery [11, 50], and more broadly; (3) address the trade-off between scalability and consistency [51]. Consider, for instance, deterministic databases [22, 34, 35, 47, 48]: retrieving transactions from a single shared log allows these databases to shorten or eliminate distributed commit protocols, avoid distributed deadlocks, and achieve, in principle, superior transactional scalability [44, 47, 48].

An ideal implementation of the shared log abstraction should be capable of growing elastically in response to the needs of its client applications, without compromising availability; recover quickly from failures; adopt the data layout that best matches the performance requirement of its clients; and scale write throughput without giving up on total order. Unfortunately, no single shared log today can offer this combination of features. In particular, no shared log provides both total order and *seamless reconfiguration*, i.e., the capability to reconfigure the service without compromising its global availability.

The state-of-the-art Corfu [21] can adapt to applications' needs by adding or removing storage servers, while maintaining total order across records stored on different servers. However, any change in the set of storage servers makes Corfu unavailable until the new configuration has been committed at all storage servers and clients. The Corfu data layout is defined by an inflexible round-robin policy, with significant performance implications: for example, reads require playing back the log where relevant updates are interspersed with unrelated records (a potential performance bottleneck) and writes cannot be directed to the closest storage server to reduce latency. vCorfu [51], an object store based on Corfu, addresses the issue of slow reads by complementing the Corfu shared log with *materialized streams*, log-like data structures that store together updates that refer to the same object. For this gain in performance, vCorfu pays in robustness: whenever a log replica and a stream replica fail concurrently—a more likely event as the system scales up [25]—vCorfu is at risk of losing data. Finally, the tension between scaling across multiple storage servers and guaranteeing total order ultimately limits Corfu's write throughput. The optimized Corfu implementation used in Tango [22] achieves, to the best of our knowledge, the best throughput among today's totally ordered shared logs but, at about 570K writes/sec, its performance falls short of the needs of applications like Taobao [16], Alibaba's online market, which ran millions of database writes/sec at its 2017 peak [1].

[1]A shared log is also known as a *message bus*, but not all message buses provide a durable message store.

Scalog, the new shared log that this paper introduces, aims to address these limitations. Like Corfu, Scalog can scale horizontally by adding *shards* and guarantees a single total order for all records, across all shards. However, reconfiguring Scalog by adding or removing shards requires no global coordination and does not affect its availability. Further, Scalog's API gives applications the flexibility to select which records will be stored in which shard: this allows Scalog to replicate the functionality offered by vCorfu's materialized streams without trading off robustness. Indeed, Scalog operates under weaker failure assumptions (and hence is inherently more robust) than prior totally-ordered shared logs [21,22,51]: it assumes that faulty servers will *crash* [29], rather than *fail-stop* [45], thus sidestepping the so-called "split-brain syndrome" [26].[2] Finally, though Scalog cannot scale write throughput indefinitely, it can deliver throughput almost two orders of magnitude higher than Corfu's, with comparable latency.

Scalog's properties derive from a new way of decoupling global ordering from data dissemination. Decoupling these two steps is not a new idea. For example, in Corfu, the sequencer that globally orders records is not responsible for their replication; once the order has been decided, replication is left to the clients, thus allowing data dissemination to scale until ordering ultimately becomes the bottleneck.

The key to Scalog's singular combination of features is to turn on its head how decoupling has traditionally been achieved. In Corfu (as well as Facebook's LogDevice [12]), order comes before persistence: records are first assigned unique sequence numbers in the total order, and then replicated; in Scalog, the opposite is true: records are first replicated, and only then assigned a position in the total order.

As mentioned above, Corfu requires that all clients and storage servers hold the same function to map sequence numbers to specific shards, causing Corfu to be temporarily unavailable when shards are added or removed. By ordering only records that have already been replicated, Scalog sidesteps the need to resolve the delicate case in which a client, having reserved a slot in the total order for one of its records, fails before making that record persistent. Without this burden, Scalog can seamlessly reconfigure without any loss of availability, and give applications the flexibility to independently specify which shards should store their records, thus matching vCorfu's data locality without the need of dedicated stream replicas.

Specifically, Scalog clients write records directly to storage servers, where they are (trivially) FIFO ordered without the mediation of a global sequencer. Records received by a storage server are then immediately replicated across the other storage servers in the same shard. To produce a total order, Scalog periodically interleaves the FIFO ordered sequences of records stored at each server.

[2]The essential difference is that crash failures cannot be accurately detected, while in the fail-stop model, it is assumed that failures can be detected accurately by some oracle. Violation of this assumption can lead to inconsistencies.

We recognize that not all applications require a global total order, and many industrial applications have been built using shared logs such as Kafka [36] that only provide a total order per shard. However, our unique way of providing total order comes at practically no cost to throughput even under reconfiguration, while latency within a datacenter is no more than a few milliseconds. Programmers thus only need to consider performance when deciding how to shard their applications, an otherwise difficult balancing game between achieving the required throughput and correctness [18, 27, 28, 44]. Also, a global total order supports reproducibility, simplifying finding bugs in today's complex distributed applications.

Our evaluation of a Scalog prototype implemented on a CloudLab cluster [4] confirms that Scalog's persistence-first approach comes closer to an ideal implementation of the shared log abstraction in three main respects:

- It provides seamless reconfiguration. Our prototype sees no increase in latency or drop in throughput while Scalog is being reconfigured.
- It offers applications the flexibility to select where the records they produce should be stored. We use this capability to build vScalog, a Scalog-based object store that matches the read latency of vCorfu (and achieves twice its read throughput) while offering stronger fault-tolerance guarantees.
- It offers (almost) guilt-free total ordering of log records across multiple shards. While Scalog does not eliminate the trade-off between scalable write throughput and total order, it pushes the pain point much further: its maximum throughput is essentially limited by the maximum number of shards times the maximum throughput of each shard. With 17 shards, each with two storage servers, each processing 15K writes/sec, our prototype achieves a total throughput of 255K totally ordered writes/sec. Through emulation, we demonstrate that, at a latency of about 1.6 ms, Scalog can handle about 3,500 shards, or about 52M writes/sec—two orders of magnitude higher than the best reported value to date at comparable latency [22].

2 Motivation and Design

We motivate Scalog and its design principles with an online marketplace that enables sellers to list and advertise their merchandise, and allows buyers to browse and purchase. Page views and purchases are stored in a log that is used for multiple purposes, including extracting statistics (such as the number of unique visitors), training machine learning algorithms that can recommend merchandise and sellers to buyers, and simplifying fault tolerance by providing applications with a shared "ground truth" about the system's state.

This example highlights six key requirements for the underlying shared log. First, the log requires *auto-scaling*, the

`append`(r)	Append record r, and return the global sequence number.
`trim`(l)	Delete records before global sequence number l.
`subscribe`(l)	Subscribe to records starting from global sequence number l.
`setShardPolicy`(p)	Set the policy for which records get placed at which storage servers in which shards.
`appendToShard`(r)	Append record r, and return the global sequence number and shard identifier.
`readRecord`(l,s)	Request the record with sequence number l from shard s.

Table 1: Scalog API

ability to dynamically increase or decrease available throughput as needs change (e.g., during the holiday seasons) without causing any downtime. Second, for reproducibility during debugging and consistent failure recovery, the log should be totally ordered. Third, the log must minimize latency, for example, by allowing log clients to write to the nearest replica. Fourth, the log must provide high append throughput to support large volumes of store activity. Fifth, the log must provide high sequential read throughput to support analytics, which periodically read sub-sequences of the log. Finally, the log must be fault tolerant, as the online services that depend on it should be uninterrupted. Below, we discuss how Scalog addresses these requirements.

2.1 Scalog API

Scalog provides the abstraction of a totally ordered shared log. Table 1 presents a simplified API that omits support for authentication and authorization, as well as the ability to subscribe only to records that satisfy a specific predicate.

The first three methods are sufficient for most applications. The `append` method adds a record to the log. When it returns, the client is guaranteed that the record is *committed*, meaning that it cannot be lost (it has been replicated onto multiple disks) and that it has been assigned a *global sequence number* (its unique log position among committed records). The `trim` method allows a prefix of the log to be garbage collected. Finally, the `subscribe` method subscribes to committed log records starting from global sequence number l. Scalog guarantees that (1) if `append`(r) returns a sequence number, each subscriber will eventually deliver r; and (2) any two subscribers deliver the same records in the same order.[3] Note that these guarantees are sufficient to implement a replicated state machine [46] using Scalog.

To achieve high throughput and support flexible allocation of resources, Scalog structures a log as a collection of *shards*, each in turn containing a collection of records. Applications can exploit the existence of shards to optimize performance with the remaining three API methods. The `setShardPolicy` method lets applications specify a function used to assign records to storage servers and shards. The `appendToShard` method behaves as `append`, but in addition returns the identifier of the shard where the record is stored. The `readRecord` method allows random access to records by sequence number, assuming the shard identifier is known (e.g., for having been returned by a prior invocation of `appendToShard`). Under concurrent access, Scalog offers fully linearizable semantics [32]—the strongest possible consistency guarantee.

Besides this API, Scalog provides various management interfaces that allow reconfiguring the log seamlessly in response to failures and to the changing needs of the applications it serves. Specifically, Scalog can create new shards on-the-fly (if load increases), as well as turn shards from *live* to *finalized*. New records can only be appended to live shards; once finalized, a shard is immutable.

Finalizing shards serves three purposes. First, Scalog optimizes finalized shards for read throughput. To prevent read-heavy analytics workloads from affecting the performance of online services, an operator may create new shards, finalize the old shards (effectively, creating a checkpoint), and then run the analytics workload on the finalized shards. Second, when a storage server in a shard fails, append throughput may be affected; rather than recovering the failed server, Scalog allows finalizing the entire shard and replacing it with a new one (see §3). If one wishes to restore the level of durability, additional replicas may be created after a shard is finalized. Third, finalized shards may be garbage collected: this is how resources are reclaimed after a log is trimmed.

2.2 "Order first" Considered Harmful

Current totally ordered log implementations [6, 12, 21, 22] share a similar architecture: to append a new record, a client first obtains the record's position in the log, the *log sequence number*, via some *sequencer*, and then proceeds to make the record persistent. This design raises two challenges.

The first challenge is supporting flexible data placement and seamless reconfiguration. The difficulty comes from having to maintain the consistency of the log when failures occur—a dilemma that arises whenever a storage system makes decisions about an item's metadata before making persistent the item itself [20,30]. Under failure, a record may get lost; this "hole" in the log needs to be filled before other tasks can read beyond the missing entry. Solving this problem requires a costly system-wide agreement on a mapping from log sequence numbers to where records are stored: changes to this mapping are exceedingly expensive, since, until a new mapping is agreed upon, the system cannot operate. For applications using the log, this cost translates into two main limitations. First, they have no practical way of dynamically optimizing the placement of the records they generate, since frequent changes to the mapping would be prohibitively ex-

[3]These guarantees hold only in the absence of trimming. Trimmed records may never be delivered to some subscribers.

pensive; second, each time storage servers are added or removed for any reason, they experience a system-wide outage until the new mapping is committed and distributed [21, 22].

The second challenge is that the sequencer can quickly become a bottleneck: designing a sequencer capable of operating at high throughput requires significant engineering effort, frequently involving custom hardware, such as programmable switches (e.g., NOPaxos [40]) or write-once disks (e.g., Corfu [21]).

2.3 Scalog Design Overview

By adopting a persistence-first architecture, Scalog avoids these challenges. It achieves no-downtime reconfiguration, quick failure recovery, and high throughput, without using custom hardware, via a new, simple, protocol for totally ordering persistent records across multiple shards.

In Scalog, each shard is a group of storage servers that mutually replicate each other's records. Scalable throughput is achieved by creating many high-throughput shards, as in Kafka [50]; however, unlike Kafka, which only provides total order within individual shards, Scalog delivers a single total order across all shards.

Persistence in Scalog is straightforward. A client sends a record to a storage server of its choice, before knowing the record's global sequence number. Storage servers append incoming records, which may come from different clients, to a *log segment* which they replicate by forwarding new records through FIFO channels to all other storage servers within their shard. Thus, each storage server maintains a *primary log segment* as well as backup log segments for every other storage server in its shard. Because of FIFO channels, every backup log segment is a prefix of the primary log segment.

Scalog's second key insight is leveraging the FIFO ordering of records at each storage server to leapfrog the throughput limits of traditional sequencers.

Periodically, each storage server reports the lengths of the log segments it stores to an *ordering layer*. The ordering layer, also periodically, determines which records have been fully replicated and informs the storage servers. Using the globally ordered sequence of reports from the ordering layer, a storage server can interleave its log segments into a global order consistent with the original partial order. Afterward, the storage server can inform clients that their records are both durably replicated and totally ordered.

The ordering layer of Scalog interleaves not only records but also other reconfiguration events. As a result, all storage servers see the same update events in the same order. When a storage server in a shard fails, Scalog's ordering layer will no longer receive reports from the storage server and naturally exclude further records. Other shards are not affected. Thus, clients connected to a shard containing a faulty storage server can quickly reconnect and send requests to servers in other shards. Concurrently, the affected shard is finalized.

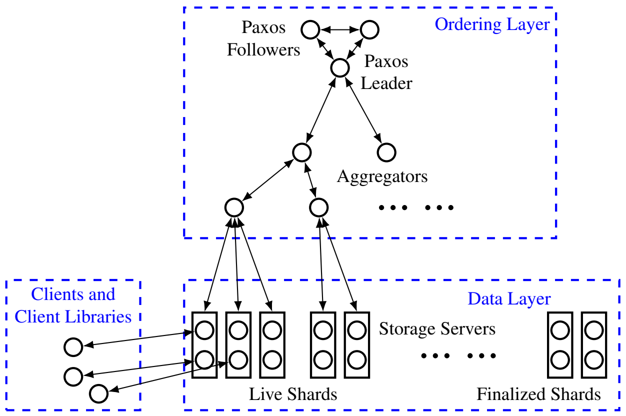

Figure 1: Scalog's architecture: arrows denote communication links; circles denote servers; each rectangle denotes one shard. Servers in the same shard communicate with each other. In this example, both shards and the Paxos instance in the ordering layer are configured to tolerate one crash.

3 Architecture

Figure 1 presents an overview of Scalog's architecture, highlighting its three components: a *client library*, used to issue `append`, `subscribe`, and `trim` operations; a *data layer*, consisting of a collection of shards, storing and replicating records received from clients; and an *ordering layer*, responsible for totally ordering records across shards.

Client Library. The library implements the Scalog API and communicates with the data layer (see Table 1).

Data Layer. Scalog's data layer distributes load along two dimensions: each log consists of multiple shards, and each shard consists of multiple storage servers. Each storage server is in charge of a *log segment*. Clients send records directly to a storage server within a shard. When a storage server receives a record from a client, it stores the record in its own log segment. For durability, each server replicates the records in its log segment onto the other storage servers in its shard. To tolerate f failures, a shard must contain at least $n = f + 1$ storage servers.

Ordering Layer. The ordering layer periodically summarizes the fully replicated prefix of the primary log segment of each storage server in a *cut*, which it then shares with all storage servers. In a Scalog deployment with m shards, each comprising n storage servers, the cut has $m \cdot n$ entries, each mapping a storage server identifier to the sequence number of the latest durable record in its log segment. The storage servers use these cuts to deterministically assign a unique global sequence number to each durable record in their log segments. Besides enabling global ordering, the ordering layer is also responsible for notifying storage servers of reconfigurations.

The ordering layer must address two concerns: fault tolerance and scalability under high ordering load. Scalog addresses the first concern by implementing the ordering layer logic using Paxos [38]. The second concern is that the over-

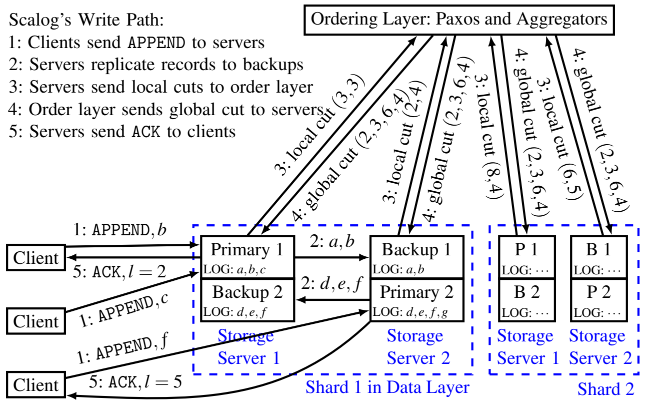

Figure 2: Scalog message flow for `append` operations

head of managing TCP connections and handling the ordering requests could overwhelm the ordering layer when there are a large number of shards. This concern is addressed with the help of the aggregators, illustrated in Figure 1. Scalog spreads the load using a tree of aggregators that relay ordering information from the storage servers at the leaves up to the replicated ordering service. Each leaf aggregator collects information from a subset of storage servers (we assume servers in the same shard report to the same leaf aggregator) and determines the most recent durable record in their log segment before passing the information up. Aggregators use soft state and do not need to be replicated—if suspected of failure, they can easily be replaced. The ordering reports passed up the tree are self-sufficient, and need not be delivered in FIFO order. The aggregator tree is maintained by the replicated service in its root—no decentralized algorithms are needed to eliminate loops and orphans.

4 Scalog's Workflow

To further elucidate how Scalog works, we present a detailed explanation of the execution paths for *append*, *read*, and *trim* (garbage collection) operations.

4.1 Append Operations

When an application process first invokes its client library to start appending data to the log, the client library chooses a shard according to the current sharding policy set by `setShardPolicy`(p). If no policy has been specified, Scalog applies its default selection policy, choosing a random storage server in a random live shard as the write target.

Having established a destination shard s and storage server d, the application process can add records to the log. When `append`(r) or `appendToShard`(r) is invoked, the client library forwards record r to storage server d in an `APPEND` message (Figure 2, Step 1) and awaits an acknowledgment.

As shown in Step 2 of Figure 2, each storage server replicates in FIFO order the records it receives onto its peer storage servers in s. In-shard replication resembles Primary-Backup (PB) [19, 24]: each storage server acts as both Primary for the records received directly from clients and Backup for the records in the log segments of its peer storage servers in the shard. Scalog differs from PB in how storage servers learn which records in their log segment have become durable. Instead of relying on direct acknowledgments from its peers, each storage server periodically reports to the ordering layer a *local cut*—an integer vector summarizing the records stored in this storage server's log segments (Step 3 in Figure 2). Because log segment replication occurs in FIFO order, each integer in the local cut is an accurate count of the number of records stored in the corresponding log segment.

The ordering layer combines these local cuts to determine the latest durable record in the log segment of each storage server. Let v_i be the local cut for server i in shard s; $v_i[i]$ represents the number of records in i's log segment (i.e., those that i, serving as Primary, received directly from its clients) while $v_i[j], j \neq i$, is the number of records that server i is backing up for its peer storage server j. The ordering layer can then compute the number of durable records in i's log segment as the element-wise minimum of all $v_j[i]$ for all storage servers j in s. For instance, assume $f = 1$ and suppose the ordering layer has received from the two storage servers r_1 and r_2 in shard s the local cuts $v_1 = \langle 3,3 \rangle$ and $v_2 = \langle 2,4 \rangle$. Then, $\langle 2,3 \rangle$ expresses all durable records in shard s (see Shard 1 in Figure 2). By repeating this process for all storage servers in every shard, the ordering layer assembles a *global cut*, a map that represents records stored in all log segment replicas and therefore durable. To prevent the number of entries in global cuts from growing indefinitely, we use a single integer to represent the total number of records in all finalized shards. The ordering layer then forwards each global cut to all storage servers (Step 4 in Figure 2).

The totally ordered sequence of cuts can be used to induce a total ordering on individual records. Summing the sequence numbers in the elements of a cut gives the total number of records that are ordered up to and including that cut. The difference between any two cuts determines which records are covered by those two cuts. We use a deterministic function that specifies how to order the records in between two consecutive cuts. In our current implementation, we use a simple lexicographic ordering: records in lower-numbered shards go before records in higher-numbered shards, and within a shard records from lower-numbered storage servers go before records from higher-numbered storage servers.

Therefore, upon receipt of a global cut, a storage server can determine which records in its primary log segment are now globally ordered, and then acknowledge the corresponding append requests by returning the record's global sequence number to the client (Step 5 in Figure 2). Should a storage server fail, a client can ask any of its backup for the current status of its records.

Note that the load on the ordering layer is independent of the write throughput—it only depends on the number of storage servers and the frequency of their reports.

4.2 Read Operations

Applications can read from the log either by subscribing or by requesting specific records. The `subscribe` operation broadcasts the request to a random storage server in each shard. Upon receiving a `subscribe`(l) request, the storage server sends the client all records it already stores whose global sequence number is at least l and then continues forwarding future committed records.

Recall that an application process, by calling `appendToShard`(r), obtains the shard identifier s that stores record r, as well as its global sequence number l. If at a later time the process needs to bring r back in memory, it can do so by invoking `readRecord`(l,s). In response, the client library contacts a random storage server in s to read the record associated with global sequence number l. The receiving storage server then computes $l_{\max}$, the largest global sequence number it has observed, by applying the deterministic scheme of §4.1 to the latest cut received from the ordering layer, and proceeds to compare l and $l_{\max}$. If $l \leq l_{\max}$, the storage server uses l to look for r in its local log and, if it finds it, returns it; otherwise, if the record has been trimmed (see §4.3), it returns an error. If $l > l_{\max}$, the storage server waits for new cuts from the ordering layer and updates $l_{\max}$ until $l \leq l_{\max}$; only then does it proceed, as in the previous case, returning to the application process either r or an error message. Allowing responses only from storage servers for which $l \leq l_{\max}$ is critical to guarantee linearizability for concurrent read and append operations, as it prevents stale storage servers from incorrectly returning error messages. The client library may, however, timeout, waiting for a storage server to respond; if so, the client library contacts another storage server in s (the storage server holding r in its log segment is guaranteed to eventually respond).

4.3 Trim Operations

Calling `trim`(l) garbage collects the log prior to the record with global sequence number l. The client library broadcasts the `trim`(l) operation to all storage servers in all shards; upon receipt, they proceed to delete the appropriate prefix of the log stored in their respective log segments.

4.4 Reconfiguration and Failure Handling

Reconfiguration can happen often in Scalog, not only to recover from failures (which are more likely as scale increases), but also to handle growing throughput or needed capacity. For example, an application that needs to run a read-intensive analytics job can finalize the shards storing the relevant data, making them read-only. For these reasons, Scalog strives to make adding and finalizing shards seamless.

4.4.1 Adding and Finalizing Shards

Adding a new shard is straightforward: as soon as the shard and its servers register with the ordering layer, the new shard can be advertised to clients. Other shards are unaffected, but for the larger-sized cut, its storage servers will henceforth receive from the ordering layer.

We distinguish two types of shard finalization: scheduled finalization and emergency finalization. Scheduled finalizations are initiated in anticipation of shard workload changes. To transition clients off of shards facing impending finalization, Scalog supports a management operation that causes the ordering layer to stop accepting ordering reports from a shard after a configurable number of committed cuts. This gives clients a "grace period" so that they can smoothly transition to another live shard. Emergency finalizations are needed when a server in a shard fails (see *Finalize & Add* in §4.4.2); these failed shards are finalized immediately.

4.4.2 Handling Storage Server Failures

Failing or straggling storage servers are detected either by Paxos servers directly connected to them or by aggregators. Problems are notified to the ordering layer, which in turn initiates reconfiguration. Applications have three options to configure how Scalog handles slow or failed storage servers.

Finalize & Add (Requires at least $f+1$ storage servers per shard): If a storage server is suspected of having failed or is intolerably slow, its entire shard s is finalized. Clients of s can redirect their writes to other shards; concurrently, a new shard is added to restore the log's overall throughput. Because the ordering layer totally orders finalization operations and cuts, the latest cut before s is finalized reveals which records s successfully received and ordered: these records can be retrieved from any of the surviving storage servers in the shard. Records received but not incorporated in s's latest cut must be retransmitted by the originating clients to different shards. Corfu also responds to a storage server failure by finalizing its shard and adding a new one. During this process, however, all Corfu's shards are unavailable; in contrast, Scalog's non-faulty shards are unaffected (see §6.2).

Applications that require data locality may run application processes in storage servers (see §5.3). *Finalize & Add* would force those processes, if an entire shard is finalized, to migrate. Instead, Scalog supports two alternative options.

Remove & Replace (Requires at least $f+1$ storage servers per shard): As in vCorfu, Scalog can replace a failed storage server with a new one, which can then copy records from its shard's surviving storage servers. During this process, the affected shard is temporarily unavailable for writes (but continues to serve reads). This option suffers from a longer service recovery time [25].

Mask (Requires at least $2f+1$ storage servers per shard): At the cost of extra resources, this option ensures that, if no more than f of its storage servers fail, a shard will continue to process both reads and writes. This option also masks straggling storage servers. For long-term availability, new storage servers can be added to replace faulty ones; they can copy records from the shard's surviving servers.

	Replicas per Shard	Data Locality	Service Recovery Time
Finalize & Add	$f+1$	No	Short
Remove & Replace	$f+1$	Yes	Long
Mask	$2f+1$	Yes	Zero
Corfu	$f+1$	No	Short
vCorfu	$f+1$	Yes	Long

Table 2: Trade-offs of different approaches to handling storage server failures

All options guarantee linearizable semantics under crash failures, but they provide different trade-offs with respect to resource usage, data locality, and service recovery time after a failure. Table 2 summarizes these trade-offs and compares these options with failure recovery in Corfu and vCorfu.

4.4.3 Handling Ordering Layer Failures

Failures in the ordering layer can affect replicas running Scalog's ordering logic as well as aggregators. Replica failures are handled by Paxos; aggregator failures are handled by leveraging the statelessness of aggregators. A storage server or an aggregator that suspects its neighboring aggregator of having failed reports to the ordering layer, which responds by creating a new aggregator to replace the suspected one. A mistaken suspicion does not harm correctness, as both the new and the wrongly suspected aggregator correctly report local ordering information to their parent.

A distinguishing feature of Scalog is that Scalog suffers no net throughput loss because of ordering layer failures. Because of Scalog's approach to decoupling ordering from data replication, storage servers continue accepting client append requests and ordering records locally in their log segments, independent of the status of the ordering layer. Any temporary loss of throughput caused by an ordering layer failure is thus made up for as soon as the failure is recovered, when these locally ordered records are seamlessly inserted in the next cut issued by the repaired ordering layer. It does cause a spike in throughput because the repair interleaves all delayed records that are already replicated in one single cut. This is in contrast to sequencer-based logs where, after throughput halts because of a sequencer failure and reconfiguration [17, 21]), throughput goes back to normal instead of compensating for the loss of availability.

5 Applications

Applications can configure Scalog and customize sharding policies to satisfy their requirements. This section discusses typical applications that benefit from Scalog and demonstrates how to configure Scalog and set sharding policies.

5.1 The Online Marketplace

The online marketplace we used to motivate the Scalog design logs user activities (sellers listing products, buyers browsing and purchasing products, etc.) to Scalog for analytics and fault tolerance. To satisfy the requirements discussed in §2, we configured Scalog to use *Finalize & Add* to handle storage server failures and for a sharding policy we let each application process write to the nearest storage server.

If an application process writes at a rate that may overwhelm a single shard, it may select multiple shards to distribute the writes. Periodically, analytics jobs read Scalog, which may negatively affect the write rate; therefore, before performing analytics jobs, the online marketplace finalizes shards and adds new shards: the online marketplace writes to newly added shards, and analytics jobs read from finalized shards. This isolation makes sure analytics reads do not negatively affect online writes.

Using the API discussed in §2, the online marketplace calls `append` to log user activities. Periodically, analytics jobs use the `subscribe` API to extract data. When any of the system components fail, the online marketplace calls `subscribe` to replay the log and reproduce its state.

5.2 Scalog-Store

Modeled after Corfu-Store [21], Scalog-Store uses Scalog as its underlying storage. Scalog-Store configures Scalog to handle storage server failures using *Finalize & Add*, as it is the same as how Corfu handles failures. Like the online marketplace's sharding policy, the sharding policy is for an application process to select the nearest storage server.

Scalog-Store supports the same operations as Corfu-Store: atomic `multi-get`, `multi-put`, and `test-and-multi-put` (conditional `multi-put`). Scalog-Store uses a *mapping server* with an in-memory hash map that maps each key to a pair (l,s) containing a global sequence number l and a shard identifier s where the latest record containing the value of that key is stored.

To implement `multi-get`, which takes a set of keys as input, a client retrieves, in a single atomic request, the (l,s) pairs for the keys from the mapping server. The client then calls `readRecord`(l,s) for each pair to get each key's value.

To implement `multi-put`, a client first executes `appendToShard`$(\langle key, value\rangle)$ for each key to receive corresponding (l,s) pairs. Next, the client creates a *commit record* that contains the set of $(key,(l,s))$ records for each key and uses `appendToShard` to add the commit record to the log. (An optimization for single-key `multi-put` operations is only to log a commit record containing the key and value.) The client then forwards the commit record to the mapping server, which updates its hash map accordingly and responds. `multi-put` finishes on receipt of the response. Should the mapping server crash, a new server can re-read the log and rebuild a current hash map.

The implementation of `test-and-multi-put` is similar to that of `multi-put`, but adds a test condition to the commit record. Upon receiving the forwarded commit record, the mapping server evaluates the test condition to decide whether to commit the operation. If so, the mapping server processes the operation normally; otherwise, the mapping server processes the operation as a *no-op*. Finally, the mapping server returns the result to the client.

5.3 vScalog

Modeled after vCorfu [51], an object store based on Corfu, vScalog is an object store that runs on Scalog. The key difference between vScalog and vCorfu is how they guarantee data locality. vCorfu maintains a separate log, a so-called *materialized stream*, for each object, in addition to a global shared log. A client has to write an object update to the shared log for total order and to the materialized stream for data locality. vScalog, instead, leverages Scalog's sharding policy to map each object to one shard, effectively using each Scalog shard as a materialized stream. As a result, the single shared log guarantees both total order and data locality. vScalog can configure Scalog to handle storage server failures using either *Remove & Replace* or *Mask*; our implementation uses *Remove & Replace* because it is how vCorfu handles failures.

Compared with vCorfu, vScalog offers two main advantages. First, it is more robust: it can tolerate f failures in each shard, while vCorfu cannot handle a log replica and a stream replica failing simultaneously. Second, it offers higher read throughput: it lets clients read from all the replicas in a shard, while vCorfu's clients only read from stream replicas. A disadvantage is that vScalog requires all transactions, including those that will eventually abort, to be written to the log. The fundamental reason goes back to Scalog's persistence-first architecture, as the predicate on a `test-and-multi-put` operation may depend on the position of the corresponding record in the log, which Scalog decides after the record is replicated.

6 Evaluation

The goal of Scalog is to provide a scalable totally ordered shared log with seamless reconfiguration. In our assessment of Scalog, we ask the following questions:

- How do reconfigurations impact Scalog? (§6.1)
- How well does Scalog handle failures? (§6.2)
- How much write throughput can Scalog achieve and what is the latency of its write operations? (§6.3)
- How well do Scalog read operations perform in different settings? (§6.4)
- How do Scalog applications perform? (§6.5)

We have implemented a prototype of Scalog in golang [7], using Google protocol buffers [9] for communication. To tolerate f failures, the ordering layer runs Paxos with $2f+1$ replicas and each shard comprises $f+1$ storage servers; unless otherwise specified, we set $f=1$.

Some of our experiments use Corfu as a baseline for Scalog. To enable an "apples-to-apples" comparison, we implemented a prototype of Corfu in golang: it uses one server as a sequencer, $f+1$ servers for each storage shard, and Google protocol buffers for communication. Our Corfu implementation achieves higher throughput and lower latency than Corfu's open-source implementation [5]. To simplify comparison with published Corfu benchmarks, we fix the record size at 4KB.

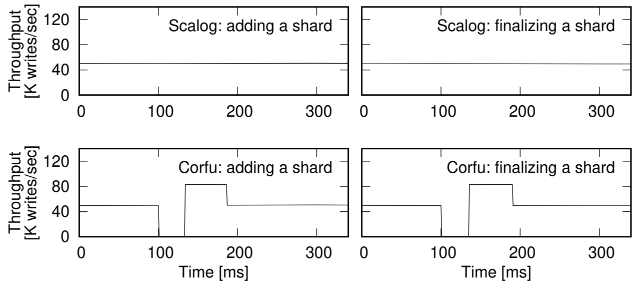

Figure 3: Throughput during reconfiguration

We run our experiments on 40 c220g1 servers in Cloudlab's Wisconsin datacenter. Each server has two Intel E5-2630 v3 8-core CPUs at 2.40GHz, 128GB ECC memory, a 480GB SSD, and a 10Gbps intra-datacenter network connection. Since exploring the limits of Scalog's write throughput requires many more than the 40 servers available to us, we resorted to simulation for results that report on larger configurations (specifically, those in Figure 5 in §6.3.2).

6.1 Reconfiguration

To evaluate how Scalog and Corfu perform when shards are added and finalized, we run both with six shards, each shard having two storage servers ($f=1$). We target 50K writes/sec, roughly half of the maximum throughput in this setting. We either add a shard or finalize a shard at $t=100$ms.

Figure 3 shows that Scalog's throughput is unaffected by adding or finalizing shards. When shards are added, clients can continue to use the original shards. Clients connected to shards are notified prior to finalization (we set the value of the configuration variable described in §4.4 to 10). During reconfiguration, throughput in Corfu ceases for roughly 30 ms because all storage servers must be notified before the new configuration can be used [21].

6.2 Failure Recovery

To evaluate how Scalog and Corfu perform under failure, we again deploy them with six shards, each with two storage servers, and use 50K writes/sec. To evaluate performance under aggregator failure, we add two aggregators to Scalog, each handling half of the shards. We measure throughput under four failure scenarios in Scalog: Paxos leader failure, Paxos follower failure, aggregator failure, and storage server failure, and under two failure scenarios in Corfu: sequencer failure and storage server failure. In each scenario, we intentionally kill one server at time $t=2$s and measure how throughput is affected. Figure 4 reports the results for the six failure scenarios:

Scalog's Paxos leader and Corfu's sequencer. Although records are temporarily unable to commit, Scalog's storage servers can continue receiving new records, which are com-

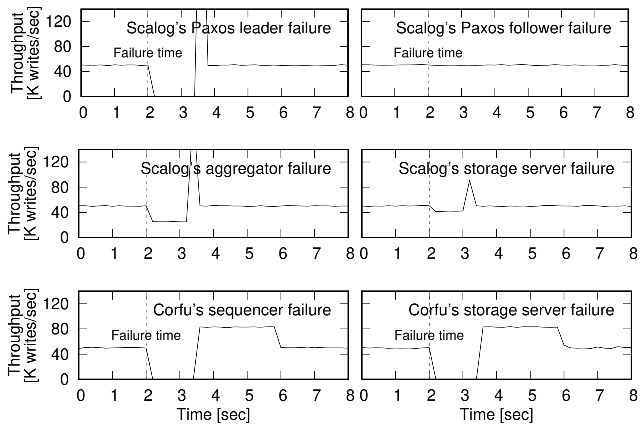

Figure 4: Throughput under different failure scenarios

mitted as soon as a new Paxos leader is elected. Hence, after a dip, throughput temporarily spikes to catch up, and total throughput is unaffected, although latency suffers until a new leader is elected. On the other hand, Corfu's clients compete for log positions when the sequencer is unavailable [21]. Heavy contention among clients causes Corfu's throughput to drop to nearly zero until a replacement sequencer joins [17]. Thereupon, Corfu runs at peak throughput until it catches up and stores all the delayed records; during this time, Corfu experiences higher latency.

Scalog's Paxos follower. No effect on throughput or latency.

Scalog's aggregator. Again, although the affected storage servers (in this case, half of all storage servers) are temporarily unable to commit new records, they can continue to receive them. Thus, the effects on throughput and latency are similar to those of a Paxos leader failure.

Scalog's and Corfu's storage servers. We compare Scalog's *Finalize & Add* with Corfu because they have the same trade-offs. In Scalog's *Finalize & Add*, the faulty server's shard is finalized. Throughput decreases temporarily until the failure is detected (relying, in our setting, on a one-second timeout) and all clients connected to the finalized shard are redirected to storage servers in other shards. Throughput is restored after slightly more than a second. In Corfu, the faulty storage server triggers a change in the mapping function; while this takes place, Corfu is unavailable [21]. Again, once the failure recovery completes, Corfu is saturated until all buffered records are stored.

6.3 Write Performance

We measure Scalog's write latency and throughput by running each client in a closed loop in which it sends a record and then awaits an acknowledgment. Latency measures the time difference between when a client sends the record and when it receives the acknowledgment. Throughput measures the number of write operations per second over all clients.

Corfu's peak throughput depends on the number of shards and the sequencer's throughput. Scalog's peak throughput depends on the number of shards and the configuration of the aggregators; in addition, it also depends on the length of the interleaving interval. By increasing the interleaving interval, Scalog can increase its throughput because a higher interleaving interval allows Scalog's ordering layer to manage larger numbers of shards and storage servers at the expense of higher latency. To compare fairly against Corfu, we run our evaluation with a fixed interleaving interval, set at 0.1ms to match Corfu's write latency. As we will see in §6.3.2, even with this short interval, Scalog already supports many more storage servers than we have resources to deploy.

6.3.1 System Configuration

In both systems, as the number of shards increases, ordering becomes a bottleneck. To properly configure each system to measure its peak throughput, we run microbenchmarks to determine, (1) the maximum throughput of a single shard (using $f+1$ storage servers) and (2) the maximum number of shards that their respective ordering layer can handle.

Throughput from one shard. A shard in Scalog peaks at 18.7K writes/sec; our implementation of Corfu, while outperforming previously reported figures for Corfu [21], reaches 13.9K writes/sec. The difference is due to how the two systems enforce total order at each storage server. In Scalog, where storage servers sequence records in the order in which they receive them, it is natural to write these records to disk sequentially. In contrast, records in Corfu are ordered by the sequencer, not by the storage servers. Records from different clients may reach storage servers out of order. Corfu storage servers first skip over missing records and later perform random writes to fix the log once those records are received.

The number of shards each system can support depends on the maximum load Scalog's aggregators can sustain and the maximum throughput of Corfu's sequencer.

Scalog's aggregators. We measure the number of shards and child aggregators that an aggregator can handle by having its neighboring servers (be they storage servers, the Paxos leader, or other aggregators) send synthetic messages. We find that each aggregator can handle either 24 storage servers (i.e., 12 shards in our $f=1$ setting) or 23 child aggregators, while the ordering layer can handle up to either 12 shards or 22 aggregators. We use these numbers to estimate the maximum number of shards that Scalog can support for a given number of aggregators.

Corfu's sequencer. We find that the sequencer of our Corfu implementation handles about 530K writes/sec, comparable to the optimized Corfu implementation used in Tango [22].

We want the throughput of both systems to scale linearly in the number of shards until ordering becomes the bottleneck. To avoid overloading the storage servers, we then configure each shard in Scalog and Corfu at 80% of their peak throughput, respectively, at 15.0K writes/sec and 11.1K writes/sec. To avoid overloading Scalog's Paxos leader and aggregators,

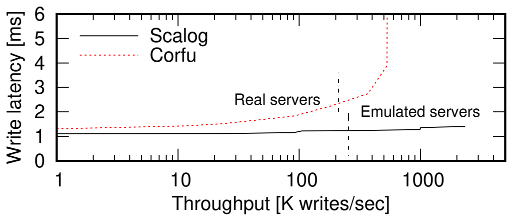

Figure 5: Latency vs throughput for Scalog and Corfu. The vertical dotted line separates results obtained with real servers from those obtained through emulation. For Scalog, we emulate storage servers, but not aggregators. Scalog's maximum throughput in this configuration is limited by the number of machines available to us.

we never assign to the ordering layer or to individual aggregators more than half of maximum load they can sustain (i.e., either six shards or 11 aggregators); if the load exceeds what the system's current configuration can handle under this policy, we add a new layer of aggregators. Thus, we configure these systems as follows:

Scalog. We add one shard for every 15.0K writes/sec of throughput. With up to six shards, we do not use aggregators. Between 7 and 66 shards, we use one layer of aggregation, with one aggregator for every six shards. With more than 66 shards, we use multiple layers of aggregators, where the ordering layer handles at most 11 aggregators, each aggregator handles at most 11 child aggregators, and each leaf aggregator handles at most six shards.

Corfu. We add one shard for every 11.1K writes/sec of throughput, until the sequencer becomes a bottleneck.

6.3.2 Write Scalability

We now proceed to determine how much load Scalog and Corfu can handle and, in particular, the throughput and latency that they achieve. Unfortunately, we only have access to 40 servers in CloudLab; in cases that require more servers, we emulate storage servers and their load. When communicating with the ordering layer, each (emulated) storage server reports to be receiving records at the same throughput and latency as a real storage server, though it is not receiving records from clients. This setup allows one physical machine to emulate hundreds of storage servers.

Let l_1 be the time elapsed at the client between submitting a record and learning that it is committed, and let l_2 be the time elapsed between submitting a report to the ordering layer and learning the corresponding cut. Both are measured using real storage servers. For our emulation, we use as latency the sum of (1) the time elapsed at the *emulated* storage server between submitting a report to the ordering layer and learning the corresponding cut and (2) $l_1 - l_2$.

Figure 5, which presents throughput/latency measurements as we increase the number of shards, shows that Scalog significantly outperforms Corfu's throughput while experiencing lower latency.

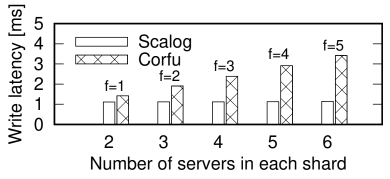

Figure 6: Write latency vs. shard size

Corfu's maximum throughput is limited by the sequencer at 530K writes/sec. Emulating only storage servers, but not aggregators, with our 40 machines, Scalog reaches 2.34M writes/sec, but is still far from being saturated. To explore the limits of the workload that can be handled by Scalog's ordering layer, we deployed Paxos with multiple layers of aggregators: we used physical servers for the Paxos replicas and the uppermost layer of aggregators, and emulated additional layers of aggregators as necessary against an emulated workload corresponding to a varying number of storage servers. We found that, before Paxos becomes a bottleneck, Scalog can handle up to 3,500 shards with three layers of aggregators, which translates to 52M writes/sec.[4] This throughput could be further increased by using a larger interleaving interval, trading latency for throughput.

Scalog's latency in Figure 5 grows slightly (by about 0.1 ms) whenever a new layer of aggregators is added, but remains lower than Corfu's. Based on our experiments with one and two layers of aggregators, we estimate the latency at 52M writes/sec to be around 1.6 ms (the client perceived latency is 1.3 ms when there are no aggregators, plus three layers of aggregators at about 0.1 ms per layer).

Corfu's latency is negatively impacted by two factors: first, Corfu replicates records across storage servers using client-driven chain replication [49] that writes to each server in sequence; second, since Corfu's clients may (and, in sufficiently long runs, likely will) write records to any storage server, the overhead paid by servers in managing client connections grows with the number of clients.

Finally, we investigate how write throughput and latency are affected by f, the number of failures that a shard tolerates. We find that throughput in both Scalog and Corfu is not significantly affected when varying f; thus, we focus our discussion on latency. Figure 6 shows that, for a single shard, client-perceived latency in Scalog is roughly constant, while in Corfu, latency increases linearly with f. The reason is, again, that Corfu replicates a record within a shard by writing sequentially to each of its storage servers, while Scalog allows a record to be replicated in parallel on multiple storage servers. Thus, as the number of storage servers in the shard increases to tolerate higher values of f, so does the latency gap between Scalog and Corfu.

[4]We use emulation to measure the maximum number of shards the ordering layer can handle. We are unable to assess other scaling issues (e.g., the network bottleneck), because we do not have access to a sufficiently large testing infrastructure.

6.4 Read Performance

Unlike writes, reads in Corfu and Scalog follow similar paths with identical performance. We therefore only focus on Scalog's read latency and throughput.

Using a single storage server s, we measure latency with a single client and measure throughput as a function of the number of clients. To evaluate the performance of sequential reads, we have a client call `subscribe`(l), where $l \leq l_{max}$, the maximum global sequence number the storage server has observed (see §4.2). We measure latency as the time between the `subscribe` call and the receipt of the first record; for throughput, we divide the number of records between $[l, l_{max}]$ in s by the time needed to receive them. To evaluate random reads, we have a client call `readRecord`(l,s) in a closed loop, where l is randomly generated such that $l \leq l_{max}$ and record l is stored in shard s.

Normally, the client library connects to all shards for `subscribe`(l) and chooses a random server in shard s for `readRecord`(l,s) (§4.2); instead, for these measurements we modified the client library so that it connects only to the storage server in s that is the focus of our evaluation.

When the client reads data that is still stored in the memory of the storage server, the throughput for both `subscribe` and `readRecord` is 280K records/sec (i.e., the limit of a storage server's network bandwidth) and the latency for both a `readRecord` request and for receiving the first record after a `subscribe` call is about 0.09 ms.

When the client reads data that is no longer in memory (as is often the case with finalized shards), latency and throughput are limited by the performance of storage server disks. With our hardware, `readRecord` achieves 4.5K records/sec throughput and 0.31 ms latency; as for `subscribe`, by reading sequentially and returning 256KB log chunks, it achieves 57K records/sec throughput with 1.21 ms latency to receive the first record; larger chunks improve throughput somewhat, but at the cost of significantly higher latency.

When a client reads from many storage servers concurrently (whether from one or multiple shards), throughput is limited by the client's network bandwidth, which is on average 280K records/sec in our evaluation.

6.5 Impact on Applications

We focus on the applications discussed in §5. Of these, the online marketplace uses Scalog to store user activities using `append` and reads the log using `subscribe`, so its performance is simply that of Scalog. The other two applications are more involved and deserve a more careful investigation.

6.5.1 Scalog-Store

We have implemented prototypes in golang using protocol buffers of both Scalog-Store and Corfu-Store based on our Scalog and Corfu implementations.

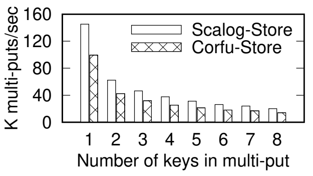

Figure 7: throughput of `multi-put` with 10 shards

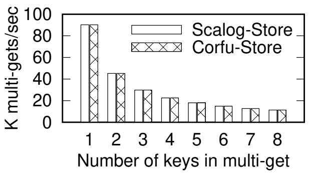

Figure 8: throughput of `multi-get` with 10 shards

In this experiment, both Scalog-Store and Corfu-Store run on 20 storage servers (10 shards). The keys are 64-bit integers, while values are 4088 bytes (creating 4KB records).

Figure 7 shows that Scalog-Store has higher `multi-put` throughput than Corfu-Store, because each storage server in Scalog has higher throughput (see §6.3.1). For both Scalog-Store and Corfu-Store, the throughput of `multi-put` operations is limited by the throughput of the log given the limited number of shards we have available. An exception is when Scalog-Store has 10 shards and one key in `multi-put`, when the bottleneck is the mapping server.

If we had many more shards but few keys in `multi-put` operations, then the mapping server would be the bottleneck for both Scalog-Store and Corfu-Store, and we would expect the `multi-put` throughput to be the same. However, if we increase the number of keys, we would expect Scalog-Store to eventually have higher throughput than Corfu-Store because the bottleneck will eventually shift to the log. This is because the throughput of the mapping server does not deteriorate much with the number of keys and the throughput that the log has to provide equals the number of keys times the throughput of the mapping server. For Corfu-Store, the shift happens when there are eight keys. Because Scalog provides superior throughput to Corfu, Scalog-Store can provide higher `multi-put` throughput when the number of keys is larger than eight.

To summarize, Scalog-Store achieves higher per-shard write throughput than Corfu-Store, because Scalog-Store uses fewer shards to achieve the same total throughput. When there are eight or more keys in each `multi-put` operation, Corfu reaches its maximum throughput and becomes a bottleneck while Scalog does not.

For both Scalog-Store and Corfu-Store, the throughput of `multi-get` operations (Figure 8) is limited by random read throughput of storage servers.

6.5.2 vScalog

Starting respectively from our Scalog and Corfu implementations, we prototyped vScalog and vCorfu in golang, using protocol buffers. We implemented each object as a key-value pair and ran each system as a key-value store.

We first measure the maximum write throughput of a single materialized stream, since it limits the maximum update rate of a single object. Our evaluation shows that one materialized stream of vScalog and vCorfu achieves 18.6K writes/sec and 13.6K writes/sec, respectively, which are roughly the same as the respective single shard throughputs of Scalog and Corfu shown in §6.3.1. The client perceived latencies for vScalog and vCorfu are 1.2ms and 1.5ms, respectively; vCorfu is slower because it writes to disks sequentially while vScalog writes to disks in parallel.

Next we measure the total throughput of vScalog and vCorfu. Our experiments show that, using the same number of shards, vScalog has roughly the same throughput as Scalog. Using the same number of stream replicas in vCorfu as the number of shards in Corfu, and given enough log replicas, vCorfu and Corfu also achieve approximately the same throughput. However, the single shard throughput of vCorfu's underlying shared log reduces to 9.3K writes/sec (due to the cost of writing a commit bit, matching the 40% penalty reported in [51]).

7 Limitations

Scalog's current prototype suffers from several limitations. Some seem to be relatively easy to address: for example, while Scalog allows applications to dynamically add and finalize shards, it does not provide automated policies to trigger such actions. Other limitations are common to storage systems that operate at large scale: as server failures become frequent, the steps needed for recovery may complicate the scheduling and allocation of resources. Others yet, however, appear to be more fundamental to Scalog's design. In particular, although Scalog offers unprecedented throughput at latency comparable to, or better than, prior shared log implementations, it is not well suited for applications that require ultra-low latency (such as high-speed trading), highly-predictable latency and throughput, or low tail latencies. The question of whether it is possible to drastically reduce latency while maintaining Scalog's throughput and ordering properties remains open. Finally, some issues are outside of Scalog's current scope: in particular, Scalog's design does not address security concerns.

8 Related Work

The shared log abstraction is, implicitly or explicitly, at the core of state machine replication protocols [46], and Scalog draws inspiration from several of them.

In Vertical Paxos [39], configurations can change from slot to slot, allowing for seamless reconfiguration similar to Scalog. Like Scalog, EPaxos [43] allows all replicas to accept client requests. However, EPaxos only builds a *partial* order consistent with specified dependencies among records; in addition, maintaining and checking dependencies creates a bottleneck. In networks that almost never reorder messages, NOPaxos [40] achieves very high throughput and low latency using a custom hardware switch to order records.

Mencius [42] and Derecho [23] partition log slots among multiple leaders. Essentially, each process creates a locally ordered log, which is then interleaved in round-robin order. Similarly, Calvin [48] dispatches to multiple sequencers transaction requests, which are compiled into batches. The batches are then interleaved in round-robin order to build a total order. Scalog generalizes this idea and allows for more flexibility in how the logs are interleaved, which is not sensitive to slow servers.

Kafka [36], a widely-used shared log system, uses sharding to scale and provides total order within each shard, but not across them. Pravega [15] provides a sharded log similar to Kafka and focuses on a rich set of reconfiguration operations that support scaling. FuzzyLog [41] builds a partially ordered log by tracking Lamport's happened-before relation [37] between records stored in different shards. DistributedLog [6] also supports sharding and provides a totally ordered log, but its single-writer-multiple-reader access model is not conducive to high write throughput.

To provide both total order and high throughput, it is necessary to separate ordering from data dissemination. Like Scalog, Corfu [21] separates ordering from data dissemination and relies on sharding. A function, maintained in ZooKeeper [33], maps sequence numbers to shards. A client first obtains a sequence number for a record from the Corfu sequencer, and forwards the record to the shard indicated by the mapping function. Each shard comprises a collection of replicas, each consisting of a *flash unit* (an SSD plus FPGA to implement a write-once block device), kept consistent using a variant of chain replication [49].

LogDevice [12] is similar to Corfu, but replaces the mapping function with a non-deterministic record placement strategy. By allowing clients to write to any shard, LogDevice achieves flexible data placement. However, all records still need to be ordered by a sequencer similar to DistributedLog's single writer [6], limiting throughput.

9 Conclusion

Inspired by crash-resistant storage systems, Scalog departs from previous implementations of the totally ordered shared log abstraction by making records persistent before determining their positions in the log. This simple but essential change of perspective lets Scalog scale out elastically and recover from failures quickly; allows applications to customize which storage servers should hold their records; and enables a new ordering protocol that, by interleaving the local orders built by each storage server as a side product of replicating records, achieves almost two order of magnitude higher throughput than the state-of-art shared log implementation.

Frequency Configuration for Low-Power Wide-Area Networks in a Heartbeat

Abstract

Low-power Wide-Area Networks (LP-WANs) are seen as a leading candidate to network the Internet-of-Things at city-scale. Yet, the battery life and performance of LP-WAN devices varies greatly based on their operating frequency. In multipath-rich urban environments, received signal power varies rapidly with a low-power transmitter's frequency, impacting its transmission time, data rate and battery life. However, the low bandwidth of LP-WANs means that there are hundreds of operating frequencies to choose from. Among them, we show how choosing a select few of these frequencies($\leq$3.55%) effectively triples the battery life when compared to the rest for LP-WAN devices.

This paper presents Chime, a system enabling LP-WAN base stations to identify an optimal frequency of operation after the client sends one packet at one frequency. Chime achieves this by analyzing the wireless channels of this packet across many base stations to disentangle multipath and ascertain an optimal frequency that maximizes client battery life and minimizes interference. We implement Chime on a campus-scale test-bed and achieve a median gain of 3.4 dB in SINR leading to a median increase in battery life of 230% ($\sim$1.4-5.7 years), data rate by 3.3$\times$ and reduction in interference of 2.8$\times$ over commodity LP-WANs.

1 Introduction

Recent years have seen the emergence of Low-Power Wide-Area Networks (LP-WANs) as a promising technology to connect the Internet of Things. LP-WAN technologies (like LoRaWAN [2], SIGFOX [61], 3GPP's NB-IoT [35], LTE-M [5]) allow devices to send data at low data rate (few kbps) to base stations several miles away powered by batteries with targeted lifetimes of 5-10 years. However, recent studies [17, 19, 28] show a contrasting reality in dense urban deployments where LP-WAN clients deep inside buildings experience significantly lower battery lives ($\sim$1-2 yrs) owing to heavy signal attenuation. They further show that over 97% of the energy consumption in an LP-WAN client can be directly attributed to its radio front-end.

While many parameters influence the battery-drain from a client's radio front-end, the main parameter that it can control is its operating frequency. With the opening up of the TV whitespaces, narrowband LP-WAN clients have several hundreds of operating frequencies to choose from [16]. While there is rich work on spectrum sensing, particularly to avoid interference, in Wi-Fi [24] and LTE [38], LP-WANs differ in an important way: base stations span asymmetrically higher bandwidth compared to clients. This means that base stations can directly monitor multiple frequency bands and advise clients on frequencies with minimal interference. Yet, base stations are unaware of the precise signal power at which an LP-WAN client's signal will be received across frequencies. Our extensive experiments (Sec. 3) over a wide-area campus testbed show a promising opportunity in this respect: We show how, when set to a select few frequencies ($\leq$ 3.55% of all available frequencies), signals from an LP-WAN client are received at much higher signal power ($\sim$3-4 dB) at base stations. This increases client data-rate ($\sim$2-8 $\times$) and reduces their transmission time, effectively tripling their battery life[1] relative to the median frequency. Unfortunately, finding these optimal frequencies is challenging because they correlate poorly by interpolating measurements along space, time or frequency of operation. Further, simply sifting through even a few frequencies (e.g. as with Wi-Fi [11]) in the hope of finding the optimal ones would itself drain the battery inordinately.

This paper presents Chime, a solution that explores the feasibility of offloading the LP-WAN client frequency configuration problem to the more well-equipped LP-WAN base stations. Chime considers static clients (e.g. sensors) in urban environments whose multipath characteristics, while complex, change relatively slowly over time. Chime uses the fact that while a single base station cannot ascertain the complex multipath, multiple spatially-distributed LP-WAN base stations

[1]Battery Life estimates derived from prior energy models (see Sec.3)

can collaboratively identify an optimal operating frequency for a client based on a single association packet it transmits when it wakes up, regardless of its initial operating frequency. Such an association packet is a standard feature of many LP-WAN protocols [51] posing minimal power overhead for the LP-WAN client. Chime achieves this by building a novel system that uses the wireless channel-state information of this packet at one frequency received across multiple base stations to disentangle the multipath and predict the long-term battery drain for the different operating frequencies. Further, Chime also predicts the extent of unwanted interference the client produces at base stations across different frequencies. Thus, Chime passively infers an optimal client operating frequency, without prior calibration of the environment or known client location.

Chime exploits the recent trend of massive and unplanned deployment of LP-WAN base stations [32]. For instance, LoRaWAN base stations are proposed to be deployed in Comcast MachineQ set-top boxes [32, 36], meaning that many LP-WAN base stations will likely be single-antenna and often deployed indoors. Chime proposes a novel algorithm (see Sec. 5) to synchronize these multiple single or multi-antenna LP-WAN base stations to emulate a large city-scale distributed antenna array. In particular, Chime builds on past work in the cellular context (e.g. R2-F2 [50]) that separates signal paths using multi-antenna arrays while dealing with new challenges pertaining to distributed, irregular arrays of antennas and low-power user devices. Chime first models the received signals from a client across synchronized base stations to disentangle the different paths that the signals may traverse as they reflect off different objects. These signals combine to reinforce or cancel each other leading to varying signal power across the operating frequencies of the client. Chime then estimates how these separated signal components recombine at different client frequencies to find the one maximizing battery-life and throughput, while minimizing interference.

A key challenge in estimating the multipath in urban environments is receiving time-synchronized phase measurements across multiple LP-WAN base stations to emulate a distributed MIMO array. While recent work has successfully demonstrated distributed MIMO for WiFi [22] and cellular networks [40], LP-WAN packets last over $10\times$ longer and therefore require much more accurate and long-lasting phase synchronization. Further, low-power devices experience large hardware imperfections meaning that the phase of the wireless channel varies drastically even within one packet. Hence, any phase measurements made over time across base stations would simply appear unsynchronized and random. Chime overcomes this challenge by never measuring the phase of a low-power client in isolation, instead always measuring it relative to a high-power master base station whose signal propagation characteristics we know *a priori*. We design this master base station's signal so that it can be measured at exactly the same time and frequency as the low-power client, without significantly interfering with it. Sec. 5 describes this novel algorithm that directly compensates for phase drifts over time of the low-power client relative to a reference signal due to hardware imperfections.

Next, Chime must use the synchronized phase measurements of a client's association packet to infer how the signal propagates through environment. However, inferring all paths of the signals using measurements from a few single-antenna base stations [53] that are geographically separated is challenging. Chime exploits the fact that though wireless signals in urban wide-area networks traverse diverse paths to base stations at different locations, they often share a very small number of common large reflectors (e.g. buildings, trees, big vehicles, etc.). Our approach aims to discover these dominant reflectors in the environment using the small number of wireless channel measurements and model the signal propagation (Sec. 6), while accounting for variations in the size, shape and orientation of these reflectors. Chime recombines signals in these dominant paths across frequencies to accurately predict an optimal frequency of operation for improved throughput and lower interference (Sec. 7).

Limitations and Scope: We emphasize that Chime: (1) Considers static LP-WAN clients (e.g. sensors, metering devices); (2) Models macroscopic environmental changes but neglects fleeting reflectors (trade-offs discussed in Sec. 6.2) (3) Assumes LP-WAN clients send an association packet to base station upon waking up. Yet, Chime remains broadly applicable to most sensor networking deployments.

Evaluation and Results: We deploy Chime using LoRa as the low power technology and Semtech SX1276 chips as the client RF transceivers. Our base-stations are USRP N210s deployed on six buildings in a 0.7 km $\times$ 0.5 km area surrounding a university campus. Our results show that:

- Chime provides a net increase in battery-life of 1.4-5.7 years (230%) achieving at an average 79% of the optimum.
- Chime can increase network throughput by $3.3\times$ compared to commodity LoRa.
- Chime can reduce interference from LP-WAN clients at base stations by 2.1 dB, by predicting the weakest frequency.

Contributions: Our specific contributions include:

- A wide-area motivation study that demonstrates the inability of spectral, temporal and spatial interpolation for identifying an optimal operating frequency of an LP-WAN client.
- A novel solution for collaboratively identifying an optimal operating frequency of an LP-WAN client at the base stations using only one transmitted packet from the client.
- A system that demonstrates significant increase in battery life and throughput by identifying an optimal frequency of operation for LP-WAN radios while accounting for multipath, interference and noise.
- A wide-area deployment across a university campus showing 1.4-5.7 years of increased battery-life for LP-WAN clients.

2 Related Work

Related work can be broadly categorized as follows:

Low-Power Wide-Area Networks: Recent years have witnessed much interest in LP-WANs on both cellular (LTE-M [5] and NB-IoT [35]) and unlicensed spectrum (Semtech's LoRa [2,27,44] and SigFox [39,61]), with some proposals extending to the TV whitespaces [20]. Recent work on LP-WAN has explored interference management [19,23], developing battery-free solutions [30,45] and system deployments on the whitespaces [48] to name a few. Chime complements this past work by considering rapid frequency configuration, a problem crucial for tackling with rapidly changing channel quality in urban spaces and improving battery-life.

Spectrum sensing: Cognitive radio and spectrum sensing solutions are primarily aimed at identifying vacant frequency bands to minimize interference with other users [56]. Many of these solutions rely on long-term statistics of channel occupancy and signal power using temporal [9,15,29,60] and spatial correlation [12,14,46,59] to make predictions. More recent work attempts to minimize feedback by relying on sparse recovery techniques such as compressed sensing [34,43,55] or eigen-value based methods [8,57].

For LP-WANs, channel occupancy, interference and noise can be directly inferred by the base stations because they span much larger bandwidth [10] compared to clients. Further, past work on spectrum sensing does not focus on predicting received signal power at the base station from a client across frequencies. This is precisely Chime's goal based on measurements at one frequency from a single client radio.

Optimal radio configuration: Perhaps the solutions most closely related to this paper are systems in the Wi-Fi [41] and cellular context [50]. CSpy [41] exploits the properties of OFDM wide-band transmissions from Wi-Fi client on one Wi-Fi frequency band to accurately model wireless channels at other Wi-Fi frequency bands. R2-F2 [50] predicts both channel magnitude and phase of LTE cellular signals based on measurements in one frequency, exploiting the properties of OFDM and large multi-antenna base stations.

In contrast the LP-WAN context brings three unique challenges to the problem of finding an optimal operating frequency. First, there are too many frequencies to choose from across whitespaces ($\sim$800MHz of bandwidth). For example, just running through all of them will consume about 6% of the client's battery life[2]. Second, these radio configurations demonstrate extremely poor correlation across frequency, time and space, ruling out statistical techniques to estimate the optimal frequency of operation (see large-scale study in Sec. 3). Finally, the vast majority of LP-WAN base stations are single-antenna [36] and often deployed indoors, ruling out past work that exploits bulky and expensive multi-antenna array infrastructure [7,50]. Indeed, while Chime builds on R2-F2 [50], analyzing multipath across distributed single-antenna base stations for frequency configuration in the LP-WAN context is its key contribution.

3 Motivation - Empirical Study

To motivate the battery-saving opportunities in finding an optimal frequency configuration and the core-challenges in finding it, we present our findings from a detailed empirical study. We focus on a simple question: "Can an optimal frequency of operation of an LP-WAN client be found by exploiting prior measurements made over time, frequency or space?". We deploy 20 LoRaWAN clients at multiple locations periodically sending packets across a month iterating over 160 frequency configurations in an outdoor campus-scale testbed (see Sec. 9 for a detailed description of our testbed). Each client was static and placed in a weather-proof case in indoor and outdoor locations with signal power measured from a single base station. While we do not consider mobile clients, we consider varying outdoor environments over time to measure channel quality and estimated battery life for each frequency.

Estimating battery life: Prior studies have shown that the RF front-end is responsible for most of the battery consumption of a LoRaWAN device [17]. We use these prior LoRaWAN battery models [17] to estimate the energy consumed per packet at different datarates. We then use operational characteristics for the Semtech SX1276 transceiver [4] to map the signal-to-interference plus noise ratio (SINR) to the appropriate datarates. They show that improving signal strength from a LoRaWAN client can reduce the transmission time, thus increasing battery-life. The reason the battery life increases so much with a few dB improvement in SINR is that, unlike WiFi, every better data rate in LP-WANs halves the packet transmission time [4]. Thus, across the SINR thresholds of these data rates, your client battery life doubles, quadruples and so on. Our results show high variation in the RSSI of a LoRa client at base stations across time, frequency and space.

Correlation across time: Upon investigating the data across clients to the base station, we discover that most frequencies change in signal strength even across a few minutes (Fig. 2). Our results (Fig. 3) show that using historical measurements over different time spans on a set of frequencies to predict the optimal one (via polynomial interpolation) achieves 38.27% of the optimum at best. Our detailed study of urban multipath in Sec. 10.2 shows that this stems from gradual aggregate change in reflectors in the environment at these timescales.

Correlation across Frequency: Our results reveal that the optimal frequency-of-operation is extremely difficult to stumble upon with a random guess or even predict using a modest amount of frequency hopping. As shown in Fig. 1, 50% of all operating frequencies provide just 27.58% of optimum battery life while 90% of them still provide only 67.09% of the optimum. Indeed, only 1.58% of the operating frequencies are

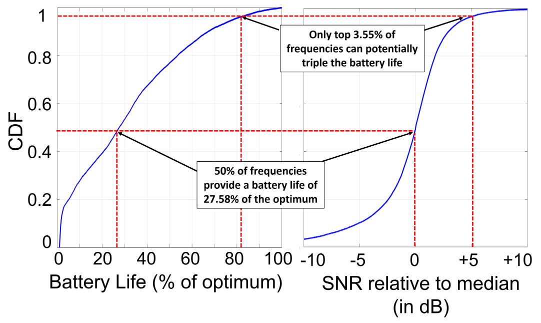

Figure 1: **Percentile of battery life**: few frequencies have good SINRs providing battery lives close to the optimum

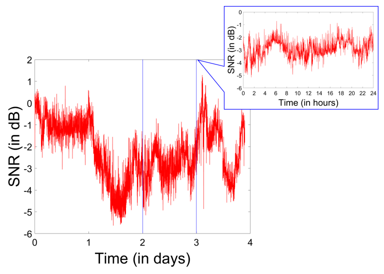

Figure 2: **Channel Variance**: Channel quality varies dynamically across days and even minutes

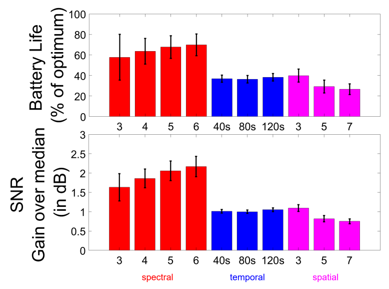

Figure 3: **Interpolation**: percentile of battery life of the optimum frequency from interpolation

at 90% of the optimum while only 3.55% triple the median battery life. Further, sampling several frequencies in hope of finding the top 3.55% would itself incur battery-drain, zeroing out the benefits. We observe that even adjacent transmission frequencies perceive a difference of about 20 dB of signal strength which, in outdoor environments, is enough to make a LoRa device undetectable. We further evaluate whether polynomial interpolation from sampling a limited number of frequencies sufficiently improves battery life and observe (Fig. 3) that it achieves at best 70.07% of the optimum.

Correlation across Space: We evaluate whether measurements from neighboring clients can be leveraged to find an optimal frequency of operation for a client. We consider various number of clients placed in a linear array spaced at 15 cm and predict an optimal frequency of the client in the middle via polynomial interpolation. As shown in Fig. 3, this achieves at best 39.90% of the optimum battery life.

4 Overview of Chime

This section provides an overview of Chime's approach and challenges. Chime's primary goal is to accurately measure an optimal operating frequency for an LP-WAN client by making it transmit only one packet on one frequency band. It primarily aims to predict the received signal power of the client across all frequencies at base stations. Since base stations span a wide bandwidth, they can readily measure channel occupancy and noise levels across frequencies, leaving received signal power from a client as the primary unknown.

Chime's system architecture is designed as follows: Upon waking up and for signal association, each LP-WAN device transmits a beacon packet on its arbitrarily chosen initial frequency of operation (a standard feature of common LP-WAN protocols). Chime then processes the received signals from this packet across the base stations at the cloud via a wired backhaul to infer an optimal frequency of operation. Note that since the powered base stations and the cloud perform all computation, this does not impact client battery life. The nearest base station then reports the estimated frequency to the client in its acknowledgment of the beacon.

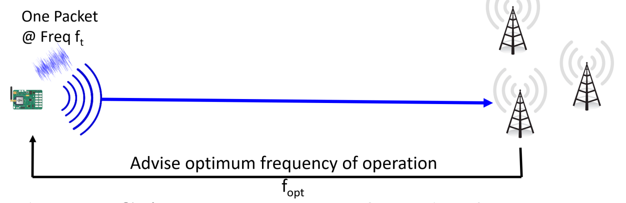

Figure 4: **Chime**: Frequency configuration for LP-WANs

Assumptions: While Chime does not consider mobile clients, we do consider dynamic outdoor environments. While Chime does not model fleeting reflectors in environment, it models long-term changes in multipath as it re-analyzes the current multipath based on transmissions from the client beacon and the master base station.

The rest of this paper describes three challenges in achieving the above design: (1) ***Synchronizing Distributed Base Stations:*** Chime first develops a synchronization system that allows multiple base stations to coordinate. In doing so, it eliminates the time-varying and long-lasting phase errors due to hardware impediments, such as frequency, timing and phase offsets of low-cost and low-power wireless hardware (see Sec. 5). (2) ***Disentangling Signal Paths:*** Next, Chime analyzes the root cause of why signal power from the client would vary across frequencies in the first place – wireless multipath. Specifically, signals from the client traverse multiple paths as they reflect off buildings, trees and other objects before reaching the base stations. Signals along these paths can reinforce each other or cancel each other, depending on the frequency of operation. At the cloud, Chime combines measurements from the distributed array of base stations to decouple the different paths the signal traversed from the client, even if the geometry of these base stations is arbitrary and the environment is multipath-rich (see Sec. 6). (3) ***Estimating Optimal Frequency:*** Chime then recombines the signal components at all possible operating frequencies to determine their expected signal power across base stations. Chime can then use this information, along with the known interference and ambient noise at these frequencies perceived at base stations to determine the best frequency-of-operation (see Sec. 7).

5 Synchronizing Base Stations

In this section, we describe our approach to synchronize transmissions from the LP-WAN client between spatially distributed base stations. Recall that Chime relies on synchronized phase measured across different base stations from a single client device to extract signal multipath. However, these phase measurements experience time-varying errors owing to the hardware imperfections of LP-WAN radios. Four distinct hardware impediments contribute to these phase errors: (1) Carrier Frequency offset (CFO): occurs due to subtle differences between the carrier frequency that any two radios operate on; (2) Sampling Frequency offset (SFO): occurs due to small differences between the sampling rate of the two radios; (3) Detection Delay: is produced because the packet from the client is detected with different delays across base stations; (4) Phase Lock Loop (PLL): produces an arbitrary constant phase offset at each base station's received signal, every time it tunes to a frequency. Chime's synchronization algorithm seeks to process these wireless channels across base stations to eliminate these phase errors.

Let the measured channel between the client and the base station be denoted by $\tilde{h}_{C\to B_1}$ whose phase is $\tilde{\theta}_{C\to B_1}$. Mathematically, we can write the phase of the measured wireless channel $\tilde{\theta}_{C\to B_1}$ at time t as a function of the phase of the true channel $\theta_{C\to B_1}$ between them, as well as various phase errors. Let us define the following hardware impediments: (1) Carrier Frequency Offset (CFO): $f_C - f_{B_1}$ as the difference in carrier frequency between the client and base station. (2) Detection Delay and Sampling Frequency Offset (SFO): $t_C - t_{B_1}$ denote the effective offset in time owing to detection delay at the base station and sampling frequency offset. (3) Phase offset from the PLL: $\phi_C - \phi_{B_1}$ the phase error owing to the PLL of the client and base station locking to different values each time these radios start receiving at a center frequency. The phase of the channel at time t is:

$$\begin{aligned}\tilde{\theta}_{C\to B_1} = \theta_{C\to B_1} - (2\pi(f_C - f_{B_1})t \\ + 2\pi f_C(t_C - t_{B_1}) + (\phi_C - \phi_{B_1}))\end{aligned} \tag{1}$$

The rest of this section describes our approach to eliminate each of the above errors across base stations.

5.1 Eliminating Phase Errors

To eliminate phase errors in Eqn. 1, Chime leverages multiple base stations. Specifically, we recall that a client's transmission at time t can be recorded by multiple base stations, which can measure the corresponding wireless channels. Chime eliminates hardware impediments by exploiting the common phase shifts they induce to these channels.

Mathematically, Chime estimates the wireless channel at a second base station B_2 from the same client at the same time t. This wireless channel is written as:

$$\begin{aligned}\tilde{\theta}_{C\to B_2} = \theta_{C\to B_2} - (2\pi(f_C - f_{B_2})t \\ + 2\pi f(t_C - t_{B_2}) + (\phi_C - \phi_{B_2}))\end{aligned} \tag{2}$$

By subtracting Eqn. 1 and Eqn. 2 above, we get:

$$\begin{aligned}\tilde{\theta}_{C\to B_2} - \tilde{\theta}_{C\to B_1} = \theta_{C\to B_2} - \theta_{C\to B_1} \\ +2\pi(f_{B_2} - f_{B_1})t + 2\pi f(t_{B_2} - t_{B_1}) + (\phi_{B_2} - \phi_{B_1})\end{aligned} \tag{3}$$

Note that the above difference in phases is independent of hardware impediments owing to the client, i.e. its center frequency f_C, time-delay t_C or initial phase ϕ_C. However, as it is dependent on the impediments of the two base stations, Chime still needs to estimate the phase errors due to hardware differences between pairs of spatially distributed base stations.

To estimate these phase differences, Chime relies on a master base station (B_M, one of the base stations) at a known location. The master sends a signal at the same time t and frequency f_C as the client (we address the challenges in achieving this without causing collisions in Sec. 5.2). We then measure the difference in phase at the two base stations of the channel from the master base station:

$$\begin{aligned}\tilde{\theta}_{B_M\to B_2} - \tilde{\theta}_{B_M\to B_1} = \theta_{B_M\to B_2} - \theta_{B_M\to B_1} \\ +2\pi(f_{B_2} - f_{B_1})t + 2\pi f(t_{B_2} - t_{B_1}) + (\phi_{B_2} - \phi_{B_1})\end{aligned} \tag{4}$$

Notice that Eqn. 3 and Eqn. 4 have the same effect of hardware impediments on their right-hand side. By subtracting these two phase values, we obtain a quantity independent of hardware offsets:

$$\begin{aligned}\tilde{\theta}_{C\to B_2} - \tilde{\theta}_{C\to B_1} - \tilde{\theta}_{B_M\to B_2} + \tilde{\theta}_{B_M\to B_1} \\ = \theta_{C\to B_2} - \theta_{C\to B_1} - \theta_{B_M\to B_2} + \theta_{B_M\to B_1}\end{aligned} \tag{5}$$

The above quantity is independent of hardware offsets of the client and base stations and therefore directly captures the multiple signal paths along which the signal traverses. Assuming the channel between master base station and other base stations can be computed (described in Sec. 5.2) at the same time and frequency as the client, the term $\theta_{B_M\to B_1} - \theta_{B_M\to B_2}$ can be compensated for. Chime therefore estimates the following product of channels h_{12}^{conj} – a complex number we call the *offset-free channel* whose phase value is exactly $\theta_{C\to B_2} - \theta_{C\to B_1}$ – a function purely of the client and base stations (note: $(.)^*$ is the complex conjugate).

$$h_{12}^{\text{conj}} = \frac{\tilde{h}_{C\to B_2}(\tilde{h}_{C\to B_1})^* \tilde{h}_{B_M\to B_1} h_{B_M\to B_2}}{\tilde{h}_{B_M\to B_2} h_{B_M\to B_1}} \tag{6}$$

Chime can then use this offset-free channel, which is free of all time-varying phase offsets, to disentangle signal paths from the client, without being impacted by hardware impediments (Sec. 6). Note that while the phase of a single offset-free channel is ambiguous due wrapping of phase over 2π, we combine the information across multiple such channels to estimate the multipath. This approach resembles that of many phase-based localization systems [26, 49, 54].

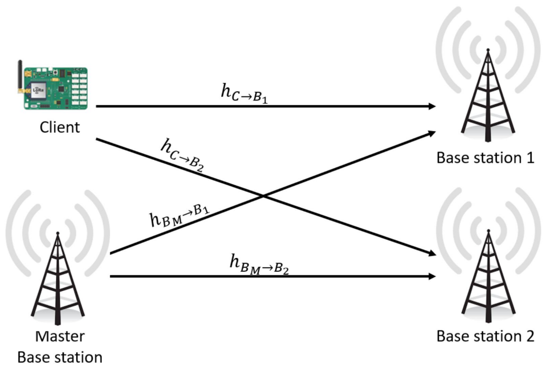

Figure 5: **Wireless channels** between client and base stations

5.2 Removing offsets between base stations

To obtain offset-free channels as in Eqn. 6 above, the base stations need to measure channels from the master base station at the same time and frequency as the client that is being tracked . However, doing so would result in collision between the master base station packet and client packet, causing neither of their packets to be decoded. As a result, one needs to carefully design transmissions of master base station to avoid collision with the client transmissions.

A naive approach would be to transmit the master's signal a short time interval prior to every client's transmission. By picking an extremely short interval between the reference and client, one can neglect the additional phase drift that may accumulate. While this approach is commonly used in distributed MIMO in Wi-Fi [33] and cellular [42], it does not apply to LP-WANs. This is because LP-WAN packets span hundreds of milliseconds [2, 13, 21]. Such long packets cause phase measurements to drift significantly within a packet rendering *a priori* synchronization futile. Thus, Chime needs a mechanism to estimate phase measurements at the same exact time and frequency from both reference and client by analyzing their packets transmitted concurrently.

Chime circumvents this challenge by designating one of the base stations to transmit a concurrent signal on an adjacent frequency band relative to the client. This **master base station** transmits its signal at the same time as the client, sending a known sequence in parallel with its transmission. The base stations can thus estimate the wireless channels of both the master and client transmissions at the same time, albeit across adjacent frequency bands. Chime then extrapolates the wireless channels of both the master and client to estimate its phase value at the guard band between them. While prior works [42, 58] have used beacon-based synchronization mechanisms, Chime uses piece-wise cubic spline extrapolation of both the magnitude and phase of the wireless channels across these bands for the master base station and client to estimate the magnitude and phase at the guard band in-between. Given that these estimates occur at the same time and frequency (i.e. the guard band) across both the master and client, we can now use them in Eqn. 6 to accurately synchronize base stations and eliminate the effect of hardware imperfections.

When does the master base station transmit? To facilitate the master base station to decode the preamble and transmit simultaneously on an adjacent channel, Chime ensures that the association packet's preamble is sufficiently long to accommodate this. An alternative option in the cellular context (e.g. NB-IoT) is to allocate dedicated spectrum for the base station alongside the client's association packet.

Why does interpolation work? Interpolation across frequency to estimate the channel seems to have inherent contradiction with our motivation results in Section 3. However, it is a well known fact that outdoor channels, have a coherence bandwidth of about 250-500 KHz. Thus, while the channel demonstrates frequency-selective fading over large bandwidths, the narrowband channel over 125 KHz is relatively flat [37]. Thus, interpolation of client and master base station channel will give a reasonable estimate of their channel at the guard band. Note that since the base stations are high powered agents, they can indeed transmit constantly and will have significantly larger transmit power than the clients. Thus, with a dense enough deployment of base stations (expected for LP-WANs [3, 6, 36]), the signal of the master base station will be received at other base stations.

6 Separating Signal Paths

Given the wireless offset-free channels of the form h_{jk}^{conj} from a client to a base station pair (j,k), we next seek to separate the set of signal paths that signals traverse from the clients to the n base stations. The key challenge in doing so is to decouple the large number of signal paths using channel measurements from a small number of base stations. Fortunately, our results in Sec. 10 as well as extensive past literature [50] in outdoor urban wireless networks demonstrate that wireless channels tend to have small number of dominant paths. As a result, Chime exploits this sparsity to identify the dominant signal paths using only a small number of available base stations. While there have been solutions proposed for WiFi [41] and cellular networks [50], these techniques either model certain behavior of signals in indoor environment or require heavy infrastructure such as an array of antennas unavailable at the base station. Furthermore, LP-WAN base stations are arranged irregularly, making it challenging to employ traditional antenna array algorithms.

6.1 Irregular Distributed Arrays

Chime separates multiple signal paths by actively modeling wireless signal characteristics of a distributed array of base stations with an irregular, but known geometry. To do so, Chime uses a maximum-likelihood [18] approach to identify the best propagation characteristics that fit the observed channels. In particular, given that only a small number of signal

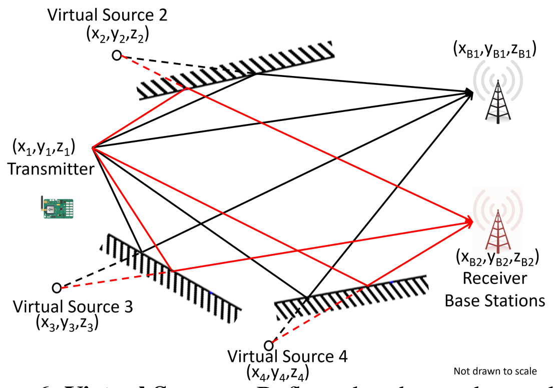

Figure 6: **Virtual Sources:** Reflected paths can be modeled as virtual sources that are mirror images of the transmitter

paths dominate (Sec. 10.2), Chime iterates over a set of m virtual source coordinates (x_p, y_p, z_p) for $p = 1, \dots, m$, which denote candidate locations for the client as well as one virtual source for each dominant path from a reflecting surface. As shown in Fig. 6, these virtual sources are simply the mirror image of the source about any reflecting surface. One can then compute the distances from these virtual sources to each base station (whose coordinates are known) to compute the total path length experienced by each reflected signal component. Chime then uses this information to compute the optimal attenuations and phase-shifts for each signal path that fit the observed channels and the given geometry of virtual sources. It then identifies and outputs the set of virtual sources, attenuations and phase shifts that best-fit the observed channels. Key to Chime's algorithm is an approach that both carefully chooses the number of paths m and efficiently searches over the space of virtual source coordinates.

Problem Formulation: Mathematically, Chime's algorithm begins by iterating over a set of candidate locations for the virtual sources corresponding to a client. For ease of exposition, we make two simplifying assumptions which we will relax later in this section: (1) Dominant reflectors are large, therefore shared by all base stations; (2) Dominant reflectors are planar and infinite. We further only consider single-bounce reflectors and assume multi-bounce reflected paths can be broken down into equivalent single-bounce reflectors. Let us assume for the moment that there are m such sources with known coordinates: (x_p, y_p, z_p) for $p = 1, \dots, m$. Let us denote $\mathcal{B}_q$ to be the coordinates of the n base stations. Consider a signal along path p traversing a distance of $d_{pj} = ||(x_p, y_p, z_p) - \mathcal{B}_j||$ to base station j from its virtual source (x_p, y_p, z_p). Then the phase of the channel from this source is of the form $-2\pi\frac{d_{pj}}{\lambda}$ and magnitude $\frac{1}{d_{pj}}$, where λ is the signal wavelength [47]. Let h_{jk}^{conj} denote the offset-free channels (see Sec. 5) received by each pair of base stations (i, j). Recall that h_{jk}^{conj} contains the product of channels to two base stations $h_{C\to B_j} h^*_{C\to B_k}$ so the phases of each pair of signal paths subtract and their magnitudes multiply. Hence, h_{jk}^{conj} is a weighted sum of complex numbers whose phase is of the form $-2\pi\frac{d_{pj}-d_{qk}}{\lambda}$ and magnitude is of the form $\frac{1}{d_{pj}d_{qk}}$, whose weights are unknown.

At this point, we formulate the following minimization problem that attempts to find the complex weights, $\alpha_{p,q}$, based on how well they fit the observed channels:

$$\min_{\{\alpha_{p,q}\}} \varepsilon$$

$$\left|\left| \left[h_{jk}^{\text{conj}}\right]_{1\times n^2} - [\alpha_{p,q}]_{1\times m^2} E_{m^2\times n^2} \right|\right| \le \varepsilon$$

$$E_{m^2\times n^2} = \left[\frac{1}{d_{pj}d_{qk}} e^{-i2\pi\frac{d_{pj}-d_{qk}}{\lambda}}\right]_{p,q=1,\dots,m;\ j,k=1,\dots,n}$$

where $i = \sqrt{-1}$. Given d_{pj}'s and d_{qk}'s, the above optimization problem can be solved in closed-form using a least-squares fit as (note: $(.)^{\text{pinv}}$ is pseudo-inverse.):

$$\alpha^{\text{est}} = \left[h_{jk}^{\text{conj}}\right]_{1\times n^2} E^{\text{pinv}}_{m^2\times n^2} \tag{7}$$

At this point, we can estimate the goodness-of-fit of the assumed coordinates of the virtual sources corresponding to the client $\{(x_p, y_p, z_p)\}_{p=1,\dots m}$ based on how well the estimated channels agree with the observed channels. We define the goodness-of-fit of virtual source coordinates $\{(x_p, y_p, z_p)\}_{p=1,\dots m}$ as:

$$G(\{(x_p, y_p, z_p)\}_{p=1,\dots m}) = 1/\left|\left|\left[h_{jk}^{\text{conj}}\right] - \alpha^{\text{est}} E\right|\right|$$

Thus, our problem of disentangling the multipath reduces to finding the coordinates of virtual sources in a given geographical domain $\mathcal{D}$, $C^{\text{opt}} = \{(x_p^{\text{opt}}, y_p^{\text{opt}}, z_p^{\text{opt}})\}_{p=1,\dots,m}$ as:

$$C^{\text{opt}} = \underset{\{(x_p,y_p,z_p)\}_{p=1,\dots,m}\in\mathcal{D}\}}{\arg\max} G(\{(x_p, y_p, z_p)\}_{p=1,\dots,m})$$

Run-time Optimization: Running the above optimization through an exhaustive grid search is prohibitive. Instead, Chime solves it numerically using a stochastic gradient descent algorithm [25] that begins optimization at a few of initial points (e.g. a coarse grid) in parallel. We then perform a finer numerical gradient-based search at these points and report the coordinates for which we obtain the global maximum of goodness-of-fit. Also, prior information about the topography of the deployment space, known reflectors, and location of the transmitter, while not necessary, can speed up the search process. Upon optimization, Chime can fully characterize the m dominant taps by the virtual source coordinates C^{opt} and corresponding phase shifts: $\alpha^{\text{opt}} = \left[h_{jk}^{\text{conj}}\right] E^{\text{pinv}}$.

6.2 Designing Optimization Parameters

Channels are Sparse and Changing: Key to our optimization above is an accurate estimate of the number of dominant signal paths m. Choosing a small number of signal paths would lead to inefficiency and a poor overall goodness-of-fit relative to the observed wireless channel. However, choosing a large number of signal paths leads to over-fitting, or requires large number of base stations, and eventually, a poor estimate of the optimal frequency to operate on. Fortunately, our results in Sec. 10.2 demonstrate that the number of dominant signal paths in practical outdoor settings is small, a median of 2, beyond which we tend to over-fit. Furthermore, given a number of base stations, estimating a certain number of dominant paths give the best results. We analyze this optimum sparsity in Sec. 10.3 empirically and use the appropriate m for performing the optimization. In Sec. 10.2 we show that even though multipath is sparse, the dominant taps change over the time-scale of minutes causing the optimal frequency to change. Of course, most large reflectors (buildings) do not move to cause this change. Hence, we surmise this is the aggregate effect of one or more smaller static objects (e.g. parked vehicles, objects close to the transmitter/receiver) that move at these time scales.

Multiple, Non-Linear and Fleeting Reflectors: Note while reflecting surfaces may be non-linear in the real world, in our model, we only consider linear reflectors. We thus model the multiple reflections off a non-linear reflector or multiple reflectors as a composite linear reflector. Indeed, while this assumption may sometimes lead to erroneous estimation of reflectors [52] due to increased path length, we see that by expanding the physical size of our search space for virtual sources, the error in estimating multipath is minimal. We also ran simulation based experiments which attempt to estimate multiple reflections with a single reflector over a larger search space (due to larger path distances). The results show that error in finding the virtual source is negligible as long as the peak is 7 dB above noise across the ISM band. Practically, Chime only needs a source which exhibits similar distances to the base stations as the different paths to the base stations. We also ignore fleeting and small reflectors, which occur only for one of the base stations, since they have minimal amortized effect across the received signals of the base stations. Our results in Sec.10.3 show that these assumptions work reasonably well for urban environments.

Finite Reflectors: Our approach above assumes infinite planar reflectors which is not true in real world. To encode the finiteness of the reflectors we can introduce a new parameter β_p which is a boolean vector of length n to each virtual source p where β_{pj}=1 denotes whether the signal from virtual source p reaches base station j. This means that

$$E_{m^2\times n^2} = \left[\frac{\beta_{pj}\beta_{qk}}{d_{pj}d_{qk}}e^{-i2\pi\frac{d_{pj}-d_{qk}}{\lambda}}\right]_{p,q=1,\ldots,m;\ j,k=1,\ldots,n}$$

would be sufficient to model finite reflectors. However, simply looking for all possible β is inefficient. Instead we add two new parameters Φ_k and ψ_k which represent the starting angle and spanning angle of the planar reflector. We can reduce the possible β by imposing practical and geographical constraints. This means we only have to optimize for $2m$ extra parameters instead of nm. We can estimate the β matrix by

Figure 7: **Chime**'s algorithm in a nutshell

using the source locations$\{x_k, y_k, z_k\}$ and the angles Φ_k, ψ_k and applying the correct constraints. This means that the number of variables does not increase significantly and can be modeled with additional base stations.

Mobility: While our solution does not consider mobility of client, we believe even with the knowledge of location of the client device, we **cannot** use the reflectors computed during previous run of Chime to assist the next run. This is because LP-WAN devices transmit very rarely (about every 15 minutes or more), which according to our observations in Sec. 3 demonstrate change in multipath of even static clients. This will lead to a complete change in the reflectors of the client device. Thus, under Chime's constraints, we will indeed need to recompute every reflector again.

Extending to Multiple Frequencies To recover the dominant signal paths using the algorithm above, one would need to ensure that $m < n$, i.e. the number of dominant signal paths is sparse and well below the number of base stations in the vicinity of the LP-WAN client. We note that not all these base stations need to be able to decode the client's transmission at the highest rate – they can simply compute wireless channels from the preamble. However, in the instance that too few base stations are available in the vicinity of the client, Chime can improve its performance by measuring wireless channels at more frequency bands, e.g. by requesting the client to hop across a few bands. In effect, the additional measurements across base stations makes sure our optimization in Eqn. 7 is not under-determined.

7 Estimating Optimal Frequency

Having disentangled the multiple signal paths emerging from the client, Chime can estimate an optimal frequency of operation by recombining these signal paths across the various available transmission frequencies. It can then identify the operating frequency by choosing the transmission frequency with the highest signal power, while also accounting for other factors such as noise and interference.

Computing Signal Power The first step to selecting the best operating frequency is to determine the signal power at each frequency band. In particular, given the offset-free channels h^{conj}_{jk} between a pair of base stations (j,k) from Sec. 5 and the multipath propagation characteristics ($\{\alpha_{p,q}\}$ and $\{(x_p, y_p, z_p)\}$) from Sec. 6, we write the offset-free channel $h^{\text{conj}}_{jk,@f}$ at any frequency f and wavelength λ_f as:

$$h^{\text{conj}}_{jk,@f} = [\alpha_{p,q}]_{1\times m^2} E \qquad \text{, where:}$$

$$E = \left[\frac{1}{d_{pj} d_{qk}} e^{-i2\pi \frac{d_{pj}-d_{qk}}{\lambda_f}} \right]_{p,q=1,\dots,m;\ j,k=1,\dots,n}$$

Here, d denotes the distances between virtual sources and base stations as defined in Sec. 6.

Notice that the magnitude of $|h^{\text{conj}}_{jk,@f}|^2$ is simply the product of the signal power from the client at base station i and base station j. However, Chime needs to recover the individual power of the wireless channels at each frequency to compare them across frequencies. Extracting these individual powers from $h^{\text{conj}}_{jk,@f}$ is challenging, because its phase was carefully constructed to remove any hardware impediments.

Chime addresses this challenge by performing its algorithm in Sec. 6 on a second set of input wireless channels. We define these wireless channels, h^{rat}_{jk} as:

$$h^{\text{rat}}_{jk} = \frac{\tilde{h}_{C\to B_k}(t)\tilde{h}_{B_M\to B_j}(t) h_{B_M\to B_k}}{\tilde{h}_{C\to B_j}(t)\tilde{h}_{B_M\to B_k}(t) h_{B_M\to B_j}}$$

Notice that the phase of h^{rat}_{jk} is identical to that of h^{conj}_{jk}, and is therefore also free from phase errors due to hardware impediments of LP-WAN radios. Its magnitude however is **different** – the ratio of the magnitude of the wireless channels to each base stations. One can therefore apply Chime's algorithm (Sec. 6) with h^{rat}_{jk} instead of h^{conj}_{jk} as input and obtain as output the corresponding wireless channel at frequency f: $h^{\text{rat}}_{jk,@f}$. It is then easy to see that the power of the signal from the client to base stations j and k on frequency f is:

$$|h_{C\to B_j,@f}|^2 = h^{\text{conj}}_{jk,@f} / h^{\text{rat}}_{jk,@f} \tag{8}$$

$$|h_{C\to B_k,@f}|^2 = (h^{\text{conj}}_{jk,@f})^* h^{\text{rat}}_{jk,@f} \tag{9}$$

Selecting Optimal Radio Configuration Beyond signal power at the target frequency that Chime computes, data rate is also influenced by ambient noise, interference and attenuation introduced by the transmit/receive chains across frequencies. Fortunately, LP-WAN base stations can easily measure all these quantities as they span a wide band of frequencies [31]. Chime therefore uses these measurements to compute the effective SINR of the client across frequencies to choose the one best optimizing its battery life.

8 Extensions of Chime

While Chime is designed to compute an optimal frequency for an LP-WAN client to conserve battery-life, its approach can be used to complement related problems in LP-WAN:

Coherent Combining: In addition to magnitude, recall that Chime also provides the relative phase of wireless channels between base stations. This is useful in computing the expected wireless channels when the base stations collaborate to coherently combine the received signal across base stations in order to decode them (e.g. Charm [17] performs coherent combining in the LP-WAN context to decode weak transmissions from clients). By knowing both the magnitude and relative phase of wireless channels at each base station across frequencies, Chime can identify the frequency-band for which the expected power of the coherently combined signal will be maximum. Hence, Chime improves the performance of coherent combining in LP-WANs (Sec. 10.5).

Finding Nulls: Just as Chime can find the radio configuration where a client's signal power to any base station is maximum, it can also find frequency where signal power is minimum. This is valuable in *nulling* interference from an unwanted client at a base station by requesting it to transmit at a frequency where interference is lower with one or more base stations. Sec. 10.6 presents results evaluating Chime's performance in finding nulls from a client to base station.

9 Implementation and Evaluation

We implement Chime on Ettus USRP N210s as base stations and reference transmitter for removing phase offsets (see Sec. 5).These base stations measure phase based on our customized code in UHD to measure phase for Chirp Spread Spectrum modulated data at line rate. We use Semtech SX1276 chips as LoRaWAN client transmitters. Each picks a single frequency from the ones supported by the transmitter and transmits a small "chirp" for the base stations to hear. The master base station (USRP N210) is designed to transmit on an adjacent band all the time for convenience of implementation(see Sec. 5.2). We set the client spreading factor to 10 bits per symbol and the bandwidth to 125KHz (standard mode of operation). Each base station has a reliable link to the cloud via a wired backend. Chime's code is implemented in MATLAB/C++ using an in-house UHD-compatible LoRaWAN demodulator and processes the received wireless channels across base stations at the cloud. We only consider infinite length reflectors to evaluate our system. Note that we perform coherent combining across base stations only for Sec. 10.5 where we combine Charm with Chime.

Wide-Area Deployment: Unless specified otherwise, we evaluate Chime over four months across CMU campus and surrounding neighborhoods spanning an area of 0.5km $\times$ 0.7km in Pittsburgh leading to complex multipath scenarios as shown in Fig. 8. Our deployment consists of 11 LP-WAN

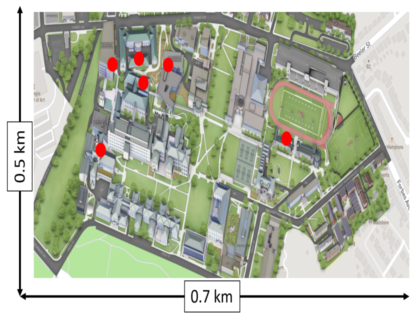

Figure 8: **Chime Deployment**: Red circles denote base station locations

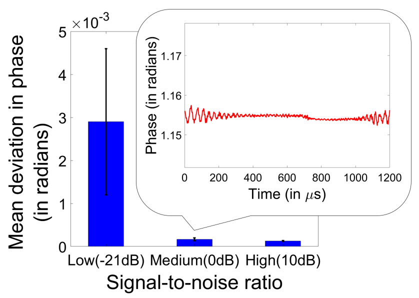

Figure 9: **Phase Stability**: Phase of offset-free channel h_{jk}^{conj} in multipath-rich scenarios is stable across SINRs

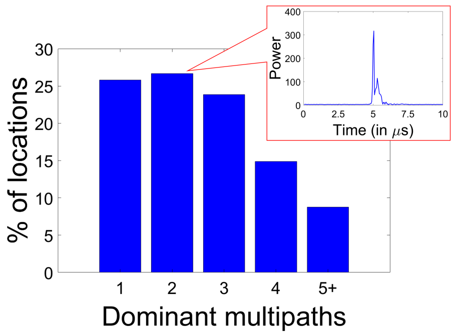

Figure 10: **Multipath Sparsity:** Histogram of # dominant paths shows sparsity of multipath in urban environment

base stations serving different areas, all placed in different buildings – 5 indoors and 6 outdoors. The campus has a variety of tall buildings, trees, other large occlusions and hilly terrain. Our frequencies of operation include the 915 MHz ISM band and some bands in 500 MHz TV white spaces (FCC experimental hardware license). We deploy up to 30 static LoRaWAN clients at various locations (changing every few days) to collect thousands of wireless channel traces across distances relative to the base stations. While each client is not mobile, we do consider a dynamic environment. Each client transmits at a rate of 5-15 packets per hour. Further, clients chose an arbitrary frequency of operation for their initial association packet. Note that our experiments in Sec. 10.2 are in a 0.36 km^2 downtown area of Pittsburgh to study multipath (described further in Sec. 10.2).

Ground Truth & Baseline: We obtain ground truth by making clients hop on all frequencies to find an optimal one. However, only the wireless channel corresponding to a single packet on one frequency band is provided to Chime, unless stated otherwise. We compare Chime against three baseline systems: (1) Standard LoRaWAN which chooses initial frequency arbitrarily; (2) Interpolation across frequency (as described in Sec. 3), when data across multiple frequencies is available; (3) Charm, a system that performs coherent combining across base stations [17].

Runtime: Our current implementation takes $\sim$ 31 sec to explore the search space of reflectors on a desktop with Core-i7 8700K and Nvidia GTX 1060 GPU with 64 GB RAM where E matrices are prefetched in memory for search space of virtual sources. This could be significantly optimized with prior knowledge of the reflectors (topography) or parallelization on a GPU cluster – a task for future work.

10 Experimental Results

10.1 Stability of Phase

Setup: An LP-WAN transmitter is moved across 25 locations in our wide-area testbed and multiple traces are collected from base stations spread across 4 months for static clients. We remove the phase offsets and plot the mean and standard deviation of the instability (standard deviation) in the phase of the offset-free channel (Sec. 5) across pairs of base stations for various SINRs.

Results: Fig. 9 shows the phase measurements of the offset-free channel are stable across pairs of base stations with a mean standard deviation of less than 5×10^{-3} even at SINRs as low as -21 dB. This validates the stability in measurement of the phase of offset-free channels at low SINRs.

10.2 Multipath in Urban Environments

We next study the multipath in the downtown of a large city in the U.S. to validate the sparsity assumption in Sec. 6.1.

Setup: We have a base station transmit wide band chirps of 20 MHz moved over a path length of 5 km in a urban downtown environment. Another base station is used to receive these signals. We then collect data from over 600 different GPS-tagged locations over 0.36 km^2. We correlate with transmitted chirp to estimate the number of taps in the signal. We also keep a transmitter-receiver pair 600 m away in a NLOS suburban environment to evaluate the change in sparsity of multipath and the associated channels over time.[3]

Results: Fig. 10 shows that almost 77% of locations have less than 3 dominant taps in the wireless channel affecting the signal, showing the channel is predominantly sparse as we assume. We also note that at least one of these dominant taps change over time scales of a few minutes, even for static clients. We surmise this is due to some smaller static reflectors in the environment moving gradually over time in aggregate leading to a small number of gradually moving taps. Fig. 11 shows how long the paths between the client and the base station typically are stable. We define *persistence* of a path as the time until which atleast 80% of the energy received remains within the original path components. We see that with 90% likelihood the sparse multipath changes within 10 mins. If we ignore the most dominant path, we see that secondary reflectors change even faster.

[3]Our data and code are available at [1].

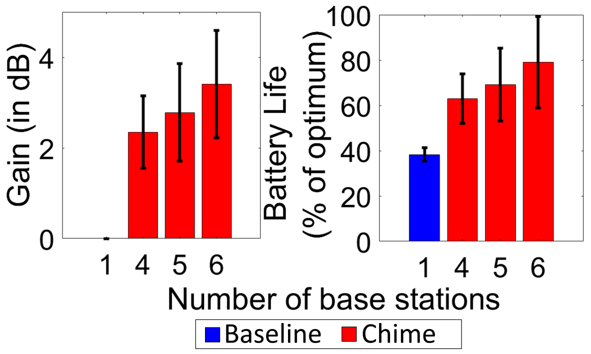

Figure 13: (Left) Gain in SINR(dB) by using Chime vs. median frequency of operation; (Right) Battery life of Chime vs. temporal interpolation technique

10.3 Chime's Gains across Base Stations

We demonstrate the gains achieved by using Chime for identifying an optimal frequency of operation.

Setup: We collect 20 measurements of 100 packets each, spread across 3 months from 5 locations across campus at six base stations at a given frequency f_i. Using these packets, we compute the offset-free channel for each of the base station pairs. We then apply Chime's algorithm to compute an optimal frequency-of-operation. We compute the **gain** (in dB) as the improvement of SINR at the computed operation frequency vs. the median SINR across all possible frequencies. Finally, we measure the improvement in the **battery life** of LP-WAN transmitters due to lower transmission time by using Chime as the percentage of maximum battery life achievable by choosing the optimum frequency of operation. The results are averaged over choice of initial frequency.

Sparsity: As we increase the number of base stations, more and more complex multipath patterns emerge. This is to be expected, given that more base stations are influenced by a larger number of reflectors. This means that 2 multipath sources are not enough to correctly estimate the complex multipath patterns and hence more multipath sources are required to assess the optimum frequency of operation. This can usually be rectified by adding more variables (estimating more sources) which can result in a better fit for the equations. The table shows the median optimum sparsity vs. # base stations:

# Base stations	**Optimal Sparsity**
4	2 sources
5	3 sources
6	4 sources

SINR Prediction: Next, we measure how accurately Chime predicts the accurate SINR of the optimal frequency of operation, across the 915 MHz ISM band. Specifically, we compute the CDF of the difference in SINR between the predicted and actual SINR at the optimal frequency of operation. Fig. 12 plots the results across number of base stations with only 2.7 dB of difference (median) with 6 base stations and 4 multipath(MP) sources considered. To put this in perspective, the SINR at an arbitrary frequency would differ from the optimal by as much as 6.1 dB (median). Our results once again validate Chime's sparsity assumptions and our modeling approach. It shows that the gap between the association packet and transmission ($\sim$10-15 ms) is too short for environmental dynamism to change the channels for static clients.

SINR Gain: Next we analyze the gain in SINR achieved by Chime with increasing number of base stations. Our baseline for the gain is the median frequency-of-operation which emulates choosing an operation frequency at random. As shown in Fig. 13, we achieve a gain of about 2.4 dB with 4 base stations which increases as we increase the number of base stations (with optimum sparsity). With 6 base stations, we achieve a mean increase in the SINR of about 3.4 dB.

Battery Life Gain: Finally, we compare the battery life[4] achieved by Chime with that of choosing frequency of operation based on temporal interpolation. As shown in Fig. 13, we see a stark improvement of 107% in the battery life using Chime which provides a mean of 79% of the optimum over the baseline approaches. This result shows that Chime can provide high gains for dense urban deployments.

These gains in signal power allow transmitters to send at faster rates and reducing the transmission time of the LP-WAN clients. We use methodology explained in Sec. 3 to estimate the expected battery life of the client when streaming sensed data at the optimal data rate to the base station. As shown in Fig. 14, we see a 230% increase in the battery life of the LP-WAN transmitters over the median frequency of operation which is significant for rarely transmitting devices whose lifetime increases from 2.5 years to 8.2 years.

10.4 Chime's Gains across Frequency

We study the gain in SINR and improvement in data rate that can be obtained by sampling more frequencies to further help the base stations to find an optimal frequency using Sec. 6.2.

Setup: We collect phases from 6 receiver base stations at frequencies ranging from 902-928 MHz with an interval of 500 kHz. The frequencies chosen in each case for training are randomized to ensure correctness and the gains obtained in each case are averaged across 5 client locations across

[4]Battery Life estimates derived from prior energy models (see Sec.3)

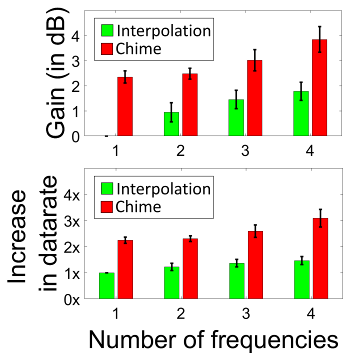

Figure 15: **Gain in SINR and improvement in datarate vs. interpolation** for # of frequencies used for training

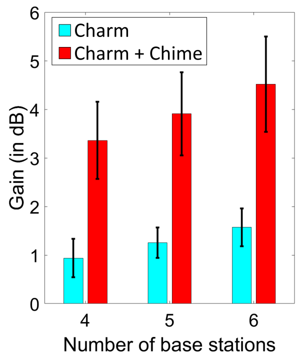

Figure 16: **Chime + Charm**: Improvement in Gain(dB) when Charm is assisted by Chime

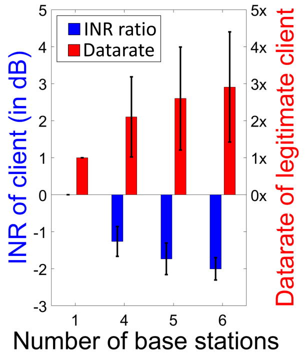

Figure 17: **Nulling of unwanted interference** leads to improved data rate for legitimate client with Chime

multiple weeks. We compute the improvement in data rates achieved due to higher signal strength. As we are sampling multiple frequencies, our baseline will be the spectral interpolation using these frequencies (as described in Sec. 3).

Results: We observe a steady increase in gain with increasing number of frequencies used for training which improves battery-life. The improvement is significantly more than that of the baseline. An important side-benefit of Chime is the improvement in data rate which also progressively increases. As the SINR of the received signal improves, it enables clients to transmit at faster data rates. While LP-WAN clients are infrequent and low-rate transmitters, this improves overall spectrum utilization in congested large-scale deployments.

10.5 Chime with Coherent Combining

In this experiment, we measure Chime's performance in improving Charm's [17] capability of coherent combining.

Setup: We perform the same experiment as Sec. 10.3. However, to compute the frequency-of-operation, we optimize for the sum of the SINR at the base stations instead of an individual base station. Then, we coherently combine the signals at that frequency as shown in [17]. The base line is näive Charm [17] which chooses a frequency randomly.

Results: Fig. 16 shows a median SINR increase of 4.5 dB with six base stations which can significantly improve the battery life of LP-WAN clients in urban environments. As expected, the improvement is much better than that by choosing a random frequency of operation by about 2.5-3 dB.

10.6 Can Chime Null Interference?

This section predicts nulls, i.e. a bad frequency of transmission for an interfering client to a given base station to provide improvement in signal strength of legitimate client.

Setup: We perform the same experiment as Sec. 10.3. We measure the reduction in interference by using Chime to correctly estimate the frequency with the worst channel estimate. We compute the reduction in Interference to Noise Ratio (INR) for a legitimate client in another channel. We measure the resulting gains in data-rate for the legitimate transmitter due to reduction in interference by the interferer.

Results: Fig. 17 shows that we can achieve up to 2.8× gain in the data rates of the legitimate transmitter by allocating the interferer a null frequency. We further show that as we increase the number of base stations, the accuracy of estimating nulls increases which shows that we can get better and better gains for the legitimate transmitter.

11 Conclusion and Future Work

This paper presents Chime, a system that allows an LP-WAN client to choose its optimal frequency simply by sending a single packet on one frequency band. Chime achieves this by analyzing the paths signals traverse from the client to distributed and coordinated base stations. Chime was evaluated in a campus-scale testbed, leading to a median battery life increase of 1.4-5.7 years over commodity LP-WANs.

While Chime's emphasis is on optimal frequency, we believe it provides the building blocks for a comprehensive interference management and distributed MIMO system built for LP-WANs. Designing such an end-to-end system to provide enormous battery savings to low-power clients, while respecting their hardware limitations remains an important problem for future work.

Acknowledgments

This work was supported by Kavčić-Moura award and National Science Foundation grants 1823235, 1718435 and 1837607. We extend warm gratitude to Prof. Srinivasa Narasimhan, Angy Malloy and Robotics Institute at CMU for allowing us to setup remote base stations for wide-scale deployment. Finally, the authors would like to thank our shepherd Lin Zhong, anonymous NSDI reviewers, Vyas Sekar, Peter Steenkiste, Atulya, Adhishree and members of WiSe and WiTech lab for their constructive feedback and support.

Abstract

We propose *Accel-Brake Control* (ABC), a simple and deployable explicit congestion control protocol for network paths with time-varying wireless links. ABC routers mark each packet with an "accelerate" or "brake", which causes senders to slightly increase or decrease their congestion windows. Routers use this feedback to quickly guide senders towards a desired target rate. ABC requires no changes to header formats or user devices, but achieves better performance than XCP. ABC is also incrementally deployable; it operates correctly when the bottleneck is a non-ABC router, and can coexist with non-ABC traffic sharing the same bottleneck link. We evaluate ABC using a Wi-Fi implementation and trace-driven emulation of cellular links. ABC achieves 30-40% higher throughput than Cubic+Codel for similar delays, and 2.2× lower delays than BBR on a Wi-Fi path. On cellular network paths, ABC achieves 50% higher throughput than Cubic+Codel.

1 Introduction

This paper proposes a new explicit congestion control protocol for network paths with wireless links. Congestion control on such paths is challenging because of the rapid time variations of the link capacity. Explicit control protocols like XCP [29] and RCP [43] can in theory provide superior performance on such paths compared to end-to-end [10, 13, 14, 16, 23, 24, 46, 50] or active queue management (AQM) [36, 37] approaches (§2). Unlike these approaches, explicit control protocols enable the wireless router to directly specify a target rate for the sender, signaling both rate decreases and rate increases based on the real-time link capacity.

However, current explicit control protocols have two limitations, one conceptual and the other practical. First, existing explicit protocols were designed for fixed-capacity links; we find that their control algorithms are sub-optimal on time-varying wireless links. Second, they require major changes to packet headers, routers, and endpoints to deploy on the Internet.

Our contribution is a simple and deployable protocol, called Accel-Brake Control (ABC), that overcomes these limitations, building on concepts from a prior position paper [22]. In ABC (§3), a wireless router marks each packet with one bit of feedback corresponding to either *accelerate* or *brake* based on a measured estimate of the current link rate. Upon receiving this feedback via an ACK from the receiver, the sender increases its window by one on an accelerate (sends two packets in response to the ACK), and decreases it by one on a brake (does not send any packet). This simple mechanism allows the router to signal a large dynamic range of window size changes within one RTT: from throttling the window to 0, to doubling the window.

Central to ABC's performance is a novel control algorithm that helps routers provide very accurate feedback on time-varying links. Existing explicit schemes like XCP and RCP calculate their feedback by comparing the current *enqueue rate* of packets to the link capacity. An ABC router, however, compares the *dequeue rate* of packets from its queue to the link capacity to mark accelerates or brakes. This change is rooted in the observation that, for an ACK-clocked protocol like ABC, the current dequeue rate of packets at the router provides an accurate prediction of the future incoming rate of packets, one RTT in advance. In particular, if the senders maintain the same window sizes in the next RTT, they will send one packet for each ACK, and the incoming rate in one RTT will be equal to the current dequeue rate. Therefore, rather than looking at the current enqueue rate, the router should signal changes based on the anticipated enqueue rate in one RTT to better match the link capacity. The impact of this subtle change is particularly significant on wireless links, since the enqueue and dequeue rates can differ significantly when the link capacity varies.

ABC also overcomes the deployability challenges of prior explicit schemes, since it can be implemented on top of the existing explicit congestion notification (ECN) [41] infrastructure. We present techniques that enable ABC to co-exist with non-ABC routers, and to share bandwidth fairly with legacy flows traversing a bottleneck ABC router (§4).

We have implemented ABC on a commodity Wi-Fi router running OpenWrt [18]. Our implementation (§5.1) reveals an important challenge for implementing explicit protocols on wireless links: how to determine the link rate for a user at a given time? The task is complicated by the intricacies of the Wi-Fi MAC's batch scheduling and block acknowledgements. We develop a method to estimate the Wi-Fi link rate and demonstrate its accuracy experimentally. For cellular links, the 3GPP standard [1] shows how to estimate the link rate; our evaluation uses emulation with cellular packet traces.

We have experimented with ABC in several wireless network settings. Our results are:

1. In Wi-Fi, compared to Cubic+Codel, Vegas, and Copa, ABC achieves 30-40% higher throughput with similar delays. Cubic, PCC Vivace-latency and BBR incur 70%–6× higher 95th percentile packet delay with similar throughput.
2. The results in emulation over 8 cellular traces are

*Work done largely while a visiting student at MIT CSAIL.
†Work done largely while a PhD student at MIT CSAIL.

Scheme	Norm. Utilization	Norm. Delay (95%)
ABC	1 (78%)	1 (242ms)
XCP	0.97	2.04
Cubic+Codel	0.67	0.84
Copa	0.66	0.85
Cubic	1.18	4.78
PCC-Vivace	1.12	4.93
BBR	0.96	2.83
Sprout	0.55	1.08
Verus	0.72	2.01

summarized below. Despite relying on single-bit feedback, ABC achieves 2× lower 95th percentile packet delay compared to XCP.

3. ABC bottlenecks can coexist with both ABC and non-ABC bottlenecks. ABC flows achieve high utilization and low queuing delays if the bottleneck router is ABC, while switching to Cubic when the bottleneck is a non-ABC router.
4. ABC competes fairly with both ABC and non-ABC flows. In scenarios with both ABC and non-ABC flows, the difference in average throughput of ABC and non-ABC flows is under 5%.

2 Motivation

Link rates in wireless networks can vary rapidly with time; for example, within one second, a wireless link's rate can both double and halve [46].[1] These variations make it difficult for transport protocols to achieve both high throughput and low delay. Here, we motivate the need for explicit congestion control protocols that provide feedback to senders on both rate increases and decreases based on direct knowledge of the wireless link rate. We discuss why these protocols can track wireless link rates more accurately than end-to-end and AQM-based schemes. Finally, we discuss deployment challenges for explicit control protocols, and our design goals for a deployable explicit protocol for wireless links.

Limitations of end-to-end congestion control: Traditional end-to-end congestion control schemes like Cubic [23] and NewReno [24] rely on packet drops to infer congestion and adjust their rates. Such schemes tend to fill up the buffer, causing large queuing delays, especially in cellular networks that use deep buffers to avoid packet loss [46]. Fig. 1a shows performance of Cubic on an LTE link, emulated using a LTE trace with Mahimahi [35]. The network round-trip time is 100 ms and the buffer size is set to 250 packets. Cubic causes significant queuing delay, particularly when the link capacity drops.

Recent proposals such as BBR [14], PCC-Vivace [16] and Copa [10] use RTT and send/receive rate measurements to estimate the available link rate more accurately. Although these schemes are an improvement over loss-based schemes, their performance is far from optimal on highly-variable links. Our experiments show that they either cause excessive queuing or underutilize the link capacity (e.g., see Fig. 7). Sprout [46] and Verus [50] are two other recent end-to-end protocols designed specifically for cellular networks. They also have difficulty tracking the link rate accurately; depending on parameter settings, they can be too aggressive (causing large queues) or too conservative (hurting utilization). For example, Fig. 1b shows how Verus performs on the same LTE trace as above.

The fundamental challenge for any end-to-end scheme is that to estimate the link capacity, it must utilize the link fully and build up a queue. When the queue is empty, signals such as the RTT and send/receive rate do not provide information about the available capacity. Therefore, in such periods, all end-to-end schemes must resort to some form of "blind" rate increase. But for networks with a large dynamic range of rates, it is very difficult to tune this rate increase correctly: if it is slow, throughput suffers, but making it too fast causes overshoots and large queuing delays.[2] For schemes that attempt to limit queue buildup, periods in which queues go empty (and a blind rate increase is necessary) are common; they occur, for example, following a sharp increase in link capacity.

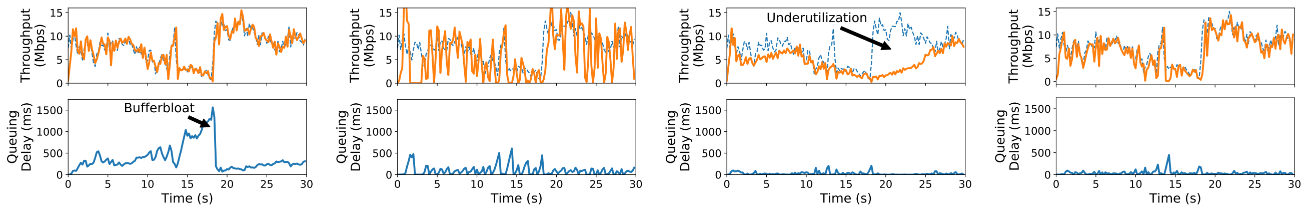
AQM schemes do not signal increases: AQM schemes like RED [19], PIE [37] and CoDel [2] can be used to signal congestion (via ECN or drops) before the buffer fills up at the bottleneck link, reducing delays. However, AQM schemes do not signal rate increases. When capacity increases, the sender must again resort to a blind rate increase. Fig. 1c shows how CoDel performs when the sender is using Cubic. Cubic+CoDel reduces delays by 1 to 2 orders of magnitude compared to Cubic alone but leaves the link underutilized when capacity increases.

Thus, we conclude that, both end-to-end and AQM-based schemes will find it difficult to track time-varying wireless link rates accurately. Explicit control schemes, such as XCP [29] and RCP [43] provide a compelling alternative. The router provides multiple bits of feedback per packet to senders based on direct knowledge of the wireless link capacity. By telling senders precisely how to increase or decrease their rates, explicit schemes can quickly adapt to time-varying links, in principle, within an RTT of link capacity changes.

Deployment challenges for explicit congestion control: Schemes like XCP and RCP require major changes to packet headers, routers, and endpoints. Although the changes are technically feasible, in practice, they create significant deployment challenges. For instance, these protocols require new packet fields to carry multi-bit feedback information. IP or TCP options could in principle be used for these fields. But many wide-area routers drop packets with IP options [20], and using TCP options creates problems due to middleboxes [25] and IPSec encryption [30]. Another important challenge is co-existence with legacy routers and legacy transport

[1]We define the link rate for a user as the rate that user can achieve if it keeps the bottleneck router backlogged (see §5).

[2]BBR attempts to mitigate this problem by periodically increasing its rate in short pulses, but our experiments show that BBR frequently overshoots the link capacity with variable-bandwidth links, causing excessive queuing (see Appendix A).



(a) Cubic (b) Verus (c) Cubic+CoDel (d) ABC

Figure 1: **Performance on a emulated cellular trace —** The dashed blue in the top graph represents link capacity, the solid orange line represents the achieved throughput. Cubic has high utilization but has very high delays (up to 1500 milliseconds). Verus has large rate variations and incurs high delays. Cubic+CoDel reduces queuing delays significantly, but leaves the link underutilized when capacity increases. ABC achieves close to 100% utilization while maintaining low queuing delays (similar to that of Cubic+CoDel).

protocols. To be deployable, an explicit protocol must handle scenarios where the bottleneck is at a legacy router, or when it shares the link with standard end-to-end protocols like Cubic.

Design goals: In designing ABC, we targeted the following properties:

1. *Control algorithm for fast-varying wireless links:* Prior explicit control algorithms like XCP and RCP were designed for fixed-capacity links. We design ABC's control algorithm specifically to handle the rapid bandwidth variations and packet transmission behavior of wireless links (e.g., frame batching at the MAC layer).
2. *No modifications to packet headers:* ABC repurposes the existing ECN [41] bits to signal both increases and decreases to the sender's congestion window. By spreading feedback over a sequence of 1-bit signals per packet, ABC routers precisely control sender congestion windows over a large dynamic range.
3. *Coexistence with legacy bottleneck routers:* ABC is robust to scenarios where the bottleneck link is not the wireless link but a non-ABC link elsewhere on the path. Whenever a non-ABC router becomes the bottleneck, ABC senders ignore window increase feedback from the wireless link, and ensure that they send no faster than their fair share of the bottleneck link.
4. *Coexistence with legacy transport protocols:* ABC routers ensure that ABC and non-ABC flows share a wireless bottleneck link fairly. To this end, ABC routers separate ABC and non-ABC flows into two queues, and use a simple algorithm to schedule packets from these queues. ABC makes no assumptions about the congestion control algorithm of non-ABC flows, is robust to the presence of short or application-limited flows, and requires a small amount of state at the router.

Fig. 1d shows ABC on the same emulated LTE link. Using only one bit of feedback per packet, the ABC flow is able to track the variations in bottleneck link closely, achieving both high throughput and low queuing delay.

3 Design

ABC is a window-based protocol: the sender limits the number of packets in flight to the current congestion window. Window-based protocols react faster to the sudden onset of congestion than rate-based schemes [11]. On a wireless link, when the capacity drops and the sender stops receiving ACKs, ABC will stop sending packets immediately, avoiding further queue buildup. In contrast, a rate-based protocol would take time to reduce its rate and may queue up a large number of packets at the bottleneck link in the meantime.

ABC senders adjust their window size based on explicit feedback from ABC routers. An ABC router uses its current estimate of the link rate and the queuing delay to compute a *target rate*. The router then sets one bit of feedback in each packet to guide the senders towards the target rate. Each bit is echoed to a sender by a receiver in an ACK, and it signals either a one-packet increase ("accelerate") or a one-packet decrease ("brake") to the sender's congestion window.

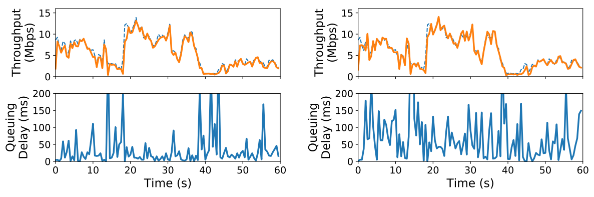
3.1 The ABC Protocol

We now present ABC's design starting with the case where all routers are ABC-capable and all flows use ABC. We later discuss how to extend the design to handle non-ABC routers and scenarios with competing non-ABC flows.

3.1.1 ABC Sender

On receiving an "accelerate" ACK, an ABC sender increases its congestion window by 1 packet. This increase results in two packets being sent, one in response to the ACK and one due to the window increase. On receiving a "brake," the sender reduces its congestion window by 1 packet, preventing the sender from transmitting a new packet in response to the received ACK. As we discuss in §4.3, the sender also performs an additive increase of 1 packet per RTT to achieve fairness. For ease of exposition, let us ignore this additive increase for now.

Though each bit of feedback translates to only a small change in the congestion window, when aggregated over an RTT, the feedback can express a large dynamic range of window size adjustments. For example, suppose a sender's window size is w, and the router marks accelerates on a fraction f of packets in that window. Over the next RTT, the sender will receive $w \cdot f$ accelerates and $w - w \cdot f$ brakes. Then, the sender's window size one RTT later will be $w + wf - (w - wf) = 2wf$ packets. Thus, in one RTT, an ABC router can vary the sender's window size between zero ($f = 0$) and double its current value ($f = 1$). The set of achievable



(a) Dequeue (b) Enqueue

Figure 2: **Feedback —** Calculating $f(t)$ based on enqueue rate increases 95th percentile queuing delay by 2×.

window changes for the next RTT depends on the number of packets in the current window w; the larger w, the higher the granularity of control.

In practice, ABC senders increase or decrease their congestion window by the number of newly acknowledged bytes covered by each ACK. Byte-based congestion window modification is a standard technique in many TCP implementations [8], and it makes ABC robust to variable packet sizes and delayed, lost, and partial ACKs. For simplicity, we describe the design with packet-based window modifications in this paper.

3.1.2 ABC Router

Calculating the target rate: ABC routers compute the target rate $tr(t)$ using the following rule:

$$tr(t) = \eta\mu(t) - \frac{\mu(t)}{\delta}(x(t) - d_t)^+, \tag{1}$$

where $\mu(t)$ is the link capacity, $x(t)$ is the observed queuing delay, d_t is a pre-configured delay threshold, η is a constant less than 1, δ is a positive constant (in units of time), and y^+ is $\max(y,0)$. This rule has the following interpretation. When queuing delay is low ($x(t) < d_t$), ABC sets the target rate to $\eta\mu(t)$, for a value of η slightly less than 1 (e.g., $\eta = 0.95$). By setting the target rate a little lower than the link capacity, ABC aims to trade a small amount of bandwidth for large reductions in delay, similar to prior work [7,27,32]. However, queues can still develop due to rapidly changing link capacity and the 1 RTT of delay it takes for senders to achieve the target rate. ABC uses the second term in Equation (1) to drain queues. Whenever $x(t) > d_t$, this term reduces the target rate by an amount that causes the queuing delay to decrease to d_t in at most δ seconds.

The threshold d_t ensures that the target rate does not react to small increases in queuing delay. This is important because wireless links often schedule packets in batches. Queuing delay caused by batch packet scheduling does not imply congestion, even though it occurs persistently. To prevent target rate reductions due to this delay, d_t must be configured to be greater than the average inter-scheduling time at the router.

ABC's target rate calculation requires an estimate of the underlying link capacity, $\mu(t)$. In §5, we discuss how to estimate the link capacity in cellular and WiFi networks, and we present an implementation for WiFi.

Packet marking: To achieve a target rate, $tr(t)$, the router computes the fraction of packets, $f(t)$, that should be marked as accelerate. Assume that the current *dequeue rate* — the rate at which the router transmits packets — is $cr(t)$. If the accelerate fraction is $f(t)$, for each packet that is ACKed, the sender transmits $2f(t)$ packets on average. Therefore, after 1 RTT, the *enqueue rate* — the rate at which packets arrive to the router — will be $2cr(t)f(t)$. To achieve the target rate, $f(t)$ must be chosen such that $2cr(t)f(t)$ is equal to $tr(t)$. Thus, $f(t)$ is given by:

$$f(t) = \min\left\{\frac{1}{2}\cdot\frac{tr(t)}{cr(t)}, 1\right\}. \tag{2}$$

An important consequence of the above calculation is that $f(t)$ is computed based on the *dequeue* rate. Most explicit protocols compare the enqueue rate to the link capacity to determine the feedback (e.g., see XCP [29]).

ABC uses the dequeue rate instead to exploit the ACK-clocking property of its window-based protocol. Specifically, Equation (2) accounts for the fact that when the link capacity changes (and hence the dequeue rate changes), the rate at the senders changes automatically within 1 RTT because of ACK clocking. Fig. 2 demonstrates that computing $f(t)$ based on the dequeue rate at the router enables ABC to track the link capacity much more accurately than using the enqueue rate.

ABC recomputes $f(t)$ on every dequeued packet, using measurements of $cr(t)$ and $\mu(t)$ over a sliding time window of length T. Updating the feedback on every packet allows ABC to react to link capacity changes more quickly than schemes that use periodic feedback updates (e.g., XCP and RCP).

Packet marking can be done deterministically or probabilistically. To limit burstiness, ABC uses the deterministic method in Algorithm 1. The variable `token` implements a token bucket that is incremented by $f(t)$ on each outgoing packet (up to a maximum value `tokenLimit`), and decremented when a packet is marked accelerate. To mark a packet accelerate, `token` must exceed 1. This simple method ensures that no more than a fraction $f(t)$ of the packets are marked accelerate.

```
token = 0;
for each outgoing packet do
    calculate $f(t)$ using Equation (2);
    token = min(token + $f(t)$, tokenLimit);
    if packet marked with accelerate then
        if token > 1 then
            token = token − 1;
            mark accelerate;
        else
            mark brake;
```

Algorithm 1: Packet marking at an ABC router.

Multiple bottlenecks: An ABC flow may encounter multiple ABC routers on its path. An example of such a scenario is when two smartphone users communicate over an ABC-compliant cellular network. Traffic sent from one user to the other will traverse a cellular uplink and cellular downlink, both of which could be the bottleneck. To support such situations, an ABC sender should send traffic at the smallest of the router-computed target rates along their path. To achieve this goal, each packet is initially marked accelerate by the sender. ABC routers may change a packet marked accelerate to a brake, but not vice versa (see Algorithm 1). This rule guarantees that an ABC router can unilaterally reduce the fraction of packets marked accelerate to ensure that its target rate is not exceeded, but it cannot increase this fraction. Hence the fraction of packets marked accelerate will equal the minimum $f(t)$ along the path.

3.1.3 Fairness

Multiple ABC flows sharing the same bottleneck link should be able to compete fairly with one another. However, the basic window update rule described in §3.1.1 is a multiplicative-increase/multiplicative-decrease (MIMD) strategy,[3] which does not provide fairness among contending flows (see Fig. 3a for an illustration). To achieve fairness, we add an additive-increase (AI) component to the basic window update rule. Specifically, ABC senders adjust their congestion window on each ACK as follows:

$$w \leftarrow \begin{cases} w+1+1/w & \text{if accelerate} \\ w-1+1/w & \text{if brake} \end{cases} \tag{3}$$

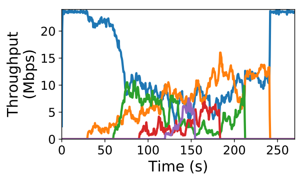
This rule increases the congestion window by 1 packet each RTT, in addition to reacting to received accelerate and brake ACKs. This additive increase, coupled with ABC's MIMD response, makes ABC a multiplicative-and-additive-increase/multiplicative-decrease (MAIMD) scheme. Chiu and Jain [15] proved that MAIMD schemes converge to fairness (see also [5]). Fig. 3b shows how with an AI component, competing ABC flows achieve fairness.

To give intuition, we provide a simple informal argument for why including additive increase gives ABC fairness. Consider N ABC flows sharing a link, and suppose that in steady state, the router marks a fraction f of the packets accelerate, and the window size of flow i is w_i. To be in steady state, each flow must send 1 packet on average for each ACK that it receives. Now consider flow i. It will send $2f+1/w_i$ packets on average for each ACK: $2f$ for the two packets it sends on an accelerate (with probability f), and $1/w_i$ for the extra packet it sends every w_i ACKs. Therefore, to be in steady state, we must have: $2f+1/w_i=1 \implies w_i=1/(1-2f)$. This shows that the steady-state window size for all flows must be the same, since they all observe the same fraction f of accelerates. Hence, with equal RTTs, the flows will have the same throughput, and otherwise their throughput will be inversely proportional to their RTT. Note that the RTT unfairness in ABC is similar to that of schemes like Cubic, for which the throughput of a flow is inversely proportional to its RTT. In §7.5, we show experiments where flows have different RTTs.

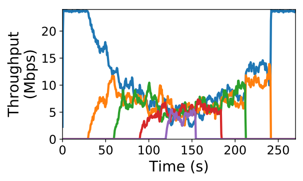
3.1.4 Stability Analysis

ABC's stability depends on the values of η and δ. η determines the target link utilization, while δ controls how long

[3] All the competing ABC senders will observe the same accelerate fraction, f, on average. Therefore, each flow will update its congestion window, w, in a multiplicative manner, to $2fw$, in the next RTT.



(a) ABC w/o AI



(b) ABC with AI

Figure 3: **Fairness among competing ABC flows —** 5 flows with the same RTT start and depart one-by-one on a 24 Mbit/s link. The additive-increase (AI) component leads to fairness.

it will take for a queue to drain. In Appendix C, we prove the following result for a fluid model of the ABC control loop.

Theorem 1. *Consider a single ABC link, traversed by N ABC flows. Let τ be the maximum round-trip propagation delay of the flows. ABC is* globally asymptotically stable *if*

$$\delta > \frac{2}{3} \cdot \tau. \tag{4}$$

Specifically, if $\mu(t)=\mu$ for $t>t_0$ (i.e., the link capacity stops changing after some time t_0), the enqueue/dequeue rate and the queuing delay at the ABC router will converge to certain values r^* and x^* that depend on the system parameters and the number of flows. In all cases: $\eta\mu < r^* \le \mu$.

This stability criterion is simple and intuitive. It states that δ should not be much smaller than the RTT (i.e, the feedback delay). If δ is very small, ABC reacts too forcefully to queue build up, causing under-utilization and oscillations.[4] Increasing δ well beyond $2/3\tau$ improves the stability margins of the feedback loop, but hurts responsiveness. In our experiments, we used $\delta=133$ ms for a propagation RTT of 100 ms.

4 Coexistence

An ABC flow should be robust to presence of non-ABC bottlenecks on its path and share resources fairly with non-ABC flows sharing the ABC router.

4.1 Deployment with non-ABC Routers

An ABC flow can encounter both ABC and non-ABC routers on its path. For example, a Wi-Fi user's traffic may traverse both a Wi-Fi router (running ABC) and an ISP router (not running ABC); either router could be the bottleneck at any given time. ABC flows must therefore be able to detect and react to traditional congestion signals—both drops and ECN—and they must determine when to ignore accelerate feedback from ABC routers because the bottleneck is at a non-ABC router.

We augment the ABC sender to maintain two congestion windows, one for tracking the available rate on ABC routers (w_{abc}), and one for tracking the rate on non-ABC bottlenecks (w_{nonabc}). w_{abc} obeys accelerates/brakes using Equation (3), while w_{nonabc} follows a rule such as

[4] Interestingly, if the sources do not perform additive increase or if the additive increase is sufficiently "gentle," ABC is stable for any value of δ. See the proof in Appendix C for details.

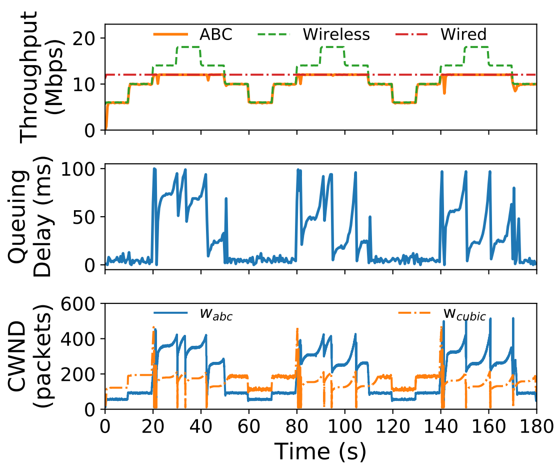


Figure 4: **Coexistence with non-ABC bottlenecks —** When the wired link is the bottleneck, ABC becomes limited by w_{cubic} and behaves like a Cubic flow. When the wireless link is the bottleneck, ABC uses w_{abc} to achieve low delays and high utilization.

Cubic [23] and responds to drop and ECN signals.[5] An ABC sender must send packets to match the lower of the two windows. Our implementation mimics Cubic for the non-ABC method, but other methods could also be emulated.

With this approach, the window that is not the bottleneck could become large. For example, when a non-ABC router is the bottleneck, the ABC router will continually send accelerate signals, causing w_{abc} to grow. If the ABC router later becomes the bottleneck, it will temporarily incur large queues. To prevent this problem, ABC senders cap both w_{abc} and w_{nonabc} to 2× the number of in-flight packets.

Fig. 4 shows the throughput and queuing delay for an ABC flow traversing a path with an ABC-capable wireless link and a wired link with a droptail queue. For illustration, we vary the rate of the wireless link in a series of steps every 5 seconds. Over the experiment, the bottleneck switches between the wired and wireless links several times. ABC is able to adapt its behavior quickly and accurately. Depending on which link is the bottleneck, either w_{nonabc} (i.e., w_{cubic}) or w_{abc} becomes smaller and controls the rate of the flow. When the wireless link is the bottleneck, ABC maintains low queuing delay, whereas the queuing delay exhibits standard Cubic behavior when the wired link is the bottleneck. w_{cubic} does not limit ABC's ability to increase its rate when the wireless link is the bottleneck. At these times (e.g., around the 70 s mark), as soon on w_{abc} increases, the number of in-flight packets and the cap on w_{cubic} increases, and w_{cubic} rises immediately.

4.2 Multiplexing with ECN Bits

IP packets have two ECN-related bits: ECT and CE. These two bits are traditionally interpreted as follows:

ECT	CE	Interpretation
0	0	Non-ECN-Capable Transport
0	1	ECN-Capable Transport ECT(1)
1	0	ECN-Capable Transport ECT(0)
1	1	ECN set

Routers interpret both 01 and 10 to indicate that a flow is ECN-capable, and routers change those bits to 11 to mark a packet with ECN. Upon receiving an ECN mark (11), the receiver sets the *ECN Echo (ECE)* flag to signal congestion to the sender. ABC reinterprets the ECT and CE bits as follows:

ECT	CE	Interpretation
0	0	Non-ECN-Capable Transport
0	1	**Accelerate**
1	0	**Brake**
1	1	ECN set

ABC send all packets with accelerate (01) set, and ABC routers signal brakes by flipping the bits to 10. Both 01 and 10 indicate an ECN-capable transport to ECN-capable legacy routers, which will continue to use (11) to signal congestion.

With this design, receivers must be able to echo both standard ECN signals and accelerates/brakes for ABC. Traditional ECN feedback is signaled using the ECE flag. For ABC feedback, we repurpose the NS (nonce sum) bit, which was originally proposed to ensure ECN feedback integrity [17] but has been reclassified as historic [31] due to lack of deployment. Thus, it appears possible to deploy ABC with only simple modifications to TCP receivers.

Deployment in proxied networks: Cellular networks commonly split TCP connections and deploy proxies at the edge [42, 45]. Here, it is unlikely that any non-ABC router will be the bottleneck and interfere with the accel-brake markings from the ABC router. In this case, deploying ABC may not require any modifications to today's TCP ECN receiver. ABC senders (running on the proxy) can use either 10 or 01 to signal an accelerate, and routers can use 11 to indicate a brake. The TCP receiver can echo this feedback using the ECE flag.

4.3 Non-ABC flows at an ABC Router

ABC flows are potentially at a disadvantage when they share an ABC bottleneck link with non-ABC flows.[6] If the non-ABC flows fill up queues and increase queuing delay, the ABC router will reduce ABC's target rate. To ensure fairness in such scenarios, ABC routers isolate ABC and non-ABC packets in separate queues.

We assume that ABC routers can determine whether a packet belongs to an ABC flow. In some deployment scenarios, this is relatively straightforward. For example, in a cellular network deployment with TCP proxies at the edge of the network [42, 45], the operator can deploy ABC at the proxy, and configure the base station to assume that all traffic from the proxy's IP address uses ABC. Other deployment

[5] We discuss how ABC senders distinguish between accelerate/brake and ECN marks in §4.2.

[6] ABC and non-ABC flows may also share a non-ABC link, but in such cases, ABC flows will behave like Cubic and compete fairly with other traffic.

scenarios may require ABC senders to set a predefined value in a packet field like the IPv6 flow label or the IPv4 IPID.

The ABC router assigns weights to the ABC and non-ABC queues, respectively, and it schedules packets from the queues in proportion to their weights. In addition, ABC's target rate calculation considers only ABC's share of the link capacity (which is governed by the weights). The challenge is to set the weights to ensure that the average throughput of long-running ABC and non-ABC flows is the same, no matter how many flows there are.

Prior explicit control schemes address this problem using the TCP loss-rate equation (XCP) or by estimating the number of flows with Zombie Lists (RCP). Relying on the TCP equation requires a sufficient loss rate and does not handle flows like BBR. RCP's approach does not handle short flows. When one queue has a large number of short flows (and hence a low average throughput), RCP increases the weight of that queue. However, the short flows cannot send faster, so the extra bandwidth is taken by long-running flows in the same queue, which get more throughput than long-running flows in the other queue (see §7.5 for experimental results).

To overcome these drawbacks, a ABC router measures the average rate of the K largest flows in each queue using the Space Saving Algorithm [34], which requires $O(K)$ space. It considers any remaining flow in either queue to be short, and it calculates the total rate of the short flows in each queue by subtracting the rate of the largest K flows from the queue's aggregate throughput. ABC uses these rate measurements to estimate the rate demands of the flows. Using these demands, ABC periodically computes the max-min fair rate allocation for the flows, and it sets the weight of each of the two queues to be equal to the total max-min rate allocation of its component flows. This algorithm ensures that long-running flows in the two queues achieve the same average rate, while accounting for demand-limited short flows.

To estimate the demand of the flows, the ABC router assumes that the demand for the top K flows in each queue is X% higher than the current throughput of the flow, and the aggregate demand for the short flows is the same as their throughput. If a top-K flow is unable to increase its sending rate by X%, its queue's weight will be larger than needed, but any unfairness in weight assignment is bounded by X%. Small values of X limit unfairness but can slow down convergence to fairness; our experiments use $X = 10\%$.

5 Estimating Link Rate

We describe how ABC routers can estimate the link capacity for computing the target rate (§3.1.2). We present a technique for Wi-Fi that leverages the inner workings of the Wi-Fi MAC layer, and we discuss options for cellular networks.

5.1 Wi-Fi

We describe how an 802.11n access point (AP) can estimate the average link rate. For simplicity, we first describe our solution when there is a single user (client) connected to the AP. Next, we describe the multi-user case.

We define *link rate* as the potential throughput of the user (i.e., the MAC address of the Wi-Fi client) if it was backlogged at the AP, i.e., if the user never ran out of packets at the AP. In case the router queue goes empty at the AP, the achieved throughput will be less than the link rate.

Challenges: A strawman would be to estimate the link rate using the physical layer bit rate selected for each transmission, which would depend on the modulation and channel code used for the transmission. Unfortunately, this method will overestimate the link rate as the packet transmission times are governed not only by the bitrate, but also by delays for additional tasks (e.g., channel contention and retransmissions [12]). An alternative approach would be to use the fraction of time that the router queue was backlogged as a proxy for link utilization. However, the Wi-Fi MAC's packet batching confounds this approach. Wi-Fi routers transmit packets (frames) in batches; a new batch is transmitted only after receiving an ACK for the last batch. The AP may accumulate packets while waiting for a link-layer ACK; this queue buildup does not necessarily imply that the link is fully utilized. Thus, accurately measuring the link rate requires a detailed consideration of Wi-Fi's packet transmission protocols.

Understanding batching: In 802.11n, data frames, also known as MAC Protocol Data Units (MPDUs), are transmitted in batches called A-MPDUs (Aggregated MPDUs). The maximum number of frames that can be included in a single batch, M, is negotiated by the receiver and the router. When the user is not backlogged, the router might not have enough data to send a full-sized batch of M frames, but will instead use a smaller batch of size $b < M$. Upon receiving a batch, the receiver responds with a single Block ACK. Thus, at a time t, given a batch size of b frames, a frame size of S bits,[7] and an ACK inter-arrival time (i.e., the time between receptions of consecutive block ACKs) of $T_{IA}(b,t)$, the current dequeue rate, $cr(t)$, may be estimated as

$$cr(t) = \frac{b \cdot S}{T_{IA}(b,t)}. \tag{5}$$

When the user is backlogged and $b = M$, then $cr(t)$ above will be equal to the link capacity. However, if the user is not backlogged and $b < M$, how can the AP estimate the link capacity? Our approach calculates $\hat{T}_{IA}(M,t)$, the estimated ACK inter-arrival time *if the user was backlogged and had sent M frames in the last batch.*

We estimate the link capacity, $\hat{\mu}(t)$, as

$$\hat{\mu}(t) = \frac{M \cdot S}{\hat{T}_{IA}(M,t)}. \tag{6}$$

To accurately estimate $\hat{T}_{IA}(M,t)$, we turn to the relationship between the batch size and ACK inter-arrival time. We can

[7] For simplicity, we assume that all frames are of the same size, though our formulas can be generalized easily for varying frame sizes.

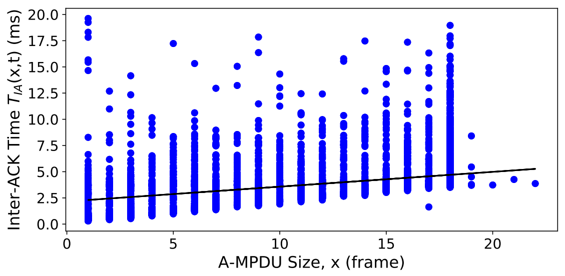

Figure 5: **Inter-ACK time v. batch (A-MPDU) size —** Inter-ACK times for a given batch size exhibits variation. The solid black line represents the average Inter-ACK time. The slope of the line is S/R, where S is the frame size in bits and R is the link rate in bits per second.

decompose the ACK interval time into the batch transmission time and "overhead" time, the latter including physically receiving an ACK, contending for the shared channel, and transmitting the physical layer preamble [21]. Each of these overhead components is independent of the batch size. We denote the overhead time by $h(t)$. If R is the bitrate used for transmission, the router's ACK inter-arrival time is

$$T_{IA}(b,t) = \frac{b \cdot S}{R} + h(t). \tag{7}$$

Fig. 5 illustrates this relationship empirically. There are two key properties to note. First, for a given batch size, the ACK inter-arrival times vary due to overhead tasks. Second, because the overhead time and batch size are independent, connecting the average values of ACK inter-arrival times across all considered batch sizes will produce a line with slope S/R. Using this property along with Equation (7), we can estimate the ACK inter-arrival time for a backlogged user as

$$\begin{aligned}\hat{T_{IA}}(M,t) &= \frac{M \cdot S}{R} + h(t)\\ &= T_{IA}(b,t) + \frac{(M-b) \cdot S}{R}.\end{aligned} \tag{8}$$

We can then use $\hat{T}_{IA}(M,t)$ to estimate the link capacity with Equation (6). This computation is performed for each batch transmission when the batch ACK arrives, and passed through a weighted moving average filter over a sliding window of time T to estimate the smoothed time-varying link rate. T must be greater than the inter-ACK time (up to 20 ms in Fig. 5); we use $T = 40$ ms. Because ABC cannot exceed a rate-doubling per RTT, we cap the predicted link rate to double the current rate (dashed slanted line in Fig. 5).

To evaluate the accuracy of our link rate estimates, we transmit data to a single client through our modified ABC router (§7.1) at multiple different rates over three Wi-Fi links (with different modulation and coding schemes). Fig. 6 summarizes the accuracy of the ABC router's link rate estimates. With this method, the ABC Wi-Fi router is able to predict link rates within 5% of the true link capacities.

Extension to multiple users. In multi-user scenarios, each receiver will negotiate its own maximum batch size (M) with the router, and different users can have different transmission rates. We now present two variants of our technique for (1) when the router uses per-user queues to schedule packets of different users, and (2) when the users share a single FIFO (first-in first-out) queue at the router.

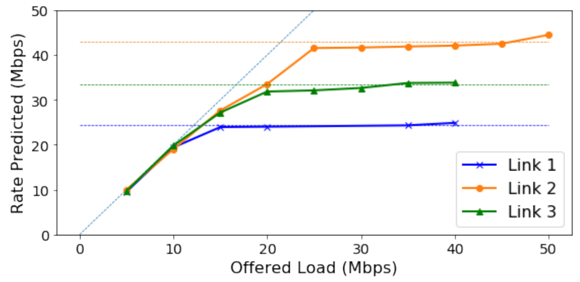

Figure 6: **Wi-Fi Link Rate Prediction —** ABC router link rate predictions for a user that was not backlogged and sent traffic at multiple different rates over three different Wi-Fi links. Horizontal lines represent the true link capacity, solid lines summarize the ABC router's link capacity prediction (each point is an average over 30 seconds of predictions), and the dashed slanted line represents the prediction rate caps. ABC's link rate predictions are within 5% of the ground truth across most sending rates (given the prediction cap).

Per-user queues. In this case each user calculates a separate link rate estimate. Recall that the link rate for a given user is defined as the potential throughput of the user if it was backlogged at the router. To determine the link rate for a user x, we repeat the single-user method for the packets and queue of user x alone, treating transmissions from other users as overhead time. Specifically, user x uses Equations (8) and (6) to compute its link rate ($\hat{\mu}_x(t)$) based on its own values of the bit rate (R_x) and maximum batch size (M_x). It also computes its current dequeue rate ($cr_x(t)$) using Equation (5) to calculate the accel-brake feedback. The inter-ACK time ($T_{IA_x}(b,t)$), is defined as the time between the reception of consecutive block-ACKs for user x. Thus, the overhead time ($h_x(t)$) includes the time when other users at the same AP are scheduled to send packets. Fairness among different users is ensured via scheduling users out of separate queues.

Single queue. In this case the router calculates a single aggregate link rate estimate. The inter-ACK time here is the time between two consecutive block-ACKs, regardless of the user to which the block-ACKs belong to. The router tries to match the aggregate rate of the senders to the aggregate link rate, and uses the aggregate current dequeue rate to calculate accel-brake feedback.

5.2 Cellular Networks

Cellular networks schedule users from separate queues to ensure inter-user fairness. Each user will observe a different link rate and queuing delay. As a result, every user requires a separate target rate calculation at the ABC router. The 3GPP cellular standard [1] describes how scheduling information at the cellular base station can be used to calculate per-user link rates. This method is able to estimate capacity even if a given user is not backlogged at the base station, a key property for the target rate estimation in Equation (1).

6 Discussion

We discuss practical issues pertaining to ABC's deployment.

Delayed Acks: To support delayed ACKs, ABC uses byte counting at the sender; the sender increases/decreases its window by the new bytes ACKed. At the receiver, ABC uses the state machine from DCTCP [6] for generating ACKs and echoing accel/brake marks. The receiver maintains the state of the last packet (accel or brake). Whenever the state changes, the receiver sends an ACK with the new state. If the receiver is in the same state after receiving m packets (the number of ACKs to coalesce), then it sends a delayed ACK with the current state. Our TCP implementation and the experiments in §7 use delayed ACKs with $m = 2$.

Lost ACKs: ABC's window adjustment is robust to ACK losses. Consider a situation where the sender receives a fraction $p < 1$ of the ACKs. If the accelerate fraction at the router is f, the current window of the sender is w_{abc}, then in the next RTT, the change in congestion window of the sender is $fpw_{abc} - (1-f)pw_{abc} = (2f-1)pw_{abc}$. As a result, lost ACKs only slow down the changes in the congestion window, but whether it increases or decreases doesn't depend on p.

ABC routers don't change prior ECN marks: ABC routers don't mark accel-brake on incoming packets that contain ECN marks set by an upstream non-ABC router. Since packets with ECN set can't convey accel-brake marks, they can slow down changes in w_{abc} (similar to lost ACKs). In case the fraction of packets with ECN set is small, then, the slow down in changes to w_{abc} will be small. If the fraction is large, then the non-ABC router is the likely bottleneck, and the sender will not use w_{abc}.

ECN routers clobbering ABC marks: An ECN router can overwrite accel-brake marks. The ABC sender will still track the non-ABC window, w_{nonabc}, but such marks can slow down adjustment to the ABC window, w_{abc}.

ABC on fixed-rate links: ABC can also be deployed on fixed-rate links. On such links, its performance is similar to prior explicit schemes like XCP.

7 Evaluation

We evaluate ABC by considering the following properties:

1. **Performance:** We measure ABC's ability to achieve low delay and high throughput and compare ABC to end-to-end schemes, AQM schemes, and explicit control schemes (§7.3).
2. **Multiple Bottlenecks:** We test ABC in scenarios with multiple ABC bottlenecks and mixtures of ABC and non-ABC bottlenecks (§7.4).
3. **Fairness:** We evaluate ABC's fairness while competing against other ABC and non-ABC flows (§7.5).
4. **Additional Considerations:** We evaluate how ABC performs with application-limited flows and different network delays. We also demonstrate ABC's impact on a real application's performance (§7.6).

7.1 Prototype ABC Implementation

ABC transport: We implemented ABC endpoints in Linux as kernel modules using the pluggable TCP API.

ABC router: We implemented ABC as a Linux queuing discipline (qdisc) kernel module using OpenWrt, an open source operating system for embedded networked devices [18]. We used a NETGEAR WNDR 3800 router configured to 802.11n. We note that our implementation is portable as OpenWrt is supported on many other commodity Wi-Fi routers.

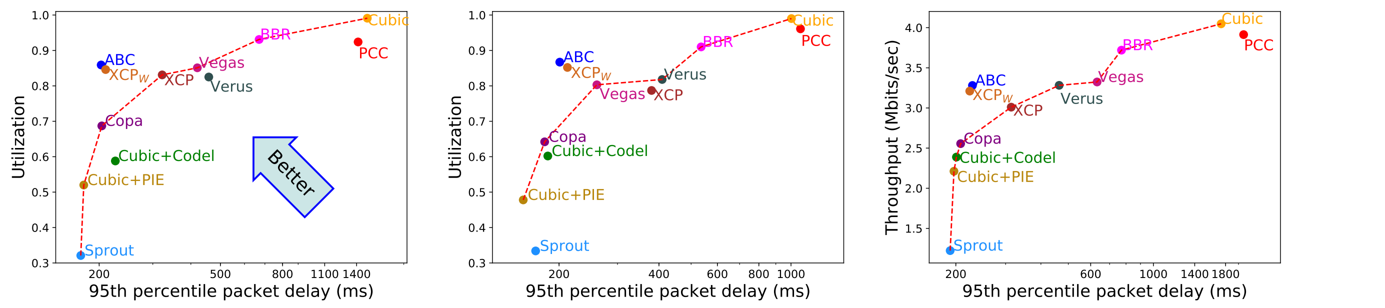
ABC's WiFi link rate estimation exploits the inner workings of the MAC 802.11n protocol, and thus requires fine-grained values at this layer. In particular, the ABC qdisc must know A-MPDU sizes, Block ACK receive times, and packet transmission bitrates. These values are not natively exposed to Linux router qdiscs, and instead are only available at the network driver. To bridge this gap, we modified the router to log the relevant MAC layer data in the cross-layer socket buffer data structure (skb) that it already maintains per packet.

7.2 Experimental Setup

We evaluated ABC in both Wi-Fi and cellular network settings. For Wi-Fi, experiments we used a live Wi-Fi network and the ABC router described in §7.1. For cellular settings, we use Mahimahi [35] to emulate multiple cellular networks (Verizon LTE, AT&T, and TMobile). Mahimahi's emulation uses packet delivery traces (separate for uplink and downlink) that were captured directly on those networks, and thus include outages (highlighting ABC's ability to handle ACK losses).

We compare ABC to end-to-end protocols designed for cellular networks (Sprout [46] and Verus [50]), loss-based end-to-end protocols both with and without AQM (Cubic [23], Cubic+Codel [36], and Cubic+PIE [37]), recently-proposed end-to-end protocols (BBR [14], Copa [10], PCC Vivace-Latency (referred as PCC)) [16]), and TCP Vegas [13]), and explicit control protocols (XCP [29], RCP [43] and VCP [47]). We used TCP kernel modules for ABC, BBR, Cubic, PCC, and Vegas; for these schemes, we generated traffic using iperf [44]. For the end-to-end schemes that are not implemented as TCP kernel modules (i.e., Copa, Sprout, Verus), we used the UDP implementations provided by the authors. Lastly, for the explicit control protocols (i.e., XCP, RCP, and VCP), we used our own implementations as qdiscs with Mahimahi to ensure compatibility with our emulation setup. We used Mahimahi's support of Codel and Pie to evaluate AQM.

Our emulated cellular network experiments used a minimum RTT of 100 ms and a buffer size of 250 MTU-sized packets. Additionally, ABC's target rate calculation (Equation (1)) used $\eta = 0.98$ and $\delta = 133$ ms. Our Wi-Fi implementation uses the link rate estimator from §5, while our emulated cellular network setup assumes the realistic scenario that ABC's router has knowledge of the underlying link capacity [1].



(a) Downlink (b) Uplink (c) Uplink+Downlink

Figure 7: **ABC vs. previous schemes on three Verizon cellular network traces —** In each case, ABC outperforms all other schemes and sits well outside the Pareto frontier of previous schemes (denoted by the dashed lines).

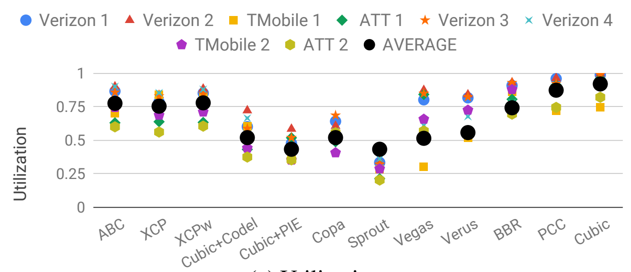
7.3 Performance

Cellular: Fig. 7a and 7b show the utilization and 95^{th} percentile per packet delay that a single backlogged flow achieves using each aforementioned scheme on two Verizon LTE cellular link traces. ABC exhibits a better (i.e., higher) throughput/delay tradeoff than all prior schemes. In particular, ABC sits well outside the Pareto frontier of the existing schemes, which represents the prior schemes that achieve higher throughput or lower delay than any other prior schemes.

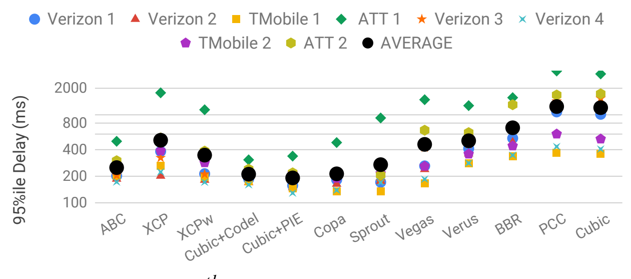
Further analysis of Fig. 7a and 7b reveals that Cubic+Codel, Cubic+PIE, Copa, and Sprout are all able to achieve low delays that are comparable to ABC. However, these schemes heavily underutilize the link. The reason is that, though these schemes are able to infer and react to queue buildups in a way that reduces delays, they lack a way of quickly inferring increases in link capacity (a common occurrence on time-varying wireless links), leading to underutilization. In contrast, schemes like BBR, Cubic, and PCC are able to rapidly saturate the network (achieving high utilization), but these schemes also quickly fill buffers and thus suffer from high queuing delays. Unlike these prior schemes, ABC is able to quickly react to *both* increases and decreases in available link capacity, enabling high throughput and low delays.

We observed similar trends across a larger set of 8 different cellular network traces (Fig. 8). ABC achieves 50% higher throughput than Cubic+Codel and Copa, while only incurring 17% higher 95^{th} percentile packet delays. PCC and Cubic achieve slightly higher link utilization values than ABC (12%, and 18%, respectively), but incur significantly higher per-packet delays than ABC (394%, and 382%, respectively). Finally, compared to BBR, Verus, and Sprout, ABC achieves higher link utilization (4%, 39%, and 79%, respectively). BBR and Verus incur higher delays (183% and 100%, respectively) than ABC. Appendix E shows mean packet delay over the same conditions, and shows the same trends.

Comparison with Explicit Protocols: Fig. 7 and 8 also show that ABC outperforms the explicit control protocol, XCP, despite not using multi-bit per-packet feedback as XCP does. For XCP we used $\alpha = 0.55$ and $\beta = 0.4$, the highest permissible stable values that achieve the fastest possible link rate convergence. XCP achieves similar average throughput to ABC, but with 105% higher 95^{th} percentile delays. This performance discrepancy can be attributed to the fact that ABC's control rule is better suited for the link rate variations in wireless networks. In particular, unlike ABC which updates its feedback on every packet, XCP computes aggregate feedback values (ϕ) only once per RTT and may thus take an entire RTT to inform a sender to reduce its window. To overcome this, we also considered an improved version of XCP that recomputes aggregate feedback on each packet based on the rate and delay measurements from the past RTT; we refer to this version as XCP_w (short for XCP wireless). As shown in Fig. 7 and Fig. 8, XCP_w reduces delay compared to XCP, but still incurs 40% higher 95^{th} percentile delays (averaged across traces) than ABC. We also compared with two other explicit schemes, RCP and VCP, and found that ABC consistently outperformed both, achieving 20% more utilization on average. (Appendix F).

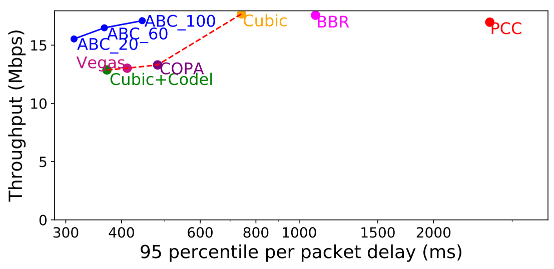


(a) Utilization

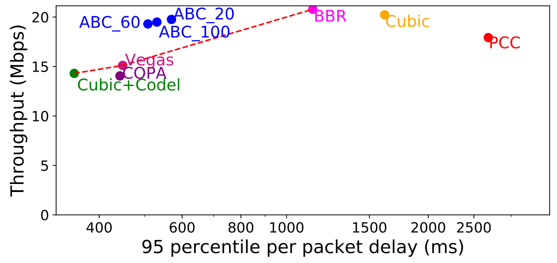


(b) 95^{th} percentile per-packet delay

Figure 8: **95^{th} percentile per-packet delay across 8 cellular link traces —** On average, ABC achieves similar delays and 50% higher utilization than Copa and Cubic+Codel. PCC and Cubic achieve slightly higher throughput than ABC, but incur 380% higher 95^{th} percentile delay than ABC.



(a) Single user



(b) Two users, shared queue

Figure 9: **Throughout and mean delay on Wi-Fi —** For the multi-user scenario, we report the sum of achieved throughputs and the average of observed 95th percentile delay across both users. We consider three versions of ABC (denoted ABC _*) for different delay thresholds. All versions of ABC outperform all prior schemes and sit outside the pareto frontier.

Wi-Fi: We performed similar evaluations on a live Wi-Fi link, considering both single and multi-user scenarios. We connect senders to a WiFi router via Ethernet. Each sender transmits data through the WiFi router to one receiver. All receivers' packets share the same FIFO queue at the router. In this experiment, we excluded Verus and Sprout as they are designed specifically for cellular networks. To mimic common Wi-Fi usage scenarios where endpoints can move and create variations in signal-to-noise ratios (and thus bitrates), we varied the Wi-Fi router's bitrate selections by varying the MCS index using the Linux `iw` utility; we alternated the MCS index between values of 1 and 7 every 2 seconds. In Appendix 16, we also list results for an experiment where we model MCS index variations as Brownian motion—results show the same trends as described below. This experiment was performed in a crowded computer lab with contention from other Wi-Fi networks. We report average performance values across three, 45 second runs. We considered three different ABC delay threshold (d_t) values of 20 ms, 60 ms, and 100 ms; note that increasing ABC's delay threshold will increase both observed throughput and RTT values.

Fig. 9 shows the throughput and 95th percentile per-packet delay for each protocol. For the multi-user scenario, we report the sum of achieved throughputs and the average 95th percentile delay across all users. In both the single and multi-user scenarios, ABC achieves a better throughput/delay tradeoff than all prior schemes, and falls well outside the Pareto frontier for those schemes. In the single user scenario, the ABC configuration with $d_t = 100$ ms achieves up to 29% higher throughput than Cubic+Codel, Copa and Vegas. Though PCC-Vivace, Cubic and BBR achieve slightly higher throughput (4%) than this ABC configuration, their delay values are considerably higher (67%-6×). The multi-user scenario showed similar results. For instance, ABC achieves 38%, 41% and 31% higher average throughput than Cubic+Codel, Copa and Vegas, respectively.

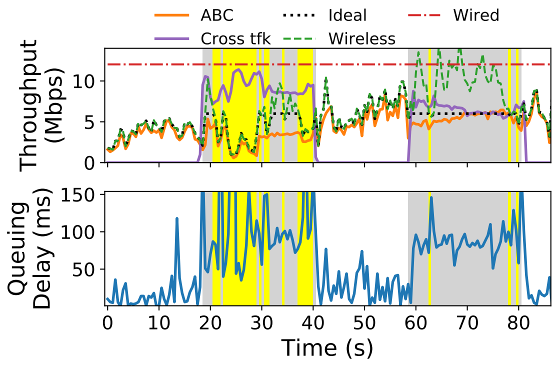


Figure 10: **Coexistence with non-ABC bottlenecks —** ABC tracks the ideal rate closely (fair share) and reduces queuing delays in the absence of cross traffic (white region).

7.4 Coexistence with Various Bottlenecks

Coexistence with ABC bottlenecks: Fig. 7c compares ABC and prior protocols on a network path with two cellular links. In this scenario, ABC tracks the bottleneck link rate and achieves a better throughput/delay tradeoff than prior schemes, and again sits well outside the Pareto frontier.

Coexistence with non-ABC bottlenecks: Fig. 10 illustrates throughput and queuing delay values for an ABC flow traversing a network path with both an emulated wireless link and an emulated 12 Mbits/s fixed rate (wired) link. The wireless link runs ABC, while the wired link operates a droptail buffer. ABC shares the wired link with on-off cubic cross traffic. In the absence of cross traffic (white region), the wireless link is always the bottleneck. However, with cross traffic (yellow and grey regions), due to contention, the wired link can become the bottleneck. In this case, ABC's fair share on the wired link is half of the link's capacity (i.e., 6 Mbit/s). If the wireless link rate is lower than the fair share on the wired link (yellow region), the wireless link remains the bottleneck; otherwise, the wired link becomes the bottleneck (grey region).

The black dashed line in the top graph represents the ideal fair throughput for the ABC flow throughout the experiment. As shown, in all regions, ABC is able to track the ideal rate closely, even as the bottleneck shifts. In the absence of cross traffic, ABC achieves low delays while maintaining high link utilization. With cross traffic, ABC appropriately tracks the wireless link rate (yellow region) or achieves its fair share of the wired link (grey region) like Cubic. In the former cross traffic scenario, increased queuing delays are due to congestion caused by the Cubic flow on the wired link. Further, deviations from the ideal rate in the latter cross traffic scenario can

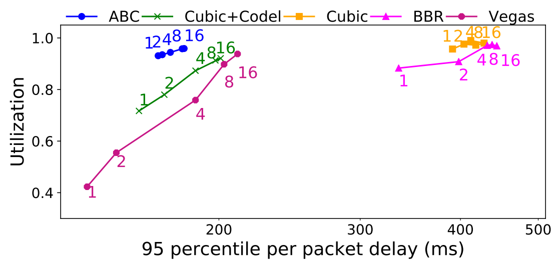

Figure 11: **Coexistence among ABC flows —** ABC achieves similar aggregate utilization and delay irrespective of the number of connections. ABC outperforms all previous schemes.

be attributed to the fact that the ABC flow is running as Cubic, which in itself takes time to converge to the fair share [23].

7.5 Fairness among ABC and non-ABC flows

Coexistence among ABC flows: We simultaneously run multiple ABC flows on a fixed 24 Mbits/s link. We varied the number of competing flows from 2 to 32 (each run was 60 s). In each case, the Jain Fairness Index [28] was within 5% from the ideal fairness value of 1, highlighting ABC's ability to ensure fairness.

Fig. 11 shows the aggregate utilization and delay for concurrent flows (all flows running the same scheme) competing on a Verizon cellular link. We varied the number of competing flows from 1 to 16. ABC achieves similar aggregate utilization and delay across all scenarios, and, outperforms all other schemes. For all the schemes, the utilization and delay increase when the number of flows increases. For ABC, this increase can be attributed to the additional packets that result from additive increase (1 packet per RTT per flow). For other schemes, this increase is because multiple flows in aggregate ramp-up their rates faster than a single flow.

RTT Unfairness: We simultaneously ran 2 ABC flows on a 24 Mbits wired bottleneck. We varied the RTT of flow 1 from 20ms to 120ms. RTT of flow 2 was fixed to 20ms. Fig. 12 shows the ratio of the average throughput of these 2 flows (average throughput of flow 2 / flow 1, across 5 runs) against the ratio of their RTTs (RTT of flow 1 / flow 2). Increasing the RTT ratio increases the throughput ratio almost linearly and the throughput is inversely proportional to the RTT. Thus, the unfairness is similar to existing protocols like Cubic.

Next, we simultaneously ran 6 ABC flows. The RTT of the flows vary from 20ms to 120ms. Table 1 shows the RTT and the average throughput across 5 runs. Flows with higher RTTs have lower throughput. However, note that the flow with the highest RTT (120ms) still achieves ∼35 % of the throughput as flow with the lowest RTT (20ms).

Coexistence with non-ABC flows: We consider a scenario where 3 ABC and 3 non-ABC (in this case, Cubic) long-lived flows share the same 96 Mbits/s bottleneck link. In addition, we create varying numbers of non-ABC short flows (each of size 10 KB) with Poisson flow arrival times to offer a fixed average load. We vary the offered load values, and report

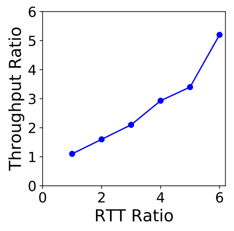

Figure 12: **RTT unfairness**

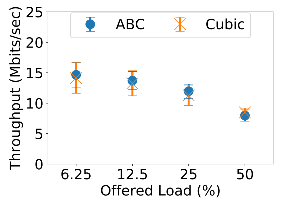
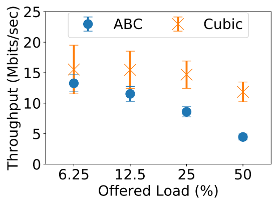
RTT (ms)	Tput (Mbps)
20	6.62
40	4.94
60	4.27
80	3.0
100	2.75
120	2.40

Table 1: **RTT unfairness**



(a) ABC



(b) RCP's Zombie List

Figure 13: **Coexistence with non-ABC flows —** Across all scenarios, the standard deviation for ABC flows is small and the flows are fair to each other. Compared to RCP's Zombie List strategy, ABC's max-min allocation provides better fairness between ABC and non-ABC flows. With ABC's strategy, the difference in average throughput of ABC and Cubic flows is under 5%.

results across 10 runs (40 seconds each). We compare ABC's strategy to coexist with non-ABC flows to RPC's Zombie list approach (§4.3).

Fig. 13 shows the mean and standard deviation of throughput for long-lived ABC and Cubic flows. As shown in Fig. 13a, ABC's coexistence strategy allows ABC and Cubic flows to fairly share the bottleneck link across all offered load values. Specifically, the difference in average throughput between the ABC and Cubic flows is under 5%. In contrast, Fig. 13b shows that RCP's coexistence strategy gives higher priority to Cubic flows. This discrepancy increases as the offered load increases, with Cubic flows achieving 17-165% higher throughput than ABC flows. The reason, as discussed in §4.3, is that long-lived Cubic flows receive higher throughput than the average throughput that RCP estimates for Cubic flows. This leads to unfairness because RCP attempts to match average throughput for each scheme.Fig. 13 also shows that the standard deviation of ABC flows is small (under 10%) across all scenarios. This implies that in each run of the experiment, the throughput for each of the three concurrent ABC flows is close to each other, implying fairness across ABC flows. Importantly, the standard deviation values for ABC are smaller than those for Cubic. Thus, ABC flows converge to fairness faster than Cubic flows do.

7.6 Additional Results

ABC's sensitivity to network latency: Thus far, our emulation experiments have considered fixed minimum RTT values of 100 ms. To evaluate the impact that propagation delay on ABC's performance, we repeated the experiment from Fig. 8 on the RTT values of 20 ms, 50 ms, 100 ms, and 200 ms. Across all RTTs, ABC outperforms all prior schemes, again achieving a more desirable throughput/latency trade off (see Appendix G).

Application-limited flows: We created a single long-lived ABC flow that shared a cellular link with 200 application-limited ABC flows that send traffic at an aggregate of 1 Mbit/s. Despite the fact that the application-limited flows do not have traffic to properly respond to ABC's feedback, the ABC flows (in aggregate) still achieve low queuing delays and high link utilization. See Appendix G for details.

Perfect future capacity knowledge: We considered a variant of ABC, PK-ABC, which knows an entire emulated link trace in advance. This experiment reflects the possibility of resource allocation predictions at cellular base stations. Rather than using an estimate of the current link rate to compute a target rate (as ABC does), PK-ABC uses the expected link rate 1 RTT in the future. On the same setup as Fig. 7b, PK-ABC reduces 95^{th} percentile per-packet-delays from 97 ms to 28 ms, compared to ABC, while achieving similar utilization (~90%).

ABC's improvement on real applications: We evaluated ABC's improvement for real user-facing applications on a multiplayer interactive game, Slither.io [3]. We loaded Slither.io using a Google Chrome browser which ran inside an emulated cellular link with a background backlogged flow. We considered three schemes for the backlogged flow: Cubic, Cubic+Codel, and ABC. Cubic fully utilizes the link, but adds excessive queuing delays hindering gameplay. Cubic+Codel reduces queuing delays (improving user experience in the game), but underutilizes the link. Only ABC is able to achieve both high link utilization for the backlogged flow and low queuing delays for the game. A video demo of this experiment can be viewed at `https://youtu.be/Dauq-tfJmyU`.

Impact of η: This parameter presents a trade-off between throughput and delay. Increasing η increases the throughput but at the cost of additional delay (see Appendix B).

8 Related Work

Several prior works have proposed using LTE infrastructure to infer the underlying link capacity [26, 33, 48]. CQIC [33] and piStream [48] use physical layer information at the receiver to estimate link capacity. However, these approaches have several limitations that lead to inaccurate estimates. CQIC's estimation approach considers historical resource usage (not the available physical resources) [48], while piStream's technique relies on second-level video segment downloads and thus does not account for the short timescale variations in link rate required for per-packet congestion control. These inaccuracies stem from the opacity of the base station's resource allocation process at the receiver. ABC circumvents these issues by accurately estimating link capacity directly at the base station.

In VCP [47], router classifies congestion as low, medium, or high, and signals the sender to either perform a multiplicative increase, additive increase, or multiplicative decrease in response. Unlike an ABC sender, which reacts to ACKs individually, VCP senders act once per RTT. This coarse-grained update limits VCP's effectiveness on time-varying wireless paths. For instance, it can take 12 RTTs to double the window. VCP is also incompatible with ECN, making it difficult to deploy.

In BMCC [39, 40], a router uses ADPM [9] to send link load information to the receiver on ECN bits, relying on TCP options to relay the feedback from the receiver to the sender. MTG proposed modifying cellular base stations to communicate the link rate explicitly using a new TCP option [26]. Both approaches do not work with IPSec encryption [30], and such packet modifications trigger the risk of packets being dropped silently by middleboxes [25]. Moreover, unlike ABC, MTG does not ensure fairness among multiple flows for a user, while BMCC has the same problem with non-BMCC flows [38, 39].

XCP-b [4] is a variant of XCP designed for wireless links with unknown capacity. XCP-b routers use the queue size to determine the feedback. When the queue is backlogged, the XCP-b router calculates spare capacity using the change in queue size and uses the same control rule as XCP. When the queue goes to zero, XCP-b cannot estimate spare capacity, and resorts to a blind fixed additive increase. Such blind increase can cause both under-utilization and increased delays (§2.)

Although several prior schemes (XCP, RCP, VCP, BMCC, XCP-b) attempt to match the current enqueue rate to the capacity, none match the future enqueue rate to the capacity, and so do not perform as well as ABC on time-varying links.

9 Conclusion

This paper presented a simple new explicit congestion control protocol for time-varying wireless links called ABC. ABC routers use a single bit to mark each packet with "accelerate" or "brake", which causes senders to slightly increase or decrease their congestion windows. Routers use this succinct feedback to quickly guide senders towards a desired target rate. ABC outperforms the best existing explicit flow control scheme, XCP, but unlike XCP, ABC does not require modifications to packet formats or user devices, making it simpler to deploy. ABC is also incrementally deployable: ABC can operate correctly with multiple ABC and non-ABC bottlenecks, and can fairly coexist with ABC and non-ABC traffic sharing the same bottleneck link. We evaluated ABC using a WiFi router implementation and trace-driven emulation of cellular links. ABC achieves 30-40% higher throughput than Cubic+Codel for similar delays, and 2.2× lower delays than BBR on a Wi-Fi path. On cellular network paths, ABC achieves 50% higher throughput than Cubic+Codel.

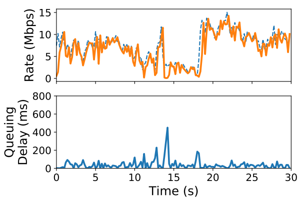
(a) BBR



(b) ABC

Figure 14: **Comparison with BBR —** BBR overshoots the link capacity, causing excessive queuing. Same setup as Fig. 1.

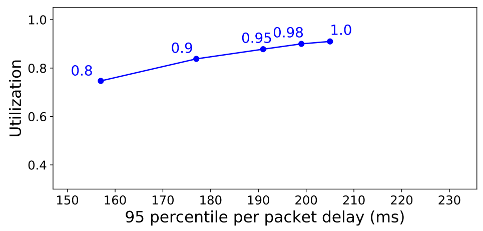


Figure 15: **Impact of** η **—** Performance of ABC with various values of η (target utilization). η presents a trade-off between throughput and delay. Same setup as Fig. 1.

A BBR overestimates the sending rate

Fig. 14 shows the throughput and queuing delay of BBR on a Verizon cellular trace. BBR periodically increases its rate in short pulses, and frequently overshoots the link capacity with variable-bandwidth links, causing excessive queuing.

B Impact of η

Fig. 15 shows the performance of ABC with various values of η on a Verizon cellular trace. Increasing η increases the link utilization, but, also increases the delay. Thus, η presents a trade-off between throughput and delay.

C Stability Analysis

This section establishes the stability bounds for ABC's control algorithm (Theorem 1).

Model: Consider a single ABC link, traversed by N ABC flows. Let $\mu(t)$ be the link capacity at time t. As $\mu(t)$ can be time-varying, we define stability as follows. Suppose that at some time t_0, $\mu(t)$ stops changing, i.e., for $t > t_0$ $\mu(t) = \mu$ for some constant μ. We aim to derive conditions on ABC's parameters which guarantee that the aggregate rate of the senders and the queue size at the routers will converge to certain fixed-point values (to be determined) as $t \to \infty$.

Let τ be the common round-trip propagation delay on the path for all users. For additive increase (§4.3), assume that each sender increases its congestion window by 1 every l seconds. Let $f(t)$ be the fraction of packets marked accelerate, and, $cr(t)$ be the dequeue rate at the ABC router at time t. Let τ_r be time it takes accel-brake marks leaving the ABC router to reach the sender. Assuming that there are no queues other than at the ABC router, τ_r will be the sum of the propagation delay between ABC router and the receiver and the propagation delay between receiver and the senders. The aggregate incoming rate of ACKs across all the senders at time t, $R(t)$, will be equal to the dequeue rate at the router at time $t - \tau_r$:

$$R(t) = cr(t - \tau_r). \tag{9}$$

In response to an accelerate, a sender will send 2 packets, and, for a brake, a sender won't send anything. In addition to responding to accel-brakes, each sender will also send an additional packet every l seconds (because of AI). Therefore, the aggregate sending rate for all senders at time t, $S(t)$, will be

$$\begin{aligned} S(t) &= R(t) \cdot 2 \cdot f(t - \tau_r) + \frac{N}{l} \\ &= 2cr(t - \tau_r) f(t - \tau_r) + \frac{N}{l}. \end{aligned} \tag{10}$$

Substituting $f(t - \tau_r)$ from Equation (2), we get

$$S(t) = tr(t - \tau_r) + \frac{N}{l}. \tag{11}$$

Let τ_f be the propagation delay between a sender and the ABC router, and $eq(t)$ be the enqueue rate at the router at time t. Then $eq(t)$ is given by

$$\begin{aligned} eq(t) &= S(t - \tau_f) \\ &= tr(t - (\tau_r + \tau_f)) + \frac{N}{l} \\ &= tr(t - \tau) + \frac{N}{l}. \end{aligned} \tag{12}$$

Here, $\tau = \tau_r + \tau_f$ is the round-trip propagation delay.

Let $q(t)$ be the queue size, and, $x(t)$ be the queuing delay at time t:

$$x(t) = \frac{q(t)}{\mu}.$$

Ignoring the boundary conditions for simplicity ($q(t)$ must be ≥ 0), the queue length has the following dynamics:

$$\begin{aligned} \dot{q}(t) &= eq(t) - \mu \\ &= tr(t - \tau) + \frac{N}{l} - \mu \\ &= \left((\eta - 1) \cdot \mu + \frac{N}{l} \right) - \frac{\mu}{\delta} (x(t - \tau) - d_t)^+, \end{aligned}$$

where in the last step we have used Equation (1). Therefore the dynamics of $x(t)$ can be described by:

$$\begin{aligned} \dot{x}(t) &= \left((\eta - 1) + \frac{N}{\mu \cdot l} \right) - \frac{1}{\delta} (x(t - \tau) - d_t)^+ \\ &= A - \frac{1}{\delta} (x(t - \tau) - d_t)^+, \end{aligned} \tag{13}$$

where $A = \left((\eta - 1) + \frac{N}{\mu \cdot l} \right)$, and, A is a constant given a fixed number of flows N. The delay-differential equation in Equation (13) captures the behavior of the entire system. We use it to analyze the behavior of the queuing delay, $x(t)$, which in turn informs the dynamics of the target rate, $tr(t)$, and enqueue rate, $eq(t)$, using Equations (1) and (12) respectively.

Stability: For stability, we consider two possible scenarios 1) $A<0$, and 2) $A \geq 0$. We argue the stability in each case.

Case 1: $A<0$. In this case, the stability analysis is straightforward. The fixed point for queuing delay, x^*, is 0. From Equation (13), we get

$$\dot{x}(t) = A - \frac{1}{\delta}(x(t-\tau)-d_t)^+ \leq A < 0. \tag{14}$$

The above equation implies that the queue delay will decrease at least as fast as A. Thus, the queue will go empty in a bounded amount of time. Once the queue is empty, it will remain empty forever, and the enqueue rate will converge to a fixed value. Using Equation (12), the enqueue rate can will converge to

$$\begin{aligned} eq(t) &= tr(t-\tau)+\frac{N}{l} \\ &= \eta\mu+\frac{N}{l}-\frac{\mu}{\delta}(x(t-\tau)-d_t)^+ \\ &= \eta\mu+\frac{N}{l} \\ &= (1+A)\mu. \end{aligned} \tag{15}$$

Note that $\eta\mu<(1+A)\mu<\mu$. Since both the enqueue rate and the queuing delay converge to fixed values, the system is stable for any value of δ.

Case 2: $A>0$: The fixed point for the queuing delay in this case is $x^* = A\cdot\delta + d_t$. Let $\tilde{x}(t) = x(t) - x^*$ be the deviation of the queuing delay from its fixed point. Substituting in Equation (13), we get

$$\begin{aligned} \dot{\tilde{x}}(t) &= A - \frac{1}{\delta}(\tilde{x}(t-\tau)+A\cdot\delta)^+ \\ &= -max(-A, \frac{1}{\delta}\tilde{x}(t-\tau)) \\ &= -g(\tilde{x}(t-\tau)), \end{aligned} \tag{16}$$

where $g(u) = \max(-A, \frac{1}{\delta}u)$ and $A>0$.

In [49] (Corollary 3.1), Yorke established that delay-differential equations of this type are globally asymptotically stable (i.e., $\tilde{x}(t) \to 0$ as $t \to \infty$ irrespective of the initial condition), if the following conditions are met:

1. $\mathbf{H}_1$**:** g is continuous.
2. $\mathbf{H}_2$**:** There exists some α, s.t. $\alpha\cdot u^2 > ug(u) > 0$ for all $u \neq 0$.
3. $\mathbf{H}_3$**:** $\alpha\cdot\tau < \frac{3}{2}$.

The function $g(\cdot)$ trivially satisfies $\mathbf{H}_1$. $\mathbf{H}_2$ holds for any $\alpha \in (\frac{1}{\delta}, \infty)$. Therefore, there exists an $\alpha \in (\frac{1}{\delta}, \infty)$ that satisfies both $\mathbf{H}_2$ and $\mathbf{H}_3$ if

$$\frac{1}{\delta}\cdot\tau < \frac{3}{2} \implies \delta > \frac{2}{3}\cdot\tau. \tag{17}$$

This proves that ABC's control rule is asymptotically stable if Equation (17) holds. Having established that $x(t)$ converges to $x^* = A\cdot\delta + d_t$, we can again use Equation (12) to derive the fixed point for the enqueue rate:

$$eq(t) = \eta\mu + \frac{N}{l} - \frac{\mu}{\delta}(x(t-\tau)-d_t)^+ \to \mu, \tag{18}$$

as $t \to \infty$.

Note while, we proved stability assuming that the feedback delay τ is a constant and the same value for all the senders, the proof works even if the senders have different time-varying feedback delays (see Corollary 3.2 in [49]). The modified stability criterion in this case is $\delta > \frac{2}{3}\cdot\tau^*$, where τ^* is the maximum feedback delay across all senders.

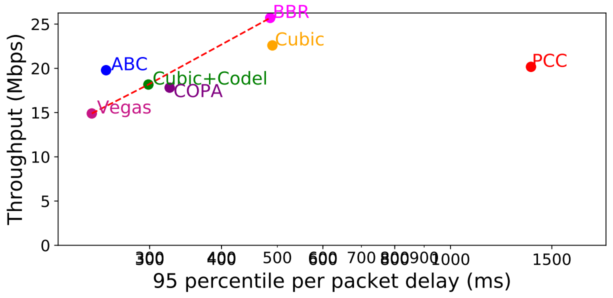

Figure 16: **Throughput and 95th percentile delay for a single user in WiFi —** We model changes in MCS index as bownian motion, with values changing every 2 seconds. We limit the MCS index values to be between 3 and 7. ABC outperforms all other schemes.

D Wi-Fi Evaluation

In this experiment we use the setup from Fig. 9a. To emulate movement of the receiver, we model changes in MCS index as brownian motion, with values changing every 2 seconds. Fig. 16 shows throughput and 95th percentile per packet delay for a number of schemes. Again, ABC outperforms all other schemes achieving better throughput and latency trade off.

E Low Delays and High Throughput

Fig. 17 shows the mean per packet delay achieved by various schemes in the experiment from Fig. 8. We observe the trend in mean delay is similar to that of 95th percentile delay (Fig. 8b). ABC achieves delays comparable to Cubic+Codel, Cubic+PIE and Copa. BBR, PCC Vivace-latency and Cubic incur 70-240% higher mean delay than ABC.

F ABC vs Explicit Control Schemes

In this section we compare ABC's performance with explicit congestion control schemes. We consider XCP, VCP, RCP and our modified implementation of XCP (XCP$_w$). For XCP

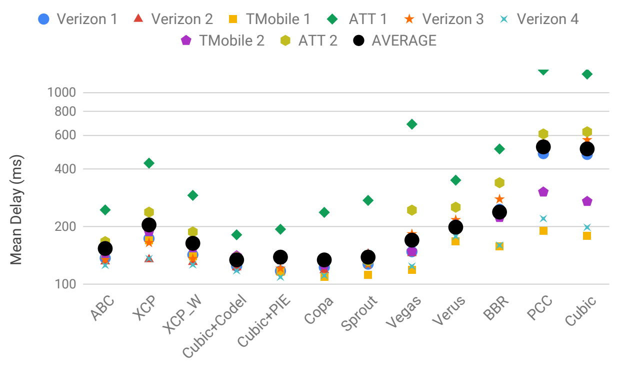

Figure 17: **Utilization and mean per-packet delay across 8 different cellular network traces —** On average, ABC achieves similar delays and 50% higher utilization than Copa and Cubic+Codel. BBR, PCC, and Cubic achieve slightly higher throughput than ABC, but incur 70-240% higher mean per-packet delays.

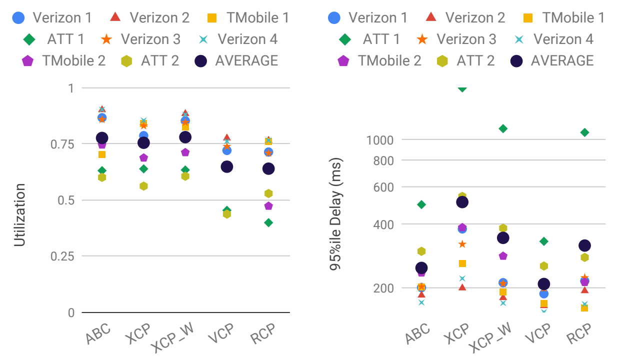


(a) Utilization (b) Delay

Figure 18: **ABC vs explicit flow control —** ABC achieves similar utilization and 95th percentile per-packet delay as XCP and XCP$_w$ across all traces. Compared to RCP and VCP, ABC achieves 20% more utilization.

and XCP$_w$, we used constant values of $\alpha = 0.55$ and $\beta = 0.4$, which the authors note are the highest permissible stable values that achieve the fastest possible link rate convergence. For RCP and VCP, we used the author-specified parameter values of $\alpha = 0.5$ and $\beta = 0.25$, and $\alpha = 1$, $\beta = 0.875$ and $\kappa = 0.25$, respectively. Fig. 18 shows utilizations and mean per packet delays achieved by each of these schemes over eight different cellular link traces. As shown, ABC is able to achieve similar throughput as the best performing explicit flow control scheme, XCP$_w$, without using multibit per-packet feedback. We note that XCP$_w$'s 95th percentile per-packet delays are 40% higher than ABC's. ABC is also able to outperform RCP and VCP. Specifically, ABC achieves 20% higher utilization than RCP. This improvement stems from the fact that RCP is a rate based protocol (not a window based protocol)—by signaling rates, RCP is slower to react to link rate fluctuations (Figure 19 illustrates this behavior). ABC also achieves 20% higher throughput than VCP, while incurring slightly higher delays. VCP also signals multiplicative-increase/multiplicative-decrease to the sender. But unlike ABC, the multiplicative increase/decrease constants are fixed. This coarse grained feedback limits VCP's performance on time varying links.

Fig. 19 shows performance of ABC, RCP and XCP$_w$ on a simple time varying link. The capacity alternated between 12 Mbit/sec and 24 Mbit/sec every 500 milliseconds. ABC and XCP$_w$ adapt quickly and accurately to the variations in bottleneck rate, achieving close to 100% utilization. RCP is a rate base protocol and is inherently slower in reacting to congestion. When the link capacity drops, RCP takes time to drain queues and over reduces its rates, leading to under-utilization.

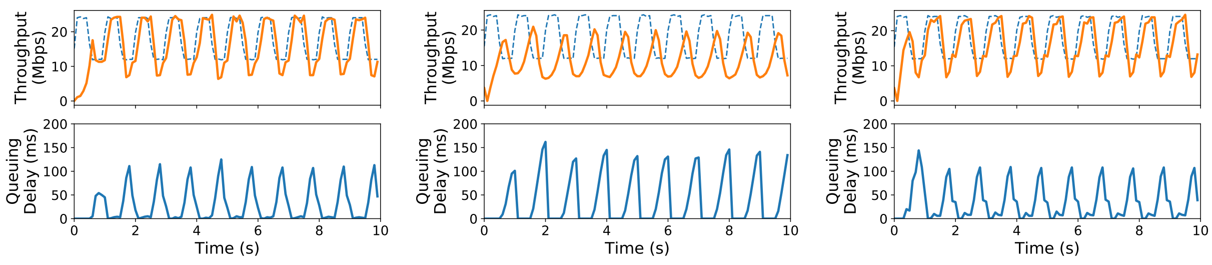
G Other experiments

Application limited flows

We created a single long-lived ABC flow that shared a cellular link with 200 application-limited ABC flows that send traffic at an aggregate of 1 Mbit/s. Fig. 20 shows that, despite the fact that the application-limited flows do not have traffic to properly respond to ABC's feedback, the ABC flows (in aggregate) are still able to achieve low queuing delays and high link utilization.

ABC's sensitivity to network latency:

Thus far, our emulation experiments have considered fixed minimum RTT values of 100 ms. To evaluate the impact that propagation delay has on ABC's performance, we used a modified version of the experimental setup from Fig. 8. In particular, we consider RTT values of 20 ms, 50 ms, 100 ms, and 200 ms. Fig. 21 shows that, across all propagation delays, ABC is still able to outperform all prior schemes, again achieving a more desirable throughput/latency trade off. ABC's benefits persist even though schemes like Cubic+Codel and Cubic+PIE actually improve with decreasing propagation delays. Performance with these schemes improves because bandwidth delay products decrease, making Cubic's additive increase more aggressive (improving link utilization).



(a) ABC (b) RCP (c) XCP$_w$

Figure 19: **Time series for explicit schemes —** We vary the link capacity every 500ms between two rates 12 Mbit/sec and 24 Mbit/sec.The dashed blue in the top graph represents bottleneck link capacity. ABC and XCP$_w$ adapt quickly and accurately to the variations in bottleneck rate, achieving close to 100% utilization. RCP is a rate base protocol and is inherently slower in reacting to congestion. When the link capacity drops, RCP takes time to drain queues and over reduces its rates, leading to under-utilization.

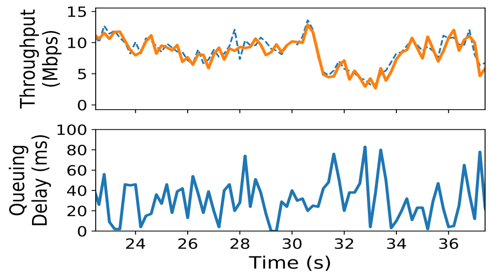


Figure 20: **ABC's robustness to flow size —** With a single backlogged ABC flow and multiple concurrent application-limited ABC flows, all flows achieve high utilization and low delays.

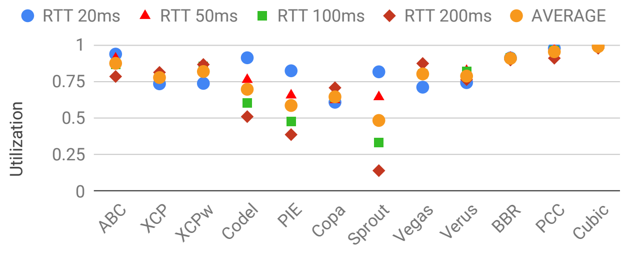
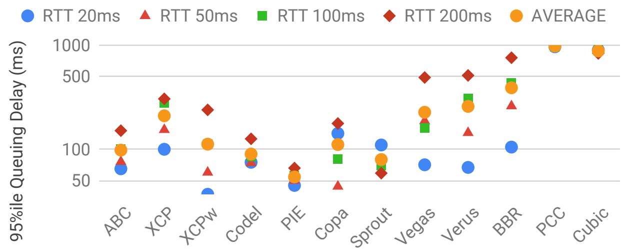


(a) Utilization



(b) per-packet queuing delay

Figure 21: **Impact of propagation delay on performance —** On a Verizon cellular network trace with different propagation delays, ABC achieves a better throughput/delay tradeoff than all other schemes.

AmphiLight: Direct Air-Water Communication with Laser Light

Abstract

Air-water communication is fundamental for efficient underwater operations, such as environmental monitoring, surveying, or coordinating of heterogeneous aerial and underwater systems. Existing wireless techniques mostly focus on a single physical medium and fall short in achieving high-bandwidth bidirectional communication across the air-water interface. We propose a bidirectional, direct air-water wireless communication link based on laser light, capable of (1) adapting to water dynamics with ultrasonic sensing and (2) steering within a full 3D hemisphere using only a MEMS mirror and passive optical elements. In real-world experiments, our system achieves static throughputs up to 5.04 Mbps, zero-BER transmission ranges up to 6.1 m in strong ambient light conditions, and connection time improvements between 47.1% and 29.5% during wave dynamics.

1 Introduction

The underwater world is still largely unexplored, yet surveying and monitoring submerged sites is fundamental for many applications including archaeology [18], biology [40], and disaster response [42]. It is generally recognized that using multiple heterogeneous cyberphysical assets – e.g., flying vehicles for a bird's eye view and underwater sensors and vehicles for informed data collection – will advance such efforts [19, 28, 59]. One of the challenges for underwater autonomous deployments is limited communication between assets underwater and in the air. This hinders the situational awareness and coordination of underwater vehicles, data-processing, and human supervision [47]. One conventional strategy is to periodically let the underwater vehicle surface to share data [54], which is inefficient due to time not being spent on the task. Another strategy is to deploy an infrastructure (e.g., network of buoys) at the water surface, connected to both the underwater assets (via acoustic transducers, completely in the water) and the ground station (via tethering or WiFi [30]). This deployment configuration increases the cost and logistical overhead, limiting the overall scalability [39].

We seek solutions that support direct wireless communi-

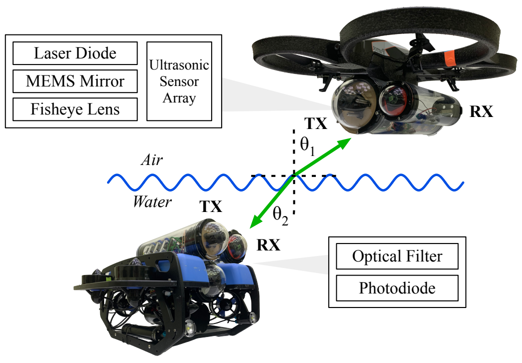

Figure 1: *Our envisioned application scenario of air-water communication allowing aerial drones and underwater robots to communicate directly and bidirectionally.*

cation between air and underwater nodes without the need of surface relays. Existing wireless communication technologies, however, mainly focus on a *single* physical medium and thus do not effectively cross the physical air-water boundary, impairing communication performance. As examples, acoustic communication is the mainstream for underwater scenarios but does not cross the air-water boundary since acoustic waves are mostly reflected by the air-water interface [49]; on the other hand, wireless technologies using radio frequencies (RF) are widely deployed in the air but not underwater since radio signals suffer from severe attenuation in the water (3.5–5 dB/m) and result in short communication ranges [45, 70]. A recent work [67] designs a direct water-air communication link by combining an acoustic link in the water and RF sensing in the air. Nevertheless, this method only enables a unidirectional link (from water to air), supports only centimeter-level distances above the water, and achieves severely low data rates (400 bps) that are insufficient for most underwater monitoring applications [26].

In this paper, we study the use of laser light to build a high-bandwidth, bidirectional air-water communication link (Fig. 1). Light is the most suitable medium because the majority (90%) of its energy penetrates the air-water interface with only less than 10% energy reflected back.[1] Compared to acoustics, light communication supports much shorter communication latency with faster propagation speeds. Compared to RF, it endures much lower attenuation in the water. In particular, light in the blue/green range (420 nm – 550 nm) attenuates less than 0.5 dB/m in water [5,45]. We specifically consider blue/green *laser* light because of its superior communication properties: (1) nanosecond-level switching speed, (2) narrow (5–10 nm) spectral power distribution,[2] allowing optical energy to be concentrated to the wavelength range associated with the smallest attenuation in the water/air, and (3) low beam divergence maximizing the energy efficiency and enhancing communication distance. Gbps-level data rates have already been demonstrated using laser light for air-water communication, albeit assuming calm water and with bulky benchtop equipment that are not portable to drones or robots [21,71].

The key contribution of our work is addressing numerous practical challenges currently unsolved (even with the assumption that the locations of the nodes – one underwater and one in air – are fixed and known) and providing a system framework, *AmphiLight*, for a robust laser-based air-water communication link. *First*, we judiciously design the basic communication link to overcome issues of existing laser hardware and improve its portability for communication. *Second*, to handle strong ambient light interference, we exploit the narrow spectral power distribution of laser light by placing a narrow optical filter in front of an ultra-sensitive receiver (silicon photomultiplier) to filter out ambient light and maintain sufficient signal-to-noise ratios (including at meter-level distances with low-power laser diodes). *Third*, to adapt to environmental dynamics, we propose a new optical system to enable precise, full-hemisphere laser steering using low-cost, portable hardware. It couples a fine-grained MEMS mirror with a miniature fisheye lens to achieve $\pm 90^\circ$ steering range in two dimensions. *Finally*, we address water dynamics by augmenting the link with ultrasonic sensing and a forecasting method. The ultrasonic sensor array at the transmitter samples the depth of a small number of locations at the air-water interface. These depth values are used to reconstruct a continuous water surface and compute the optimal incident point for the transmitter to steer the laser beam to reach the receiver.

We implement a proof-of-concept AmphiLight prototype using off-the-shelf hardware. Our prototype consists of the following elements: (1) a self-contained, waterproof laser transmitter utilizing a microcontroller, FPGA, MEMS mirror, and passive optical components; (2) an array of low-cost, ultrasonic depth sensors for reconstructing the water's surface; (3) a waterproof laser receiver capable of detecting the nanosecond laser pulses. We conduct experiments in various settings to examine both link performance and robustness. We summarize our key findings as below:

- AmphiLight achieves bidirectional, 5.04 Mbps throughputs with BERs less than 10^{-3} up to 6.5 m in the air and 2.5 m underwater;
- AmphiLight adapts to wave dynamics (10 – 12 cm wave amplitude and 1-Hz wave frequency) with a 47.1% throughput improvement over no laser steering;
- AmphiLight is robust against environmental factors including strong sunlight and air/water turbulence at meter ranges;
- The ultrasonic sensing achieves an accuracy of 1.5 cm in the air and 0.5–1.0 cm in the water.

2 System Challenges

Despite the potential of green-blue laser light for direct air-water communication, we face numerous systems challenges in achieving high link speed and link reliability.

Laser Hardware Limitations. Although laser diodes (LDs) are small and relatively inexpensive – making them strong contenders for mobile applications – integrating them into portable platforms for high-speed communication is challenging due to heating and power issues. Our experiments with off-the-shelf LDs show that their temperature rises over time when constantly on.[3] The temperature rise causes the central emission wavelength to shift by a few nanometers [7], which is undesirable as shown later in §3.1. Better heat dissipation requires dedicated temperature controllers and active heatsinks, which are bulky (9 lbs), expensive ($\geq$\$1000), and power hungry (up to 60 W) [8].

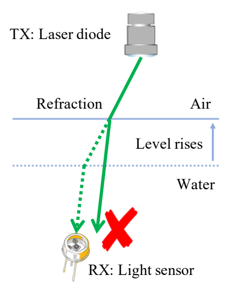
Additionally, commercial LDs are limited in terms of their optical output powers and wavelength availability. Specifically, blue and green TO-Can LDs are typically limited to 450 nm and 520 nm with optical powers between 30 mW and 140 mW and high power options between 900 mW and 3 W [9]. To maintain stable output power, LDs are typically powered with bench-top power supplies with current and voltage limits or mobile drivers that do not support fast modulation bandwidths (e.g., only up to 2 MHz [16]). The power consumption of low-power LDs ranges from a few milliwatts to multiple watts, making mobile-friendly micro-controllers incapable of consistent, safe, and efficient LD operation.

Ambient Light Interference. Given the sparse availability of blue/green LDs, low-power options are the only choice for mobile applications. Thus, strong ambient light, especially in outdoor scenarios, imposes a nontrivial challenge of maintaining high data rates with reasonable signal-to-noise ratios (SNR) at meter-level distances. Even worse, outdoor sunlight can easily saturate sensitive photodiodes (PDs) at the receiver, making it unresponsive to encoded light changes

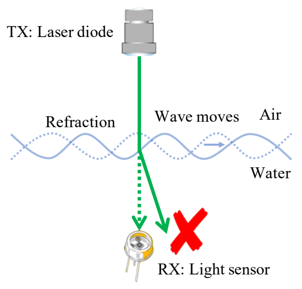
[1] If the incident angle is less than 50°.

[2] By contrast, the spectral power of light emitted from an LED can span up to 100 nm [2,68].

[3] When powering a PLT3520 LD with a Thorlabs S1PLM38 passive heatsink using 6 V and 150 mA, the LD casing temperature increased from 81 °F to over 145 °F, measured by a Lasergrip 774 infrared thermometer.



(a) Level change



(b) Wave

Figure 2: Water dynamics degrade the link reliability due to light refraction at the air-water interface. (a) Precipitation and tide can raise the water level, which permanently translates the refracted light and disrupts the aligned link. (b) Periodic waves can swing the refracted light, resulting in recurrent misalignment with the receiver.

from the transmitter. To illustrate this point, we measured the SNR of an off-the-shelf PD (OPT101) under varying ambient light intensities. Specifically, we collocate a LX1330B light meter with OPT101 and place a 140 mW LD and Osram 5500T03 LED 20 cm away, where the LED light emulates ambient light interference. Next, we vary the intensity of the LED and measure the resulting SNR at the PD. As the LED illuminance approaches values associated with outdoor ambient light (e.g., $\geq$10,000 lx in indirect sunlight), the SNR quickly drops below 3 dB (specifically, 3.2 dB at 5700 lx and 0.6 dB at 8070 lx). Furthermore, PDs capable of detecting low-level light need to have sufficiently high gain, making them susceptible to saturation under intense ambient light (the OPT101 became saturated when the LED intensity approached 14,500 lx).

Laser Beam Steering. Supporting arbitrary underwater/aerial robot locations demands precise steering of the narrow laser beam in a wide range. Existing laser steering mechanisms, however, face a fundamental tradeoff between steering range and granularity. Traditionally, FSO beam steering [37, 44, 58, 60, 64, 75] uses mechanical gimbals for 360° coarse-grained steering and then additional mechanisms for secondary, fine-grained adjustments [36, 46, 57]. Although mechanical gimbals can support a large angular steering range, they are bulky, imprecise, and not intended for use in mobile settings. On the other hand, the mechanisms used for fine-grained steering (e.g., microelectromechanical-systems (MEMS) mirrors [29, 41, 50, 51, 77], acousto-optic deflectors (AODs) [60, 69], tunable lenses [22, 52, 82, 82]) only achieve millirad/single degree steering ranges [46], constraining the receiver location to a narrow cone around the transmitter.

Environmental Dynamics. In real world environments, such as lakes or oceans, the water's surface is dynamic, rendering a laser link unsustainable due to refraction at the air-water interface. The impact of water dynamics is twofold: (1) A change in water level caused by precipitation or a tide can disrupt the optical link permanently. For example, a rise in the water level will move the incident point on the surface to a new position if the incident angle is not 0°. Consequently, the refracted light will be translated and miss the underwater receiver (Fig. 2(a)). Based on geometry, the horizontal displacement of the light beam is $\Delta h(\tan\alpha - \tan\beta)$, where Δh is the level change, α is the incident angle, and β is the angle of refraction. A level change of 1 m[4] with a 30° incident angle results in 17 cm displacement of the beam, far beyond the diameter of common light sensors (a few mm); (2) Periodic surface waves caused by wind or moving objects can swing the refracted light around the receiver. The oscillation causes the optical link to deviate from the receiver (Fig. 2(b)). Our experiment shows that waves with $\sim$10 cm peak-to-peak amplitudes make the link unavailable for $\sim$70% of the time.

3 Basic Laser Link Design

We present the basic laser communication link design able to (1) achieve sufficient data rates (i.e., Mbps for underwater drone communication and sensing) with off-the-shelf laser diodes and (2) support a hemispherical steering range to connect the transmitter and receiver at arbitrary locations.

3.1 Transmitter & Receiver

Transmitter. To support Mbps throughputs and low energy consumption – important tradeoff design for underwater drones – we adopt the DarkLight concept in [65]. Specifically, DarkLight applies overlapping pulse position modulation (OPPM), where data is encoded into the position of the rising edge of a light pulse within a symbol. We extend DarkLight to LDs, leveraging LD's fast switching speeds to increase the data rate while still maintaining a low duty cycle. This leads to a significant improvement in throughput from Kbps with LEDs to Mbps with LDs, as shown later in §6. Reducing the duty cycle removes the need for a dedicated temperature controller as the laser will remain off the majority of the time. Furthermore, a low duty cycle reduces the power consumption issues typically associated with laser communication, allowing us to power the LD with a microcontroller without sacrificing the data rate.

Even though OPPM is the most suitable choice for sustained communication[5] given the current laser hardware limitations, the AmphiLight framework is general and can be combined with other modulation schemes. As advances in LD hardware will better address heating[6] and power issues in the future, other modulations schemes such as OOK or OFDM can be easily integrated into AmphiLight to further boost link data rates. However, with higher-power modulation schemes, the effects of turbulence, especially over long distances, might degrade the overall link quality. Regard-

[4]For reference, the tidal range (height difference between high tide and low tide) can reach 16 m [11].

[5]If the communication between drones is intermittent, higher-power modulation schemes should not raise the temperature to dangerous levels, even with only passive cooling.

[6]In the case of an underwater drone, the surrounding water could be leveraged to passively cool the hardware without requiring additional power or expensive components.

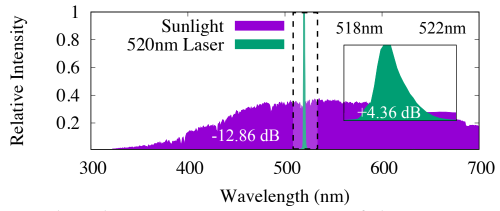


Figure 3: *The relative intensity spectrum of the sun compared to a low-power LD. Utilizing a narrow bandpass filter from 518 nm to 522 nm, the SNR can be increased from -12.86 dB to 4.36 dB.*

less, fully leveraging the GHz switching speeds of LDs, an OOK implementation could achieve throughputs in the Gbps range with only a few mJ/bit.

Receiver. We address the key challenge of the receiver design – to extract signals from low-power LDs amid strong ambient light interference while maintaining meter-level distances – via two design elements. First, we add a narrow optical bandpass filter ($30 – $200) that allows only the narrow wavelength range of the laser light (confined only to a few nm [53]) to pass, and filter out the majority of the ambient light energy and significantly boost the signal-to-noise ratios (SNRs). As an example, Fig. 3 plots the spectral power distribution of outdoor sunlight (measured on a sunny noon in August, 2019), as well as that of a low-power LD [13], measured by a Thorlabs CCS100 spectrometer. We observe that the weak laser light is buried in the strong sunlight. Nevertheless, adding an off-the-shelf bandpass filter [12] with a ± 2 nm bandwidth, we drastically improve the SNR. Additionally, spectral filtering also addresses the problem of sensor saturation under strong ambient light.

Second, we utilize an ultra-sensitive silicon photomultiplier (SiPM) light sensor, i.e., an array of avalanche photodiodes (APDs), with high gains, large active areas, and large angular responses [14].[7] Given the SiPM's significantly higher gain compared to traditional light sensors, we are able to maintain a sufficiently high SNR even with low-powered LDs at meter-level distances. We further increase the SNR by using an RF amplifier with a DC-bias cutoff, allowing us to amplify only the low-power laser light.

3.2 Full-Hemisphere Beam Steering

We adapt the fine-grained steering mechanism from FSO by expanding its limited steering range with a judiciously-designed optical circuit. Specifically, we combine a small-angle MEMS mirror with a miniature fisheye lens [24] to enlarge the small-angle steering to $\pm 90^\circ$ in two dimensions.

As shown in Figure 4(a), a fisheye lens is a combination of wide-angle lenses typically used to create hemispherical images for photographs. Fisheye lenses concentrate light rays coming from a full hemisphere to a small image plane at the focal length, limited by the form factor of digital camera image sensors. We exploit this optical feature to expand the

[7]We measured the SiPM's SNR to be between 13.03 dB and 13.95 dB between -70° and 80°.

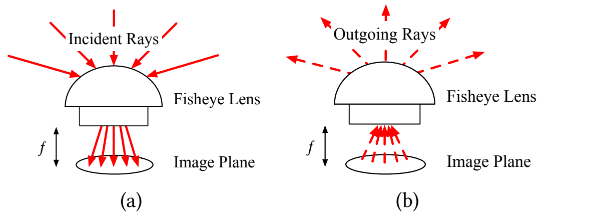

Figure 4: *(a) Light enters the fisheye lens and is projected onto a small image plane, compressing the wide incoming light directions into a smaller range. (b) We consider the inverse of the propagation path to enlarge a narrow steering range to full hemisphere.*

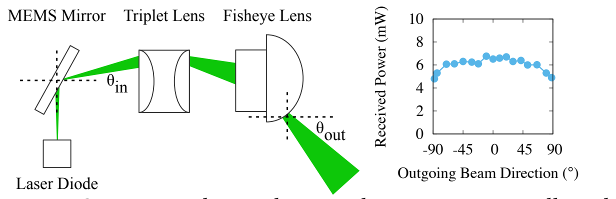

Figure 5: *Our proposed optical circuit design, using a small-angle MEMS mirror and fisheye lens. Not only can we achieve a full $\pm 90^\circ$ range in two dimensions, but the received power only deviates by 28% at extreme angles.*

narrow steering range of MEMS mirror. Specifically, given the path symmetry of light propagation, we consider the inverse direction of the light path by sending a light ray through the image plane. This leads to an outgoing light ray steered to a larger irradiance angle (Fig. 4(b)), thus expanding the small input steering range to an entire hemisphere.

Fig. 5 shows the optical circuit for laser beam steering. An achromatic triplet lens [83] is added to keep a constant focal point on the fisheye lens (i.e., correcting for spherical aberrations) [15]. It also concentrates the outgoing light ray from the MEMS mirror to the image plane of fisheye lens to match the desired inverse propagation path.

4 Addressing Water Surface Dynamics

Armed with the basic link design, we now set out to address challenges from dynamics at the air-water interface, aiming to improve link robustness in practical settings. To mitigate the misalignment caused by water dynamics, a straw-man approach is to expand/diffuse the laser beam to keep the receiver within the light coverage during water dynamics. This approach, however, greatly lowers the energy efficiency of communication and demands high-power LDs to support meter-level distances. Another approach is to blindly steer the laser beam and scan all directions to search for the direction that reaches the receiver. The resulting overhead to scan the whole steering range (up to hundreds of ms with existing MEMS mirrors), however, reduces the link throughput. It also requires a feedback channel from the receiver, which may be equally unavailable due to misalignment.

Instead, we consider a more proactive approach where the system continuously senses the condition (both the water level and the shape of the wavy surface) of the air-water interface, computes the optimal direction to reach the receiver,

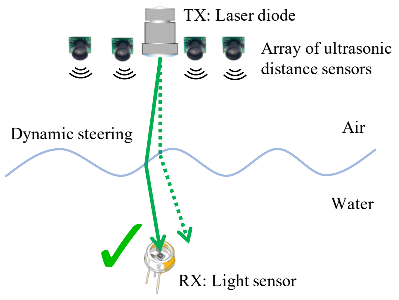

Figure 6: Addressing water dynamics by continuously sensing the water with an array of ultrasonic sensors, interpolating the surface, computing the optimal path to the receiver, and steering the laser.

and then steers the laser beam correspondingly to sustain the link's connection (Fig. 6).

4.1 Sensing Waves

To sense the water surface condition, we start by examining the efficacy of existing techniques. Vision-based methods with depth cameras have been widely used to reconstruct the 3D shape of objects. These methods, however, are unable to sense the shape of water surfaces because light mostly penetrates the air-water interface and reflects almost no light for the depth camera to reconstruct the surface. Our experiments with an Intel RealSense D435i depth camera shows that depth information is only correct when a piece of paper is placed on the water surface. Alternatively, one can consider RF-based methods, i.e., mmWave radar which has been shown to sense the distance from air to water at μm-level accuracy [67]. Given the severe attenuation of RF signals in the water, however, RF-based methods cannot be applied to underwater transmitters for sensing the water surface. Additionally, reconstructing the water surface requires an array of mmWave radars that can cost thousands of dollars.

The above exploration leads us to consider the acoustic medium. Specifically, we consider ultrasonic distance sensors to avoid interference from ambient noises. Ultrasonic distance sensors work in both air and water, and thus can be used by both aerial and underwater transmitters to sense the air-water interface and adapt the outgoing laser beam direction. Additionally, the accuracy of ultrasonic distance sensors are on the mm-level and are affordable (e.g., \$1 each).

Depth Sampling via Ultrasonic Sensing. To sense the shape of the water surface, a single ultrasonic sensor is insufficient. Instead, we employ an array of M sensors that are uniformly distributed on the transmitter plane. Because all sensors operate at the same acoustic frequency and are close to each other, simultaneous measurements cause interference. Therefore, we instruct the sensors to sample the distance sequentially. The sequential measurements result in a sensing latency that grows linearly with the number of sensors and proportionally to the distance between the transducers and water surface. In our implementation with 16 sensors, generating each snapshot of the surface is approximately 50 ms (20 Hz frame rate) which can impair the efficacy of beam steering for faster waves.[8]

To lower the latency of the sensor array, we propose to forecast the height samples of the water surface. Instead of waiting for the readings from all sensors to be ready, we can forecast the distances based on historical data. It is possible to forecast the height of the water because water surface waves are periodic. Specifically, we output distances from all sensor positions once a new reading is available from a sensor (e.g., at time t_{cur}). If the readings from other sensors are not ready at that time, we will use the forecasted distances. Because the water wave is periodic, we can use the Fourier transform for forecasting, i.e., estimate the frequency and phase of the waves despite the variable latency. Specifically, we buffer a window of the most recent N readings for each sensor x_k ($k \in [0, N-1]$),[9] compute the Discrete-time Fourier Transform (DFT) in the window, estimate the period of the major frequency component T, and forecast the reading x_N by linear interpolation at time $t_{x_N} - T$. If the timestamp of x_N is ahead of t_{cur}, we will linearly interpolate between x_{N-1} and x_N. Our measurements show that the forecast distances using historical readings align well with the measured distances. Forecasting reduces the sensing latency of each frame (i.e., time period between adjacent frames) to 1/16 of the non-forecast method, approximately 3 ms. Since the movement of the water waves between frames is the source of sensing errors, the forecasting error is 1/16 of the non-forecast error. This forecasting method assumes a single major frequency in the water waves. For more complicated waves, in the future we can investigate advanced forecasting methods, such as ARIMA and RNN (which require training and higher computational cost).

Reconstructing Wave Surface. To reconstruct a continuous wave surface for every frame, we need to interpolate between the discrete distance samples output by the array. We adopt a bicubic surface model [33] to fit the outputs:

$$h(x,y) = \sum_{i=0}^{3}\sum_{i=0}^{3} a_{ij} x^i y^j \,,$$

where (x,y) is the coordinate on the horizontal plane relative to the center of the sensor array, $h(x,y)$ is the height of wave at (x,y), and a_{ij}'s are the parameters of the surface. Bicubic surface is widely used in 2D interpolation. We choose this model for its shape flexibility and computational simplicity. We fit the model using linear regression, which is computationally inexpensive and suitable for real-time reconstruction. The linear system is $\boldsymbol{h} = \boldsymbol{X}\boldsymbol{\beta} + \beta_0$, where $\boldsymbol{h}$ is a vector of the measurement distances by each sensor, and $\boldsymbol{X}$ is a matrix that is constructed by the coordinates of the

[8]Typical frequency of water surface waves is 0.1 Hz–3 Hz [61].

[9]$N = 256$ in our implementation. Longer windows can produce finer-grained frequency resolution in the frequency domain and better forecast accuracy, yet entail longer buffers and higher computational cost.

sensors. Put formally, $\boldsymbol{X}$ is calculated as:

$$\boldsymbol{X} = \begin{bmatrix} x_1^3y_1^3 & x_1^3y_1^2 & x_1^3y_1 & x_1^3 & \cdots & y_1^3 & y_1^2 & y_1 \\ x_2^3y_2^3 & x_2^3y_2^2 & x_2^3y_2 & x_2^3 & \cdots & y_2^3 & y_2^2 & y_2 \\ & & & & \vdots & & & \\ x_M^3y_M^3 & x_M^3y_M^2 & x_M^3y_M & x_M^3 & \cdots & y_M^3 & y_M^2 & y_M \end{bmatrix},$$

where each row is for a sensor. The coefficients $\boldsymbol{\beta}$ and β_0 are the parameters of the surface, i.e., $\boldsymbol{\beta} = \{a_{ij} | i, j \in \{0,1,2,3\}\} - \{a_{00}\}$.[10] The model, therefore, contains 16 parameters[11] in total. With M ultrasonic sensors and thus M measurements, we employ regularized linear regression to prevent overfitting and the loss function is

$$f(\boldsymbol{\beta}, \beta_0) = \sum_{i=1}^{M} \left(h_i - \beta_0 - \sum_{j=1}^{15} \beta_j \boldsymbol{X}_{ij} \right) + \lambda \sum_{j=1}^{15} \beta_j^2,$$

where λ is a hyper-parameter that controls the penalty on the parameters. In our implementation, $\lambda = 5 \times 10^{-5}$.

4.2 Computing the Incident Point

Once the shape of the surface wave is estimated, we next seek an incident point on the surface such that the refracted light can reach the receiver. The incident light and refracted light must be subject to Snell's law. However, this equation is intractable because of the trigonometric functions, i.e, we have to solve the incident point position numerically. First, we model the problem as an optimization problem (Fig. 7). For every possible point on the surface, we are able to determine the direction of the refracted light ($\vec{r}$) according to Snell's law and the direction from the incident point to the receiver ($\vec{t}$). If the discrepancy between the two directions (θ) is zero, the previous equation is exactly solved. Therefore, we are looking for the incident point that minimizes the discrepancy θ, i.e., maximize $\cos\theta$:

$$\text{Maximize} \qquad \cos\theta = \frac{\vec{r} \cdot \vec{t}}{|\vec{r}||\vec{t}|} \tag{1a}$$

$$\text{subj. to:} \qquad \vec{r} = p\vec{m} + \vec{n} \tag{1b}$$

$$p = \frac{p|\vec{m}|}{|\vec{n}|} = \frac{\sin\beta}{\sin(\alpha - \beta)} \tag{1c}$$

$$\vec{n} = \left(\frac{\partial h}{\partial x}, \frac{\partial h}{\partial y}, -1 \right) \tag{1d}$$

Here $\vec{n}$ is the surface normal unit vector, $\vec{m}$ is the direction vector of the incident light, n_{water} is the refractive index of water, and $\frac{\sin\alpha}{\sin\beta} = n_{\text{water}}$. To calculate $\vec{r}$, we first determine the direction of the surface normal ($\vec{n}$) according to 1d. Suppose the direction vector of the incident light is $\vec{m}$, which

[10] β_0 is another name for a_{00}.

[11] Although we estimate the model parameters without any prior knowledge, we could utilize the physics of dispersion [4] to model the constraints between the different parameters (e.g., between wavelength and wave speed). This could improve the accuracy of the model, but is beyond the scope of this paper.

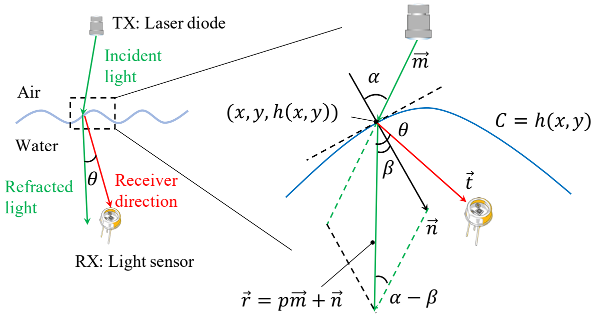

Figure 7: Geometric model of finding the optimal path to reach the receiver. We model finding the incident point on the surface such that the laser can reach the receiver as an optimization problem. This figure shows a single solution in the solution space, where the optimization happens over all possible solutions. We minimize the angle discrepancy (θ) between the refracted light ($\vec{r}$) and the target path that reaches the receiver ($\vec{t}$) subject to Snell's law which governs the relation between the angles of incidence (α) and refraction (β).

is also a unit vector. According to Snell's law, the incident light, the refracted light, and the surface normal are coplanar. The refracted light's direction can thus be written in the form of 1b, where p is calculated according to law of sines and Snell's law (1c). Assuming the transmitter is in the air and the receiver is underwater, n_{water} is the refractive index of water (we can take the reciprocal if the transmitter and receiver exchange positions). Notice that all the quantities are functions of (x, y).

Algorithm 1: Find outgoing beam direction

```
Input: $\boldsymbol{p}_0$: initial incident point, $\boldsymbol{r}$: receiver position, $\boldsymbol{b}$: surface
       shape parameters                                  // TX: (0,0,0)
Output: $(\gamma_x, \gamma_y)$: outgoing beam angle along $x$-axis and $y$-axis
$\alpha \leftarrow 0.01$                                 // learning rate
$\boldsymbol{p}_n \leftarrow \boldsymbol{p}_0$           // next point to test
$\varepsilon \leftarrow 0.005$                           // accuracy tolerance
$N \leftarrow 100$                                       // max iteration
for $i \leftarrow 1$ to $N$ do
    $\boldsymbol{p} \leftarrow \boldsymbol{p}_n$
    /* compute gradient and error                        */
    $\nabla, e \leftarrow$ gradient$(\boldsymbol{p}, \boldsymbol{r}, \boldsymbol{b})$
    if $e < \varepsilon$ then
        break
    $\boldsymbol{p}_n = \boldsymbol{p} + \alpha\nabla$
end
$z = h(\boldsymbol{p})$                                  // z coordinate on surface
$\gamma_x = \arctan(\boldsymbol{p}_x / abs(z))$
$\gamma_y = \arctan(\boldsymbol{p}_y / abs(z))$
return $(\gamma_x, \gamma_y)$
```

We solve the optimization problem by gradient ascent (Algo. 1). We compute the gradient ($\nabla\cos\theta$) following the chain rule. For each frame, we set the initial incident point as the incident point of the previous frame. The spatial and temporal continuity of the water wave and the observation of the optimization result show that the new incident point should be close to the previous one because the change of the surface shape is small between adjacent frames. All the computation, including the forecasting, surface reconstruction, and path finding, can be completed within 1 ms. Note that wave sensing, path finding, and beam steering occur in parallel with the data transmission, incurring no overhead on the optical link. Notably, our algorithm has the potential to fail if some of the characteristics are beyond the sensing capabilities of the ultrasonic array: wavelength is smaller than the separation between the ultrasonic sensors; wave frequency is higher than the sensing frequency. We discuss improvements to the sensing and reconstruction in §7.

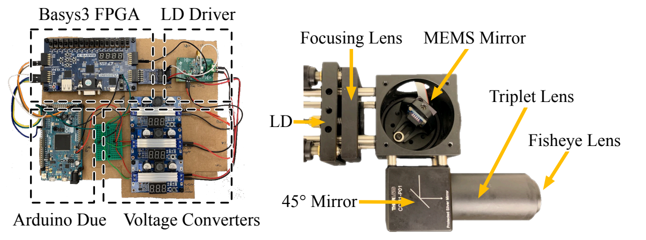
5 Prototype Implementation

Our prototype includes a transmitter, which encompasses the optical circuit, electronic circuit, modulation scheme, and ultrasonic sensor array, and a receiver that includes optical filtering and receiver hardware.

Transmitter. Our transmitter utilizes a small, mobile optical circuit relying on a single MEMS mirror and passive optical components to achieve a hemispherical steering range. The complete package is shown in Fig. 8(b). We mount a 140 mW TO-Can PLT3520D LD ($89) within a Thorlabs S1LM38 passive heatsink and focus the light to a 2° half-angle beam with an A110TM-A aspheric lens ($90). We use a 3.6 mm MEMS mirror mounted on an A7B1.1 actuator in a TINY20.4 package from MirrorcleTech ($798), providing roughly $\pm 6.6^\circ$ mechanical deflection on the x/y axes and 0.003° angular resolution.[12] The mirror is fixed to a MirrorcleTech mount and screwed into a Thorlab B5C1 optics mount. The cage cube platform is rotated 45° relative to the mounted LD. We mount a Thorlabs TRH254-040-A triplet lens ($78, $\approx$ 1% loss) and Sunnex DSL419B-NIR-F2.0 miniature fisheye lens ($99, $\approx$ 10.5% loss) within a Thorlabs SM1L20 lens tube. We decreased the distance between optimal components to maximize the final output power. Since the MEMS mirror's center point changes with gravity, we mount the lens tube on a Thorlabs CCM1-P01 45° mirror cube, allowing us to evaluate the parallel and perpendicular hemispheres without changing the mirror's alignment.

Fig. 8(a) shows the designed electronic circuit to transmit data. An Arduino Due ($32) processes the payload and split it into M-bit chunks. We implement an FPGA pulse timer on a Basys3 ($149) with a clock speed of 100 MHz. We establish a serial connection between the Arduino and the FPGA and transmit the required OPPM parameters (e.g., symbol length, slot width, pulse width) and processed payload to the FPGA. The FPGA parses the data and outputs the pulses on a single GPIO pin. To supply enough power to the LD, we utilize a TI LMG1020EVM-006 laser diode driver ($154) which also shortens the input pulse width up to 45%. To communicate between the FPGA and driver, we shift the logic levels with a Digilent 410-320 PMOD logic level shifter ($14). Finally, to

[12]Our MEMS mirror has a mechanical range $\pm 6.6090^\circ$ on the x-axis and $\pm 6.5586^\circ$ on the y-axis. Furthermore, the mirror's ADC has a resolution of 12 bits, making the angular resolution 0.003° on the x and y axes.



(a) Electronic Circuit (b) Optical Circuit

Figure 8: *(a) Electronic circuit, 20 cm × 10 cm × 7.5 cm and weighing 0.7 lbs, used to transmit nanosecond laser pulses. (b) Optical circuit to achieve full-hemisphere beam steering. The optical circuit is 11 cm × 11 cm × 5 cm and weighs 1.8 lbs.*

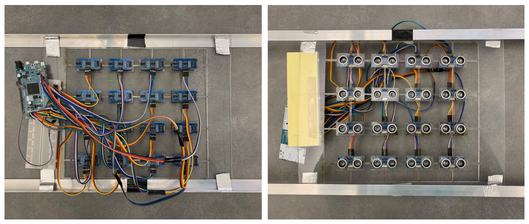
maintain mobility, we power all the components with the Arduino preprocessor and three voltage step-up converters.

To achieve a sufficient throughput in our prototype, we encode five bits per symbol and decrease the slot width to its minimum value (i.e., one clock cycle of 10 ns). To ensure the LD reaches its peak power within one pulse, we set the pulse width to 150 ns resulting in a duty cycle of 13.70%. Since SiPM's experience exponential decay, we add a 300 ns guard interval, T_G, at the end of each symbol for the sensor to reset. A 2 μs fixed delay occurs after the last symbol, giving the receiver time to differentiate between adjacent packets. Our modulation parameters enable a maximum throughput of 5.04 Mbps. Note that faster FPGAs exist (e.g., up to 600 Mhz clock speeds [17]) which would support shorter slot widths and consequently faster throughputs (up to 30.22 Mbps with a slot width of 1.7 ns).

Finally, as shown in Fig. 9, we implement our ultrasonic sensing array using 4×4 HC-SR04 sensors [6] ($4 each), each sensor 6 cm apart from adjacent nodes.[13] The 16 sensors measure the distance from the transmitter plane to the water surface sequentially. Currently, the sensing latency of every data frame is approximately 3 ms with forecasting at a distance of 20 cm above the water. Notably, as the distance increases, the measurement will become less accurate since the ultrasonic beam will cover a larger area and the sensing latency will be higher due to the increased propagation delay. In our implementation, we set the exit condition of our gradient ascent algorithm (Algo. 1) using an error tolerance of 0.005 radians. We implement the wave shape fitting and optical path determination using C++. We leverage the MLpack library for the regularized linear regression and FFTW for the forecasting. Finally, our ultrasonic sensor array can be replicated for underwater transmitter by employing cheap waterproof ultrasonic sensors [10] and we discuss various ways to reduce the sensing latency increase the wave sensing accuracy in §7.

Receiver. Given the effects of ambient light on the receiver SNR, we implement wavelength filtering tuned to the emission wavelength of our LD. Although bandpass filters are the

[13]This distance was determined given the 15° FoV of each sensor.



(a) Top of array (b) Bottom of array

Figure 9: *Top and bottom views of our ultrasonic array. The array is 26 cm × 36 cm × 5 cm and weighs 1 lbs.*

optimal choice given their narrow pass regions (e.g., 5 nm–10 nm), they require incident light to be nearly perpendicular to the filter for it to pass [1]. Since we aim to support arbitrary positions and orientations of the receiver, we instead complement our SiPM sensor's large angular response with a large-FOV colored glass filter – a Thorlabs FGV9 filter ($40) that passes light between 485nm and 565nm. In stronger ambient light conditions, a bandpass filter can be implemented with a concentrating lens (e.g., fisheye lens) in front of it (essentially using the same optical setup as the transmitter).

Finally, to detect the laser pulses, we use a KETEK PM3315-WB-B0 SiPM ($72, active area of 5 mm × 5 mm and 3 dB acceptance angle of 180°) connected to a KETEK PEPCB-EVAL bias board ($65). The SiPM is biased with 5.0 V and 5 mA, shortening the decay time of the sensor to around 60 ns. The signal from the bias board is fed to a MiniCircuits ZX60-P103LN+ RF amplifier ($70) powered with 5 V and 100 mA. We then utilize a Keysight MSOS254A 2.5 Ghz, 20 GSa/s oscilloscope to record the pulses received by the SiPM and demodulate the signals with MATLAB. We discuss our initial results at bringing real time demodulation to our transmitter via an analog circuit in §7.

6 Evaluation

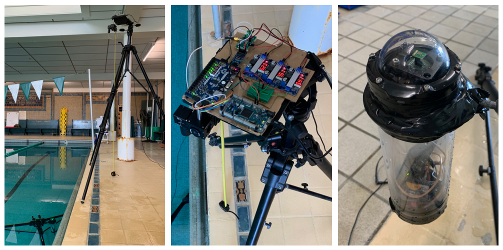
We extensively evaluate the link performance and reliability of our air-water laser link in various settings.

6.1 Overall Performance

We first examine link throughput, bit error rates (BER), and communication distance. In these experiments, the transmitter and receiver are manually aligned. The angle of irradiance from the transmitter and the incident angle into the receiver are all zero unless otherwise specified. Experiments are mostly conducted in two settings: 1) a swimming pool (22.8 m × 10 m × 1.8 m); and 2) a water tank with clear fresh water (1.6 m × 1.75 m × 0.63 m). The ambient light intensity was between 380 lx and 450 lx throughout the experiments and the power consumption for each component can be found in Tab. 1.

Table 1: *Power consumption of various components.*

Component	Voltage (V)	Current (mA)	Power (mW)
TX (5.04 Mbps)	7.7	300	2300
Sensing Array	9.3	67	623
SiPM Bias	5.0	5	25



(a) Setup (b) TX (c) RX

Evaluation Methodology. To capture nanosecond laser pulses, we use a Keysight MSOS254A oscilloscope to record the data, which is then transferred to a laptop for demodulation. This methodology, however, is limited by oscilloscope's buffer size. Specifically, the timing resolution of the oscilloscope is inversely proportional to the capture window size, meaning longer capture windows have inaccurate timing resolutions (i.e., laser pulses are missed or misaligned, causing demodulation errors and higher BERs).

To overcome this issue, we transition from our stationary oscilloscope receiver to an Arduino Due receiver. Specifically, we first obtain a mapping between the SNR and throughput/BER using the oscilloscope receiver to decode data in real time. Then when switching to the Arduino receiver, we instruct the transmitter to send a continuous wave for the Arduino to measure the SNR and map it to the corresponding throughput/BER. We have validated the accuracy of this methodology in experiments with a water tank in a lab setting, where we observe negligible differences between the estimated and actual throughput/BER with these two receivers. This methodology greatly facilitates our experiments during dynamic waves. Our ongoing work is to fabricate an analog circuit for detecting nanosecond light pulses without the need of an oscilloscope or expensive GHz-level ADC (§7).

Calm Water. We start by examining the link performance link under calm water. As shown in Fig. 10, we first place the receiver in a waterproof container with an SMA cable protruding from the bottom of the enclosure and connected to our oscilloscope on land. Second, we place the receiver underwater in a swimming pool and vary the distance to the surface from 0.5 m to 1.1 m. Third, we fix the transmitter to a tripod and place it on the bank of the pool, varying the height from 1 m to 2 m. Finally, we ensure the angle of irradiance out of the transmitter and incident angle into the receiver is below 10° at all times.

As shown in Fig. 11(a) and 11(b), we measure the average throughputs and BERs for each distance configuration. Throughout our experiments, the mean throughput was constantly above 5.03 Mbps and the BER below 0.01. Notably, the limited depth of the swimming pool and low ceiling height reduced the measurable range considerably. To further evaluate the potential of our link, we measure the range of the link separately in the air and in the water. To measure the

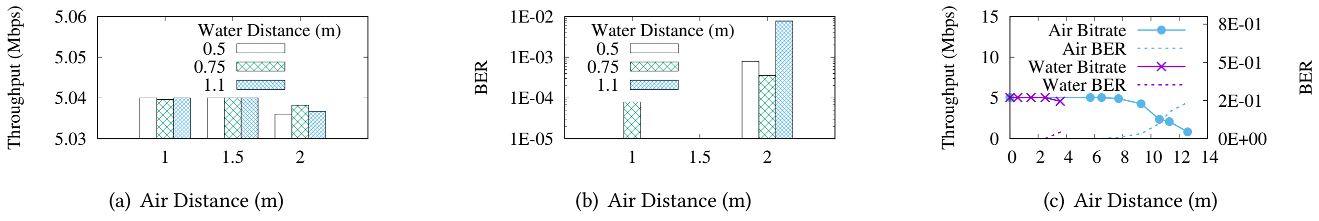

Figure 11: *Link performance under calm water. (a) and (b) plot the throughput and BER under various combinations of air and water distances (limited by the swimming pool setting). (c) plots the performance in pure air and water.*

range in the water, we place two mirrors at the long ends of a 50 cm fish tank and bounce the laser between them to increase the propagation path. As depicted in Fig. 11(c), we are able to achieve a zero-BER range in the air up to 6.5 m and a zero-BER range in the water up to 2.5 m. Consequently, we expect the air portion of our joint results to approach 6 m before the link degrades. Given the power loss associated with the light hitting the mirrors, however, we expect the underwater range to extend beyond our measured 2.5 m.

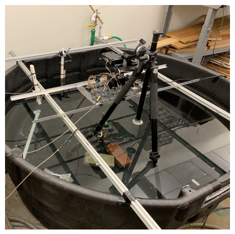
Next, to validate link bidirectionality, we place TX in a waterproof enclosure (weighs 4.8 lbs and measures 11.5 cm $\times$ 36 cm $\times$ 11.5 cm). To fit TX in the waterproof tube, we perform the following modifications: (1) remove the MEMS mirror and fix the laser directly to the triplet lens/fisheye lens tube; (2) replace the 140 mW PLT3520D LD with an 80 mW PLT5520B LD to mount within an adjustable focus enclosure; (3) power TX with a 9-V battery and decrease the LD driver supply to 6.5 V. We then fix the underwater distance to 17 cm and vary the air distance from 32 cm to 71 cm. We record the receiver's SNR and throughput in each direction. As shown in Tab. 2, the throughputs remained stable with a comparable decrease at 71 cm[14] corresponding to a mean BER of 0.00016 (RX underwater) and 0.00028 (TX underwater). Furthermore, the SNRs at each distance configuration varied, at most, by 2.6% indicating a symmetric link. The small discrepancy is most likely due to small offsets in beam alignment.

Table 2: *The difference in throughput and SNR for two directions.*

Air dist. (m)	Throughput % difference	SNR % difference
0.32	0.000%	2.6421%
0.54	0.000%	1.0572%
0.71	0.01191%	2.4117%

Dynamic Water. We now move on to examining link performance under water dynamics. We augment the TX with the ultrasonic sensor array and conduct the experiments in the water tank setting (Fig. 12) because of the ease of mounting the sensor array. We place the sensor array and TX 33 cm above the water surface in the middle of the tank to better simulate real-world conditions, e.g., the middle of a lake. To generate waves, we stir the water by hand for ten seconds, creating roughly uniform waves with amplitudes between 10 – 12 cm and wave frequency of approximately

[14]This range is smaller than our measured zero-BER range given the optical circuit modifications (i.e., lower power LD) and decreased transmitter power supply.



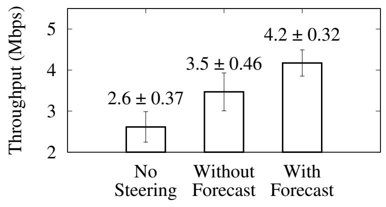


Figure 12: *Experiment setup and results with dynamic water surface.*

1 Hz. We then wait five seconds before recording the SNR on our Arduino for an additional ten seconds. To determine the connection percentage, we look at the percentage of time SNR is above 13.18 dB, the required threshold to maintain 5.04 Mbps throughput with 8×10^{-5} BER. To compute the throughput, we multiply the measured connection time by the corresponding mapped throughput.

We compare our method to two baselines: (1) *No steering*, where the direction of the light is fixed without any response to the waves, resulting in a frequent loss of link connection during wave dynamics; (2) *Wave sensing w/o forecasting*, which is a variant of our proposed sensing method in §4 without the forecasting, i.e., the system collects data from all ultrasonic sensors before estimating the wave surface and steering the laser beam. We test each method in ten trials. Fig. 12 compares the throughput under various methods, where error bars covering standard deviations are also included. We make the following observations: *First*, methods with wave sensing improves link throughput, achieving 29.5% and 47.1% increases compared to no steering. The improvement is due to the higher percentage of link connection with wave sensing. Without steering, the link is disconnected 48.13% of the time because of the periodic wave surface changes, whereas active sensing and laser steering improves the connection percentage to 82.80%. *Second*, between the sensing methods with and without forecasting, forecasting achieves an additional gain because of its reduction in sensing delay, resulting in faster adaptation of the beam direction to wave movement. *Third*, compared to prior work [67] which only supports throughputs up to 400 bps, our system maintains a throughput of 4.2 Mbps with OPPM during wave dynamics – a 10,500 times improvement.

6.2 Link Reliability

Types of Water Waves. While our prior experiments with dynamic water show the high potential of our sens-

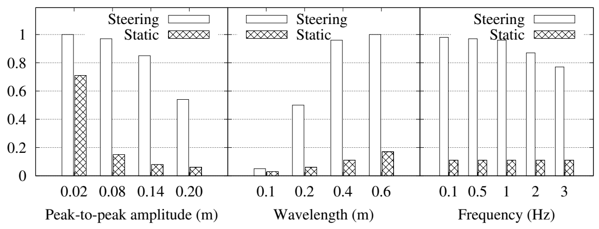

Figure 13: *Influence of water wave parameters on the reliability of the laser link.*

ing method, the results are under a single type of wave. It is practically difficult to precisely generate waves with known parameters and compare methods under exactly the same water waves. To gain a deeper understanding on the impact of different wave characteristics and compare methods more fairly, we build a simulator to generate synthetic waves and emulate the performance using various methods. Specifically, we simulate the water surface with a sinusoidal wave $h(x,y,t) = A\sin(\omega x + \varphi t)$[15], which is widely used in computer graphics to synthesize water waves [32,56]. To exclude the influence of modulation, we use the percentage of the throughput relative to the static link to represent the link reliability. In our simulation, TX and ultrasonic sensor array are placed 20 cm above the water surface. Because the half-angle of our laser beam is 2°, we consider the data to be decodable if the angle deviation between the RX and the laser beam center is less than 2°. We simulate the process for a whole period of the wave because the wave is periodic. By default, the wave's wavelength is 40 cm, peak-to-peak amplitude is 10 cm, and frequency is 1 Hz.

Fig. 13 compares our method to that without steering as we vary the wave characteristics including wave amplitude, wavelength, and frequency. We observe that our method significantly improves link reliability in most scenarios. We also gain two additional insights: (1) The performance of wave sensing degrades with increasing amplitude. This is due to the regularization in the surface interpolation, which gives a higher penalty for more curly waves. The performance also degrades with decreasing wavelength, which is constrained by the Nyquist sampling theorem. The distance between the acoustic sensor dictates the smallest wavelength that our method can reconstruct with high fidelity. A straightforward solution to address both degradations is to increase the density of the acoustic sensors at the expense of raising costs and complexity of sensor placement. A more sophisticated solution is to employ compressive sensing with incoherent sampling. We will discuss this more in §7. (2) The performance degrades gradually when the frequency increases in the normal range (0.1–3 Hz [61]). Even with the fastest waves (3 Hz), our method can sustain more than 75% of the throughput. If higher reliability is desirable, we can further lower the sensing latency by using frequency-division multiplexing among the acoustic sensors, which will increase

[15] $2A$ is peak-to-peak amplitude. $2\pi/\omega$ is wavelength. $2\pi/\varphi$ is frequency.

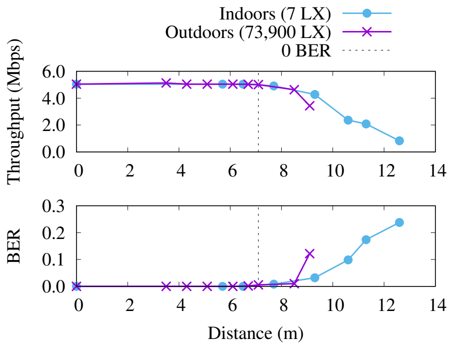

Figure 14: *Comparing link performance under two extreme light conditions: low light indoors and strong sunlight outdoors.*

the hardware complexity of the sensors. Compared to [67], which could support a sustained link up to 16 cm waves and no communication past 22 cm, our system maintains a ≥ 80% reliability up to 14 cm and 50% reliability up to 20 cm.

Sunlight. Given that our ultimate application scenario is outdoors, we evaluate the impact of strong sunlight on our link. Focusing on the air portion of the link, we vary the distance between the TX and RX in both indoor and outdoor scenarios and compare the resulting throughputs/BERs. We compare two extremes: a low-light condition indoors with illuminance between 5 and 7 lx and the strong-light condition (73.900 lx) outdoors, typical for direct sunlight at noon [3]. As shown in Fig. 14, the link performance under strong sunlight is similar to indoors within an 8 m link distance. It achieves zero-BER at 6.1 m distance outdoors, compared to zero-BER at 6.5 m indoors with low ambient light. The link distance under low light is slightly larger because of its higher SNR. This demonstrates that our RX design is robust to strong sunlight, benefiting from the narrow emission bandwidth of laser light and spectral filtering.

Air Turbulence. Air turbulence is known to affect light propagation due to the change in pressure/temperature [34, 73]. We next investigate its impact on the laser link and ultrasonic sensing. Given that pressure/temperature differentials are difficult to generate without dedicated equipment, we generate air current with a typical tabletop fan. Specifically, we place a laser and target 13 m apart. Next, we align the laser so it is in the middle of the target. We then place a fan on one side of the laser and turn it to its highest setting. Within one minute, we observed no changes in beam's alignment. The reason is that the distances supported by the system are immune to their effects, since air turbulence only degrades the signal quality at distances greater than 1 km [81].

Furthermore, we investigate the accuracy of our ultrasonic sensing with the inclusion of wind. We place a fan close to the acoustic path of the ultrasonic sensor that is continuously measuring the distance to the water surface. Results show that the measurement accuracy is not affected by the air flow or the acoustic noise caused by the wind. This is because the velocity of sound (340 m/s) is higher than wind (a few m/s) and the acoustic frequency of ultrasonic sensors is beyond that of wind in the audible range.

Water Turbulence. We also investigate whether water turbulence has an impact on the laser beam's propagation. We place a laser on one end of a 50-cm fish tank and a crosshair target on the other, aligning the two when the water is still. We then stir the water turbulently and observe the beam's propagation through the water. As long as the beam does not strike any object or the water's surface, we observed that the path remains throughout the turbulent flow. This result is expected given the short range tested. Similar to air turbulence, water turbulence is caused by changes in pressure and temperature [72, 78]. In other words, turbulent changes in temperature/pressure cause the refractive indices of eddies to change and bend light as it travels along its path. Water turbulence, however, can be much higher than in the atmosphere given the higher density levels underwater [35].

6.3 Ultrasonic Sensing

Our final set of experiments examines the accuracy of the ultrasonic sensing component.

Sensing in the Air. First, we evaluate the efficacy of ultrasonic sensing with a benchmark experiment. Because accurate reconstruction of liquid surfaces remains an open question in computer vision [20, 38, 56, 76] and also in ocean engineering where numerical models used for predicting ocean waves are at kilometer scale [23, 48, 66], we are unable to obtain the ground truth of an actual water surface. Therefore, we emulate the shape of waves by curving a piece of glossy poster paper by a peak-to-peak amplitude of 10 cm and wavelength of 24 cm. The sensor array is placed 20 cm above the emulated wave. We move the sensor array above different sections (e.g., crest and trough) of the wave to show the flexibility of the bicubic surface model. We manually measure the wave height at multiple positions as ground truth. Results show our sensing method and surface model successfully sense the height of the wave and reconstruct the wave shape with a median error of 1.5 cm.

Sensing in the Water. We validate the efficacy of underwater ultrasonic sensing with another benchmark experiment. We place a BlueRobotics Echosounder on a BlueRobotics BlueROV 2 underwater robot and record the acoustic distance over time. We sent 16 pings/second, fixed the gain to -4.4, and decreased the speed of sound from 1450 m/s to 1400 m/s to compensate for the chlorine water in the pool. Additionally, we use a tape measure to measure the distance from the sensor to the surface. After varying the distance between 56 cm and 89 cm, we observed an accuracy of 0.5 cm to 1 cm depending on the depth (the resolution decreased with larger ranges), which is similar to that in the air. Thus, we expect an array of sensors should perform similarly.

7 Discussion

Mobility. Currently, when our receiver changes its location (e.g., moves from the air to under water), the transmitter is unable to track and steer. However, since our transmitter is capable of steering to any arbitrary location within full hemisphere, we expect it can solve the mobility problem associated with air-to-water communication. The small beam divergence associated with laser light can enable the transmitter's laser beam to be reused for passive sensing. In that scenario, accurate retroreflectors can be collocated with each receiver and allow the transmitter to sense whether it has hit its target. The transmitter can then switch to transmission mode for a fixed duration and then resume sensing once complete. We can also combine the acoustic sensors and the retroreflected laser light to locate the receiver underwater to provide the coordinates of the receiver as input to determine the path while the receiver is moving.

Analog Receiver. Another ongoing work is to enable real-time demodulation with an analog circuit and microcontroller. Our analog circuit is a cascade of four stages: (1) amplifier, (2) envelope detector, (3) comparator and (4) demodulator. After amplification, the signal's long-term average amplitude is extracted with the envelope detector. Whenever the signal exceeds half of its long-term average amplitude, the comparator trips, and an OPPM pulse is registered. The threshold and original unbiased signal are then fed to a nanosecond-level comparator to determine whether the received voltage is an OPPM pulse. To determine the timing between pulses, we feed the output of the comparator to a time-to-digital converter (e.g., TI TDC7201-ZAX-EVM). After synchronizing the clocks of the transmitter and the receiver, we can use an off-the-shelf microcontroller (e.g., Arduino) to start the timer before each symbol. The comparator output is then wired to stop the time-to-digital converter, which stores timing information until encountering the next stop signal. To ensure that no pulses are lost, the microcontroller reads the previous timing information before sending the next start signal.

Improving Wave Sensing. Since the sensing accuracy affects the accuracy of the wave reconstruction, it also contributes to the accuracy of the laser beam steering. Therefore, if we can further improve the sensing accuracy and latency, then we can reduce the ultrasonic beam angle, utilize a lower power transceiver, and still maintain the reliability and throughput of the link. *First*, we can greatly increase the frame rate of the waving sensing by frequency division multiplexing. The current acoustic sensor array relies on sequential distance measurements to prevent interference. Assigning near sensors to different acoustic frequencies, however, can eliminate the interference at the cost of more expensive sensors with broader modulation bandwidth [43]. *Second*, given the form factor of ultrasonic sensors ($\sim$1 cm), we are unable to achieve a spatial resolution as high as that of cameras because of the limited number of depth samples. To overcome this limit, we can employ compressed sensing to reconstruct wave shape with finer granularity by incoherent sampling conditioning on the sparsity of the spatial frequency of water waves. The challenge of applying compressed sensing is its high computational cost [27] due to the real-time requirement of laser beam steering. *Third*, we can exploit the characteristics of the water waves in the time domain to improve the accuracy. For example, we can leverage Guassian process to model the similarity of frequencies at near positions of the wave.

Real-World Evaluation. We recorded various preliminary ocean dynamics to validate our AmphiLight methodology and simulation results. Specifically, we built a waterproof buoy to measure the frequency and peak-to-peak amplitude of waves in Barbados over a two-day period. From our results, we observed waves with an average frequency between 1 Hz and 1.5 Hz and peak-to-peak amplitudes between 5 cm and 8 cm. Furthermore, we measured the throughput of our system under the same wave conditions, and observed an average throughput of 3.1 Mbps corresponding to a connection time of only 61%. Comparing these measurements to our simulation results in Fig. 13, our AmphiLight system is capable of compensating for waves with these characteristics.

In terms of link range, the maximum distance achievable in a real-world environment depends on the laser and ultrasonic sensors. As for the laser, the limiting factor is the optical output power (i.e., the higher power the laser, the farther it will travel before attenuating). In our implementation, there was some optical output power loss in the optical circuit. Specifically, our fisheye lens had an optical loss of $\approx$10.5% and extensive scattering right after exiting the lens. Additionally, the sensing range of the ultrasonic transceivers was another limiting factor. In our current prototype, low-cost transceivers emit low-power waves with large beam divergences, limiting the link range to a few meters. To accommodate real-world scenarios, where the waves are dynamic and unpredictable, the laser power and sensing power should be increased and beam divergence decreased (e.g. < 1 degree) to maintain a sufficient range.

8 Related Work

Air-Water Communication. Air-water communication is a topic far less explored. An early work [55] in 1992 reported a laser link between an aircraft and a submerged submarine, though minimal details about the system design and implementation were disclosed. In the concept figure, the aircraft broadcasts a laser beam with large field of view, which potentially imposes a high energy budget. A later work [21] demonstrated a static laser link achieving 5.3 Gbps data rate over a 5-m air channel and a 21-m water channel, using benchtop equipment (e.g., benchtop power supplies, arbitrary wave-form generator). It validated the potential of laser light for air-water communication, though assumed a static environment without addressing practical challenges such as scattering and waves. [71] further considered the impact of water height on laser communication to build an adaptive water-air-water link. Assuming a calm water surface, their proposed system does not address issues arising from capillary waves common in real applications. [80] focused on advancing modulation scheme design to mitigate the impact of atmospheric turbulence. Although a water channel was also included as part of the propagation path in the evaluation, no water-related dynamics were addressed in their design. Unlike above works exploring narrow-beam laser light with strict alignment requirements, [63] studied a diffuse optical link with different modulation schemes (e.g., OFDM, QAM) and the impact of waves on the resulting data rates. In comparison, our work considers a narrow and collimated laser beam to save energy while presenting systems solutions to address water wave movement. A recent work [67] combined acoustics and RF to realize the direct link from water to air. Our work differs in that (1) we explore a different medium, (2) our methodology supports bidirectional communication, and (3) we achieve much higher data rates.

Wireless Optical Communication. Wireless optical communication has been well studied in airborne and underwater scenarios individually [45, 62, 79, 81]. The highest reported data rates are 40 Gbps for an airborne link (tested between two buildings $\sim$1 km apart using a laser with an undisclosed optical power [31]) and 12.4 Gbps for an underwater link (evaluated in a water tank up to $\sim$10 m [74] using a 26 mW laser). In water, the attenuation of light (0.39 dB/m) falls between acoustic (0.1–4 dB/km) and RF (3.5–5 dB/m), resulting in a typical communication range of tens of meters [45]. Specifically for robotics applications, [25] demonstrated the use of an LED-based optical link for remote control of their robot. Inspired by these prior works, we establish an optical link across the air-water boundary. We focus on using off-the-shelf hardware to build a portable transmitter and receiver suitable for mobile underwater and aerial robots. Furthermore, we address practical systems challenges specifically related to wave dynamics to enhance link robustness.

9 Conclusion

We presented AmphiLight, a new system framework that enables a bidirectional air-water communication link using laser light. The implemented prototype uses an off-the-shelf MEMS mirror, fisheye lens, LD, and SiPM. Together, with the ultrasonic sensing design, the system performs robustly in real-world experiments. Final results showed throughputs up to 5.04 Mbps at 6.5 m in the air and 2.5 m underwater, making AmphiLight a promising technology to be deployed on flying and underwater drones.

Abstract

Modern cloud systems have a vast number of components that continuously undergo updates. Deploying these frequent updates quickly without breaking the system is challenging. In this paper, we present Gandalf, an end-to-end analytics service for safe deployment in a large-scale system infrastructure. Gandalf enables rapid and robust impact assessment of software rollouts to catch bad rollouts before they cause widespread outages. Gandalf monitors and analyzes various fault signals. It will correlate each signal against all the ongoing rollouts using a spatial and temporal correlation algorithm. The core decision logic of Gandalf includes an ensemble ranking algorithm that determines which rollout may have caused the fault signals, and a binary classifier that assesses the impact of the fault signals. The analysis result will decide whether a rollout is safe to proceed or should be stopped.

By using a lambda architecture, Gandalf provides both real-time and long-term deployment monitoring with automated decisions and notifications. Gandalf has been running in production in Microsoft Azure for more than 18 months, serving both data-plane and control-plane components. It achieves 92.4% precision and 100% recall (no high-impact service outages in Azure Compute were caused by bad rollouts) for data-plane rollouts. For control-plane rollouts, Gandalf achieves 94.9% precision and 99.8% recall.

1 Introduction

In a cloud-scale system infrastructure like Microsoft Azure, various teams need to frequently make software changes in code and configurations to deploy new features, fix existing bugs, tune performance, *etc.* With the sheer scale and complexity of such infrastructure, even a small defect in updating one component may lead to widespread failures with significant customer impact such as unavailability of the virtual machine service. Indeed, many catastrophic service outages are caused by some small changes [2, 3, 4, 5, 19].

Each software change, therefore, must be rigorously reviewed and extensively tested. Nevertheless, some bugs could remain uncaught due to the discrepancies between testing and production environment in cluster size, hardware SKU (stock keeping unit), OS/library versions, unpredictable workloads, complex component interactions, *etc.*

Thus, even when a software change passes testing, instead of updating all nodes at once, it is common practice to apply the change to production gradually following a safe deployment policy in the order of stage, canary, pilot, light region, heavier region, half region pairs, other half of region pairs. Figures 1 and 2 respectively show the scope and duration for rollouts in Azure infrastructure. More than 70% of the rollouts target multiple clusters, and more than 20% of the rollouts last for 1,000+ minutes.

Such characteristics imply that the very process of rolling out changes in production during the deployment phase presents an opportunity to catch bad changes in a realistic setting. If faults caused by a deployment can be caught at an early stage, it allows the release manager to stop the bad deployment and roll back the change in time to prevent it from causing broader impact such as a whole-region or worldwide unavailability.

Yet, accurately assessing the impact of a deployment in a cloud system is challenging. Solutions like component-level watchdogs [31] that check for a handful of component-level fault signatures are effective for capturing obvious, immediate issues. They alone, however, are insufficient in catching production issues that are minor locally but severe globally across clusters and/or regions. They may also miss latent issues such as memory leaks that happen hours after a rollout. Additionally, a component-level watchdog may fail to catch issues that arise only when interacting with other components, *e.g.*, cross-components API contract violations.

Besides false negative, false alarm poses another challenge. Figure 3 plots the number of deployments in Azure during a recent three-month window. We can see that hundreds of rollout tasks are happening every day. In addition, transient faults such as service API timeouts and temporary network issues are common in production. All of these events can eas-

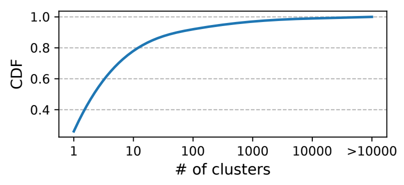

Figure 1: CDF of the scope (number of target clusters) of a rollout.

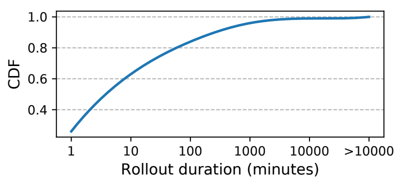

Figure 2: CDF of the rollout duration (in minutes).

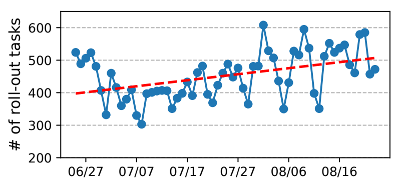

Figure 3: Number of rollout tasks per day. The red dotted line is a trend line.

ily mislead a local deployment health monitor to incorrectly attribute a failure to an innocent rollout. These false alarms would cause the innocent rollout to be stopped and prevent timely changes from being applied. Even worse, developers also waste significant time and resources in investigating such false alarms. Consequently, they would not trust future decisions from the monitoring system.

In this paper, we present Gandalf, an end-to-end analytics service that addresses the aforementioned challenges to ensure safe deployment in cloud infrastructure. Instead of analyzing each rollout separately based on individual component logs, Gandalf takes a top-down approach to assess the impact of rollouts holistically. Gandalf continuously monitors a rich set of signals from the infrastructure telemetry data including service-level logs, performance counters, and process-level events. When a system anomaly is detected, Gandalf analyzes if it is caused by a rollout. If a bad rollout is identified, Gandalf makes a "no-go" decision to stop it. Gandalf also provides detailed supporting evidence and an interactive front-end for engineers to understand the issue and the root cause easily.

The core decision logic of Gandalf is a novel model composed of anomaly detection, correlation analysis and impact assessment. The model first detects anomaly from raw telemetry data. It then identifies if a rollout is highly correlated to the detected failures through both temporal and spatial correlation and an ensemble ranking algorithm. Finally, the model uses a Gaussian discriminant classifier to decide if the impact caused by the suspicious rollout is significant enough to stop the deployment.

We design Gandalf system with a lambda architecture [6], combining a real-time decision engine with a batch decision engine. The real-time engine monitors a one-hour time-window before and after the deployment to detect immediate issues; the batch engine analyzes system behavior in a longer time-window (30 days) to detect more complex, latent issues. When Gandalf identifies a bad rollout, it automatically notifies the deployment engine to stop the rollout and fires a ticket with supporting evidence to the owning team.

Gandalf has been running in production for more than 18 months to ensure the safe deployment of Microsoft Azure infrastructure components (*e.g.*, host agents for Compute and Network, host OS). In an 8-month usage window, for data-plane rollouts, Gandalf captured 155 critical failures at the early stage and achieved a precision of 92.4% with 100%

recall (meaning that no high-impact incidents, *i.e.*, Sev0-2 outages, were caused by bad rollouts); for control plane, Gandalf achieved 94.9% precision and 99.8% recall, with only two missed issues and two false alarms while monitoring 1200+ region-level deployments. Gandalf has made a significant contribution to getting Azure availability closer to its 99.999% objective by limiting the blast radius of customer VM downtime caused by unsafe rollouts.

Gandalf has also improved the deployment experience for release managers: (1) from looking at scattered evidence to using Gandalf as a single source of truth; (2) from being skeptical about Gandalf decisions to enforcing them; (3) from ad-hoc diagnosis to interactive troubleshooting.

2 Background and Problem Statement

2.1 Deployment in IaaS Cloud

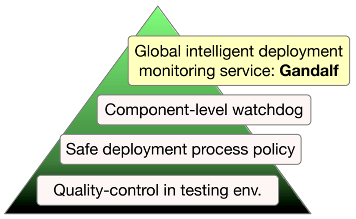
In IaaS cloud, the software stack on the physical nodes and virtual machines (VM) consists of many layers of components. Each component may frequently undergo changes on its independent rollout schedule to add features and fix bugs. These rollouts need to be executed with high velocity and minimum customer impact. For example, in early 2018, Azure quickly deployed a fix to mitigate the Meltdown [30] and Spectre [26] CPU vulnerabilities through a host OS update to keep Azure customers secure. The updates were deployed to millions of nodes that host customer VMs.

As shown in Figure 4, two main kinds of rollouts happen in Azure. The *data-plane* rollouts deploy changes for components running within the hosting environment of customer VMs. For Azure, those components include the host OS, the guest OS, and various software plugins, called agents, inside the host and guest OS. In contrast, *control-plane* rollouts deploy changes to tenant-level services. These services are composed of distributed running instances to manage the system infrastructure and provide interfaces for their functionalities. These control-plane components include the Azure Resource Manager (ARM) [1], which allows customers to query, create, update, and delete VMs with REST APIs and the CRP/NRP/DiskRP (Compute/Network/Disk Resource Provider), which handle customer requests and provision corresponding resources (e.g., virtual disks for VMs). These services are typically structured as loosely-coupled microservices in Azure that communicate with each other via APIs. While loose coupling allows each service to be deployed independently, their deployments also have intricate impacts on each other. Thus, a simple change in one service, while causing no failure in that service, might break the contract with another service and affect a large number of customer API calls if the defective change gets deployed to production.

2.2 Deployment Monitoring System

Requirements To ensure high availability of the VMs and services, rollouts are carefully monitored. Traditionally, safe deployment is a manual process that relies on email communications, multi-party approval, ad-hoc build test validation, and experience-based decisions, which is unsustainable at the scale of Azure. An automated deployment monitoring system is needed to globally oversee rollout progress and automatically stop bad rollout before it causes widespread impact. A deployment monitoring system should detect various anomalies in the large volume of infrastructure telemetry data. In addition, the monitoring system should accurately analyze if the observed failure is caused by a bad deployment or by another issue (e.g., random hardware faults). For the former case, the system should attribute the failure to the responsible deployment among all the ongoing deployments, stop the rollout immediately, and provide supporting evidence for developers to speed up further investigation. For the latter case, the system should not incorrectly blame and stop an innocent deployment.

Target Based on our experience, four kinds of failures happen in production environment: *(1)* hardware issues that happen randomly, *e.g.*, due to firmware bugs, temperature; *(2)* chronic software "hiccups", *e.g.*, due to race conditions; *(3)* hardware-induced outages, *e.g.*, power outage, broken network cable; *(4)* software outage due to bad code or settings in a recent build. Ambient software/hardware issues can be surfaced through separate anomaly detection solutions. In this work, we focus on deployment-related outages, *i.e.*, category *(4)*. Among the four layers of safe-deployment mechanisms



Global intelligent deployment monitoring service: **Gandalf**
Component-level watchdog
Safe deployment process policy
Quality-control in testing env.

Figure 5: Azure's four-layer mechanisms to ensure safe deployment.

in Azure as shown in Figure 5, Gandalf serves as the last safeguard, focus on catching system-level failures, including non-obvious and latent issues, caused by bad deployments.

3 Gandalf System Design

The importance of catching failures during rollouts and the complexity of rollouts in Azure infrastructure motivate the design and implementation of *Gandalf*. Gandalf is an end-to-end, continuous monitoring system for safe deployment. It automates the assessment of rollout impact, the approval or stopping of a rollout, the notification to the owning teams, and the collection of detailed evidence for investigation.

3.1 Design Challenges

In designing Gandalf, we need to address several challenges.

Supporting changes in system and signals. In Azure infrastructure, hundreds of thousands of update events with a large number of fault signals happen every day across the software stack in millions of physical nodes, VMs, and tenants. Gandalf needs to ingest a comprehensive set of data sources and efficiently process them in order to provide timely responses to developers. Furthermore, since Azure extensively employs agile development and micro-service designs, new components emerge and existing components evolve with changing failure patterns and telemetry signals [37]. Gandalf needs to support easy onboarding of new components and telemetry signals while maintaining a robust core decision logic.

Dealing with ambient noise. Ambient faults happen frequently due to diverse reasons such as hardware faults [20], network timeouts, and gray failures [24]. Many of them are unrelated to deployments and can be successfully tolerated. Gandalf needs to deal with such noise. Figure 6 shows an ambient noise example: container faults happened before and after a host OS update on 200+ clusters in Azure; but they were not caused by the host OS deployment—instead, they were caused by firmware defects that prevent the container from starting. User behaviors also affect failure patterns. For example, a customer might invoke a large number of `CreateVM` calls during weekdays. This could lead to an increase of API failures on weekdays and a decrease on weekends. Only monitoring the increase of faults after a deployment could then result in a wrong conclusion.

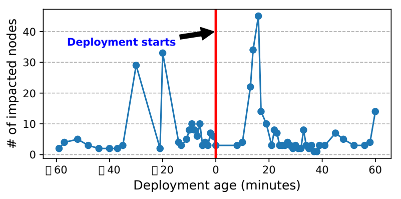


Figure 6: Ambient faults in deployment.

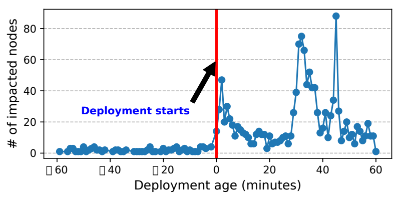

Figure 7: Spike of faults after deployment.

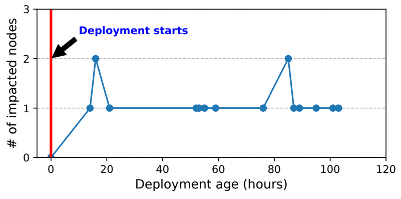

Figure 8: Latent faults after deployment.

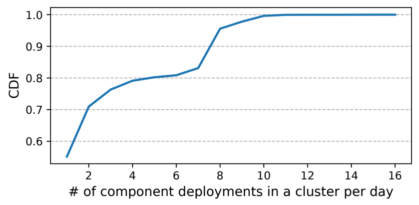

Figure 9: CDF of component count rolled out per cluster in a day.

Balancing speed and coverage. Developers want to get immediate feedback on bad rollouts. Figure 7 shows a typical spike of node faults that happened minutes after a bad rollout. Gandalf needs to quickly alert and stop the bad deployment upon detecting such failures. But a quick decision may be unsound if the failure patterns are subtle. Figure 8 shows an example of a latent issue detected more than 32 hours after the deployment. From the figure, we can see that there is no obvious spike after the deployment of the component. The faults are observed slowly in a long period. Those latent failures are usually only triggered by specific user workloads, e.g., accessing a specific directory or turning on a system service. Therefore, Gandalf needs to detect cross-cluster, latent issues even when a rollout has been ongoing for a while. Covering such latent issues takes longer time by nature.

Identifying the culprit. An n-to-n mapping relationship exists between components and failures: one component may cause multiple types of failure, while a single type of failure may be caused by issues in multiple components. Figuring out which failure is likely caused by which component is not easy due to the complexity of component behaviors. Figure 3 shows that more than 300 deployments take place in Azure every day and the number is increasing. Figure 9 further plots the number of deployment on a cluster per day, showing that about 45% of the clusters have multiple deployments per day.

3.2 System Overview

Figure 10 shows the overview of Gandalf. Gandalf takes a top-down approach in deployment monitoring by consuming telemetry data across clusters for holistic analyses. Gandalf processes three types of data: (1) *performance data* such as CPU performance counters and memory usage in the node; (2) *failure signals* such as agent faults, container faults, OS crashes, node reboots and API call exceptions; (3) *update events* that describe the component deployment information.

In order to balance speed and coverage for safe deployment, the analysis engine of Gandalf is structured in a lambda architecture [6] with a speed layer and a batch layer. The speed layer focuses detects simple, immediate issues and provides quick feedback to developers. The batch layer detects latent, more complex failures and provides more detailed evidence for developers to investigate the issue.

The analysis results from the streaming processed data and batch processed data are consolidated into the serving layer. The serving layer is built as a highly-reliable and scalable web service. The web service stores the analytics results in batch and streaming tables and provides interfaces for various reporting applications to consume the results. The applications include a monitoring front-end for developers to view the rollout status in real-time, a diagnosis UI for investigating problematic rollout, and REST APIs to directly query the result data. Based on the decisions, Gandalf will notify the corresponding component team and create an incident ticket accordingly. Besides notifications, Gandalf publishes the binary decisions for different components into a key/value store to communicate with the deployment engine. The deployment engine subscribes to the signals in the key/value store and stops the rollout if a “no-go” decision is made.

3.3 Data Sources

As a deployment monitoring system, Gandalf continuously ingests deployment events in the Azure infrastructure. These events describe the software build version along with the deployment timestamp and location information. To focus on the system-level impact of rollouts, Gandalf consumes comprehensive signals from various data sources such as service logs, Windows OS events, performance counters, and machine/process/service-level exceptions. Typically each signal is ingested from a separate table in the telemetry data collected in Azure infrastructure. For certain signals, Gandalf performs pre-processing to parse the raw data (e.g., log messages) and extract a failure signature (e.g., an error code). These pre-processed signals are aggregated based on their timestamps, node IDs and service types during the analysis.

When onboarding a new component to Gandalf, the component team needs to provide information about where Gandalf can get the deployment events and the telemetry signals relevant to the component. To ease the correlation analysis

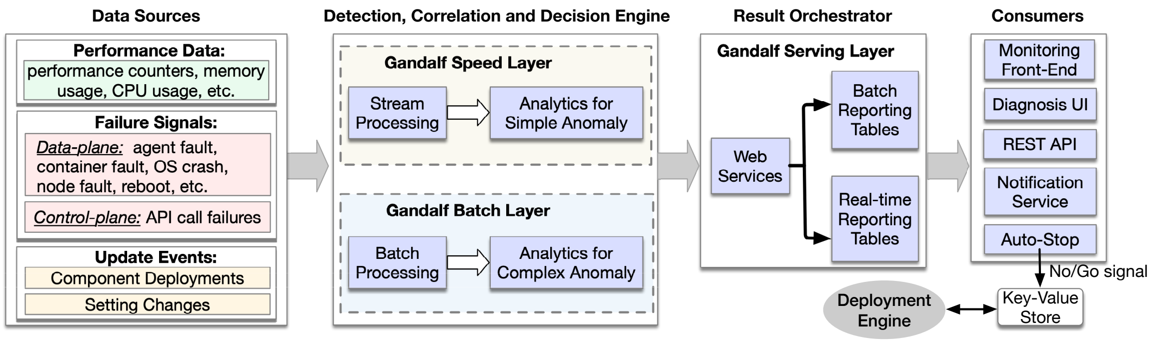

Figure 10: Overview of Gandalf system.

Attribute	Description

Table 2: Gandalf fault signal input data schema.

between telemetry signals and deployment events, Gandalf requires the information to be structured in a unified data schema as shown in Table 1 and Table 2.

3.4 Stream and Batch Processing

To balance speed and coverage, Gandalf is designed in a lambda architecture [6] with both streaming and batch analysis engines. The speed layer consumes data from a fast pipeline, Microsoft Kusto [7], which is a column-oriented cloud storage supporting analytics with a few minutes of data source delay and up to seconds of query delay. Kusto has a custom query language based on the data-flow model, with native support for streaming operators. Although Kusto has short delays, it cannot efficiently handle a large volume of data using complex algorithms. Therefore, the analysis engine in the speed layer only considers fault signals that happen 1 hour before and after each deployment in each node, and runs lightweight analysis algorithms to provide a rapid response. In Azure, most catastrophic issues happen within 1 hour after the rollout. Latent faults occurring after 1 hour will be captured by the batch layer later.

The Gandalf batch layer consumes data from Cosmos, which is a Hadoop like file system that supports SQL-like query language with up to hours of data source delay. Despite the relatively long delay, Cosmos is an ideal platform for processing an extremely large volume of data using complex models (*e.g.*, it supports external C++ plugins) to detect complex failure and latent issues. This allows the batch layer to analyze faults in a larger time window (30-day period) with advanced algorithms. The lambda architecture allows us to provide both fast decision making and higher coverage over time. A no-go decision can be triggered anytime within the window if the impact scope is large enough.

Both stream and batch analysis in Gandalf are performed in an incremental fashion. Every 5 minutes, the stream processing fetches the latest data streams from Kusto and passes it to the analysis engine in the speed layer. The batch processing runs as an hourly Cosmos job to process the data since the last processing time. The partial results from analyzing each 5 mins mini-batch or hourly batch are aggregated with other partial results in the analysis window to update the overall result. The incremental analysis improves the efficiency as well as the fault tolerance of Gandalf—if the analysis job is restarted, it can resume from the last checkpoint.

3.5 Result Orchestration and Actions

The serving layer of Gandalf is implemented as a highly-reliable and scalable web service using the Azure service fabric framework [8]. After each run of Gandalf's anomaly detection and correlation algorithms (which we will describe in Section 4), the results from the speed and batch layers are stored in two separate reporting tables through the web service. These results contain the deployment impact assessment, the recommended decisions (*"go"* or *"no-go"*), the anomaly patterns, the correlation information, etc.

In general, the telemetry data Gandalf analyzes is both streamed into Kusto and dumped into Cosmos hourly/daily. Given that the data ingested by the speed and batch layer is essentially the same, the reporting results in the two tables are mostly consistent. For example, if the speed layer quickly detects a bad deployment, the batch layer will likely catch it as well, albeit slower. The scenarios when they are inconsistent is mainly when the batch layer reaches a *"no-go"* decision while the speed layer decides a *go*. This is by design since the batch layer makes more informed decisions and covers latent issues that the speed layer cannot detect.

Various DevOps applications pull the results from the reporting tables. This way, the Gandalf system is well integrated into the DevOps workflow. Among the applications, the most important one is the notification service. When the notification service notices a new no-go decision, it sends an email about the decision to the owning team and creates an incident ticket with details. It also notifies the deployment engine via a key-value store to approve or stop the rollout.

3.6 Monitoring and Diagnosis Front-End

Gandalf provides a web front end to enable real-time rollout monitoring and issue diagnosis support for release managers and developers. The feature teams can proactively watch the rollout KPIs (e.g., rollout progress, NodeFaults, Container Faults, OS Crashes, Allocation Failures and etc.) in real-time while waiting for the decision from the Gandalf notification service. After the decision of a rollout is made and sent to the corresponding team, Gandalf provides information to help developers investigate the issue and make a quick fix as needed. For example, Gandalf provides pivot information of the identified issues (*i.e.*, the issue happens only in instances that have specific attributes like SKU).

The Gandalf front-end provides the following views: (i) a binary decision page that summarizes all rollout decisions for different components and build versions in different environments; (ii) a rollout profile page that displays the batch processed decisions and associated diagnosis information; (iii) an issue profile page for a bad rollout with diagnosis information such as the impacted nodes and clusters or the trend in different environments; (iv) a real-time tracking page that shows the rollout progress, related failures, etc.

4 Gandalf Algorithm Design

Existing Algorithms. In designing the algorithms for Gandalf, we considered existing options from supervised learning, anomaly detection and correlation analysis but found major limitations for each of them. Supervised learning is difficult to apply because system behaviors and customer workloads as well as failure patterns and failure-update correlation keep changing. In addition, learning from historical change behaviors does not necessarily help predict the future mapping between failure patterns and new updates. Existing anomaly detection algorithms alone are also insufficient. This is because many rollouts may happen simultaneously in the infrastructure but anomaly detection itself does not tell which deployment is responsible for the anomalies. For correlation analysis, most state-of-the-art methods focus on temporal correlation based on Pearson correlation [34], which cannot capture the complex causal relationship in our scenario.

Anomaly Detection
Ensemble Voting
Spatial & Temporal Correlation
Time Decaying
Blamed component
Fault signatures
Decision process: assess the impact of the blamed component and failures
Binary decision + supporting evidence

Figure 11: Gandalf correlation model.

Overview. The Gandalf model consists of three main steps: *(1)* anomaly detection detects system-level failures from raw telemetry data; *(2)* correlation analysis identifies the components responsible for the detected failures among multiple rollouts; *(3)* the decision step evaluates the impacted scope and decides whether the rollout should be stopped or not. The correlation step in (2) is further divided into four parts, namely, ensemble voting, temporal correlation, spatial correlation and exponential time decay. Figure 11 shows the overall analysis process in the Gandalf. In the following Section, we describe each step of the algorithm in detail.

4.1 Anomaly Detection

The raw telemetry data that Gandalf analyzes, such as OS events, log messages, and API call statuses, may be imprecise. Therefore, Gandalf first derives concise fault signatures from raw data to distinguish different faults. A raw fault event log usually contains both error codes and error messages. One error code could map to multiple faults if it is too generic. For example, a POST API call that requests compute resources could return `HTTP ERROR 500` for different reasons like `AllocationFailure` or `NetworkExecutionError`. Directly analyzing the error codes would mix different faults, diluting the signal and leading to wrong conclusions. The error messages, on the other hand, are usually non-structured plain text with many unnecessary details. Gandalf processes the raw error messages and applies text clustering [10] to generate fault signatures. We first replace the unique identifiers such as VM ID, subscription ID with dummy identifiers using an empirical log parser similar to prior work [18, 22]. Then we run a simplified incremental hierarchical clustering model [36] to group up all processed text into a set of error patterns, *e.g.*, "Null References" grouped together with `NullReferenceException`.

After obtaining the fault signatures, Gandalf detects anomalies based on the occurrences of each fault signature. Ambient faults, such as hardware and network glitches or gray failures [24], are common in a large-scale cloud system. Simple threshold-based anomaly detection is ineffective because the system and the customer behaviors change over time. With thousands of signatures, it is also unrealistic to manually set thresholds for each. Gandalf instead estimates the baseline from past data using Holt-Winters forecasting [14] to detect anomalies. The training period is set to the past 30 days and the step interval is set to one hour. When the observed value deviates from the expected value by more than 4σ, the point will be marked as an anomaly.

For some components, the occurrences of different fault signatures vary significantly. For example, the volume of client errors could be much higher than platform errors. To better compare the impact of different fault signatures, Gandalf calculates z-score [28], $z_i = \frac{x_i - \mu}{\sigma}$, for each anomaly against historical data in its correlation process.

4.2 Correlation Analysis

A detected failure may not be caused by a bad rollout but other factors such as random firmware issues. In addition, at any point, many concurrent rollout tasks can take place in a large system. Therefore, once anomalies are detected, Gandalf needs to correlate the observed failures with deployment events, and evaluate the impact of the failure on the fly. Note that this identified component might be the triggering component but not necessarily always the root cause.

4.2.1 Ensemble Voting

Since many components are deployed concurrently, we use a vote-veto mechanism to establish the relationship between the faults and the rollout components. For a fault e that happens at timestamp t^f and a rollout component c deployed at t^d on the same node, each fault e votes for all the components deployed before it (i.e., $t^d < t^f$) within a window size w_b and vetoes all the components deployed after it (i.e, $t^d > t^f$) within a window size w_a. Since the deployments are rolled out continuously on different nodes at different time, as shown in Figure 12, we aligned the votes $V(e,c)$ and vetoes $VO(e,c)$ for deployed component c across all nodes based on the fault age as defined as $age(e,c) = t^f - t^d$. P_i are the votes aggregated on WD_i as

$$P_i = \sum_k V(e, c|WD_i), \tag{1}$$

where $age(e,c) < WD_i$. By default, 4 different hour windows are used as WD_1=1, WD_2=24, WD_3=72, WD_4 is the duration between the deployment and the latest data point; k is the number of nodes with the pairs. Similarly, B is the veto aggregated in a single 72 hour window as

$$B = \sum_k VO(e, c|WD_{-1}), \tag{2}$$

where $age(e,c) < WD_{-1}$ and WD_{-1}=72.

4.2.2 Temporal and Spatial Correlation

After ensembling the votes of faults to the components, we calculate the temporal correlation score as

$$ST(e,c) = \sum_{i \in [1,4]} w_i \log\left(\frac{(P_i - B + 1)}{B+1}\right), \tag{3}$$

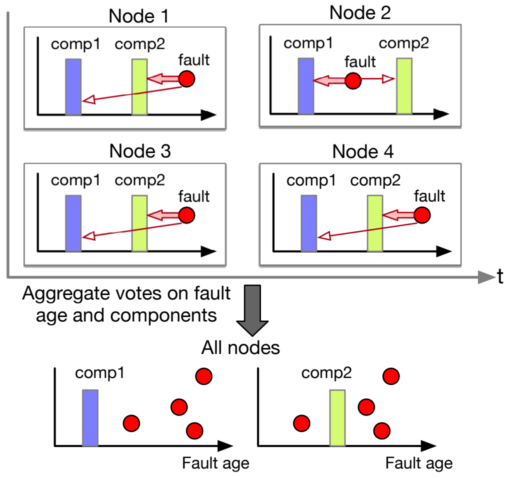

Figure 12: Faults alignment by fault age during ensemble voting. The circle represents a fault. The vertical bar is when a component gets deployed in a node. The arrow blames a fault to a deployment, where the arrow size represents correlation strength.

where $P_i > B$. w_i is the weight of the time window WD_i in Section 4.2.1. This kernel function tries to filter out the ambient faults.

As we do not have ground-truth samples to train the values of w_i in the above equation, we set them empirically. A naïve way would be to assign them the same value. This does not work well in practice because a component deployed closer to a fault usually has a higher correlation, implying the constraint $w_1 > w_2 > w_3 > w_4$. We learned over time that setting *exponential weights* (EW) for w_1 to w_4 works well. The intuition behind exponential weights (EW) is that faults happening right after the deployment are much more likely to have causal relationship than the faults happening a long time after the deployment.

We then evaluate the spatial correlation through

$$SS(e,c|t_1,t_2) = N_f / N_{df}, \tag{4}$$

where N_f is the number of nodes with fault e during the deployment period t_1 to t_2 for component c, and N_{df} represents the total number of nodes with fault e, regardless of whether c was deployed during the same period. If $SS(e,c|t_1,t_2) < \beta$, where β is the confidence level, we will ignore the blaming of the pair. The confidence level can be set as 99% or 90% for different sensitivity. We then identify the blamed component c_j by associating the faults to the component with the largest temporal correlation:

$$blame(e) = \arg\max_{c_j} ST(e, c_j) \tag{5}$$

4.2.3 Time Decaying

The blaming score is calculated based on the fault age as shown in Equation 3. If the same fault signature appears again, the fault may still blame the old rollout if the fault age between the old rollout and the fault signature is smaller. We need to focus on new rollouts and gradually dampen the impact of the old rollout because newly observed faults are less likely to be triggered by the old rollout. In order to achieve this, we apply an exponential time decay factors on the blaming score:

$$blame(e) = blame(e) * (\frac{e^{-t} - e^{-w_s}}{e^{-1} - e^{-w_s}}) * b + a \tag{6}$$

4.3 Decision process

Finally, we make a go/no-go decision for the component c_j by evaluating the impacting scopes of the deployment such as the number of impacted clusters, the number of impacted nodes, number of customers are impacted, *etc.* Instead of setting static thresholds for each feature, the decision criteria are trained dynamically with a Gaussian discriminant classifier [9]. The training data is generated from historical deployment cases with feedback from components teams. Note that the impacting scope feature set used in this step is typically organizational policy oriented so it is stable and independent from software changes or bug fixes. Thus it is feasible to obtain good labels for this learning approach comparing to the input features used in correlation analysis.

4.4 Incorporating Domain Knowledge

Gandalf by default treats the input fault signals equally but also allows developers to specify the importance of certain faults with customizable weights. The weights are relative values ranging from 0 to 100, representing the least to the most importance. The default weight for a fault signal is 1.

Weights are usually adjusted by developers reactively, e.g., after investigating a reported issue. For example, developers for certain service may find out the `TimeoutException` tend to be noisy so they reduce its weight to 0.01 for that service; for the Disk Resource Provider, developers may set the weight of `NullReferenceException` to 10 so that Gandalf becomes more sensitive to this failure signature because it is a strong indicator of a code bug. If the weight is set to 0, this failure signature is whitelisted. For example, since developers know that during the rollout of NodeOSBaseImage, node reboots are expected, the weight for `NodeReboot` can be set to 0 to exclude it from the correlation analysis. In general, developers rarely set a fault weight to 0 to avoid missing true issues unless the signal keeps causing false alarms or to encode special rule like the previous example. Since Gandalf exposes the weight settings to developers through a database table, developers sometimes use scripts to adjust weights in a batch, e.g., lowering weights for all `AllocationFailure*` signatures.

5 Evaluation

Gandalf is a production service in Azure. In this Section, we evaluate its business impact, provide three case studies, and analyze the effectiveness of the core algorithms (Section 4).

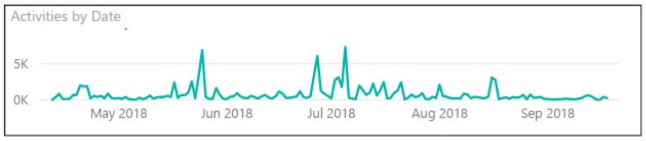

Figure 13: User activities of Gandalf real-time monitoring UI.

5.1 Business Impact

Adoption. The Gandalf service has been running in production and monitoring the Azure infra rollout safety for more than 18 months. It has been widely adopted for the deployments of data-plane components and control-plane services (Section 2.1) across the entire fleet. Specifically, Gandalf currently monitors 19 component rollouts in the data plane including Host OS updates, Agent Package updates, GuestOS updates, *etc.*, as well as 4 control-plane component updates including Compute Resource Provider, Disk Resource Provider, Azure Front End, and Fabric Controller. Figure 13 shows the usage of Gandalf front-end by release managers and developers. Usually, hundreds of page-visits occur every day. When a large rollout happens, the daily number of page visits can reach several thousand.

Scale. The Gandalf system processes on average 270K platform events daily, 770K events on peak days, and logs about 600 million API calls per day in the control plane, including more than 2,000 fault types. The total data volume analyzed is more than 20 TB per day.

Deployment Speed. Gandalf has significantly improved the release velocity. For each deployment, Gandalf can make decisions in about 5 minutes end-to-end on the speed layer, and in about 3 hours on the batch layer. Gandalf cuts the deployment time for the entire production fleet by more than half (Figure 14). As a result, billions of customer API requests will benefit from new features much earlier.

Gandalf streamlines the traditionally cumbersome deployment workflow. Prior to Gandalf, the component-level watchdogs were sometimes noisy or missed important failures. Thus, extensive email communications were needed among the release manager, feature owners and dependent component teams to clear suspicious failure alerts and obtain approval. As a 24/7 monitoring system, Gandalf removes the majority of these costs. Meanwhile, Gandalf provides rich supporting evidence for each alert to facilitate further investigation.

As Azure grows with ever more data to analyze, Gandalf can benefit from additional innovations that improve the performance of analytics systems [29, 35, 38]. For example, if we can cut the delay of our streaming layer from 5 minutes to 10s, it will greatly improve the deployment speed. On the other hand, even with ultra-low data processing latency, Gandalf still needs to wait to accumulate enough evidence for high-confidence decisions. If the rollout quality can be predicted beforehand, the system will have higher business impact. We leave this as our future work.

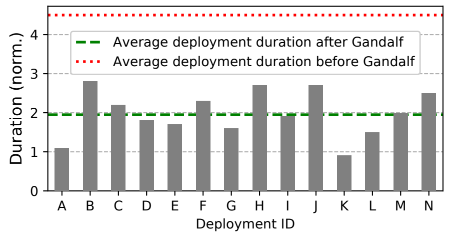

Figure 14: Deployment duration before and after adopting Gandalf

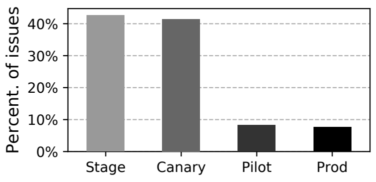

Figure 15: Percentage of issues detected in each environment.

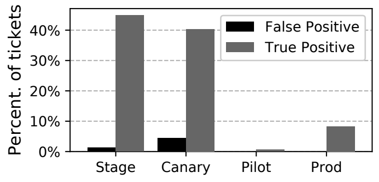

Figure 16: Accuracy of tickets issued by Gandalf in each environment.

5.2 Accurately Preventing Bad Rollouts

Azure enforces a safe deployment policy for all rollouts. Before a component update can be pushed to production, it must pass tests in several environments in the order of Stage, Canary and Pilot. Figure 15 shows the percentage of issues we detected in different environments for rollouts in the data plane. We can see that almost all (99.2%) suspicious rollouts are blocked before reaching production. The rest (0.8%) is blocked in the early stage of production. This means Gandalf effectively limits the blast radius of most bad rollouts.

Once Gandalf stops a rollout, it will send an alert ticket to the corresponding team. Figure 16 shows the accuracy of the alerting in different environments. We can see that most of the false alerting are issued in Stage and Canary environment, which is well aligned to the Gandalf design goal. The false positive rate in Stage and Canary is higher compared to other environments because there are higher levels of noisy failure signals in these environments. Latent issues may mislead the Gandalf service. For example, a faulty agent update accidentally deletes an important folder but does not cause immediate faults. Later, a GuestOS update by customer touched that folder and triggered faults, causing Gandalf to mis-blame the GuestOS deployment.

Overall, in an 8-month usage window from Jan. 2018 to Nov. 2018, Gandalf captured 155 critical failures at the early stage of the data-plane rollouts and achieved a precision of 92.4% with 100% recall (no high-impact incidents were caused by bad rollouts). The detected failures are diverse, including agent faults, OS crashes, node faults, unhealthy containers and VM reboots, which would have caused widespread availability outages. For the control plane, Gandalf has made decisions for 1200+ region-level deployments. The precision is 94.9% and recall is 99.8%. Gandalf filed 39 incidents and only 2 of them are false alarms. Meanwhile, Gandalf automatically approved all other region-level deployments and only missed 2 true issues. One false negative occurred because of incomplete logs. The other was due to the faulty component throwing generic timeout exceptions instead of specific errors, which misled Gandalf.

The most common issues Gandalf caught are compatibility issues and contract breaking issues. Compatibility issues arise when updates are tested in an environment with latest

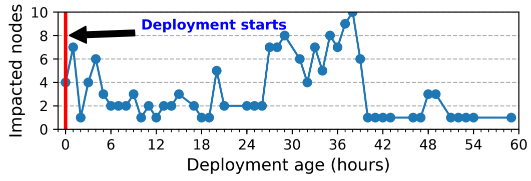

Figure 17: Latent faults caused by network agent deployment.

hardware or software stack but the deployed nodes may have different hardware SKUs or OS or library versions. Contract breaking issues occur when the component does not obey its API specifications and break dependent components.

5.3 Case Studies

We share three representative cases of bad rollouts that Gandalf successfully prevented.

***Case I*: Cross-component Impact.** Release managers tend to ignore faults from other components, which may miss cross-component reliability issues. Gandalf makes informed decision based on anomaly detection and correlation analysis, and is sensitive to such issues. In one case of deploying a Compute Resource Provider (CRP) service update, Fabric Controller (FC) lease failures occurred. When Gandalf first made a no-go decision for the deployment in Canary regions, CRP team claimed these failures were irrelevant to CRP rollout based on their past experience. Therefore, the release manager directly requested to bypass the no-go decision and unblock the rollout. Later on, Gandalf issued another no-go decision in Pilot regions for the same reason, indicating a strong correlation between this failure and CRP rollout. With such evidence, CRP team did a deeper investigation and confirmed it was indeed a regression in CRP. When the customers in Pilot regions reported relevant issues, a hotfix had already been deployed. Because of Gandalf, the regression was caught before it could enter production.

***Case II*: Impact in Specific Region.** After a rollout passes the Pilot regions, release managers typically assume the software updates are in high quality. But Gandalf keeps monitoring throughout the deployment process. Issues that arise at this stage are usually not caused by code bugs of the deployed component but rather the incompatible settings in a specific

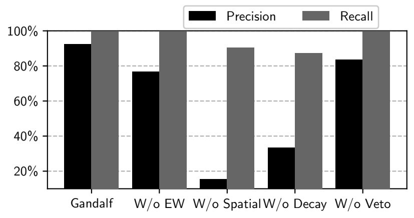

Figure 18: The effectiveness of each Gandalf correlation algorithm.

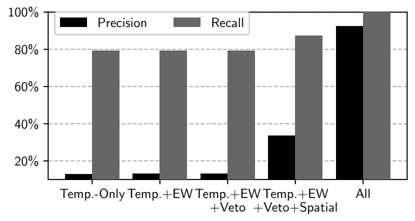

Figure 19: Accumulative effects of correlation algorithms.

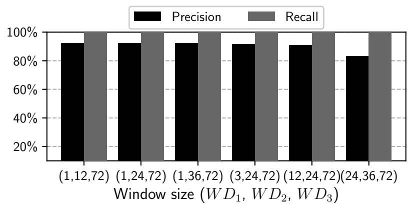

Figure 20: Effectiveness of Window Size.

region. Gandalf is effective in detecting these region-specific issues. For example, during one DiskRP service deployment, Gandalf made a no-go decision in SouthFrance, a late-stage production region. The alert turned out to be caused by a compatibility bug introduced by another component, which is only exposed after the latest DiskRP being deployed in this specific region. With the timely alerting and mitigation, only 3 subscriptions were impacted.

***Case III*: Latent Impact.** Gandalf detects not only immediate issues that happened right after the deployment but also latent issues that happen several hours or even days after deployments. Gandalf detects the latent issues in the early stage and prevents it from affecting customers in production environment. Figure 17 shows a deployment case of a Network Agent in Canary. OS crashed during 24 hours to 72 hours after the deployment and Gandalf issued a Sev2 alert (i.e., large customers impacts). The root cause was a conflict between old firmware version and new driver version. When the network agent rollout upgraded the NIC firmware and drivers, the firmware upgrade script missed one of the hardware revisions. Gandalf accurately attributed the faults to the Network Agent deployment even though the failures occurred 24 hours after the deployment, while many other concurrent updates was ongoing in these clusters.

5.4 Effectiveness of Correlation Algorithms

In this Section, we evaluate the effectiveness of the Gandalf correlation algorithms. The results are from real rollouts in Azure between Jan. 2018 to Nov. 2018.

Parameter Settings. w_i in Equation 3 is respectively set to 8, 4, 2, 1, so that the weights are exponentially decreased along the time windows. The spatial correlation threshold β is set to be 0.8 to tolerate noise in the telemetry data. The w_s in Equation 6 is set to 90 as the longest monitoring period of a rollout is 90 days. b is set to 1 and a is set to 0.2 so that the decay factor is scaled between $[0.2, 1]$.

Exponential Weights. Figure 18 shows that without the exponential weights (EW) used in temporal correlation for different time windows, the precision decreases but the recall remains the same. The reason is that given a spike of faults, without EW, the blame score is high for a bunch of components in addition to the real one, which leads to low precision but the same recall. EW treats component with different fault ages differently, which increase the precision.

Spatial Correlation. Figure 18 shows that by incorporating spatial correlation, Gandalf correlation precision is increased by 77%. The reason is that multiple components are often rolled out in similar time frame in a large system. The temporal correlation results can be very noisy. By incorporating the spatial correlation, the noisy results can be greatly reduced. As the algorithm can accurately identify the problematic components and prevent it from causing high impacts to customers, the recall also increases.

Time Decaying. Figure 18 shows that without the time decaying algorithm, the precision decreases by 58.8% and the recall decreases by 12.7%. The reason is that after a fault (*e.g.*, connection timeout) is detected in a bad rollout, the bug causing the fault will be fixed. Later, the same timeout fault might still occur due to other bugs in another component being deployed. If we do not have the time decaying algorithm, the fault may be still blamed on the old component while missing the faulty new component.

Veto. Gandalf uses a veto mechanism to reduce ambient noise. Figure 18 shows that without the vetos, the precision decreases by 8.7% and the recall rate is the same. The reason is that if the failure signature appears before the rollout, the failure is more likely not related to the rollout. If we only look at the failure after the deployment, we are more likely to stop rollout based on the ambient signals.

Accumulative Effects of Algorithms. Figure 19 shows the accumulative effect of different algorithms. Comparing Figure 19 with Figure 18, we can find that the spatial algorithm and the time decaying algorithm contribute most to precision. Although the individual algorithm such as veto, exponential weights is important as shown in Figure 18, without the spatial correlation algorithm and the time decaying algorithm, their effects alone on precision are relatively small.

5.4.1 Impact of Window Size

Figure 20 shows the effect of window size settings. We can see that the choices of window size do not significantly affect precision. This is because the main purpose of different windows is to differentiate the importance of the time between

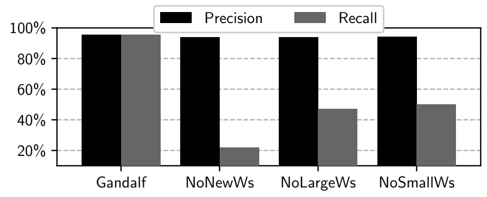

Figure 21: Impact of weight settings for control plane.

updates and anomalies. As long as the window size can provide different weights to the time interval between faults and update events, the precision should be similar as the spatial and temporal correlation algorithms are the major contributor to noise reduction. However, from the figure we can see that if WD_1 and WD_2 windows are too large, the precision decreases. The window size has no effects on the recall due to the same reason as that of the EW effectiveness.

5.4.2 Effectiveness of Weight Adjustments

Figure 21 shows how weight adjustments impact Gandalf decisions on the control-plane rollouts from 01/01/2019 to 03/06/2019. In this experiment, we compare Gandalf decisions using customized weights with 1) decisions without weight adjustment for all new faults (*NoNewWs*); 2) decisions without weight adjustments for all important faults (*NoLargeWs*), *i.e.*, all large weights changed back to 1; 3) decisions without weight adjustment for all noisy faults (*NoSmallWs*), *i.e.*, all small weights changed back to 1. We can see that *NoNewWs* decreases the precision slightly (1.8%) and decreases the recall significantly (73.2%). *NoLargeWs* and *NoSmallWs* have a similar effect on precision and recall. The experiments show that customizing weights can significantly improve recall while maintaining high precision.

From Sep. 2018 to Mar. 2019, 47% of the fault signatures are assigned with non-default weights, with 5 to 10 weights customized for a typical component/team. During this period, only the weights of 18 signatures in total are adjusted 4 times by developers. Thus, the tuning efforts overall are small.

6 Discussion

Gandalf has been running in Azure production environment for more than 18 months. In this section, we share perspectives from our users (Azure engineers and release managers) and lessons we learned along the way.

6.1 Transforming Deployment Experience

"We can call it a very good day for Gandalf!"

"This is a good case for Gandalf and a lesson or two for us"

"Gandalf has helped our rollout to the better. Thanks!"

– Comments from our users

The impact of Gandalf goes beyond accurately preventing bad rollouts. We are thrilled to witness how Gandalf has transformed the engineers and release managers' experience in deploying software changes:

From looking for scattered evidence to using a single source of truth. Before Gandalf was created, component-level watchdogs are used for safe deployment. These watchdogs only have isolated views about individual components. It is therefore difficult to rely on them for safe deployment. Consequently, release managers still need manual efforts to check the deployment behavior from additional data sources and communicate across related teams for ensuring deployment safety. The additional communication cost and decision overhead caused the deployment period to be long. Gandalf ingests comprehensive data sources in the data plane and control plane, and runs system-level analysis with anomaly detection and correlation models. Therefore, Gandalf can provide a single source of truth with various dimensions.

From skeptic to advocate. When some teams adopt Gandalf, the experienced engineers may be initially skeptical about Gandalf's data-driven approach and its decisions. As Gandalf detects complex failures that even experts can miss, the engineers start to trust Gandalf decisions and enforce the team to carefully investigate each "no-go" alert by Gandalf. For many teams, the deployment policy has become that the rollout will not continue to the next region unless Gandalf gives a green light decision.

From ad-hoc diagnosis to interactive troubleshooting. Before Gandalf, when an alert was sent to a component team, the engineers needed to write various queries for multiple data sources or access some sample nodes to grep the fault traces for diagnosis. Gandalf provides an interactive diagnosis portal to directly show the fault details. In particular, Gandalf aggregates the VM-level, node-level and cluster-level faults and buckets these faults based on their fault types. For example, faults "`Failed function: RuntimeVmBaseContainer::ValideXBlockBaseDisk: 0x81700035, XDiskLeaseIdMismatchWithBlobOperation: 0xc1425034`" will be bucketed into `ContainerFault-Creation-DiskLeaseIdMismatch`. Developers can drill down each fault bucket interactively to inspect the detailed fault source such as error messages and logs. The portal also shows the historical baselines to illustrate the difference so that the developers can better understand the impact scope and severity. Moreover, the portal shows the pivot analysis results, *e.g.*, SKU Gen2.3, that highlight potential causes.

6.2 Lessons Learned

We also learned several lessons while we built Gandalf. First, while F-score is a widely used metric to balance the precision and recall of a decision model, in reality, different components may favor precision and recall differently. For teams with limited engineering capacity, they often prefer a system that only sends true alerts so that engineers can focus on investigating true issues. For teams that manage mission-critical services, 100% recall is a strict requirement. Missing any true issues causes much more damage than false alarms. A monitoring system should be tailored for different needs. For example, to fix the Meltdown and Spectre CPU vulnerability, the updates needed to be deployed to millions of nodes quickly. Since the rollout would impact millions of customers, Gandalf was optimized for extremely high recall and feature teams used the interactive portal to proactively monitor the rollout. False alarms were less critical in this scenario as engineer resources were enough to investigate all Gandalf reported issues.

Second, transparency and supporting evidence are crucial to build trust. It is difficult to trust machine decisions, especially on critical tasks. In cloud deployments, the release manager holds the same opinion because a simple false decision could be extremely harmful. That is why a black-box service that is not explainable is hard to be adopted for deployment monitoring even if the decisions are highly accurate. To gain trust, we design the Gandalf model to match the human decision process and make every step transparent. Gandalf surfaces rich supporting evidence, including the ranked list of faults, where the faults occurred, comparison of the time-series signal data before and after deployment, statistical summaries of the impact scope (*e.g.*, how many nodes and customers are affected). Such evidence helps explain to release managers why Gandalf makes each decision.

Third, analytics models should be adaptive. Many standard anomaly detection and time series algorithms are ineffective in a large-scale production system if applied without domain knowledge. It is almost impossible or at least extremely costly to learn such domain knowledge purely from the data. This is especially true when the system is constantly evolving, *e.g.*, an increasing number of new fault signals will emerge. We work closely with engineers to continuously incorporate their input into Gandalf decision model (because domain knowledge may not be fully discovered in one shot!).

7 Related Work

Time-series based anomaly detection models [13] provide high-quality alerts in DevOps. Instead of checking raw logs, DevOps can focus on the anomalous failure events while new build is rolling out [39]. Hangal and Lam first introduce DIDUCE [21], a practical tool that detects complex program errors and identifies root causes. Wang *et al.* [40] propose entropy-based anomaly testing, which uses arbitrary metrics distributions instead of fixed thresholds, for online systems anomaly detection. Fu *et al.* [17] propose classification algorithms to identify performance issue beacons. Laptev *et al.* [27] design a generic time-series anomaly detection framework, EGADS for Yahoo. Cohen*et al.* [16] use Tree-Augmented Naive Bayes models (TAN) to correlate SLO with system states as signatures. Panorama [23] detects gray failures through instrumenting observability hooks in the source code of observer components. However, without correlating anomalies with operational events, these work cannot identify which rollout is responsible or whether the detected anomalies are unrelated to deployments.

A number of tools have been built to analyze the correlation between KPI signals and system state changes. Bahl *et al.* [11, 12, 15] propose an inference graph that captures the dependencies between all components of the IT infrastructure by combining together these individual views of dependency and tries to locate the root cause. Azure is growing so fast that it is hard to build such dependency graph accurately at low cost. Several other methods are proposed for correlating systems signals and events [25, 32, 33, 41, 42]. But they mainly focus on extracting correlations in temporal dimension. Pure temporal correlation is insufficient for accurately identifying bad rollouts in our scenario.

8 Conclusion

In cloud infrastructures that undergo frequent changes, ensuring bad rollouts are accurately caught at the early stage is crucial to prevent catastrophic service outage and customer impact. In this paper, we present Gandalf, an end-to-end analytics service for safe deployment of cloud infrastructure. Gandalf assesses system-level impact of deployments by designing anomaly detection, correlation analysis and failure impact analysis algorithms in its decision model. It uses a lambda architecture to provide both real-time and batch deployment monitoring, with automated deployment decisions, a notification service and a diagnosis front-end. Gandalf has been running in Azure production for more than 18 months. Gandalf blocked 99.2% of the bad rollouts before they enter production. For data-plane rollouts, Gandalf achieved 92.4% precision with 100% recall. For control-plane rollouts, Gandalf achieved 94.9% precision and 99.8% recall.

Acknowledgments

We thank the anonymous NSDI reviewers and our shepherd, Sujata Banerjee, for their valuable comments. We thank Microsoft Azure engineers who have been closely working with us, giving us feedback, adopting and using the Gandalf system, especially Chango Valtchev, Pengfei Huang, Alp Onalan, Francis David, Naga Govindaraju, Richard Russo, Roy Wang, Huaming Huang, Abhishek Kumar, Yue Zhao, Binit Mishra, Rishabh Tewari, Raza Naqvi, Igal Figlin, Anupama Vedapuri, and Cristina del Amo Casado. We thank Girish Bablani, Mark Russinovich, Dongmei Zhang, and Marcus Fontoura for their great support and sponsorship.

Experiences with Modeling Network Topologies at Multiple Levels of Abstraction

Abstract

Network management is becoming increasingly automated, and automation depends on detailed, explicit representations of data about the state of a network and about an operator's intent for its networks. In particular, we must explicitly represent the desired and actual topology of a network. Almost all other network-management data either derives from its topology, constrains how to use a topology, or associates resources (e.g., addresses) with specific places in a topology.

MALT, a Multi-Abstraction-Layer Topology representation, supports virtually all network management phases: design, deployment, configuration, operation, measurement, and analysis. MALT provides interoperability across our network-management software, and its support for abstraction allows us to explicitly tie low-level network elements to high-level design intent. MALT supports a declarative style, simplifying what-if analysis and testbed support.

We also describe the software base that supports efficient use of MALT, as well as numerous, sometimes painful lessons we have learned about curating the taxonomy for a comprehensive, and evolving, representation for topology.

1 Introduction

As our networks get bigger and more complex, we must automate all phases of network management. Automation depends on precise and accurate representations of the desired and actual network. While network management requires many categories of data, the most central is a representation of desired or actual network topology. Almost all other network-management data either derives from topology, or provides policy for how we want to create and use the topology, or associates resources (such as IP addresses or hardware inventory) with specific places in a topology.

At Google, we have learned the value of driving our network management processes, from capacity planning through network design, deployment, configuration, operation, and measurement, using a common standard representation of topology – a "model." Such a representation needs to address multiple problems, including:

- Some management processes, e.g., capacity planning, need to operate on abstractions, such as the amount of future capacity between two cities (before we know how that capacity is implemented). Other processes, e.g., configuration for routers, or fault localization, must operate on low-level details (fibers, switches, interfaces, SDN controllers, racks, connectors, etc.). Still other processes, e.g., risk analysis, must reason about dependencies between abstract and physical concepts. Therefore, we must **represent multiple levels of abstraction, and the relationships between them**.
- In our experience, it is impossible for an unchanging schema to successfully represent a constantly-changing network, especially with frequent technical innovations. Therefore, the representation must support **extensibility and evolution** as first-class features.
- We must support constant change to our network, with many concurrent changes happening at once. We must also support "what-if" analyses of options for future topologies. While humans often prefer an imperative style ("add this", "move that", "change that"), we have found that using versioned sequences of **declarative** models removes a lot of complexity created by imperative operations. For example, with a declarative model we can validate the consistency of an entire network before committing a change.
