- Different parts of our network follow different design and operational styles, managed by different teams. By **sharding** our models on carefully-chosen boundaries, we enable these teams to use their preferred styles without excessive interference. Sharding also improves concurrency. At the same time, these shards do overlap, and we prefer, when possible, to use tools that work across our entire network, so a **uniform representation** ensures interoperability.

This paper describes MALT (for *Multi-Abstraction-Layer Topology*), the representation we have developed for network topology, the software and processes we have built around it, and the lessons we have learned. MALT's primary goal is to provide a single representation suitable for almost all use-cases related to network topology. Our path from "we need a uniform topology representation; how hard could that be?" to our current ecosystem has exposed that creating a coherent set of design decisions, and getting this to work at scale, was much harder than we expected[1].

The main contributions of this paper vs. prior work are to explain the value of a multi-abstraction-layer representation that supports the full lifecycle of a network, and to expose some pitfalls that await designers of similar representations.

2 Uses for MALT

We model our global WAN [10], cloud-scale datacenter [20], and office-campus networks using MALT, including both Software-Defined Network (SDN) and traditional network designs. Over 100 teams in Google and hundreds of engineers and operators use MALT regularly; we now require most systems working with network topology to use MALT.

Our uses have expanded over the past five years, and continue to expand to new phases of network lifecycles, and to new network types. A common theme across these uses is that they enable automation of diverse and interacting management processes, through a uniform representation of the intent for, and structure of, our current and future network.

Broadly, our primary uses for MALT have been in three areas: operating our user-facing WAN; WAN capacity planning and design; and datacenter fabric design and operation.

Operational management of user-facing WAN: We use MALT when configuring network elements, managing the control plane of an in-service network, and monitoring the network for failures and other behaviors. We represent the network's "as-built" state in a MALT model in which all entities related to device management, including routers, interfaces, links, Points of Presence (POPs), etc, are visible to management workflows, which only operate by updating this model, and never by directly updating devices. An API supports specific, well-defined update operations on this model; all updates are validated before being used to generate the corresponding device configurations. Operations include adding devices or links, or changing device (entity) attributes to control monitoring and alerting.

WAN capacity planning and design: We must explore many options for evolving network capacity to meet predicted demands. MALT's support for multiple layers of abstraction, including layer-1 elements (e.g., fiber cables and transponders) and layer-3 elements (routers, line cards, etc.), allows simulation of each option against specific failure models, so that we can jointly optimize failure resilience and network cost.

[1]While many enterprise networks are smaller than Google's, we believe that MALT's approach would also be beneficial at much smaller scales.

Consider an example where our demand forecast suggests adding capacity between two POPs. We construct *candidate* MALT models for each possible option for long-haul fiber spans, optical line system elements, and available router ports in those POPs. Then we compare options for incremental cost, lead times for hardware or fibers, and availability. We commit to one option, which becomes the *planned* MALT model, used to generate a detailed design and bill of materials which is consumed by deployment teams.

Topology design for datacenter fabrics: Web-scale datacenter fabrics are far too large for us to directly manage each individual device. Our fabrics are structured as abstract blocks of switches [20]. We use MALT to describe the fabric in terms of these abstract blocks, their sizes, and policies governing how they should be interconnected. This abstraction makes it possible to reason about the topology. Once the complete high-level design is determined, the abstract topology is transformed mechanically into a fully concretized fabric model, also represented in MALT, from which device configurations and other management artifacts can be generated. We maintain both the abstract and concrete representations in MALT, to enable correlation between a given device and the abstract entity that generated it.

While we have many uses for MALT, our network management processes often use data that is *not* about topology, and for which we use other abstract or concrete representations; § 8 discusses what we exclude from MALT.

2.1 Motivations for MALT

The use cases above illustrate three motivations for MALT:

- **Support for the full lifecycle of a network**: As described above, we use MALT models for capacity planning, reliability analysis, high-level and detailed design, deployment planning and auditing, and as one kind of input to the generation of device and SDN-controller configuration. MALT also supports our monitoring, bandwidth management, and some debugging operations. We regularly find new uses, often without having to make major schema changes.
- **Uniformity**: Prior to adopting MALT, we had many systems that maintained representations of network topology for their own uses. These systems often have to exchange topology data. Without a single, uniform representation, this leads not only to O(N^2) translations, but also the potential for data loss or ambiguity, both of which make real automation nearly impossible. Uniformity also allows hundreds of software engineers to write interoperable systems without massive coordination overheads (which also tend to grow as N^2).
- **Multiple levels of abstraction**: Many design, operation, repair, and analysis processes require a clear understanding of the relationships between high-level design intent

and low-level realizations. For example, when we analyze a WAN plan to understand whether it will meet its availability SLO [1], we need to know the physical locations of the underlying fibers – e.g., whether two fibers run across the same bridge or under the same cornfield. MALT allows us to explicitly represent these abstraction relationships (see §3.3), which allows software to operate on data, rather than relying on inference.

2.2 Support for the entire network lifecycle

We present some illustrations of how we could use MALT models for various points in the lifecycle of our networks.

Consider a WAN with 10gbps capacity between London and Paris, which want to increase to 20gbps. Such increments often take months, so we start by creating a model ① (see Fig. 1) of our WAN for (say) 6 months from now, with this capacity set to 20gbps. We then look for available submarine and terrestrial cable capacity that collectively provides an additional 10gbps between the two cities. There might be several possible cable paths, so we can create "what-if" ② models for each option, and then analyze each option with respect to costs, lead-times, and historical failure probabilities, before committing to a "plan of record" (POR) model ③ for the WAN connectivity.

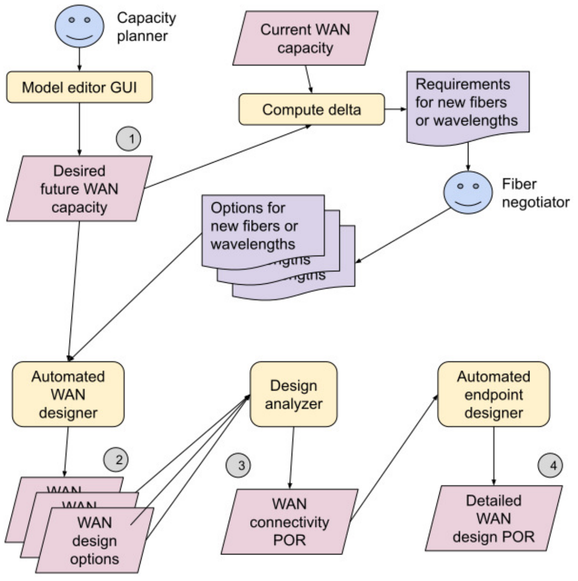

Figure 1: Multiple MALT models for WAN planning

Then we must choose endpoint equipment (routers, optical line systems, etc.) and either ensure we have enough free ports on existing equipment, or order new systems; again, we often explore multiple options (different vendors, different router configurations, etc.) before choosing a final POR model ④ that covers both WAN links and terminating equipment. (This also includes ensuring that routers can physically fit into available racks, and that we have enough power and cooling.)

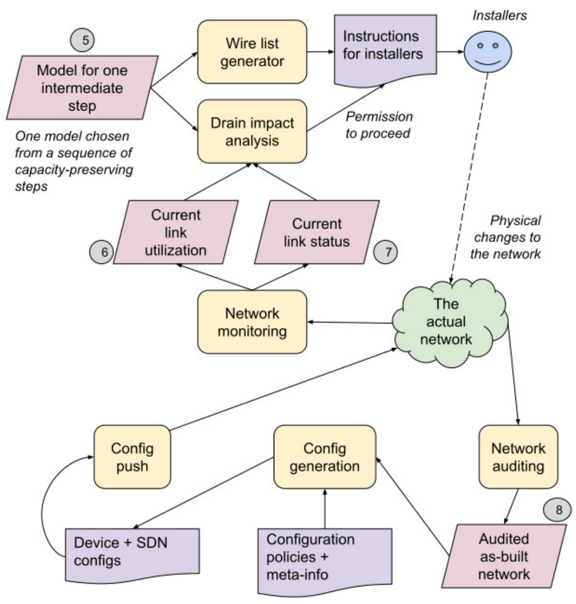

Figure 2: Multiple MALT models for a capacity expansion

Now consider a datacenter capacity expansion (see Fig. 2). Because we expand live networks [23], we must split up the physical changes into multiple steps, to maintain capacity headroom – e.g., an 8-step procedure should reduce capacity by at most 12.5% per step. For each step, we generate an intermediate model ⑤, which we subject to an an automated "drain-impact analysis" just before executing the step. This analysis uses two additional models: the current link utilizations ⑥ to estimate near-term future demands, and a model representing failed links ⑦ to account for their impact on available capacity.[2]

Once a step is ready, we trigger the human operations to carry it out. Humans are fallible, and so is hardware, so before "un-draining" the new links, we audit the work, via both automated and manual checks. In some cases, we might decide that an error (e.g., using the wrong patch-panel port) is harmless, but to avoid further confusion, we update a model ⑧ of the "as-built" network, so that future changes will not conflict with reality.

After the new hardware is deployed, we must update router configurations. Rather than having humans do that, we auto-generate all such "config" from MALT models and other meta-information [12]. We also use these models to auto-generate configurations for our SDN control plane.

While many of the processes in Figs. 1 and 2 operate on the entire graph of a WAN or datacenter network, others use a query API (§ 6). For example, the wire-list generator (Fig. 2) can query to extract just a set of switch ports and their locations, while ignoring most of a model.

Automation: We asserted a goal of ubiquitous automation. In fact, we have not yet automated every step shown in Fig. 1,

[2]In practice, we merge ⑥ and ⑦ into a single input, also critical to our Bandwidth Enforcer system for online WAN-bandwidth allocation [13].

but most of Fig. 2 now uses MALT-based automation. Full automation requires disciplined, hard work; MALT's goal is to enable that work, not to make it happen by magic.

2.3 Antecedents to MALT

Our efforts to model network topology started with various independently-developed, non-interoperable representations – not through a conscious decision, but because each of multiple teams realized they needed topology modeling. E.g., we had one way to represent datacenter and B4 WAN [10] network *designs* (Fig. 2, ⑤), and an entirely different representation, to support bandwidth allocation [13], for link *status and utilization* (Fig. 2, ⑥+⑦); the necessary format conversion was hard to maintain. Other teams maintained database-style records for each WAN router, but resorted to spreadsheets or diagrams to represent WAN topology, without machine-readable abstractions tying capacity intent (Fig. 1, ①) to specific links (Fig. 1, ④).

The lack of abstraction and interoperability between these formats created significant complexity for our operations and software. While MALT has not entirely eliminated that complexity, it gives us a clear path.

3 The MALT representation

We chose to use an "entity-relationship model" representation for MALT. (In § 5.3 we explain why we chose not to expose a relational database). In an entity-relationship model, entities represent "things," which have have "kinds" (types), names, and attributes, Entities are connected via relationships, which (in MALT) have kinds, but neither names nor attributes. MALT uses a somewhat simplified form of the classic entity-relationship model [4].

Our current schema has O(250) entity-kinds, including (among many other things) **data-plane elements**, such as packet switches, switch ports, links between ports, etc.; **control-plane elements**, such as SDN controller applications, switch-stack "control points" (local control planes), machines for SDN controllers, etc. **"Sheet-metal-plane" elements**, such as racks, chassis, and line-cards. Designing, curating, and evolving this taxonomy has been challenging; we discuss our experiences in § 9.

We have a set of about 20 relationship-kinds, including "contains" (e.g., a line card contains a packet-switch chip), "controls" (e.g., an SDN controller application controls a switch's local control plane), and "originates" (e.g., a link originates at one port, and terminates at another).

By convention, we name entity-kinds such as `EK_PACKET_SWITCH` and `EK_RACK`, and relationship-kinds such as `RK_CONTAINS` and `RK_ORIGINATES`.

For each entity-kind, we define a set of attributes. Some entity-kinds have lots of attributes, some have only a few. Typical attributes include:

- the "state" of an entity: is it planned? deployed? configured? operational? faulty? under repair? etc. (We defined a uniform "state machine," although adopting this standard ubiquitously has been challenging.)
- the index of an entity within its parent (e.g., "this is linecard #3 within the containing chassis").
- IP addresses and VLAN IDs assigned to interfaces – useful when generating device configuration.
- the maximum capacity (bits per second) for elements such as ports and links – useful for capacity-planning and traffic engineering.

but attributes can be rather arcane, such as one meaning "during the transition from IPv4 to IPv6, this network requires hosts, rather than switches, to perform 6to4 decapsulation."

A complete MALT "model" consists of a set of entities and a set of relationships between those entities. A model also includes some metadata, such as the provenance of the model (what software created it, when, and from what inputs) and its profile(s) (§3.5).

Fig. 3 shows a trivial example of a MALT entity-relationship (E-R) graph, depicting a connection between two routers. Each router contains one L3 interface and an L2 "port" for that interface. The interfaces are connected by a pair of unidirectional L3 "logical packet links" that each traverses, in this case, a single L2 "physical packet link." (Link entities in MALT are always unidirectional, which means that they usually come in pairs.)

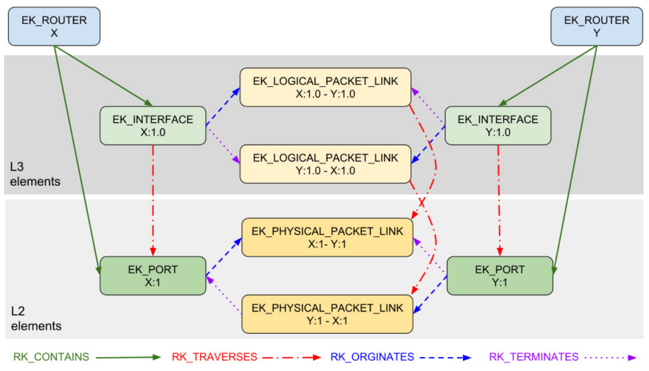

Figure 3: Trivial MALT entity-relationship graph

Note that the E-R graph is not isomorphic to the network graph – links in the network are represented as nodes (entities) in MALT's E-R graph.

Appendix A provides a more detailed example, showing how we model a datacenter network.

3.1 Entity-IDs

MALT entities have *entity-IDs* composed of an entity-kind and an entity-name. E.g., in Fig. 3, one router has an entity-ID of `EK_DEVICE/X` and one link's ID is `EK_PHYSICAL_PACKET_LINK/X:1-Y:1`. Entity-IDs must be globally unique, with respect to an implicit namespace that (by default) covers all of Google, and within a single "snapshot" view of our modeling data (we will clarify this concept in § 4).

While we typically use human-sensible names for entities, this is not necessary for automated systems (although it simplifies debugging!). We have learned (from rather bitter experience) to ruthlessly ban any code that parses an entity-name to extract any meaning; instead, the attributes defined for an entity-kind should encode *anything* that could be extracted from a name. (§11.4 discusses why using names in entity-IDs might not have been the best decision.)

3.2 Allowed relationships

The complete MALT schema consists of a set of entity-kinds (with attributes), a set of relationship-kinds, and a set of allowed relationships. For example, we allow a packet-switch to contain a port, but not vice-versa. These rules constrain producers, but this is good, because it means that model-consuming code need not handle arbitrary relationships.

Relationships can be directed or bidirectional, and 1:1, 1:many, many:1, or (rarely) many:many. We currently allow about 700 relationships between pairs of entity-kinds; this is a small subset of the millions that could be constructed, but we only allow those that support sensible abstractions (a simple form of static validation).

3.3 Multiple levels of abstraction

While MALT's primitive entity-kinds, including those listed above but also others, are sufficient to describe a wide variety of networks, one of the motivations for MALT was that it should allow us to represent multiple levels of abstraction and the relationships between them. Some use cases, for example, involve refining highly-abstracted designs into more concrete ones, but we also may need to reverse an abstraction, and ask (for example) "what abstract thing does this concrete thing belong to?".

We typically create abstraction via hierarchical groupings, such as entity-kinds for:

- **logical switches**: sets of primitive switches, interconnected (e.g., as a "superblock" in a Jupiter [20] network) so that they provide the illusion of one larger switch with more ports than any single switch.
- **trunk links**: parallel sets of links that provide more bandwidth than a single physical link.
- **control domains**: sets of elements controlled by one replica-group of SDN controllers.
- **Geographic elements**: a hierarchy of, e.g., cities, buildings, and spaces within buildings.
- **Dependencies**: sets of entities that could fail together (due to SPOFs, or to sharing a power source) or that must be kept diverse, to avoid accidental SPOFs.

For a WAN, the layering can be quite deep, starting with highly-abstracted city-to-city links, through several levels of trunking to individual L2 links, and through four or five levels of optical-transport-network hierarchy [22, fig. 12].

We also have relationship-kinds that help with abstraction:

- `RK_CONTAINS` for hierarchical containment.
- `RK_AGGREGATES` to indicate, for example, which singleton links are aggregated into a trunk link, or which packet switches are aggregated into a logical switch.
- `RK_TRAVERSES`: e.g., an end-to-end MAC (L2) link is constructed from the ordered *traversal* of a series of L1 links connected by splices and patch panels.

C
Fiber (L1) adjacencies between POPs

Figure 4: Layered abstractions in WAN planning

Fig. 4 shows how we can use multiple layers in WAN planning. The top layer shows two WAN tunnels (as in B4 [10]) between POPs B and C, including one via A; the middle layer shows how these tunnels map onto L3 router adjacencies; the bottom layer shows how the L1 fiber path for the $B-C$ L3 adjacency runs through POP A. This means that the $A-B$ fiber path has become a single point of failure (SPOF) Because MALT includes all of these abstractions (abstract flows, IP adjacencies, fiber paths) in the same model, with explicit relationships between them, we can easily map this SPOF back to the tunnels it affects.

3.4 Machine- and human-readable formats

Since MALT is designed to support automation, we normally represent models in a binary format compatible with RPC interfaces. However, developers occasionally need to view (and less often, edit) models or individual components, so we can convert between binary and a textual format. We also have a "shorthand" format for concise text-based representation; this is especially useful for creating test cases.

3.5 Profiles

While we have just one "global" MALT schema, which provides uniformity across all of our networks, we have found it useful to introduce *profiles*, which restrict how the schema is used. We use profiles for purposes including:

- To specialize the schema for certain network types. For example, the profile for a data-center network might assert that the uplinks from aggregation switches are always connected to the downlinks from spine switches, while the profile for an office-campus network might assert that there is always a firewall between the public Internet and the campus network.
- To support evolution, via profile versioning. As we discuss in §10, we are continually evolving both the global

schema and our profiles, which sometimes means changing the way we represent a concept; we need to ensure that model-producers and model-consumers agree on which representation is in use.
- To decouple the release cycles of complex graphs of software systems, so that model producers can move forward without forcing *all* model consumers to migrate at the same time.

A profile is, in effect, a contract between a producer and a consumer. We defined a machine-readable profile specification, which allows us to mechanically check that a model actually meets one more or profiles (as asserted, by the producer, in the model's metadata).

A profile is identified by its name (e.g., "Jupiter"), a major version number, and a minor version number. If we make an incompatible change, such as inserting a new structural layer that turns a one-hop relationship path into a two-hop path, we need to increment the major version.

If two profile-IDs differ only in their minor-version numbers, this implies backward-compatibility: a model with the higher minor-version can be read safely by a consumer already tested against the lower version. The converse does not apply; models with an out-of-date minor version might be missing information that recent consumers expect. (§10 discusses how hard it has been to define "backwards-compatible" in the face of certain coding practices.)

Machine-checkable profiles can express constraints narrower than the entire schema; for example, we can require that certain relationships are present (or not present), or that certain attributes have values within a constrained range. However, our current profile-specification language is not expressive enough to represent certain global policies, such as "no IP address may be assigned to two different interfaces" — we validate that using other means.

4 Division into multiple shards

One might imagine a single model for Google's entire collection of networks, but we actually divide this data into *thousands* of MALT model "shards," for many reasons:
- **Separation of ownership**: Many teams contribute to the design and operation of our networks; things are much simpler when we shard models, so that each shard has a single owner. Such sharding clarifies responsibility, and can avoid the need for complex consistency-maintenance protocols.
- **Distinct profiles**: Different parts of our overall network conform to different profiles (§3.5); sharding allows us to cleanly associate a profile with the data that it covers.
- **Profile evolution**: We cannot change all software instantaneously when introducing a new profile version; instead, we support old versions for a phase-out period. This means that we must represent the same information using multiple profiles, stored as per-version shards. (§10 covers evolution in detail.)
- **Performance**: A single model of our entire network would be too large to fit in the memory of a single server. Also, while many applications extract small sub-models from storage via query RPCs, some do need to retrieve larger subsets; using a "Get" RPC to retrieve one or a few shards is a lot more efficient. (However, if we use too many shards, that leads to per-shard overhead; we try to strike a good balance.)
- **Protection and fault domains**: All software has bugs, and we must defend against security breaches; sharding allows us to limit the damage from a faulty program, and it allows us to set ACLs that restrict users to the shards they actually need. (For example, someone operating on a edge router in Paris does not need access to a datacenter switch in Rome.)
- **Lifecycle stages**: We use several sets of shards to represent distinct points in the lifecycle of a network: e.g., planning, deployment, and operation.
- **Alternative universes**: We need to represent not just a single timeline, but alternative future designs for our networks – e.g., to analyze multiple options for purchasing WAN connectivity or multiple orderings for capacity augments. We especially need to create isolated universes for testing software and operational procedures.

Model sharding requires some support from the query mechanism; §6.2 describes our "multi-shard query" (MSQ) API. It also sometimes requires the same entity to appear in multiple shards (so that no shard has dangling relationships); to avoid violating our uniqueness rule for entity-IDs, we add "linkage" metadata to these repeated entities. Linkage allows us to unambiguously resolve these repeated entities.

Note that, as discussed in §5, each update to a shard creates a new "instance" or version. This is another dimension in which we have many shards.

Given our heavy use of sharding and instances, we need a way to specify a version-consistent snapshot that spans multiple shards; §5.2 describes the "model set" abstraction that supports this.

5 MALT storage

While one might consider treating MALT as a database schema, we instead choose to think of a set of MALT entities and relationships (i.e., a shard) as a named value. One can think of a MALT shard as a file; in fact, we can store a shard as a file, either in binary or in a human-readable format.

We *prefer* to store shards in a purpose-built repository, MALTshop, that provides several important features:
- It is logically centralized, with a single UNIX-like namespace for shards, so we know where to look for any shard (past, present, or future). MALTshop maintains statistics and logs, making it easy to discover who is using the shards and what features are in use.

- It has a distributed, highly-available implementation.
- It provides a basic Get/Put/Patch API, but most model-reading code employs its Query API (see §6).
- Shards are versioned; each update (via a whole-shard Put or diff-based Patch API) creates a new, immutable *instance*, which is permanently bound to a sequence number (but can be mutably bound to a named *label*). Small updates are efficiently implemented via copy-on-write, so the cost of creating and maintaining many versions of a large shard can be relatively low.
- The repository supports ACLs on shards, which provides the basis for security mechanisms. We have not found a need to bear the burden of ACLs on individual entities; those could be layered above MALTshop in an application-specific service, if necessary.

5.1 MALTshop implementation details

MALTshop stores its state in Spanner, a reliable, consistent, distributed SQL database [6], which handles many of the harder problems. The SQL schema has tables for shards, instances, entities, and relationships; an entity's attributes are stored as a SQL blob. Updates to the MALT schema do not require changes to the SQL schema.

While our initial SQL schema supported a simple implementation of MALTshop, as usage increased we realized that the schema did not always support good performance, and read-modify-write operations made it tricky to avoid corruption when a server failed. We are now migrating to a new SQL schema that should improve performance and data integrity; the details are too complex to describe in this paper. Because the SQL schema is *entirely* hidden from all applications, this migration is transparent to all users.

MALTshop uses several kinds of cache, including a client-side cache library that currently supports only "Get" operations, but ultimately should reduce many RPC round-trips, and a server-side cache that greatly reduces the cost of computing diffs between two recent instances of a shard (an operation some of our applications use heavily).

MALTshop, due to Spanner's scalability, itself scales well. We currently store thousands of shards, each with many versions; the largest shards have millions of entities and millions of relationships. Occasionally MALTshop serves thousands of queries per second, but usually the load is lower.

5.2 Model sets

Because we shard our models extensively, and each shard may have many instances (versions), operations that span multiple shards need a way to specify a consistent snapshot, which we support with a "model set" abstraction. When a model-generator creates a set of shard instances, it also obtains a new "model set ID" (MSID), and uses a metadata service to register a binding between the MSID, some attributes, and its constituent shard instances. We therefore usually pass an MSID between systems, rather than lists of instance IDs. The metadata service allows applications to find the latest MSID, or to look up an MSID based on various attributes.

5.3 Discussion: dataflow rather than database

Given our ability to efficiently store (and thus share) immutable versions of MALT shards, it is convenient to think of a single shard instance as a value – a snapshot of a database, rather than a mutable instance of a database. While these values can be quite large, and in many cases an application is only interested in a small subset of a shard, this approach allows us to construct many network management pipelines as dataflow graphs, where streams of MALT shard instances flow between stateless functional operators.

We use these dataflow graphs primarily for planning, design, and analysis applications – systems that operate the existing network do use MALT imperatively (see §11.2). Also, once the planning process must trigger actions with expensive effects (e.g., ordering or installing hardware), we must use imperative operations – isolated to separate shards.

Why not just represent a network topology as a relational database, as is done in many other systems (for example, COOLAID [5])? Some of our previous systems were indeed implemented as RDBMSs, with SQL queries. In our experience, an RDBMS worked nicely for simple use cases, but:

- an RDBMS by itself does not provide clear patterns for new types of abstractions or their graph-type relationships (aggregation, hierarchy, etc.). When we used an RDBMS, we effectively imposed an implicit entity-relationship schema; why not just make that explicit?
- a first-class abstraction of individual shards makes it much simpler to express per-shard profiles, versioning, labels, access controls, and retention policies. It also make it easier to reason about how these shards flow from one system to another – for what-if analysis and isolated software testing, or to parallelize datacenter-expansion projects (as in Fig. 2).
- layering our MALT schema over an SQL schema makes it simpler to do "soft deprecation" of entities, relationships, and attributes, without having to impose those changes on older shard instances or their users.
- layering MALT over SQL makes it easy for us to change the SQL schema, for better performance, without requiring any client changes.
- we can also provide the MALTshop API (albeit with limited performance) on top of a simple file system, which is useful for disaster-recovery scenarios when Spanner might be down or unreachable.

None of these are impossible in SQL (manifestly, since MALTshop expresses all of these with an underlying SQL schema), but by hiding the SQL schema from clients via MALT's abstractions, we make our clients far less brittle. Overall, we have found the dataflow approach far easier to reason about, and in some cases, more efficient. In a few real-time applications (e.g., SDN controllers), we do express a network's topology in a private, purpose-built, in-memory database (with update-in-place).

Other graph-processing systems likewise have avoided RDBMSs, for reasons such as articulated by Hunger *et al.* [9] and for Pregel [16].

6 Querying MALT models

While our model-producing software tends to generate an entire shard in one operation, our model-consuming software generally does not operate on all entities in a shard, but rather only on small subsets. In this respect, our software differs from traditional graph-processing algorithms [16]. (There are exceptions: systems for drain-impact analysis, or WAN cost optimization, do look at entire networks.)

Model consumers extract subsets that meet some predicate via a *query language*, which walks an entity-relationship graph to extract a chosen subset model. Typical queries might be of the form "find all of the top-of-rack switches in datacenter X", "find the switches managed by SDN controller Y", "find all the cable strands that share connector C", or "given port P1 on switch S1, find the corresponding port P2 on switch S2 such that P1 is connected to P2."

Designing a query language for MALT has been surprisingly hard; we are on our second language (and we also toyed with the idea of using a Datalog-style language). Our first query language was sufficient, but it was often hard for users to understand how to express a correct and efficient query. Our second language is easier to use, because it operates on paths through the E-R graph, rather than sets of entities; paths are the more natural abstraction.

Sometimes it is difficult or impossible to use a single query to return exactly the right subset; this leads to a pattern where the application issues a remote query to retrieve a larger-than-desired sub-model, and then applies a local (in-memory) query to further refine the results. In some cases, it is simpler, or even necessary, to post-process the query results using a traditional programming language.

Sometimes people ask "if that's so hard, why not just use SQL?" MALTshop effectively compiles MALT queries to SQL queries, so on the one hand: sure! but on the other hand, these SQL queries are substantially more complex, and also deeply depend on the underlying SQL schema, which we do not want to expose to applications (because we have already had to revise it several times.) We also want to use the same language for both MALTshop and efficiently querying in-memory shards, as shown in Fig. 5; SQL would not support that.

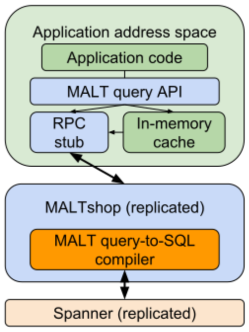

Figure 5: Query layering

In our current language, a query is expressed as a sequence of commands. Each command operates on a "frontier" of active "nodes," which (approximately) are references to entities. Query commands can move the nodes around the input model[3] along relationship edges. As each active node moves around the input model, the query execution engine keeps track of the path it took.

The output is one or more result models, optionally annotated with labels, which includes all active nodes at the end of the query, plus the full path they took (relationships and stepped-over entities) to get to their final position. Some commands remove ("prune") active nodes; these also generally remove, from the result, earlier entities that the node previously visited, if not also visited by another path.

Queries always start with a `find` command, which looks at all entities in the input model, subject to constraints such as an entity-kind and/or some attribute values; e.g.:

```
find EK_PACKET_SWITCH/tor17
```

to start the query at a packet switch named "tor17", or

```
find EK_VLAN { id: 13 }
```

to start the query at all VLANs with a VLAN-ID of 13.

Queries often involve following relationships, e.g.:

```
find EK_PACKET_SWITCH/tor17
  until RK_CONTAINS EK_PORT
```

to return all of the ports contained in that switch.

The language includes many other commands; we lack space to describe the full language.

Query implementation: Queries traverse relationships in a model, marking paths to keep or prune. For complex queries, this may require many iterations through the model.

Queries can be executed locally in-memory, or remotely by MALTshop. For locally-indexed models, these iterations are inexpensive. However, MALTshop has to translate queries into repeated calls to its SQL database. To make this efficient, the query engine requests SQL data in batches.

6.1 "Canned queries"

Queries that are simple to state in English may turn into long sequences of commands. These have proved challenging to write, for many of our users. They can also be fragile with respect to profile changes; when complex, profile-dependent queries are scattered across code owned by many developers, profile change inevitably leads to bugs. Therefore, we have a library of "canned queries." When a profile owner creates a new profile version, that engineer is also responsible for creating (and testing!) a new version of any canned query affected by that change. This gives the responsibility for managing complex queries to the experts on the underlying representations.

[3]That is, change the binding between an active node and an entity.

We define canned queries as needed. For example, one canned query might return all of the L2 links between a given pair of switches; another might return the rack where a given line card is located (useful when trying to repair that card).

6.2 Multi-shard queries

As described in §4, we split the representation of our entire network into many sets of shards. However, some applications would like to form queries that span shard boundaries. Also, we want the freedom to revise our sharding plan (we have done this several times), and we do not want model-consuming code to depend on that plan. Therefore, most applications that query MALTshop actually use a *multi-shard query* (MSQ) API, which allows a query to specify a set of shard pathnames (using wildcards), rather than a single shard; MALTshop then executes the query against a view composed of those shards.

MSQ is efficient, because MaltShop's underlying SQL schema has an index that identifies entities appearing in multiple shards, and limits the queries to only those shards. Performing MSQ in-memory is not feasible, due to the size and time it takes to load and index all the shards.

The introduction of MSQ significantly simplified many applications. For example, prior to MSQ, code looking for "peer ports" at the boundaries between datacenter and WAN networks had to issue separate queries in multiple shards, using the output of the first query to compose the second one. Also, the code had to know which specific shards to query. Code using MSQ does this in one query, and knows much less about shard boundaries.

7 Software infrastructure

In addition to MALTshop (§5) we have developed a library to provide common functions for MALT developers, and additional software to help us use and manage MALT models.

7.1 Model-generation systems

We do not want humans to create detailed models via direct editing; this would be tedious and unreliable. Instead, humans generate highly-abstracted representations (typically via GUIs or text editing) that become input to model-generation software that produces concrete models. We sometimes do this in multiple steps, where the MALT output from one step becomes the input to future steps. At each step, the models become more detailed, based on late-bound design decisions and/or more-specialized profile-specific code.

We have been migrating to a "declarative dataflow" approach to model generation (as in Figs. 1 and 2), away from early systems that used imperative inputs ("add this switch") and that packaged all model-generation steps into one execution. Imperative, non-modular systems (not surprisingly) turned out to be hard to maintain, evolve, and test.

At each step in such a dataflow graph, we can apply our automatic profile-checker (§3.5) to detect some software bugs or incomplete inputs.

7.2 Model-visualization systems

While MALT is designed to support automation, humans often need to look at models. We have visualization systems to support two distinct use cases:

- **Network visualization**: Network operators, capacity planners, and customers want to visualize their network topologies, without knowing how these are represented in MALT. Our network visualizer GUI displays network nodes and the links between them, with statistics and other attributes, and lets a user zoom between abstraction levels. MALT's inherent support for multiple levels of abstraction made this tool easier to write.[4]
- **Model visualization**: Developers of MALT software and models want to visualize the structure of their models, rather than of the network. Our MALTviewer allows them to navigate through entity-relationship graphs, with integral support for the MALT query language.

We considered developing a GUI-based tool to create and edit MALT models, but so far, creating models by expansion of concise, high-level intent (as in §7.1) has sufficed.

8 What does not belong in MALT?

While MALT is central to our network management systems, we do not believe it should be extended beyond expressing topology. People have sought to add other kinds of network-management data (sometimes just to exploit MALTshop rather than investing in another storage system), but these typically do not fit well into an entity-relationship schema. Other categories deserve more-appropriate representations, including:

- **Generated configuration** for devices and SDN controllers; our config generators read MALT models, but their output data belongs in OpenConfig YANG models [18]. We built a "ConfigStore" service more suited to this use case than MALTshop is, because access patterns (especially queries) to "config" are quite different.
- **Policies** for how to use the network topology, such as BGP policies. We believe these are most accessible to the operators who manage these policies when they are expressed using a configuration representation, such as OpenConfig or a vendor-specific one. We allowed some early users of MALT to embed BGP policies in the schema, but that proved to be awkward and complex. (Alternatively, Propane [2] is a domain-specific language for expressing BGP policy.)

[4]A similar tool allows us to visualize the network overlaid onto a geographic map; this is especially useful for planning WAN and campus links that must avoid single points of failure. However, this tool still gets its data from a predecessor to MALT.

- **Abstracted forwarding tables** (AFTs) that represent the observed FIBs in our network; these are useful for applications such as Traffic Engineering and our Bandwidth Enforcer system [13], and for techniques such as Header Space Analysis [11]. AFTs are similar to OpenFlow [17] rules, and might be suitable for representing ACLs, although today we use a DSL for ACLs.
- **Allocated resources**, such as IP addresses, Autonomous System Numbers (ASNs), and ports on switches and patch panels. Since we must not allocate any one of these resources to multiple "owners," these are best represented in a database that supports modify-in-place operations, exactly what we would rather not do for declarative topology models.
- **Inventory**, including support for SOX compliance and other finance-related applications. Often these records exist before we have a topology to place them in.
- **Monitoring data** from SNMP and similar systems. MALT is not efficient at representing time-series data, and Google already has robust, massively-scalable systems for monitoring and alerting, so while we do distill some data from monitoring pipelines to correlate it with topology, as in Fig. 1, we do not use MALT as the primary representation for this data.

We tie these representations together using foreign keys, including MALT entity-IDs (e.g., an AFT is tied to a particular MALT "control point").

It can be tricky to define a bright line between "topology" (appropriate to represent in MALT) and non-topology data. Partly this is driven by a need to store some information in two places, for efficiency and availability – for example, we allocate blocks of IP addresses from an IP-address DB, and then record these blocks in MALT models as attributes of subnetwork entities. However, when we debate "does this data belong in MALT?" the usual reason for the complexity of the debate is that we had not quite got our taxonomy right; relatively few cases have been truly hard calls.

9 Schema design principles and processes

The MALT schema must allow us to represent a broad variety of network designs completely and consistently; code with special cases for different structures is likely to be unreliable and hard to maintain. Schema design turned out to be harder than we expected; we have learned several principles that were not obvious to us at the start. We could not create good abstractions *a priori* for a complex, evolving set of networks, but had to test and refine our abstractions against our experience with many real-life use cases[5].

One meta-lesson was that we needed to establish a formal MALT Review Board (MRB), composed of experienced schema designers, who could take a company-wide and long-term view of proposed changes. Prior to establishing the MRB, the schema accreted many ad hoc, inconsistent, or duplicative features. Using a multi-person board, rather than a single owner, to review schema changes also allows us to parallelize the work, and to maintain consistency as employees come and go. We also have a written "style guide," both as advice to engineers proposing schema changes, and to guide new MRB members. However, our weekly MRB meeting constantly finds new issues to debate at length.

9.1 Orthogonality

We value uniformity: we want our tools to process models for many different kinds (and generations) of networks, without lots of special cases. Sometimes this is straightforward; the MRB often prevents proposals attempting to create a new entity-kind (EK) for an existing concept, or a narrower-than-necessary proposal for a new concept.

We also value simplicity; initially we thought this meant that we should be conservative in creating EKs. However, we learned that overloading one entity-kind with concepts that are not similar enough leads to the use of subtypes (expressed as attributes), which creates complexity in model-consuming code and in the formulation of queries.

We developed two tests to define "similar enough?":

- Do the various use cases share the same relationship structure, or would one expect different relationships based on the subtype? If the latter, we prefer to use a distinct ("orthogonal") EK for each use case, rather than having a kitchen sink of relationships for an EK.
- Do the use cases mostly share the same entity attributes, or are there several mostly-disjoint subsets of the attributes, based on subtype? If the latter, we prefer multiple EKs. (Subtyping violates the "prefer composition over inheritance" principle.)

These are not rigid rules. Sometimes we must guess about future use cases, or just make an arbitrary decision.

An example of why we need these rules: we initially defined `EK_PORT` to refer to singleton ports, trunk ports, VLAN ports, and patch-panel ports. This "simple" structure leads to models where a VLAN `EK_PORT` can contain a trunk `EK_PORT` which can contain multiple singleton `EK_PORTs` – and queries on ports have a lot of complexity to distinguish which subtype they care about. We ended up with over 60 possible relationships involving `EK_PORT`, and about the same number of attributes, most of which are never used together (which makes it hard to check whether a model producer has properly populated the attributes and relationships required for specific use cases).[6]

Entity attributes often use enumerated types. We learned to value multiple, orthogonal attributes over the superficially-

[5] And as we learned these lessons and have evolved our schema, we have also learned just how hard evolution itself can be; see §10.

[6] We have only partially fixed this mess, because lots of existing code uses `EK_PORT`, but without explicitly indicating for which use case.

simpler goal of "fewer attributes." For example, initially "Vendor ID" was an implicit proxy for "switch stack operating system." We had to break that out as a separate "OS" attribute, rather than creating enum values representing the cross-product of vendor-ID and several other features.

9.2 Separation of aspects

We initially modeled a router as a single EK_DEVICE entity. Since routers have lots of substructures, we used lots of attributes to define their various aspects. However, we now model these distinct aspects as explicit entities, separating data-plane aspects, control-plane aspects, and physical ("sheet-metal-plane") aspects. So, for example, we model a simple packet switch with this relationship structure:

```
EK_CHASSIS RK_CONTAINS EK_PACKET_SWITCH
EK_CHASSIS RK_CONTAINS EK_CONTROL_POINT
EK_CONTROL_POINT RK_CONTROLS EK_PACKET_SWITCH
```

This allows model consumers (and their queries) to focus on specific subgraphs: for example, systems that analyze network performance or utilization focus on the data plane subgraph (EK_PACKET_SWITCH, EK_INTERFACE, EK_*_LINK, etc.), while systems involved in hardware installation focus on the physical subgraph (EK_RACK, EK_CHASSIS, etc.) Ultimately, this allows most systems to work correctly no matter how we re-organize control-plane, data-plane, and physical-plane structures. (Especially in space-limited testbeds, we often need to use non-standard packaging, which required lot of special cases in software before we separated these aspects.)

Somewhat similarly, we also use separate entity-kinds to represent the abstract intent and the concrete realization of a complex structure, such as a Clos network. In our model-generation pipeline, we use the "intent" entities in the inputs to a step that generates the concrete entities; the output includes the inputs, tied to the concrete entities via RK_REALIZED_BY relationships, so that the intent is visible to consumers of the concrete models.

10 Profile evolution

We must continually change our MALT schema, both to handle new kinds of network designs, and to rethink how we have represented things in the past (taxonomy is hard; we have made a *lot* of mistakes). Additions are fairly easy, but other changes create a lot of pain for software maintainers, and the risk of misinterpretation.

While we expected the schema evolution, the challenges that created were much larger than we initially expected. Because many systems interact via models, and models persist (often for years), we have had to create processes and software tools to ensure compatibility. Also, networking concepts can evolve faster within one company than in the public Internet – and faster than our ability to rapidly upgrade our software base, or educate software engineers.

We developed several mechanisms to cope with evolution:

- **Stability rules**, to avoid schema changes that create unnecessary churn (but these can lead to accretion of the equivalent of "dead code" in the schema).
- **Profiles and profile versions**, as discussed in §3.5. Before we had profiles, evolution was especially painful, because there was no explicit way for a consumer to know which of several possible interpretations to place on a model.

  Because profiles are versioned, our model-generators can simultaneously produce shards for the same network design in several versions; this allows us to update producers and consumers independently.
- **Feature flags**, which specify explicitly which individual features are enabled (or disabled) in models produced for a given profile version, so that consumer code can condition its behavior on the presence or absence of specific features, rather than complex logic based on version numbers. For example, a feature-flag might indicate that a given profile version supports IPv6 address prefixes; these might have been previously allowed in the MALT *schema*, but not generated in the *models* until a given profile version.
- **Profile-version deprecation policies**, which allow us to (gently) force consumers to migrate off of old versions, so the producers do not have to support them forever.
- **Canned queries**, described in §6.1, which insulate the less-complex model consumers from profile-specific details. (Not all consumers can fully rely on canned queries for insulation, and model producers might have to be migrated for each profile.)

As mentioned in §3.5, if two profiles differ only in their minor-version number, code for the lower version should be able to consume models of the higher version. Unfortunately, it has been tricky to define rules for "backwards compatibility," especially in the face of some fragile coding practices. For example, code often does a switch statement on an enumeration attribute. Not all code properly handles a newly-defined enum value; some code crashes, and other code blithely treats the new value as equivalent to an older value, leading to silent failures. We have thus gradually become more cautious about allowing profile changes without incrementing the major version, but such increments often lead to tedious "requalification" of software.

These mechanisms also make it easier to change our shard boundaries: canned queries hide the boundaries from most users; for others, we use a profile-version change to signal a sharding change.

Overall, these techniques are helpful, but not sufficient, to avoid the pain of profile evolution; we continually look for new approaches.

Other systems have had to grapple with evolution, with varying success. For example, the QUIC protocol designers made version-negotiation a fundamental aspect of the protocol design, and then relied on it to rapidly iterate through many versions [14].

11 Lessons and challenges

After using and evolving MALT for several years, we have come to appreciate both the benefits of this approach, and some of its challenges.

11.1 Benefits and challenges of adoption

Prior to MALT, we had many non-interoperable topology representations, including multiple formal ones, many spreadsheets, drawings, and sometimes just folklore. Convergence on a single, well-curated, machine-focused representation has yielded benefits including far simpler interoperability between systems, dramatic reduction in some code complexity (and complete elimination of a few code bases), and a motivation to invest in improved data quality.

However, converting from older representations, especially the few that were already the basis for islands of automation, has been painful. (Parts of our network-management world that had no prior formal representation have often been easier to migrate to MALT, because they have little existing code to worry about.)

Things that make representation conversion difficult include differences in model structure (e.g., tabular vs. entity-relationship); differences in the handling of defaults; differences in rules for constructing names; and (quite frequently) incomplete or inaccurate documentation on the semantics of the old representation. We also discovered that, since older representations tended to be weakly validated (at best), and existing consumer code was tolerant of missing or inaccurate data, we kept running into data we could not understand (or wrongly thought we did).

We learned, as MALT supported an increase in data-driven automation, that a good representation cannot save us from dirty data. If the data is missing or wrong, automation fails in depressing ways.

We observed an interesting pattern: operators typically start by focusing on operating the "built" system, and see no need for formal representation of the entire lifecycle (as in Figs. 1 and 2). Then, as the network gets larger and more complex, they gradually realize they must be involved in planning and design phases, so that the network is actually operable and well-documented. This pattern reinforces the value of a uniform, multi-abstraction-layer representation.

Similarly, network test engineers initially believe they can manage their small, idiosyncratic testbeds informally. But they learn that end-to-end network deployment and management processes in a testbed needs to work exactly as they do in production (or else you have not actually tested everything), which motivates formal modeling even for testbeds. A side benefit is that they waste less time doing manual work for which automated, MALT-based tooling exists. (However, testbeds are often weird, which adds complexity to model-generation tools.)

11.2 Designing via a declarative approach

Our prior network-design systems were mostly imperative, with complex APIs of the form "add these links" or "remove this switch." Humans naturally think imperatively, but these APIs became an impediment to modular composition, due to their complexity. They also made it difficult to create isolated universes for what-if analysis and testing.

MALT supports (but does not require) a declarative design process, in which each stage process tells the next stage what it wants, not how to get it. APIs become simpler; all conceptual complexity is now explicit in the models. To create a testbed or what-if model, we can simply create a copy of an existing model, modify it, and then run the normal pipeline.

Our network-design world is not fully declarative: since humans still create the top-level design intent, our UIs support some imperative operations. In cases where operators want to make minor, rapid changes, we primarily use MALT imperatively.

11.3 The dangers of string parsing

We are trying to stamp out string-parsing, because parsers (and regular expressions) embody assumptions about how strings encode information. When we later must change a format (e.g., to allow longer fields), we have found it hard to search code for all of the relevant parsers (coders have many creative ways to parse strings), so we discover many of these only when something breaks at run-time. Instead, we have learned to discourage string-encoded data, and to provide explicit attributes and/or relationship. (E.g., if an entity is named "router.paris.33" then it needs a relationship to the entity for "paris" and an `index_in_parent` attribute.)

11.4 Human-readable names vs. UUIDs

§3.1 describes how MALT entity-IDs are (entity-kind, entity-name) tuples. This eased the initial adoption of MALT, because our existing code and operator procedures all used human-sensible names. In hindsight, we should have used opaque universally unique identifiers (UUIDs) as primary keys, and kept the display name as an attribute. With name-based entity-IDs, renaming becomes hard, because we have to track down all references to an entity-name, including those in external systems.

Name-based IDs can be especially tricky when creating designs for abstract components, which need IDs, before we know their ultimate names, which are often late-bound. We currently ameliorate that problem by a "placeholder" mechanism that lets us rebind references to entities, but names held in non-MALT systems still lead to problems. UUIDs introduce their own challenges, which we lack space to describe.

12 Related work

Many large enterprises face similar network-management challenges, so prior papers have described systems related to MALT, but almost none have focused specifically on the challenges of a multi-layer abstraction and how to evolve it. Propane/AT [3] does describe ways to model abstract groups of switches and their adjacencies, but not how to include finer levels of detail. Most other work uses the term "topology" only to refer to IP or routing-session adjacencies.

COOLAID [5] used a declarative-language approach based on Datalog. COOLAID focused on reasoning about configuration management of an existing network, rather than topology design or abstract intent. (Their emphasis on reasoning is complementary to MALT.)

Facebook's Robotron [21] followed a "configuration-as-code" paradigm, rather than a declarative representation; this appears to limit its use to a single administrative domain, and to complicate its use for what-if analyses. Robotron does not handle multi-step or concurrent design changes [21, §8]. Robotron supports "high-level design intent"; it is unclear if this extends to abstractions for capacity planning.

Alibaba's NetCraft [15] manages "the life cycle of network configuration, including the generation, update, transition and diagnosis of [configuration]," using a multi-layer graph, but apparently not abstractions that support network planning or design. One layer represents a BGP mesh (contrasted to Propane [2] which represents BGP *policy*).

Google's Zero-Touch Networking (ZTN) [12] provides an automation framework which utilizes both MALT and OpenConfig [18] as interoperable data representations.

MALT's design was inspired by UML [19] and the DMTF "Common Information Model" standard, which uses an object-relationship representation of "managed elements." UML focuses mostly on modeling systems, not on network topologies. DTMF includes a layer-3 interface profile [7], but also seems to have little coverage of network topology *per se*. (OpenConfig might well subsume this aspect of DTMF.)

SmartFrog [8] was a framework for automated management of configuration for multi-component software systems. While it differs from MALT in numerous ways, SmartFrog's *templates* are similar to MALT's entity-kinds, and SmartFrog also addressed lifecycle issues.

13 Conclusions and future work

Our experience has shown that, while it was challenging to design both MALT's representation and an ecosystem that supports its widespread use, we have gained great value from a declarative, multi-layered approach to representing network topology. MALT supports the full lifecycle of our networks, allowing us to make knowledge explicit in our models, rather than hidden in code.

Others wishing to learn from our experience might want to consider these challenges that surprised us:

- **Shared schemas need curation**: a representation whose goal is to create interoperability between disparate teams and processes cannot be evolved by uncoordinated accretion; curation by a centralized team (the MRB § 9) has a hard but necessary job.
- **Support for evolution**: we added explicit support for schema evolution, and explicit profiles, later than we should have (§ 10).
- **Simplicity $\neq$ fewer concepts**: Our initial attempts to limit the number of concepts (entity-kinds) led to complexity via overloading; in retrospect, orthogonality via many simple concepts brings simplicity (§ 9.1).
- **Query language**: Our three-layered approach (canned queries at the top, a powerful query language in the middle, and a well-hidden SQL layer at the bottom) seems to create the right balance between expressive power vs. ease of use, but we struggled to find that balance (§ 6).
- **Migration**: Migrating users from previous representations created considerable pain, some of which could have been avoided if we had learned our other lessons much sooner.

We also had some positive surprises:

- **Support for lots of models**: all of our previous systems maintained just one model or database. MALTshop's ability to give near-arbitrary names to models, and to use immutable versions, enabled many use cases we had not initially considered, and enabled sharding (§ 5).
- **Extension to other domains**: Because our software base (§7) is largely agnostic to the MALT schema itself, it could support multiple domains with distinct schemas. We plan to explore modeling network-like domains, such as liquid cooling and power distribution.

Future work: We believe MALT can be extended to cover several other kinds of networks; this remains future work. These include cloud networks, and especially "hybrid" networks that include both cloud and "on-premises" enterprise networks. (MALTshop would need to support multiple, isolated namespaces for shards and for entities.) MALT could also be extended to explicitly model Software-as-a-Service connectivity.

MALT might support wireless networks, with some redesign. The features that make wireless networks "interesting," such as mobile nodes, hidden terminals, and dynamic channel fading, will challenge some implicit assumptions we made for MALT.

Acknowledgements

Hundreds (at least) of our colleagues have contributed code, models, queries, documents, and sometimes painful experience to the MALT journey, and continue to do so; we cannot possibly name them all. We also thank the NSDI reviewers, and our shepherd Sujata Banerjee, for their helpful feedback.

A Example of MALT modeling

We use the Jupiter datacenter fabric design [20] to illustrate MALT modeling with a fine-grained, although incomplete and very simplified, example. In general, we use one shard (§ 4) for each such fabric.

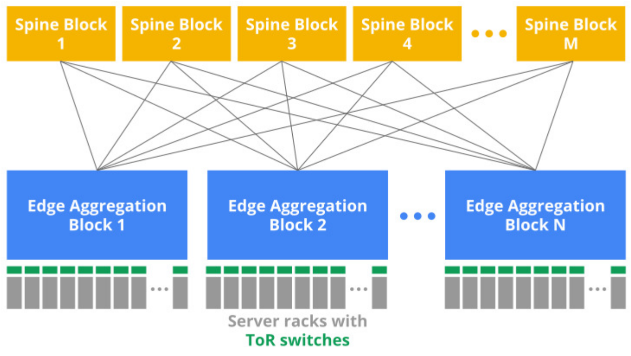

Figure 6: Overall structure of Jupiter (after [20])

Figs. 6–8 provide a summary of Jupiter's components: a fabric is made up of *aggregation blocks* connected to each other via a set of *spine blocks*. An aggregation block is a set of *middle blocks*, each of which is a Clos fabric made up of many switch chips. (Each spine block is also one Clos fabric.) Aggregation blocks connect to ToR switches. (A special kind of aggregation block, a *border router*, has the same structure but connects to WAN links rather than to ToR uplinks.)

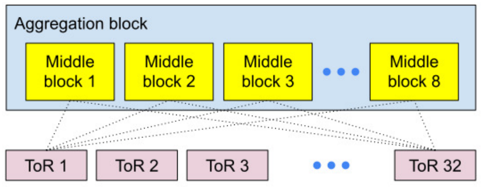

Figure 7: Jupiter aggregation block (after [20])

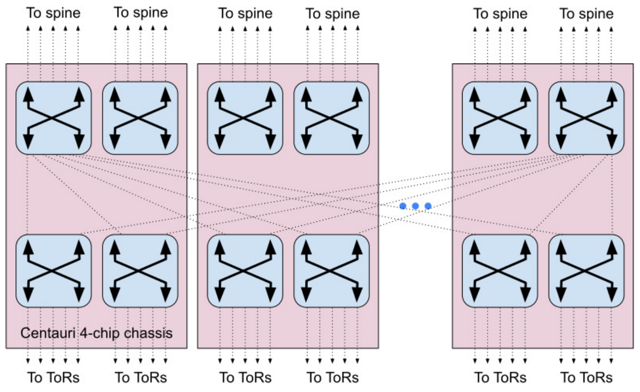

Figure 8: Jupiter middle block (after [20])

As described in [20] and shown in Fig. 8, we package four switch chips on one "Centauri" *chassis*. A ToR is one such chassis; a middle block is four chassis; we package multiple chassis into each *rack*.

Thus, a Jupiter has several hierarchies: a "data plane" hierarchy of packet switch chips and larger switch-like abstractions; a "sheet metal plane" hierarchy of racks, chassis, and chips; and a "control plane" hierarchy.

We can model the top-level data-plane hierarchy for a small Jupiter called "ju1" as (using our shorthand syntax):

```
EK_JUPITER/ju1 RK_CONTAINS EK_AGG_BLOCK/ju1.a1
EK_JUPITER/ju1 RK_CONTAINS EK_AGG_BLOCK/ju1.a2
EK_JUPITER/ju1 RK_CONTAINS EK_AGG_BLOCK/ju1.a3
EK_JUPITER/ju1 RK_CONTAINS EK_AGG_BLOCK/ju1.a4

EK_JUPITER/ju1 RK_CONTAINS EK_SPINE_BLOCK/ju1.s1
 ...
EK_JUPITER/ju1 RK_CONTAINS EK_SPINE_BLOCK/ju1.s4

EK_AGG_BLOCK/ju1.a1 RK_CONTAINS EK_TOR/ju1.a1.t1
...
EK_AGG_BLOCK/ju1.a1 RK_CONTAINS EK_TOR/ju1.a1.t32
```

An aggregation block abstractly contains multiple middle blocks:

```
EK_AGG_BLOCK/ju1.a1 RK_CONTAINS
  EK_MIDDLE_BLOCK/ju1.a1.m1
...
EK_AGG_BLOCK/ju1.a1 RK_CONTAINS
    EK_MIDDLE_BLOCK/ju1.a1.m8
```

A middle block is a "logical switch" abstractly containing multiple switch chips:

```
EK_MIDDLE_BLOCK/ju1.a1.m1 RK_CONTAINS
  EK_PACKET_SWITCH/ju1.a1.m1.c1
...
EK_MIDDLE_BLOCK/ju1.a1 RK_CONTAINS
    EK_PACKET_SWITCH/ju1.a1.m1.c16
```

Chips within middle blocks are connected, so we also have to indicate the 8 *ports* on each switch chip:

```
  EK_PACKET_SWITCH/ju1.a1.m1.c16 RK_CONTAINS
    EK_PORT/ju1.a1.m1.c16.p1
  ...
  EK_PACKET_SWITCH/ju1.a1.m1.c16 RK_CONTAINS
    EK_PORT/ju1.a1.m1.c16.p16
```

and then the 64 bidirectional L3 links between the ports in the upper and lower layers of the block – just *one* of which would become (note that links in MALT are unidirectional):

```
  EK_PORT/ju1.a1.m1.c1.p9 RK_ORIGINATES
    EK_LOGICAL_PACKET_LINK/ju1.a1.m1.l1f
  EK_PORT/ju1.a1.m1.c9.p1 RK_TERMINATES
    EK_LOGICAL_PACKET_LINK/ju1.a1.m1.l1f
  EK_PORT/ju1.a1.m1.c9.p1 RK_ORIGINATES
    EK_LOGICAL_PACKET_LINK/ju1.a1.m1.l1r
  EK_PORT/ju1.a1.m1.c1.p9 RK_TERMINATES
    EK_LOGICAL_PACKET_LINK/ju1.a1.m1.l1r
```

Fig. 3 shows how L3 links traverse L2 links, which in turn might traverse multiple fibers, patch panels, etc. (not shown).

We similarly need to represent the internal connections in each spine block (just as in a middle block) and the connections between middle-block ports and spine-block ports, and those between middle-block ports and ToR ports. (Note that middle blocks in an aggregation block are not directly connected to each other.)

There are clearly a *lot* of links in a Jupiter network. Therefore, we use automated tools to design the cables that bundle these links. Those tools need to know the spatial locations of the ports to which these links connect; therefore, MALT also allows us to represent the physical containment hierarchy: each rack contains 16 chassis, which each contains 4 packet switches, which each contains 16 ports.

```
EK_RACK/ju1.a1.m1 RK_CONTAINS EK_CHASSIS/ju1.a1.m1.chass1
...
EK_RACK/ju1.a1.m1 RK_CONTAINS EK_CHASSIS/ju1.a1.m1.chass16

EK_CHASSIS/ju1.a1.m1.chass1 RK_CONTAINS
  EK_PACKET_SWITCH/ju1.a1.m1.c1
...
EK_CHASSIS/ju1.a1.m1.chass1 RK_CONTAINS
  EK_PACKET_SWITCH/ju1.a1.m1.c4

EK_PACKET_SWITCH/ju1.a1.m1.c16 RK_CONTAINS
   EK_PORT/ju1.a1.m1.c16.p1
... (as above)
```

Jupiter is a software-defined network, so we also represent the network control plane and its connectivity – information required to automatically generate configuration for packet switches and for controllers. We start by abstracting the switch-local CPU as a "control point" for the switch – what SDN controllers will communicate with:

```
EK_CHASSIS/ju1.a1.m1.chass1 RK_CONTAINS
  EK_CONTROL_POINT/ju1.a1.m1.chass1
EK_CONTROL_POINT/ju1.a1.m1.chass1 RK_CONTAINS
  EK_INTERFACE/ju1.a1.m1.chass1.if1
EK_INTERFACE/ju1.a1.m1.chass1.if1 RK_TRAVERSES
  EK_PORT/ju1.a1.m1.chass1.port1
EK_PORT/ju1.a1.m1.chass1.port1 RK_ORIGINATES
  EK_LOGICAL_PACKET_LINK/...
```

Note that MALT allows us to give two different entities the same name, as long as they have different entity-kinds – here, the control point has the same name as its containing chassis.

Since a Centauri chassis has one CPU for 4 switch chips, we model this as:

```
EK_CONTROL_POINT/ju1.a1.m1.chass1 RK_CONTROLS
  EK_PACKET_SWITCH/ju1.a1.m1.c1
...
EK_CONTROL_POINT/ju1.a1.m1.chass1 RK_CONTROLS
  EK_PACKET_SWITCH/ju1.a1.m1.c4
```

We can then represent the relationships between a set of SDN switches and their controllers via indirection: all switches with the same set of controller replicas are grouped into a "control domain" (we generally have one control domain per aggregation block, to provide fault tolerance):

```
EK_CONTROL_DOMAIN/ju1.dom1 RK_CONTAINS
  EK_CONTROL_POINT/ju1.a1.m1.chass1
...
EK_CONTROL_DOMAIN/ju1.dom16 RK_CONTAINS
  EK_CONTROL_POINT/ju1.a16.m8.chass1
```

This indirection allows us to represent a pool of controller replicas responsible for all switches in a control domain:

```
EK_CONTROLLER/ju1.controller1.1 RK_CONTROLS
  EK_CONTROL_DOMAIN/ju1.dom1
...
EK_CONTROLLER/ju1.controller1.4 RK_CONTROLS
  EK_CONTROL_DOMAIN/ju1.dom1
```

We can also represent – omitted here due to lack of space – that controllers run on a pool of dedicated server machines, how these machines are arranged in racks, are connected to the network, etc.

Attributes: So far, this appendix has only described entities and relationships. Each entity has a set of attributes; space only permits us to show a few (simplified) examples. A specific port might include these attributes:

```
port_attr: <
  device_port_name: "port-1/24"
  openflow: <
    of_port_number: 24
  >
  port_role: PR_SINGLETON
  port_attributes: <
    physical_capacity_bps: 40000000000
  >
>
```

while a specific L3 interface might include these:

```
interface_attr: <
  address: <
    ipv4: <
      address: "10.1.2.3"
      prefixlen: 32
    >

Abstract

Serverless containers and functions are widely used for deploying and managing software in the cloud. Their popularity is due to reduced cost of operations, improved utilization of hardware, and faster scaling than traditional deployment methods. The economics and scale of serverless applications demand that workloads from multiple customers run on the same hardware with minimal overhead, while preserving strong security and performance isolation. The traditional view is that there is a choice between virtualization with strong security and high overhead, and container technologies with weaker security and minimal overhead. This tradeoff is unacceptable to public infrastructure providers, who need both strong security and minimal overhead. To meet this need, we developed Firecracker, a new open source Virtual Machine Monitor (VMM) specialized for serverless workloads, but generally useful for containers, functions and other compute workloads within a reasonable set of constraints. We have deployed Firecracker in two publically-available serverless compute services at Amazon Web Services (Lambda and Fargate), where it supports millions of production workloads, and trillions of requests per month. We describe how specializing for serverless informed the design of Firecracker, and what we learned from seamlessly migrating Lambda customers to Firecracker.

1 Introduction

Serverless computing is an increasingly popular model for deploying and managing software and services, both in public cloud environments, e.g., [4, 16, 50, 51], as well as in on-premises environments, e.g., [11,41]. The serverless model is attractive for several reasons, including reduced work in operating servers and managing capacity, automatic scaling, pay-for-use pricing, and integrations with sources of events and streaming data. Containers, most commonly embodied by Docker, have become popular for similar reasons, including reduced operational overhead, and improved manageability. Containers and Serverless offer a distinct economic advantage over traditional server provisioning processes: multitenancy allows servers to be shared across a large number of workloads, and the ability to provision new functions and containers in milliseconds allows capacity to be switched between workloads quickly as demand changes. Serverless is also attracting the attention of the research community [21,26,27,44,47], including work on scaling out video encoding [13], linear algebra [20, 53] and parallel compilation [12].

Multitenancy, despite its economic opportunities, presents significant challenges in isolating workloads from one another. Workloads must be isolated both for security (so one workload cannot access, or infer, data belonging to another workload), and for operational concerns (so the noisy neighbor effect of one workload cannot cause other workloads to run more slowly). Cloud instance providers (such as AWS EC2) face similar challenges, and have solved them using hypervisor-based virtualization (such as with QEMU/KVM [7, 29] or Xen [5]), or by avoiding multi-tenancy and offering bare-metal instances. Serverless and container models allow many more workloads to be run on a single machine than traditional instance models, which amplifies the economic advantages of multi-tenancy, but also multiplies any overhead required for isolation.

Typical container deployments on Linux, such as those using Docker and LXC, address this density challenge by relying on isolation mechanisms built into the Linux kernel. These mechanisms include *control groups* (*cgroups*), which provide process grouping, resource throttling and accounting; *namespaces*, which separate Linux kernel resources such as process IDs (PIDs) into namespaces; and *seccomp-bpf*, which controls access to syscalls. Together, these tools provide a powerful toolkit for isolating containers, but their reliance on a single operating system kernel means that there is a fundamental tradeoff between security and code compatibility. Container implementors can choose to improve security by limiting syscalls, at the cost of breaking code which requires the restricted calls. This introduces difficult tradeoffs: implementors of serverless and container services can choose between hypervisor-based virtualization (and the potentially unacceptable overhead related to it), and Linux containers (and the related compatibility vs. security tradeoffs). We built Firecracker because we didn't want to choose.

Other projects, such as Kata Containers [14], Intel's Clear Containers, and NEC's LightVM [38] have started from a similar place, recognizing the need for improved isolation, and choosing hypervisor-based virtualization as the way to achieve that. QEMU/KVM has been the base for the majority of these projects (such as Kata Containers), but others (such as LightVM) have been based on slimming down Xen. While QEMU has been a successful base for these projects, it is a large project ($>$ 1.4 million LOC as of QEMU 4.2), and has focused on flexibility and feature completeness rather than overhead, security, or fast startup.

With Firecracker, we chose to keep KVM, but entirely replace QEMU to build a new Virtual Machine Monitor (VMM), device model, and API for managing and configuring MicroVMs. Firecracker, along with KVM, provides a new foundation for implementing isolation between containers and functions. With the provided minimal Linux guest kernel configuration, it offers memory overhead of less than 5MB per container, boots to application code in less than 125ms, and allows creation of up to 150 MicroVMs per second per host. We released Firecracker as open source software in December 2018[1], under the Apache 2 license. Firecracker has been used in production in Lambda since 2018, where it powers millions of workloads and trillions of requests per month.

Section 2 explores the choice of an isolation solution for Lambda and Fargate, comparing containers, language VM isolation, and virtualization. Section 3 presents the design of Firecracker. Section 4 places it in context in Lambda, explaining how it is integrated, and the role it plays in the performance and economics of that service. Section 5 compares Firecracker to alternative technologies on performance, density and overhead.

1.1 Specialization

Firecracker was built specifically for serverless and container applications. While it is broadly useful, and we are excited to see Firecracker be adopted in other areas, the performance, density, and isolation goals of Firecracker were set by its intended use for serverless and containers. Developing a VMM for a clear set of goals, and where we could make assumptions about the properties and requirements of guests, was significantly easier than developing one suitable for all uses. These simplifying assumptions are reflected in Firecracker's design and implementation. This paper describes Firecracker in context, as used in AWS Lambda, to illustrate why we made the decisions we did, and where we diverged from existing VMM designs. The specifics of how Firecracker is used in Lambda are covered in Section 4.1.

[1] https://firecracker-microvm.github.io/

Firecracker is probably most notable for what it does not offer, especially compared to QEMU. It does not offer a BIOS, cannot boot arbitrary kernels, does not emulate legacy devices nor PCI, and does not support VM migration. Firecracker could not boot Microsoft Windows without significant changes to Firecracker. Firecracker's process-per-VM model also means that it doesn't offer VM orchestration, packaging, management or other features — it replaces QEMU, rather than Docker or Kubernetes, in the container stack. Simplicity and minimalism were explicit goals in our development process. Higher-level features like orchestration and metadata management are provided by existing open source solutions like Kubernetes, Docker and `containerd`, or by our proprietary implementations inside AWS services. Lower-level features, such as additional devices (USB, PCI, sound, video, etc), BIOS, and CPU instruction emulation are simply not implemented because they are not needed by typical serverless container and function workloads.

2 Choosing an Isolation Solution

When we first built AWS Lambda, we chose to use Linux containers to isolate functions, and virtualization to isolate between customer accounts. In other words, multiple functions for the same customer would run inside a single VM, but workloads for different customers always run in different VMs. We were unsatisfied with this approach for several reasons, including the necessity of trading off between security and compatibility that containers represent, and the difficulties of efficiently packing workloads onto fixed-size VMs. When choosing a replacement, we were looking for something that provided strong security against a broad range of attacks (including microarchitectural side-channel attacks), the ability to run at high densities with little overhead or waste, and compatibility with a broad range of unmodified software (Lambda functions are allowed to contain arbitrary Linux binaries, and a significant portion do). In response to these challenges, we evaluated various options for re-designing Lambda's isolation model, identifying the properties of our ideal solution:

Isolation: It must be safe for multiple functions to run on the same hardware, protected against privilege escalation, information disclosure, covert channels, and other risks.

Overhead and Density: It must be possible to run thousands of functions on a single machine, with minimal waste.

Performance: Functions must perform similarly to running natively. Performance must also be consistent, and isolated from the behavior of neighbors on the same hardware.

Compatibility: Lambda allows functions to contain arbitrary Linux binaries and libraries. These must be supported without code changes or recompilation.

Fast Switching: It must be possible to start new functions and clean up old functions quickly.

Soft Allocation: It must be possible to over commit CPU, memory and other resources, with each function consuming only the resources it needs, not the resources it is entitled to.

Some of these qualities can be converted into quantitative goals, while others (like isolation) remain stubbornly qualitative. Modern commodity servers contain up to 1TB of RAM, while Lambda functions use as little as 128MB, requiring up to 8000 functions on a server to fill the RAM (or more due to soft allocation). We think of overhead as a percentage, based on the size of the function, and initially targeted 10% on RAM and CPU. For a 1024MB function, this means 102MB of memory overhead. Performance is somewhat complex, as it is measured against the function's entitlement. In Lambda, CPU, network, and storage throughput is allocated to functions proportionally to their configured memory limit. Within these limits, functions should perform similarly to bare metal on raw CPU, IO throughput, IO latency and other metrics.

2.1 Evaluating the Isolation Options

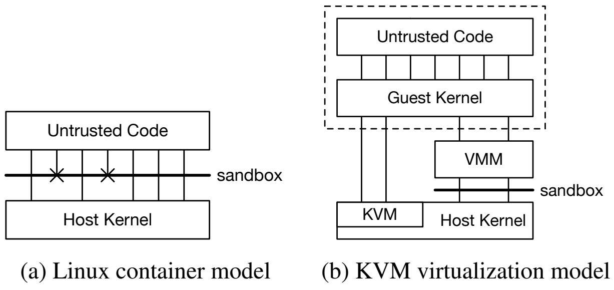
Broadly, the options for isolating workloads on Linux can be broken into three categories: *containers*, in which all workloads share a kernel and some combination of kernel mechanisms are used to isolate them; *virtualization*, in which workloads run in their own VMs under a hypervisor; and *language VM isolation*, in which the language VM is responsible for either isolating workloads from each other or from the operating system. [2]

Figure 1 compares the security approaches between Linux containers and virtualization. In Linux containers, untrusted code calls the host kernel directly, possibly with the kernel surface area restricted (such as with seccomp-bpf). It also interacts directly with other services provided by the host kernel, like filesystems and the page cache. In virtualization, untrusted code is generally allowed full access to a guest kernel, allowing all kernel features to be used, but explicitly treating the guest kernel as untrusted. Hardware virtualization and the VMM limit the guest kernel's access to the privileged domain and host kernel.

2.1.1 Linux Containers

Containers on Linux combine multiple Linux kernel features to offer operational and security isolation. These features include: *cgroups*, providing CPU, memory and other resource

[2] It's somewhat confusing that in common usage *containers* is both used to describe the mechanism for packaging code, and the typical implementation of that mechanism. Containers (the abstraction) can be provided without depending on containers (the implementation). In this paper, we use the term *Linux containers* to describe the implementation, while being aware that other operating systems provide similar functionality.



(a) Linux container model (b) KVM virtualization model

Figure 1: The security model of Linux containers (a) depends directly on the kernel's sandboxing capabilities, while KVM-style virtualization (b) relies on security of the VMM, possibly augmented sandboxing

limits; *namespaces*, providing namespacing for kernel resources like user IDs (uids), process IDs (pids) and network interfaces; *seccomp-bpf*, providing the ability to limit which syscalls a process can use, and which arguments can be passed to these syscalls; and *chroot*, proving an isolated filesystem. Different Linux container implementations use these tools in different combinations, but *seccomp-bpf* provides the most important security isolation boundary. The fact that containers rely on syscall limitations for their security represents a tradeoff between security and compatibility. A trivial Linux application requires 15 unique syscalls. Tsai et al [57] found that a typical Ubuntu Linux 15.04 installation requires 224 syscalls and 52 unique *ioctl* calls to run without problems, along with the */proc* and */sys* interfaces of the kernel. Nevertheless, meaningful reduction of the kernel surface is possible, especially as it is reasonable to believe that the Linux kernel has more bugs in syscalls which are less heavily used [32].

One approach to this challenge is to provide some of the operating system functionality in userspace, requiring a significantly smaller amount of kernel functionality to provide the programmer with the appearance of a fully featured environment. Graphene [56], Drawbridge [45], Bascule [6] and Google's gvisor [15] take this approach. In environments running untrusted code, container isolation is not only concerned with preventing privilege escalation, but also in preventing information disclosure side channels (such as [19]), and preventing communication between functions over covert channels. The richness of interfaces like */proc* have showed this to be challenging (CVE-2018-17972 and CVE-2017-18344 are recent examples).

2.1.2 Language-Specific Isolation

A second widely-used method for isolating workloads is leveraging features of the language virtual machine, such as the Java Virtual Machine (JVM) or V8. Some language VMs (such as V8's *isolates* and the JVM's security managers) aim to run multiple workloads within a single process, an approach which introduces significant tradeoffs between functionality (and compatibility) and resistance to side channel attacks such as Spectre [30, 39]. Other approaches, such as Chromium site isolation [46], Alto [31] and SAND [1] use a process per trust domain, and instead aim to prevent the code from escaping from the process or accessing information from beyond the process boundary. Language-specific isolation techniques were not suitable for Lambda or Fargate, given our need to support arbitrary binaries.

2.1.3 Virtualization

Modern virtualization uses hardware features (such as Intel VT-x) to provide each sandbox an isolated environment with its own virtual hardware, page tables, and operating system kernel. Two key, and related, challenges of virtualization are density and overhead. The VMM and kernel associated with each guest consumes some amount of CPU and memory before it does useful work, limiting density. Another challenge is startup time, with typical VM startup times in the range of seconds. These challenges are particularly important in the Lambda environment, where functions are small (so relative overhead is larger), and workloads are constantly changing. One way to address startup time is to boot something smaller than a full OS kernel, such as a unikernel. Unikernels are already being investigated for use with containers, for example in LightVM [38] and Solo5 [59]. Our requirement for running unmodified code targeting Linux meant that we could not apply this approach.

The third challenge in virtualization is the implementation itself: hypervisors and virtual machine monitors (VMMs), and therefore the required *trusted computing base* (TCB), can be large and complex, with a significant attack surface. This complexity comes from the fact that VMMs still need to either provide some OS functionality themselves (type 1) or depend on the host operating system (type 2) for functionality. In the type 2 model, The VMM depends on the host kernel to provide IO, scheduling, and other low-level functionality, potentially exposing the host kernel and side-channels through shared data structures. Williams et al [60] found that virtualization does lead to fewer host kernel functions being called than direct implementation (although more than their libOS-based approach). However, Li et al [32] demonstrate the effectiveness of a 'popular paths' metric, showing that only 3% of kernel bugs are found in frequently-used code paths (which, in our experience, overlap highly with the code paths used by the VMM).

To illustrate this complexity, the popular combination of Linux Kernel Virtual Machine [29] (KVM) and QEMU clearly illustrates the complexity. QEMU contains $>$ 1.4 million lines of code, and can require up to 270 unique syscalls [57] (more than any other package on Ubuntu Linux 15.04). The KVM code in Linux adds another 120,000 lines. The NEMU [24] project aims to cut down QEMU by removing unused features, but appears to be inactive.

Efforts have been made (such as with Muen [9] and Nova [55]) to significantly reduce the size of the Hypervisor and VMM, but none of these minimized solutions offer the platform independence, operational characteristics, or maturity that we needed at AWS.

Firecracker's approach to these problems is to use KVM (for reasons we discuss in section 3), but replace the VMM with a minimal implementation written in a safe language. Minimizing the feature set of the VMM helps reduce surface area, and controls the size of the TCB. Firecracker contains approximately 50k lines of Rust code (96% fewer lines than QEMU), including multiple levels of automated tests, and auto-generated bindings. Intel Cloud Hypervisor [25] takes a similar approach, (and indeed shares much code with Firecracker), while NEMU [24] aims to address these problems by cutting down QEMU.

Despite these challenges, virtualization provides many compelling benefits. From an isolation perspective, the most compelling benefit is that it moves the security-critical interface from the OS boundary to a boundary supported in hardware and comparatively simpler software. It removes the need to trade off between kernel features and security: the guest kernel can supply its full feature set with no change to the threat model. VMMs are much smaller than general-purpose OS kernels, exposing a small number of well-understood abstractions without compromising on software compatibility or requiring software to be modified.

3 The Firecracker VMM

Firecracker is a Virtual Machine Monitor (VMM), which uses the Linux Kernel's KVM virtualization infrastructure to provide minimal virtual machines (MicroVMs), supporting modern Linux hosts, and Linux and OSv guests. Firecracker provides a REST based configuration API; device emulation for disk, networking and serial console; and configurable rate limiting for network and disk throughput and request rate. One Firecracker process runs per MicroVM, providing a simple model for security isolation.

Our other philosophy in implementing Firecracker was to rely on components built into Linux rather than re-implementing our own, where the Linux components offer the right features, performance, and design. For example we pass block IO through to the Linux kernel, depend on Linux's process scheduler and memory manager for handling contention between VMs in CPU and memory, and we use TUN/TAP virtual network interfaces. We chose this path for two reasons. One was implementation cost: high-quality operating system components, such as schedulers, can take decades to get right, especially when they need to deal with multi-tenant workloads on multi-processor machines. The implementations in Linux, while not beyond criticism [36], are well-proven in high-scale deployments.

The other reason was operational knowledge: within AWS, our operators are highly experienced at operating, automating, optimizing Linux systems (for example, Brendan Gregg's books on Linux performance [18] are popular among Amazon teams). Using KVM in Linux, along with the standard Linux programming model, allows our operators to use most of the tools they already know when operating and troubleshooting Firecracker hosts and guests. For example, running *ps* on a Firecracker host will include all the MicroVMs on the host in the process list, and tools like *top*, *vmstat* and even *kill* work as operators expect. While we do not routinely provide access to in-production Firecracker hosts to operators, the ability to use the standard Linux toolset has proven invaluable during the development and testing of our services. In pursuit of this philosophy, Firecracker does sacrifice portability between host operating systems, and inherits a larger trusted compute base.

In implementing Firecracker, we started with Google's Chrome OS Virtual Machine Monitor *crosvm*, re-using some of its components. Consistent with the Firecracker philosophy, the main focus of our adoption of *crosvm* was removing code: Firecracker has fewer than half as many lines of code as *crosvm*. We removed device drivers including USB and GPU, and support for the 9p filesystem protocol. Firecracker and *crosvm* have now diverged substantially. Since diverging from *crosvm* and deleting the unneeded drivers, Firecracker has added over 20k lines of new code, and changed 30k lines. The rust-vmm project[3] maintains a common set of open-source Rust crates (packages) to be shared by Firecracker and crosvm and used as a base by future VMM implementers.

3.1 Device Model

Reflecting its specialization for container and function workloads, Firecracker provides a limited number of emulated devices: network and block devices, serial ports, and partial i8042 (PS/2 keyboard controller) support. For comparison, QEMU is significantly more flexible and more complex, with support for more than 40 emulated devices, including USB, video and audio devices. The serial and i8042 emulation implementations are straightforward: the i8042 driver is less than 50 lines of Rust, and the serial driver around 250. The network and block implementations are more complex, reflecting both higher performance requirements and more inherent complexity. We use *virtio* [40, 48] for network and block devices, an open API for exposing emulated devices from hypervisors. *virtio* is simple, scalable, and offers sufficiently good overhead and performance for our needs. The entire *virtio* block implementation in Firecracker (including MMIO and data structures) is around 1400 lines of Rust.

We chose to support block devices for storage, rather than filesystem passthrough, as a security consideration. Filesystems are large and complex code bases, and providing only block IO to the guest protects a substantial part of the host kernel surface area.

[3]https://github.com/rust-vmm/community

3.2 API

The Firecracker process provides a REST API over a Unix socket, which is used to configure, manage and start and stop MicroVMs. Providing an API allows us to more carefully control the life cycle of MicroVMs. For example, we can start the Firecracker process and pre-configure the MicroVM and only start the MicroVM when needed, reducing startup latency. We chose REST because clients are available for nearly any language ecosystem, it is a familiar model for our targeted developers, and because OpenAPI allows us to provide a machine- and human-readable specification of the API. By contrast, the typical Unix approach of command-line arguments do not allow messages to be passed to the process after it is created, and no popular machine-readable standard exists for specifying structured command-line arguments. Firecracker users can interact with the API using an HTTP client in their language of choice, or from the command line using tools like *curl*.

REST APIs exist for specifying the guest kernel and boot arguments, network configuration, block device configuration, guest machine configuration and cpuid, logging, metrics, rate limiters, and the metadata service. Common defaults are provided for most configurations, so in the simplest use only the guest kernel and one (root) block device need to be configured before the VM is started.

To shut down the MicroVM, it is sufficient to kill the Firecracker process, or issue a *reboot* inside the guest. As with the rest of Firecracker, the REST API is intentionally kept simple and minimal, especially when compared to similar APIs like Xen's Xenstore.

3.3 Rate Limiters, Performance and Machine Configuration

The machine configuration API allows hosts to configure the amount of memory and number of cores exposed to a MicroVM, and set up the *cpuid* bits that the MicroVM sees. While Firecracker offers no emulation of missing CPU functionality, controlling *cpuid* allows hosts to hide some of their capabilities from MicroVMs, such as to make a heterogeneous compute fleet appear homogeneous.

Firecracker's block device and network devices offer built-in rate limiters, also configured via the API. These rate limiters allow limits to be set on operations per second (IOPS for disk, packets per second for network) and on bandwidth for each device attached to each MicroVM. For the network, separate limits can be set on receive and transmit traffic. Limiters are implemented using a simple in-memory token bucket, optionally allowing short-term bursts above the base rate, and a one-time burst to accelerate booting. Having rate limiters be configurable via the API allows us to vary limits based on configured resources (like the memory configured for a Lambda function), or dynamically based on demand. Rate limiters play two roles in our systems: ensuring that our storage devices and networks have sufficient bandwidth available for control plane operations, and preventing a small number of busy MicroVMs on a server from affecting the performance of other MicroVMs.

While Firecracker's rate limiters and machine configuration provide the flexibility that we need, they are significantly less flexible and powerful than Linux *cgroups* which offer additional features including CPU credit scheduling, core affinity, scheduler control, traffic prioritization, performance events and accounting. This is consistent with our philosophy. We implemented performance limits in Firecracker where there was a compelling reason: enforcing rate limits in device emulation allows us to strongly control the amount of VMM and host kernel CPU time that a guest can consume, and we do not trust the guest to implement its own limits. Where we did not have a compelling reason to add the functionality to Firecracker, we use the capabilities of the host OS.

3.4 Security

Architectural and micro-architectural side-channel attacks have existed for decades. Recently, the publication of Meltdown [34], Spectre [30], Zombieload [49], and related attacks (e.g. [2, 37, 54, 58]) has generated a flurry of interest in this area, and prompted the development of new mitigation techniques in operating systems, processors, firmware and microcode. Canella et al [10] and ARM [33] provide good summaries of the current state of research. With existing CPU capabilities, no single layer can mitigate all these attacks, so mitigations need to be built into multiple layers of the system. For Firecracker, we provide clear guidance on current side-channel mitigation best-practices for deployments of Firecracker in production[4]. Mitigations include disabling Symmetric MultiThreading (SMT, aka HyperThreading), checking that the host Linux kernel has mitigations enabled (including Kernel Page-Table Isolation, Indirect Branch Prediction Barriers, Indirect Branch Restricted Speculation and cache flush mitigations against L1 Terminal Fault), enabling kernel options like Speculative Store Bypass mitigations, disabling swap and samepage merging, avoiding sharing files (to mitigate timing attacks like Flush+Reload [61] and Prime+Probe [42]), and even hardware recommendations to mitigate RowHammer [28, 43]. While we believe that all of these practices are necessary in a public cloud environment, and enable them in our Lambda and Fargate deployments of Firecracker, we also recognize that tradeoffs exist between performance and security, and that Firecracker consumers in less-demanding environments may choose not to implement some of these mitigations. As with all security mitigations, this is not an end-point, but an ongoing process of understanding and responding to new threats as they surface.

Other side-channel attacks, such as power and temperature, are not addressed by Firecracker, and instead must be handled elsewhere in the system architecture. We have paid careful attention to mitigating these attacks in our own services, but anybody who adopts Firecracker must understand them and have plans to mitigate them.

3.4.1 Jailer

Firecracker's jailer implements an additional level of protection against unwanted VMM behavior (such as a hypothetical bug that allows the guest to inject code into the VMM). The jailer implements a wrapper around Firecracker which places it into a restrictive sandbox before it boots the guest, including running it in a *chroot*, isolating it in *pid* and network namespaces, dropping privileges, and setting a restrictive *seccomp-bpf* profile. The sandbox's *chroot* contains only the Firecracker binary, */dev/net/tun*, cgroups control files, and any resources the particular MicroVM needs access to (such as its storage image). The *seccomp-bpf* profile whitelists 24 syscalls, each with additional argument filtering, and 30 ioctls (of which 22 are required by KVM ioctl-based API).

4 Firecracker In Production

4.1 Inside AWS Lambda

Lambda [51] is a compute service which runs functions in response to events. Lambda offers a number of built-in language runtimes (including Python, Java, NodeJS, and C#) which allows functions to be provided as snippets of code implementing a language-specific runtime interface. A "Hello, World!" Lambda function can be implemented in as few as three lines of Python or Javascript. It also supports an HTTP/REST runtime API, allowing programs which implement this API to be developed in any language, and provided either as binaries or a bundle alongside their language implementation. Lambda functions run within a sandbox, which provides a minimal Linux userland and some common libraries and utilities. When Lambda functions are created, they are configured with a memory limit, and a maximum runtime to handle each individual event[5]. Events include those explicitly created by calling the Lambda *Invoke* API, from HTTP requests via AWS's Application Load Balancer and API Gateway, and from integrations with other AWS services including storage (S3), queue (SQS), streaming data (Kinesis) and database (DynamoDB) services.

Typical use-cases for AWS Lambda include backends for IoT, mobile and web applications; request-response and event-

[4]https://github.com/firecracker-microvm/firecracker/blob/master/docs/prod-host-setup.md

[5]As of early 2019, Lambda limits memory to less than 3GB and runtime to 15 minutes, but we expect these limits to increase considerably over time.

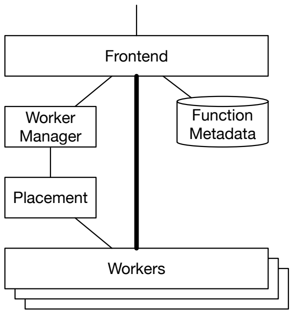


Figure 2: High-level architecture of AWS Lambda event path, showing control path (light lines) and data path (heavy lines)

sourced microservices; real-time streaming data processing; on-demand file processing; and infrastructure automation. AWS markets Lambda as *serverless* compute, emphasizing that Lambda functions minimize operational and capacity planning work, and entirely eliminate per-server operations for most use-cases. Most typical deployments of Lambda functions use them with other services in the AWS suite: S3, SQS, DynamoDB and Elasticache are common companions. Lambda is a large-scale multi-tenant service, serving trillions of events per month for hundreds of thousands of customers.

4.1.1 High-Level Architecture

Figure 2 presents a simplified view of the architecture of Lambda. Invoke traffic arrives at the frontend via the *Invoke* REST API, where requests are authenticated and checked for authorization, and function metadata is loaded. The frontend is a scale-out shared-nothing fleet, with any frontend able to handle traffic for any function. The execution of the customer code happens on the Lambda worker fleet, but to improve cache locality, enable connection re-use and amortize the costs of moving and loading customer code, events for a single function are sticky-routed to as few workers as possible. This sticky routing is the job of the Worker Manager, a custom high-volume (millions of requests per second) low-latency (<10ms 99.9th percentile latency) stateful router. The Worker Manager replicates sticky routing information for a single function (or small group of functions) between a small number of hosts across diverse physical infrastructure, to ensure high availability. Once the Worker Manager has identified which worker to run the code on, it advises the invoke service which sends the payload directly to the worker to reduce round-trips. The Worker Manager and workers also implement a concurrency control protocol which resolves the race conditions created by large numbers of independent invoke services operating against a shared pool of workers.

Each Lambda worker offers a number of *slots*, with each slot providing a pre-loaded execution environment for a function. Slots are only ever used for a single function, and a single concurrent invocation of that function, but are used for many serial invocations of the function. The MicroVM and the process the function is running in are both re-used, as illustrated by Listing 1 which will return a series of increasing numbers when invoked with a stream of serial events.

Listing 1 Lambda function illustrating slot re-use. The returned number will count up over many invokes.

```
var i = 0;
exports.handler = async (event, context) => {
    return i++;
};
```

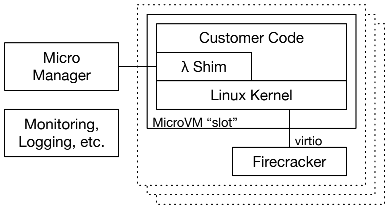

Figure 3: Architecture of the Lambda worker

Where a slot is available for a function, the Worker Manager can simply perform its lightweight concurrency control protocol, and tell the frontend that the slot is available for use. Where no slot is available, either because none exists or because traffic to a function has increased to require additional slots, the Worker Manager calls the Placement service to request that a new slot is created for the function. The Placement service in turn optimizes the placement of slots for a single function across the worker fleet, ensuring that the utilization of resources including CPU, memory, network, and storage is even across the fleet and the potential for correlated resource allocation on each individual worker is minimized. Once this optimization is complete — a task which typically takes less than 20ms — the Placement service contacts a worker to request that it creates a slot for a function. The Placement service uses a time-based lease [17] protocol to lease the resulting slot to the Worker Manager, allowing it to make autonomous decisions for a fixed period of time.

The Placement service remains responsible for slots, including limiting their lifetime (in response to the life cycle of the worker hosts), terminating slots which have become idle or redundant, managing software updates, and other similar activities. Using a lease protocol allows the system to both maintain efficient sticky routing (and hence locality) and have clear ownership of resources. As part of its optimization responsibilities, the placement service also consumes load and health data for each slot in each worker.

4.1.2 Firecracker In The Lambda Worker

Figure 3 shows the architecture of the Lambda worker, where Firecracker provides the critical security boundary required to run a large number of different workloads on a single server.

Each worker runs hundreds or thousands of MicroVMs (each providing a single *slot*), with the number depending on the configured size of each MicroVM, and how much memory, CPU and other resources each VM consumes. Each MicroVM contains a single sandbox for a single customer function, along with a minimized Linux kernel and userland, and a shim control process. The MicroVM is a primary security boundary, with all components assuming that code running inside the MicroVM is untrusted. One Firecracker process is launched per MicroVM, which is responsible for creating and managing the MicroVM, providing device emulation and handling VM exits.

The shim process in each MicroVM communicates through the MicroVM boundary via a TCP/IP socket with the MicroManager, a per-worker process which is responsible for managing the Firecracker processes. MicroManager provides slot management and locking APIs to placement, and an event invoke API to the Frontend. Once the Frontend has been allocated a slot by the WorkerManager, it calls the MicroManager with the details of the slot and request payload, which the MicroManager passes on to the Lambda shim running inside the MicroVM for that slot. On completion, the MicroManager receives the response payload (or error details in case of a failure), and passes these onto the Frontend for response to the customer. Communicating into and out of the MicroVM over TCP/IP costs some efficiency, but is consistent with the design principles behind Firecracker: it keeps the MicroManager process loosely coupled from the MicroVM, and re-uses a capability of the MicroVM (networking) rather than introducing a new device. The MicroManager's protocol with the Lambda shim is important for security, because it is the boundary between the multi-tenant Lambda control plane, and the single-tenant (and single-function) MicroVM. Also, on each worker is a set of processes that provides monitoring, logging, and other services for the worker. Logs and metrics are provided for consumption by both humans and automated alarming and monitoring systems, and metrics are also provided back to Placement to inform its view of the load on the worker.

The MicroManager also keeps a small pool of pre-booted MicroVMs, ready to be used when Placement requests a new slot. While the 125ms boot times offered by Firecracker are fast, they are not fast enough for the scale-up path of Lambda, which is sometimes blocking user requests. Fast booting is a first-order design requirement for Firecracker, both because boot time is a proxy for resources consumed during boot, and because fast boots allow Lambda to keep these spare pools small. The required mean pool size can be calculated with Little's law [35]: the pool size is the product of creation rate and creation latency. Alternatively, at 125ms creation time, one pooled MicroVM is required for every 8 creations per second.

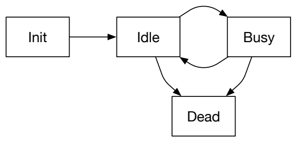

Figure 4: State transitions for a single slots on a Lambda worker

4.2 The Role of Multi-Tenancy

Soft-allocation (the ability for the platform to allocate resources on-demand, rather than at startup) and multi-tenancy (the ability for the platform to run large numbers of unrelated workloads) are critical to the economics of Lambda. Each slot can exist in one of three states: *initializing*, *busy*, and *idle*, and during their lifetimes slots move from *initializing* to *idle*, and then move between *idle* and *busy* as invokes flow to the slot (see Figure 4). Slots use different amounts of resources in each state. When they are *idle* they consume memory, keeping the function state available. When they are *initializing* and *busy*, they use memory but also resources like CPU time, caches, network and memory bandwidth and any other resources in the system. Memory makes up roughly 40% of the capital cost of typical modern server designs, so *idle* slots should cost 40% of the cost of busy slots. Achieving this requires that resources (like CPU) are both soft-allocated and oversubscribed, so can be sold to other slots while one is *idle*.

Oversubscription is fundamentally a statistical bet: the platform must ensure that resources are kept as busy as possible, but some are available to any slot which receives work. We set some compliance goal X (e.g., 99.99%), so that functions are able to get all the resources they need with no contention $X\%$ of the time. Efficiency is then directly proportional to the ratio between the Xth percentile of resource use, and mean resource use. Intuitively, the mean represents revenue, and the Xth percentile represents cost. Multi-tenancy is a powerful tool for reducing this ratio, which naturally drops approximately with $\sqrt{N}$ when running N uncorrelated workloads on a worker. Keeping these workloads uncorrelated requires that they are unrelated: multiple workloads from the same application, and to an extent from the same customer or industry, behave as a single workload for these purposes.

4.3 Experiences Deploying and Operating Firecracker

Starting in 2018, we migrated Lambda customers from our first isolation solution (based on containers per function, and AWS EC2 instances per customer) to Firecracker running on AWS EC2 bare metal instances, with no interruption to availability, latency or other metrics. Each Lambda slot exists for at most 12 hours before it is recycled. Simply changing the recycling logic to switch between Firecracker and legacy implementations allowed workloads to be migrated with no change in behavior.

We took advantage of users of Lambda inside AWS by migrating their workloads first, and carefully monitoring their metrics. Having access to these internal customer's metrics and code reduced the risk of early stages of deployment, because we didn't need to rely on external customers to inform us of subtle issues. This migration was mostly uneventful, but we did find some minor issues. For example, our Firecracker fleet has Symmetric MultiThreading (SMT, aka Hyperthreading) disabled [52] while our legacy fleet had it enabled[6]. Migrating to Firecracker changed the timings of some code, and exposed minor bugs in our own SDK, and in Apache Commons HttpClient [22, 23]. Once we moved all internal AWS workloads, we started to migrate external customers. This migration has been uneventful, despite moving arbitrary code provided by hundreds of thousands of AWS customers.

Throughout the migration, we made sure that the metrics and logs for the Firecracker and legacy stacks could be monitored independently. The team working on the migration carefully compared the metrics between the two stacks, and investigated each case where they were diverged significantly. We keep detailed per-workload metrics, including latency and error-rate, allowing us to use statistical techniques to proactively identify anomalous behavior. Architecturally, we chose to use a common production environment for both stacks as far as possible, isolating the differences between the stacks behind a common API. This allowed the migration team to work independently, shifting the target of the API traffic with no action from teams owning other parts of the architecture.

Our deployment mechanism was also designed to allow fast, safe, and (in some cases) automatic rollback, moving customers back to the legacy stack at the first sign of trouble. Rollback is a key operational safety practice at AWS, allowing us to mitigate customer issues quickly, and then investigate. One case where we used this mechanism was when some customers reported seeing DNS-related performance issues: we rolled them back, and then root-caused the issue to a misconfiguration causing DNS lookups not to be cached inside the MicroVM.

One area of focus for our deployment was building mechanisms to patch software, including Firecracker and the guest and host kernels, quickly and safely and then audit that patches have reached the whole fleet. We use an *immutable infrastructure* approach, where we patch by completely re-imaging the host, implemented by terminating and re-launching our AWS EC2 instances with an updated machine image (AMI). We chose this approach based on a decade of experience operating AWS services, and learning that it is extremely difficult to keep software sets consistent on large-scale mutable fleets (for example, package managers like *rpm* are non-deterministic, producing different results on across a fleet). It also illustrates the value of building higher-level services like Lambda on lower-level services like AWS EC2: we didn't need to build any host management or provisioning infrastructure.

[6]We disable SMT on the Firecracker fleet as a sidechannel mitigation. On the legacy fleet the same threats are mitigated by pinning VMs to cores.

5 Evaluation

In Section 2, we described six criteria for choosing a mechanism for isolation in AWS Lambda: Isolation, Overhead, Performance, Compatibility, Fast Switching and Soft Allocation. In this section we evaluate Firecracker against these criteria as well as other solutions in this space. We use Firecracker v0.20.0 as the base line and use QEMU v4.2.0 (statically compiled with a minimal set of options) for comparison. We also include data for the recently released Intel Cloud Hypervisor [25], a VMM written in Rust sharing significant code with Firecracker, while targeting a different application space.

Our evaluation is performed on an EC2 *m5d.metal* instance, with two Intel Xeon Platinum 8175M processors (for a total of 48 cores with hyper-threading disabled), 384GB of RAM, and four 840GB local NVMe disks. The base OS was Ubuntu 18.04.2 with kernel 4.15.0-1044-aws. The configuration and scripts used for all our experiments, and the resulting data, is publicly available[7].

5.1 Boot Times

Boot times of MicroVMs are important for serverless workloads like Lambda. While Lambda uses a small local pool of MicroVMs to hide boot latency from customers, the costs of switching between workloads (and therefore the cost of creating new MicroVMs) is very important to our economics. In this section we compare the boot times of different VMMs. The boot time is measured as the time between when VMM process is forked and the guest kernel forks its `init` process. For this experiment we use a minimal `init` implementation, which just writes to a pre-configured IO port. We modified all VMMs to call `exit()` when the write to this IO port triggers a VM exit.

All VMMs directly load a Linux 4.14.94 kernel via the command line (i.e. the kernel is directly loaded by the VMM and not some bootloader). The kernel is configured with the settings we recommend for MicroVMs (minimal set of kernel driver and no kernel modules), and we use a file backed minimal root filesystem containing the `init` process. The VMs are configured with a single vCPU and 256MB of memory.

Figure 5 shows the cumulative distribution of (wall-clock) kernel boot times for 500 samples executed serially, so only one boot was taking place on the system at a time. Firecracker results are presented in two ways: end-to-end, including forking the Firecracker process and configuration through the API; and pre-configured where Firecracker has already been set up

[7]`https://github.com/firecracker-microvm/nsdi2020-data`

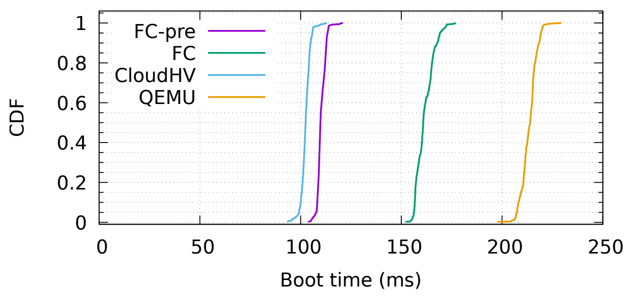

Figure 5: Cumulative distribution of wall-clock times for starting MicroVMs in serial, for pre-configured Firecracker (FC-pre), end-to-end Firecracker, Cloud Hypervisor, and QEMU.

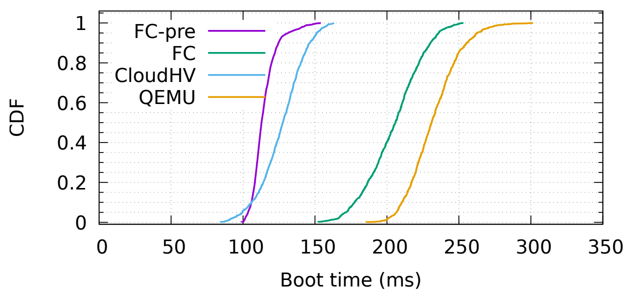

Figure 6: Cumulative distribution of wall-clock times for starting 50 MicroVMs in parallel, for pre-configured Firecracker (FC-pre), end-to-end Firecracker, Cloud Hypervisor,and QEMU.

through the API and time represent the wall clock time from the final API call to start the VM until the `init` process gets executed.

Pre-configured Firecracker and the Cloud Hypervisor perform significantly better than QEMU, both on average and with a tighter distribution, booting twice as fast as QEMU. The end-to-end Firecracker boot times are somewhat in-between, which is expected since we currently perform several API calls to configure the Firecracker VM. Cloud Hypervisor boots marginally faster than pre-configured Firecracker. We suspect subtle differences in the VM emulation to be the reason.

We then booted 1000 MicroVMs with 50 VMs launching concurrently. While any highly-concurrent test will give results that vary between runs, the results in Figure 6 are representative: Firecracker and QEMU perform similarly for end-to-end comparisons, roughly maintaining the 50ms gap already seen with the serial boot times above. Like with serial boot times, pre-configured Firecracker and Cloud Hypervisor show significantly better results, with pre-configured Firecracker out-performing Cloud Hypervisor both in average boot times as well as a tighter distribution with a 99th percentile of 146ms vs 158ms. We also repeated the experiment with starting 100 MicroVMs concurrently and see a similar trend, albeit with a slightly wider distribution with the 99th percentile for pre-configure Firecracker going up to 153ms.

Based on these results, we are investigating a number of optimizations to Firecracker. We could move the Firecracker configuration into a single combined API call would close the gap between the pre-configured and end-to-end boot times. We also investigate to move some of the VM initialization into the VM configuration phase, e.g., allocating the VM memory and loading the kernel image during the configuration API call. This should improve considerably the pre-configured boot times.

The choice of VMM is, of course, only one factor impacting boot times. For example, both Firecracker and Cloud Hypervisor are capable of booting uncompressed Linux kernels while QEMU only boots compressed kernel images. Cloud Hypervisor is also capable of booting compressed kernel. Decompressing the kernel during boot adds around 40ms. The kernel configuration also matters. In the same test setup, the kernel which ships with Ubuntu 18.04 takes an additional 900ms to start! Part of this goes to timeouts when probing for legacy devices not emulated by Firecracker, and part to loading unneeded drivers. In our kernel configuration, we exclude almost all drivers, except the *virtio* and serial drivers that Firecracker supports,build all functionality into the kernel (avoiding modules), and disable any kernel features that typical container and serverless deployments will not need. The compressed kernel built with this configuration is 4.0MB with no modules, compared to the Ubuntu 18.04 kernel at 6.7MB with 44MB of modules. We also recommend a kernel command line for Firecracker which, among other things, disables the standard logging to the serial console (saving up to 70ms of boot time). Note, we use similar optimizations for the other VMMs in iur tests.

For the tests above, all MicroVMs were configured without networking. Adding a statically configured network interface adds around 20ms to the boot times for Firecracker and Cloud Hypervisor and around 35ms for QEMU. Finally, QEMU requires a BIOS to boot. For our test we use *qboot* [8], a minimal BIOS, which reduces boot times by around 20ms compared to the default BIOS. Overall the boot times compare favourable to those reported in the literature, for example [38] reported boot times for an unmodified Linux kernel of 180ms.

5.2 Memory overhead

For Lambda, memory overhead is a key metric, because our goal is to sell all the memory we buy. Lower memory overhead also allows for a higher density of MicroVMs. We measure the memory overhead for the different VMMs as the difference between memory used by the VMM process and the configured MicroVM size. To measure the size of the VMM process we parse the output of the `pmap` command and add up all non-shared memory segments reported. This way our

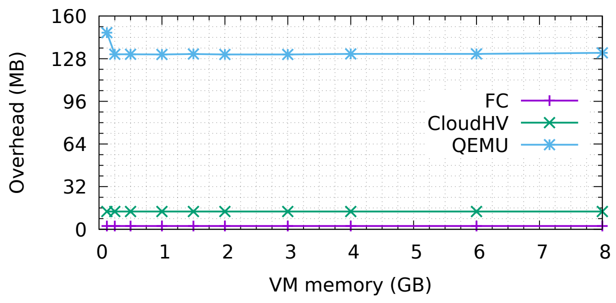

Figure 7: Memory overhead for different VMMs depending on the configured VM size.

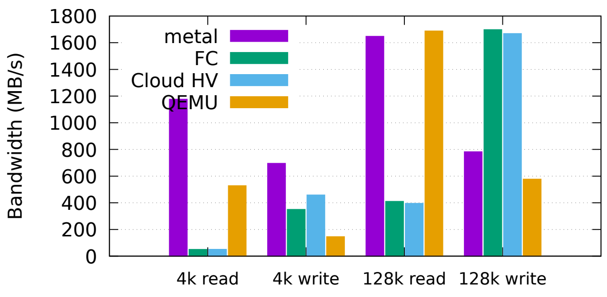

Figure 8: IO throughput on EC2 m5d.metal and running inside various VMs.

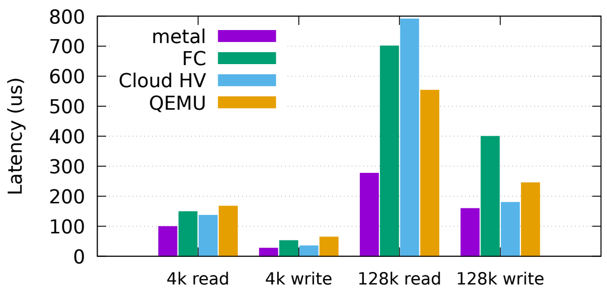

Figure 9: 99th percentile IO latency on EC2 m5d.metal and running inside various VMMs.

calculation excludes the size of the VMM binary itself.

Figure 7 shows that all three VMMs have a constant memory overhead irrespective of the configured VM size (with the exception of QEMU, where for a 128MB sized VM, the overhead is slightly higher). Firecracker has the smallest overhead (around 3MB) of all VMM sizes measured. Cloud Hypervisors overhead is around 13MB per VM. QEMU has the highest overhead of around 131MB per MicroVM. In particular for smaller MicroVMs, QEMU's overhead is significant.

We also measured the memory available inside the MicroVM using the `free` command. The difference in memory available between the different VMMs is consistent with the data presented above.

5.3 IO performance

In this section, we look at the IO performance of the different VMMs both for disks and networking. For all tests we use VMs configured with 2 vCPUs and 512MB of memory. For block IO performance tests we use `fio` [3], and rate limiting was disabled in Firecracker. `fio` is configured to perform random IO directly against the block device, using direct IO through libaio, and all tests were backed by the local NVMe SSDs on the *m5d.metal* server. Figure 8 shows the performance of random read and write IO of small (4kB) and large (128kB) blocks (queue depth 32). The results reflect two limitations in Firecracker's (and Cloud Hypervisor's) current block IO implementation: it does not implement flush-to-disk so high write performance comes at the cost of durability (particularly visible in 128kB write results), and it is currently limited to handling IOs serially (clearly visible in the read results). The hardware is capable of over 340,000 read IOPS (1GB/s at 4kB), but the Firecracker (and Cloud Hypervisor) guest is limited to around 13,000 IOPS (52MB/s at 4kB). We expect to fix both of these limitations in time. QEMU clearly has a more optimized IO path and performs flushing on write. For 128k reads and writes it almost matches the performance of the physical disk, but for 4k operations the higher transaction rate highlights its overheads.

Figure 9 shows 99th percentile latency for block IO with a queue depth of 1. Here Firecracker fares fairly well for small blocks: 4kB reads are only 49µs slower than native reads. Large blocks have significantly more overhead, with Firecracker more than doubling the IO latency. Writes show divergence in the implementation between Firecracker and Cloud Hypervisor with the latter having significantly lower write latency. The write latency of Firecracker and Cloud Hypervisor have also be considered with care since neither supports flush on write.

Tests with multiple MicroVMs showed no significant contention: running multiple tests each with a dedicated disk, both Firecracker and QEMU saw no degradation relative to a single MicroVM.

Network performance tests were run with *iperf3*, measuring bandwidth to and from the local host over a *tap* interface with 1500 byte MTU. We measured both the performance of a single stream as well as 10 concurrent streams. The results are summarised in Table 1. The host (via the tap interface) can achieve around 44Gb/s for a single stream and 46Gb/s for 10 concurrent streams. Firecracker only achives around 15Gb/s for all scenarios while Cloud Hypervisor achieves slight higher performance, likely due to a slight more optimised virtio implementation. The QEMU throughput is roughly the same as for Could Hypervisor. While Firecracker has a little lower throughput than the other VMMs we have not seen this to be a limitation in our production environment.

As with block IO, performance scaled well, with up to 16 concurrent MicroVMs able to achieve the same bandwidth.

VMM	1 RX	1 TX	10 RX	10 TX
loopback	44.14	44.14	46.92	46.92
FC	15.61	14.15	15.13	14.87
Cloud HV	23.12	20.96	22.53	N/A
Qemu	23.76	20.43	19.30	30.43

Table 1: `iperf3` throughput in Gb/s for receiving (RX) in the VM and transmitting (TX) from the VM for a single and ten concurrent TCP streams.

We expect that there are significant improvements still possible to increase latency and throughput for both disk IO and networking. Some improvements, such as exposing parallel disk IOs to the underlying storage devices, are likely to offer significantly improved performance. Nevertheless, the virtio-based approach we have taken with Firecracker will not yield the near-bare-metal performance offered by PCI pass-through (used in our standard EC2 instances); hardware is not yet up to the task of supporting thousands of ephemeral VMs.

5.4 Does Firecracker Achieve Its Goals?

Using the six criteria from Section 2, we found that while there is scope for improving Firecracker (as there is scope for improving all software), it does meet our goals. We have been running Lambda workloads in production on Firecracker since 2018.

Isolation: The use of virtualization, along with side-channel hardening, implementation in Rust, extensive testing and validation makes us confident to run multiple workloads from multiple tenants on the same hardware with Firecracker.

Overhead and Density: Firecracker is able to run thousands of MicroVMs on the same hardware, with overhead as low a 3% on memory and negligible overhead on CPU.

Performance Block IO and network performance have some scope for improvement, but are adequate for the needs of Lambda and Fargate.

Compatibility: Firecracker MicroVMs run an unmodified (although minimal) Linux kernel and userland. We have not found software that does not run in a MicroVM, other than software with specific hardware requirements.

Fast Switching: Firecracker MicroVMs boot with a production kernel configuration and userland in as little as 150ms, and multiple MicroVMs can be started at the same time without contention.

Soft Allocation: We have tested memory and CPU oversubscription ratios of over 20x, and run in production with ratios as high as 10x, with no issues.

In response to this success, we have deployed Firecracker in production in AWS Lambda, where it is being used successfully to process trillions of events per month for millions of different workloads.

6 Conclusion

In building Firecracker, we set out to create a VMM optimized for serverless and container workloads. We have successfully deployed Firecracker to production in Lambda and Fargate, where it has met our goals on performance, density and security. In addition to the short-term success, Firecracker will be the basis for future investments and improvements in the virtualization space, including exploring new areas for virtualization technology. We are excited to see Firecracker being picked up by the container community, and believe that there is a great opportunity to move from Linux containers to virtualization as the standard for container isolation across the industry.

The future is bright for MicroVMs, both in and out of the cloud. Challenges remain in further optimizing performance and density, building schedulers than can take advantage of the unique capabilities of MicroVM-based isolation, and in exploring alternative operating systems and programming models for serverless computing. We expect that there is much fruitful research to do at the VMM and hypervisor levels. Directions we are interested in include: increasing density (especially memory deduplication) without sacrificing isolation against architectural and microarchitectural side-channel attacks; compute hardware optimized for high-density multi-tenancy; high-density host bypass for networking, storage and accelerator hardware; reducing the size of the virtualization trusted compute base; and dramatically reducing startup and workload switching costs. The hardware, user expectations, and threat landscape around running multitenant container and function workloads are changing fast. Perhaps faster than at any other point in the last decade. We are excited to continue to work with the research and open source communities to meet these challenges.

7 Acknowledgements

The Firecracker team at AWS, and the open source community, made Firecracker and this paper possible. Production experience and feedback from the AWS Lambda and Fargate teams was invaluable. Thanks to Tim Harris, Andy Warfield, Radu Weiss and David R. Richardson for their valuable feedback on the paper.

Rex: Preventing Bugs and Misconfiguration in Large Services Using Correlated Change Analysis

Sonu Mehta[1], Ranjita Bhagwan[1], Rahul Kumar[1], Chetan Bansal[1], Chandra Maddila[1], B. Ashok[1], Sumit Asthana[1], Christian Bird[2], and Aditya Kumar[1]

[1]Microsoft Research India
[2]Microsoft Research Redmond

Abstract

Large services experience extremely frequent changes to code and configuration. In many cases, these changes are correlated across files. For example, an engineer introduces a new feature following which they also change a configuration file to enable the feature only on a small number of experimental machines. This example captures only one of numerous types of correlations that emerge organically in large services. Unfortunately, in almost all such cases, no documentation or specification guides engineers on how to make correlated changes and they often miss making them. Such misses can be vastly disruptive to the service.

We have designed and deployed Rex, a tool that, using a combination of machine learning and program analysis, learns *change-rules* that capture such correlations. When an engineer changes only a subset of files in a change-rule, Rex suggests additional changes to the engineer based on the change-rule. Rex has been deployed for 14 months on 360 repositories within Microsoft that hold code and configuration for services such as Office 365 and Azure. Rex has so far positively affected 4926 changes without which, at the very least, code-quality would have degraded and, in some cases, the service would have been severely disrupted.

1 Introduction

Large-scale services run on a foundation of very large codebases and configuration repositories. To run uninterrupted, a service not only depends on correct code, but also on correct network and security configuration, and suitable deployment specification. This causes various dependencies both within and across components/sources of the service which emerge organically. When an engineer changes a certain region of code or configuration, these dependencies require them to make changes to other code or configuration regions. For instance, when an engineer adds a new feature to a service, they may need to add a function to test the feature. Also, they may need to configure the service to deploy the new feature only to a small set of machines to test it further. Similarly, when an engineer renames a service API, they must also change firewall rule specifications so that the rules apply to the now renamed API rather than to the old one.

Such correlations can occur between code files across components, between code and configuration files, or between configuration files. Unfortunately, unlike pure code, which goes through compilation, reviewing and systematic testing to weed out bugs, these correlations are often not specified, checked for, and are left undocumented. Consequently engineers, with no documentation or specification to go by, often miss making necessary changes to code or configuration files. This can delay deployment, increase security risks and, in some cases, even disrupt the service completely. Disruptions due to such correlations are surprisingly frequent [12]. For instance, an engineer recently caused a disruption at Salesforce because they did not perform all necessary dependent configuration changes related to a change they initiated [22].

To address this problem, we present Rex, a tool that learns these correlations using a combination of machine learning and program analysis. Using *association rule mining* on many months of file changes, Rex determines sets of files that often change together. Rex also uses *differential syntax analysis* to learn *change-rules*: each change-rule captures a set of correlated changes across files. When an engineer makes a file change, Rex analyzes the change and uses the change-rules to suggest additional changes if required.

While the idea of using association rule mining to determine correlations in code and configuration has been proposed before [6, 35, 37], previous work has not concentrated on generalizing the algorithm. To the best of our knowledge, Rex is the first tool that combines association rule mining with syntactic analysis to determine change-rules. Moreover, Rex takes the crucial step of making correlated change analysis generalize well to multiple file-types and services, and deploying it at a large-scale. We do this through three key observations made by studying the characteristics of services:

1. Correlations occur in a multitude of unpredictable ways. Consequently, Rex's algorithm should not rely on any hard-coded domain knowledge, neither should it depend on any manual configuration or tuning.

2. Configuration management practice varies widely across services and projects. Every service has distinct configuration management and maintenance strategies as a result of which machine learning models have to be service or project-specific, with no extrapolation from one to the other. To make matters even more challenging, even a single service or project can change characteristics significantly over time. Hence, Rex's models have to be periodically retrained so that its suggestions can be accurate.

3. Care has to be taken while applying association rule mining on large code and configuration files. Services depend upon a large amount of code and configuration. Applying rule mining which is exponential in the size of the input at the level of individual code and configuration constructs is simply not feasible. We realized this early in the design process and therefore apply rule-mining at the *file-level*.

Rex is deployed on 360 Microsoft repositories which hold code and configuration for services such as Exchange Online, OneDrive, Azure, Dynamics CRM and Skype. We are currently scaling out Rex at a fast pace, on-boarding almost one repository per day. Till date, Rex has suggested 4926 changes to engineers that, if not made, may have adversely affected our services in many ways.

In this paper, we make the following contributions:

- We demonstrate different types of correlations that exist across code and configuration of large services.
- We describe a novel two-step algorithm to perform correlated change analysis involving file-level association rule mining followed by differential syntactic analysis of the changes made to the files.
- We have implemented and deployed Rex and provide an evaluation based on our deployments.
- We have performed an extensive user study to understand how useful Rex is in practice.

Section 2 describes different types of correlations Rex has found across many services. Section 3 provides an overview of Rex's approach, limitations, and challenges. Section 4 explains the algorithms Rex uses to suggest changes. Section 5 and Section 6 provide specifics on its implementation and deployment. Finally, Sections 7 and 8 describe a thorough evaluation and user study respectively.

2 Reasons for Correlated Change

Correlations occur due to various reasons. In this section, we describe several categories of correlations we found through our deployments. Table 1 shows a sample of correlated changes that engineers missed making and Rex flagged at commit-time. We note that though these examples are specific to our deployments, the problem of correlated configuration is generic and extends to other organizations as well [14, 22, 27]. We now describe these categories of correlations with the help of the examples in Table 1.

2.1 Flighting

When an engineer adds a new feature, they use canary-testing or "flighting" to deploy it in stages. They first deploy it to a small subset of machines to ensure that the feature works as planned and does not cause disruptions. Once they ensure this, they deploy the feature more widely. Hence, when the engineer adds code to implement a new feature, they also need to add configuration to files that define the set of machines that will test this feature. Services implement flighting in many different ways. Example 3 shows an instance where the engineer who develops the new feature decides which set of machines to run the feature on. Example 7, for a different service, shows an instance of a change where the engineer who develops the new feature does not directly turn on the feature: they provide a "code switch" which other engineers can use to turn on flighting. These two examples again illustrate why Rex needs to learn such varied change-rules from data and why rule-based engines would not work across services.

2.2 Replicating Code and Configuration

While clearly not recommended, we find that engineers sometimes replicate files and file contents across different logical boundaries of the service. They do this since, without replication, there will be a larger number of dependencies across files and components. This in turn will lead to less modular code-bases which may take longer to test, debug, and deploy. Example 2 shows an instance where a configuration file is replicated across different alerting frameworks. An engineer changed one, without knowing that a replica existed within the other alerting framework. Rex flagged this file and the engineer immediately changed the other file as well.

2.3 Complex Configuration

Configuring services is a complex task and, as a result, several correlations show up between configuration files. Example 4 shows an instance where an engineer renamed a microservice, but forgot to change the name of the service in the file that contained its firewall rules. This could have caused a security issue. Example 8 shows another instance where hardware configuration files are correlated, and missing this change could have caused a service disruption.

No.	File 1	File 2	Reason	If File 2 unchanged
1	Source code (JS)	Test file (JS)	An engineer added new functionality to source-code and needed to add a unit-test to test this functionality to another file.	Without the test, a **bug in File 1 may go unnoticed**.
2	Component definitions (C#)	Component definitions (C#)	An engineer changed a parameter in the definition of a set of components in File 1. An alerting framework uses File 1 to determine which components to probe and alert on. File 2, very similar to File 1, is used by a different alerting framework for the same reason. Hence, the engineer had to make the same changes to File 2 as well.	The second alerting framework would malfunction, leading to **incorrectly suppressed alerts**.
3	Feature set definitions (INI)	Flight definition (INI)	An engineer added a new feature to a service. She enabled the feature in deployment by updating a settings file. Additionally, she had to specify how to "flight" the change, i.e., which subset of machines to run the new feature on. File 2 contains these flight configurations for every feature.	The **feature will not deploy** until the engineer changes File 2.
4	Microservice Registry (XML)	Firewall rule definitions (XML)	An engineer changed a microservice's name in the microservice registry. File 2 holds a mapping from a set of microservices to the firewall rules that apply to them, so the engineer needed to change the microservice's name in File 2 as well.	The required firewall rules would not have applied to the renamed microservice, causing a **security threat**.
5	Shell script (PS1)	File storing security vulnerabilities (XML)	File 2 keeps a record of potential security vulnerabilities such as cleartext passwords and code susceptible to injection attacks. It stores a record with both the offending file name, and the line number where the vulnerability exists. A security scanner uses File 2 to *ignore* the vulnerabilities it specifies, to avoid flagging the same vulnerabilities repeatedly. Hence, when an engineer adds or removes lines from File 1, they need to appropriately change the line number of the vulnerable code in File 2 as well.	The security scanner would ignore a completely different, potentially vulnerable, line of code. This could cause a **security threat**.
6	Shell script (PS1)	Shell script (PS1)	File 1 defines a function, File 2 calls it. The engineer made a change to the function name and parameters in File 1, so they had to change how File 2 calls the function. If this code were compiled rather than interpreted, the compiler would have caught the error.	The scripts determine how the service is deployed, and hence this error would have caused **deployment to fail**.
7	Style sheet file (SCSS)	Flight definitions file (C#)	An engineer made a web-design change in File 1, and wanted to flight it on a small set of machines. File 2 contains definitions of "code switches" that engineers can use to turn on the new design change.	Without an appropriate code switch, engineers cannot turn on the design change, and hence, this would have caused unnecessary **deployment delays** of the new look.
8	Config file maintaining SKU information of machines in a Data center (XML)	File maintaining rack definitions for the data center (XML)	Operators update File 1 when a new set of machines with a new SKU is introduced to the data center. If the new machines are deployed, also need to update File 2 which specifies which machines sit in each rack.	Several other functions use these configuration files. Incorrect data center configuration can cause faulty functioning of the service and hence **disruption**.

Table 1: This table describes some real examples of correlated changes that engineers missed and Rex flagged in our deployments. The *Reason* column captures why the two files are correlated. The last column describes what may have happened, had Rex not flagged the issue and notified the engineer.

2.4 Testing

Example 1 shows that, when an engineer adds a new feature to code, they should consider adding a new test for that feature in a separate file that contains only tests. While this is fairly common across multiple code-bases and services, each code-base has its own organization structure for separating test code from the main production code. Rex automatically detects such structures without any manual input.

2.5 Scripting

Often, administrators use scripts to test and deploy services. These scripts can have complex inter-dependencies which, unlike compiled code, can go unchecked at commit-time. For instance, in Example 6, an engineer changed function definition in one script and hence they had to change the way the function was called in another script. Rex caught this issue, while existing IDEs and compilers could not.

2.6 Miscellaneous

Apart from the categories we have mentioned so far, Rex also flags somewhat rare cases of correlation which can have high impact. In Example 5, File 2 maintains a list of line-numbers of vulnerable code across different files in the code-base. The idea is to maintain a record of all vulnerabilities that have already been found and vetted by engineers. Thus, when an engineer adds *n* lines of code to File 1, they also changed the line number of the vulnerable code in File 1. Hence they need to increment the line number in File 2 by *n*. While such categories of correlations are rare, we notice multiple such rare cases. This further confirms the value of using a learning-based approach.

Note that, for simplicity, the table shows examples that involved only two files. In reality, change-rules can contain more than two files. Moreover, the correlations for similar tasks are very different for different services. Example 3 and Example 7 in Section 2.1 talks about two different ways of flighting a feature. Even within a service, the correlations are dynamic and keep changing with time. We believe no existing syntactic or semantic analysis techniques or heuristic based model could have effectively and efficiently captured such diverse and complex correlations.

3 Problem Overview

In this section, we define the problem that Rex solves, the approach to it, and describe some limitations of the approach. Finally, we lay out the challenges we faced as we designed and deployed Rex.

3.1 Approach

Rex applies association rule mining on months of commit logs to find correlated changes. Association rule mining is fundamentally an exponential algorithm. Finding correlations between individual configuration parameters and code constructs such as variables and functions will be prohibitively expensive simply because of the sheer large numbers of such constructs [28, 33, 35]. Hence to scale well, we decided to mine change-rules *at the file-level*. While the approach is coarse-grained and does not capture correlations perfectly, it makes the solution practical to deploy at a large scale.

Rex learns change-rules in two steps: *change-rule discovery* and *change-rule refinement*. In the discovery step, it uses association rule mining to find sets of files that change together "frequently". A set of parameters determine how frequently the files need to change for Rex to learn the change-rule. Section 4.2 provides more detail on this algorithm and Section 4.5 shows how we tune its parameters to maintain effectiveness through changing characteristics of the service.

After change-rule discovery, Rex runs the second step, namely, change-rule refinement. The idea is to make each change-rule, which is coarse-grained and at the file-level, more precise. Rex analyzes the change in every file of the change-rule to determine what *types* of changes are correlated. Section 4.3 describes this procedure further. Finally, Rex makes suggestions to engineers based on the learnt rules.

3.2 Design Goals

Rex's design is driven by two factors. First, it needs to be *generic*: its techniques need to work well across file-types, service-types, and programming languages. Second, it needs to be *effective*: it should find subtle misconfigurations and bugs which existing tools cannot catch. To achieve these goals, our solution has the following characteristics:

No Manual Inputs: The main goal of Rex is to help engineers find misconfigurations and bugs early, while minimally intruding upon on their already busy schedule. We therefore design it to work with existing systems and logs, and do not require any additional logging or inputs from the engineers. We believe this is one of the main reasons that Rex is being adopted widely across our organization over multiple services.

Correlation, not causation: Rex flags correlations, and does not detect causality because the cause of a specific set of correlated changes may not be captured by any logs. For instance, consider Example 2 in Table 1: changing one file of component definitions does not *cause* the change in the other. An engineer was extending the alerting infrastructure to a larger number of components, and this caused the need to change both files.

3.3 Scope

As with any machine learning-based approach, Rex is a best-effort service. Sometimes it may miss suggesting required changes (false-negatives) and conversely, it also suggests changes when none are needed (false-positives). As we describe in Section 4, we tune Rex so that it catches as many misconfigurations as possible even though this may come at the cost of a higher number of false-positives. Take for instance Example 5. We need to change File 2 only if the line-number of a vulnerable code-snippet in File 1 changes. It is fundamentally difficult for a generic technique to learn the specific semantics of this particular correlation. Rather, Rex suggests that the engineer change File 2 whenever they change File 1, even if the line-numbers in File 1 do not change. Such a suggestion will be a false-positive.

3.4 Challenges

Determining the right set of correlations has several challenges associated with it.

Imperfect Ground-truth: The largest challenge we faced as we designed Rex was imperfect ground-truth. The reasons for this are many. First, correlations are often subtle and do not necessarily cause compile errors, deployment failures, or immediate service downtime. Consider the issue in Table 1, Example 1, where the engineer needs to add a test for a newly added feature. This is not strictly necessary but definitely recommended. However engineers are often hard-pressed to commit and deploy fast and therefore may not add the test. Hence the commit logs that Rex uses may not always see the two files with the added feature and test changed together. As a consequence, Rex may not learn the change-rule that includes these two files.

Performance: Rex currently runs on 360 repositories, and its adoption is increasing rapidly. Hence we need to ensure there

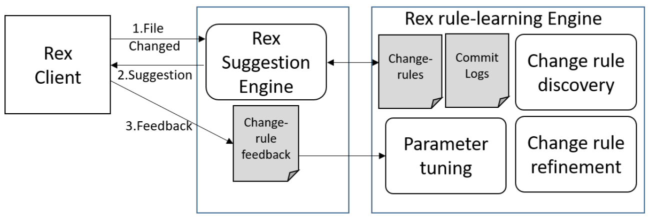

Figure 1: Rex system design.

are no manual steps involved. Additionally, we need to ensure that the rule mining algorithm does not become prohibitively expensive.

4 System Design

In this section, we provide an overview of the different components of Rex. We then describe each component in detail.

4.1 Design Overview

Figure 1 shows an overview of the Rex design. The Rex rule-learning engine periodically learns change-rules that capture which files change together and how. It uses several months of commit logs to do this. For each commit, the commit log contains information about which files changed, and how they changed. Rex's rule-learning engine runs two processes to learn rules: change-rule discovery (Section 4.2) and change-rule refinement (Section 4.3).

The Rex suggestion engine interfaces between the client that uses Rex and the rule-learning engine. When an engineer changes a file, the Rex client notifies the suggestion engine of the change. The suggestion engine looks up applicable change-rules to determine if the engineer may have missed changing a correlated file. If so, the suggestion engine suggests the additional file change back to the client. Our current implementation of the Rex client is built for various source control systems such as Git [29]. It adds suggestions as pull-request comments, whenever required, after every commit in a pull-request. More details on this are in Section 5.

When the Rex client provides the suggestion back to the engineer, they either accept the suggestion by editing the suggested file or not. Rex uses this behavior as feedback to the rule-learning engine. Using this implicit feedback, Rex automatically tunes parameters used to learn the change-rules. Section 4.5 provides more details on the tuning module and why this is essential to scale Rex across hundreds of repositories. Very few engineers provide explicit feedback by replying or resolving the comment and we do not use this because such feedback is very limited and is inherently biased towards negative examples.

```
/…/ServiceLibrary/package.xml =>
/…/ServiceLibrary/src/NuGetPackage/NuGetPackage.nuproj
```

a) Example rule that requires a version number increment in the suggested file.

```
/…/configuration/dailyRun.xml =>
/…/configuration/dogfoodRun.xml
```

b) Example rule that learns nearly identical configuration files.

```
/…/Framework/src/Actions/RunDailyWorkflows.cs, /…/Config/Engine.Settings.ini
=> /…/Config/DWEngine.flight.ini
```

c) Example rule that learns that engineer added code AND added configuration used by the code, so they need to specify how to flight this code.

Figure 2: Some example rules from the change-rule discovery step. Note that rules are not limited to only file pairs. Example c) shows an example where two files are learned on the LHS.

4.2 Change-rule Discovery

In this section, we describe the first-step towards learning rules, which is change-rule discovery. We use six months of commit data for rule-mining. First, Rex prunes the commit logs to exclude commits that are aggregates of smaller commits caused by merging branches (squashed changes), or porting a set of commits across branches. Since these commits put together a set of smaller commits that may not have any relation with each other, they do not capture true correlations between files. Moreover, such large commits make mining rules prohibitively expensive. Figure 2 shows some examples of rules that Rex has learned.

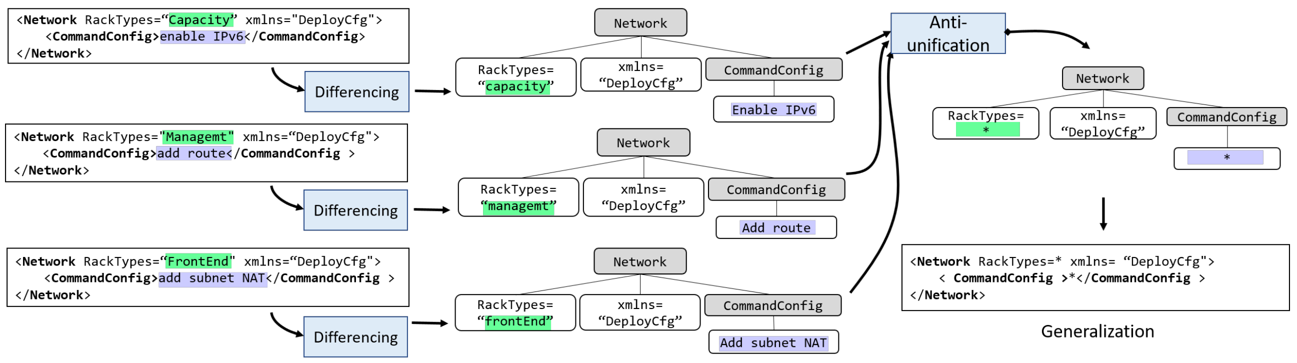
Rex runs the rule mining algorithm considering each commit as a transaction. First, it discovers *frequent item-sets* using the FP-Growth algorithm [13]. A frequent item-set is a set of files that change together very often. Mathematically, we define a frequent item-set as $\mathbf{F} = \{f_1, \ldots, f_n\}$ where files f_1 through f_n have changed together at least s_{min} times. s_{min} is the *minimum support* defined for the model. The *support* of the frequent item-set, $s_\mathbf{F}$, is defined as the number of times files f_1 through f_n change together. Hence, $s_\mathbf{F} \geq s_{min}$.

Next, the algorithm generates change-rules from frequent item-sets. From the frequent item-set $\mathbf{F}$, Rex learns the rule $\mathbf{X} \implies \mathbf{Y}$ such that $\mathbf{X} \subset \mathbf{F}, \mathbf{Y} \subset \mathbf{F}, \mathbf{X} \cap \mathbf{Y} = \phi, \mathbf{X} \cup \mathbf{Y} = \mathbf{F}$.

The *confidence* of the rule is the number of times all the files in $\mathbf{F}$ change together (support of file-set $\mathbf{F}$) divided by the number of times all the files in $\mathbf{X}$ change together (support of file-set $\mathbf{X}$). The rule's confidence is therefore $s_{\mathbf{X}\cup\mathbf{Y}}/s_\mathbf{X}$. Hence, the more often files in sets $\mathbf{X}$ and $\mathbf{Y}$ change together, the higher the confidence of the rule. Rex learns a rule only if it has confidence above a minimum confidence c_{min}.

4.3 Change-rule Refinement

In this Section, we describe the change-rule refinement process. Currently our implementation supports configuration files, but it can be extended to support code files as well. In our description, we concentrate on `xml` files though the same



```
<Network RackTypes="Capacity" xmlns="DeployCfg">
    <CommandConfig>enable IPv6</CommandConfig>
</Network>
```

```
<Network RackTypes="Managemt" xmlns="DeployCfg">
    <CommandConfig>add route</CommandConfig >
</Network>
```

```
<Network RackTypes="FrontEnd" xmlns="DeployCfg">
    <CommandConfig>add subnet NAT</CommandConfig >
</Network>
```

```
<Network RackTypes=* xmlns= "DeployCfg">
    < CommandConfig >*</CommandConfig >
</Network>
```

Figure 3: Steps of change-rule refinement for a rule `network_dc1.xml` $\implies$ `network_dc2.xml`. Three separate commits are made to a single configuration file. Each one adds an XML attribute `Network`, but with different values. From each of these three, Rex learns difference trees that codify the additions. All these difference trees are input to the anti-unification algorithm which outputs a generalization for this type of addition.

techniques apply to other file-types such as `json`.

Consider the following examples which have arisen in our deployments:

Ex 1. Network configuration: An engineer adds new commands to a file `NetConfig_dc1.xml` that configure racks in data center 1. These changes need to be applied to all data centers, and hence, the engineer has to change similar configuration files for other data centers as well, say `NetConfig_dc2.xml`. Rex should therefore suggest these changes if the engineer does not make them. However, in many cases, the engineer makes changes to `NetConfig_dc1.xml` that apply only to data center 1 and not to data center 2. For instance, they may add a new subnet only to data center 1. In this case, Rex should not suggest changing `NetConfig_dc2.xml`. Change-rule discovery alone cannot differentiate these two scenarios.

Ex 2. Role-based access control: Several of our services implement role-based access control. Engineers often define a new role in a file `RoleDefn.xml`. When they do so, they should also change `RoleMembership.xml`, which specifies the users or groups that are associated with the new role. However, if the engineer is only modifying an already existing role definition in `RoleDefn.xml`, they need not change `RoleMembership.xml`.

These examples show that, in some cases, for a rule $\mathbf{X} \implies \mathbf{Y}$, $\mathbf{Y}$ changes only if $\mathbf{X}$ changes in a specific way. While for code, compilers often catch such correlations and dependencies, configuration files lack an equivalent safety net.

Change-rule refinement has two parts. First, given a configuration file x_C, it learns all *generalizations* of additions, deletions and modifications made to x_C, where a generalization is in the form of a regular expression. Next, for any change-rule $\mathbf{X} \implies \mathbf{Y}$ already learned by change-rule discovery where $x_C \in \mathbf{X}$, it refines the rule further. We now describe these two steps in detail.

4.3.1 Learning generalizations

Figure 3 shows an example of this. Rex creates a set of all commits $\mathbf{C}$ that modify x_C. For every commit in $\mathbf{C}$, Rex computes a syntactic difference between the old and new version of x_C. To do this, Rex constructs *parse trees* for both versions, and then uses a novel differencing algorithm to compute the difference between the two parse trees, which we call a *difference tree*. For example, in Figure 3, three changes were added to x_C in three different commits. Each change added an XML node named `network`, but with varying attribute values. In each case, Rex's differencing algorithm outputs a difference tree capturing the difference. The shaded vertices are XML nodes, while the unshaded vertices are XML attributes.

Next, from the difference trees, Rex learns generalizations of the changes that happen to the configuration file. To extract these generalizations, Rex uses the process of *anti-unification* [15, 23]. The anti-unification algorithm learns regular expressions that are the *most specific generalizations* of the difference trees. In each of the three changes shown in Figure 3, the `xml` attribute `RackTypes` has different values. The `xml` attribute `CommandConfig` too has different text values. Taking the three difference trees as input, the anti-unification algorithm outputs the generalized difference tree, and thereby the most specific generalization of the three changes.

While Figure 3 describes one example generalization, a file x_C may have many more such generalizations. Rex learns all such generalizations of additions, deletions and modifications to the configuration file x_C. Say this set is $G(x_C) = \{g_1, g_2, \ldots, g_n\}$.

4.3.2 Refining Rules

Next, given a rule learned during change-rule discovery $\mathbf{X} \implies \mathbf{Y}$, where $x_C \in \mathbf{X}$, Rex learns more fine-grained rules of the form $\{\mathbf{X}, (x_C, g_i)\} \implies \mathbf{Y}, g_i \in G(x_C)$. This rule says that when all files in $\mathbf{X}$ change, Rex will suggest changing $\mathbf{Y}$

only if the change to file x_C matches generalization g_i.

This is done in the following way. Say the number of times a change in file x_C matches g_i *and* all files in $\mathbf{Y}$ change is n. Conversely, say the number of times a change in file x_C matches g_i and files in $\mathbf{Y}$ *do not* change is $\tilde{n}$. If $n/(n+\tilde{n}) > t$, where t is a threshold we call the refinement threshold, Rex refines the rule by adding the tuple (x_C, g_i) to the left-hand side of the rule. This means that Rex now makes the suggestion only if the change to x_C matches the regular expression g_i. Thus, change-rule refinement cuts down on false-positive suggestions. In all our deployments, we set t to 0.75.

Though our implementation of the differencing algorithm is specific to configuration files, we can also extend this to code files. The code differencing algorithm could learn syntactic features such as “function added", “if-condition changed", etc. We could refine rules for code using these features. Based on a careful empirical study we conducted while going through true-positives and false-positives that change-rule discovery generated, we observed that a lot of issues with code files are already addressed by compilers. So, we do not see many false-positives for code files when the engineer has commited changes, because in most cases, engineers commit changes after compiling the code. This will become more clear in the next section 4.4 where we describe how these rules are used. Rex uses these rules to make recommendations for missing files after an engineer has committed a change. Such a tool for code files would be helpful for developers if the suggestions are made at IDE (Integrated Development Environment) level. We leave this for future-work.

4.4 Suggestion Engine

In this Section, we describe how the Rex suggestion engine uses the rules learned by change-rule discovery and change-rule refinement.

When an engineer commits a code or configuration change, the Rex client calls the suggestion engine which determines the set of rules that match the commit. If there is a match, the suggestion engine checks if any of the files in $\mathbf{Y}$ are unchanged by the commit. If it does find such a file, the suggestion engine recommends that the files be changed. If the engineer does indeed change the suggested files, the suggestion is considered a *true-positive*. Else, the suggestion is a *false-positive*. These numbers are used both for parameter tuning (Section 4.5) and evaluation for Rex (Section 7).

4.5 Parameter Tuning

As we deployed Rex on more projects and services, we noticed that the frequency and the nature of changes varied widely, not just across projects and services, but also within the same project at different times. Hence, once a day, Rex uses the feedback from the suggestion engine to tune models.

Figure 4: Screenshot of a Rex pull-request comment. Sensitive text has been masked.

Association rule mining has two main tunable parameters, the minimum support s_{min} and the minimum confidence c_{min}. Rex tunes only s_{min} and sets c_{min} to a constant, relatively low value of 0.5. This is because while we want change-rule discovery to learn a relatively large set of rules, perhaps some with low confidence, we use change-rule refinement to make the rules more precise.

We train various models by varying the value of s_{min}. We do not set s_{min} to values less than 4, since that leads to too many rules and slows down rule-mining. We then evaluate each model on one month's data and pick the *best* one using the described approach. We apply the model after every commit[1]. We measure the number of false-positives and true-positives. In addition, we also compute *false-negatives* for a model. This is the number of true-positives that the model with s_{min} set to 4 found, but the current model did not. Hence, we compute every model's false-negatives relative to the model with the lowest value of s_{min}, which learns the largest number of rules.

From these numbers, we can compute precision, recall and F1-score for each model. Finally, we pick the model with the highest F1-score and deploy it.

5 Implementation

Rex is implemented using C# on top of the .NET framework and deployed using a combination of services provided by Microsoft Azure [19]. Rex is currently deployed on 360 repositories across multiple Microsoft services. There are three main components of Rex:

Data Ingestion and Loading: Using Azure DevOps [18] and Github [11] APIs, batch jobs execute at predefined intervals to ingest information about pull requests, commits, files, diffs, etc. for each repository where Rex is enabled. All data is stored using SQL databases. Currently, there is a one-to-one mapping between a repository and a database. The SQL database schema is normalized and allows for efficient querying of commit and file data. Newly onboarded repositories are back filled with 6 months of data.

[1]Our evaluations are GIT-specific, so we apply Rex after every commit to a pull-request. This approach extends to other version control systems as well.

Learning: For each repository, every day a new *model* is learned. Currently, Rex uses the FP-growth algorithm [13] to learn association rules from the six months of commit history in a repository. Rex also analyzes `xml` files more deeply using XmlDiffAndPatch [10] in order to perform change-rule refinement using the anti-unification algorithm [15, 23]. The learned model and metadata about the model is saved in the respective database for the repository; thus, resulting in a *repository-local* model.

Decorator: The *pull-request decorator* performs the functionality of the suggestion engine. It subscribes to events in each repository using APIs. For each pull-request that is created or updated, the decorator mines details on the fly, performs inferencing of the pull-request using the latest model stored in the repository database and creates systematic comments in the pull-request for all valid and new Rex suggestions.

6 Deployment

Deploying Rex is easy: an administrator of a repository only needs to provide a URL of their repositories. Repo admins need not provide any inputs to Rex, they need not configure it, and hence the effort to on-board a repository is minimal. We started deploying Rex with one repository in October 2018. Since then, its adoption has steadily grown. Rex is now deployed on 360 repositories for services such as Exchange Online, OneDrive, Azure, Dynamics CRM, and Skype.

No.	Metrics	Min	Max
1	Total No. of Files	26	99235
2	% of Config Files in Repository	16%	100%
3	Avg.No. of Pull-Requests Per-day	1	279
4	No. of Engineers	3	2885

Table 2: Characteristics of repositories on which Rex runs.

Deployments are on very different types of repositories. Table 2 summarizes the characteristics of the 360 repositories that Rex is deployed on. The characteristics vary widely: we host one of the largest git repositories in the world, while we also host small, relatively inactive repositories. Row 2 captures that our repositories have varying amount of code and configuration. Some repositories hold only configuration information, while others hold mostly code.

6.1 Lessons

In this section, we will outline some lessons and insights we have gathered from these varied deployments. We believe these insights hold in general for tools such as MUVI [16], DeepBugs [20], EnCore [35] and Getafix [24] which use machine learning to flag bugs and misconfigurations.

1. We should distinguish between model precision vs deployment precision. No ML-based tool is perfect, and hence the best way to evaluate it is by observing its precision, which is the ratio of the number of true-positives to the total number of suggestions made. In our implementation, a Rex suggestion is a *true-positive* if, after it is made on a pull-request, the engineer adds the suggested change *within the same pull-request*.

For bug and misconfiguration-detection tools, one needs to compute two types of precision: *model precision* and *deployment precision*. Model precision is the ratio of true-positives to total suggestions that the model makes on test data as opposed to a real deployment. Rex uses the last six months of commit logs as test data. The deployment precision is the ratio of the true positives *actually observed in deployment* to the total number of suggestions shown to engineers.

Invariably, deployment precision is significantly lower than the model precision. This is because Rex provides suggestions only when the engineer makes a Git pull-request. This is after the engineer has had an opportunity to weed out bugs and misconfiguration through subsequent commits made after some unit-testing and reviewing. For instance, say Rex predicts correlations in 100 cases, of which 90 are correct (true-positives) and 10 are incorrect (false-positives). The model precision is thus quite high, i.e. 90%. In actual deployment though, say engineers remember to make the right changes in 88 of the 90 cases Rex discovered. Hence rex shows suggestions only in the 2 remaining cases. On the other hand, Rex does make the same 10 false-positive suggestions. Thus the deployment precision for Rex is $2/(10+2) = 16.7\%$. The deployment precision may seem low, but it is important to note that the suggestions made by Rex are for less obvious correlations which the engineer is unaware of.

2. Flagging high-impact misses offsets the effect of low deployment precision. In the example shown above, the 2 useful suggestions made by Rex in deployment could actually avert severe service disruption. By interviewing several engineers we found that Rex is indeed flagging such issues, and as a result, the engineers consider the low deployment precision acceptable. Therefore when we deploy Rex afresh for a project, we ensure that engineers understand this trade-off and yet appreciate the utility. Also, for this reason, we tune Rex not just for high precision but also for high recall relative to the baseline model, as described in Section 4.5.

Engineers want suggestion interpretability: Engineers like to know why Rex makes a particular suggestion. Therefore, along with every suggestion, we also provide an explanation which shows the past commits from which Rex learned the rule. If an engineer would like to understand the reason for a Rex suggestion, they can view this explanation.

7 Evaluation

Rex has been in deployment for about a year now and has so far found 4926 true-positive suggestions across 360 repositories, many of which have helped avoid severe service outages. In this section, we evaluate Rex. The questions we ask are:

1. *How does change-rule discovery perform?*
2. *What value does change-rule refinement add over change-rule discovery?*
3. *How useful is the parameter-tuning process?*
4. *What is the performance overhead of Rex?*

7.1 Rex Precision

In this section, we evaluate both model precision and deployment precision as we explained in Section 6.1. We first evaluate change-rule discovery.

Table 3 shows the model and deployment precision for change-rule discovery for 7 repositories across 4 services: OneDrive, Azure, Exchange Online and Dynamics CRM. The model was trained on 6 months of commit data and tested on 6 subsequent months of test data. We find that the model precision varies between 66.09% and 82.11%. The deployment precision varies between 6.84% and 16.74%. Notice that a higher model precision does not necessarily imply a higher deployment precision. Consider Azure1 and OneDrive1. Though they both have relatively high model precisions, OneDrive1 has a high deployment precision (16.74%) whereas Azure1's deployment precision is only 6.84%. We believe this variability is due to various reasons specific to the repository, such as the complexity of the repository, the nature of the configuration and the learned rules, etc. Our user study in Section 8 explains this to some extent. We now compare precision for change-rule discovery with and without change-rule refinement (CRR). We use the same train-test split used to evaluate change-rule discovery. We run this experiment only for configuration files written in `xml`, `config`, `csproj`, `proj`, `resx` and `wxs` formats since our differencing algorithm supports them. We do not consider code files. Hence, the deployment precision numbers vary slightly from the results in Table 3.

Table 4 shows the performance of Rex, with and without change-rule refinement, for 6 repositories. In each case, while model precision does improve, the deployment precision improves significantly. For Exchange3, which had a very low deployment precision of 5.03%, the deployment precision with change-rule refinement increased to 18.00%, an increase of about 250%.

7.2 Parameter Tuning

In this section, we justify the importance of tuning the minimum support s_{min} for change-rule discovery both across repositories and also within a single repository.

Tuning across repositories:

The repositories that Rex is deployed on are extremely varied and dynamic, with the number of pull-requests varying

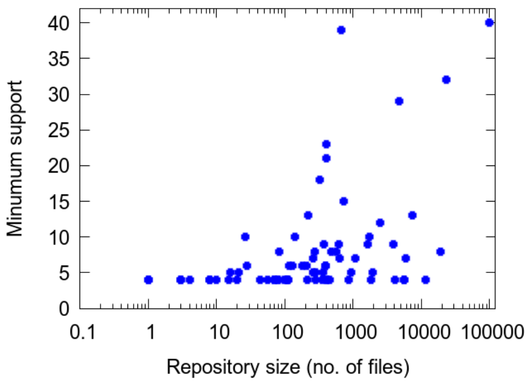

Figure 5: Tuned s_{min} vs repository size

between 1 to 279 per-day. Figure 5 plots, for every repository, the tuned value of minimum support s_{min} against the size of the repository at a given point of time. The size of the repository is the number of files in the repository. While there is a clear correlation of 0.56 between repository size and s_{min}, the repository size by itself does not clearly tell us what the value of s_{min} should be. For instance, for size 700, depending on the repository, s_{min} varies from 4 to 23. This implies that we need to tune s_{min} for each individual repository.

Tuning within a repository: Even within a repository, characteristics change over time. Figures 6a- 6d show the variation of s_{min} with time for four repositories. This variation can be due to multiple reasons. First, decreased commit rates require Rex to lower s_{min} so that a healthy suggestion rate is maintained, even though precision may drop. Second, engineers may add new files to the repository in which case the s_{min} may need to be lowered to learn rules specific to these files.

To understand this fluctuation better, Figures 6e- 6h plot precision, recall and F1-score for one run of the parameter-tuning algorithm for four repositories. Note that the recall here refers to the recall based on the number of true-positive suggestions made by the baseline model with $s_{min} = 4$. The graph shows values of precision, recall and F1-score normalized by the respective values for the baseline model ($s_{min} = 4$). As expected, for all four repositories, as support increases, the model learns fewer rules, and there is a drop in recall. Surprisingly though, as s_{min} increases, precision increases predictably only for Repository 4, and to some extent for Repository 2. Repositories 1 and 3 see some local increases in precision, but overall, it follows a downward-trend.

On analysis of these repositories, we found that majority of true-positives in this case were generated by the rules having low s_{min}. On increasing s_{min}, we do not retain these rules and thus the number of true-positives drop significantly. Even though there is drop in false-positives with the increase in s_{min}, the drop in true-positives is significant to bring the precision value down. This unpredictability in behavior motivates the need to perform regular tuning of Rex models.

Repository	Model Metrics				Deployment Metrics			
	Total	True Positives	False Positives	Precision	Total	True Positives	False Positives	Precision
Exchange1	1869	1342	527	71.80%	519	50	469	9.63%
Exchange2	5216	3659	1557	70.15%	1318	146	1172	11.08%
Exchange3	3634	2635	999	72.51%	932	66	866	7.08%

OneDrive2	367	277	90	75.48%	108	20	88	18.52%
DynamicsCRM1	1666	1101	565	66.09%	490	59	431	12.04%

Table 3: Model and Deployment Precision for Change-Rule Discovery

Repository	Model Metrics			Deployment Metrics		
	Precision (Without CRR)	Precision (With CRR)	Improvement	Precision (Without CRR)	Precision (With CRR)	Improvement
Exchange1	71.80%	85.76%	19.44%	10.86%	20.51%	88.93%
Exchange2	70.15%	83.94%	19.66%	10.23%	18.18%	77.69%
Exchange3	73.37%	75.00%	3.43%	5.04%	18.00%	250.42%
Azure1	82.11%	91.25%	11.14%	8.00%	15.38%	90.00%
OneDrive2	75.48%	78.36%	3.69%	37.50%	100%	166.67%
DynamicsCRM1	66.09%	89.64%	35.64%	40.00%	58.33%	45.83%

Table 4: Improvement in Model and Deployment precision with Change-rule refinement(CRR) over Change-rule discovery

7.3 Performance

The suggestion engine is relatively quick, taking approximately 2 seconds to evaluate a pull-request and make a suggestion. In this section, we explore the time it takes to perform the tuning operation across all repositories. This is the most expensive step in the Rex pipeline since it involves multiple runs of the association rule mining algorithm.

Figure 7 shows the tuning time against the size of the repository. Note that both axes are on a logarithmic scale. The largest repository with about 100000 files also takes 370 seconds to tune the model. The two red points in the graph are outliers. They take significantly longer to tune than the other repositories of similar size as the average number of files in each commit is more than other repositories and so each round of association rule mining takes longer.

8 User Study

To understand the relevance of Rex, we performed an extensive user study by sending emails to 328 engineers working across 5 of the repositories on which Rex is deployed. The user study was conducted in three phases:

Phase 1: When we manually examined Rex's suggestions in deployment, we noticed that often, users did not accept some suggestions even though they seemed useful. We therefore asked 30 engineers from 3 teams to subjectively comment on the utility of Rex's suggestions. From their responses, we categorized the suggestions into three categories:

1. Accepted: Some suggestions clearly point out file-changes that are absolutely required and if not acted upon, will lead to bugs/build failures/service disruption. Example 6 in Table 1 shows an example . If the engineer alters a function signature in a script, then they also have to change the way they call the function from another script. Else, service deployment will fail. Engineers usually act on such suggestions. These are what constitute Rex true-positives.

2. Relevant but not accepted: These are suggestions that engineers find useful but do not act upon. For instance, some rules capture the association of test files with core functional code (Example 1 in Table 1). When an engineer makes changes to code by adding a new feature, Rex often recommends editing the test file. While the suggestion makes the engineer consider it, they may not do so, either because the test will delay deployment, or because they decide to add it later. Another example is Example 5 where Rex will make the suggestion, but is unable to infer that the suggestion is valid only if the line-number of the offending code changes. It is up to the engineer to decide if they have indeed changed the line-number of the offending code, and if not, they will not act on the suggestion. However it is still useful since it brought the engineer's attention to the issue.

3. Irrelevant:These suggestions are not relevant to the engineers and thus are not acted upon. For instance, when an engineer is working on a new project, they modify the project configuration file very often, mostly adding new references. Rex therefore learns a lot of spurious change-rules that associate code files with the configuration file. With time, the engineer stops adding reference files, and hence, most suggestions

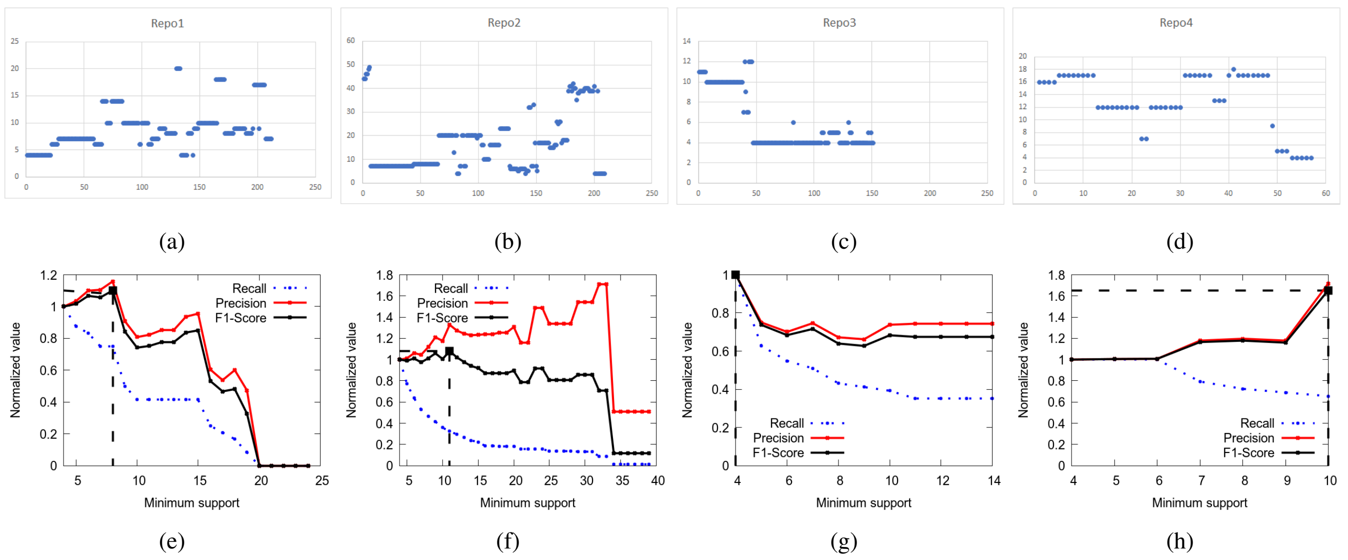

Figure 6: For four repositories, the top row shows how s_{min} varies with time. For each repository, the bottom row shows the precision, recall and F1-score as a function of s_{min}. The black square on the F1-score plot shows the maximum F1-score.

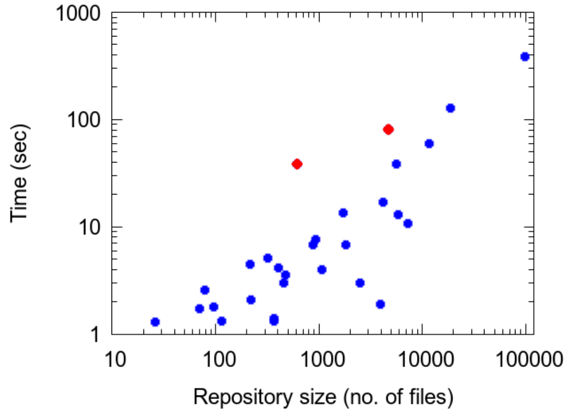

Figure 7: Tuning time vs repository size

based on this change-rule are irrelevant. Since Rex retunes its model regularly, it does eventually drop this change-rule.

Phase 2: Rex true-positives or suggestions that were accepted can be easily estimated by tracking files that got changed in the later iterations of the pull-request. False-positives, on the other hand may either be relevant or irrelevant. To understand what fraction of false-positives may still be relevant, we sent emails to 263 engineers who had not accepted Rex's suggestions. We asked them to categorize Rex's suggestion they saw into one of four categories:

1. The recommendation was relevant but you could not act upon it for some reason.
2. The recommendation was relevant in general but not in this case. Yet, it helped to think through the suggestion.
3. The recommendation was relevant in general but not in this case. You'd rather not have seen the suggestion.
4. The recommendation was not relevant at all.

We received a total of 156 responses. 99 engineers selected the first or second option, i.e., they found the suggestions relevant, i.e. in 99 out of 156 cases, even though Rex's suggestion was a false-positive, it was still useful to the engineer.

Phase 3 : We also used feedback from users to understand the impact of Rex suggestions that were accepted. What if Rex had not made those suggestions and the engineer did not make the correlated changes? To understand this, we sent emails to 65 engineers who had accepted Rex suggestions (true-positives). We provided them with the following options:

1. The recommendation was relevant and had the file not been edited, it could have (broken the build)/(led to service disruption)/(introduced a bug). [High Impact]
2. The recommendation was good to have but the impact of not editing the suggested file would be low. [Low Impact/Good to have]

We received a total of 16 responses. 7 engineers chose option 1. We quote some of their comments here:

"In fact without the suggested change, the code would not have worked."

"If the file is not edited, the build would have failed."

"The suggestion was valid and saved later service disruptions and time"

9 engineers found the suggestion having low impact but without that change, code quality would have been impacted negatively. Some of the responses from engineers include :

"It was good to have edited the additional files for consistency, but it would not have caused any live site impact"

"Even though the build/tests would have been successful, it was a good-to-have suggestion. Adding these files helped unit test the code changes."

From this user study, we infer that Rex is making many more relevant suggestions than the hit rate suggests. Rex is also catching a good number of high-impact suggestions which, if not accepted, would have caused breaks in the build pipeline of the service or even service disruption.

9 Related Work

Rex takes inspiration from two categories of previous work: configuration management in large systems, and code dependency analysis in empirical software engineering. In this section, we describe related-work in these areas.

9.1 Configuration Management

Previous work has explored automated bug and misconfiguration detection using both black-box [16, 24, 30, 31] and white-box techniques [34, 35]. It has also shown how detecting misconfigurations early can help bring down the cost of service disruptions significantly [34].

EnCore [34] uses pre-defined or user-specified templates to detect misconfigurations, which allows it to detect more fine-grained correlations between individual configuration parameters. Through interviews with practitioners, we found that requiring manual inputs posed a severe impediment to adoption. Hence we designed Rex to not require any manual inputs, and to automatically learn templates (generalizations) using change-rule refinement. As a consequence, Rex may not detect rules at as fine a granularity as EnCore.

An orthogonal body of work [14, 25, 28] targets the problem by proposing tool-suites that make it easier for engineers to manage and validate configuration across large services. Facebook's holistic configuration [28] also illustrates the effort required to detect misconfigurations, by using automated canary testing for changed configurations, and using user-defined invariants to drive configuration changes. However, none of these specifically target the problem of correlated configurations explicitly.

9.2 Code Suggestions

Previous work has explored the idea of providing suggestions to engineers to change certain parts of code based on the changes they have already made. Some efforts rely on detecting structural dependencies in code based on program analysis to suggest related components [16, 21, 36]. Others determine couplings between classes in managed code using several semantic and logical techniques [6]. This body of work studies how code dependencies and couplings influence a software engineer's view of related changes. However, they are mostly analyses and learnings, and in most cases, have not been extended to design and deployment of a generic tool that detects such couplings and suggests changes to engineers.

Most related in this space to Rex is work that infers transactions using association rule mining on code version histories [37]. The authors have developed a tool that uses association rule mining to suggest related code changes within an IDE. However, they do not follow it up with inductive generalization/anti-unification which was necessary to reduce the false-recommendations. To speed up the mining process, the consequent of a rule is constrained to have single entity. Hence the rules detected by the tool will be a subset of the rules Rex learns. They mine rules on the fly, each rule taking a few seconds which does not scale well for large-scale deployments. Rex is a more generic technique and has been deployed widely across different services.

MUVI [16] uses frequent itemset mining to find correlated variable accesses in code. If the programmer does not access all correlated variables together, or does not guard them with the same lock, MUVI flags a potential bug. Getafix [23] uses code change analysis to guide testing and to find bugs related to certain properties, such as a missing null-check. Both MUVI and Getafix are designed to discover very specific kinds of bugs, such as multiple access correlations in the case of MUVI and null dereferencing in the case of Getafix. The goal of Rex is to be generic and applicable to a wide range of scenarios across multiple service deployments. We believe that such tools could work very well alongside Rex.

10 Conclusion

This paper presents Rex, a widely deployed and scalable service that performs correlated change analysis using change-rule discovery and change-rule refinement to identify development gaps in code changes being proposed by engineers. Many lessons have been learned during the development and deployment of Rex, which have been outlined and presented in this paper. Most significantly, engineers are always looking for more tools and services to help their process, and Rex fits into their workflow naturally and effectively. Rex has had significant impact in avoiding bad deployments, service outages, build breaks, and buggy commits.

Abstract

We present operational experience running *Snowflake*, a cloud-based data warehousing system with SQL support similar to state-of-the-art databases. Snowflake design is motivated by three goals: (1) compute and storage elasticity; (2) support for multi-tenancy; and, (3) high performance. Over the last few years, Snowflake has grown to serve thousands of customers executing millions of queries on petabytes of data every day.

This paper presents Snowflake design and implementation, along with a discussion on how recent changes in cloud infrastructure (emerging hardware, fine-grained billing, etc.) have altered the many assumptions that guided the design and optimization of Snowflake system. Using data collected from various components of our system during execution of 70 million queries over a 14 day period, our study both deepens the understanding of existing problems and highlights new research challenges along a multitude of dimensions including design of storage systems and high-performance query execution engines.

1 Introduction

Shared-nothing architectures have been the foundation of traditional query execution engines and data warehousing systems. In such architectures, *persistent* data (*e.g.*, customer data stored as tables) is partitioned across a set of compute nodes, each of which is responsible only for its local data. Such shared-nothing architectures have enabled query execution engines that scale well, provide cross-job isolation and good data locality resulting in high performance for a variety of workloads. However, these benefits come at the cost of several major disadvantages:

- **Hardware-workload mismatch:** Shared-nothing architectures make it hard to strike a perfect balance between CPU, memory, storage and bandwidth resources provided by compute nodes, and those required by workloads. For instance, a node configuration that is ideal for bandwidth-intensive compute-light bulk loading may be a poor fit for compute-extensive bandwidth-light complex queries. Many customers, however, want to run a mix of queries without setting up a separate cluster for each query type. Thus, to meet performance goals, resources usually have to be over-provisioned; this results in resource underutilization on an average and in higher operational costs.
- **Lack of Elasticity:** Even if one could match the hardware resources at compute nodes with workload demands, static parallelism and data partitioning inherent to (inelastic) shared-nothing architectures constrain adaptation to data skew and time-varying workloads. For instance, queries run by our customers have extremely skewed intermediate data sizes that vary over five orders of magnitude (§4), and have CPU requirements that change by as much as an order of magnitude within the same hour (§7). Moreover, shared-nothing architectures do not admit efficient elasticity; the usual approach of adding/removing nodes to elastically scale resources requires large amounts of data to be reshuffled. This not only increases network bandwidth requirements but also results in significant performance degradation since the set of nodes participating in data reshuffling are also responsible for query processing.

Traditional data warehousing systems were designed to operate on recurring queries on data with predictable volume and rate, *e.g.*, data coming from within the organization: transactional systems, enterprise resource planning application, customer relationship management applications, etc. The situation has changed significantly. Today, an increasingly large fraction of data comes from less controllable, external sources (*e.g.*, application logs, social media, web applications, mobile systems, etc.) resulting in ad-hoc, time-varying, and unpredictable query workloads. For such workloads, shared-nothing architectures beget high cost, inflexibility, poor performance and inefficiency, which hurts production applications and cluster deployments.

To overcome these limitations, we designed Snowflake — an elastic, transactional query execution engine with SQL support comparable to state-of-the-art databases. The key insight in Snowflake design is that the aforementioned limitations of shared-nothing architectures are rooted in tight coupling of compute and storage, and the solution is to decouple the two! Snowflake thus disaggregates compute from persistent storage; customer data is stored in a persistent data store (*e.g.*, Amazon S3 [5], Azure Blob Storage [8], etc.) that provides high availability and on-demand elasticity. Compute elasticity is achieved using a pool of pre-warmed nodes, that can be assigned to customers on an on-demand basis.

Snowflake system design uses two key ideas (§2). First, it uses a custom-designed storage system for management and exchange of ephemeral/intermediate data that is exchanged between compute nodes during query execution (*e.g.*, tables exchanged during joins). Such an ephemeral storage system was necessary because existing persistent data stores [5, 8] have two main limitations: (1) they fall short of providing the necessary latency and throughput performance to avoid compute tasks being blocks on exchange of intermediate data; and (2) they provide stronger availability and durability semantics than what is needed for intermediate data. Second, Snowflake uses its ephemeral storage system not only for intermediate data, but also as a write-through "cache" for persistent data. Combined with a custom-designed query scheduling mechanism for disaggregated storage, Snowflake is able to reduce the additional network load caused by compute-storage disaggregation as well as alleviate the performance overheads of reduced data locality.

Snowflake system has now been active for several years and today, serves thousands of customers executing millions of queries over petabytes of data, on a daily basis. This paper describes Snowflake system design, with a particular focus on ephemeral storage system design, query scheduling, elasticity and efficiently supporting multi-tenancy. We also use statistics collected during execution of $\sim$70 million queries over a period of 14 contiguous days in February 2018 to present a detailed study of network, compute and storage characteristics in Snowflake. Our key findings are:

- Customers submit a wide variety of query types; for example, read-only queries, write-only queries and read-write queries, each of which contribute to $\sim$28%, $\sim$13% and $\sim$59%, respectively, of all customer queries.
- Intermediate data sizes can vary over multiple orders of magnitude across queries, with some queries exchanging hundreds of gigabytes or even terabytes of intermediate data. The amount of intermediate data generated by a query has little or no correlation with the amount of persistent data read by the query or the execution time of the query.
- Even with a small amount of local storage capacity, skewed access distributions and temporal access patterns common in data warehouses enable reasonably high average cache hit rates (60-80% depending on the type of query) for persistent data accesses.
- Several of our customers exploit our support for elasticity (for $\sim$20% of the clusters). For cases where customers do request elastic scaling of resources, the number of compute nodes in their cluster can change by as much as two orders of magnitude during the lifetime of the cluster.
- While the peak resource utilization can be high, the average resource utilization is usually low. We observe average CPU, Memory, Network Tx and Network Rx utilizations of $\sim$51%, $\sim$19%, $\sim$11%, $\sim$32%, respectively.

Our study both corroborates exciting ongoing research directions in the community, as well as highlights several interesting venues for future research:

- **Decoupling of compute and ephemeral storage:** Snowflake decouples compute from persistent storage to achieve elasticity. However, currently, compute and ephemeral storage are still tightly coupled. As we show in §4, the ratio of compute capacity and ephemeral storage capacity in our production clusters can vary by several orders of magnitude, leading to either under utilization of CPU or thrashing of ephemeral storage, for ad-hoc query processing workloads. To that end, recent academic work on decoupling compute from ephemeral storage [22, 27] is of extreme interest. However, more work is needed in ephemeral storage system design, especially in terms of providing fine-grained elasticity, multi-tenancy, and cross-query isolation (§4, §7).
- **Deep storage hierarchy:** Snowflake ephemeral storage system, similar to recent work on compute-storage disaggregation [14, 15], uses caching of frequently read persistent data to both reduce the network traffic and to improve data locality. However, existing mechanisms for improving caching and data locality were designed for two-tier storage systems (memory as the main tier and HDD/SSD as the second tier). As we discuss in §4, the storage hierarchy in our production clusters is getting increasingly deeper, and new mechanisms are needed that can efficiently exploit the emerging deep storage hierarchy.
- **Pricing at sub-second timescales:** Snowflake achieves compute elasticity at fine-grained timescales by serving customers using a pool of pre-warmed nodes. This was cost-efficient with cloud pricing at hourly granularity. However, most cloud providers have recently transitioned to sub-second pricing [6], leading to new technical challenges in efficiently achieving resource elasticity and resource sharing across multiple tenants. Resolving these challenges may require design decisions and tradeoffs that may be different from those in Snowflake's current design (§7).

This paper focuses on Snowflake system architecture along with compute, storage and network characteristics observed in our production clusters. Accordingly, we focus on details that are necessary to make the paper self-contained (§2). For details on Snowflake query planning, optimization, concurrency control mechanisms, etc., please refer to [12]. To aid future research and studies, we are releasing an anonymized version of the dataset used in this paper; this dataset comprising statistics collected per-query for ∼70 million queries. The dataset is available publicly along with documentation and scripts to reproduce all results in this paper at https://github.com/resource-disaggregation/snowset.

Our study has an important caveat. It focuses on a specific system (Snowflake), a specific workload (SQL queries), and a specific cloud infrastructure (S3). While our system is large-scale, has thousands of customers executing millions of queries, and runs on top of one of the most prominent infrastructures, it is nevertheless limited. We leave it to future work an evaluation of whether our study and observations generalize to other systems, workloads and infrastructures. However, we are hopeful that just like prior workload studies on network traffic characteristics [9] and cloud workloads [28] (each of which also focused on a specific system implementation running a specific workload on a specific infrastructure) fueled and aided research in the past, our study and publicly released data will be useful for the community.

2 Design Overview

We provide an overview of Snowflake design. Snowflake treats persistent and intermediate data differently; we describe these in §2.1, followed by a high-level overview of Snowflake architecture (§2.2) and query execution process (§2.3).

2.1 Persistent and Intermediate data

Like most query execution engines and data warehousing systems, Snowflake has three forms of application state:

- *Persistent data* is customer data stored as tables in the database. Each table may be read by many queries, over time or even concurrently. These tables are thus long-lived and require strong durability and availability guarantees.
- *Intermediate data* is generated by query operators (*e.g.*, joins) and is usually consumed by nodes participating in executing that query. Intermediate data is thus short-lived. Moreover, to avoid nodes being blocked on intermediate data access, low-latency high-throughput access to intermediate data is preferred over strong durability guarantees. Indeed, in case of failures happening during the (short) lifetime of intermediate data, one can simply rerun the part of the query that produced it.
- *Metadata* such as object catalogs, mapping from database tables to corresponding files in persistent storage, statistics, transaction logs, locks, etc.

This paper primarily focuses on persistent and intermediate data, as the volume of metadata is typically relatively small and does not introduce interesting systems challenges.

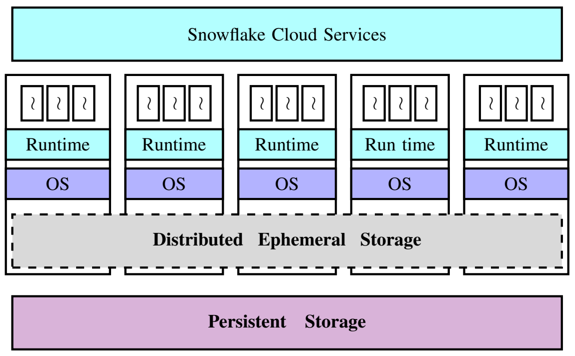

Figure 1: **Snowflake (Virtual) Warehouse Architecture (§2.2).**

2.2 End-to-end System Architecture

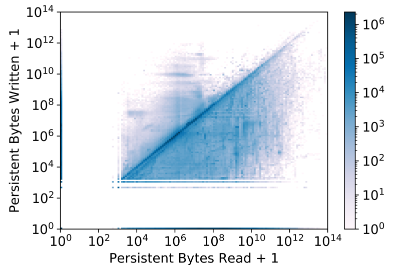
Figure 1 shows the high-level architecture for Snowflake. It has four main components — a centralized service for orchestrating end-to-end query execution, a compute layer, a distributed ephemeral storage system and a persistent data store. We describe each of these below[1].

Centralized Control via Cloud Services. All Snowflake customers interact with and submit queries to a centralized layer called Cloud Services (CS) [12]. This layer is responsible for access control, query optimization and planning, scheduling, transaction management, concurrency control, etc. CS is designed and implemented as a multi-tenant and long-lived service with sufficient replication for high availability and scalability. Thus, failure of individual service nodes does not cause loss of state or availability, though some of the queries may fail and be re-executed transparently.

Elastic Compute via Virtual Warehouse abstraction. Customers are given access to computational resources in Snowflake through the abstraction of a *Virtual Warehouse* (VW). Each VW is essentially a set of AWS EC2 instances on top which customer queries execute in a distributed fashion. Customers pay for compute-time based on the VW size. Each VW can be elastically scaled on an on-demand basis upon customer request. To support elasticity at fine-grained timescales (*e.g.*, tens of seconds), Snowflake maintains a pool of pre-warmed EC2 instances; upon receiving a request, we simply add/remove EC2 instances to/from that VW (in case of addition, we are able to support most requests directly from our pool of pre-warmed instances thus avoiding instance startup time). Each VW may run multiple concurrent queries. In fact, many of our customers run multiple VWs (*e.g.*, one for data ingestion, and one for executing OLAP queries).

Elastic Local Ephemeral Storage. Intermediate data has different performance requirements compared to persistent data (§2.1). Unfortunately, existing persistent data stores do not meet these requirements (*e.g.*, S3 does not provide the desired low-latency and high-throughput properties needed

[1]This paper describes design and implementation of Snowflake using Amazon Web Services as an example infrastructure; however, Snowflake runs on Microsoft Azure and Google Cloud Platform as well.



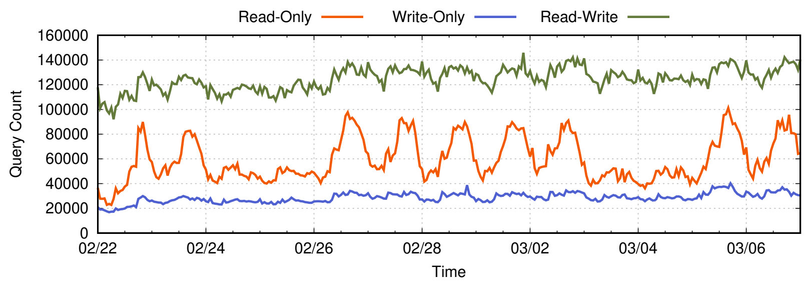


Figure 2: **Persistent data read/write, and submission time characteristics of queries in our dataset. (left)** Scatter plot with each point representing a query based on the total number of persistent data bytes read and written by the query. The density of points is concentrated along three regions: (1) read-only queries along x-axis; (2)write-only queries along y-axis; and, (3) read-write queries along the middle region. **(right)** for each query class, the number of queries submitted at different times of day over the 14 day period, binned on an hourly basis. Read-only queries have significantly higher variation in load compared to the other query classes, with spikes during daytime hours on weekdays.

for intermediate data to ensure minimal blocking of compute nodes); hence, we built a distributed ephemeral storage system custom-designed to meet the requirements of intermediate data in our system. The system is co-located with compute nodes in VWs, and is explicitly designed to automatically scale as nodes are added or removed. We provide more details in §4 and §6, but note here that as nodes are added and removed, our ephemeral storage system does not require data repartitioning or reshuffling (thus alleviating one of the core limitations of shared-nothing architectures). Each VW runs its own independent distributed ephemeral storage system which is used only by queries running on that particular VW.

Elastic Remote Persistent Storage. Snowflake stores all its persistent data in a remote, disaggregated, persistent data store. We store persistent data in S3 despite the relatively modest latency and throughput performance because of S3's elasticity, high availability and durability properties. S3 supports storing immutable files — files can only be overwritten in full and do not even allow append operations. However, S3 supports read requests for parts of a file. To store tables in S3, Snowflake partitions them horizontally into large, immutable files that are equivalent to blocks in traditional database systems [12]. Within each file, the values of each individual attribute or column are grouped together and compressed, as in PAX [2]. Each file has a header that stores offset of each column within the file, enabling us to use the partial read functionality of S3 to only read columns that are needed for query execution.

All VWs belonging to the same customer have access to the same shared tables via remote persistent store, and hence do not need to physically copy data from one VW to another.

2.3 End-to-end query execution

Query execution begins with customers submitting their query text to CS for execution on a specific customer VW. At this stage, CS performs query parsing, query planning and optimization, producing a set of tasks that need to be executed. It then schedules these tasks on compute nodes of the VW; each task may perform read/write operations on both ephemeral storage system and remote persistent data store. We describe the scheduling and query execution mechanisms in Snowflake in §5. CS continually tracks the progress of each query, collects performance counters, and upon detecting a node failure, reschedules the query on compute nodes within the VW. Once the query is executed, the corresponding result is returned back to the CS and eventually to the customer.

3 Dataset

Snowflake collects statistics at each layer of the system — CS collects and stores information for each individual VW (size over time, instance types, failure statistics, etc.), performance counters for individual queries, time spent in different phases of query execution, etc. Each node collects statistics for ephemeral and persistent store accesses, resource (CPU, memory and bandwidth) utilization characteristics, compression properties, etc. To aid future research and studies, we are publicly releasing a dataset containing most of these statistics for ∼70 million queries over a period of 14 days, aggregated per-query. The dataset is publicly available at https://github.com/resource-disaggregation/snowset. For privacy reasons, the dataset does not contain information on query plans, table schemas and per-file access frequencies. To ensure reproducibility, this paper uses only those statistics that are contained in publicly released dataset.

Query Classification. We classify queries in the dataset based on number of persistent data bytes read and written (Figure 2 (left)). Figure 2 (right) shows number of queries submitted at different times of day for each query class.

- **Read-only queries:** Queries along the x-axis are the ones that do not write any persistent data; however, the amount of data read by these queries can vary over nine orders of magnitude. These queries contribute to ∼28% of all customer queries, and represent ad-hoc and interactive OLAP

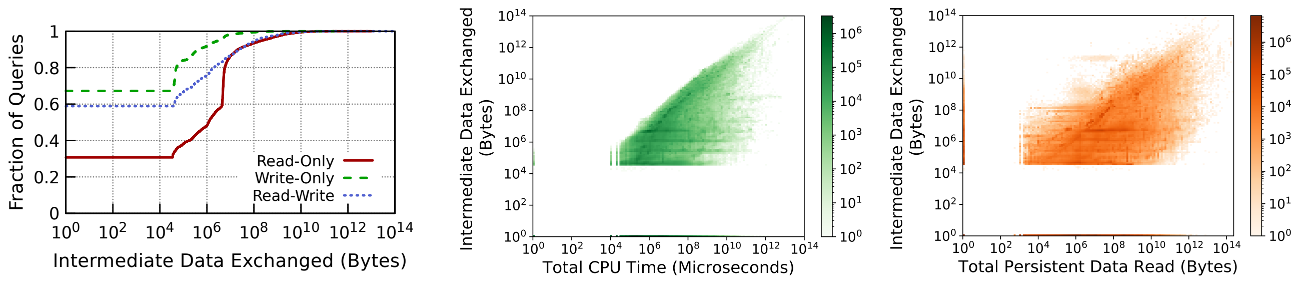

Figure 3: **Intermediate data characteristics. (left)** Intermediate data sizes vary over multiple orders of magnitude across queries; a non-trivial fraction of queries in each query class exchange zero intermediate data, while some read-only and read-write queries exchange $10-100$TB of intermediate data. **(center)** Scatter plot with each point representing a query based on its total CPU time and amount of intermediate data exchanged by the corresponding query; queries with the same total CPU time exchange vastly different amounts of intermediate data. **(right)** Scatter plot with each point representing a query based on its total persistent data read and amount of intermediate data exchanged by the corresponding query; queries that read the same amount of persistent data exchange vastly different amounts of intermediate data.

workloads [10] typical in data warehouses, where the result is usually small in size and is directly returned to the client. The right figure demonstrates an interesting trend for read-only queries — the number of such queries submitted by customers spike during daytime hours on weekdays.

- **Write-only queries:** Queries along the y-axis are the ones that do not read any persistent data; however, the amount of data written by these queries can vary over eight orders of magnitude. These queries contribute to ~13% of all customer queries, and essentially represent data ingestion queries that bring data into the system. Unlike read-only queries, we observe that the rate of submission for write-only queries is fairly consistent across time.
- **Read-Write (RW) queries:** The region in the middle of the plot contains ~59% of customer queries, and represents queries that both read and write persistent data. Here we see a wide spectrum of queries. Many queries have read-write ratio close to 1, in terms of number of bytes, that represent Extract Transform Load (ETL) pipelines [29, 31, 32] typical in data warehouses. For other queries, the read-write ratio can vary over multiple orders of magnitude.

The above classification is based on number of persistent data bytes read and written by the queries, a measure that is not an artifact of Snowflake's architecture; rather, it is a property of the queries themselves. Indeed, even if these queries were to run on, say, any other data analytics framework (*e.g.*, Hadoop) or even a single node database (*e.g.*, MySQL), the persistent read/write characteristics would remain the same. We do not classify queries based on semantics as the focus of this paper is on systems characteristics, and our dataset does not contain detailed information about individual query plans. We will use the above query classification throughout the paper.

4 Ephemeral Storage System

Snowflake uses a custom-designed distributed storage system for management and exchange of intermediate data, due to two limitations in existing persistent data stores [5, 8]. First, they fall short of providing the necessary latency and throughput performance to avoid compute tasks being blocks on intermediate data exchange. Second, they provide much stronger availability and durability semantics than what is needed for intermediate data. Our ephemeral storage system allows us to overcome both these limitations. Tasks executing query operations (*e.g.*, joins) on a given compute node write intermediate data locally; and, tasks consuming the intermediate data read it either locally or remotely over the network (depending on the node where the task is scheduled, §5).

4.1 Storage Architecture, and Provisioning

We made two important design decisions in our ephemeral storage system. First, rather than designing a pure in-memory storage system, we decided to use both memory and local SSDs — tasks write as much intermediate data as possible to their local memory; when memory is full, intermediate data is spilled to local SSDs. Our rationale is that while purely in-memory systems can achieve superior performance when entire data fits in memory, they are too restrictive to handle the variety of our target workloads. Figure 3 (left) shows that there are queries that exchange hundreds of gigabytes or even terabytes of intermediate data; for such queries, it is hard to fit all intermediate data in main memory.

The second design decision was to allow intermediate data to spill into remote persistent data store in case the local SSD capacity is exhausted. Spilling intermediate data to S3, instead of other compute nodes, is preferable for a number of reasons — it does not require keeping track of intermediate data location, it alleviates the need for explicitly handling out-of-memory or out-of-disk errors for large queries, and overall, allows to keep our ephemeral storage system thin and highly performant.

Future Directions. For performance-critical queries, we want intermediate data to entirely fit in memory, or at least in SSDs,

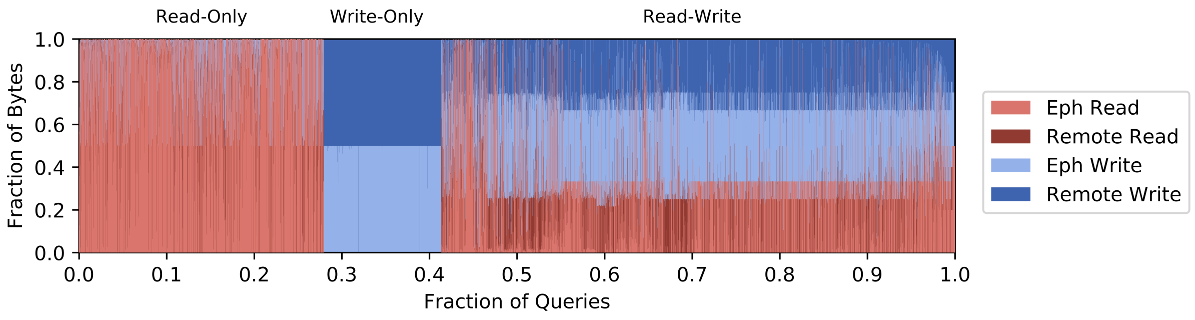

Figure 4: **Persistent data I/O traffic distribution between ephemeral storage system and remote persistent data store.** Each vertical bar corresponds to a query, the four colors correspond to read/write from ephemeral/remote systems, and the y-axis represents the fraction of total persistent data that was served by the corresponding storage system. Queries are sorted, within each class, in decreasing order of number of persistent data bytes read/written. Discussion in §4.2.

and not spill to S3. This requires accurate resource provisioning. However, provisioning CPU, memory and storage resources while achieving high utilization turns out to be challenging due to two reasons. The first reason is limited number of available node instances (each providing a fixed amount of CPU, memory and storage resources), and significantly more diverse resource demands across queries. For instance, Figure 3 (center) shows that, across queries, the ratio of compute requirements and intermediate data sizes can vary by as much as six orders of magnitude. The available node instances simply do not provide enough options to accurately match node hardware resources with such diverse query demands.

Second, even if we could match node hardware resources with query demands, accurately provisioning memory and storage resources requires a priori knowledge of intermediate data size generated by the query. However, our experience is that predicting the volume of intermediate data generated by a query is hard, or even impossible, for most queries. As shown in Figure 3, intermediate data sizes not only vary over multiple orders of magnitude across queries, but also have little or no correlation with amount of persistent data read or the expected execution time of the query.

To resolve the first challenge, we could decouple compute from ephemeral storage. This would allow us to match available node resources with query resource demands by independently provisioning individual resources. However, the challenge of unpredictable intermediate data sizes is harder to resolve. For such queries, simultaneously achieving high performance and high resource utilization would require both decoupling of compute and ephemeral storage, as well as efficient techniques for fine-grained elasticity of ephemeral storage system. We discuss the latter in more detail in §6.

4.2 Persistent Data Caching

One of the key observations we made during early phases of ephemeral storage system design is that intermediate data is short-lived. Thus, while storing intermediate data requires large memory and storage capacity *at peak*, the demand is low *on an average*. This allows statistical multiplexing of our ephemeral storage system capacity between intermediate data and frequently accessed persistent data. This improves performance since (1) queries in data warehouse systems exhibit highly skewed access patterns over persistent data [10]; and (2) ephemeral storage system performance is significantly better than that of (existing) remote persistent data stores.

Snowflake enables statistical multiplexing of ephemeral storage system capacity between intermediate data and persistent data by "opportunistically" caching frequently accessed persistent data files, where opportunistically refers to the fact that intermediate data storage is always prioritized over caching persistent data files. However, a persistent data file cannot be cached on any node — Snowflake assigns input file sets for the customer to nodes using consistent hashing over persistent data file names. A file can only be cached at the node to which it consistently hashes to; each node uses a simple LRU policy to decide caching and eviction of persistent data files. Given the performance gap between our ephemeral storage system and remote persistent data store, such opportunistic caching of persistent data files improves the execution time for many queries in Snowflake. Furthermore, since storage of intermediate data is always prioritized over caching of persistent data files, such an opportunistic performance improvement in query execution time can be achieved without impacting performance for intermediate data access.

Maintaining the right system semantics during opportunistic caching of persistent data files requires a careful design. First, to ensure data consistency, the "view" of persistent files in ephemeral storage system must be consistent with those in remote persistent data store. We achieve this by forcing the ephemeral storage system to act as a write-through cache for persistent data files. Second, consistent hashing of persistent data files on nodes in a naïve way requires reshuffling of cached data when VWs are elastically scaled. We implement a lazy consistent hashing optimization in our ephemeral storage system that avoids such data reshuffling *altogether*; we describe this when we discuss Snowflake elasticity in §6.

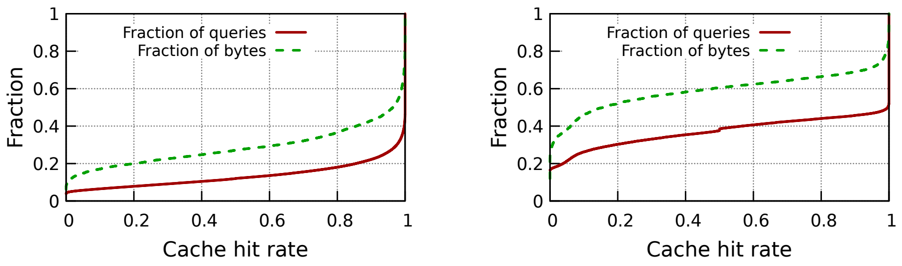

Figure 5: **Cache hit rate distribution of Read-only (left) and Read-Write queries (right).** We plot the CDFs for both, the queries (independent of their persistent data read sizes) and for bytes (queries weighed by the amount of persistent data read). For example, for Read-only queries, 80% of the queries have hit rate greater than 75%, but these queries account for only a little more than 60% of the total number of persistent bytes read by all Read-only queries.

Persistent data being opportunistically cached in the ephemeral storage system means that some subset of persistent data access requests could be served by the ephemeral storage system (depending on whether or not there is a cache hit). Figure 4 shows the persistent data I/O traffic distribution, in terms of fraction of bytes, between the ephemeral storage system and remote persistent data store. The write-through nature of our ephemeral storage system results in amount of data written to ephemeral storage being roughly of the same magnitude as the amount of data written to remote persistent data store (they are not always equal because of prioritizing storage of intermediate data over caching of persistent data).

Even though our ephemeral storage capacity is significantly lower than that of a customer's persistent data (around 0.1% on an average), skewed file access distributions and temporal file access patterns common in data warehouses [7] enable reasonably high cache hit rates (avg. hit rate is close to 80% for read-only queries and around 60% for read-write queries). Figure 5 shows the hit rate distributions across queries. The median hit rates are even higher.

Future Directions. Figure 4 and Figure 5 suggest that more work is needed on caching. In addition to locality of reference in access patterns, cache hit rate also depends on effective cache size available to the query relative to the amount of persistent data accessed by the query. The effective cache size, in turn, depends on both the VW size and the volume of intermediate data generated by concurrently executing queries. Our preliminary analysis has not led to any conclusive observations on the impact of the above two factors on the observed cache hit rates, and a more fine-grained analysis is needed to understand factors that impact cache hit rates.

We highlight two additional technical problems. First, since end-to-end query performance depends on both, cache hit rate for persistent data files and I/O throughput for intermediate data, it is important to optimize how the ephemeral storage system splits capacity between the two. Although we currently use the simple policy of always prioritizing intermediate data, it may not be the optimal policy with respect to end-to-end performance objectives (*e.g.*, average query completion time across all queries from the same customer). For example, it may be better to prioritize caching a persistent data file that is going to be accessed by many queries over intermediate data that is accessed by only one. It would be interesting to explore extensions to known caching mechanisms that optimize for end-to-end query performance objectives [7] to take intermediate data into account.

Second, existing caching mechanisms were designed for two-tier storage systems (memory as the main tier and HDD/SSD as the second tier). In Snowflake, we already have three tiers of hierarchy with compute-local memory, ephemeral storage system and remote persistent data store; as emerging non-volatile memory devices are deployed in the cloud and as recent designs on remote ephemeral storage systems mature [22], the storage hierarchy in the cloud will get increasingly deeper. Snowflake uses traditional two-tier mechanisms — each node implements a local LRU policy for evictions from local memory to local SSD, and an independent LRU policy for evictions from local SSD to remote persistent data store. However, to efficiently exploit the deepening storage hierarchy, we need new caching mechanisms that can efficiently coordinate caching across multiple tiers.

We believe many of the above technical challenges are not specific to Snowflake, and would apply more broadly to any distributed application built on top of disaggregated storage.

5 Query (Task) Scheduling

We now describe the query execution process in Snowflake. Customers submit their queries to the Cloud Services (CS) for execution on a specific VW. CS performs query parsing, query planning and optimization, and creates a set of tasks to be scheduled on compute nodes of the VW.

Locality-aware task scheduling. To fully exploit the ephemeral storage system, Snowflake colocates each task with persistent data files that it operates on using a locality-aware scheduling mechanism (recall, these files may be cached in ephemeral storage system). Specifically, recall that Snowflake assigns persistent data files to compute nodes using consistent

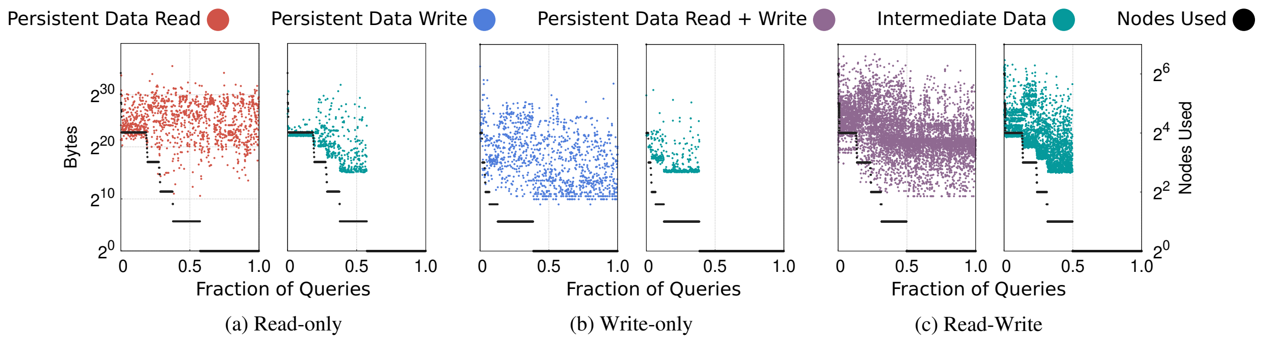

Figure 6: **Persistent data read / write and intermediate data exchange characteristics of queries sorted by the number of nodes used.** Each plot uses the same axis for bytes (left axis) and nodes used (right axis). Persistent Read and write bytes vary by three orders of magnitude across each node count.

hashing over table file names. Thus, for a fixed VW size, each persistent data file is cached on a specific node. Snowflake schedules the task that operates on a persistent data file to the node on which its file consistently hashes to.

As a result of this scheduling scheme, query parallelism is tightly coupled with consistent hashing of files on nodes — a query is scheduled for cache locality and may be distributed across all the nodes in the VW. For instance, consider a customer that has 1million files worth of persistent data, and is running a VW with 10 nodes. Consider two queries, where the first query operates on 100 files, and the second query operates on 100,000 files; then, with high likelihood, both queries will run on all the 10 nodes because of files being consistently hashed on to all the 10 nodes.

Figure 6 illustrates this— the number of persistent bytes read and written vary over orders of magnitude, almost independent of the number of nodes in the VW. As expected, the intermediate data exchanged over the network increases with the number of nodes used.

Work stealing. It is known that consistent hashing can lead to imbalanced partitions [19]. In order to avoid overloading of nodes and improve load balance, Snowflake uses *work stealing*, a simple optimization that allows a node to steal a task from another node if the expected completion time of the task (sum of execution time and waiting time) is lower at the new node. When such work stealing occurs, the persistent data files needed to execute the task are read from remote persistent data store rather than the node at which the task was originally scheduled on. This avoids increasing load on an already overloaded node where the task was originally scheduled (note that work stealing happens only when a node is overloaded).

Future Directions. Schedulers can place tasks onto nodes using two extreme options: one is to colocate tasks with their cached persistent data, as in our current implementation. As discussed in the example above, this may end up scheduling all queries on all nodes in the VW; while such a scheduling policy minimizes network traffic for reading persistent data, it may lead to increased network traffic for intermediate data exchange. The other extreme is to place all tasks on a single node. This would obviate the need of network transfers for intermediate data exchange but would increase network traffic for persistent data reads. Neither of these extremes may be the right choice for all queries. It would be interesting to codesign query schedulers that would pick just the right set of nodes to obtain a sweet spot between the two extremes, and then schedule individual tasks onto these nodes.

6 Resource Elasticity

In this section, we discuss how BlowFish design achieves one of its core goals: resource elasticity, that is, scaling of compute and storage resources on an on-demand basis.

Disaggregating compute from persistent storage enables Snowflake to independently scale compute and persistent storage resources. Storage elasticity is offloaded to persistent data stores [5]; compute elasticity, on the other hand, is achieved using a pre-warmed pool of nodes that can be added/removed to/from customer VWs on an on-demand basis. By keeping a pre-warmed pool of nodes, Snowflake is able to provide compute elasticity at the granularity of tens of seconds.

6.1 Lazy Consistent Hashing

One of the challenges that Snowflake had to resolve in order to achieve elasticity efficiently is related to data management in ephemeral storage system. Recall that our ephemeral storage system opportunistically caches persistent data files; each file can be cached only on the node to which it consistently hashes to within the VW. The problem is similar to shared-nothing architectures: any fixed partitioning mechanism (in our case, consistent hashing) requires large amounts of data to be reshuffled upon scaling of nodes; moreover, since the very same set of nodes are also responsible for query processing, the system observes a significant performance impact during the scaling process.

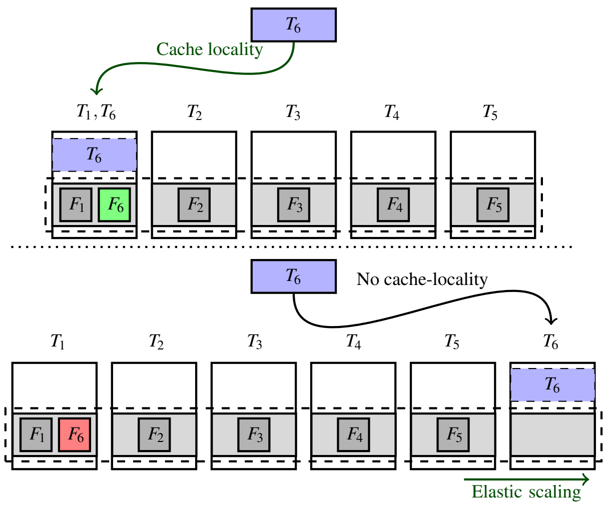

Figure 7: **Snowflake uses lazy consistent hashing to avoid data reshuffling during elastic scaling of VWs. (Top)** VW in steady state with all task inputs cached. **(Bottom)** VW immediately after adding one node. See discussion in §6.1.

Snowflake resolves this challenge using a lazy consistent hashing mechanism, that completely avoids any reshuffling of data upon elastic scaling of nodes by exploiting the fact that a copy of cached data is stored at remote persistent data store. Specifically, Snowflake relies on the caching mechanism to eventually "converge" to the right state. For instance, consider the example in Figure 7 that shows a VW with 6 tasks $T_1, T_2, \ldots, T_6$, with task T_i operating on a single file F_i. Suppose at time t_0, we have 5 nodes in the VW and that node N_1 stores files F_1 and F_6, and nodes $N_2 - N_5$ store file $F_2 - F_5$, respectively. Suppose at time $t > t_0$, a node N_6 is added to the warehouse. Then, rather than immediately reshuffling the files (which would result in F_6 being moved from node N_1 to N_6), Snowflake will wait until task T_6 is executed again. When the next time T_6 is scheduled (*e.g.*, due to work stealing or the same query being executed again), Snowflake will schedule it on N_6 since consistent hashing will now place file F_6 on that node. At this time, file F_6 will be read by N_6 from remote persistent store and cached locally. File F_6 on node N_1 will no longer be accessed and will eventually be evicted from the cache. Such lazy caching allows Snowflake to achieve locality without reshuffling data and without interfering with ongoing queries on nodes already in the VW.

6.2 Elasticity Characteristics

Our customer warehouses exhibit several interesting elasticity characteristics. Figure 8 shows that many of our customers already exploit our support for elasticity (for ∼20% of the VW). For such cases where customers do request VW resizing, the number of nodes in their VW can change by as much as two orders of magnitude during the lifetime of the VW! Figure 9 (top) shows two cases where customers leverage elasticity rather aggressively (even at hourly granularity).

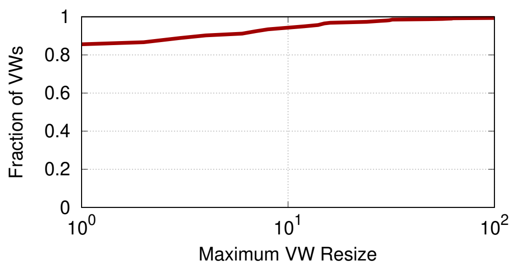

Figure 8: **VW elasticity usage.** 82% of all VW never exploit elasticity; however, some of the customers elastically scale their VW size by as much as two orders of magnitude!

Future Directions. Figure 8 also shows that our customers do not exploit our support for elasticity for more than 80% of the VW. Even for customers that do request VW resizing, there are opportunities for further optimizations — Figure 9 shows that query inter-arrival times in these VW are much finer-grained than the granularity of VW scaling requested by our customers. We believe the main reason for these characteristics is that customers lack the visibility (and the right demand estimation) into the system to accurately request scaling their VW to meet the demand. VW1 in Figure 9, for instance, is one of the heavily utilized VW from a large customer; the characteristics for this VW demonstrate how elastic scaling can mismatch the demand (approximated by query inter-arrival time). Since the time the dataset in the paper was recorded, a lot of work has been done to improve support for auto-scaling VW at the granularity of inter-query arrival times. However, much more work needs to be done.

First, we would like to achieve elasticity at intra-query granularity. Specifically, resource consumption can vary significantly even within the lifetime of individual queries. This is particularly prevalent in long running queries with many internal stages. Hence, in addition to auto-scaling VW at the granularity of query inter-arrivals, we would ideally like to support some level of task-level elasticity even during the execution of a query.

Second, we would like to explore serverless-like platforms. Serverless infrastructures such as AWS Lambda, Azure Functions and Google Cloud Functions which provide auto-scaling, high elasticity and fine-grained billing, are seeing increasing adoption across many application types. However, the key barrier for Snowflake to transition to existing serverless infrastructures is their lack of support for isolation, both in terms of security and performance [34]. Snowflake serves several customers who store and query sensitive and confidential data, and thus require strong isolation guarantees. One possibility for Snowflake is to build its own custom serverless-like compute platform. We believe this is an intriguing direction to explore, but will require resolving several challenges in efficient remote ephemeral storage access (§4.1), and in multi-tenant resource sharing (which we will discuss in §7).

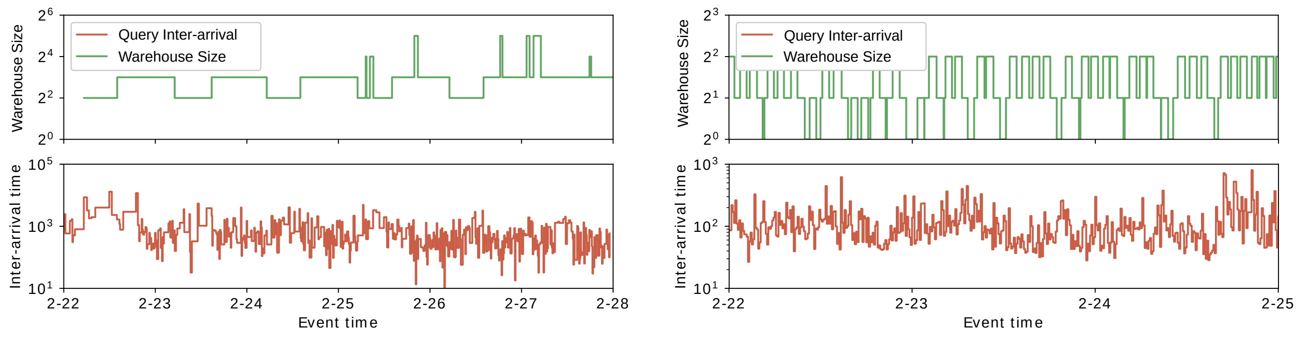

Figure 9: **Comparison of VW resizing (elastic scaling) and query inter-arrival times, binned per minute, for two heavily utilized VW1 (left) and VW2 (right).** Customers request VW resizing at much coarser grained timescales than query inter-arrival times for both VW. Note the difference in x-axis: 7 days and 4 days for VW1 and VW2, respectively.

7 Multi-tenancy

Snowflake currently supports multi-tenancy through the VW abstraction. Each VW operates on an isolated set of nodes, with its own ephemeral storage system. This allows Snowflake to provide performance isolation to its customers. In this section, we present a few system-wide characteristics for our VWs and use these to motivate an alternate sharing based architecture for Snowflake.

The VW architecture in Snowflake leads to the traditional performance isolation versus utilization tradeoff. Figure 10 (top four) show that our VWs achieve fairly good, but not ideal, average CPU utilization; however, other resources are usually underutilized on an average. Figure 11 provides some reasons for the low average resource utilization in Figure 10 (top four): the figure shows the variability of resource usage across VW; specifically, we observe that for up to 30% of VW, standard deviation of CPU usage over time is as large as the mean itself. This results in underutilization as customers tend to provision VWs to meet peak demand. In terms of peak utilization, several of our VWs experience periods of heavy utilization, but such high-utilization periods are not necessarily synchronized across VWs. An example of this is shown in Figure 10 (bottom two), where we see that over a period of two hours, there are several points when one VW's utilization is high while the other VW's utilization is simultaneously low.

While we were aware of this performance isolation versus utilization tradeoff when we designed Snowflake, recent trends are pushing us to revisit this design choice. Specifically, maintaining a pool of pre-warmed instances was cost-efficient when infrastructure providers used to charge at an hourly granularity; however, recent move to per-second pricing [6] by all major cloud infrastructure providers has raised interesting challenges. From our (provider's) perspective, we would like to exploit this finer-grained pricing model to cut down operational costs. However doing so is not straightforward, as this trend has also led to an increase in customer-demand for finer-grained pricing. As a result, maintaining a pre-warmed pool of nodes for elasticity is no longer cost-effective: previously in the hourly billing model, as long as at least one customer VW used a particular node during a one hour duration, we could charge that customer for the entire duration. However, with per-second billing, we cannot charge unused cycles on pre-warmed nodes to any particular customer. This cost-inefficiency makes a strong case for moving to a sharing based model, where compute and ephemeral storage resources are shared across customers: in such a model we can provide elasticity by statistically multiplexing customer demands across a shared set of resources, avoiding the need to maintain a large pool of pre-warmed nodes. In the next subsection, we highlight several technical challenges that need to be resolved to realize such a shared architecture.

7.1 Resource Sharing

The variability in resource usage over time across VW, as shown in Figure 11, indicates that several of our customer workloads are bursty in nature. Hence, moving to a shared architecture would enable Snowflake to achieve better resource utilization via fine-grained statistical multiplexing. Snowflake today exposes VW sizes to customers in abstract "T-shirt" sizes (small, large, XL etc.), each representing different resource capacities. Customers are not aware of how these VWs are implemented (no. of nodes used, instance types, etc.). Ideally we would like to maintain the same abstract VW interface to customers and change the underlying implementation to use shared resources instead of isolated nodes.

The challenge, however, is to achieve isolation properties close to our current architecture. The key metric of interest from customers' point of view is query performance, that is, end-to-end query completion times. While a purely shared architecture is likely to provide good average-case performance, maintaining good performance at tail is challenging. The two key resources that need to be isolated in VWs are compute and ephemeral storage. There has been a lot of work [18, 35, 36] on compute isolation in the data center context,

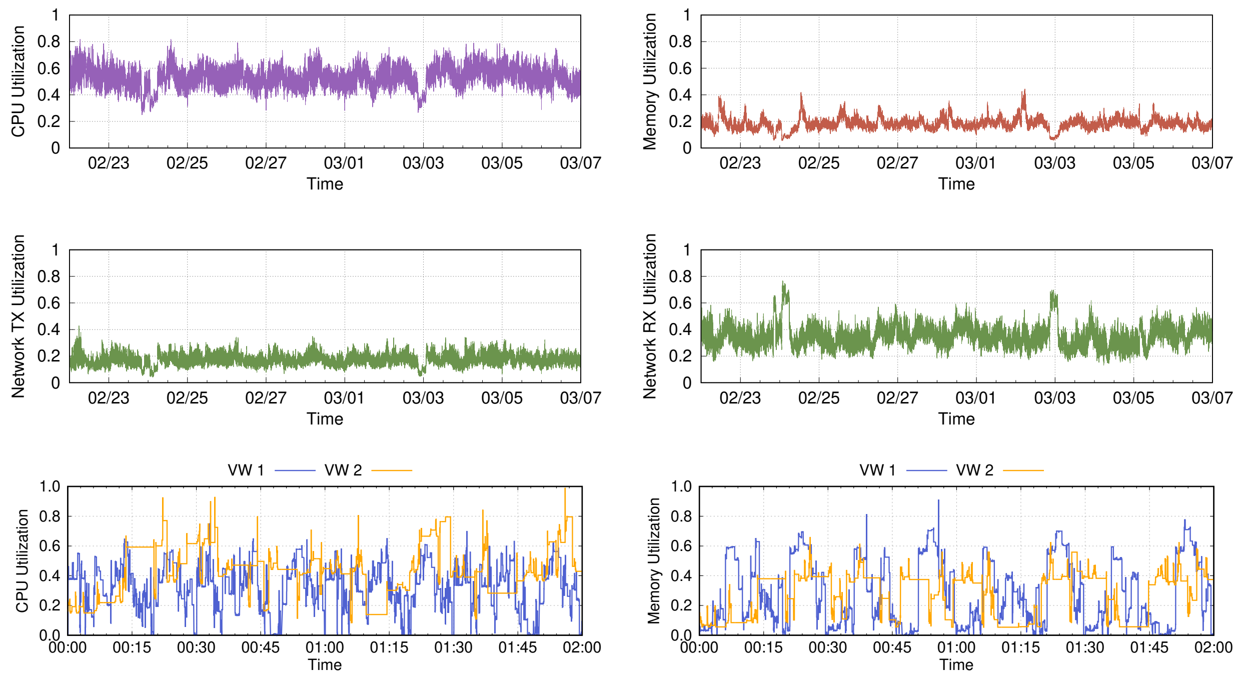

Figure 10: **System-wide CPU, Memory, and Network TX/RX utilization over time, averaged across all VWs. (top four)**. Average CPU, Memory, Network TX and Network RX utilizations are roughly 51%, 19%, 11%, 32%, respectively, indicating that there is significant room for improvement. **(bottom two)** zoomed-in CPU and Memory utilization for two highly active VW over a 2 hour duration. At several points, we see that one of the warehouses experiences high utilization while the other sees low utilization.

that Snowflake could leverage. Moreover, the centralized task scheduler and uniform execution runtime in Snowflake make the problem easier than that of isolating compute in general purpose clusters. Here, we instead focus on the problem of isolating memory and storage, which has only recently started to receive attention in the research community [25].

The goal here is to design a shared ephemeral storage system (using both memory and SSDs) that supports fine-grained elasticity without sacrificing isolation properties across tenants. With respect to sharing and isolation of ephemeral storage, we outline two key challenges. First, since our ephemeral storage system multiplexes both cached persistent data and intermediate data, both of these entities need to be jointly shared while ensuring cross-tenant isolation. While Snowflake could leverage techniques from existing literature [11, 26] for sharing cache, we need a mechanism that is additionally aware of the co-existence of intermediate data. Unfortunately, predicting the effective lifetime of cache entries is difficult. Evicting idle cache entries from tenants and providing them to other tenants while ensuring hard isolation is not possible, as we cannot predict when a tenant will next access the cache entry. Some past works [11, 33] have used techniques like idle-memory taxation to deal with this issue. We believe there is more work to be done, both in defining more reasonable isolation guarantees and designing lifetime-aware cache sharing mechanisms that can provide such guarantees.

The second challenge is that of achieving elasticity without cross-tenant interference: scaling up the shared ephemeral storage system capacity in order to meet the demands of a particular customer should not impact other tenants sharing the system. For example, if we were to naïvely use Snowflake's current ephemeral storage system, isolation properties will be trivially violated. Since all cache entries in Snowflake are consistently hashed onto the same global address space, scaling up the ephemeral storage system capacity would end up triggering the lazy consistent hashing mechanism for all tenants. This may result in multiple tenants seeing increased cache misses, resulting in degraded performance. Resolving this challenge would require the ephemeral storage system to provide private address spaces to each individual tenant, and upon scaling of resources, to reorganize data only for those tenants that have been allocated additional resources.

Memory Disaggregation. Average memory utilization in our VWs is low (Figure 10); this is particularly concerning since DRAM is expensive. Although sharing resource sharing would improve CPU and memory utilization, it is unlikely to lead to optimal utilization across both dimensions. Further, variability characteristics of CPU and memory are significantly different (Figure 11), indicating the need for independent scaling of these resources. Memory disaggregation [1, 14, 15] provides a fundamental solution to this problem. However, as discussed in §4.2, accurately provisioning re-

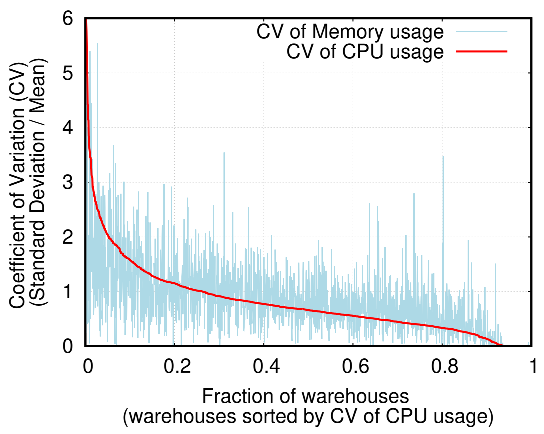

Figure 11: **Coefficient of Variation (CV) of CPU and memory usage over time, across customer VWs.** We see significant variability with respect to both resources.

sources is hard; since over-provisioning memory is expensive, we need efficient mechanisms to share disaggregated memory across multiple tenants while providing isolation guarantees.

8 Related Work

In this section we discuss related work and other systems similar to Snowflake. Our previous work [12] discusses SQL-related aspects of Snowflake and presents related literature on those aspects. This paper focuses on the disaggregation, ephemeral storage, caching, task scheduling, elasticity and multi-tenancy aspects of Snowflake; in the related work discussion below, we primarily focus on these aspects.

SQL-as-a-Service systems. There are several other systems that offer SQL functionality as a service in the cloud. These include Amazon Redshift [16], Aurora [4], Athena [3], Google BigQuery [30] and Microsoft Azure Synapse Analytics [24]. While there are papers that describe the design and operational experience of some of these systems, we are not aware of any prior work that undertakes a data-driven analysis of workload and system characteristics similar to ours.

Redshift [16] stores primary replicas of persistent data within compute VM clusters (S3 is only used for backup); thus, it may not be able to achieve the benefits that Snowflake achieves by decoupling compute from persistent storage. Aurora [4] and BigQuery [30] (based on the architecture of Dremel [23]) decouple compute and persistent storage similar to Snowflake. Aurora, however, relies on a custom-designed persistent storage service that is capable of offloading database log processing, instead of a traditional blob store. We are not aware of any published work that describes how BigQuery handles elasticity and multi-tenancy.

Decoupling compute and ephemeral storage systems. Previous work [20] makes the case for flash storage disaggregation by studying a key-value store workload from Facebook. Our observations corroborate this argument and further extend it in the context of data warehousing workloads. Pocket [22] and Locus [27] are ephemeral storage systems designed for serverless analytics applications. If we were to disaggregate compute and ephemeral storage in Snowflake, such systems would be good candidates. However, these systems do not provide fine-grained resource elasticity during the lifetime of a query. Thus, they either have to assume a priori knowledge of intermediate data sizes (for provisioning resources at the time of submitting queries), or suffer from performance degradation if such knowledge is not available in advance. As discussed in §4.1, predicting intermediate data sizes is extremely hard. It would be nice to extend these systems to provide fine-grained elasticity and cross-query isolation. Technologies for high performance access to remote flash storage [13, 17, 21] would also be integral to efficiently realize decoupling of compute and ephemeral storage system.

Multi-tenant resource sharing. ESX server [33] pioneered techniques for multi-tenant memory sharing in the virtual machine context, including ballooning and idle-memory taxation. Memshare [11] considers multi-tenant sharing of cache capacity in DRAM caches in the single machine context, sharing un-reserved capacity among applications in a way that maximizes hit rate. FairRide [26] similarly considers multi-tenant cache sharing in the distributed setting while taking into account sharing of data between tenants. Mechanisms for sharing and isolation of cache resources similar to the ones used in these works would be important in enabling Snowflake to adopt a resource shared architecture. As discussed previously, it would be interesting to extend these mechanisms to make them aware of the different characteristics and requirements of intermediate and persistent data.

9 Conclusion

We have presented operational experience running *Snowflake*, a data warehousing system with state-of-the-art SQL support. The key design and implementation aspects that we have covered in the paper relate to how Snowflake achieves compute and storage elasticity, as well as high-performance in a multi-tenancy setting. As Snowflake has grown to serve thousands of customers executing millions of queries on petabytes of data every day, we consider ourselves at least partially successful. However, using data collected from various components of our system during execution of $\sim$70 million queries over a 14 day period, our study highlights some of the shortcomings of our current design and implementation and highlights new research challenges that may be of interest to the broader systems and networking communities.

Millions of Tiny Databases

Fan Ping
Amazon Web Services

Abstract

Starting in 2013, we set out to build a new database to act as the configuration store for a high-performance cloud block storage system (Amazon EBS).This database needs to be not only highly available, durable, and scalable but also strongly consistent. We quickly realized that the constraints on availability imposed by the CAP theorem, and the realities of operating distributed systems, meant that we didn't want one database. We wanted millions. Physalia is a transactional key-value store, optimized for use in large-scale cloud control planes, which takes advantage of knowledge of transaction patterns and infrastructure design to offer both high availability and strong consistency to millions of clients. Physalia uses its knowledge of datacenter topology to place data where it is most likely to be available. Instead of being highly available for all keys to all clients, Physalia focuses on being extremely available for only the keys it knows each client needs, from the perspective of that client.

This paper describes Physalia in context of Amazon EBS, and some other uses within Amazon Web Services. We believe that the same patterns, and approach to design, are widely applicable to distributed systems problems like control planes, configuration management, and service discovery.

1 Introduction

Traditional architectures for highly-available systems assume that infrastructure failures are statistically independent, and that it is extremely unlikely for a large number of servers to fail at the same time. Most modern system designs are aware of broad failure domains (data centers or availability zones), but still assume two modes of failure: a complete failure of a datacenter, or a random uncorrelated failure of a server, disk or other infrastructure. These assumptions are reasonable for most kinds of systems. Schroder and Gibson found [51] that (in traditional datacenter environments), while the probability of a second disk failure in a week was up to 9x higher when a first failure had already occurred, this correlation drops off to less than 1.5x as systems age. While a 9x higher failure rate within the following week indicates some correlation, it is still very rare for two disks to fail at the same time. This is just as well, because systems like RAID [43] and primary-backup failover perform well when failures are independent, but poorly when failures occur in bursts.

When we started building AWS in 2006, we measured the availability of systems as a simple percentage of the time that the system is available (such as 99.95%), and set Service Level Agreements (SLAs) and internal goals around this percentage. In 2008, we introduced AWS EC2 Availability Zones: named units of capacity with clear expectations and SLAs around correlated failure, corresponding to the datacenters that customers were already familiar with. Over the decade since, our thinking on failure and availability has continued to evolve, and we paid increasing attention to *blast radius* and correlation of failure. Not only do we work to make outages rare and short, we work to reduce the number of resources and customers that they affect [55], an approach we call *blast radius reduction*. This philosophy is reflected in everything from the size of our datacenters [30], to the design of our services, to operational practices.

Amazon Elastic Block Storage (EBS) is a block storage service for use with AWS EC2, allowing customers to create block devices on demand and attach them to their AWS EC2 instances. volumes are designed for an annual failure rate (AFR) of between 0.1% and 0.2%, where failure refers to a complete or partial loss of the volume. This is significantly lower than the AFR of typical disk drives [44]. EBS achieves this higher durability through replication, implementing a chain replication scheme (similar to the one described by van Renesse, et al [54]). Figure 1 shows an abstracted, simplified, architecture of EBS in context of AWS EC2. In normal operation (of this simplified model), replicated data flows through the chain from client, to primary, to replica, with no need for coordination. When failures occur, such as the failure of the primary server, this scheme requires the services of a *configuration master*, which ensures that updates to the order and membership of the replication group occur atomically, are

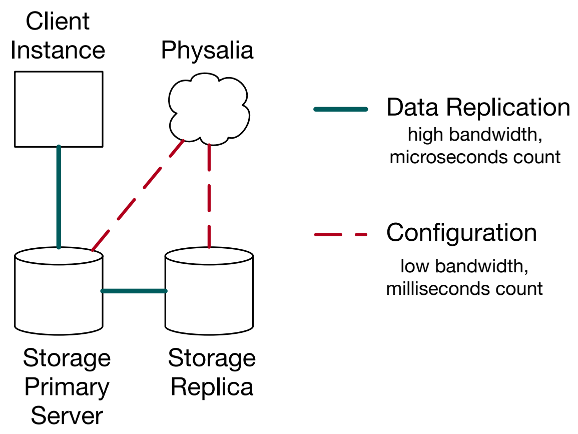

Figure 1: Simplified model of one EBS volume connected to an AWS EC2 instance. For the volume to be available for IO, either both the master and replica, or either storage server and Physalia, must be available to the instance.

well ordered, and follow the rules needed to ensure durability.

The requirements on this *configuration master* are unusual. In normal operation it handles little traffic, as replication continues to operate with no need to contact the *configuration master*. However, when large-scale failures (such as power failures or network partitions) happen, a large number of servers can go offline at once, requiring the *master* to do a burst of work. This work is latency critical, because volume IO is blocked until it is complete. It requires strong consistency, because any eventual consistency would make the replication protocol incorrect. It is also most critical at the most challenging time: during large-scale failures.

Physalia is a specialized database designed to play this role in EBS, and other similar systems at Amazon Web Services. Physalia offers both consistency and high availability, even in the presence of network partitions, as well as minimized blast radius of failures. It aims to fail gracefully and partially, and strongly avoid large-scale failures.

1.1 History

On 21 April 2011, an incorrectly executed network configuration change triggered a condition which caused 13% of the EBS volumes in a single Availability Zone (AZ) to become unavailable. At that time, replication configuration was stored in the EBS control plane, sharing a database with API traffic. From the public postmortem [46]:

> When data for a volume needs to be re-mirrored, a negotiation must take place between the AWS EC2 instance, the EBS nodes with the volume data, and the EBS control plane (which acts as an authority in this process) so that only one copy of the data is designated as the primary replica and recognized by the AWS EC2 instance as the place where all accesses should be sent. This provides strong consistency of EBS volumes. As more EBS nodes continued to fail because of the race condition described above, the volume of such negotiations with the EBS control plane increased. Because data was not being successfully re-mirrored, the number of these calls increased as the system retried and new requests came in. The load caused a brown out of the EBS control plane and again affected EBS APIs across the Region.

This failure vector was the inspiration behind Physalia's design goal of limiting the *blast radius* of failures, including overload, software bugs, and infrastructure failures.

1.2 Consistency, Availability and Partition Tolerance

As proven by Gilbert and Lynch [22], it is not possible for a distributed system to offer both strong consistency (in the sense of linearizability [31]), and be available to all clients in the presence of network partitions. Unfortunately, all real-world distributed systems must operate in the presence of network partitions [6], so systems must choose between strong consistency and availability. Strong consistency is non-negotiable in Physalia, because it's required to ensure the correctness of the EBS replication protocol. However, because chain replication requires a configuration change during network partitions, it is especially important for Physalia to be available during partitions.

Physalia then has the goal of optimizing for availability during network partitions, while remaining strongly consistent. Our core observation is that we do not require all keys to be available to all clients. In fact, each key needs to be available at only three points in the network: the AWS EC2 instance that is the client of the volume, the primary copy, and the replica copy. Through careful placement, based on our system's knowledge of network and power topology, we can significantly increase the probability that Physalia is available to the clients that matter for the keys that matter to those clients.

This is Physalia's key contribution, and our motivation for building a new system from the ground up: infrastructure aware placement and careful system design can significantly reduce the effect of network partitions, infrastructure failures, and even software bugs. In the same spirit as Paxos Made Live [12], this paper describes the details, choices and tradeoffs that are required to put a consensus system into production. Our concerns, notably blast radius reduction and infrastructure awareness, are significantly different from that paper.

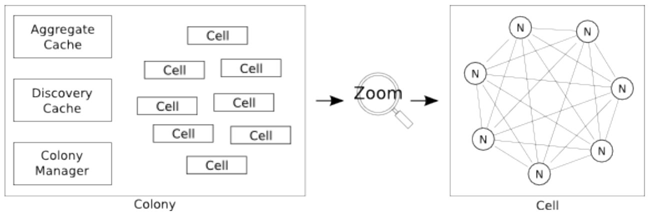

Figure 2: Overview of the relationship between the colony, cell and node.

2 The Design of Physalia

Physalia's goals of blast radius reduction and partition tolerance required careful attention in the design of the data model, replication mechanism, cluster management and even operational and deployment procedures. In addition to these top-level design goals, we wanted Physalia to be easy and cheap to operate, contributing negligibly to the cost of our dataplane. We wanted its data model to be flexible enough to meet future uses in similar problem spaces, and to be easy to use correctly. This goal was inspired by the concept of *misuse resistance* from cryptography (GCM-SIV [27], for example), which aims to make primitives that are safer under misuse. Finally, we wanted Physalia to be highly scalable, able to support an entire EBS availability zone in a single installation.

2.1 Nodes, Cells and the Colony

The Portuguese man o' war (*Physalia physalis*) is not one animal, but a siphonophore: a colonial organism made up of many specialized animals called zooids. These zooids are highly adapted to living in the colony, and cannot live outside it. Nevertheless, each zooid is a stand-alone organism, including everything that is required for life. Physalia's high-level organization is similar: each Physalia installation is a *colony*, made up of many *cells*. The *cells* live in the same environment: a mesh of *nodes*, with each node running on a single server. Each *cell* manages the data of a single partition key, and is implemented using a distributed state machine, distributed across seven nodes. Cells do not coordinate with other cells, but each node can participate in many cells. The colony, in turn, can consist of any number of cells (provided there are sufficient nodes to distribute those cells over). Figure 2 captures the relationship between colony, cell and node. Figure 3 shows the cell: a mesh of nodes holding a single Paxos-based distributed state machine, with one of the nodes playing the role of *distinguished proposer*.

The division of a colony into a large number of cells is our main tool for reducing radius in Physalia. Each node is only used by a small subset of cells, and each cell is only used by a small subset of clients.

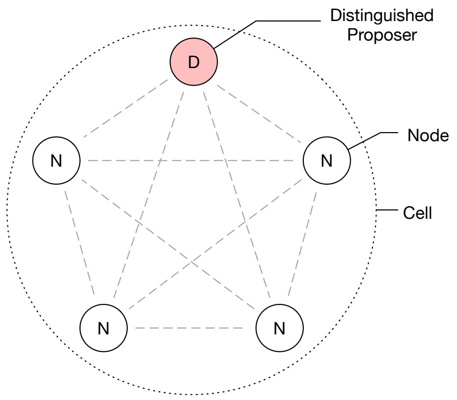

Figure 3: A cell is a group of nodes, one of which assumes the role of distinguished proposer.

Each Physalia colony includes a number of control plane components. The control plane plays a critical role in maintaining system properties. When a new cell is created, the control plane uses its knowledge of the power and network topology of the datacenter (discovered from AWS's datacenter automation systems) to choose a set of nodes for the cell. The choice of nodes balances two competing priorities. Nodes should be placed close to the clients (where *close* is measured in logical distance through the network and power topology) to ensure that failures *far away* from their clients do not cause the cell to fail. They must also be placed with sufficient diversity to ensure that small-scale failures do not cause the cell to fail. Section 3 explores the details of placement's role in availability.

The cell creation and repair workflows respond to requests to create new cells (by placing them on under-full nodes), handling cells that contain failed nodes (by replacing these nodes), and moving cells closer to their clients as clients move (by incrementally replacing nodes with closer ones).

We could have avoided implementing a seperate control-plane and repair workflow for Physalia, by following the example of elastic replication [2] or Scatter [23]. We evaluated these approaches, but decided that the additional complexity, and additional communication and dependencies between shards, were at odds with our focus on blast radius. We chose to keep our cells completely independent, and implement the control plane as a seperate system.

2.2 Physalia's Flavor of Paxos

The design of each cell is a straightforward consensus-based distributed state machine. Cells use Paxos [35] to create an ordered log of updates, with batching and pipelining [48] to improve throughput. Batch sizes and pipeline depths are kept small, to keep per-item work well bounded and ensure short time-to-recovery in the event of node or network failure. Physalia uses a custom implementation of Paxos written

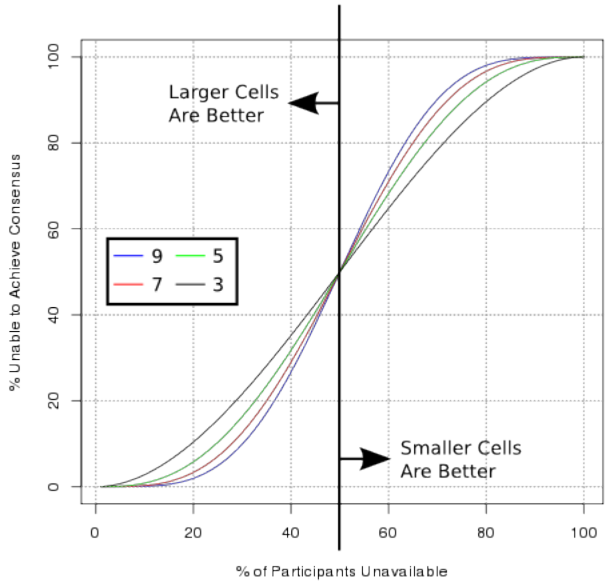

Figure 4: The size of cells is a trade-off between tolerance to large correlated failures and tolerance to random failures.

in Java, which keeps all required state both in memory and persisted to disk. In typical cloud systems, durability is made easier by the fact that systems can be spread across multiple datacenters, and correlated outages across datacenters are rare. Physalia's locality requirement meant that we could not use this approach, so extra care in implementation and testing were required to ensure that Paxos is implemented safely, even across dirty reboots.

In the EBS installation of Physalia, the cell performs Paxos over seven nodes. Seven was chosen to balance several concerns:

- *Durability* improves exponentially with larger cell size [29]. Seven replicas means that each piece of data is durable to at least four disks, offering durability around 5000x higher than the 2-replication used for the volume data.

- Cell size has little impact on mean *latency*, but larger cells tend to have lower high percentiles because they better reject the effects of slow nodes, such as those experiencing GC pauses [17].

- The effect of cell size on *availability* depends on the type of failures expected. As illustrated in Figure 4, smaller cells offer lower availability in the face of small numbers of uncorrelated node failures, but better availability when the proportion of node failure exceeds 50%. While such high failure rates are rare, they do happen in practice, and a key design concern for Physalia.

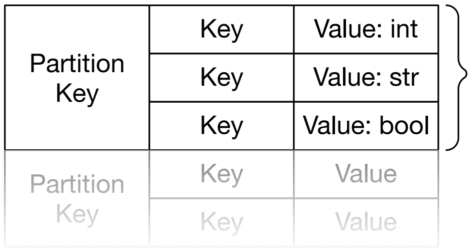

Figure 5: The Physalia schema.

- Larger cells consume more resources, both because Paxos requires $O(\text{cellsize})$ communication, but also because a larger cell needs to keep more copies of the data. The relatively small transaction rate, and very small data, stored by the EBS use of Physalia made this a minor concern.

The control plane tries to ensure that each node contains a different mix of cells, which reduces the probability of correlated failure due to load or poison pill transitions. In other words, if a poisonous transition crashes the node software on each node in the cell, only that cell should be lost. In the EBS deployment of Physalia, we deploy it to large numbers of nodes well-distributed across the datacenter. This gives the Physalia control plane more placement options, allowing it to optimize for widely-spread placement.

In our Paxos implementation, proposals are accepted optimistically. All transactions given to the proposer are proposed, and at the time they are to be applied (i.e. all transactions with lower log positions have already been applied), they are committed or ignored depending on whether the write conditions pass. The advantage of this optimistic approach is that the system always makes progress if clients follow the typical optimistic concurrency control (OCC) pattern. The disadvantage is that the system may do significant additional work during contention, passing many proposals that are never committed.

2.3 Data Model and API

The core of the Physalia data model is a partition key. Each EBS volume is assigned a unique partition key at creation time, and all operations for that volume occur within that partition key. Within each partition key, Physalia offers a transactional store with a typed key-value schema, supporting strict serializable reads, writes and conditional writes over any combination of keys. It also supports simple in-place operations like atomic increments of integer variables. Figure 5 shows the schema: one layer of partition keys, any number (within operational limitations) of string keys within a partition, and one value per key. The API can address only one partition key at a time, and offers strict serializable batch and conditional operations within the partition.

The goal of the Physalia API design was to balance two competing concerns. The API needed to be expressive enough for clients to take advantage of the (per-cell) transactional nature of the underlying store, including expressing conditional updates, and atomic batch reads and writes. Increasing API expressiveness, on the other hand, increases the probability that the system will be able to accept a transition that cannot be applied (a poison pill). The Physalia API is inspired by the Amazon DynamoDB API, which supports atomic batched and single reads and writes, conditional updates, paged scans, and some simple in-place operations like atomic increments. We extended the API by adding a compound read-and-conditional-write operation.

Phsyalia's data fields are strong but dynamically typed. Supported field types include byte arrays (typically used to store UTF-8 string data), arbitrary precision integers, and booleans. Strings are not supported directly, but may be offered as a convenience in the client. Floating-point data types and limited-precision integers are not supported due to difficulties in ensuring that nodes will produce identical results when using different software versions and hardware (see [24] and chapter 11 of [1]). As in any distributed state machine, it's important that each node in a cell gets identical results when applying a transition. We chose not to offer a richer API (like SQL) for a similar reason: our experience is that it takes considerable effort to ensure that complex updates are applied the same way by all nodes, across all software versions.

Physalia provides two consistency modes to clients. In the consistent mode, read and write transactions are both linearizable and serializable, due to being serialized through the state machine log. Most Physalia clients use this consistent mode. The eventually consistent mode supports only reads (all writes are consistent), and offers a consistent prefix [7] to all readers and monotonic reads [53] within a single client session. Eventually consistent reads are provided to be used for monitoring and reporting (where the extra cost of linearizing reads worth it), and the discovery cache (which is eventually consistent anyway).

The API also offers first-class leases [25] (lightweight time-bounded locks). The lease implementation is designed to tolerate arbitrary clock skew and short pauses, but will give incorrect results if long-term clock rates are too different. In our implementation, this means that the fastest node clock is advancing at more than three times the rate of the slowest clock. Despite lease safety being highly likely, leases are only used where they are not critical for data safety or integrity.

In the Physalia API, all keys used to read and write data, as well as conditions for conditional writes, are provided in the input transaction. This allows the proposer to efficiently detect which changes can be safely batched in a single transaction without changing their semantics. When a batch transaction is rejected, for example due to a conditional put failure, the proposer can remove the offending change from the batch and re-submit, or submit those changes without batching.

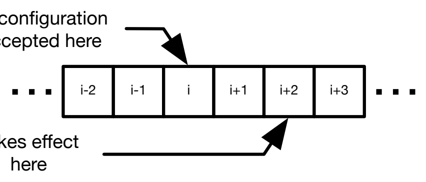

Figure 6: Changes in membership are placed into the log, but only take effect some time later (pictured here is $\alpha = 2$)

2.4 Reconfiguration, Teaching and Learning

As with our core consensus implementation, Physalia does not innovate on reconfiguration. The approach taken of storing per-cell configuration in the distributed state machine and passing a transition with the existing jury to update it follows the pattern established by Lampson [37]. A significant factor in the complexity of reconfiguration is the interaction with pipelining: configuration changes accepted at log position i must not take effect logically until position $i+\alpha$, where α is the maximum allowed pipeline length (illustrated in Figure 6). Physalia keeps α small (typically 3), and so simply waits for natural traffic to cause reconfiguration to take effect (rather than stuffing no-ops into the log). This is a very sharp edge in Paxos, which doesn't exist in either Raft [42] or Viewstamped Replication [41].

Physalia is unusual in that reconfiguration happens frequently. The colony-level control plane actively moves Physalia cells to be close to their clients. It does this by replacing far-away nodes with close nodes using reconfiguration. The small data sizes in Physalia make cell reconfiguration an insignificant portion of overall datacenter traffic. Figure 7 illustrates this process of movement by iterative reconfiguration. The system prefers safety over speed, moving a single node at a time (and waiting for that node to catch up) to minimize the impact on durability. The small size of the data in each cell allows reconfiguration to complete quickly, typically allowing movement to complete within a minute.

When nodes join or re-join a cell they are brought up to speed by *teaching*, a process we implement outside the core consensus protocol. We support three modes of teaching. In the bulk mode, most suitable for new nodes, the teacher (any existing node in the cell) transfers a bulk snapshot of its state machine to the learner. In the log-based mode, most suitable for nodes re-joining after a partition or pause, the teacher ships a segment of its log to the learner. We have found that this mode is triggered rather frequently in production, due to nodes temporarily falling behind during Java garbage collection pauses. Log-based learning is chosen when the size of the missing log segment is significantly smaller than the size of the entire dataset.

Finally, packet loss and node failures may leave persistent holes in a node's view of the log. If nodes are not able to find

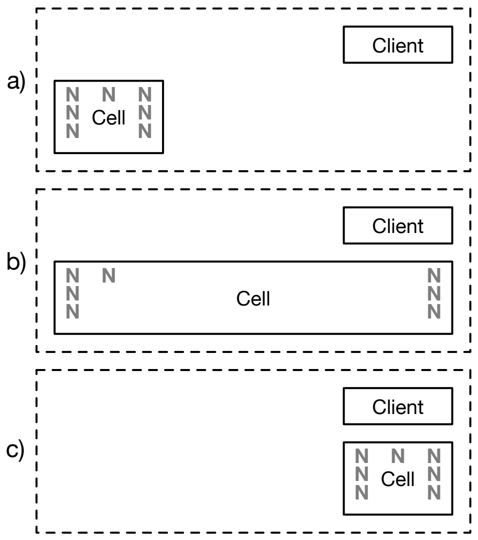

Figure 7: When Physalia detects that a cell's client has moved (a), it replaces nodes in the cell with ones closer to the client (b), until the cell is entirely nearby the client (c).

another to teach them the decided value in that log position (or no value has been decided), they use a whack-a-mole learning mode. In whack-a-mole mode, a learner actively tries to propose a no-op transition into the vacant log position. This can have two outcomes: either the acceptors report no other proposals for that log position and the no-op transition is accepted, or another proposal is found and the learner proposes that value. This process is always safe in Paxos, but can affect liveness, so learners apply substantial jitter to whack-a-mole learning.

2.5 The Discovery Cache

Clients find cells using a distributed *discovery cache*. The *discovery cache* is a distributed eventually-consistent cache which allow clients to discover which nodes contain a given cell (and hence a given partition key). Each cell periodically pushes updates to the cache identifying which partition key they hold and their node members. Incorrect information in the cache affects the liveness, but never the correctness, of the system. We use three approaches to reduce the impact of the *discovery cache* on availability: client-side caching, forwarding pointers, and replication. First, it is always safe for a client to cache past discovery cache results, allowing them to refresh lazily and continue to use old values for an unbounded period on failure. Second, Physalia nodes keep long-term (but not indefinite) forwarding pointers when cells move from node to node. Forwarding pointers include pointers to all the nodes in a cell, making it highly likely that a client will succeed in pointer chasing to the current owner provided that it can get to at least one of the past owners. Finally, because the discovery cache is small, we can economically keep many copies of it, increasing the probability that at least one will be available.

2.6 System Model and Byzantine Faults

In designing Physalia, we assumed a system model where messages can be arbitrarily lost, replayed, re-ordered, and modified after transmission. Message authentication is implemented using a cryptographic HMAC on each message, guarding against corruption occurring in lower layers. Messages which fail authentication are simply discarded. Key distribution, used both for authentication and prevention of unintentional Sybil-style attacks [20] is handled by our environment (and therefore out of the scope of Physalia), optimising for frequent and low-risk key rotation.

This model extends the "benign faults" assumptions of Paxos [11] slightly, but stops short of Byzantine fault tolerance[1]. While Byztantine consensus protocols are well understood, they add significant complexity to both software and system interactions, as well as testing surface area. Our approach was to keep the software and protocols simpler, and mitigate issues such as network and storage corruption with cryptographic integrity and authentication checks at these layers.

3 Availability in Consensus Systems

State-machine replication using consensus is popular approach for building systems that tolerate faults in single machines, and uncorrelated failures of a small number of machines. In theory, systems built using this pattern can achieve extremely high availability. In practice, however, achieving high availability is challenging. Studies across three decades (including Gray in 1990 [26], Schroeder and Gibson in 2005 [50] and Yuan et al in 2014 [57]) have found that software, operations, and scale drive downtime in systems designed to tolerate hardware faults. Few studies consider a factor that is especially important to cloud customers: large-scale correlated failures which affect many cloud resources at the same time.

3.1 Physalia vs the Monolith

It is well known that it is not possible to offer both all-clients availability and consistency in distributed databases due to the presence of network partitions. It is, however, possible to offer both consistency and availability to clients on the majority side of a network partition. While long-lived network partitions are rare in modern datacenter networks, they do occur, both due to the network itself and other factors (see Bailis and Kingsbury [6] and Alquraan et al [5] for surveys of

[1]This approach is typical of production consensus-based systems, including popular open-source projects like Zookeeper and etcd

causes of network partitions). Short-lived partitions are more frequent. To be as available as possible to its clients, Physalia needs to be on the same side of any network partition as them. For latency and throughput reasons, EBS tries to keep the storage replicas of a volume close to the AWS EC2 instances the volumes are attached to, both in physical distance and network distance. This means that client, data master and data replica are nearby each other on the network, and Physalia needs to be nearby too. Reducing the number of network devices between the Physalia database and its clients reduces the possibility of a network partition forming between them for the simple reason that fewer devices means that there's less to go wrong.

Physalia also optimizes for blast radius. We are not only concerned with the availability of the whole system, but want to avoid failures of the whole system entirely. When failures happen, due to any cause, they should affect as small a subset of clients as possible. Limiting the number of cells depending on a single node, and clients on a single cell, significantly reduce the effect that one failure can have on the overall system.

This raises the obvious question: does Physalia do better than a monolithic system with the same level of redundancy? A monolithic system has the advantage of less complexity. No need for the discovery cache, most of the control plane, cell creation, placement, etc. Our experience has shown that simplicity improves availability, so this simplification would be a boon. On the other hand, the monolithic approach loses out on partition tolerance. It needs to make a trade-off between being localized to a small part of the network (and so risking being partitioned away from clients), or being spread over the network (and so risking suffering an internal partition making some part of it unavailable). The monolith also increases blast radius: a single bad software deployment could cause a complete failure (this is similar to the node count trade-off of Figure 4, with one node).

3.2 Placement For Availability

The EBS control plane (of which the Physalia control plane is a part) continuously optimizes the availability of the EBS volume $P(A_{\mathrm{v}})$ to the client AWS EC2 instance, and the EBS storage servers that store the volume. This is most interesting to do when the client instance is available. If the volume is unavailable at the same time as the client instance, we know that the instance will not be trying to access it. In other words, in terms of the availability of the volume (A_{v}), and the instance (A_{i}), the control plane optimizes the conditional probability $P(A_{\mathrm{v}}|A_{\mathrm{i}})$. The ideal solution to this problem is to entirely co-locate the volume and instance, but EBS offers the ability to detach a volume from a failed instance, and re-attach it to another instance. To make this useful, volumes must continue to be durable even if the instance suffers a failure. Placement must therefore balance the concerns of having the volume close enough for correlated availability, but far enough away for sufficiently independent durability to meet EBS's durability promise.

As an example, consider an idealized datacenter with three levels of network (servers, racks and rows) and three power domains (A, B and C). The client instance is on one rack, the primary copy on another, and replica copy on a third, all within the same row. Physalia's placement will then ensure that all nodes for the cell are within the row (there's no point being available if the row is down), but spread across at least three racks to ensure that the loss of one rack doesn't impact availability. It will also ensure that the nodes are in three different power domains, with no majority in any single domain.

This simple scheme faces two challenges. One is that real-world datacenter topology is significantly more complex, especially where datacenters contain multiple generations of design and layout. Another is that EBS volumes move by replication, and their clients move by customers detaching their volumes from one instance and attaching them to another. The Physalia control plane continuously responds to these changes in state, moving nodes to ensure that placement constraints continue to be met.

3.3 Non-Infrastructure Availability Concerns

Another significant challenge with building high-availability distributed state machines is correlated work. In a typical distributed state machine design, each node is processing the same updates and the same messages in the same order. This leads the software on the machines to be in the same state. In our experience, this is a common cause of outages in real-world systems: redundancy does not add availability if failures are highly correlated. Having all copies of the software in the same state tends to trigger the same bugs in each copy at the same time, causing multiple nodes to fail, either partially or completely, at the same time. Another issue is that the correlated loads cause memory, hard drives, and other storage on each host to fill up at the same rate. Again, this causes correlated outages when each host has the same amount of storage. Poison pill transactions may also cause outages; these are transactions that are accepted by the cell but cannot be applied to the state machine once consensus is reached.

Software deployments and configuration changes also contribute to downtime. Good software development practices, including code review and automated and manual testing, can reduce the risk of software changes but not entirely eliminate it. Incremental deployment, where code is rolled out slowly across the fleet and rolled back at the first sign of trouble, is a required operational practice for highly available systems. The fault-tolerant nature of distributed state machines makes this approach less effective: because the system is designed to tolerate failure in less than half of hosts, failure may not be evident until new code is deployed to half of all hosts. Practices like positive validation, where the deployment system checks that new nodes are taking traffic, reduce but do not eliminate this risk.

Poison pills are a particularly interesting case of software failure. A poison pill is a transaction which passes validation and is accepted into the log, but cannot be applied without causing an error. Pipelining requires that transactions are validated before the state they will execute on is fully known, meaning that even simple operations like numerical division could be impossible to apply. In our experience, poison pills are typically caused by under-specification in the transaction logic (*"what does dividing by zero do?"*, *"what does it mean to decrement an unsigned zero?"*), and are fixed by fully specifying these behaviors (a change which comes with it's own backward-compatibility challenges).

All of these factors limit the availability of any single distributed state machine, as observed by its clients. To achieve maximum availability, we need many such systems spread throughout the datacenter. This was the guiding principle of Physalia: instead of one database, build millions.

3.4 Operational Practices

Our experience of running large distributed systems is that operations, including code and configuration deployments, routine system operations such as security patching, and scaling for increased load, are dominant contributors to system downtime, despite ongoing investments in reducing operational defect rates. This conclusion isn't particular to the environment at AWS. For example, Jim Gray found in 1990 that the majority of failures of Tandem computers were driven by software and operations [26]. Operational practices at AWS already separate operational tasks by region and availability zone, ensuring that operations are not performed across many of these units at the same time.

Physalia goes a step further than this practice, by introducing the notion of *colors*. Each cell is assigned a color, and each cell is constructed only of nodes of the same color. The control plane ensures that colors are evenly spread around the datacenter, and color choice minimally constrains how close a cell can be to its clients. Physalia's very large node and cell counts make this possible. When software deployments and other operations are performed, they proceed color-by-color. Monitoring and metrics are set up to look for anomalies in single colors. Colors also provide a layer of isolation against load-related and poison pill failures. Nodes of different colors don't communicate with each other, making it significantly less likely that a poison pill or overload could spread across colors.

3.5 Load in Sometimes-Coordinating Systems

Load is another leading cause of correlated failures. Fundamentally, a consensus-based system needs to include more than half of all nodes in each consensus decision, which means that overload can take out more than half of all nodes. Colors play a role in reducing the blast radius from load spikes from a few clients, but the load on Physalia is inherently spiky.

During normal operation, load consists of a low rate of calls caused by the background rate of EBS storage server failures, and creation of new cells for new volumes. During large-scale failures, however, load can increase considerably. This is an inherent risk of *sometimes-coordinating* systems like EBS: recovery load is not constant, and highest during bad network or power conditions. See Section 5.2.1 for a brief exploration of the magnitude of these spikes.

Per-cell Physalia throughput, as is typical of Paxos-style systems, scales well up to a point, with significant wins coming from increased batch efficiency. Beyond this point, however, contention and the costs of co-ordination cause goodput to drop with increased load (as predicted by Gunther's model [28]). To avoid getting into this reduced-goodput mode, cells reject load once their pipelines are full. While this isn't a perfect predictor of load, it works well because it decreases attempted throughput with increased latency (and is therefore stable in the control theory sense), and gets close to peak system throughput. Clients are expected to exponentially back off, apply jitter, and eventually retry their rejected transactions. As the number of clients in the Physalia system is bounded, this places an absolute upper limit on load, at the cost of latency during overload.

4 Testing

The challenge of testing a system like Physalia is as large as the challenge of designing and building it. Testing needs to cover not only the happy case, but also a wide variety of error cases. Our experience mirrors the findings of Yuan, et al [57] that error handling is where many bugs hide out, and Alquraan et al [5] that network partitions are rare events that easily hide bugs. As Kingsbury's Jepsen [33] testing work has found, many consensus implementations also have bugs in the happy path. Good testing needs to look everywhere. To get the coverage required, we needed to make the bar to building a new test case extremely low.

4.1 The SimWorld

To solve this problem, we picked an approach that is in wide use at Amazon Web Services, which we would like to see broadly adopted: build a test harness which abstracts networking, performance, and other systems concepts (we call it a *simworld*). The goal of this approach is to allow developers to write distributed systems tests, including tests that simulate packet loss, server failures, corruption, and other failure cases, as *unit tests* in the same language as the system itself. In this case, these *unit tests* run inside the developer's IDE (or with *junit* at build time), with no need for test clusters or other infrastructure. A typical test which tests correctness under packet loss can be implemented in less than 10 lines of Java code, and executes in less than 100ms. The Physalia team have written hundreds of such tests, far exceeding the coverage that would be practical in any cluster-based or container-based approach.

The key to building a *simworld* is to build code against abstract physical layers (such as networks, clocks, and disks). In Java we simply wrap these thin layers in interfaces. In production, the code runs against implementations that use real TCP/IP, DNS and other infrastructure. In the *simworld*, the implementations are based on in-memory implementations that can be trivially created and torn down. In turn, these in-memory implementations include rich fault-injection APIs, which allow test implementors to specify simple statements like:

```
net.partitionOff(PARTITION_NAME, p5.
    getLocalAddress());
...
net.healPartition(PARTITION_NAME);
```

Our implementation allows control down to the packet level, allowing testers to delay, duplicate or drop packets based on matching criteria. Similar capabilities are available to test disk IO. Perhaps the most important testing capability in a distributed database is time, where the framework allows each actor to have it's own view of time arbitrarily controlled by the test. Simworld tests can even add Byzantine conditions like data corruption, and operational properties like high latency. We highly recommend this testing approach, and have continued to use it for new systems we build.

4.2 Additional Testing Approaches

In addition to unit testing, we adopted a number of other testing approaches. One of those approaches was a suite of automatically-generated tests which run the Paxos implementation through every combination of packet loss and reordering that a node can experience. This testing approach was inspired by the TLC model checker [56], and helped us build confidence that our implementation matched the formal specification.

We also used the open source Jepsen tool [33] to test the system, and make sure that the API responses are linearizable under network failure cases. This testing, which happens at the infrastructure level, was a good complement to our lower-level tests as it could exercise some under-load cases that are hard to run in the *simworld*.

Finally, we performed a number of *game days* against deployments of Physalia. A game day is a failure simulation that happens in a real production or production-like deployment of a system, an approach that has been popular at Amazon for 20 years. Game days test not only the correctness of code, but also the adequacy of monitoring and logging, effectiveness of operational approaches, and the team's understanding of how to debug and fix the system. Our game day approach is similar to the chaos engineering approach pioneered by Netflix [32], but typically focuses on larger-scale failures rather than component failures.

4.3 The Role of Formal Methods

TLA+ [36] is a specification language that's well suited to building formal models of concurrent and distributed systems. We use TLA+ extensively at Amazon [39], and it proved exceptionally useful in the development of Physalia. Our team used TLA+ in three ways: writing specifications of our protocols to check that we understand them deeply, model checking specifications against correctness and liveness properties using the TLC model checker, and writing extensively commented TLA+ code to serve as the documentation of our distributed protocols. While all three of these uses added value, TLA+'s role as a sort of automatically tested (via TLC), and extremely precise, format for protocol documentation was perhaps the most useful. Our code reviews, *simworld* tests, and design meetings frequently referred back to the TLA+ models of our protocols to resolve ambiguities in Java code or written communication. We highly recommend TLA+ (and its Pluscal dialect) for this use.

One example of a property we checked using TLA+ is the safety of having stale information in the discovery cache. For correctness, it is required that a client acting on stale information couldn't cause a *split brain* by allowing a group of old nodes to form a quorum. We started with the informal argument that the reconfiguration protocol makes $f > \frac{N}{2}$ of the pre-reconfiguration nodes aware of a configuration change, and therefore aware if they have been deposed from the jury. In other words, at most $\lfloor \frac{N}{2} \rfloor$ nodes may have been deposed from the jury without being aware of the change, and because they do not form a quorum they cannot pass *split brain* proposals. This argument becomes successively more complex as multiple reconfigurations are passed, especially during a single window of α. Multiple reconfigurations also introduce an ABA problem when cells move off, and then back onto, a node. TLA+ and TLC allowed us to build confidence in the safety of our protocols in this complex case and cases like it.

5 Evaluation

Evaluating the performance of a system like Physalia is challenging. Performance, including throughput and latency, are important, but the most important performance metrics are how the system performs during extremely rare large-scale outages. We evaluate the performance of Physalia in production, and evaluate the design through simulations. We also use simulations to explore some particularly challenging whole-system aspects of Physalia.

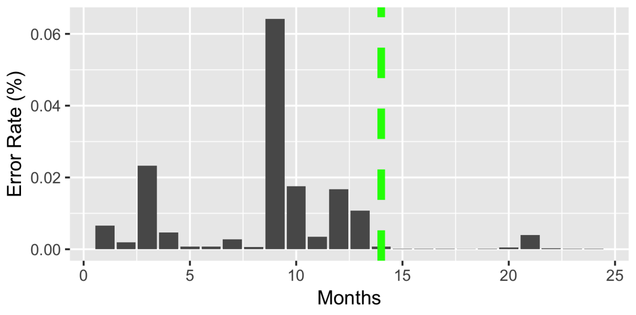

Figure 8: Mean availability of the configuration store from the perspective of the EBS primary, bucketed by month, for a production colony. The vertical line shows the deployment of Physalia in this datacenter, replacing a legacy system.

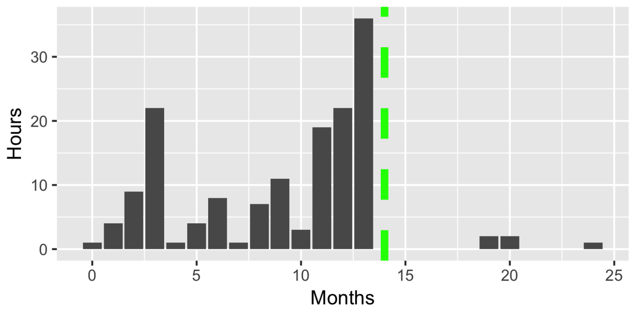

Figure 9: Number of hours per month where EBS masters experienced an error rate $> 0.05\%$ in a production colony. The vertical line shows the deployment of Physalia.

5.1 Production Experience

Physalia is deployed in production in AWS, running in over 60 availability zones. Figure 8 shows the effect that it's deployment has had on one measure of volume availability: how often the primary copy of the volume is able to contact the configuration store on the first try. The deployment of Physalia shows a clear ($p = 7.7x10^{-5}$) improvement in availability. Availability failures in the previous system were caused both by infrastructure failures and by transient overload (see Section 3.5).

Figure 9 shows the same data in a different way, looking at compliance against an internal error rate goal, significantly stricter than the external SLA for EBS. In this case, the internal goal is 0.05%, and we count the number of hours where this goal is exceeded.

In production deployments within AWS, Physalia deployments at availability-zone scale routinely serve thousands of requests per second. Latency varies between read and write optimizations. Linearizable reads can sometimes be handled by the distinguished proposer. Writes, on the other hand, need to complete a Paxos round before they are committed, and therefore require substantially more communication. Figure 10 presents a multi-day view of read and write latency percentiles, calculated on a one-minute bucket. In this typical installation, reads take less than 10ms at the 99th percentile, and writes typically take less than 50ms.

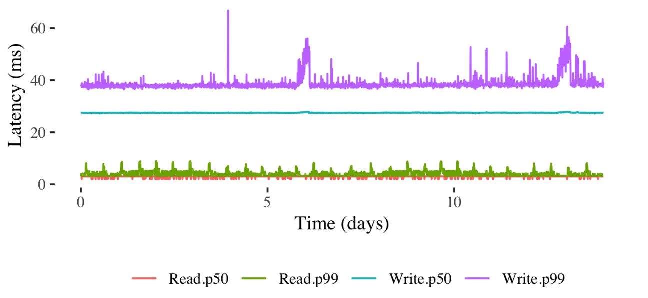

Figure 10: Physalia read and write latencies for one large-scale cluster. p50 is the 50th percentile, and p99 is the 99th.

In a distributed state machine, not only must operations be applied deterministically across all replicas, but they must be applied the same way by all production versions. Our operational and testing practices handle this edge case by testing between adjacent versions. Early in our production rollout, a bug in our deployment tools lead to a *rollback* to an old version of the code base on a small number of nodes. These nodes applied transactions differently, simply not applying a conditional they didn't understand, leading to state to diverge on the cells where they were members. While we fixed this issue quickly with little customer impact, we took three important lessons away from it. First, Postel's famous robustness principle (*be conservative in what you do, be liberal in what you accept from others*) [45] does not apply to distributed state machines: they should not accept transactions they only partially understand and allow the consensus protocol to treat them as temporarily failed. Second, our testing processes needed to cover more than adjacent versions, and include strong mechanisms for testing rollback cases (both expected and unexpected). The third lesson is perhaps the most important: control planes should exploit their central position in a systems architecture to offer additional safety. When the rollback issue occurred, affected cells were corrupted in a way that caused the control plane to see them as empty, and available for deletion. The control plane dutifully took action, deleting the cells. Based on this experience, we modified the control plane to add rate limiting logic (don't move faster than the expected rate of change), and a *big red button* (allowing operators to safely and temporarily stop the control plane from taking action). Control planes provide much of the power of the cloud, but their privileged position also means that they have to act safely, responsibly, and carefully to avoid introducing additional failures.

5.2 Design Validation via Simulation

The statistical behavior of a system as complex as Physalia can be difficult, if not intractable, to analyze in closed form. From early in the feasibility stages to production deployment, we used simulation to understand the dynamic behavior of the system, explore alternative system designs, and calculate baselines for our testing. In this section, we present some simulation results, and conclude by comparing the performance of the system to those results.

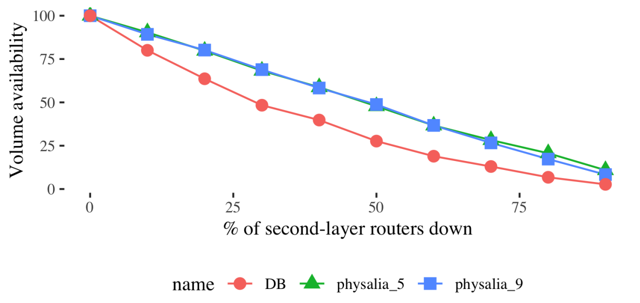
The availability offered by a Physalia deployment is highly sensitive to the failure modes of the underlying infrastructure, and the statistical properties of each of those failure modes. These results use a simplified (and outdated) model of a datacenter network: servers are organized into racks, each with a top-of-rack switch (*tor*), which in turn connects to one or more aggregation routers (*aggs*), which connect to one or more core routers (*cores*). Typical real-world networks contain some redundancy. For example, a *tor* is likely to connect to more than one *agg*. In these results we've left out redundancy for simplicity's sake, but the results are qualitatively similar (although the failure statistics are very different), once redundancy is considered.

One significant area that we explored with simulation is placement. Globally optimizing the placement of Physalia volumes is not feasible for two reasons, one is that it's a non-convex optimization problem across huge numbers of variables, the other is that it needs to be done online because volumes and cells come and go at a high rate in our production environment. Figure 11 shows the results of using one very rough placement heuristic: a sort of *bubble sort* which swaps nodes between two cells at random if doing so would improve locality. In this simulation, we considered 20 candidates per cell. Even with this simplistic and cheap approach to placement, Physalia is able to offer significantly (up to 4x) reduced probability of losing availability.

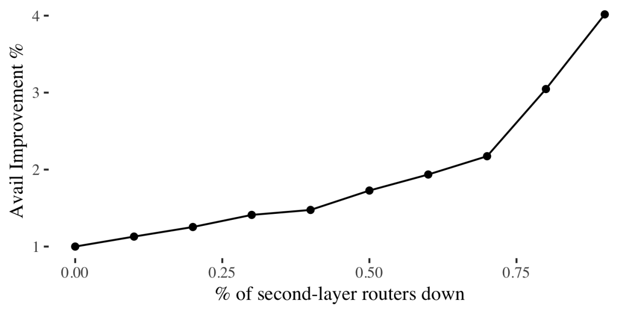
5.2.1 Simulations of System Load

As discussed in Section 3.5, load on Physalia can vary dramatically with different network conditions. Simulation of failures in different network topologies allows us to quantify the maximum expected load. Figure 12 shows the results of simulating *agg* failures (in the same model used above) on offered load to Physalia. A volume needs to call Physalia if the client AWS EC2 instance can get to either the master or replica EBS server, but the master and replica can't get to each other.

At small failure rates, expected load increases linearly with the count of failed devices, up to maximum of 29%. Beyond this, load drops off, as volumes become likely to be completely disconnected from the client. Multiplying this graph (or, ideally one simulated on actual datacenter topology) with the expected values of device failures yields a graph of the expectation of the magnitude of maximum load on Physalia (or, indeed, any configuration master in an EBS-like replicated system). These results closely match what we have observed of the real-world behavior of the EBS deployment of Physalia.



(a)



(b)

Figure 11: Simulated availability of volumes using Physalia, versus a baseline of a single-point database, under network partitions caused by device failures at the *agg* layer. (a) shows raw results for cell sizes 5 and 9, and (b) shows the ratio between Physalia and baseline availability.

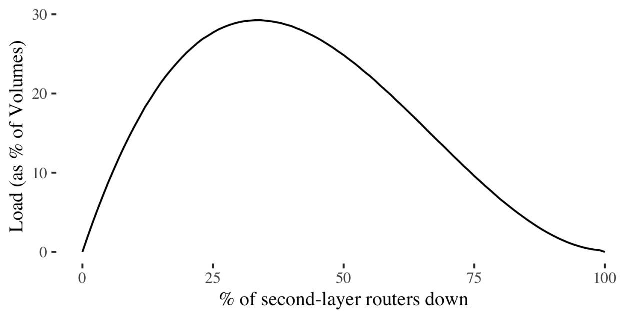


Figure 12: Load on Physalia vs. *agg* failure rate for a simulated 3-tier datacenter network.

6 Related Work

Physalia draws ideas from both distributed co-ordination systems and distributed databases. Distributed co-ordination systems, like Zookeeper [19], Chubby [9], Boxwood [38] and etcd [14], have the goal of providing a highly-available and strongly-consistent set of basic operations that make implementing larger distributed systems easier. Physalia's design approach is similar to some of these systems, being based on the state machine replication pattern popularized by the work of Schneider [49], Oki [40] and Lampson [37]. Physalia's key differences from these systems are its fine-grained consensus (millions of distributed state machines, rather than a single one), and infrastructure awareness. This makes Physalia more scalable and more resistant to network partitions, but also significantly more complex.

The problem of providing highly-available distributed storage in fallible datacenter networks faces similar challenges to global and large-scale systems like OceanStore [34] and Farsite [3], with emphasis on moving data close to its expected to improve availability and latency. While the design of Physalia predates the publication of Spanner [15] and CosmosDB, Physalia takes some similar design approaches with similar motivation.

Horizontal partitioning of databases is a long-established idea for both scaling and availability. Systems like Dynamo [18] and its derivatives dynamically move partitions, and rely on client behavior or stateless proxies for data discovery. Dynamic discovery of high-cardinality data, as addressed by Physalia's discovery cache and forwarding pointers, has been well explored by systems like Pastry [47] and Chord [52]. Optimizing data placement for throughput and latency is also a well-established technique (such as in Tao [8], and Dabek et al [16]), but these systems are not primarily concerned with availability during partitions, and do not consider blast radius.

Physalia's approach to infrastructure-aware placement reflects some techniques from software-defined networking (SDN) [21]. Another similarity with SDN (and earlier systems, like RCP [10]) is the emphasis on separating control and data planes, and allowing the data plane to consist of simple packet-forwarding elements. This reflects similar decisions to separate Physalia from the data plane of EBS, and the data- and control planes of Physalia itself.

Infrastructure awareness, an important part of Physalia's contribution, seems to be an under-explored area in the systems literature. Some systems (like SAUCR [4], and the model proposed by Chen et al [13]) are designed to change operating modes when infrastructure failures occur or request patterns change, but we are not aware of other database explicitly designed to include data placement based on network topology (beyond simple locality concerns).

7 Conclusion

Physalia is a classic consensus-based database which takes a novel approach to availability: it is aware of the topology and datacenter power and networking, as well as the location of the clients that are most likely to need each row, and uses data placement to reduce the probability of network partitions. This approach was validated using simulation, and the gains have been borne out by our experience running it in production at high scale across over 60 datacenter-scale deployments. Its design is also optimized to reduce blast radius, reducing the impact of any single node, software, or infrastructure failure.

While few applications have the same constraints that we faced, many emerging cloud patterns require strongly consistent access to local data. Having a highly-available strongly-consistent database as a basic primitive allows these systems to be simpler, more efficient, and offer better availability.

Acknowledgments

The authors would like to thank David R. Richardson, Madhu Parthasarathy, Divya Jain, Surya Dhoolam, and the Physalia team for their work in supporting, developing and refining Physalia. We would also like to thank Marc Levy, Allan Vermeulen and James Hamilton for reviewing the initial Physalia design. Allan Vermeulen's work on distributed systems testing deeply informed our approach.

Abstract

Despite the well-known existence of load-balanced forwarding paths in the Internet, current active topology Internet-wide mapping efforts are multipath agnostic – largely because of the probing volume and time required for existing multipath discovery techniques. This paper introduces D-Miner, a system that marries previous work on high-speed probing with multipath discovery to make Internet-wide topology mapping, inclusive of load-balanced paths, feasible. We deploy D-Miner and collect multiple IPv4 interface-level topology snapshots, where we find >64% more edges, and significantly more complex topologies relative to existing systems. We further scrutinize topological changes between snapshots and attribute forwarding differences not to routing or policy changes, but to load balancer "remapping" events. We precisely categorize remapping events and find that they are a much more frequent contributor of path changes than previously recognized. By making D-Miner and our collected Internet-wide topologies publicly available, we hope to help facilitate better understanding of the Internet's true structure and resilience.

1 Introduction

An important component of today's Internet is multipath routing [18, 29, 45], where traffic to a destination network is *load-balanced* to support higher capacities and provide redundancy. Prior work developed active measurement techniques to discover multipath routing [17], while showing that multipath topologies can be quite complex [45]. However, high probing loads and runtime have been impediments to their widespread uptake. As a result, today's IP and router topology snapshots, e.g., [21, 41], incompletely represent the true, multipath, complex forwarding topology. Indeed, our measurements discover >2.7M more edges (64%) in the topology as compared to current state-of-the-art, and significantly more complex topologies than previously reported, including >5k edges in a single provider's topology corresponding to a single /24 destination prefix that they advertise.

The Internet measurement community has long aimed to capture a complete topology of the Internet, especially as it has become clear that partial topologies can lead to faulty conclusions about the network's properties [15, 24, 46]. Obtaining not just accurate, but complete topologies is crucial to understanding the network's resilience to outages and attacks [35, 43], as well as aiding in the conception of applications ranging from content distribution to network security [48]. Further, these topologies play a vital supporting role in other measurement inferences, for instance determining AS relationships, mapping inter-domain congestion [32], and geolocation [31] to name a few.

We developed D-Miner to gather Internet-wide multipath topology maps. D-Miner is a system that marries two recent advancements in active topology discovery: i) high-speed randomized probing techniques [19] and ii) multipath detection algorithms [17]. At its core, D-Miner rapidly sends probes in a randomly permuted order to avoid overloading any single path, and iteratively completes its view of the network. Whereas prior multipath discovery approaches perform a stateful breadth-first search path exploration to attain confidence in the degree of load balancing along the path, D-Miner decouples probing from statistical inference thereby enabling probe randomization and high-rate probing, while amortizing total probing cost. D-Miner maintains a set of "unresolved" nodes – nodes for which the degree of load balancing is uncertain – and proceeds in rounds until the topology is, statistically, complete (§3). Having implemented D-Miner, we evaluate its performance and overhead (§4). Together, these techniques enable, for the first time, *scalable* multipath topology discovery and Internet-wide mapping.

Using complete Internet-wide snapshots collected using D-Miner, we scrutinize dynamics and topological changes. We find that many "routing changes" are instead due to "load balancer remapping" events – where the load balancer changes its current mapping between flow identifiers and paths. We precisely categorize these events and measure their prevalence, finding that they are a much larger and frequent contributor of path changes than previously recognized (§5).

Finally, we deployed D-Miner and collected multiple topology snapshots over a one-week period in August, 2019. From these snapshots, we characterize the prevalence, size, extent, and location of load-balancing on the modern Internet (§6). Our contributions thus include:

1. Development and evaluation of D-Miner, a novel scalable active multipath topology discovery system.
2. Deployment of D-Miner to gather the first Internet-wide IP-level topology snapshots inclusive of load balancing.
3. Detailed characterization of Internet dynamics, including a taxonomy of load balancer remapping events and their extent and prevalence.
4. Public release of D-Miner's code and survey results [4].

2 Background and related work

We first review different types of load balancing commonly found in the Internet. Then, we provide an overview of the Multipath Detection Algorithm (MDA) [44], the current state-of-the-art technique for actively discovering load balancing, and Yarrp, a method for high-speed topology discovery. We finish this section by describing other related work.

2.1 Load balancing

Load balancing is used to increase aggregate network capacity and provide redundancy and resilience to failures. Two types of load balancing are configurable on routers [3, 6, 12]: deterministic and non-deterministic. When a packet arrives on a router configured with deterministic load balancing (i.e., per-flow load balancing), and multiple equal-cost routing paths are available to the packet's destination, the router chooses a path by computing a hash over the packet's header fields [23]. This set of fields used to compute the hash is called the flow identifier, and typically includes either the source and destination addresses (per-destination) or the source and destination addresses and ports (per-flow). Two packets belonging to the same flow are thus sent over the same path, and this helps the performance of transport protocols that react to delayed or out-of-order packets, as well as enabling middleboxes to have visibility into all the packets of a flow. Herein, we use the terms "flow identifier" and "flow" interchangeably.

Non-deterministic is also known as per-packet load balancing. In this configuration, when a packet arrives at a router with multiple equal-cost paths to the destination, the router selects among the paths in a round robin fashion.

Our Internet scale survey in §6 confirms two previous results of Augustin et al. [18] and Vermeulen et al. [45]: (1) load balancing is prevalent in the network, as 64.7% of our traces from a source to any /24 prefix contained at least one load balancing router (branching point); and (2) non-deterministic load balancing is rare, with only 1.9% of the branching points identified as implementing this behavior.

2.2 MDA

The Traceroute tool [30] sends probe packets to find forwarding paths. It exploits the IPv4 time-to-live (TTL) header field to induce routers along a forwarding path to send ICMP error messages, thereby revealing the router's interface addresses. The original Traceroute design did not foresee the later emergence of load-balanced paths in the Internet, and it gives incomplete and incorrect results in the face of load balancing [16]. Paris Traceroute [16] was developed specifically to accurately reveal a path through a per-flow load-balanced network. Paris Traceroute ensures that all probe packets, across different TTLs, have consistent flow identifiers, thereby ensuring that all measurement packets take the same path in a load-balanced network. However, in its basic implementation, Paris Traceroute reveals only a single path to the destination.

The Multipath Detection Algorithm (MDA) stochastically varies Paris Traceroute's flow identifiers in an attempt to enumerate all paths to a destination. For a given vertex with k known outgoing load-balanced edges, the number of probes with randomly selected flow IDs needed to verify that it has no more than k edges is denoted n_k, and is termed a "stopping point" [44]. For example, when 1, 10, or 100 outgoing edges have already been identified, $n_1 = 6$, $n_{10} = 57$, or $n_{100} = 757$ probes are, respectively, required in order to ensure a no more than 0.05 probability to fail to enumerate all outgoing edges.

Unfortunately, the stateful nature of the MDA and its reliance on establishing confidence in the behavior of each potential branching point along the path in a sequential manner are hinderences to its use for Internet-wide topology studies.

Note, the MDA technique has previously been validated [18, 44]. From this perspective, if D-Miner achieves the same level of statistical guarantees that the MDA provides, it validates D-Miner as well. §4 shows that D-Miner fulfills this condition.

2.3 Yarrp

Yarrp [19, 20] introduced the notion of high-speed topology probing via stateless operation, and random permutation of targets and TTLs. Whereas previous route tracing techniques, e.g., [34], iteratively probe TTLs toward each destination, Yarrp randomizes its probing and decouples probing from topology reconstruction. This randomization avoids overloading particular paths or routers, thereby permitting higher probing rates. Further, Yarrp encodes all of the necessary state, e.g., originating TTL and time, into probes such that the quoted replies permit state to be reconstituted. In this fashion, Yarrp demonstrated the ability to perform Internet-wide route tracing at more than 100k pps.

2.4 Other related work

For more than two decades now, Internet mapping has been an active area of research. It allows researchers to better un-

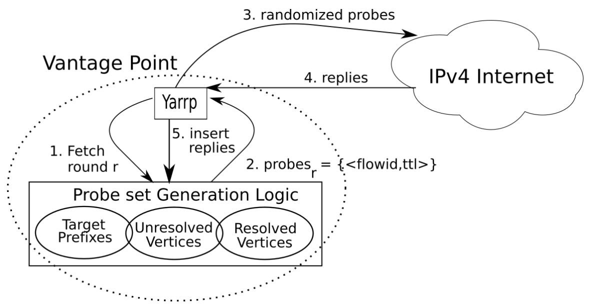

Figure 1: D-Miner high-level conceptual overview

derstand the structure of the Internet [22, 28] and to design better protocols [46]. Today, one can either obtain an Internet snapshot of the whole Internet without load-balanced paths, or a reduced snapshot of the Internet with load-balanced paths. Mapping systems such as CAIDA's Ark [24] perform continuous surveys from hundreds of vantage points by launching Paris Traceroute measurements to one random address in every globally advertised /24 prefix. A complete set of measurements towards all of the /24 prefixes is called a cycle. Because the address in the /24 is randomly chosen, aggregating results from multiple cycles reveal some load balancing. However, Ark is not explicitly designed to reveal load balancing, does not send enough probes to find all load balancing (particularly when chained), and does not provide any confidence bounds on discovery. Yarrp [19], described in §2.3, performs Internet scale surveys at high speed, but is also not capable of revealing the load-balanced paths. D-Miner enables researchers, for the first time, to obtain snapshots the entire Internet inclusive of all load-balanced paths.

This new and more complete view of the topology allows D-Miner to expand the results on load balancing characterization at Internet scale. Augustin et al. made the first study of load-balanced paths a decade ago, finding topologies having up to 16 such paths [18]. More recently, Vermeulen et al. have shown that per-flow load-balanced paths have become more complex, by finding topologies with up to 92 interfaces at the same TTL [45]. In both of those studies, the set of destination prefixes was a subset of the entire Internet, with, respectively, $\sim$120k and $\sim$350k targets. In contrast our survey contains traces to $\sim$14.4M /24 destination prefixes.

D-Miner allows us to provide new insights into Internet dynamics induced by load balancing. In §5.2, we show that a "routing change" is more nuanced that previously understood, and that such changes can be due in part to the remapping behavior of production load balancers. Paxson's canonical work on Internet dynamics [39] studied *persistence* and *prevalence* of routes. Given a source/destination pair, persistence characterizes the number of different routes observed across time between this pair. The prevalence of a route defines if, within the set of routes that have been observed, one is more dominant than another. The main result was that Internet routes were globally stable across time. Note that this work was performed two decades ago and did not take load balancing into account. Almost a decade ago, Cunha et al. reappraised Paxon's work in light of load balancing [26], and found that Paxson's results still held. They also stated that load balancing remapping is infrequent. We show that it is a widespread phenomenon in today's Internet.

More recently Cunha et al. developed DTrack [27], a system that maintains an inferred topology and attempts to detect and predict path changes, although such prediction is difficult. Our work helps provide insight into potential root causes of this prediction difficulty.

3 Algorithm

D-Miner is designed to capture Internet topology snapshots inclusive of all load-balanced paths. At its heart, D-Miner uses Yarrp's randomized and stateless probing to achieve high probing rates. To this, it adds probe set generation logic that keeps track, on a per-node basis, of whether all outbound load-balanced edges have been discovered with high probability. The logic guides Yarrp through multiple rounds until the full discovery criterion has been satisfied for almost all nodes.

See Figure 1 for a high-level schematic of D-Miner. Yarrp and the probe set generation logic are deployed at a single vantage point from which Yarrp probes a set of target prefixes in the IPv4 Internet. D-Miner proceeds in rounds, maintaining sets of "resolved" and "unresolved" vertices. Resolved vertices correspond to nodes where all outgoing load balanced links have been discovered with high probability toward the set of target prefixes. Conversely, unresolved vertices require further probing to ascertain whether any load balanced edges emergent from a node have not yet been discovered.

D-Miner's main steps are: (1) Yarrp requests the set of probes for round *r*; (2) the probe set generation logic returns the `<flow ID,TTL>` pairs that correspond to the current set of unresolved vertices; (3) these pairs are randomized and probes are sent at high speed using the Yarrp technique; (4) as replies return, they are processed by Yarrp; and (5) they are used to update the set of known nodes and each node's state as either an unresolved or a resolved vertex. Rounds continue until 99% of the target prefixes have been resolved.

Whereas Yarrp is totally stateless, D-Miner requires state to be retained from round to round. A key challenge is to manage that state in a manner that does not diminish Yarrp's performance. Our solution is discussed in §3.2.

3.1 Bootstrapping D-Miner

Since D-Miner is guided by the set of unresolved vertices, it requires a boostrapping round to seed the set. This round is a slightly modified version of a classic Yarrp snapshot of the IPv4 Internet. Whereas Yarrp sends one probe packet per TTL to each /24 prefix, with the exception of the private and reserved IPv4 prefixes defined by RFC 6890 [25], D-Miner sends $n_1 = 6$ probes per /24, each with a different flow identifier. This number comes from the MDA stopping condition for 0.05 failure probability, described in §2.2, that there is just a single node at a given TTL when probing towards a given destination. The six flow identifiers correspond to the six first destinations in the /24. The /24 granularity corresponds to the commonly accepted longest BGP prefix [42].

In the classic MDA, the n_1 packets all have a common destination, however D-Miner varies the flow identifier by varying the destination within the target prefix. This allows it to find per-destination-prefix load balanced paths in addition to the per-flow load balanced paths that classic MDA finds.

As stated in §2.3, Yarrp uses a pseudo random permutation of 32 bits to determine the parameters for each successive probe: the first 24 bits determine the /24 destination prefix and the first 5 bits of the remaining byte determine the TTL. This leaves 3 bits, which is sufficient for D-Miner to select $n_1 = 6$ different addresses within the destination prefix.

3.2 Maintaining State

Yarrp encodes the originating TTL, timestamp, and checksum in the probe header fields. These values are visible in the quotations that arrive in the probe replies, allowing Yarrp to reconstruct the probe that generated a particular ICMP without maintaining any internal state. While each individual Yarrp probing round is stateless, D-Miner must maintain state from round to round in to keep track of which vertices have been resolved and which ones remain unresolved. To this end, D-Miner extracts the following data from each reply: the original probe's source and destination IP addresses, port numbers, and original TTL; and the reply's source IP address and ICMP type and code.

So that D-Miner could obtain rapid results for complex queries on tables of billions of rows, we sought a database system that is optimized for online analytical processing, settling on ClickHouse [2]. The data from each reply is inserted and ordered by: source IP address, /24 destination prefix, destination IP address, TTL, source port number, and destination port number. ClickHouse is highly parallelized and its `groupArray` features make the algorithm calculations described in §3.3 and the analyses of §4, §5, and §6 tractable.

3.3 Subsequent probing round computation

Once the replies have been inserted into the database, we query it to generate the next round of probes. Our goal, conceptually, is to calculate the set of additional probes with new flow identifiers required to meet the remaining statistical guarantees for each /24 prefix, given the current knowledge of the topology. Mathematically, the next round probes is the minimal expected set of probes needed to reach the statistical guarantees for each branching point, grouped by /24 prefix.

3.3.1 Reducing MDA statefulness

This section describes our algorithm to generate a new batch of probes given a topology and the set of probes already sent.

Let us fix a source and a /24 destination prefix. We present an example in Figure 2 to help provide intuition. This topology illustrates a possible result after each of three hypothetical rounds of probing. Each link is annotated with the number of probes that expired at the ingress interface of the subsequent node. At round 1, D-Miner sent $n_1 = 6$ probe packets per TTL, each with varying destinations in the destination prefix to vary the flow identifier. The value of n_1 is determined by the desired failure probability to find all the successors of a branching point. In this work we set $n_1 = 6$, corresponding to a failure probability of 0.05, which is the default value used by the MDA implementation in previous work [18, 27].

Recall, after sending 6 probes and only discovering a single successor, we have a probability of 0.95 that there is indeed only a single successor ($n_1 = 6$), while we must send 11 probes to achieve the same probability that there are only two successors ($n_2 = 11$). To understand how we compute the next batch of probes, we introduce the following notation:

Let us fix the TTL to h.

Let R_h be the set of nodes discovered at TTL h that have not been resolved yet.

Let D_h be the probability distribution of nodes responding for TTL h after the current probing round. For example, in Figure 2 after the first round of six probes per TTL, $D_2 = \left\{\mathrm{v}_2 = \frac{4}{6}, \mathrm{v}_3 = \frac{2}{6}\right\}$.

Let k_v be the number of successors for node v.

Let t_h be the number of probes already sent at TTL h.

Let n_k be the stopping point described in §2.2.

Proposition 1. *Given h, R_h and D_h, the minimal expected number of probes needed to reach MDA statistical guarantees for all the elements of R_h is:*

$$\max_{v \in R_h}\left(\frac{n_{k_v}}{D_h(v)} - t_h\right) \qquad \text{At TTL } h$$

$$\max_{v \in R_h}\left(\frac{n_{k_v}}{D_h(v)} - t_{h+1}\right) \qquad \text{At TTL } h+1$$

Proof. Let $v \in R_h$. The MDA hypothesis, which is that v might have a $(k_v+1)^{\text{th}}$ successor tells us that we need to send n_{k_v} probe packets with TTL h that first reach v, and then send n_{k_v} with the same flow identifiers to TTL $h+1$. Let X_v be the random variable representing the number of probes that reach node v given D_h. Our objective is to find the minimum number of probes N such that:

$$\forall v, E[X_v] = D_h(v)N >= n_{k_v} \qquad (1)$$

For this condition to hold, we must set N at minimum to:

$$N = \max_{v \in R_h} \frac{n_{k_v}}{D_h(v)}$$

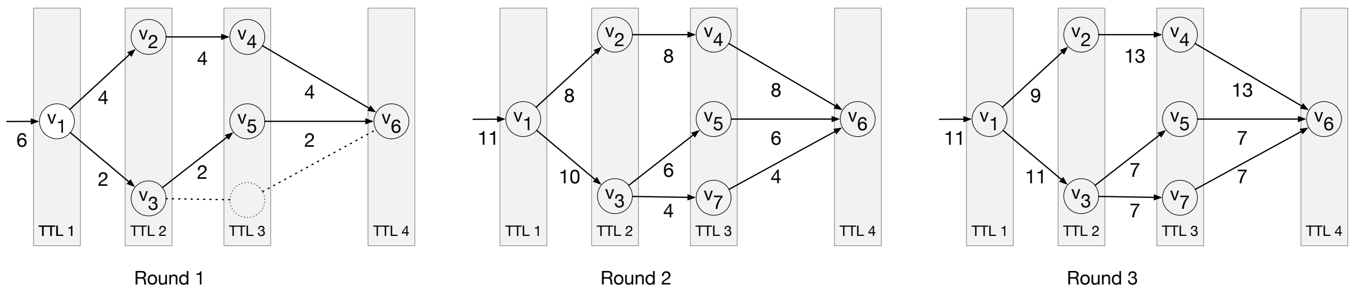

Figure 2: Example topology resolved by three rounds of D-Miner probing. Link annotations represent number of probes expiring at ingress interface of subsequent node.

We have:

$$\forall v, E[X_v] = D_h(v) \max_{v' \in R_h} \frac{n_{k_{v'}}}{D_h(v')} >= D_h(v) \frac{n_{k_v}}{D_h(v)} = n_{k_v} \quad (2)$$

We just subtract the number t of probes that we have already sent to TTL h, and this concludes the proof. □

Every TTL h generates a number of additional probes for TTL h and TTL $h+1$. For each TTL h, we therefore have two possible values: the one generated by additional probes for TTL $h-1$ and the one generated by additional probes for TTL h. So that the condition given in Eq. 1 holds for every node of the topology, we choose the maximum between these two values (rounding fractional values to integers).

Let us perform the numerical application on the topology of Figure 2. After round 1, we have discovered the topology on the left side of the figure. At TTL1, Node v_1 has two successors, $D_1(v_1) = 1$. 6 probes have been sent to TTL 1 and 6 probes have been sent to TTL 2. Proposition 1 brings $n_2 - 6 = 5$ additional probes for TTL 1 and 2. At TTL 2, Node v_2 has one successor, and $D_2(v_2) = \frac{2}{3}$. Node v_3 has one successor, and $D_2(v_3) = \frac{1}{3}$. 6 probes have been sent to TTL 2 and 6 probes have been sent to TTL 3. Proposition 1 brings $3n_1 - 6 = 12$ additional probes for TTL 2 and 3. At TTL 3, notice that v_4 and v_5 are similar to v_2 and v_3, so that Proposition 1 brings $3n_1 - 6 = 12$ additional probes for TTL 3 and TTL 4. For each TTL, we take the maximum number of probes between TTL and TTL-1. At the end, we have to send for the second round: 5 probes at TTL 1, 12 at TTL 2, 12 at TTL 3 and 12 at TTL 4.

The figure in the center shows the state of the topology after round 2. At TTL 1, we see that v_1 has been resolved because it has two successors and $11 = n_2$ flows pass through it. At TTL 2, v_2 has also been resolved because it has one successor and $8 \geq n_1$ flows have been sent through it. v_3 is not solved, because now it has two successors so it needs $n_2 = 11$ flows that pass through it. We have $D_2(v_3) = \frac{10}{18}$ and 18 probes have been sent to TTL 2 and 3. Proposition 1 brings $\frac{18}{10}n_2 - 18 = \lceil 1.8 \rceil = 2$ additional probes for TTL 2 and 3. At TTL 3, we see that v_4 and v_5 have been resolved, but v_7 has not. We have $D_3(v_7) = \frac{4}{18}$ and 18 probes have been sent to TTL 3 and 4. Proposition 1 brings $\frac{4}{18}n_1 - 18 = 9$ additional probes for TTL 3 and 4. For each TTL, we take take the maximum number of probes between TTL and TTL-1. At the end, we have to send for the third round: 0 probe at TTL 1, 2 at TTL 2, 9 at TTL 3 and 9 at TTL 4.

The figure on the right shows the state of the topology after round 3. We see that now v_3 and v_7 have been resolved, so that we consider the entire topology as resolved.

3.3.2 Varying the flow identifier

For each destination prefix and TTL where additional probes are needed, we select new flow identifiers by incrementing the last destination in the prefix used in the previous round. In the example of Figure 2, suppose that our prefix is X.Y.Z.0/24. After round 1, the first 6 IPs of the prefix have already been used as probe destinations, so we would send 5 more probes at TTL 1 from X.Y.Z.7 to X.Y.Z.11, 12 more probes at TTL 2 from X.Y.Z.7 to X.Y.Z.18, etc. If there are no more destinations available in the prefix, we change the destination port to vary the flow identifier.

3.4 Randomizing the probes

Randomizing the probes is done per-flow. For each prefix which needs additional probes sent, we group the additional probes by flow. In the example of Figure 2, after round 1, we send X.Y.Z.7 at TTL 1, TTL 2, and TTL 3, and TTL 4. All of these are packed together so that we ensure that probes with the same flow identifier are sent in a very short time window. This avoids the inference of false links due to potential routing changes during the probing time. Nevertheless, it is possible that X.Y.Z.8 probes are sent at a separate time from X.Y.Z.7. In this way we retain one of the benefits of Yarrp's randomization, to minimize potential ICMP rate limiting.

3.5 Per-Packet load balancing

As described in §3.1, the first round of probes allows us to discover if there is one or more load-balancers on the path from the vantage point to the destination prefix. However, sending only one packet per flow identifier does not reveal the nature of the load balancing, i.e., deterministic (per-destination or per-flow) or non deterministic (per packet). For per-packet load balancers, the links between interfaces of a traceroute can not be reliably inferred. Because we want to be able to flag per packet load balancers, D-Miner sends two back-to-back probes per flow instead of one until it reaches a defined threshold probability that the branching point is not a per packet load balancer. If we get two different responses for flows with the same flow identifier, the branching point is flagged as a per packet load balancer and the edges discovered after it are ignored in the results. Mathematically, an upper bound of the probability to miss that a load balancer is actually a per packet load balancer is the probability that all the pairs of probes with the same flow identifiers passing through it get the same reply IP. Suppose there is a branching point with k branches. Then the probability that all these pairs of probes get the same response is then $\frac{1}{k^p}$ where p is the number of pairs of probes sent going through this branching point. We set the threshold probability in D-Miner to 0.95, as previously done in [18].

4 Evaluation

Over one third of the edges in the Internet's topology are not being revealed by current state-of-the-art methods, as §4.4 describes. D-Miner, run from from six PlanetLab Europe vantage points, discovered more than 7.1 million edges during a week of August 2019, a time during which Ark, probing from its 112 VPs, found ~4.4 million edges and Yarrp, probing from the same PLE VPs as D-Miner, found ~2.5 million. Although this additional coverage comes at the cost of 2-4 times as many probes compared to these existing approaches (§4.4.1), we show that this volume is required due to forwarding path dynamics.

In addition to evaluating node and edge discovery, we evaluate D-Miner's algorithmic and system properties. D-Miner's round-iterative design engenders 14% higher overhead than would be incurred sending traditional source-to-destination style MDA Paris Traceroutes from the same vantage point, as §4.2 shows. This is the cost associated with D-Miner adopting a stateless and randomized (Yarrp-based) design, in exchange for the advantages conferred by this design in terms of probing speed. §4.3 evaluates D-Miner's running time. First, however, §4.1 describes the datasets we collected, and shows that 10 rounds suffice to reach statistical guarantees for 99% of the /24 destination prefixes.

4.1 Dataset

Our evaluation dataset includes three D-Miner snapshots, each consisting of 10 rounds. These snapshots were collected over a one-week period, from 6-13 August 2019, using a single vantage point at our university, which enjoys a 1 GB link to the Internet. Each snapshot was collected using a probing rate of 100,000 pps; this rate was capped out of respect for network and service provider policy concerns; D-Miner is capable of probing much faster (>800,000 pps observed).

In addition, for the topology discovery section, we have deployed D-Miner on six PlanetLab Europe (PLE) [7] nodes located in Europe and run it at a lower rate, 10,000 pps, during the same week. We used UDP probes as these have been shown to discover more links than other protocols [36]. A web page hosted at the IP address of our vantage point described the experiment and provided instructions for opting out; we did not receive any such requests during our measurements.

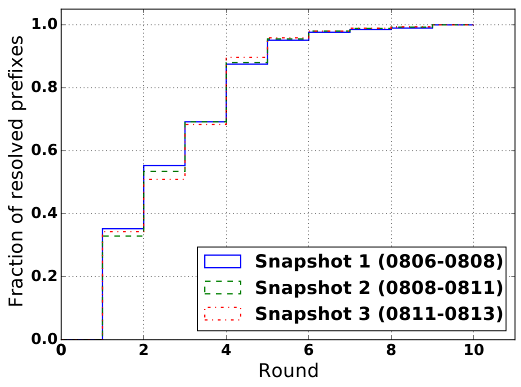

Figure 3: CDF of /24 IPv4 prefixes meeting their statistical guarantees, over three 10-round snapshots (dates in parens)

Table 1: Probing Overhead of D-Miner versus MDA.

Overhead Factor	**Snapshot 1** (Aug 6-8)	**Snapshot 2** (Aug 8-11)	**Snapshot 3** (Aug 11-13)
Loss (I)	481,359,024	448,428,279	569,173,354
Reached destination (II)	166,941,456	165,227,106	163,821,372
Last round (III)	54,023,123	46,324,355	50,012,378
Total Overhead [pkts]	**702,323,603**	**659,979,740**	**783,007,104**
D-Miner Sent [pkts]	6,976,307,081	6,569,819,008	6,598,837,985
MDA Sent [pkts]	6,273,983,478	5,909,839,268	5,815,830,881
D-Miner Overhead [%]	**12**	**12**	**14**

Figure 3 illustrates how 10 rounds of probing suffices to achieve statistical guarantees toward more than 99% of the IPv4 /24 destination prefixes. The mean portion of resolved prefixes over the three 10-round snapshots is 99.6%.

4.2 Probing overhead

Intuitively, we might expect D-Miner to have lower overhead in order to achieve scale. However, the stateless high-rate probing required comes at the cost of additional total probing. The probing overhead generated by D-Miner compared to sequentially running the traditional MDA to all of the /24 prefixes depends on three factors: (I) potential loss induced

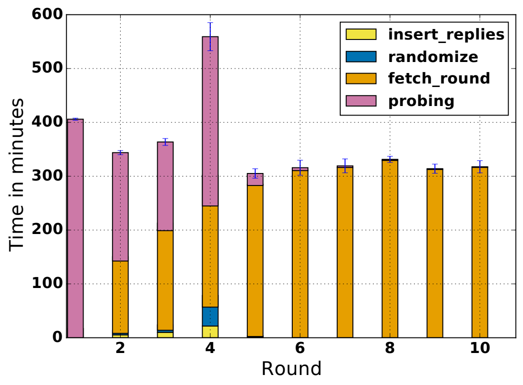

Figure 4: Time spent in each step of D-Miner for each round, averaged across three snapshots.

by a high probing rate; (II) the TTL at which the MDA would have stopped because of reaching the destination; and (III) sending more probes in the last round than required to reach the statistical guarantees. Table 1 quantifies each of these overhead factors across our three snapshots, where we find a maximum overhead of 14%.

Note that we conservatively compute the loss due to high probing rates. If for a given (destination prefix, TTL) pair, if at least one of the probes receives one response, we count all the probes sent with the same (destination prefix, TTL) pair as losses if they do not produce a response. Conversely, if no responses at all are received for this (destination prefix, TTL) pair, i.e., this hop is "anonymous"[1], we do not count these probes as lost.

To compute the TTL at which the MDA would have stopped, we find the minimum TTL for which all probes' reply IPs equal their destination IP. If we never receive a reply from the destination, we assume that MDA would act like a default linux traceroute, i.e sending probes until it reaches the maximum TTL (30).

And finally, to compute the last round overhead, we simulate for each of the destination prefixes a run of the MDA with the same flow identifiers and compute the actual probe at which it stops due to having reached the statistical guarantees.

4.3 Run time

The server used for the computation was the same as the one we used for probing, provisioned with 16 cores and 187 GB of RAM. Figure 4 shows the stacked error bars of the time spent across each round in each routine. The sum over the rounds indicates that a snapshot of 10 rounds takes an average of 3,713 minutes (about 2 days and 14 hours) to complete.

We distinguish two phases in our system: Until round 4, the `probing` routine consumes a significant portion of the total round time, however, in rounds 5–10, almost all the time is spent in the `fetch_round` routine. Note the relationship

[1]Represented as a * in traditional traceroute output [9]

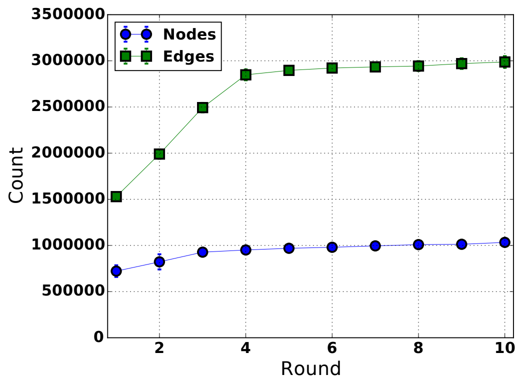

Figure 5: Per-round node / edge discovery for three snapshots.

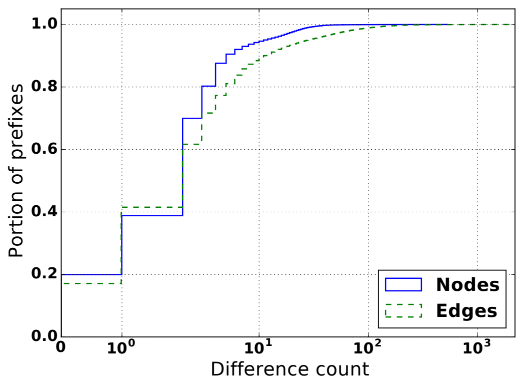

Figure 6: CDF of the minimum difference of number of nodes and edges per prefix.

between time (Figure 4) and the fraction of resolved prefixes (Figure 3). While the amount of probing time required in rounds 6-10 is relatively inexpensive as compared to the earlier rounds, we see that the algorithm is primarily optimizing at this point, with >90% of the prefixes resolved by the fifth round. Conversely, only ∼50% of the prefixes are resolved after the third round, demonstrating that the runtime cost of probing in the early rounds is required.

Notice the evolution of the time spent in the `fetch_round` routine: The time needed to compute the next round probes increases with the size of the table of our database in rounds 1–4. Then, from round 5 on, the reduction in time spent `probing` indicates that far fewer probes are sent, and consequently the table does not grow as much as during the earlier rounds. Still, the time of `fetch_round` remains constant; one must recompute the state of each branching point at each round to compute the next one.

4.4 Topology discovery

Finally, we consider the topology discovery results themselves. Note we ignore responsive target addresses (since we are only interested in the routed topology) as well as any edges connecting the destination nodes.

Table 2: Topology discovery

	Nodes				Edges			
	Snapshot 1 (Aug 6-8)	Snapshot 2 (Aug 8-11)	Snapshot 3 (Aug 11-13)	Agg.	Snapshot 1 (Aug 6-8)	Snapshot 2 (Aug 8-11)	Snapshot 3 (Aug 11-13)	Agg.
D-Miner	1,057,832	1,017,389	1,024,178	1,373,149	2,906,204	2,997,581	3,059,770	4,600,689
Yarrp	545,536	492,694	516,363	632,405	977,201	898,607	916,196	1,279,171
Multi-VP Ark	1,432,604	1,635,779	1,343,009	1,923,038	3,044,747	3,472,120	2,994,190	4,365,515
Multi-VP Yarrp	802,891				2,483,816			
Multi-VP D-Miner	1,613,301				7,143,490			

Figure 5 shows the cumulative discovery, with error bars, of each round across the three D-Miner snapshots. We find that both nodes and edges have similar behavior with two discovery phases, with an initial high discovery-per-round phase until round 3 (nodes) and 4 (edges) followed by a refinement phase from round 4 (nodes) and 5 (edges) to round 10. Note also that the number of nodes and edges varies little across the three snapshots, however, this does not mean that they discover the same set of nodes and edges as we will discuss.

It is challenging to make direct comparisons previous topology data sets – not only is the network dynamic, but the results are also significantly influenced by differing vantage point(s). Instead, we seek to make a reasonable comparison of D-Miner with existing Yarrp and Ark systems.

To compare with Yarrp, we extract from our D-Miner snapshots results given by selecting only one destination per /24 prefix in the first round. To compare against Ark, we obtain all topology traces from all 112 vantage points corresponding to the date range of our snapshots (this includes 19 "cycles" that were performed during the week). We aggregate the topology found from all cycles during the D-Miner snapshot collection to compare findings from the same time period.

Table 2 gives the comparative topology results. The "Agg." column shows the aggregated results over the three snapshots. The two last lines of Table 2 show the aggregated topology discovery results across the six PLE nodes for Yarrp and D-Miner over the same week covered by the three snapshots.

The multiple vantage point results in this table are significant. With 6 vantage points, D-Miner discovers >7M edges and approximately 1.6M nodes. To verify that this difference is primarily due to load balancing, we look at how standard Yarrp performs when used from these 6 vantage points. We see that D-Miner discovers two times more nodes and almost three times more edges than Yarrp.

Interestingly, we see that D-Miner from a single vantage point still benefits from snapshot aggregation. This means that there are non-negligible variations in the discovery of the three snapshots. Figure 6 shows the minimum per-prefix difference of number of nodes and edges discovered between the three snapshots over the 14,461,947 prefixes that we probed. As an example, for a prefix, if snapshot 1 discovers 20 nodes and 40 edges, snapshot 2 discovers 20 nodes and 34 edges, and snapshot 3 discovers 20 nodes and 36 edges, the minimum difference for nodes is 0 and 4 for edges. We observe two results: Less than 20% of the prefixes discover the same number of nodes and edges for the three snapshots, and 88.3% of the prefixes have a variation of less than 10 edges.

We believe that these variations are related to load balancing remapping (see §5.2). Indeed, the difference is not attributable to high probing rate induced loss, as Table 1 has shown than fewer than 10% of the probes were lost due to rate across the three snapshots.

Please note that we do not claim a comprehensive comparison with Ark discovery. The two systems have intrinsic differences that would not allow us to state conclusively why D-Miner or Ark would discover more than the other system. For example: (1) Ark uses ICMP probes, which has been demonstrated by Luckie et al. in [36] to discover fewer links than UDP. (2) The two systems' vantage points are not located at the same points in the network. Therefore, Ark could miss load balanced paths that are in a region of the Internet that is not accessible from its vantage points.

4.4.1 Probes sent

In total, we compute that Ark sent 5,935,460,660 probes. From Table 1 we compute that D-Miner from one vantage point sent 20,144,964,074 probes. And finally, we compute that the multiple vantage points version of D-Miner has sent 13,192,962,692 probes in total across the 6 PLE nodes.

These numbers give an idea of the overhead necessary to discover the load balanced paths. We show in the next section that reducing this number is hard because of the dynamics.

4.5 Validation on ground truth

To complement the formal and experimental analysis of our system, we solicited ground truth from operators. Of 380 interfaces with multipath edges discovered within Internet Initiative Japan (IIJ), they validated that 51 interfaces belonging to NTT were on PPPoE routers performing ECMP to IIJ. We further learned that the remaining 329 interfaces are performing ECMP inside IIJ's network.

In addition to direct correspondence with IIJ, we developed a website [14] where operators can validate links discovered by D-Miner. We received responses from three operators, for a total of 20 links. 18 validated correctly while two were declared as false. We re-conducted paris traceroute measurements to the destinations corresponding to the two false positive links. These links were found between the penultimate and the last IP seen in the traces. The last IP, which was not the destination IP, was repeating on all the subsequent TTLs until 30. Our interpretation is that this error was due to a routing loop or misconfiguration.

5 Forwarding path dynamics

With D-Miner, we reveal aspects of Internet dynamics that were under estimated [26] by the research community. 28.6% of D-Miner's probes saw their reply's IP address change, despite the flow identifier remaining constant over our three August 2019 snapshots. This would seem at first glance to be a startlingly high figure, implying more extensive routing changes than one might expect throughout the Internet [26,38]. But we provide evidence that, rather than routing changes, another phenomenon that we term *load balancer remapping* was responsible for at least 52% of these changes. These observations imply that future work should be cautious in attributing an observed `traceroute` change to a routing change.

5.1 Taxonomy of probe changes

A probe is uniquely identified by its (flow ID,TTL) pair. We say that there is a *probe change* if a probe elicits a reply from a different IP address in snapshot $i+1$ than in snapshot i. There may be as many probe changes as there are probes. We distinguish between meaningful and trivial changes.

To begin with, we do not count an *absence of response* as a meaningful change. That is, if a probe elicits a response in snapshot i and there is no reply to the probe in snapshot $i+1$, this difference may be attributable to loss or rate-limiting and is not indicative of a change. Similarly, we ignore absence in one round followed by a response in the next.

We are particularly interested in examining each probe change from the perspective of its predecessor node. Consider a probe (X,h) with flow ID X, sent with TTL h, revealing a vertex v_1; and a probe $(X,h+1)$ revealing a vertex v_2. If, in the next snapshot, (X,h) reveals v_1 again but $(X,h+1)$ reveals v_3, it is reasonable to infer that a mechanism at the router with interface v_1 is responsible for this probe change. Perhaps there has been a routing change, and the routing table at that router has been updated. Or, and this is the possibility that we focus on here: perhaps there has been no routing change, but instead that router is a load balancing router and the probe change results from a new load balancing decision for packets with flow ID X.

Previous research has identified *per-packet load balancing* [18] where a router simply disregards the flow ID X in its load balancing decision, for instance directing some packets to v_2, some to v_3, and some, perhaps, to other neighboring vertices, in a round-robin or (pseudo-)random fashion. As §3.5 describes, D-Miner tests for per-packet load balancing, and we exclude any reply variation due to that mechanism from our accounting of meaningful probe changes.

A possibility that previous literature has not explored is that a probe change could result from a per-flow or a per-destination load balancer making a load balancing change rather than a routing change. As an example, consider probe packets with flow IDs X and Y that both have the same destination IP address d. In snapshots i and $i+1$, probes (X,h) and (Y,h) both elicit replies from v_1, whereas in snapshot i, probe $(X,h+1)$ elicits a reply from v_2 and probe $(Y,h+1)$ from v_3, and in snapshot $i+1$, the replies are reversed. From one snapshot to the next, there has been no routing change for d at v_1: packets with that destination address continue to be load balanced across v_2 and v_3. But suppose the test for per-packet load balancing at v_1 has failed. We are left to consider that the probe change results from an update to the hashing decision that assigns flow IDs to next hop IP addresses. This is what we term *load balancer remapping*.

5.2 Load balancer remapping

Production systems are more nuanced in their behavior relative to the overview of load balancing in §2.1. For deterministic load balancing, in addition to header fields used to compute the hash function, a seed is generally added to avoid a phenomenon called *load balancing polarization* [1,11,13], which occurs when load balancers are chained and apply the same hashing algorithm, potentially causing load imbalance.

We experimented with Cisco routers running IOS 12 in a lab environment and confirmed that this seed is configurable. If the Cisco router reboots and has no saved seed, it generates a new random seed. For Juniper and Huawei, documentation tells us that they also use a seed [11,13].

Thus, at least for Cisco, Juniper, and Huawei routers, a flow that took a certain load balanced path before a reboot can take a very different path after the reboot. Moreover, removing or adding an interface on a load-balancing router(s) toward a destination can cause the path assignment to be recalculated [8,10]. The particulars of the load balancing implementations in production can cause the reply IP address of a probe to change, *even when no routing change has occurred, and the flow identifier is constant*.

We attempt to identify in our dataset probe changes that correspond specifically to load balancer remapping. Our conservative rule of thumb is to say that if we observe a meaningful change for probe $(X,h+1)$, but at least one of the

Figure 7: Examples of three different types of changes for probe 2 across two snapshots i (left) and $i+1$ (right). In all cases, $E_i \cap E_{i+1} \neq \emptyset \implies$ we infer these as remapping events.

edges of the predecessor vertex is the same between snapshots, then remapping is taking place. If no edges are the same, it could still be the result of load balancer remapping instead of a routing change, but without evidence to allow us to infer this. Thus, our observations will underestimate the ubiquity of remapping.

We define $E_i(p)$ to be the set of out edges in snapshot i from the predecessor vertex of a meaningful change for probe $p = (X, h)$ (again, where a probe is a flow ID X and TTL h tuple). For each candidate meaningful-probe-change, we infer that the change is due to remapping if $E_i(p) \cap E_{i+1}(p) \neq \emptyset$.

Several classes of meaninful changes can be more more precisely characterized into subcategories. Either $E_i(p)$ and $E_{i+1}(p)$ can be: (1) equals, meaning that the changes might be due to a router reboot ($E_i = E_{i+1}$); (2) one set is included in the other, corresponding to potential addition/removal of some load balanced paths ($E_i \subset E_{i+1}$ or $E_{i+1} \subset E_i$); or (3) the sets have elements in common, but no inclusion relation can be established ($(E_i \subsetneq E_{i+1}) \wedge (E_{i+1} \subsetneq E_i)$), e.g., when load balanced paths are both added and removed.

Figure 7 illustrates these three cases by depicting of remapping from one snapshot, i (left), to the next, $i+1$ (right). Consider probe 2 in Fig 7a which is a meaningful change since it elicits v_3 in the first snapshot and v_2 in the second. The edges from the predecessor of these changes are the same between snapshots, i.e., $E_i(2) = E_{i+1}(2) = (v_1, v_2), (v_1, v_3)$. Note that the reciprocal change is observed by the flow 1 probe in $i+1$, for a total of two inferred remapping events.

In the example of Figure 7b, probe 2 is again a meaningful change, but in this instance elicits a new vertex v_3 in the second snapshot. In this case, the predecessor edges in the first snapshot are a subset of the second, i.e., $E_i(2) = (v_1, v_2)$ and $E_{i+1}(2) = (v_1, v_2), (v_1, v_3)$. Finally, Figure 7c shows an example of no inclusion relation where there is both a new and deleted edge due to remapping.

5.3 Remapping observed

We now quantify probe changes and remapping observed across our three snapshots of §4.1. Because identifying remapping requires observing probing changes between two consecutive snapshots, we restrict our analysis to the set of probes with replies from two consecutive snapshots. Of the 6,019,578,262 unique flow IDs that elicited replies in our database (11,689,101,599 replies in total), we find that 3,060,133,214 of them are present in two consecutive snapshots, representing a bit more than half of the flow IDs.

To understand why nearly half of the probe replies do not appear in two consecutive snapshots, we find that for 87% (2,576,532,888) of them the probe ID has in fact been sent only in one snapshot. This is due to the adaptive nature of the D-Miner algorithm resulting in variations of discovery between snapshots presented in §4.4. If, for example, the number of edges discovered for a prefix differs across the three snapshots, the statistical guarantees tell us the number of probes that must be sent will also differ. This results in some probe IDs being sent in only one snapshot. The result is that we are likely underestimating the number of meaningful probe changes. For the remaining 13.0%, the probe was sent in two consecutive snapshots, but did not elicit two replies. This is likely due to normal packet losses in the network and possibly ICMP rate limiting [40].

We start by looking at the number of probe changes. Table 3 shows the distribution of the number of probe changes per probe. We see that 28.6% of the probes have at least one probe change. This number seems unusual if we were to consider it all as routing changes.Table 4 explains the previous 28.6% fraction by providing the distribution of 1,000,308,669 changes according to the remapping classification. The "Other" column refers to changes with no inclusion relationship but element(s) in common. Notice that the sum of these classifications is slightly smaller than total number of probe changes. The missing probe changes correspond to cases where there was no predecessor for the node corresponding to the IP reply elicited by the probe. This would happen in Figure 7 if v_1 was anonymous (a '*') for example.

We see that 52.2% of the probe changes correspond to remapping, which temper the impact of the 28.6% probe changes on routing changes. Finally, for each of the probe changes corresponding to remapping, we performed IP to AS translation on the corresponding IP reply, using August 4, 2019 BGP data from route views [5]. We found that remapping events were spread over 39,455 ASes, showing that this phenomenon is widespread. We conclude this section by noting that all of the changes between snapshots, either due to D-Miner varying the set of probes from one snapshot to another; real dynamics such as routing changes; or remapping due to reboots and/or adding/removing load balanced paths, make any efficiency optimization based on historical discovery hard. It also further corroborates Cunha et al.'s finding that it is difficult to predict path changes [27].

6 An updated Internet load balancing survey

Its been eight years since the last published survey of load balancing in the Internet [18]. Whereas this previous study was limited to MDA traceroutes to ~120k targets, in this section we undertake the task of leveraging D-Miner to perform an exhaustive survey of Internet load balancing on 14,461,947 /24 destination prefixes.

Some things have certainly changed. We now see far larger load balanced topologies, for instance, with thousands of edges, instead of tens. This section updates our understanding of load balancing in the Internet, with some of the more notable results being: 17.9% of load balancing takes place between autonomous systems (i.e., *inter-AS load balancing*); just one autonomous system accounts for the topologies that contain more than 2000 edges; 64.7% of our traces towards all of the /24 prefixes contain at least one branching point (but this might be vantage point dependent); and 1.9% of branching points are per-packet load balancers.

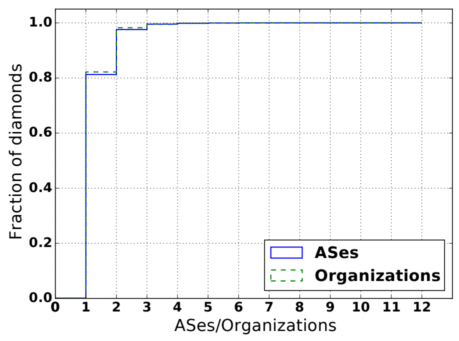

Figure 8: Intra- and inter-AS/organization load balancing.

6.1 Dataset

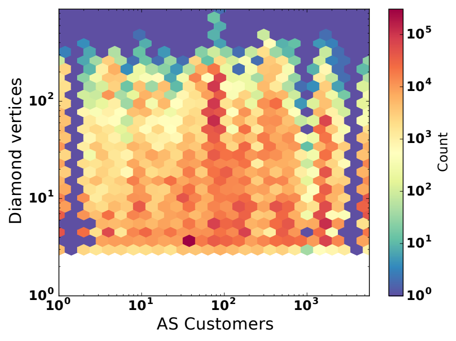
From the first snapshot of §4.1 (Aug 6-8, 2019), we extract all of the unique "diamonds" found on the load balanced paths. We adopt the same definition of a diamond as given by Augustin et al. [18]: a *diamond* is "a subgraph delimited by a divergence point followed, two or more hops later, by a convergence point, with the requirement that all flows from source to destination flow through both points." We say that two diamonds are equal if they share the same divergence and convergence points. When the divergence point or the convergence point is a $\star$ (i.e., this TTL is "anonymous"), we say that two diamonds are equal if they have identical node sets. In sending probes towards all IPv4 /24 destination prefixes, we extracted 4,029,866 unique diamonds.

6.2 Intra- and inter-AS load balancing

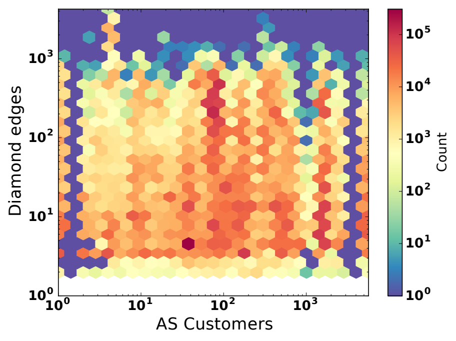
Augustin et al. found just one instance of inter-AS load balancing in their 2011 survey [18], whereas we now find it to be a more prevalent practice. We use Oregon Route Views BGP data [5] from 4 August 2019 to map IP addresses of the router interfaces comprising diamonds we discover in the Internet to autonomous systems (ASes). We further map AS numbers to organization names using CAIDA's AS Rank [33].

IP address to AS mapping is an outstanding research problem, and correct attribution is known to be difficult [37]. For instance, the IP address of a customer or peer border router is frequently allocated from her provider or peer's address space. We therefore adopt the same methodology of Augustin et al. [18] of not including the diamond's divergence or convergence point when determining the diamond's AS composition. Thus, our estimates of inter-AS load balancing are intended to be conservative.

The CDFs of Figure 8 show that, while most load balancing still takes place within a single autonomous system (AS) or organization, a significant portion takes place across two or more of them: 18.7% for ASes and 17.9% for organizations. In one case, we found a single diamond with addresses from 12 ASes (explaining why the CDF continues to 12).



(a) Vertices



(b) Edges

Figure 9: Joint distribution between the number of customers of ASes and size of the diamonds in these ASes.

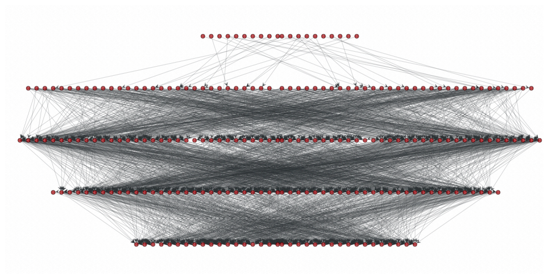


Figure 10: Extract of D-Miner trace to an Amazon /24 prefix.

6.3 ASes that host load balancers

We next investigate the relationship between the size of an AS (measured as number of customers) and the prevalence of load balancing in that AS. We use AS Rank from CAIDA [33] to perform the AS to customers mapping. When there is more than one AS in the diamond, each AS in the diamond is counted one time. Figure 9 shows no clear correlation between the number of customers in an AS and the amount of load balancing we infer, suggesting that load balancing is not limited to large networks, but is a widespread phenomenon.

However, there are some extreme cases involving large networks. We find 74 diamonds of more than 500 nodes each in the network of a French mobile network operator (SFR). Other ASes contain diamonds with $>10^3$ diamond edges, as seen in Figure 9b. There are 8,407 diamonds with more than 2,000 edges, of which 8,400 belong to Amazon – likely entry points to their datacenters. The DNS PTR records for the diamond's IP addresses are variations of the address and location, e.g., `ec2-54-178-57-0.ap-northeast-1.compute.amazonaws.com`. These names are characteristic of Amazon's cloud infrastructure. An example of such of a trace is shown in Figure 10. This figure shows the last TTLs of D-Miner tracing from a single VP to a single /24 prefix belonging to Amazon. The topology itself strongly resembles current data center design practices that use Clos architectures [47]; we requested validation from Amazon, however, they were unable to provide any corroborating information due to their internal privacy polices. This example, one of thousands in our data, shows just how complex load balanced topologies can be – complexity that would otherwise be missed without the comprehensive multipath mapping D-Miner provides.

7 Conclusion and future work

In this work we present D-Miner, the first Internet-scale system that captures a multipath view of the topology. By combining and adapting state-of-the-art multipath detection and high speed randomized topology discovery techniques, D-Miner permits discovery of the Internet's multipath topology in 2.5 days when probing at 100kpps. This high speed allows us to characterize and quantify dynamic behaviors of the Internet induced by load balancing. Finally, D-Miner enables for the first time an Internet Scale survey of load balancing that shows its widespread prevalence, both in the core and at the edge. We release the D-Miner source code and make our datasets publicly available.

Our hope is that D-Miner and our data will facilitate better understanding of the Internet's true structure, properties, and resilience. Future work includes running D-Miner with other transport protocols to compare load balancing usage between them at Internet scale, as well as adapting D-Miner to IPv6.

Our empirical data suggests that there are a set of load balanced architectures common to different provider types, for instance those deployed in data centers versus mobile operators versus transit providers. We believe there is significant opportunity to develop a taxonomy of these common architectures and classify results accordingly, as well as to identify previously unidentified load balanced architectures that are deployed in the wild. Comprehensive mapping of some of these topologies may require probing both from outside and within the provider's network; we leave an exploration of e.g., internal data center probing to future work.

Finally, in order to provide regular surveys to the community, we wish to deploy D-Miner on more vantage points at high probing speed, create periodic snapshots and perform alias resolution on the resulting discovered topologies.

Learning *in situ*: a randomized experiment in video streaming

Stanford University, [†]Tsinghua University

Abstract

We describe the results of a randomized controlled trial of video-streaming algorithms for bitrate selection and network prediction. Over the last year, we have streamed 38.6 years of video to 63,508 users across the Internet. Sessions are randomized in blinded fashion among algorithms.

We found that in this real-world setting, it is difficult for sophisticated or machine-learned control schemes to outperform a "simple" scheme (buffer-based control), notwithstanding good performance in network emulators or simulators. We performed a statistical analysis and found that the heavy-tailed nature of network and user behavior, as well as the challenges of emulating diverse Internet paths during training, present obstacles for learned algorithms in this setting.

We then developed an ABR algorithm that robustly outperformed other schemes, by leveraging data from its deployment and limiting the scope of machine learning only to making predictions that can be checked soon after. The system uses supervised learning *in situ*, with data from the real deployment environment, to train a probabilistic predictor of upcoming chunk transmission times. This module then informs a classical control policy (model predictive control).

To support further investigation, we are publishing an archive of data and results each week, and will open our ongoing study to the community. We welcome other researchers to use this platform to develop and validate new algorithms for bitrate selection, network prediction, and congestion control.

1 Introduction

Video streaming is the predominant Internet application, making up almost three quarters of all traffic [41]. One key algorithmic question in video streaming is *adaptive bitrate selection*, or ABR, which decides the compression level selected for each "chunk," or segment, of the video. ABR algorithms optimize the user's quality of experience (QoE): more-compressed chunks reduce quality, but larger chunks may stall playback if the client cannot download them in time.

In the academic literature, many recent ABR algorithms use statistical and machine-learning methods [4, 25, 38–40, 46], which allow algorithms to consider many input signals and try to perform well for a wide variety of clients. An ABR decision can depend on recent throughput, client-side buffer occupancy, delay, the experience of clients on similar ISPs or types of connectivity, etc. Machine learning can find patterns in seas of data and is a natural fit for this problem domain.

However, it is a perennial lesson that the performance of learned algorithms depends on the data or environments used to train them. ML approaches to video streaming and other wide-area networking challenges are often hampered in their access to good and representative training data. The Internet is complex and diverse, individual nodes only observe a noisy sliver of the system dynamics, and behavior is often heavy-tailed and changes with time. Even with representative throughput traces, accurately simulating or emulating the diversity of Internet paths requires more than replaying such traces and is beyond current capabilities [15, 16, 31, 45].

As a result, the performance of algorithms in emulated environments may not generalize to the Internet [7]. For example, CS2P's gains were more modest over real networks than in simulation [40]. Measurements of Pensieve [25] saw narrower benefits on similar paths [11] and a large-scale streaming service [24]. Other learned algorithms, such as the Remy congestion-control schemes, have also seen inconsistent results on real networks, despite good results in simulation [45].

This paper seeks to answer: *what does it take to create a learned ABR algorithm that robustly performs well over the wild Internet?* We report the design and findings of Puffer[1], an ongoing research study that operates a video-streaming website open to the public. Over the past year, Puffer has streamed 38.6 years of video to 63,508 distinct users, while recording client telemetry for analysis (current load is about 60 stream-days of data per day). Puffer randomly assigns each session to one of a set of ABR algorithms; users are blinded to the assignment. We find:

[1] https://puffer.stanford.edu

In our real-world setting, sophisticated algorithms based on control theory [46] or reinforcement learning [25] did not outperform simple buffer-based control [18]. We found that more-sophisticated algorithms do not necessarily beat a simpler, older algorithm. The newer algorithms were developed and evaluated using throughput traces that may not have captured enough of the Internet's heavy tails and other dynamics when replayed in simulation or emulation. Training them on more-representative traces doesn't necessarily reverse this: we retrained one algorithm using throughput traces drawn from Puffer (instead of its original set of traces) and evaluated it also on Puffer, but the results were similar (§5.3).

Statistical margins of error in quantifying algorithm performance are considerable. Prior work on ABR algorithms has claimed benefits of 10–15% [46], 3.2–14% [40], or 12–25% [25], based on throughput traces or real-world experiments lasting hours or days. However, we found that the empirical variability and heavy tails of throughput evolution and rebuffering create statistical margins of uncertainty that make it challenging to detect real effects of this magnitude. Even with a *year* of experience per scheme, a 20% improvement in rebuffering ratio would be statistically indistinguishable, i.e., below the threshold of detection with 95% confidence. These uncertainties affect the design space of machine-learning approaches that can practically be deployed [13, 26].

It is possible to robustly outperform existing schemes by combining classical control with an ML predictor trained *in situ* on real data. We describe Fugu, a data-driven ABR algorithm that combines several techniques. Fugu is based on MPC (model predictive control) [46], a classical control policy, but replaces its throughput predictor with a deep neural network trained using supervised learning on data recorded *in situ* (in place), meaning from Fugu's actual deployment environment, Puffer. The predictor has some uncommon features: it predicts *transmission time* given a chunk's file size (vs. estimating throughput), it outputs a probability distribution (vs. a point estimate), and it considers low-level congestion-control statistics among its input signals. Ablation studies (§4.2) find each of these features to be necessary to Fugu's performance.

In a controlled experiment during most of 2019, Fugu outperformed existing techniques—including the simple algorithm—in stall ratio (with one exception), video quality, and the variability of video quality (Figure 1). The improvements were significant both statistically and, perhaps, practically: users who were randomly assigned to Fugu (in blinded fashion) chose to continue streaming for 5–9% longer, on average, than users assigned to the other ABR algorithms.[2]

Our results suggest that, as in other domains, good and representative training is the key challenge for robust performance of learned networking algorithms, a somewhat different point of view from the generalizability arguments in prior

[2]This effect was driven solely by users streaming more than 3 hours of video; we do not fully understand it.

Results of primary experiment (Jan. 26–Aug. 7 & Aug. 30–Oct. 16, 2019)

Algorithm	Time stalled (lower is better)	Mean SSIM (higher is better)	SSIM variation (lower is better)	Mean duration (time on site)
Fugu	0.13%	16.64 dB	0.74 dB	33.6 min
MPC-HM [46]	0.22%	16.61 dB	0.79 dB	30.8 min
BBA [18]	0.19%	16.56 dB	1.11 dB	32.1 min
Pensieve [25]	0.17%	16.26 dB	1.05 dB	31.6 min
RobustMPC-HM	0.12%	16.01 dB	0.98 dB	31.0 min

Figure 1: In an eight-month randomized controlled trial with blinded assignment, the Fugu scheme outperformed other ABR algorithms. The primary analysis includes 637,189 streams played by 54,612 client IP addresses (13.1 client-years in total). Uncertainties are shown in Figures 9 and 11.

work [25, 37, 44]. One way to achieve representative training is to learn in place (*in situ*) on the actual deployment environment, assuming the scheme can be feasibly trained this way and the deployment is widely enough used to exercise a broad range of scenarios.[3] The approach we describe here is only a step in this direction, but we believe Puffer's results suggest that learned systems will benefit by addressing the challenge of "*how will we get enough representative scenarios for training—what is enough, and how do we keep them representative over time?*" as a first-class consideration.

We intend to operate Puffer as an "open research" project as long as feasible. We invite the research community to train and test new algorithms on randomized subsets of its traffic, gaining feedback on real-world performance with quantified uncertainty. Along with this paper, we are publishing an archive of data and results back to the beginning of 2019 on the Puffer website, with new data and results posted weekly.

In the next few sections, we discuss the background and related work on this problem (§2), the design of our blinded randomized experiment (§3) and the Fugu algorithm (§4), with experimental results in Section 5, and a discussion of results and limitations in Section 6. In the appendices, we provide a standardized diagram of the experimental flow for the primary analysis and describe the data we are releasing.

2 Background and related work

The basic problem of adaptive video streaming has been the subject of much academic work; for a good overview, we refer the reader to Yin et al. [46]. We briefly outline the problem here. A service wishes to serve a pre-recorded or live video stream to a broad array of clients over the Internet. Each client's connection has a different and unpredictable time-varying performance. Because there are many clients, it is not feasible for the service to adjust the encoder configuration in real time to accommodate any one client.

[3]Even collecting traces from a deployment environment and replaying them in a simulator or emulator to train a control policy—as is typically necessary in reinforcement learning—is not what we mean by "*in situ*."

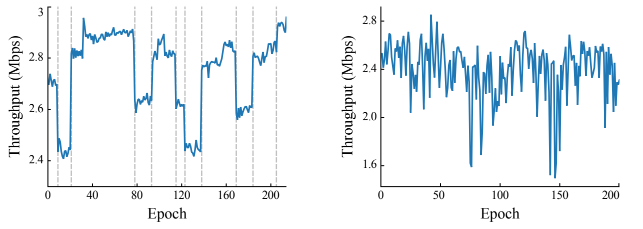
Instead, the service encodes the video into a handful of alternative compressed versions. Each represents the original video but at a different quality, target bitrate, or resolution. Client sessions choose from this limited menu. The service encodes the different versions in a way that allows clients to switch midstream as necessary: it divides the video into *chunks*, typically 2–6 seconds each, and encodes each version of each chunk independently, so it can be decoded without access to any other chunks. This gives clients the opportunity to switch between different versions at each chunk boundary. The different alternatives are generally referred to as different "bitrates," although streaming services today generally use "variable bitrate" (VBR) encoding [32], where within each alternative stream, the chunks vary in compressed size [47].

Choosing which chunks to fetch. Algorithms that select which alternative version of each chunk to fetch and play, given uncertain future throughput, are known as *adaptive bitrate* (ABR) schemes. These schemes fetch chunks, accumulating them in a playback buffer, while playing the video at the same time. The playhead advances and drains the buffer at a steady rate, 1 s/s, but chunks arrive at irregular intervals dictated by the varying network throughput and the compressed size of each chunk. If the buffer underflows, playback must stall while the client "rebuffers": fetching more chunks before resuming playback. The goal of an ABR algorithm is typically framed as choosing the optimal sequence of chunks to fetch or replace [38], given recent experience and guesses about the future, to minimize startup time and presence of stalls, maximize the quality of chunks played back, and minimize variation in quality over time (especially abrupt changes in quality). The importance tradeoff for these factors is captured in a QoE metric; several studies have calibrated QoE metrics against human behavior or opinion [6, 12, 21].

Adaptive bitrate selection. Researchers have produced a literature of ABR schemes, including "rate-based" approaches that focus on matching the video bitrate to the network throughput [20, 23, 27], "buffer-based" algorithms that steer the duration of the playback buffer [18, 38, 39], and control-theoretic schemes that try to maximize expected QoE over a receding horizon, given the upcoming chunk sizes and a prediction of the future throughput.

Model Predictive Control (MPC), FastMPC, and RobustMPC [46] fall into the last category. They comprise two modules: a *throughput predictor* that informs a predictive *model* of what will happen to the buffer occupancy and QoE in the near future, depending on which chunks it fetches, with what quality and sizes. MPC uses the model to plan a sequence of chunks over a limited horizon (e.g., the next 5–8 chunks) to maximize the expected QoE. We implemented MPC and RobustMPC for Puffer, using the same predictor as the paper: the harmonic mean of the last five throughput samples.

CS2P [40] and Oboe-tuned RobustMPC [4] are related to MPC; they constitute better throughput predictors that inform



(a) CS2P example session (Figure 4a from [40])

(b) Typical Puffer session with similar mean throughput

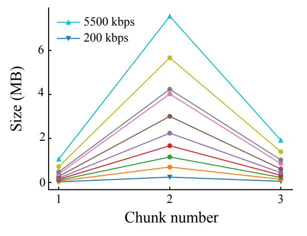
Figure 2: Puffer has not observed CS2P's discrete throughput states. (Epochs are 6 seconds in both plots.)

the same control strategy (MPC). These throughput predictors were trained on real datasets that recorded the evolution of throughput over time within a session. CS2P clusters users by similarity and models their evolving throughput as a Markovian process with a small number of discrete states; Oboe uses a similar model to detect when the network path has changed state. In our dataset, we have not observed CS2P and Oboe's observation of discrete throughput states (Figure 2).

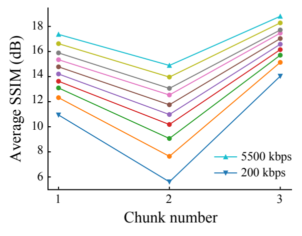
Fugu fits in this same category of algorithms. It also uses MPC as the control strategy, informed by a network predictor trained on real data. This component, which we call the Transmission Time Predictor (TTP), incorporates a number of uncommon features, none of which can claim novelty on its own. The TTP explicitly predicts the transmission time of a chunk with given size and isn't a "throughput" predictor *per se*. A throughput predictor models the transmission time of a chunk as scaling linearly with size, but it is well known that observed throughput varies with file size [7, 32, 47], in part because of the effects of congestion control and because chunks of different sizes experience different time intervals of the path's varying capacity. To our knowledge, Fugu is the first to use this fact operationally as part of a control policy.

Fugu's predictor is also *probabilistic*: it outputs not a single predicted transmission time, but a probability distribution on possible outcomes. The use of uncertainty in model predictive control has a long history [36], but to our knowledge Fugu is the first to use stochastic MPC in this context. Finally, Fugu's predictor is a neural network, which lets it consider an array of diverse signals that relate to transmission time, including raw congestion-control statistics from the sender-side TCP implementation [17, 42]. We found that several of these signals (RTT, CWND, etc.) benefit ABR decisions (§5).

Pensieve [25] is an ABR scheme also based on a deep neural network. Unlike Fugu, Pensieve uses the neural network not simply to make predictions but to make *decisions* about which chunks to send. This affects the type of learning used to train the algorithm. While CS2P and Fugu's TTP can be trained with *supervised learning* (to predict chunk transmission times recorded from past data), it takes more than data to train a scheme that makes decisions; one needs training *envi-*



(a) VBR encoding lets chunk size vary within a stream [47].



(b) Picture quality also varies with VBR encoding [32].

Figure 3: Variations in picture quality and chunk size within each stream suggest a benefit from choosing chunks based on SSIM and size, rather than average bitrate (legend).

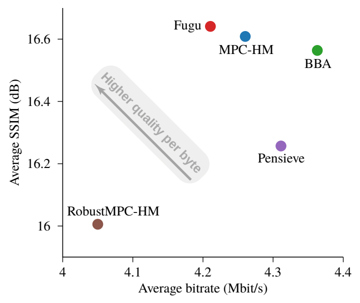


Figure 4: On Puffer, schemes that maximize average SSIM (MPC-HM, RobustMPC-HM, and Fugu) delivered higher quality video per byte sent, vs. those that maximize bitrate directly (Pensieve) or the SSIM of each chunk (BBA).

ronments that respond to a series of decisions and judge their consequences. This is known as reinforcement learning (RL). Generally speaking, RL techniques expect a set of training environments that can exercise a control policy through a range of situations and actions [3], and need to be able to observe a detectable difference in performance by slightly varying a control action. Systems that are challenging to simulate or that have too much noise present difficulties [13, 26].

3 Puffer: an ongoing live study of ABR

To understand the challenges of video streaming and measure the behavior of ABR schemes, we built Puffer, a free, publicly accessible website that live-streams six over-the-air commercial television channels. Puffer operates as a randomized controlled trial; sessions are randomly assigned to one of a set of ABR or congestion-control schemes. The study participants include any member of the public who wishes to participate. Users are blinded to algorithm assignment, and we record client telemetry on video quality and playback. A Stanford Institutional Review Board determined that Puffer does not constitute human subjects research.

Our reasoning for streaming live television was to collect data from enough participants and network paths to draw robust conclusions about the performance of algorithms for ABR control and network prediction. Live television is an evergreen source of popular content that had not been broadly available for free on the Internet. Our study benefits, in part, from a law that allows nonprofit organizations to retransmit over-the-air television signals without charge [1]. Here, we describe details of the system, experiment, and analysis.

3.1 Back-end: decoding, encoding, SSIM

Puffer receives six television channels using a VHF/UHF antenna and an ATSC demodulator, which outputs MPEG-2 transport streams in UDP. We wrote software to decode a stream to chunks of raw decoded video and audio, maintaining synchronization (by inserting black fields or silence) in the event of lost transport-stream packets on either substream. Video chunks are 2.002 seconds long, reflecting the 1/1001 factor for NTSC frame rates. Audio chunks are 4.8 seconds long. Video is de-interlaced with `ffmpeg` to produce a “canonical” 1080p60 or 720p60 source for compression.

Puffer encodes each video chunk in ten different H.264 versions, using `libx264` in `veryfast` mode. The encodings range from 240p60 video with constant rate factor (CRF) of 26 (about 200 kbps) to 1080p60 video with CRF of 20 (about 5,500 kbps). Audio chunks are encoded in the Opus format.

Puffer then uses `ffmpeg` to calculate each encoded chunk’s SSIM [43], a measure of video quality, relative to the canonical source. This information is used by the objective function of BBA, MPC, RobustMPC, and Fugu, and for our evaluation. In practice, the relationship between bitrate and quality varies chunk-by-chunk (Figure 3), and users cannot perceive compressed chunk sizes directly—only what is shown on the screen. ABR schemes that maximize bitrate do not necessarily see a commensurate benefit in picture quality (Figure 4).

Encoding six channels in ten versions each (60 streams total) with `libx264` consumes about 48 cores of an Intel x86-64 2.7 GHz CPU in steady state. Calculating the SSIM of each encoded chunk consumes an additional 18 cores.

3.2 Serving chunks to the browser

To make it feasible to deploy and test arbitrary ABR schemes, Puffer uses a “dumb” player (using the HTML5 `<video>` tag and the JavaScript Media Source Extensions) on the client side, and places the ABR scheme at the server. We have a 48-core server with 10 Gbps Ethernet in a datacenter at Stanford. The browser opens a WebSocket (TLS/TCP) connection to a daemon on the server. Each daemon is configured with a different TCP congestion control (for the primary analysis, we used BBR [9]) and ABR scheme. Some schemes are more efficiently implemented than others; on average the CPU load from serving client traffic (including TLS, TCP, and ABR) is about 5% of an Intel x86-64 2.7 GHz core per stream.

Algorithm	Control	Predictor	Optimization goal	How trained
BBA	classical (linear control)	*n/a*	$+$SSIM *s.t.* bitrate $<$ limit	*n/a*
MPC-HM	classical (MPC)	classical (HM)	$+\overline{\text{SSIM}}$, $-$stalls, $-\Delta$SSIM	*n/a*
RobustMPC-HM	classical (robust MPC)	classical (HM)	$+\overline{\text{SSIM}}$, $-$stalls, $-\Delta$SSIM	*n/a*
Pensieve	learned (DNN)	*n/a*	$+\overline{\text{bitrate}}$, $-$stalls, $-\Delta$bitrate	reinforcement learning in simulation
Fugu	classical (MPC)	learned (DNN)	$+\overline{\text{SSIM}}$, $-$stalls, $-\Delta$SSIM	supervised learning *in situ*

Figure 5: Distinguishing features of algorithms used in the primary experiment. HM = harmonic mean of last five throughput samples. MPC = model predictive control. DNN = deep neural network.

Sessions are randomly assigned to serving daemons. Users can switch channels without breaking their TCP connection and may have many "streams" within each session.

Puffer is not a client-side DASH [28] (Dynamic Adaptive Streaming over HTTP) system. Like DASH, though, Puffer is an ABR system streaming chunked video over a TCP connection, and runs the same ABR algorithms that DASH systems can run. We don't expect this architecture to replace client-side ABR (which can be served by CDN edge nodes), but we expect its conclusions to translate to ABR schemes broadly. The Puffer website works in the Chrome, Firefox, Edge, and Opera browsers, including on Android phones, but does not play in the Safari browser or on iOS (which lack support for the Media Source Extensions or Opus audio).

3.3 Hosting arbitrary ABR schemes

We implemented buffer-based control (BBA), MPC, RobustMPC, and Fugu in back-end daemons that serve video chunks over the WebSocket. We use SSIM in the objective functions for each of these schemes. For BBA, we use the formula in the original paper [18] to decide the maximum chunk size, and subject to this constraint, the chunk with the highest SSIM is selected to stream. We also choose reservoir values consistent with our 15-second maximum buffer.

Deploying Pensieve for live streaming. We use the released Pensieve code (written in Python with TensorFlow) directly. When a client is assigned to Pensieve, Puffer spawns a Python subprocess running Pensieve's multi-video model.

We contacted the Pensieve authors to request advice on deploying the algorithm in a live, multi-video, real-world setting. The authors recommended that we use a longer-running training and that we tune the entropy parameter when training the multi-video neural network. We wrote an automated tool to train 6 different models with various entropy reduction schemes. We tested these manually over a few real networks, then selected the model with the best performance. We modified the Pensieve code (and confirmed with the authors) so that it does not expect the video to end before a user's session completes. We were not able to modify Pensieve to optimize SSIM; it considers the average bitrate of each Puffer stream. We adjusted the video chunk length to 2.002 seconds and the buffer threshold to 15 seconds to reflect our parameters. For training data, we used the authors' provided script to generate 1000 simulated videos as training videos, and a combination of the FCC and Norway traces linked to in the Pensieve codebase as training traces.

3.4 The Puffer experiment

To recruit participants, we purchased Google and Reddit ads for keywords such as "live tv" and "tv streaming" and paid people on Amazon Mechanical Turk to use Puffer. We were also featured in press articles. Popular programs (e.g. the 2019 and 2020 Super Bowls, the Oscars, World Cup, and "Bachelor in Paradise") brought large spikes ($> 20\times$) over baseline load. Our current average load is about 60 concurrent streams.

Between Jan. 26, 2019 and Feb. 2, 2020, we have streamed 38.6 years of video to 63,508 registered study participants using 111,231 unique IP addresses. About eight months of that period was spent on the "primary experiment," a randomized trial comparing Fugu with other algorithms: MPC, RobustMPC, Pensieve, and BBA (a summary of features is in Figure 5). This period saw a total of 314,577 streaming sessions, and 1,904,316 individual streams. An experimental-flow diagram in the standardized CONSORT format [35] is in the appendix (Figure A1).

We record client telemetry as time-series data, detailing the size and SSIM of every video chunk, the time to deliver each chunk to the client, the buffer size and rebuffering events at the client, the TCP statistics on the server, and the identity of the ABR and congestion-control schemes. A full description of the data is in Appendix B.

Metrics and statistical uncertainty. We group the time series by user stream to calculate a set of summary figures: the total time between the first and last recorded events of the stream, the startup time, the total watch time between the first and last successfully played portion of the stream, the total time the video is stalled for rebuffering, the average SSIM, and the chunk-by-chunk variation in SSIM. The ratio between "total time stalled" and "total watch time" is known as the rebuffering ratio or stall ratio, and is widely used to summarize the performance of streaming video systems [22].

We observe considerable heavy-tailed behavior in most of these statistics. Watch times are skewed (Figure 11), and while the *risk* of rebuffering is important to any ABR algorithm, actual rebuffering is a rare phenomenon. Of the 637,189 eligible streams considered for the primary analysis across all five ABR schemes, only 24,328 (4%) of those streams had *any* stalls, mirroring commercial services [22].

These skewed distributions create more room for the play of chance to corrupt the bottom-line statistics summarizing a scheme's performance—even two identical schemes will see considerable variation in average performance until a substantial amount of data is assembled. In this study, we worked to quantify the statistical uncertainty that can be attributed to the play of chance in assigning sessions to ABR algorithms. We calculate confidence intervals on rebuffering ratio with the bootstrap method [14], simulating streams drawn empirically from each scheme's observed distribution of rebuffering ratio as a function of stream duration. We calculate confidence intervals on average SSIM using the formula for weighted standard error, weighting each stream by its duration.

These practices result in substantial confidence intervals: with at least 2.5 years of data for each scheme, the width of the 95% confidence interval on a scheme's stall ratio is between $\pm 13\%$ and $\pm 21\%$ of the mean value. This is comparable to the magnitude of the total benefit reported by some academic work that used much shorter real-world experiments. Even a recent study of a Pensieve-like scheme on Facebook [24], encompassing 30 million streams, did not detect a change in rebuffering ratio outside the level of statistical noise.

We conclude that considerations of uncertainty in real-world learning and experimentation, especially given uncontrolled data from the Internet with real users, deserve further study. Strategies to import real-world data into repeatable emulators [45] or reduce their variance [26] will likely be helpful in producing robust learned networking algorithms.

4 Fugu: design and implementation

Fugu is a control algorithm for bitrate selection, designed to be feasibly trained in place (*in situ*) on a real deployment environment. It consists of a classical controller (model predictive control, the same as in MPC-HM), informed by a nonlinear predictor that can be trained with supervised learning.

Figure 6 shows Fugu's high-level design. Fugu runs on the server, making it easy to update its model and aggregate performance data across clients over time. Clients send necessary telemetry, such as buffer levels, to the server.

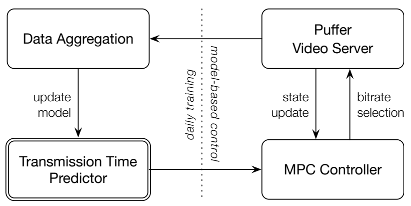

Figure 6: Overview of Fugu

The controller, described in Section 4.4, makes decisions by following a classical control algorithm to optimize an objective QoE function (§4.1) based on predictions for how long each chunk would take to transmit. These predictions are provided by the Transmission Time Predictor (TTP) (§4.2), a neural network that estimates a probability distribution for the transmission time of a proposed chunk with given size.

4.1 Objective function

For each video chunk K_i, Fugu has a selection of versions of this chunk to choose from, K_i^s, each with a different size s. As with prior approaches, Fugu quantifies the QoE of each chunk as a linear combination of video quality, video quality variation, and stall time [46]. Unlike some prior approaches, which use the average compressed bitrate of each encoding setting as a proxy for image quality, Fugu optimizes a perceptual measure of picture quality—in our case, SSIM. This has been shown to correlate with human opinions of QoE [12]. We emphasize that we use the exact same objective function in our version of MPC and RobustMPC as well.

Let $Q(K)$ be the video quality of a chunk K, $T(K)$ be the uncertain transmission time of K, and B_i be the current playback buffer size. Following [46], Fugu defines the QoE obtained by sending K_i^s (given the previously sent chunk K_{i-1}) as

$$QoE(K_i^s, K_{i-1}) = Q(K_i^s) - \lambda|Q(K_i^s) - Q(K_{i-1})| \\ - \mu \cdot \max\{T(K_i^s) - B_i, 0\}, \tag{1}$$

where $\max\{T(K_i^s) - B_i, 0\}$ describes the stall time experienced by sending K_i^s, and λ and μ are configuration constants for how much to weight video quality variation and rebuffering. Fugu plans a trajectory of sizes s of the future H chunks to maximize their expected total QoE.

4.2 Transmission Time Predictor (TTP)

Once Fugu decides which chunk from K_i^s to send, two portions of the QoE become known: the video quality and video quality variation. The remaining uncertainty is the stall time. The server knows the current playback buffer size, so what it needs to know is the transmission time: how long will it take for the client to receive the chunk? Given an oracle that reports the transmission time of any chunk, the MPC controller can compute the optimal plan to maximize QoE.

Fugu uses a trained neural-network transmission-time predictor to approximate the oracle. For each chunk in the fixed H-step horizon, we train a separate predictor. E.g., if optimizing for the total QoE of the next five chunks, five neural networks are trained. This lets us parallelize training.

Each TTP network for the future step $h \in \{0, \ldots, H-1\}$ takes as input a vector of:

1. sizes of past t chunks $K_{i-t}, \ldots, K_{i-1}$,
2. actual transmission times of past t chunks: $T_{i-t}, \ldots, T_{i-1}$,

3. internal TCP statistics (Linux `tcp_info` structure),
4. size s of a proposed chunk K^s_{i+h}.

The TCP statistics include the current congestion window size, the number of unacknowledged packets in flight, the smoothed RTT estimate, the minimum RTT, and the TCP estimated throughput (`tcpi_delivery_rate`).

Prior approaches have used Harmonic Mean (HM) [46] or a Hidden Markov Model (HMM) [40] to predict a single throughput for the entire lookahead horizon irrespective of the size of chunk to send. In contrast, the TTP acknowledges the fact that observed throughput varies with chunk size [7,32,47] by taking the size of proposed chunk K^s_{i+h} as an explicit input. In addition, it outputs a discretized probability distribution of predicted transmission time $\hat{T}(K^s_{i+h})$.

4.3 Training the TTP

We sample from the real usage data collected by *any* scheme running on Puffer and feed individual user streams to the TTP as training input. For the TTP network in the future step h, each user stream contains a chunk-by-chunk series of (a) the input 4-vector with the last element to be size of the actually sent chunk K_{i+h}, and, (b) the actual transmission time T_{i+h} of chunk K_{i+h} as desired output; the sequence is shuffled to remove correlation. It is worth noting that unlike prior work [25, 40] that learned from throughput traces, TTP is trained directly on real chunk-by-chunk data.

We train the TTP with standard supervised learning: the training minimizes the cross-entropy loss between the output probability distribution and the discretized actual transmission time using stochastic gradient descent.

We retrain the TTP every day, using training data collected over the prior 14 days, to avoid the effects of dataset shift and catastrophic forgetting [33,34]. Within the 14-day window, we weight more recent days more heavily. The weights from the previous day's model are loaded to warm-start the retraining.

4.4 Model-based controller

Our MPC controller (used for MPC-HM, RobustMPC-HM, and Fugu) is a stochastic optimal controller that maximizes the expected cumulative QoE in Equation 1 with replanning. It queries TTP for predictions of transmission time and outputs a plan $K^s_i, K^s_{i+1}, \dots, K^s_{i+H-1}$ by value iteration [8]. After sending K^s_i, the controller observes and updates the input vector passed into TTP, and replans again for the next chunk.

Given the current playback buffer level B_i and the last sent chunk K_{i-1}, let $v^*_i(B_i, K_{i-1})$ denote the maximum expected sum of QoE that can be achieved in the H-step lookahead horizon. We have value iteration as follows:

$$v^*_i(B_i, K_{i-1}) = \max_{K^s_i} \Big\{ \sum_{t_i} \Pr[\hat{T}(K^s_i) = t_i] \cdot \\ \big(QoE(K^s_i, K_{i-1}) + v^*_{i+1}(B_{i+1}, K^s_i)\big) \Big\},$$

where $\Pr[\hat{T}(K^s_i) = t_i]$ is the probability predicted by TTP for the transmission time of K^s_i to be t_i, and B_{i+1} can be derived by system dynamics [46] given an enumerated (discretized) t_i. The controller computes the optimal trajectory by solving the above value iteration with dynamic programming (DP). To make the DP computational feasible, it also discretizes B_i into bins and uses forward recursion with memoization to only compute for relevant states.

4.5 Implementation

TTP takes as input the past $t = 8$ chunks, and outputs a probability distribution over 21 bins of transmission time: $[0, 0.25), [0.25, 0.75), [0.75, 1.25), \dots, [9.75, \infty)$, with 0.5 seconds as the bin size except for the first and the last bins. TTP is a fully connected neural network, with two hidden layers with 64 neurons each. We tested different TTPs with various numbers of hidden layers and neurons, and found similar training losses across a range of conditions for each. We implemented TTP and the training in PyTorch, but we load the trained model in C++ when running on the production server for performance. A forward pass of TTP's neural network in C++ imposes minimal overhead per chunk (less than 0.3 ms on average on a recent x86-64 core). The MPC controller optimizes over $H = 5$ future steps (about 10 seconds). We set $\lambda = 1$ and $\mu = 100$ to balance the conflicting goals in QoE. Each retraining takes about 6 hours on a 48-core server.

4.6 Ablation study of TTP features

We performed an ablation study to assess the impact of the TTP's features (Figure 7). The prediction accuracy is measured using mean squared error (MSE) between the predicted transmission time and the actual (absolute, unbinned) value. For the TTP that outputs a probability distribution, we compute the expected transmission time by weighting the median value of each bin with the corresponding probability. Here are the more notable results:

Use of low-level congestion-control statistics. The TTP's nature as a DNN lets it consider a variety of noisy inputs, including low-level congestion-control statistics. We feed the kernel's `tcp_info` structure to the TTP, and find that several of these fields contribute positively to the TTP's accuracy, especially the RTT, CWND, and number of packets in flight (Figure 7). Although client-side ABR systems cannot typically access this structure directory because the statistics live on the sender, these results should motivate the communication of richer data to ABR algorithms wherever they live.

Transmission-time prediction. The TTP explicitly considers the size of a proposed chunk, rather than predicting throughput and then modeling transmission time as scaling linearly with chunk size [7, 32, 47]. We compared the TTP with an equivalent throughput predictor that is agnostic to the

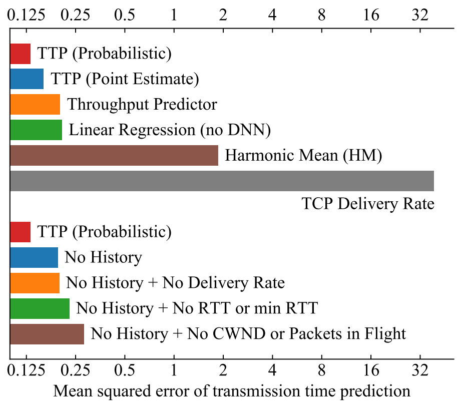

Figure 7: Ablation study of Fugu's Transmission Time Predictor (TTP). Removing any of the TTP's inputs reduced its ability to predict the transmission time of a video chunk. A non-probabilistic TTP ("Point Estimate") and one that predicts throughput without regard to chunk size ("Throughput Predictor") both performed markedly worse. TCP statistics (RTT, CWND, packets in flight) also proved helpful.

chunk's size (keeping everything else unchanged). The TTP's predictions were much more accurate (Figure 7).

Prediction with uncertainty. The TTP outputs a *probability distribution* of transmission times. This allows for better decision making compared with a single point estimate without uncertainty. We evaluated the expected accuracy of a probabilistic TTP vs. a point-estimate version that outputs the median value of the most-probable bin, and found an improvement in prediction accuracy with the former (Figure 7). To measure the end-to-end benefits of a probabilistic TTP, we deployed both versions on Puffer in August 2019 and collected 39 stream-days of data. It performed much worse than normal Fugu: the rebuffering ratio was 5× worse, without significant improvement in SSIM (data not shown).

Use of neural network. We found a significant benefit from using a deep neural network in this application, compared with a linear-regression model that was trained the same way. The latter model performed much worse on prediction accuracy (Figure 7). We also deployed it on Puffer and collected 448 stream-days of data in Aug.–Oct. 2019; its rebuffering ratio was 2.5× worse (data not shown).

Daily retraining. To evaluate our practice of retraining the TTP each day, we conducted a randomized comparison of several "out-of-date" versions of the TTP on Puffer between Aug. 7 and Aug. 30, 2019, and between Oct. 16, 2019 and Jan. 2, 2020. We compared vintages of the TTP that had been trained in February, March, April, and May 2019, alongside the TTP that is retrained each day. (We emphasize that the older TTP vintages were also learned *in situ* on two weeks of data from the actual deployment environment—they are simply earlier versions of the same predictor.) Somewhat to our

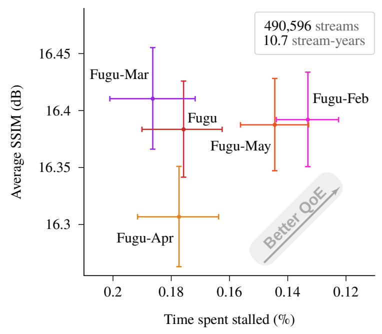

Figure 8: Fugu, which is retrained every day, did not outperform older versions of itself that were trained up to 11 months earlier. Our practice of daily retraining appears to be overkill.

surprise and disappointment, we were not able to document a benefit from daily retraining (Figure 8). This may reflect a lack of dynamism in the Puffer userbase, or the fact that once "enough" data is available to put the predictor through its paces, more-recent data is not necessarily beneficial, or some other reason. We suspect the older predictors might become stale at some point in the future, but for the moment, our practice of daily retraining appears to be overkill.

5 Experimental results

We now present findings from our experiments with the Puffer study, including the evaluation of Fugu. Our main results are shown in Figure 9. In summary, we conducted a parallel-group, blinded-assignment, randomized controlled trial of five ABR schemes between Jan. 26 and Aug. 7, and between Aug. 30 and Oct. 16, 2019. The data include 13.1 stream-years of data split across five algorithms, counting all streams that played at least 4 seconds of video. A standardized diagram of the experimental flow is available in the appendix (Figure A1).

We found that simple "buffer-based" control (BBA) performs surprisingly well, despite its status as a frequently outperformed research baseline. The only scheme to consistently outperform BBA in both stalls and quality was Fugu, but only when *all* features of the TTP were used. If we remove the probabilistic "fuzzy" nature of Fugu's predictions, *or* the "depth" of the neural network, *or* the prediction of transmission time as a function of chunk size (and not simply throughput), Fugu forfeits its advantage (§4.6). Fugu also outperformed other schemes in terms of SSIM variability (Figure 1). On a cold start to a new session, prior work [19, 40] suggested a need for session clustering to determine the quality of the first chunk. TTP provides an alternative approach: low-level TCP statistics are available as soon as the (HTTP/WebSocket, TLS, TCP) connection is established and allow Fugu to begin safely at a higher quality (Figure 10).

We conclude that robustly beating "simple" algorithms with machine learning may be surprisingly difficult, notwith-

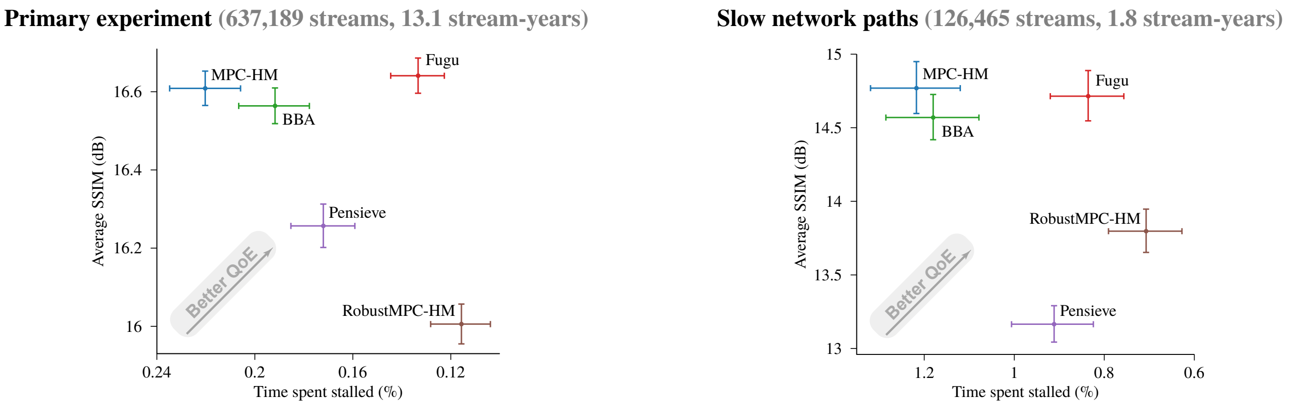

Figure 9: Main results. In a blinded randomized controlled trial that included 13.1 years of video streamed to 54,612 client IP addresses over an eight-month period, Fugu reduced the fraction of time spent stalled (except with respect to RobustMPC-HM), increased SSIM, and reduced SSIM variation within each stream (tabular data in Figure 1). "Slow" network paths have average throughput less than 6 Mbit/s; following prior work [25, 46], these paths are more likely to require nontrivial bitrate-adaptation logic. Such streams accounted for 14% of overall viewing time and 83% of stalls. Error bars show 95% confidence intervals.

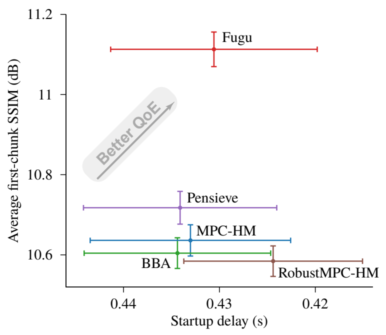

Figure 10: On a cold start, Fugu's ability to bootstrap ABR decisions from TCP statistics (e.g., RTT) boosts initial quality.

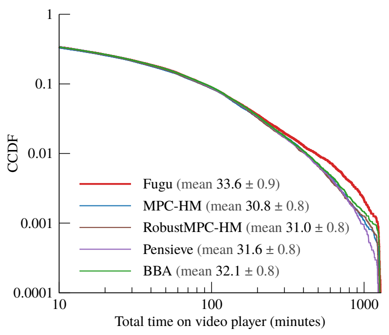

Figure 11: Users randomly assigned to Fugu chose to remain on the Puffer video player about 5%–9% longer, on average, than those assigned to other schemes. Users were blinded to the assignment. Legend shows 95% confidence intervals on the average time-on-site in minutes.

standing promising results in contained environments such as simulators and emulators. The gains that learned algorithms have in optimization or smarter decision making may come at a tradeoff in brittleness or sensitivity to heavy-tailed behavior.

5.1 Fugu users streamed for longer

We observed significant differences in the session durations of users across algorithms (Figure 11). Users whose sessions were assigned to Fugu chose to remain on the Puffer video player about 5–9% longer, on average, than those assigned to other schemes. Users were blinded to the assignment, and we believe the experiment was carefully executed not to "leak" details of the underlying scheme (MPC and Fugu even share most of their codebase). The average difference was driven solely by the upper 4% tail of viewership duration (sessions lasting more than 3 hours)—viewers assigned to Fugu are much more likely to keep streaming beyond this point, even as the distributions are nearly identical until then.

Time-on-site is a figure of merit in the video-streaming industry and might be increased by delivering better-quality video with fewer stalls, but we simply do not know enough about what is driving this phenomenon.

5.2 The benefits of learning *in situ*

Each of the ABR algorithms we deployed has been evaluated in emulation in prior work [25, 46]. Notably, the results in those works are qualitatively different from some of the real world results we have seen here—for example, buffer-based control matching or outperforming MPC-HM and Pensieve.

To investigate this further, we constructed an emulation environment similar to that used in [25]. This involved running the Puffer media server locally, and launching headless Chrome clients inside mahimahi [30] shells to connect to the server. Each mahimahi shell imposed a 40 ms end-to-end delay on traffic originating inside it and limited the downlink

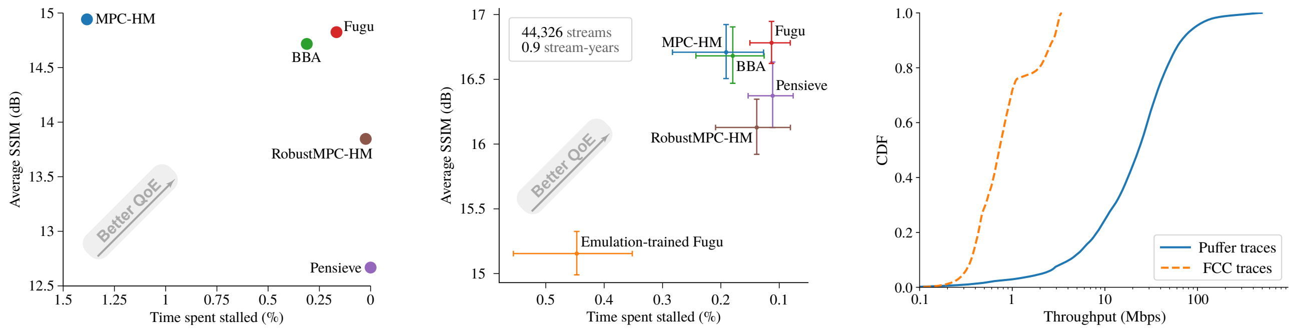

Figure 12: Left: performance in emulation, run in mahimahi [30] using the FCC traces [10], following the method of Pensieve [25]. **Middle:** During Jan. 26–Apr. 2, 2019, we randomized sessions to a set of algorithms including "emulation-trained Fugu." For Fugu, training in emulation did not generalize to the deployment environment. In addition, emulation results (left) are not indicative of real-world performance. **Right:** comparison of throughput distribution of FCC traces and of real Puffer sessions.

capacity over time to match the capacity recorded in a set of FCC broadband network traces [10]. As in the Pensieve evaluation, uplink speeds in all shells were capped at 12 Mbps. Within this test setup, we automated 12 clients to repeatedly connect to the media server, which would play a 10 minute clip recorded on NBC over each network trace in the dataset. Each client was assigned to a different ABR algorithm, and played the 10 minute video repeatedly over more than 15 hours of FCC traces. Results are shown in Figure 12.

We trained a version of Fugu in this emulation environment to evaluate its performance. Compared with the *in situ* Fugu—or with every other ABR scheme—the real-world performance of emulation-trained Fugu was horrible (Figure 12, middle panel). Looking at the other ABR schemes, almost each of them lies somewhere along the SSIM/stall frontier in emulation (left side of figure), with Pensieve rebuffering the least and MPC delivering the highest quality video. In the real experiment (middle of figure), we see a more muddled picture, with a different qualitative arrangement of schemes.

5.3 Remarks on Pensieve and RL for ABR

The original Pensieve paper [25] demonstrated that Pensieve outperformed MPC-HM, RobustMPC-HM, and BBA in both emulation-based tests and in video streaming tests on low and high-speed real-world networks. Our results differ; we believe the mismatch may have occurred for several reasons.

First, we have found that simulation-based training and testing do not capture the vagaries of the real-world paths seen in the Puffer study. Unlike real-world randomized trials, trace-based emulators and simulators allow experimenters to limit statistical uncertainty by running different algorithms on the same conditions, eliminating the effect of the play of chance in giving different algorithms a different distribution of watch times, network behaviors, etc. However, it is difficult to characterize the *systematic* uncertainty that comes from selecting a set of traces that may omit the variability or heavy-tailed nature of a real deployment experience (both network behaviors as well as user behaviors, such as watch duration).

Reinforcement learning (RL) schemes such as Pensieve may be at a particular disadvantage from this phenomenon. Unlike supervised learning schemes that can learn from training "data," RL typically requires a training *environment* to respond to a sequence of control decisions and decide on the appropriate consequences and reward. That environment could be real life instead of a simulator, but the level of statistical noise we observe would make this type of learning extremely slow or require an extremely broad deployment of algorithms in training. RL relies on being able to slightly vary a control action and detect a change in the resulting reward. By our calculations, the variability of inputs is such that it takes about 2 stream-years of data to reliably distinguish two ABR schemes whose innate "true" performance differs by 15%. To make RL practical, future work may need to explore techniques to reduce this variability [26] or construct more faithful simulators and emulators that model tail behaviors and capture additional dynamics of the real Internet that are not represented in throughput traces (e.g. varying RTT, cross traffic, interaction between throughput and chunk size [7]).

Second, most of the evaluation of Pensieve in the original paper focused on training and evaluating Pensieve using a single test video. As a result, the state space that model had to explore was inherently more limited. Evaluation of the Pensieve "multi-video model"—which we have to use for our experimental setting—was more limited. Our results are more consistent with a recent large-scale study of a Pensieve-multi-video-like scheme on 30 million streams at Facebook [24].

Third, the right side of Figure 12 shows that the distribution of throughputs in the FCC traces differs markedly from those on Puffer. This dataset shift could have harmed the performance of Pensieve, which was trained on the FCC traces. In response to reviewer feedback, we trained a version of Pensieve on throughput traces randomly sampled from real Puffer video sessions. This is essentially as close to a "learned *in situ*" version of Pensieve as we think we can achieve, but is

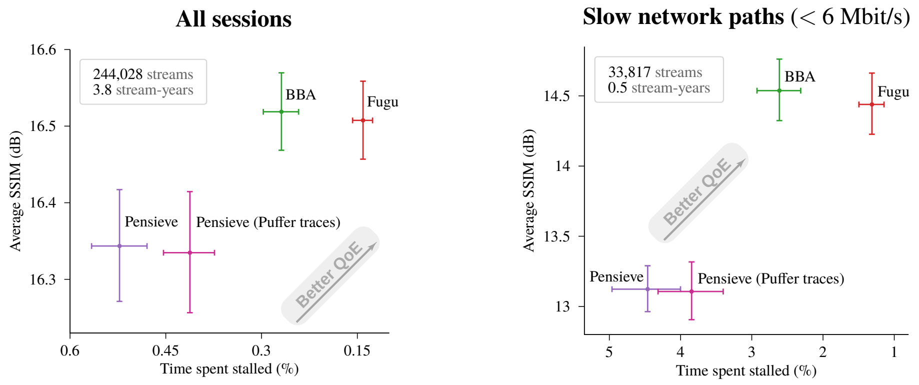

Figure 13: During Jan. 2–Feb. 2, 2020, we evaluated a version of Pensieve that was trained on a collection of network traces drawn randomly from actual Puffer sessions. This improved its performance compared with the original Pensieve, but the overall results were broadly similar.

not quite the same (§5.3). We compared "Pensieve on Puffer traces" with the original Pensieve, BBA, and Fugu between Jan. 2 and Feb. 2, 2020 (Figure 13). The results were broadly similar; the new Pensieve achieved better performance, but was still significantly worse than BBA and Fugu. The results deserve further study; they suggest that the representativeness of training data is not the end of the story when it comes to the real-world performance of RL schemes trained in simulation.

Finally, Pensieve optimizes a QoE metric centered around bitrate as a proxy for video quality. We did not alter this and leave the discussion to Section 6. Figure 4 shows that Pensieve was the #2 scheme in terms of bitrate (below BBA) in the primary analysis. We emphasize that our findings do not indicate that Pensieve cannot be a useful ABR algorithm, especially in a scenario where similar, pre-recorded video is played over a familiar set of known networks.

6 Limitations

The design of the Puffer experiment and the Fugu system are subject to important limitations that may affect their performance and generalizability.

6.1 Limitations of the experiments

Our randomized controlled trial represents a rigorous, but necessarily "black box," study of ABR algorithms for video streaming. We don't know the true distribution of network paths and throughput-generating processes; we don't know the participants or why the distribution in watch times differs by assigned algorithm; we don't know how to emulate these behaviors accurately in a controlled environment.

We have supplemented this black-box work with ablation analyses to relate the real-world performance of Fugu to the l^2 accuracy of its predictor, and have studied various ablated versions of Fugu in deployment. However, ultimately part of the reason for this paper is that we *cannot* replicate the experimental findings outside the real world—a real world whose behavior is noisy and takes lots of time to measure precisely. That may be an unsatisfying conclusion, and we doubt it will be the final word on this topic. Perhaps it will become possible to model enough of the vagaries of the real Internet "in silico" to enable the development of robust control strategies without extensive real-world experiments.

It is also unknown to what degree Puffer's results—which are about a single server in a university datacenter, sending to clients across our entire country over the wide-area Internet—generalize to a different server at a different institution, much less the more typical paths between a user on an access network and their nearest CDN edge node. We don't know for sure if the pre-trained Fugu model would work in a different location, or whether training a new Fugu based on data from that location would yield comparable results. Our results show that learning *in situ* works, but we don't know how specific the *situs* needs to be. And while we expect that Fugu could be implemented in the context of client-side ABR (especially if the server is willing to share its `tcp_info` statistics with the client), we haven't demonstrated this.

Although we believe that past research papers may have underestimated the uncertainties in real-world measurements with realistic Internet paths and users, we also may be guilty of underestimating our own uncertainties or emphasizing uncertainties that are only relevant to small or medium-sized academic studies, such as ours, and irrelevant to the industry. The current load on Puffer is about 60 concurrent streams on average, meaning we collect about 60 stream-days of data per day. Our primary analysis covers about 2.6 stream-years of data per scheme collected over an eight-month period, and was sufficient to measure its performance metrics to within about $\pm 15\%$ (95% CI). By contrast, we understand YouTube has an average load of more than 60 *million* concurrent streams at any given time. We imagine the considerations of conducting data-driven experiments at this level may be completely different—perhaps less about statistical uncertainty, and more about systematic uncertainties and the difficulties of running experiments and accumulating so much data.

Some of Fugu's performance (and that of MPC, RobustMPC, and BBA) relative to Pensieve may be due to the fact that these four schemes received more information as they ran—namely, the SSIM of each possible version of each future chunk—than did Pensieve. It is possible that an "SSIM-aware" Pensieve might perform better. The load of calculating SSIM for each encoded chunk is not insignificant—about an extra 40% on top of encoding the video.

6.2 Limitations of Fugu

There is a sense that data-driven algorithms that more "heavily" squeeze out performance gains may also put themselves at risk to brittleness when a deployment environment drifts from one where the algorithm was trained. In that sense, it is hard to say whether Fugu's performance might decay catastrophically some day. We tried and failed to demonstrate a quantitative benefit from daily retraining over "out-of-date" vintages, but at the same time, we cannot be sure that some surprising detail tomorrow—e.g., a new user from an unfamiliar network—won't send Fugu into a tailspin before it can be retrained. A year of data on a growing userbase suggests, but doesn't guarantee, robustness to a changing environment.

Fugu does not consider several issues that other research has concerned itself with—e.g., being able to "replace" already-downloaded chunks in the buffer with higher quality versions [38], or optimizing the joint QoE of multiple clients who share a congestion bottleneck [29].

Fugu is not tied as tightly to the TCP or congestion control as it might be—for example, Fugu could wait to send a chunk until the TCP sender tells it that there is a sufficient congestion window for most of the chunk (or the whole chunk) to be sent immediately. Otherwise, it *might* choose to wait and make a better-informed decision later. Fugu does not schedule the transmission of chunks—it will always send the next chunk as long as the client has room in its playback buffer.

7 Conclusion

Machine-learned systems in computer networking sometimes describe themselves as achieving near-"optimal" performance, based on results in a contained or modeled version of the problem [25, 37, 39]. Such approaches are not limited to the academic community: in early 2020, a major video-streaming company announced a $5,000 prize for the best low-delay ABR scheme, in which candidates will be evaluated in a network simulator that follows a trace of varying throughput [2].

In this paper, we suggest that these efforts can benefit from considering a broader notion of performance and optimality. Good, or even near-optimal, performance in a simulator or emulator does not necessarily predict good performance over the wild Internet, with its variability and heavy-tailed distributions. It remains a challenging problem to gather the appropriate training data (or in the case of RL systems, training environments) to properly learn and validate such systems.

In this paper, we asked: *what does it take to create a learned ABR algorithm that robustly performs well over the wild Internet?* In effect, our best answer is to cheat: train the algorithm *in situ* on data from the real deployment environment, and use an algorithm whose structure is sophisticated enough (a neural network) and yet also simple enough (a predictor amenable to supervised learning on data, informing a classical controller) to benefit from that kind of training.

Over the last year, we have streamed 38.6 years of video to 63,508 users across the Internet. Sessions are randomized in blinded fashion among algorithms, and client telemetry is recorded for analysis. The Fugu algorithm robustly outperformed other schemes, both simple and sophisticated, on objective measures (SSIM, stall time, SSIM variability) and increased the duration that users chose to continue streaming.

We have found the Puffer approach a powerful tool for networking research—it is fulfilling to be able to "measure, then build" [5] to iterate rapidly on new ideas and gain feedback. Accordingly, we are opening Puffer as an "open research" platform. Along with this paper, we are publishing our full archive of data and results on the Puffer website. The system posts new data each week, along with a summary of results from the ongoing experiments, with confidence intervals similar to those in this paper. (The format is described in Appendix B.) We redacted some fields from the public archive to protect participants' privacy (e.g., IP address) but are willing to work with researchers on access to these fields in an aggregated fashion. Puffer and Fugu are also open-source software, as are the analysis tools used to prepare the results in this paper.

We plan to operate Puffer as long as feasible and invite researchers to train and validate new algorithms for ABR control, network and throughput prediction, and congestion control on its traffic. We are eager to collaborate with and learn from the community's ideas on how to design and deploy robust learned systems for the Internet.

Acknowledgments

We are greatly indebted to Emily Marx, who joined this project after the original submission of this paper, found and corrected bugs in our analysis tools, and performed the final data analysis. We thank our shepherd, Vyas Sekar, and the ACM SIGCOMM and USENIX NSDI reviewers for their helpful feedback. We are grateful for conversations with and feedback from Danfei Xu, T.Y. Huang, Hongzi Mao, Michael Schapira, and Nils Krahnstoever, and we thank the participants in the Puffer research study, without whom these experiments could not have been conducted. This work was supported by NSF grant CNS-1909212 and by Google, Huawei, VMware, Dropbox, Facebook, and the Stanford Platform Lab.

Figure A1: CONSORT-style diagram [35] of experimental flow for the primary results (Figures 1 and 9), obtained during the period Jan. 26–Aug. 7, 2019, and Aug. 30–Oct. 16, 2019. A "session" represents one visit to the Puffer video player and may contain many "streams." Reloading starts a new session, but changing channels only starts a new stream and does not change TCP connections or ABR algorithms.

B Description of open data

The open data we are releasing comprise different "measurements"—each measurement contains a different set of time-series data collected on Puffer servers. Below we highlight the format of interesting fields in three measurements that are essential for analysis: `video_sent`, `video_acked`, and `client_buffer`.

`video_sent` collects a data point every time a Puffer server sends a video chunk to a client. Each data point contains:

- `time`: timestamp when the chunk is sent
- `session_id`: unique ID for the video session
- `expt_id`: unique ID to identify the experimental group; `expt_id` can be used as a key to retrieve the experimental setting (e.g., ABR, congestion control) when sending the chunk, in another file we are providing.
- `channel`: TV channel name
- `video_ts`: unique presentation timestamp of the chunk
- `format`: encoding settings of the chunk, including resolution and constant rate factor (CRF)
- `size`: size of the chunk
- `ssim_index`: SSIM of the chunk
- `cwnd`: congestion window size (`tcpi_snd_cwnd`)
- `in_flight`: number of unacknowledged packets in flight (`tcpi_unacked - tcpi_sacked - tcpi_lost + tcpi_retrans`)
- `min_rtt`: minimum RTT (`tcpi_min_rtt`)
- `rtt`: smoothed RTT estimate (`tcpi_rtt`)
- `delivery_rate`: estimate of TCP throughput (`tcpi_delivery_rate`)

`video_acked` collects a data point every time a Puffer server receives a video chunk acknowledgement from a client. Each data point can be matched to a data point in `video_sent` using `video_ts` (if the chunk is ever acknowledged) and used to calculate the transmission time of the chunk—difference between the timestamps in the two data points. Specifically, each data point in `video_acked` contains:

- `time`: timestamp when the chunk is acknowledged
- `session_id`
- `expt_id`
- `channel`
- `video_ts`

`client_buffer` collects client-side information reported to Puffer servers on a regular interval and when certain events occur. Each data point contains:

- `time`: timestamp when the client message is received
- `session_id`
- `expt_id`
- `channel`
- `event`: event type, e.g., was this triggered by a regular report every quarter second, or because the client stalled or began playing.
- `buffer`: playback buffer size
- `cum_rebuf`: cumulative rebuffer time in the current stream

Between Jan. 26, 2019 and Feb. 2, 2020, we collected 675,839,652 data points in `video_sent`, 677,956,279 data points in `video_acked`, and 4,622,575,336 data points in `client_buffer`.

Is Big Data Performance Reproducible in Modern Cloud Networks?

Abstract

Performance variability has been acknowledged as a problem for over a decade by cloud practitioners and performance engineers. Yet, our survey of top systems conferences reveals that the research community regularly disregards variability when running experiments in the cloud. Focusing on networks, we assess the impact of variability on cloud-based big-data workloads by gathering traces from mainstream commercial clouds and private research clouds. Our dataset consists of millions of datapoints gathered while transferring over 9 petabytes on cloud providers' networks. We characterize the network variability present in our data and show that, even though commercial cloud providers implement mechanisms for quality-of-service enforcement, variability still occurs, and is even exacerbated by such mechanisms and service provider policies. We show how big-data workloads suffer from significant slowdowns and lack predictability and replicability, even when state-of-the-art experimentation techniques are used. We provide guidelines to reduce the volatility of big data performance, making experiments more repeatable.

1 Introduction

Performance variability [13, 47] in the cloud is well-known, and has been studied since the early days [7, 35, 55] of cloud computing. Cloud performance variability impacts not only operational concerns, such as cost and predictability [14, 42], but also reproducible experiment design [3, 10, 31, 47].

Big data is now highly embedded in the cloud: for example, Hadoop [64] and Spark [65] processing engines have been deployed for many years on on-demand resources. One key issue when running big data workloads in the cloud is that, due to the multi-tenant nature of clouds, applications see performance effects from other tenants, and are thus susceptible to performance variability, including on the network. Even though recent evidence [50] suggests that there are limited potential gains from *speeding up* the network, it is still the case that variable network performance can *slow down* big data systems and introduce volatility that makes it more difficult to draw reliable scientific conclusions.

Although cloud performance variability has been thoroughly studied, the resulting work has mostly been in the context of optimizing tail latency [22], with the aim of providing more consistent application-level performance [15, 25, 29, 57]. This is subtly—but importantly—different from understanding the ways that fine-grained, resource-level variability affects the *performance evaluation* of these systems. Application-level effects are especially elusive for complex applications, such as big data, which are not bottlenecked on a specific resource for their entire runtime. As a result, it is difficult for experimenters to understand how to design experiments that lead to reliable conclusions about application performance under variable network conditions.

Modern cloud data centers increasingly rely on software-defined networking to offer flows between VMs with reliable and predictable performance [48]. While modern cloud networks generally promise isolation and predictability [7, 30], in this paper we uncover that they rarely achieve stable performance. Even the mechanisms and policies employed by cloud providers for offering quality of service (QoS) and fairness can result in non-trivial interactions with the user applications, which leads to performance variability.

Although scientists are generally aware of the relationship between repeated experiments and increased confidence in results, the specific strength of these effects, their underlying causes, and methods for improving experiment designs have not been carefully studied in the context of performance experiments run in clouds. Variability has a significant impact on sound experiment design and result reporting [31]. In the presence of variability, large numbers of experiment repetitions must be performed to achieve tight confidence intervals [47]. Although practitioners and performance engineers acknowledge this phenomenon [7, 35, 55], in practice these effects are frequently disregarded in performance studies.

Building on our vision [34], and recognizing the trend of the academic community's increasing use of the cloud for computing resources [53], we challenge the current state-of-

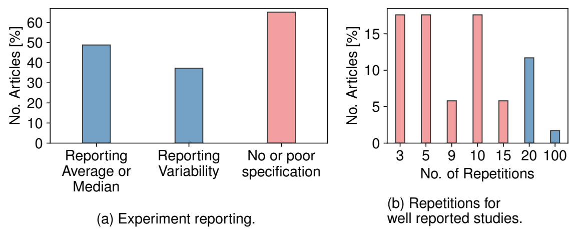

Figure 1: State-of-practice in big data articles with cloud experiments: (a) Aspects reported about experiments. Bars represent aspects that are not mutually exclusive, thus the total can exceed 100%. (b) Number of experiment repetitions performed for the properly specified articles.

practice in cloud-based systems experimentation and advocate for sound experiment design and result reporting. We show that, due to performance variability, flawed cloud-based experimentation could lead to inaccurate or even wrong conclusions. We show, in-depth, the performance implications of network variability when running big data workloads. The interplay between underlying resources and applications is complex, and leads to non-trivial performance behavior.

To characterize such interactions, we run state-of-the-art, real-world applications using Apache Spark [4]. We run big-data workloads either directly on real-world mainstream clouds, or by emulating the network behavior of such clouds. Our results show that variability highly impacts not only performance, but also credible and reproducible experimentation.

Addressing cloud users, performance engineers, and system designers, we examine the implications of *network* variability on big data, and present our main findings and contributions:

1. **Lack of sound experimentation:** Many articles in the literature that present cloud-based experiments are either under-specified (i.e., do not report statistical measures), or run inconclusive numbers of experiment repetitions (Section 2).
2. **Variability in modern cloud networks:** We conduct and analyze measurements of public and private cloud providers, characterize the level of variability, and identify specific sources (Section 3).
3. **Network variability impact on application performance reproducibility:** Low-level network variability can have significant effects on application performance, and can violate assumptions commonly used in performance modeling (such as that experiment runs are independent and identically distributed) (Section 4).
4. **Strategies for running reproducible experiments:** Given our measurement and experience with application-level benchmarks, we make recommendations for improving the reliability and reproducibility of experiments (Section 5).

2 Is Cloud Variability Disregarded?

We perform a literature survey to uncover whether and how researchers and practitioners take cloud performance variability into account when running experiments. Our findings are depicted in Figure 1 and summarized as follows:

Table 1: Parameters for the performance variability literature survey. We manually select only the articles with empirical evaluations performed using clouds.

Venues	Keywords	Years
NSDI, OSDI SOSP, SC	big data, streaming, Hadoop, MapReduce, Spark, data storage graph processing, data analytics	2008 - 2018

Table 2: Survey process. Initial filtering done automatically by keywords, then manually for cloud-based experiments. The resulting subset is significant and highly-cited.

Articles Total	Filtered Automatically by Keywords	Filtered Manually for Cloud Experiments	Citations for selected 44 articles
1,867	138	44 (15 NSDI, 7 OSDI, 7 SOSP, 15 SC)	11,203

Finding 2.1 Cloud performance variability is largely disregarded when researchers evaluate and prototype distributed systems, or compare established systems.

F2.2 Most cloud performance studies are under-specified. Most studies: (i) do not specify which performance measures are reported (i.e., mean, median); (ii) do not report minimal statistical variation data (i.e., standard deviation, quartiles); (iii) do not report the number of repetitions of an experiment.

F2.3 Most cloud performance evaluations are poorly designed: a large majority of such studies only perform small numbers of experiment repetitions (i.e., 3-10 trials), and do not assess variability or confidence.

Over the last decade, big data platforms and applications have been co-evolving with the cloud. This allowed researchers and practitioners to develop, deploy, and evaluate their applications and systems on various virtualized infrastructures. There is much evidence that clouds suffer from performance variability [7, 13, 35, 47]. It is therefore intuitive to ask if practitioners and system designers take variability into account when designing experiments or building systems. To answer these questions, we performed a systematic literature survey covering prominent conferences in the field: NSDI [44], OSDI [5], SOSP [1], and SC [2].

Survey Methodology: Table 1 shows the parameters of our survey, and Table 2 presents our survey process in-depth: (1) we started with all articles published in the aforementioned venues; (2) selected automatically a subset, based on string matching our query on keywords, title, and abstract; (3) we manually selected the articles in which the experiments were performed on a public cloud. The 44 selected articles are highly influential, having been cited **11,203** times so far[1].

The criteria we looked for when analyzing such articles

[1]according to Google Scholar on May 20, 2019

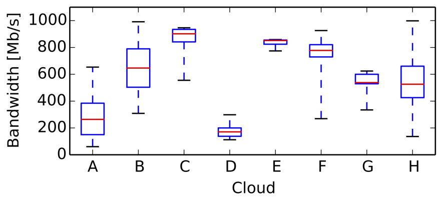

Figure 2: Bandwidth distributions for eight real-world clouds. Box-and-whiskers plots show the 1st, 25th, 50th, 75th, and 99th percentiles. (Distributions derived from the study [7] conducted by Ballani et al.)

are the following: (i) reporting average or median metrics over a number of experiments; (ii) reporting variability (such as standard deviation or percentiles) or confidence (such as confidence intervals); (iii) reporting the number of times an experiment was repeated. These are all critical criteria for determining whether a study's conclusions may be irreproducible, or worse, not fully supported by the evidence (i.e., flawed). To check the reliability of our manual filtering, it was performed by two separate reviewers, and we applied Cohen's Kappa coefficient [16] for each category presented in Figure 1a: reporting average or median, statistics, and poor specification. Our Kappa scores for each category, were 0.95, 0.81, and 0.85, respectively. Values larger than 0.8 are interpreted as near-perfect agreement between the reviewers [61].

Survey Results: *The systems community centered around cloud computing and big data disregards performance variability when performing empirical evaluations in the cloud.* Figure 1 shows the results of our survey. Out of the two reviewer's scores, we plot the lower scores, i.e., ones that are more favorable to the articles. We found that over 60% of the surveyed articles are under-specified (i.e., the authors do not mention how many times they repeated the experiments or even whether they are reporting average, median, etc.); a subset of the articles report averages or medians, but out of those, only 37% report variance or confidence (i.e., error-bars, percentiles). We further found that most articles that do report repetitions perform only 3, 5 or 10 repetitions of the experiments. The reason for such practices might be that experimenters are more used to evaluating software in controlled environments—what is true in controlled environments often does not hold in clouds.

Moreover, 76% of the properly specified studies use no more than 15 repetitions. Coupled with the effects of cloud variability, such experiment design practices could lead to wrong or ambiguous conclusions, as we show next.

2.1 How credible are experiments with few repetitions?

Experiments with few repetitions run the risk of reporting inaccurate results; the higher the variability, the greater the risk that a low-repetition experiment's results are unreliable. We

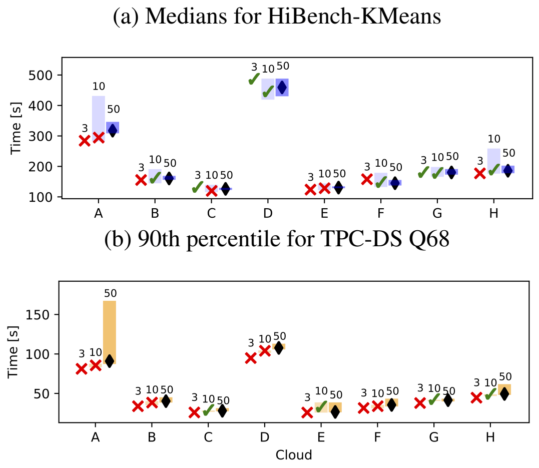

Figure 3: Medians and 90th percentiles for K-Means (a) and TPC-DS Q68 (b). Estimates are shown along with their 95% confidence intervals (CIs) for performance measurements under the A-H distributions. $\diamond$ depicts estimates 50-runs. Judged by the 50-run CIs we consider *gold standard*, accurate estimates (inside those CIs) are ✓; inaccurate estimates (outside those CIs) are $\times$ for 3- and 10-run sets.

use application-level benchmarks to show how the bandwidth distributions found by Ballani et al. [7] for eight real-world clouds—shown in Figure 2—do affect findings in practice.

We emulate the behavior of the eight clouds presented in Figure 2, which were contemporary with most articles found in our survey. In a private Spark [4] cluster of 16 machines, we limit the bandwidth achieved by machines according to distributions $A-H$. We uniformly sample bandwidth values from these distributions every $x \in \{5,50\}$ seconds. We used 50 experiment repetitions as our "gold standard" to demonstrate the intuition that running more experiments yields more accurate results, and compared them to the 3- and 10-repetitions commonly found in our literature survey. (In Section 4 we propose better methods for experiment design.)

Emulation Results: We found that experiments with few repetitions often produced medians that are *outside of* the 95% confidence intervals (CIs) for larger experiment sequences. The 95% CIs for medians represent ranges in which we would find true medians with 95% probability, if we were able to run infinite repetitions. Thus, when the low-repetition medians lie outside of the high-repetition CIs, there is a 95% probability that the former are inaccurate. This can be seen in Figure 3, which plots estimates of 95% nonparametric (asymmetric) CIs [11] for experiments using bandwidth distributions $A-H$ from Figure 2. For each bandwidth distribution, we show the medians and CIs for 3-, 5-, and 50-repetition experiments.[2] The median for the "gold standard" experiment is marked with a diamond; medians for lower-repetition experiments are shown with an "X" if outside the gold-standard 95% CI, or a check-mark if within it.

[2]Three repetitions are insufficient to calculate CIs; we plot medians because this is representative of what is often found in the literature.

The top of Figure 3 (part (a)) shows our estimates of *medians* for the K-Means application from HiBench [32]. Of the eight cloud bandwidth distributions, the 3-run median falls outside of the gold-standard CI for six of them (75%), and the 10-run median for three (38%). The bottom half of Figure 3 (part (b)) shows the same type of analysis, but this time, for tail performance [22] instead of the median. To obtain these results, we used TPC-DS [49] Query-68 measurements and the method from Le Boudec [11] to calculate nonparametric estimates for the 90th percentile performance, as well as their confidence bounds. As can be seen in this figure, it is even more difficult to get robust *tail* performance estimates.

Emulation Methodology: The quartiles in Ballani's study (Figure 2) give us only a rough idea about the probability densities and there is uncertainty about fluctuations, as there is no data about sample-to-sample variability. Considering that the referenced studies reveal no autocovariance information, we are left with using the available information to sample bandwidth uniformly. Regarding the sampling rate, we found the following: (1) As shown in Section 3 two out of the three clouds we measured exhibits significant sample-to-sample variability on the order of tens of seconds; (2) The cases F-G from Ballani's study support fine sampling rates: variability at sub-second scales [63] and at the 20s intervals [24] is significant. Therefore, we sample at relatively fine-grained intervals: 5s for Figure 3(a), and 50s for Figure 3(b). Furthermore, sampling at these two different rates shows that benchmark volatility is not dependent on the sampling rate, but rather on the distribution itself.

3 How Variable Are Cloud Networks?

We now gather and analyze network variability data for three different clouds: two large-scale commercial clouds, and a smaller-scale private research cloud. Our main findings can be summarized as follows:

F3.1 Commercial clouds implement various mechanisms and policies for network performance QoS enforcement, and these policies are opaque to users and vary over time. We found (i) token-bucket approaches, where bandwidth is cut by an order of magnitude after several minutes of transfer; (ii) a per-core bandwidth QoS, prioritizing heavy flows; (iii) instance types that, when created repeatedly, are given different bandwidth policies unpredictably.

F3.2 Private clouds can exhibit more variability than public commercial clouds. Such systems are orders of magnitude smaller than public clouds (in both resources and clients), meaning that when competing traffic does occur, there is less statistical multiplexing to "smooth out" variation.

F3.3 Base latency levels can vary by a factor of almost 10x between clouds, and implementation choices in the cloud's virtual network layer can cause latency variations over two orders of magnitude depending on the details of the application.

Table 3: Experiment summary for determining performance variability in modern cloud networks. Experiments marked with a star (*) are presented in depth in this article. Due to space limitations, we release the other data in our repository [59]. All Amazon EC2 instance types are typical offerings of a big data processing company [20].

Cloud	Instance Type	QoS (Gbps)	Exp. Duration	Exhibits Variability	Cost ($)
*Amazon	c5.XL	≤ 10	3 weeks	Yes	171
Amazon	m5.XL	≤ 10	3 weeks	Yes	193
Amazon	c5.9XL	10	1 day	Yes	73
Amazon	m4.16XL	20	1 day	Yes	153
Google	1 core	2	3 weeks	Yes	34
Google	2 core	4	3 weeks	Yes	67
Google	4 core	8	3 weeks	Yes	135
*Google	8 core	16	3 weeks	Yes	269
HPCCloud	2 core	N/A	1 week	Yes	N/A
HPCCloud	4 core	N/A	1 week	Yes	N/A
*HPCCloud	8 core	N/A	1 week	Yes	N/A

3.1 Bandwidth

We run our bandwidth measurements in two prominent commercial clouds, Amazon EC2 (us-east region) and Google Cloud (us-east region), and one private research cloud, HPCCloud[3]. Table 3 summarizes our experiments. In the interest of space, in this paper we focus on three experiments; all data we collected is available in our repository [59]. We collected the data between October 2018 and February 2019. In total, we have over 21 weeks of nearly-continuous data transfers, which amount for over 1 million datapoints and over 9 petabytes of transferred data.

The Amazon instances we chose are typical instance types that a cloud-based big data company offers to its customers [20], and these instances have AWS's "enhanced networking capabilities" [6]. On Google Cloud (GCE), we chose the instance types that were as close as possible (though not identical) to the Amazon EC2 offerings. HPCCloud offered a more limited set of instance types. We limit our study to this set of cloud resources and their network offerings, as big data frameworks are not equipped to make use of more advanced networking features (i.e., InfiniBand), as they are generally designed for commodity hardware. Moreover, vanilla Spark deployments, using typical data formats such as Parquet or Avro, are not able to routinely exploit links faster than 10 Gbps, unless significant optimization is performed [58]. Therefore, the results we present in this article are highly likely to occur in real-world scenarios.

In the studied clouds, for each pair of VMs of similar instance types, we measured bandwidth continuously for one week. Since big data workloads have different network access patterns, we tested multiple scenarios:

- **full-speed** - continuously transferring data, and summarizing performability metrics (bandwidth, retransmis-

[3]https://userinfo.surfsara.nl/systems/hpc-cloud

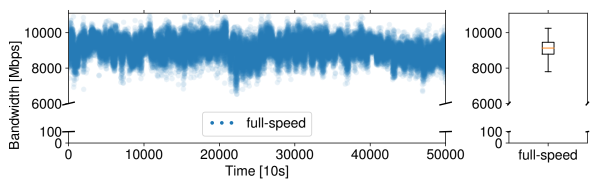

Figure 4: Variable network bandwidth performance in the HPCCloud (left); the statistical performance distribution, plotted as an IQR box; the whiskers represent 1st and 99th percentiles (right). Duration: a week of continuous experimentation; each point is average over 10 seconds.

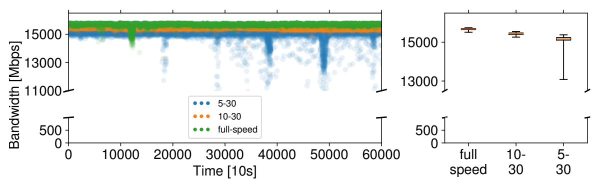

Figure 5: Variable network bandwidth performance in the Google Cloud (left), and the statistical performance distribution, plotted as an IQR box, where the whiskers are 1st and 99th percentiles (right). The duration is a week of continuous experimentation, each point is an average over 10 seconds.

sions, CPU load etc.) every 10 seconds;

- **10-30** - transfer data 10 seconds, wait 30 seconds;
- **5-30** - transfer data 5 seconds, wait 30 seconds.

The first transmission regime models highly network intensive applications, such as long-running batch processing or streaming. The last two modes mimic short-lived analytics queries, such as TPC-H, or TPC-DS.

HPCCloud. Small-scale (i.e., up to 100 physical machines and several hundred users) private (research) clouds often do not use mechanisms to enforce network QoS. We measured the network performance variability between pairs of VMs, each having 8 cores. Figure 4 plots the results. We show our measurements only for "full-speed" (i.e., continuous communication) because our other experiments show similar behavior. We observe that the network bandwidth shows high variability, ranging from 7.7 Gbps to 10.4 Gbps.

Google Cloud. GCE states that it enforces network bandwidth QoS by guaranteeing a “per-core” amount of bandwidth. Our measurements, plotted in Figure 5, fall close to the QoS reported by the provider, but access pattern affects variability to a greater degree than in other clouds. Longer streams (*full-speed*) exhibit low variability and better overall performance, while *5-30* has a long tail. This could be due to the design of the Google Cloud network, where idle flows use dedicated gateways for routing through the virtual network [18]. We observe that network bandwidth varies significantly, depending on access patterns, between 13 Gbps and 15.8 Gbps.

Amazon EC2. We discover the opposite behavior in EC2: heavier streams achieve less performance and more variability compared to lighter (shorter) streams, as shown in Figure 6. Considering the large performance differences between

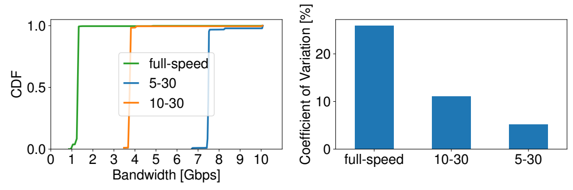

Figure 6: Variable network bandwidth performance in Amazon EC2, plotted as an empirical cumulative distribution (left), barplot of the coefficient of variation (right). The duration is a week of continuous experimentation, each data point representing an average over 10 seconds.

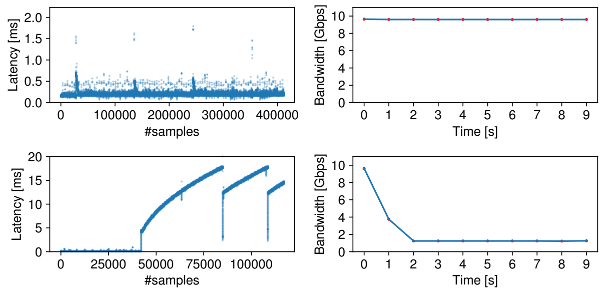

Figure 7: Example of observed Amazon EC2 latency for a 10-second TCP sample on *c5.xlarge*. Left: RTT latency for TCP packets. Right: achieved *iperf* bandwidth. Top: regular Amazon EC2 behavior. Bottom: latency behavior when a drop in bandwidth occurs.

these experiments, we plot our measurements as a CDF and a barplot of coefficient of variation to improve visibility. There are approximately 3x and 7x slowdowns between *10-30* and *5-30* and *full-speed*, respectively. The achieved bandwidth varies between 1 Gbps and 10 Gbps. We investigate the causes of this behavior in Section 3.3.

How rapidly does bandwidth vary? Our analysis shows the level of *measurement-to-measurement* variability is significant: bandwidth in HPCCloud (*full-speed*) and Google Cloud (*5-30*) varies between consecutive 10-second measurements up to 33% and 114%, respectively. While a small sample may exhibit only modest fluctuations, the long-tailed distributions we observed here strongly suggest using the analysis techniques we discuss in Section 4.1. Amazon EC2’s variability is more particular and policy-dependent (Section 3.3).

3.2 Latency

Commercial clouds implement their virtual networks using very different mechanisms and policies. We can see this in more detail by looking at the round-trip lantencies seen in Google Cloud and Amazon EC2. We measure the application-observed TCP RTT, as this is what impacts the high-level networking stacks of big data frameworks. For our experiments, we run 10-second streams of *iperf* tests, capturing all packet headers with *tcpdump*. We perform an offline analysis of the packet dumps using *wireshark*, which compares the

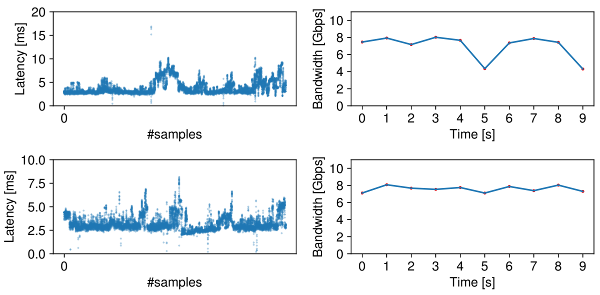

Figure 8: Example of observed Google Cloud latency for a 10-second TCP sample on a *4-core* instance. Left: RTT latency for TCP packets. Right: achieved *iperf* bandwidth.

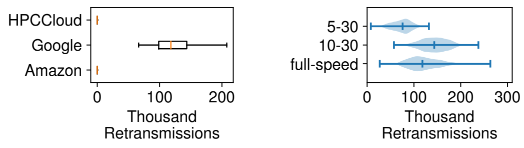

Figure 9: TCP retransmission analysis, summarized for all experiments presented before, in all clouds. Left: retransmissions as IQR boxplots, with the whiskers representing 1st and 99th percentiles; Right: violin plot for retransmissions in Google Cloud; thickness of the plot is proportional to the probability density of the data.

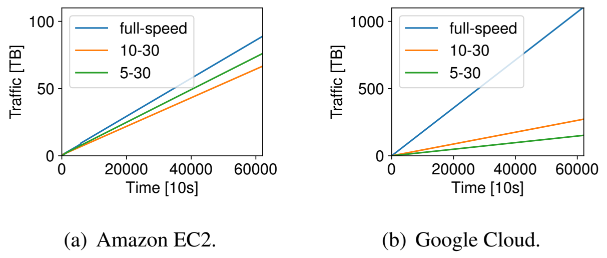
time between when a TCP segment is sent to the (virtual) network device and when it is acknowledged. Our data was collected between August and September 2019. In total, it contains over 50 million RTT datapoints.

The behavior we observe is inherently different: Google Cloud exhibits latency in the order of milliseconds, with an upper limit of 10ms. Amazon EC2 generally exhibits faster sub-millisecond latency under typical conditions, but when the traffic shaping mechanism (detailed in Section 3.3) takes effect, the latency increases by two orders of magnitude, suggesting large queues in the virtual device driver. Figure 7 shows representative patterns of latency in the Amazon EC2 cloud, while Figure 8 is representative of Google Cloud. Both figures plot latency as RTT packet data obtained from a 10-second TCP stream obtained running an *iperf* benchmark.

The behavior observed in the top half of Figure 7 lasts for approximately ten minutes of full-speed transfer on *c5.xlarge* instances. After this time, the VMs' bandwidth gets throttled down to about 1 Gbps (bottom half of Figure 7), which also significantly increases latency. On Google Cloud, there is no throttling effect, but the bandwidth and latency vary more from sample to sample.



(a) Amazon EC2. (b) Google Cloud.

Figure 10: The total amount of data transferred between the pairs of virtual machines involved in the three types of experiments performed. The total time is a week, while each point on the horizontal axis represents 10 seconds.

3.3 Identifying Mechanisms and Policies

The behavior exhibited by the two commercial providers is notably different. We uncover mechanisms and policies for enforcing client QoS by performing extra analysis, depicted in Figures 9 and 10. The former plots the number of retransmissions per experiment (part (a)) and a zoomed-in view of Google Cloud (part (b)). Amazon EC2 and HPCCloud have a negligible number of retransmissions, yet retransmission are common in Google Cloud: roughly 2% per experiment.

Figure 10 plots the total amount of traffic for Amazon EC2 and Google Cloud over the entire duration of our experiments. It is clear that in Google Cloud's case the amount of traffic generated by *full-speed* is orders of magnitude larger than for the intermittent access patterns. In Amazon EC2's case, the total amount of data sent for all three kinds of experiments is roughly equal. By corroborating this finding the more fine-grained experiments we performed presented in Figure 7, and other empirical studies [51, 62], we find that Amazon EC2 uses a *token-bucket* algorithm to allocate bandwidth to users.

Token-Bucket Analysis. The token-bucket algorithm operation can be explained as follows. When a VM is provided to the user, its associated *bucket* holds a certain amount of tokens (i.e., a budget). This budget is allowed to be spent at a high rate (i.e., 10 Gbps). When the budget is depleted (e.g., after about 10 minutes of continuous transfer on a *c5.xlarge* instance, the QoS is limited to a low rate (e.g., 1 Gbps). The bucket is also subject to a replenishing rate that we empirically found to be approximately 1 Gbit token per second, i.e., every second users receive the amount of tokens needed to send 1 Gbit of data at the high (10 Gbps) rate. Once the token bucket empties, transmission at the capped rate is sufficient to keep it from filling back up. The user must *rest* the network, and re-filling the bucket completely takes several minutes.

We analyze the behavior of multiple types of VMs from the *c5.** family, and find that their token-bucket parameters differ. More expensive machines benefit from larger initial budgets, as well as higher bandwidths when their budget depletes. Figure 11 plots the token-bucket parameter analysis for four VMs of the *c5.** family. For each VM type, we ran an *iperf* test continuously until the achieved bandwidth dropped significantly and stabilized at a lower value. For each instance type, we ran 15 tests. Figure 11 shows the time taken to empty the token bucket, the *high* (non-empty bucket) bandwidth value, and the *low* (empty bucket) bandwidth value. As the *size* (i.e., number

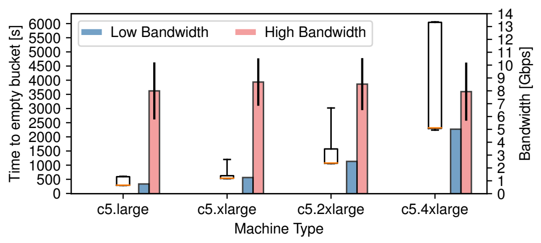


Figure 11: The token-bucket parameters identified for several instances of Amazon EC2 *c5.** family. The elapsed time to empty the token bucket is depicted with boxplots associated with *left* vertical axis. The *high* and *low* bandwidths of the token bucket are depicted with bar plots with whiskers and are associated with the *right* vertical axis.

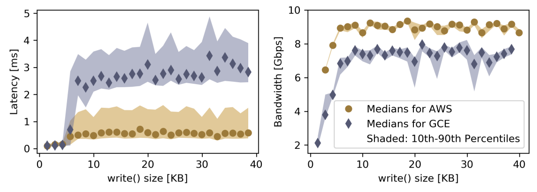

Figure 12: Measured latency and bandwidth for Amazon EC2 (*c5.xlarge*) and GCE (4-core VM with advertised 8 *Gbps*) instances as functions of the `write()` size.

of cores, amount of memory etc,) of the VM increases, we notice that the *bucket size* and the *low* bandwidth increase proportionally. However, as the magnitude of the boxplots suggests, as well as the error bars we plotted for the *high* bandwidth, these parameters are not always consistent for multiple incarnations of the same instance type.

Virtual NIC Implementations. We found that differences in EC2 and GCE's implementations of virtual NICs can lead to significantly different observed behavior. EC2's virtual NICs advertise an MTU of 9000 bytes, a standard "jumbo frame" size. GCE's only advertise an MTU of 1500 bytes (standard Ethernet frame size), but instead enable TCP Segmentation Offloading (TSO), in which the NIC accepts larger "packets" from the device driver, but then breaks them down into smaller Ethernet frames before transmission (we do not know whether this occurs at the virtual or physical NIC in GCE's implementation). Both of these techniques serve the same basic function—reducing overhead by sending fewer, larger packets on the virtual NIC, but result in different observable behavior on the host, and the details of this behavior depend heavily on the application and workload.

The most striking effect is the way that the size of the `write()`s done by the application affects latency and packet retransmission. Figure 12 plots the effects of the `write()` size on latency and bandwidth. On EC2, the size of a single "packet" tops out at the MTU of 9K, whereas on GCE, TSO can result in single "packet" at the virtual NIC being as large as 64K in our experiments. With such large "packets," perceived latency increases greatly due to the higher perceived "transmission time" for these large packets. The number of retransmissions also goes up greatly, presumably due to limited buffer space in the bottom half of the virtual NIC driver or tighter bursts on the physical NIC. In practice, the size of the "packets" passed to the virtual NIC in Linux tends to equal to the `write` on the socket (up to the cap noted above). This makes the observed behavior—and thus repeatability and the ability to generalize results between clouds—highly application-dependent. It is also worth noting that all streams are affected when one stream sends large "packets", since they share a queue in the virtual device driver. On GCE, when we limited our benchmarks to `write`s of 9K, we got near-zero packet retransmission and an average RTT of about 2.3*ms*. When the benchmark used its default `write()` size of 128K, we saw the hundreds of thousands of retransmission shown in Figure 9 and latencies as high as 10*ms*.

4 Performance Reproducibility For Big Data Applications

Having looked at low-level variability in bandwidth and latency, we now move "up" a level to applications and workloads. Our main findings are:

F4.1 Under variability resembling Google Cloud and HPCCloud, which can be modeled as stochastic noise, reproducible experiments can be obtained using sufficient repetitions and sound statistical analyses.

F4.2 Application transfer patterns exhibit non-trivial interactions with token-bucket network traffic shapers. Depending on the bucket budget and the application, significant application performance variability is incurred.

F4.3 Token-bucket traffic shapers in conjunction with (imbalanced) big data applications can create stragglers.

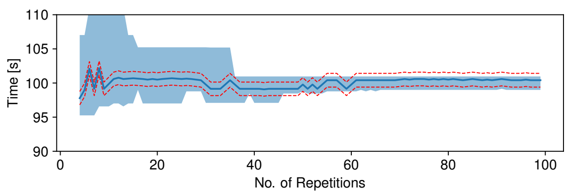
F4.4 In long-running cloud deployments that have incurred large amounts of varied network traffic, it is highly difficult to predict application performance, as it is dependent on the state of the individual nodes' remaining token-bucket budgets.

Big Data Workloads. In this section, we run the HiBench [32] and TPC-DS [49] benchmarks on Spark 2.4.0 (see Table 4) to showcase our main findings on network variability and big data workloads reproducibility. In 2015, Ousterhout et al. [50] found that big data workloads are mostly CPU bound. The workloads we chose here are no exception. However, they are *sensitive* to oscillations in the network transfer performance. Moreover, most of the CPU load in [50] is attributed to the framework's inefficiencies [19], which have been solved in later releases. As a consequence, modern Spark implementations are more sensitive to network variations.

4.1 Experiments and Stochastic Noise

As detailed in Section 3, the behavior of network performance variability for Google Cloud and HPCCloud is closer in na-

(a) Median Performance for K-Means in Google Cloud.



(b) Median Performance for TPC-DS Q65 in HPCCloud.

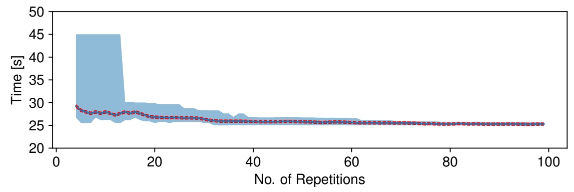


Figure 13: CONFIRM analysis for K-Means and TPC-DS Q65 on Google Cloud and HPCCloud. Median estimates (blue thick curve), 95% nonparametric confidence intervals (light blue filled space), and 1% error bounds (red dotted curves). Vertical axis not starting at 0 for visibility.

Table 4: Big data experiments on modern cloud networks.

Workload	Size	Network	Software	#Nodes
HiBench [32]	BigData	Token-bucket, Figure 14	Spark 2.4.0, Hadoop 2.7.3	12
TPC-DS [49]	SF-2000	Token-bucket, Figure 14	Spark 2.4.0, Hadoop 2.7.3	12

ture to stochastic variability given by transient conditions in the underlying resources, such as noisy neighbors. To achieve reproducible experiments under such conditions, system designers and experimenters need to carefully craft and plan their tests, using multiple repetitions, and must perform sound statistical analyses.

We ran several HiBench [32] and TPC-DS [49] benchmarks directly on the Google Cloud and HPCCloud clouds and report how many repetitions an experimenter needs to perform in order to achieve trustworthy experiments. While it is true that running experiments directly on these clouds we cannot differentiate the effects of network variability from other sources of variability, the main take-away message of this type of experiment is that this kind of stochastic variability can be accounted for with proper experimentation techniques.

On the performance data we obtained, we performed a CONFIRM [47] analysis to predict how many repetitions an experiment will require to achieve a desired confidence interval. Figure 13 presents our findings, showing that for these two common benchmarks, it can take 70 repetitions or more to achieve 95% confidence intervals within 1% of the measured median. As we saw in Section 2, this is far more repetitions than are commonly found in the literature: most papers are on the extreme left side of this figure, where the confidence intervals are quite wide. This points to the need for stronger experiment design and analysis in our community.

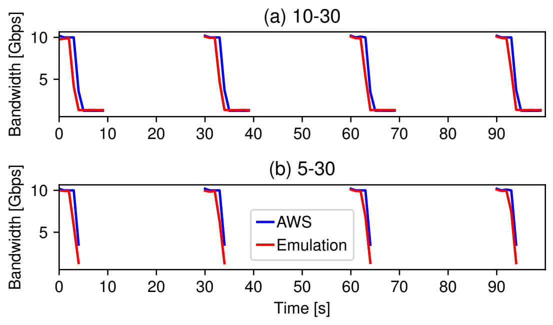

Figure 14: Validation of the emulation of the token-bucket policy of Amazon EC2. The similar aspect of the two curves indicates that emulation is high-quality.

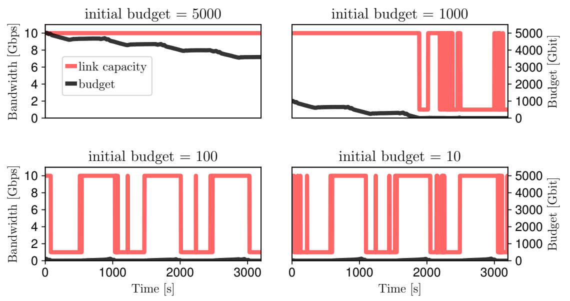

Figure 15: Link capacity allocated when running Terasort on a token bucket. Left vertical axis shows the link capacity; right vertical axis shows the token bucket budget. Budget depletes due to application network transfers.

4.2 Experiments and Token-Buckets

In contrast to Google Cloud and HPCCloud, the *token-bucket* shaping policy of Amazon EC2 is *not* stochastic noise, and needs in-depth analysis. Because token-bucket behavior is dependent on past network access patterns, *an application influences not only its own runtime, but also future applications' runtimes*.

Token-bucket Emulator. We decided to emulate the behavior of Amazon EC2 token-bucket instead of directly running applications in this cloud. We believe this type of experimentation is superior to the other two alternatives: (i) simulation, or (ii) directly running applications on the cloud. For the former, we believe the behavior of big data applications under network performance variability is far too subtle and complex to properly simulate while modeling and capturing all possible variables. For the latter, we perform the emulation in an isolated setup, i.e., a private cluster, that does not share resources. This allows us to test in isolation the effects of network performance variability, excluding as much as possible all other sources of variability one could encounter in a cloud (e.g., CPU, memory bandwidth, I/O etc.). If we were to directly run applications in a cloud, it would have been difficult to separate the effects of network variability

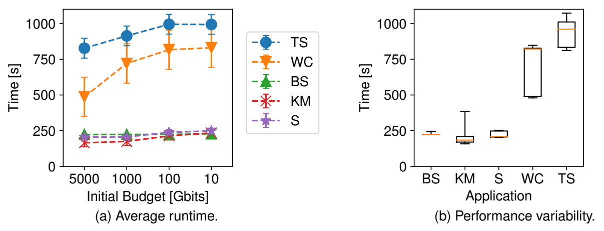

Figure 16: HiBench average runtime (left) and performance variability (right), plotted as IQR box (whiskers represent 1st and 99th percentiles), induced by token bucket budget variability. The more network-dependent applications are affected more by lower budgets.

from, for example, the effects of CPU variability.

We built a network emulator based on the Linux `tc` [33] facility. Figure 14 plots the real-world behavior encountered in Amazon EC2 in comparison with our emulation. This experiment is a zoomed-in view of the experiment in Section 3.1, where our servers were communicating for either five or ten seconds, then slept for 30 seconds. At the beginning of each experiment, we made sure that the token-bucket budget is nearly empty. During the first few seconds of the experiment the token-bucket budget gets completely exhausted. For each sending phase of 5 or 10 seconds, the system starts at a high QoS (10 Gbps bandwidth), after a few seconds the budget is emptied, and the system drops to a low QoS (1 Gbps).

Experiment Setup. We perform the experiments described in Table 4 on a 12-node cluster. Each node has 16 cores, 64GB memory, a 256GB SSD, and FDR InfiniBand network. Using the emulator presented in Figure 14, we run on the emulated Amazon EC2 token-bucket policy all applications and queries in the HiBench [32] and TPC-DS [49] benchmark suites. The emulated setup is that of the *c5.xlarge* instance type, which typically sees a high bandwidth of 10 Gbps and a low bandwidth of 1 Gbps. Throughout our experiments we vary the token bucket budget to assess its impact on big data applications. We run each workload a minimum of 10 times for each token-bucket configuration and report full statistical distributions of our experiments.

Token-bucket-induced Performance Variability. One important parameter for the token-bucket is its budget: the number of tokens available at a certain moment in time. This is highly dependent on the previous state of the virtual machine (i.e., how much network traffic has it sent recently), and has a large impact on the performance of future deployed applications. Note that it is difficult to estimate the currently-available budget for anything other than a "fresh" set of VMs: each VM has its own token bucket, the remaining budget is a function of previous runs, and, as we saw in Figure 11 the constants controlling the bucket are not always identical.

Application performance is highly dependent on the budget, and deployments with smaller budgets create more network performance variability. Figure 15 shows the network traffic behavior of the Terasort application with different initial budgets. For each budget, the subfigures show the application network profile for 5 consecutive runs. We notice a strong correlation between small budgets and network performance variability: there is much more variability for budgets $\in \{10,100\}$ Gbits, than for budgets $\in \{1000,5000\}$ Gbits.

Figure 16 shows how this effect manifests in the runtimes of HiBench: it plots the average application runtime (left) over 10 runs for budgets $\in \{10,100,1000,5000\}$ Gbits, and the performance variability over the same budgets (right). For the more network-intensive applications (i.e., TS, WC), the initial state of the budget can have a 25%–50% impact on performance.

A similar behavior is observed for the TPC-DS benchmark suite. Figure 17 shows the query sensitivity to the token budget and the variability induced by different budget levels. Figure 17(a) plots average runtime slowdown for 10-run sets of TPC-DS queries for budgets $\in \{10,100,1000\}$ Gbits, compared to the 5000 Gbit budget. For all queries, larger budgets lead to better performance. Figure 17(b) plots the performance variability over all tested budgets. Queries with higher network demands exhibit more sensitivity to the budget and hence higher performance variability.

These results clearly show that if the system is left in an unknown state (e.g., a partially-full token bucket, left over from previous experiments), the result is likely to be an inaccurate performance estimate. Evidence from Figures 16(b) and 17(b) strongly supports this, as performance varies widely for the network-intensive queries and applications depending on the token-bucket budget.

Token-bucket-induced Stragglers. Non-trivial combinations of token-bucket budgets, application scheduling imbalances, and network access patterns lead to straggler nodes. Figure 18 shows that for budget = 2500 Gbits and application TPC-DS, the application gets slowed down by a straggler: all nodes but one in the deployment do not deplete their budgets completely, thus remaining at a high bandwidth QoS of 10 Gbps. However, there is one node on which the token-bucket budget is depleted, causing its bandwidth to get limited to 1 Gbps. Exacerbating the variability, the behavior is not consistent: this node oscillates between high and low bandwidths in short periods of time. Such unpredictable behavior leads to both performance variability of the entire setup and also poor experiment reproducibility. This behavior will be prevalent in many *unbalanced* networked applications, where certain servers might perform more transfers than others. Especially in long-running clusters, the state of the individual servers' token-buckets will be highly different. As a direct consequence, the overall system will suffer from stragglers.

Repeatable experiments and token-buckets. Token-bucket policies for enforcing network QoS can have unexpected and detrimental impacts on sound cloud-based experimentation. To explore this, we compute medians and their nonparametric confidence intervals (CIs), similar to the work

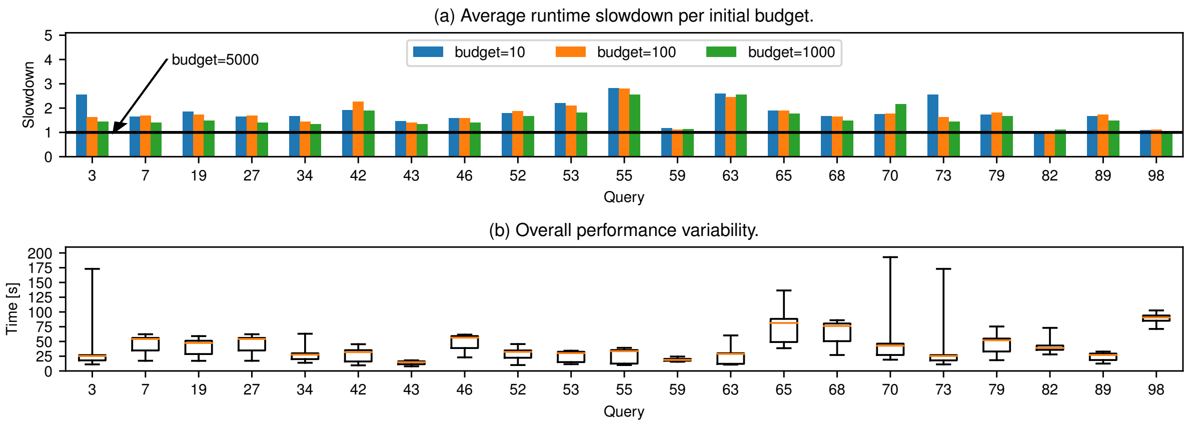

Figure 17: TPC-DS average runtime slowdown per query depending on initial budget (top); overall performance variability, summarized over initial budgets (bottom), plotted as IQR box; whiskers represent 1st and 99th percentiles.

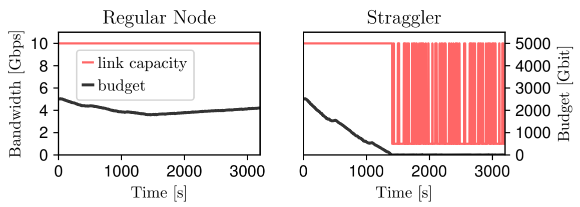

Figure 18: Link capacity allocation for TPC-DS on a token-bucket network, with initial budget = 2500 Gbit. Regular node network utilization (left); straggler node (right).

by Maricq et al. [47], across a number of initial token budgets. Figure 19 plots median estimates for two TPC-DS queries, along with 95% CIs and 10% error bounds around medians. Repetitions of the experiments are independent: each one runs on fresh machines with flushed caches, and at the the beginning of each repetition, we reset the token budget. We reduce this initial budget over time to emulate the effects that previous experiments can have on subsequent ones: what this models is an environment in which many different experiments (or repetitions of the same experiment) are run in quick succession. This is likely to happen when running many experiments back-to-back in the same VM instances.

Query 82 (in the top of Figure 19) is agnostic to the token budget. Running more repetitions of this experiment tightens the confidence intervals, as is expected in CI analysis. In contrast, query 65 (in the bottom of the figure) depends heavily on the bucket budget; as a result, as we run more experiments, depleting the bucket budget, the query slows down significantly, and the initial CI estimates turn out to be inaccurate. In fact, the CIs *widen* with more repetitions, which is unexpected for this type of analysis. This is because the token bucket breaks the assumption that experiments are independent: in this model, more repetitions deplete the bucket that the next experiment begins with. These two queries represent extremes, but, as shown in the bar graph at the bottom of the figure, 80% of all queries we ran from TPC-DS suffer effects like Query 65: most produce median estimates that are more than 10% incorrect by the time we fully deplete the budget.

This demonstrates that, when designing experiments, we cannot simply rely on the intuition that more repetitions lead to more accurate results: we must ensure that factors hidden in the cloud infrastructure are reset to known conditions so that each run is truly independent. Others have shown that cloud providers use token buckets for other resources such as CPU scheduling [62]. This affects cloud-based experimentation, as the state of these token buckets is not directly visible to users, nor are their budgets or refill policies.

5 Summary: Is Big Data Performance Reproducible in Modern Cloud Networks?

We return to our two basic questions: (1) *How reproducible are big data experiments in the cloud?*; and (2) *What can experimenters do to make make sure their experiments are meaningful and robust?* Our findings are:

F5.1: Network-heavy experiments run on different clouds cannot be directly compared. Building a cloud involves trade-offs and implementation decisions, especially at the virtualization layer. Some of these decisions are well-documented by the platforms [6,28], but others, including the ones we have examined in this paper, are not. Unfortunately, these differences can cause behaviors that result in different application performance, such as the bandwidth differences seen in Figure 10 or the latency effects seen in Figure 12.

Both of these effects are rather large, and are dependent on factors such as the size of the application's write buffer and specific patterns of communication. While these decisions presumably serve the clouds' commercial customers well, they complicate things for those who are trying to draw scientific conclusions; when comparing to previously-published performance numbers, it is important to use the same cloud to ensure that differences measured are that of the systems

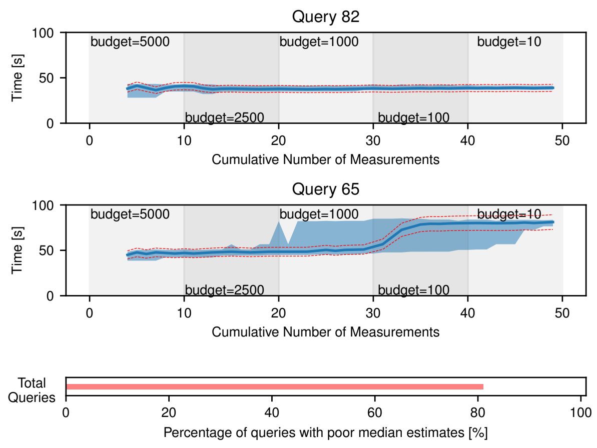

Figure 19: Median estimates (blue thick curve), 95% non-parametric confidence intervals (light blue filled space), and 10% error bounds (red dotted curves) for running two TPC-DS queries, over 5 token-bucket budgets. Bottom: number of queries for which we cannot achieve tight confidence intervals and accurate median estimates.

under test, and not artifacts of the cloud platform. Running on multiple clouds, can, however, be a good way to perform sensitivity analysis [36]: by running the same system with the same input data and same parameters on multiple clouds, experimenters can reveal how sensitive the results are to the choices made by each provider.

F5.2: Even within a single cloud, it is important to establish baselines for expected network behavior. These baselines should be published along with results, and need to be verified before beginning new experiments. Because cloud providers' policies can be opaque, and implementation details can change over time, it is possible for changes to invalidate over time experiments within the same cloud. For example, after several months of running experiments in Amazon EC2, we began encountering new behavior: prior to August 2019, all `c5.xlarge` instances we allocated were given virtual NICs that could transmit at 10 Gbps. Starting in August, we started getting virtual NICs that were capped to 5 Gbps, though not consistently (this behavior is part of the underlying cause of the distributions in Figure 11). The reasons for this are not clear, and we have no way to know whether the "new" behavior is a transient effect in response to increased congestion that month or a new, permanent policy.

If one can establish baseline expectations for how the platform will perform, and incorporate checks for them into the experimental process [37], one can at least detect when changes have occurred. Experimenters should check, through micro-benchmarks, whether specific cloud resources (e.g., CPU, network) are subject to provider QoS policies.

As opposed to contention-related variability, this type of variability is deterministic under carefully selected micro-benchmarks. In the network, these microbenchmarks should at a minimum include base latency, base bandwidth, how latency changes with foreground traffic, and the parameters to bandwidth token-buckets, if they are present. Furthermore, when reporting experiments, always include these *performance fingerprints* together with the actual data, as possible changes in results in the future could be explained by analyzing the micro-benchmark logs.

F5.3: Some cloud network variability (in particular, interference from neighbors) can be modeled as stochastic noise, and classic techniques from statistics and experiment design are sufficient for producing robust results; however, this often takes more repetitions than are typically found in the literature. Standard statistical tools such as ANOVA and confidence intervals [11, 36, 47] are effective ways of achieving robust results in the face of random variations, such as those caused by transient "noisy neighbors"; however, in order to be effective, they require many repetitions of an experiment, and, as we saw in Section 2, this bar is often not met in the literature. The more variance, the more repetitions are required, and as we saw in Figures 4, 5, and 6, network variance in the cloud can be rather high, even under 'ideal' conditions. An effective way to determine whether enough repetitions have been run is to calculate confidence intervals for the median and tail, and to test whether they fall within some acceptable error bound (e.g., 5% of value they are measuring).

F5.4: Other sources of variability cause behavior that breaks standard assumptions for statistical analysis, requiring more careful experiment design. Some of the variability we have seen (e.g., Figures 12, 18, and 19) causes behavior that breaks standard assumptions for statistical analysis (such as iid properties and stationarity). As an integral part of the experimentation procedure, samples collected should be tested for normality [56], independence [46], and stationarity [23]. When results are not normally-distributed, non-parametric statistics can be used [26]. When performance is not stationary, results can be limited to time periods when stationarity holds, or repetitions can be run over longer time frames, different diurnal or calendar cycles, etc. Techniques like CONFIRM [47] can be used to test whether confidence intervals converge as expected.

Discretizing performance evaluation into units of time, e.g., *one hour* is helpful. Gathering median performance for each interval, and applying techniques such as CONFIRM over large-numbers of gathered medians results in significant and realistic performance data. Large intervals can smooth out noise, helping to reduce unrepresentative measurements.

We also find it helpful to 'rest' the infrastructure and randomize [3] experiment order. Because it is hard to tell what performance-relevant state may build up in the hidden parts of the underlying cloud infrastructure, experimenters must ensure that the infrastructure is in as 'neutral' a state as possible at the beginning of every experiment. The most reliable way to do this is to create a fresh set of VMs for every experiment. When running many small experiments, this can be cost- or time-prohibitive: in these cases, adding delays between experiments run in the same VMs can help. Data used while gathering baseline runs can be used to determine the appropriate length (e.g., seconds or minutes) of these rests. Randomized experiment order is a useful technique for avoiding self-interference.

F5.5: Network performance on clouds is largely a function of provider implementation and policies, which can change at any time. Experimenters cannot treat "the cloud" as an opaque entity; results are significantly impacted by platform details that may or may not be public, and that are subject to change. (Indeed, much of the behavior that we document in Sections 3 and 4 is unlikely to be static over time.) Experimenters can safeguard against this by publishing as much detail as possible about experiment setup (e.g., instance type, region, date of experiment), establishing baseline performance numbers for the cloud itself, and only comparing results to future experiments when these baselines match.

Applicability to other domains. In this paper, we focused on big data applications and therefore our findings are most applicable in this domain. The cloud-network related findings we present in Section 3 are general, so practitioners from other domains (e.g., HPC) should take them in to account when designing systems and experiments. However, focusing in depth on other domains might reveal interactions between network variability and experiments that are not applicable to big data due to the intrinsic application characteristics. Therefore, while our findings in Section 4 apply to most other networked applications, they need not be complete. We also believe that a community-wide effort for gathering cloud variability data will help us automate reproducible experiment design that achieves robust and meaningful performance results.

6 Related Work

We have showed the extent of network performance variability in modern clouds, as well as how practitioners disregard cloud performance variability when designing and running experiments. Moreover, we have showed what the impact of network performance variability is on experiment design and on the performance of big data applications. We discuss our contributions in contrast to several categories of related work.

Sound Experimentation (in the Cloud). Several articles already discuss pitfalls of systems experiment design and presentation. Such work fits two categories: guidelines for better experiment design [3,17,38,47] and avoiding logical fallacies in reasoning and presentation of empirical results [10,21,31]. Adding to this type of work, we survey how practitioners apply such knowledge, and assess the impact of poor experiment design on the reliability of the achieved results. We investigate the impact of *variability* on performance reproducibility, and uncover variability behavior on modern clouds.

Network Variability and Guarantees. Network variability has been studied throughout the years in multiple contexts, such as HPC [8,9], experimental testbeds [47] and virtualized environments [35,40,55]. In the latter scenario, many studies have already assessed the performance variability of cloud datacenter networks [43, 51, 63]. To counteract this behavior, cloud providers tackle the variability problem at the infrastructure level [12,52]. In general, these approaches introduce network virtualization [30,54], or traffic shaping mechanisms [18], such as the token buckets we identified, at the networking layer (per VM or network device), as well as a scheduling (and placement) policy framework [41]. In this work, we considered both types of variability: the one given by resource sharing and the one introduced by the interaction between applications and cloud QoS policies.

Variability-aware Network Modeling, Simulation, and Emulation. Modeling variable networks [27,45] is a topic of interest. Kanev et al. [39] profiled and measured more than 20,000 Google machines to understand the impact of performance variability on commonly used workloads in clouds. Uta et al. emulate gigabit real-world cloud networks to study their impact on the performance of batch-processing applications [60]. Casale and Tribastone [14] model the exogenous variability of cloud workloads as continuous-time Markov chains. Such work cannot isolate the behavior of network-level variability compared to other types of resources.

7 Conclusion

We studied the impact of cloud network performance variability, characterizing its impact on big data experiment reproducibility. We found that many articles disregard network variability in the cloud and perform a limited number of repetitions, which poses a serious threat to the validity of conclusions drawn from such experiment designs. We uncovered and characterized the network variability of modern cloud networks and showed that network performance variability leads to variable slowdowns and poor performance predictability, resulting in non-reproducible performance evaluations. To counter such behavior, we proposed protocols to achieve reliable cloud-based experimentation. As future work, we hope to extend this analysis to application domains other than big data and develop software tools to automate the design of reproducible experiments in the cloud.

Abstract

This paper presents a new approach for caching in CDNs that uses machine learning to approximate the Belady MIN (oracle) algorithm. To accomplish this complex task, we propose a CDN cache design called Learning Relaxed Belady (LRB) to mimic a Relaxed Belady algorithm, using the concept of Belady boundary. We also propose a metric called good decision ratio to help us make better design decisions. In addition, the paper addresses several challenges to build an end-to-end machine learning caching prototype, including how to gather training data, limit memory overhead, and have lightweight training and prediction.

We have implemented an LRB simulator and a prototype within Apache Traffic Server. Our simulation results with 6 production CDN traces show that LRB reduces WAN traffic compared to a typical production CDN cache design by 4–25%, and consistently outperform other state-of-the-art methods. Our evaluation of the LRB prototype shows its overhead is modest and it can be deployed on today's CDN servers.

1 Introduction

Content Distribution Networks (CDNs) deliver content through a network of caching servers to users to improve latency, bandwidth, and availability. CDNs delivered 56% of Internet traffic in 2017, with a predicted rise to 72% by 2022 [29]. Improving CDN caching servers can significantly improve the content delivery of the Internet.

A CDN cache sits between users and Wide-Area Networks (WANs). Whenever a user requests content that is not currently cached, the CDN must fetch this content across Internet Service Providers (ISPs) and WANs. While CDNs are paid for the bytes delivered to users, they need to pay for the bandwidth required to fetch cache misses. These bandwidth costs constitute an increasingly large factor in the operational cost of large CDNs [6, 14, 17, 41, 46, 66]. CDNs are thus seeking to minimize these costs, which are typically measured as *byte miss ratios*, i.e., the fraction of bytes requested by users that are not served from cache.

The algorithm that decides which objects are cached in each CDN server plays a key role in achieving a low byte miss ratio. Yet, the state-of-the-art algorithms used in CDN caching servers are heuristic-based variants of the Least-Recently-Used (LRU) algorithm (Section 2). The drawback of heuristics-based algorithms is that they typically work well for some access patterns and poorly for others. And, even with five decades of extensive study since caching was first proposed [84]—including using machine learning to adapt heuristics to different workloads—the fundamental limitation of heuristics remains. We still observe a large gap between the byte miss ratios of the state-of-the-art online cache replacement algorithms and Belady's offline MIN algorithm [16] on a range of production traces.

To bridge this gap, this paper presents a novel machine-learning (ML) approach that is fundamentally different from previous approaches to cache replacement. Our approach does not build on heuristics, nor try to optimize heuristics-based algorithms. Our approach is to approximate Belady's MIN (oracle) algorithm, using machine learning to find objects to evict based on past access patterns. Belady's algorithm always evicts the object with the furthest next request. A naive ML algorithm that imitates this behavior would incur prohibitively high computational cost. To overcome this challenge, our key insight is that it is sufficient to approximate a *relaxed Belady algorithm* that evicts an object whose next request is beyond a threshold but not necessarily the farthest in the future.

To set a proper threshold, we introduce the *Belady boundary*, the minimum time-to-next-request of objects evicted by Belady's MIN algorithm. We show that the byte miss ratio of the relaxed Belady algorithm using the Belady boundary as its threshold is close to that of Belady's MIN algorithm. Approximating relaxed Belady gives our system a much larger set of choices to aim for, which has two major consequences for our design. It allows our system to run predictions on a small sampled candidate set—e.g., 64—which dramatically reduces computational cost. And, it allows our system to quickly adapt to changes in the workload by gathering training data that includes the critical examples of objects that relaxed Belady would have selected for replacement.

Even with the insight of relaxed Belady, the design space of potential ML architectures (features, model, loss function, etc.) is enormous. Exploring this space using end-to-end metrics like byte miss ratio is prohibitively time-consuming because they require full simulations that take several hours for a single configuration. To enable our exploration of the ML design space we introduce an eviction decision quality metric, the *good decision ratio*, that evaluates if the next request of an evicted object is beyond the Belady boundary. The good decision ratio allows us to run a simulation only once to gather

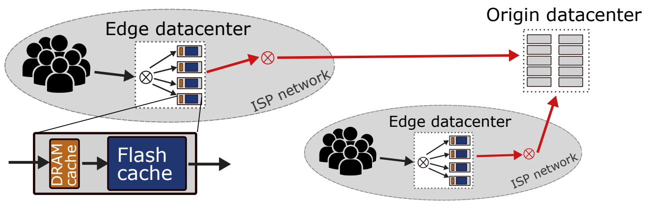

Figure 1: CDNs place servers in user proximity around the world (e.g., in a user's ISP). Incoming requests are sharded among several caching servers, which use combined DRAM and flash caches. Cache misses traverse expensive wide-area networks to retrieve data from the origin datacenter.

training data, prediction data, and learn the Belady boundary. Then we can use it to quickly evaluate the quality of decisions made by an ML architecture without running a full simulation. We use the good decision ratio to explore the design space for components of our ML architecture including its features, model, prediction target, and loss function among others.

These concepts enable us to design the Learning Relaxed Belady (LRB) cache, the first CDN cache that approximates Belady's algorithm. Using this approach in a practical system, however, requires us to address several systems challenges including controlling the computational overhead for ML training and prediction, limiting the memory overhead for training and prediction, how to gather online training data, and how to select candidates for evictions.

We have implemented an LRB simulator and an LRB prototype within Apache Traffic Server [1, 2, 10, 43].[1] Our evaluation results using 6 production CDN traces show that LRB consistently performs better than state-of-the-art methods and reduces WAN traffic by 4–25% compared to a typically deployed CDN cache—i.e., using LRU replacement that is protected with a Bloom filter [22]. Our evaluation of the prototype shows that LRB runs at a similar speed to a heuristic-based design and its computational overhead and memory overhead are small.

2 Background and Motivation

In this section, we quantify the opportunities and challenges that arise in CDN caching. We also discuss the constraints on the design space of LRB.

2.1 The Challenge of Reducing WAN Traffic

A CDN user request is directed to a nearby CDN server (e.g., using DNS or anycast [33]), which caches popular web and media objects. Each cache miss has to be fetched across the wide-area network (WAN) (Figure 1). As WAN bandwidth needs to be leased (e.g., from tier 1 ISPs), CDNs seek to

[1]The source code of our simulator and prototype alongside with documentation and the Wikipedia trace used in our evaluation is available at `https://github.com/sunnyszy/lrb` .

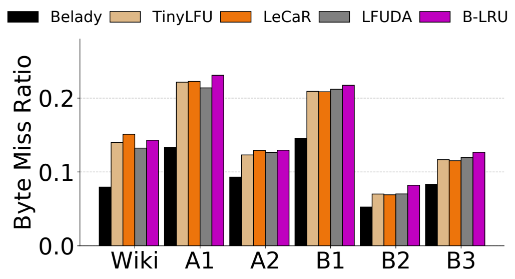

Figure 2: Simulated byte miss ratios for Belady and the top-performaning policies from Section 6 for six CDN production traces and a 1 TB flash cache size. There is a large gap of 25–40% between Belady and all other policies.

reduce WAN traffic, which corresponds to minimizing their cache's byte miss ratio.

CDN caching working sets are massive compared to available cache space. To reduce bandwidth, a CDN deploys DRAM and flash caches in each edge server.[2] A commercial CDN serves content on behalf of thousands of content providers, which are often large web services themselves. This leads to a massive working set, which is typically sharded across the (tens of) servers in an edge cluster [25, 77]. Even after sharding traffic, an individual cache serves traffic with a distinct number of bytes much larger than its capacity. Consequently, there exists significant competition for cache space.

There are significant opportunities to improve byte miss ratios. CDN traffic has a variety of unique properties compared to other caching workloads. For example, a striking property observed in prior work [63] is that around 75% of all objects do not receive a second request within two days (so-called "one-hit-wonders"). If these objects are allowed to enter the cache, the vast majority of cache space is wasted. Therefore, major CDNs deploy B-LRU, an LRU-eviction policy using a Bloom filter [63, 67, 74] to prevent one-hit-wonder objects from being admitted to the cache.

We quantify the opportunity to improve byte miss ratios over B-LRU. To this end, we use 6 production traces from 3 different CDNs, which are sharded at the granularity of a single SSD (around 1–2 TB). Figure 2 compares the byte miss ratios of B-LRU and the other top-performing policies from Section 6 to Belady's MIN [16], and we find that there remains a gap of 25–40%.

Exploiting miss ratio opportunities is challenging in practice. The key challenge is that workloads change rapidly over time and differ significantly between servers and geographic locations. These changes occur due to load balancing different types of content, e.g., web traffic is more popular in the morning and video more popular at night. Due to these rapid changes and breadth of different access patterns, prior

[2]CDNs typically prefer flash storage over HDDs as cache reads lead to random reads with very high IOPS requirements. While some CDNs have hybrid deployments, many CDNs rely entirely on flash [46, 67, 74, 78].

	PT-1	PD-2	ET-1	ET-2	CET-1	CET-2
Mean CPU	5%	3%	6%	16%	7%	18%
Peak CPU	19%	12%	10%	24%	13%	30%

Table 1: Mean and peak CPU load in Wikipedia's production deployment CDN across 6 datacenters in three different timezones, for March 2019. Peak CPU load is below 30%.

caching policies (Section 7) only achieve marginal improvements over B-LRU (Section 6). In fact, many recent caching policies lead only to gains on some traces with certain cache size configurations.

In conclusion, there is significant demand to realize caching policies that can automatically adapt to a geographic location's workload and to changes in request patterns over time. Machine learning is well suited to achieving this goal. But, leveraging machine learning for CDN caching requires us to overcome many challenges we describe in Section 4.

2.2 Opportunity and Requirements

Deployment opportunity. We find that today's CDN caches typically have spare processing capacity. Table 1 shows the CPU load in six production deployments of Wikipedia's CDN for March 2019. We see that, on average, there is 90% spare processing capacity. Even under peak load, there is still 70% CPU capacity available, as disk and network bandwidth are frequent bottlenecks. Thus, the opportunity in current deployment is that we can use this excess processing capacity as part of more sophisticated caching algorithms.

Deployment requirements. There are three key constraints when deploying on existing CDN caching servers.

- **Moderate memory overhead** of a few GBs but not 10s of GBs because large quantities are not available [19].
- **Not require TPUs or GPUs** because these are not currently deployed in CDN servers [41, 63].
- **Handle tens of thousands of requests per second** because this is the request rate seen at CDN caches [19].

3 Approximating Belady's MIN Algorithm

In order to approximate Belady's MIN algorithm in the design of an ML-based cache, this section introduces the relaxed Belady algorithm, Belady boundary, and good decision ratio.

3.1 Relaxed Belady Algorithm

It is difficult for an ML predictor to directly approximate Belady's MIN algorithm for two reasons. First, the cost of running predictions for all objects in the cache can be prohibitively high. Second, in order to find the object with the farthest next request, an ML predictor needs to predict the time to next request of all objects in the cache accurately.

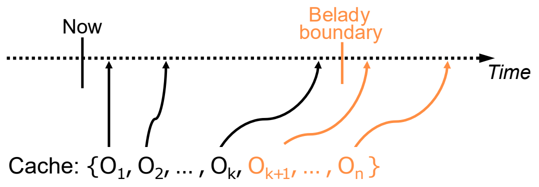

Figure 3: The relaxed Belady algorithm partitions objects into two sets based on their next requests. The next requests of $O_{k+1}, \ldots, O_n$ are beyond the threshold (Belady boundary).

To overcome these two challenges, we define the *relaxed Belady algorithm*, a variant of Belady's MIN, that randomly evicts an object whose next request is beyond a specific threshold, as shown in Figure 3. The algorithm partitions the objects of a cache into two sets each time it needs to make an eviction decision: objects whose next requests are within the threshold (set 1) and objects whose next requests are beyond the threshold (set 2). If set 2 is not empty, the algorithm randomly evicts an object from this set. If set 2 is empty, the algorithm reverts to the classical Belady among object in set 1.

The relaxed Belady algorithm has two important properties. First, if the threshold is far, its byte miss ratio will be close to that of Belady's MIN. Second, since the algorithm can evict any of the objects in set 2, not necessarily the object with farthest distance, there will be many eviction choices in the cache each time it needs to evict an object.

These properties greatly reduce the requirements for an ML predictor. Instead of predicting next requests for all objects in the cache, the ML predictor can run predictions on a small sample of candidates in the cache for an eviction as long as the sample includes objects from set 2. This allows a dramatic reduction of computational cost. In addition, it reduces the required precision of the ML predictor. It only needs to find an object whose next request is beyond the threshold instead of the farthest. This greatly reduces the memory overhead when gathering training data: instead of having to track objects indefinitely, it is sufficient to track objects until they are re-requested or cross the threshold.

Shorter thresholds thus make the task of the ML predictor more tractable. While longer thresholds move the byte miss ratio of relaxed Belady closer to Belady's MIN. It is thus important to find the proper threshold.

3.2 Belady Boundary

To systematically choose a threshold for the relaxed Belady algorithm, we introduce the *Belady boundary* as the minimum of time to next request for all evicted objects by Belady's MIN algorithm. It is intuitively meaningful—Belady's MIN kept all objects with a next request less than this boundary in the cache—but requires future information to compute. In practice, we assume that the Belady boundary is approximately stationary. This allows us to approximate the Belady boundary by computing the minimum of the next requests of

Cache size (GB)	64	128	256	512	1024
Boundary (x cache size)	3	2	2	2	2
Objects beyond boundary	19%	19%	16%	12%	10%
Increase in byte miss ratio over Belady	10%	13%	12%	11%	9%

Table 2: Comparison of the relaxed Belady algorithm to Belady MIN for the Wikipedia trace with different cache sizes.

all evicted objects by the Belady MIN algorithm during the machine learning warmup period.

Table 2 shows how the Belady boundary affects the byte miss ratio of relaxed Belady on the Wikipedia trace. We find that relaxed Belady applies random eviction to a set of objects, e.g., 19% for a 64 GB cache. While this Belady boundary enables efficient implementations, it comes at the cost of 9-13% more misses. Compared to the 25%–40% gap between state-of-the-art online algorithms and Belady's MIN (Figure 2), this increase seems acceptable.

Next, we show how to use the Belady boundary to establish a decision quality metric, which is used to make design decisions throughout Section 4.

3.3 Good Decision Ratio

To design an algorithm that makes better decisions we need to determine the quality of individual decisions. End-to-end metrics like byte miss ratio, however, reflect the aggregated quality of many decisions. When an algorithm has a byte miss ratio higher than Belady we know it made some bad decisions, but we cannot determine which of its decisions were bad. The individual misses that comprise byte miss ratio are similarly unhelpful because they are also the result of many earlier decisions.

Our eviction decision metric is defined with respect to the relaxed Belady algorithm with the Belady boundary as its threshold. Evicting an object is a *good decision* if the next request of the object is beyond the Belady boundary. It is a *bad decision* if its next request is within the Belady boundary.

We find that an algorithm's *good decision ratio*—i.e., # good decisions / # total eviction decisions—correlates strongly with the byte miss ratio it ultimately achieves (Section 6.4). This metric plays a key part in the design of LRB.

4 Design of Learning Relaxed Belady Cache

This section presents the design details of LRB, which uses ML to imitate the relaxed Belady algorithm. Accomplishing this requires simultaneously addressing two previously unsolved problems:

- How to design an ML approach that decreases byte miss ratio relative to state-of-the-art heuristics?

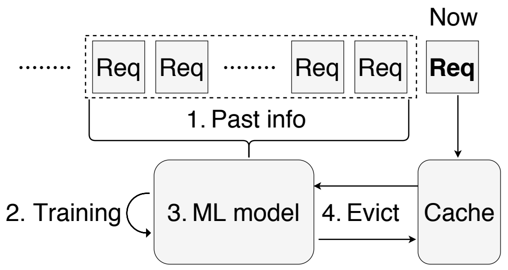

Figure 4: General architecture that uses ML for caching with 4 key design issues: 1) what past information to use for ML, 2) how to generate online training datasets, 3) what ML model to use, and 4) how to select eviction candidates.

- How to build a practical system with that approach?

Each problem introduces several challenges in isolation, simultaneously addressing them additionally requires us to balance their often-competing goals.

Figure 4 presents a general architecture that uses ML to make eviction decisions. We identify four key design issues:

(1) Past information. The first design issue is determining how much and what past information to use. More data improve training quality, but we need to limit the information in order to build a practical system, as higher memory overhead leads to less memory that can be used to cache objects.

(2) Training data. The second design issue is how to use past information for training. As workloads vary over time the model must be periodically retrained on new data. Thus, a practical system must be able to dynamically generate training datasets with proper labels.

(3) ML architecture. The third design issue is selecting a machine learning architecture that makes good decisions. This includes selecting features, the prediction target, and the loss function as well as how to translate predictions into eviction decisions. In addition, these decisions need to be compatible with available hardware resources to build a practical system.

(4) Eviction candidate selection. The final design issue is how to select eviction candidates. Although an approximation of the relaxed Belady algorithm can evict any object whose next request is beyond the Belady boundary and there are many eviction choices, we still need a method to select a small set of candidates that includes such objects with a high probability.

The rest of this section describes the design decisions of LRB for each of these design issues. Our general approach is to guide our design using the good decision ratio metric defined in Section 3.

4.1 Past information

LRB keeps information about an object only when its most recent request is within the *sliding memory window*. The information within the sliding memory window is used for training and prediction.

Setting the size of the sliding memory window is important to the performance of LRB. If the sliding memory window is too short, LRB will not have enough training data to produce a good model and may not have the information it needs during prediction to make an accurate prediction. If the sliding memory window is too long, it may take too much space away from cached data.

LRB uses each trace's validation prefix to set the sliding memory window hyperparameter. For small cache sizes, the validation prefix is long enough to derive the "optimal" sliding memory window, which achieves the highest good decision ratio. For large cache sizes, we use a least-squares regression line fit to the relationship between small cache sizes and their optimal sliding memory window parameters.

We remark that, at the beginning of a trace (or during initial deployment), LRB requires training data to build an initial model. Thus, our implementation uses LRU as a fallback until sufficient training data is available.

4.2 Training Data

Acquiring training data for our problem is challenging because the features and corresponding label exist at widely disparate times. Consider an object that is requested once and then not requested again until 5 hours later. The features of the object exist and vary at all times in the 5-hour range. The label—i.e., what we want to predict—does not exist until the end of that range, when we know the "future" by waiting until it is the present. To address the time disparity, LRB decouples generation of unlabeled training data from labeling that data.

Unlabeled training data generation. To generate unlabeled training data LRB periodically takes a random sample of objects in the sliding memory window and then records the current features of those objects. We choose to randomly sample over objects instead of over requests to avoid biasing the training data towards popular objects with many requests. Such popular objects should be represented in the training data so the model learns not to evict them. Training data for less popular objects, however, is more important because they include the objects beyond the Belady boundary—the good eviction decisions we want our model to learn. We choose to randomly sample over all objects in the sliding memory window instead of only those currently in the cache as cached objects are similarly biased.

Labeling training data. LRB uses two methods for assigning labels to training data. The first is to wait until an object is requested again. When this happens, we know the "future" and use that to determine the label. Some objects, however, will not be requested until far—e.g., 5 days—in the future.

Waiting until such objects are requested again would introduce many problems. First, it would require excessive memory overhead as we maintain features for many objects that were requested a potentially very long time ago. Second, it would make some of the training data excessively old, e.g., 5 days old. Finally, it would never include training data for objects that are never requested again—which are a significant portion of the good decisions we want our method to learn.

LRB's second method for labeling training data avoids these problems by leveraging an insight related to the Belady boundary: all objects that are not requested again for at least a boundary amount of time are equivalent good eviction decisions. Thus, once the time since last request for an object exceeds the Belady boundary we can safely label it. LRB uses this second labeling method when an object falls out of the sliding memory window.

4.3 ML Architecture

This subsection describes the components of LRB's ML architecture. For each component, we describe our choice, describe its rationale, and then use the good decision ratio to explore the design space. This exploration is complicated by the fact that each component influences the others—feature set A may be better for model X while feature set B may be better for model Y. Even with our good decision ratio doing a full exploration of all possible combinations is still prohibitive. Instead, we fix each of the other components on what we ultimately select in LRB's design and then vary the specific component.

4.3.1 Features: Deltas, EDCs, and Static

LRB uses three different types of features: deltas, exponentially decayed counters, and static features. The rationale for these features is to provide a superset of the information used by previous heuristics. Because our model learns the weight for different features adding more features should not harm its accuracy. Thus, the primary tradeoff for features is weighing how much they help the model against the overhead they incur. To minimize the overhead of the features we strive to make storing and updating them efficient (Section 5).

Deltas. Deltas indicate the amount of time between consecutive requests to an object. Delta$_1$ indicates the amount of time since an object was last requested. Delta$_2$ indicates the time in between an object's previous two requests and so on, i.e., delta$_n$ is the amount of time between an object's n^{th} and $(n-1)^{th}$ previous requests. If an object has been requested only n times, then above delta$_n$ are ∞. We include deltas as features because they subsume the information used by many successful heuristics. For instance, LRU uses delta$_1$, LRU-K uses the sum of delta$_1$ to delta$_k$, and S4LRU uses a combination of delta$_1$ to delta$_4$.

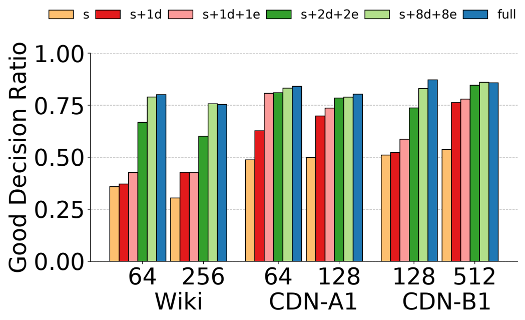

Figure 5: Good decision ratios for accumulating features for LRB on three traces at two cache sizes. LRB uses static features, 32 deltas, and 10 EDCs (full).

Exponentially decayed counters (EDCs). EDCs track an approximate per-object request count over longer time periods, where keeping exact counts would require excessive memory overhead. Each EDC$_i$ is initialized to 0. Whenever there is a request to the object, we first update Delta$_1$ and then $C_i = 1 + C_i \times 2^{-\text{Delta}_1/2^{9+i}}$. Unlike Delta$_1$, C_i will not be updated until another request arrives for the same object. The EDCs with larger values of i cover larger periods, e.g., an object that was highly popular 1 million requests ago but is now not popular would have a low EDC$_1$ but still have a high EDC$_{10}$.

The exact EDC equation is motivated by prior observation in block storage caching [57] and video popularity prediction [79], where EDCs accurately approximate the decay rate of object popularities. Tracking long-term popularity is used by many other algorithms such as LFU variants [11,75], Hyperbolic [21], and LRFU [57] (which uses a single EDC). LRB uses multiple EDCs with different decay constants to capture the request rate to the object over multiple time horizons.

Static features. Static features include additional unchanging information about an object. They include the size of the object and its type—e.g., video on demand segment, live video segment, image. We include static features because they are available, require little memory overhead, and intuitively correlate with different access patterns. For instance, live video segments might be useful in a cache for only a short period, whereas video on demand segments might be useful in the cache for much longer.

Feature effectiveness, number of deltas, number of EDCs. To determine if this set of features is effective for our ML architecture we evaluate them using the good decision ratio in the validation prefix of our traces at many cache sizes. We also use the good decision ratio to determine how many deltas we store and how many EDCs we store. Figure 5 shows the results for an accumulation of static features, Delta$_1$, EDC$_1$, Delta$_2$ and EDC$_2$, Deltas 3–8 and EDCs 3—8, and then Deltas 9–32 and EDCs 9–10 (full). As expected, the addition of more features improves the good decision ratio but has diminishing returns. Results on the other three traces and at other cache sizes are not shown but are similar.

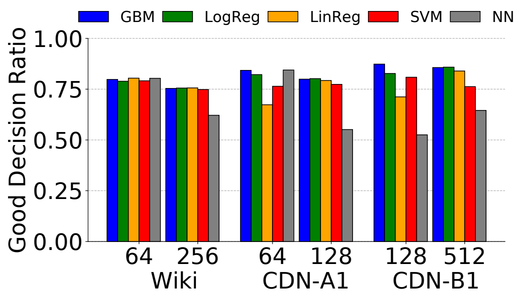

Figure 6: Good decision ratios for models. LRB uses GBM as it robustly achieves high good decision ratios on all traces/cache sizes.

The number of deltas and EDCs is each a tradeoff between giving the ML architecture more information to use for decisions and storage overhead. We settle on 32 deltas and 10 EDCs because both appear to be past the point of diminishing returns and thus we are not disadvantaging our ML architecture by stopping there. We go as high as these numbers because of the efficiency of our feature storage and our ability to control memory overhead with the sliding memory window.

4.3.2 Model: Gradient Boosting Machines

LRB uses Gradient Boosting Machines [39] (GBM) for its model, which outperform all other models we explored and are highly efficient on CPUs. We were inspired to explore GBM based on their success in many other domains with tabular data [23,30,42,61,62,72,80]. We also explored linear regression, logistic regression, support-vector machines, and a shallow neural network with 2 layers and 16 hidden nodes. Figure 6 shows the good decision ratios of the different models on three traces at two cache sizes. Results on the other traces and other cache sizes are similar and not shown. GBM robustly achieve a high good decision ratio. Additionally, GBM do not require feature normalization and can handle missing values efficiently, which are common as objects have a varying number of Deltas. In addition, GBM are highly efficient to train and use for prediction. On typical CDN server hardware, we can train our model in 300 ms. And, we can run prediction on 64 eviction candidates in 30 μs.

4.3.3 Prediction Target: log (time-to-next-request)

LRB uses regression to predict the time-to-next-request for objects that are requested within the sliding memory window. Regression enables LRB to rank these objects (as relaxed Belady) and also serves as a confidence measure for distance to the Belady boundary. Specifically, LRB predicts the log(time-to-next-request) for an object as we primarily care about which side of the boundary the next request is on. If the Belady boundary is 1M (measured by the number of requests), then the difference between predicting 100K and 2M

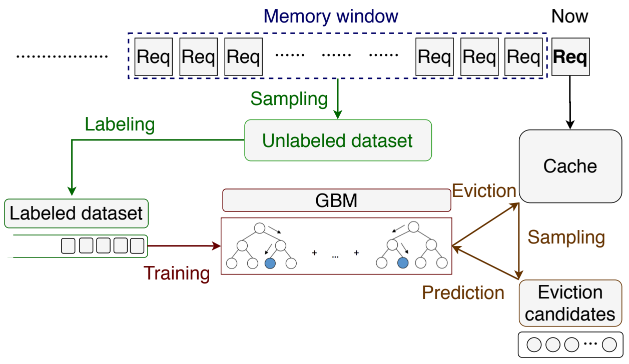

Figure 7: Detailed architecture overview of LRB.

is larger than the difference between 2M and 3M. For objects that are not requested within the sliding memory window, LRB assigns a label as 2× the window size.

We also explored predicting the time from the last request to the next request, binary classification relative to a boundary, and unmodified time-to-next-request. We chose log(time-to-next-request) because it achieved a higher good decision ratio than all of these alternatives.

4.3.4 Loss Function: L2

LRB uses L2 loss (mean square error). We also tried all eight loss functions in the LightGBM library [54]. We chose L2 loss because it achieved the highest good decision ratio.

4.3.5 Training dataset Size: 128K

LRB trains a new model once it accumulates a dataset of 128K labeled training samples. We also explored training dataset sizes that were much smaller than 128K and up to 512K. We found that good decision ratio increases with dataset size but has diminishing returns. We choose 128K because larger dataset sizes further increase training time and overhead without a noticeable improvement in good decision ratio.

4.4 Eviction Candidate Selection.

LRB randomly samples cached objects to gain eviction candidates and runs a batch prediction for all candidates. LRB evicts the candidate whose predicted next request distance is the longest.

We determine the choice for our random sample size—64 samples—using the good decision ratio. We find that 64 samples are past the point of diminishing returns, and thus choosing it does not disadvantage our ML architecture. It is also still low enough for low overhead—prediction on 64 samples takes LRB only 30 μs.

4.5 Putting All Together

Putting our design decisions together with the general architecture (Figure 4) from the beginning of the section, we have the complete design of LRB as shown in Figure 7.

LRB learns from the requested objects in a sliding memory window whose length approximates the Belady boundary. The features (deltas, EDCs, static) of these objects are stored in a compact data structure that is updated as new requests arrive, moving the sliding memory window forward.

A sampling process continuously samples data from this data structure, generating an unlabeled dataset. A separate labeling process continuously labels that data. When the labeled dataset is full (128K examples), LRB starts training a GBM model, and empties the labeled dataset. After that, whenever the labeled dataset is full again, LRB repeats the process and replaces the old model with the new one. If a current request is a cache miss and needs to evict an object, LRB randomly draws $k = 64$ eviction candidates and runs GBM predictions on them. LRB evict the candidate with the farthest predicted next access time.

5 Implementation

We have implemented a LRB prototype within Apache Traffic Server (ATS). We have also implemented a LRB simulator in order to compare with a wide range of other algorithms. The two implementations share the same code and data structures as a C++ library with about 1400 lines of code.

5.1 Prototype

ATS is a multi-threaded, event-based CDN caching server written in C++. A typical ATS configuration consists of a memory cache and a disk/SSD cache. ATS uses a space-efficient in-memory lookup data structure as an index to the SSD cache, which is accessed using asynchronous I/Os to achieve high performance.

To implement LRB, we have replaced the lookup data structures for ATS's disk cache with the architecture described in Section 4.5. We have also changed ATS to make eviction decisions asynchronously by scheduling cache admissions in a lock-free queue. A known challenge when implementing SSD-based caches is write amplification due to random writes [36, 58]. In order to implement LRB, a production implementation would rely on a flash abstraction layer such as RIPQ [78] or Pannier [58]. Unfortunately, we have no access to such flash abstraction layers (e.g., RIPQ is proprietary to Facebook). Our implementation thus emulates the workings of a flash abstraction layer, reading at random offsets and writing sequentially to the SSD.

As the memory cache is typically small, which has a negligible impact on the byte miss ratio [19], we leave this part of

Object class: # past requests	1	2	3	4	5	6-12	13-31	$\geq$32
Obj fraction (%)	36	11	5	3	2	1	<1	<1
Overhead (bytes)	25	94	98	102	106	$\leq$134	$\leq$210	214

Table 3: LRB's memory overhead depends on an object's number of past requests, which we call the object's class.

ATS unchanged. In total, the changes to ATS, excluding the LRB library, amount to fewer than 100 lines of code.

5.2 Simulator

We have implemented an LRB simulator based on the AdaptSize simulator [19]. Besides LRB, our simulator implements 14 state-of-the-art caching algorithms.[3] These include classic and learning-based algorithms. The classic algorithms include LRUK [68], LFUDA [11, 75], S4LRU [46], LRU, FIFO, Hyperbolic [21], GDSF [11] and GDWheel [60]. The learning-based algorithms include an adaptive version of TinyLFU [34] (which subsumes static TinyLFU [35]), LeCaR [81], UCB [31] (reinforcement learning), LFO [17] (supervised learning), LHD [15] and AdaptSize [19]. These 14 algorithms and the simulation environment take about 11K lines of C++. For TinyLFU, LFO, LHD, and AdaptSize, we verified parameter configurations match the authors'.

5.3 Optimizations

We have implemented two main optimizations to reduce overhead and improve performance.

Computationally efficient feature updating. To minimize the overhead of maintaining features we seek to update them rarely and for necessary updates to be efficient. LRB accomplishes this by favoring *time-invariant* features when possible, i.e., features that need only be calculated once. Static features by definition fall in this category. We choose to make deltas relative to the time in between consecutive requests instead of the time between n requests ago and the most recent request because this makes all deltas other than delta_1 time-invariant. A new request to an object shifts delta_n to delta_{n+1}. The overhead to compute delta_1 is low and we make EDC updates efficient using a lookup table with precomputed decay rates.[4]

Overall, these optimizations result in a constant and small feature update overhead per request. LRB updates an object's feature only at the times when it is requested and when it is sampled as an eviction candidate.

We compress our features to minimize their memory overhead. Our compression is based on the predominance of "one-hit wonders" (Section 2). Consequently, we treat objects for which we registered only a single request separately. Since such an object was requested only once in the sliding memory window, there is no recency information and EDC values are all 0. Instead of keeping this redundant information, we store only the key, object size, object type, the last request time, and a pointer to a struct. This reduces the memory overhead for single-request objects to 25 B on the Wikipedia trace. When objects receive more requests, we populate the struct with only as many deltas as they have past requests. This further reduces the memory overhead for all objects with fewer requests than the maximum number of deltas, 32. The struct also contains the EDCs, which are compressed to a single float [57]. Table 3 shows the distribution and overhead of objects with different number of requests.

[3]For Adaptive-TinyLFU, we integrate the original author's implementation (`https://github.com/ben-manes/caffeine`) into our simulator.

[4]The size of the table is $W/2^{10}\times 4\,\text{B}$ where W is the sliding memory window size—e.g., if W is 2^{28} (256 million), the table is $2^{18}\times 4\,\text{B} = 1\,\text{MB}$.

6 Evaluation

This section evaluates our LRB prototype. We additionally use simulations to compare LRB to a wide range of state-of-the-art caching algorithms. We aim at answering the following questions:

- What is the WAN traffic reduction using our LRB prototype compared to the ATS production system (Sec 6.2)?
- What is the overhead of our LRB prototype compared to CDN production systems (Sec 6.3)?
- How does the byte miss ratio of LRB compare to state-of-the-art research systems on a wide range of CDN traces and cache sizes (Sec 6.4)?
- What is the gap between Belady and LRB (Sec 6.5)?
- Can LRB be improved using a longer validation prefix to select the sliding memory window (Sec 6.6)?

6.1 Experimental Methodology

This subsection describes the traces, competing cache algorithms, warm-up, and the testbed in our experiments.

Traces Our evaluation uses CDN traces from three CDNs, two of which chose to remain anonymous.

- **Wikipedia**: A trace collected on a west-coast node, serving photos and other media content for Wikipedia pages.
- **CDN-A**: Two traces (A1 and A2) collected from two nodes on different continents serving a mixture of web traffic for many different content providers.
- **CDN-B**: Three traces (B1–B3) collected from nodes in the same metropolitan area, each serving a different mixture of web and video traffic for many different content providers.

Table 4 summarizes key properties of the six traces.

State-of-the-art algorithms. In the prototype experiments, we compare our LRB implementation (Section 5) to unmodified Apache Traffic Server (ATS, version 8.0.3), which approximates a FIFO eviction policy. Our simulations compare

		Wikipedia	CDN-A1	CDN-A2	CDN-B1	CDN-B2	CDN-B3
Duration (Days)		14	8	5	9	9	9
Total Requests (Millions)		2,800	453	410	1,832	2,345	1,986
Unique Obj Requested (Millions)		37	89	118	130	132	116
Total Bytes Requested (TB)		90	156	151	638	525	575
Unique Bytes Requested (TB)		6	65	17	117	66	104
Warmup Requests (Millions)		2,400	200	200	1,000	1,000	1,000
Request Obj Size	Mean (KB)	33	644	155	460	244	351
	Max (MB)	1,218	1,483	1,648	1,024	1,024	1,024

Table 4: Summary of the six production traces that are used throughout our evaluation spanning three different CDNs.

LRB with 14 state-of-the-art caching algorithms (Section 5.2). In addition, our simulations include Belady's MIN [16] and relaxed Belady (Section 3) as benchmarks.

Testbed. Our prototype testbed consists of three Google cloud VMs acting as a client, CDN caching server, and backend/origin server, respectively. The VMs are n1-standard-64 VMs with 64 VCPUs, 240 GB of DRAM. To maximize SSD throughput, we use eight local 375 GB NVMe flash drives and combine them into one logical drive using software raid.

Clients are emulated using our C++ implementation ($\approx$ 200 LOC), which uses 1024 client threads. The backend/origin server uses our own concurrent C++ implementation ($\approx$ 150 LOC). This emulation method can saturate the network bandwidth between client and caching server. The clients replay requests in a closed loop to stress the system being tested and accelerate evaluation.

In Section 6.3, clients send requests in an open loop, using the original trace timestamps to closely emulate production workloads for latency measurements. Both unmodified ATS and LRB use a 1 TB flash cache size. Our simulations are based on the request order following the request timestamps and a range of different cache sizes.

To emulate network RTTs [19], we introduce around 10 ms and 100 ms of delays to the link between client and proxy and the link between origin and proxy respectively.

Metadata overhead. Different algorithms may have different metadata overheads. For fairness, all algorithms except Adaptive-TinyLFU [5] in the experiments have deducted their metadata overheads from corresponding cache sizes in all experiments. For example, if an experiment is for a 64 GB cache, an algorithm with 2 GB of metadata overhead will use 62 GB to store its data.

Validation and warmup trace sections. The first 20% of every trace is used as a "validation" section where LRB tunes its hyperparameters (Section 4). Each experiment uses a warmup during which no metrics are recorded. The warmup section is always longer than the validation section and is defined by the time by which every algorithm has achieved a stable byte miss ratio. Table 4 lists each trace's warmup section.

[5]Our experiments used an existing implementation of Adaptive-TinyLFU simulator which does not provide overhead information.

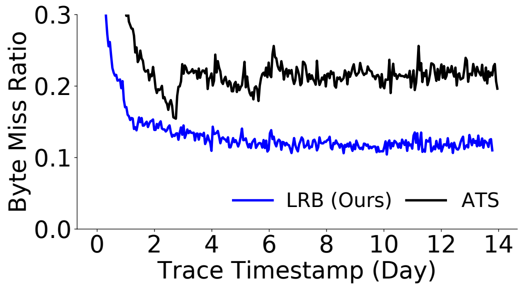

Figure 8: The byte miss ratios of LRB and unmodified ATS for the Wikipedia trace using a 1 TB cache size.

6.2 WAN Traffic Reduction of LRB Prototype

Figure 8 compares the byte miss ratios of LRB and unmodified ATS for a 1 TB cache using the Wikipedia trace. LRB achieves a better overall byte miss ratio than ATS. We observe that LRB reaches a lower miss ratio than ATS within the first day, and LRB continues to improve as it obtains more training data. Throughout the experiment, LRB's miss ratio is more stable than ATS's. We wait for both to stabilize and measure the WAN bandwidth consumption on days 12-14. LRB reduces the average bandwidth by 44% over ATS. LRB also reduces the 95^{th} percentile bandwidth (the basis of some CDN traffic contracts [6]) by 43% over ATS.

6.3 Implementation Overhead

Table 5 compares the overhead of LRB against unmodified ATS. We measure throughput, CPU, and memory utilization at peak throughput ("max" experiment). Note that Table 5 quantifies overheads for the Wikipedia trace, which is pes-

Metric	Experiment	ATS	LRB
Throughput	max	11.66 Gbps	11.72 Gbps
Peak CPU	max	9%	16%
Peak Mem	max	39 GB	36 GB
P90 Latency	normal	110 ms	72 ms
P99 Latency	normal	295 ms	295 ms
Obj Misses	normal	5.7%	2.6%

Table 5: Resource usage for ATS and LRB in throughput-bound (max) and production-speed (normal) experiments.

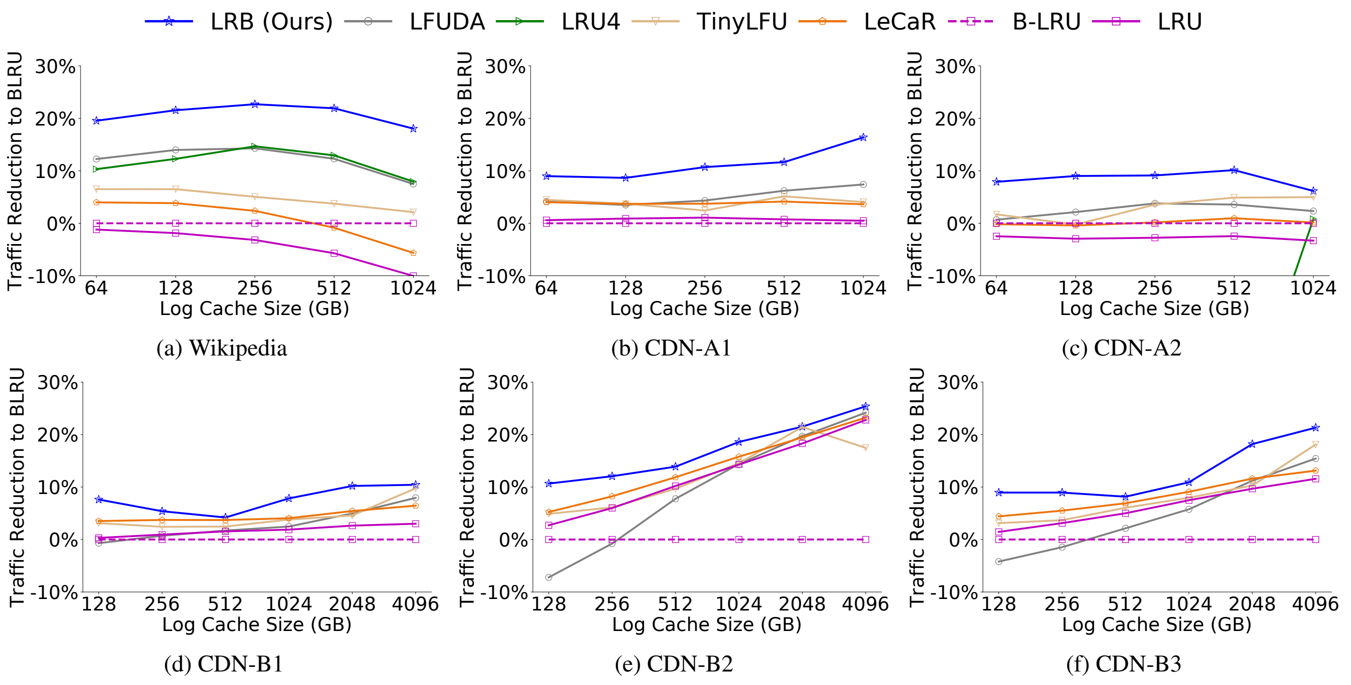

Figure 9: WAN traffic reduction over B-LRU at varying caches for Belady, LRB, and the six best state-of-the-art algorithms. LRB typically provides 4–25% WAN traffic savings over B-LRU.

simistic as all object sizes in all other traces are at least 5× larger, which results in significantly less overhead.

LRB has no measurable throughput overhead but its peak CPU utilization increases to 16% from 9% for ATS and 12% for B-LRU. We remark that even the busiest production cluster at Wikipedia ("CET-2" in Table 1 in Section 2) has sufficient CPU headroom.

We measure the number of object misses (which weights requests equally) when replaying the Wikipedia trace using its original timestamps ("normal" experiment in Table 5). LRB has less than half as many object misses as ATS. This miss reduction allows LRB to improve the 90^{th} percentile latency (P90) by 35% compared to ATS. At the 99^{th} percentile (P99), LRB achieves a similar latency to ATS because the origin server latency dominates.

Cache size	Wiki	A1	A2	B1	B2	B3
64 GB	3.0%	1.0%	1.7%	-	-	-
128 GB	2.1%	0.6%	1.4%	0.9%	0.8%	1.1%
256 GB	1.4%	0.5%	1.2%	0.8%	0.5%	0.6%
512 GB	1.0%	0.4%	1.0%	0.6%	0.4%	0.5%
1 TB	0.6%	0.3%	0.7%	0.5%	0.4%	0.4%
2 TB	-	-	-	0.4%	0.3%	0.3%
4 TB	-	-	-	0.3%	0.3%	0.3%

Table 6: Fraction of space allocated to metadata for LRB.

As LRB's memory overhead depends on the cache size and average object size in a trace, Table 6 measures the peak memory overhead for all traces and all evaluated cache sizes. Across all configurations, LRB always uses less than 3% of the cache size to store LRB metadata. While this overhead reduces the effective cache size, the small loss in byte miss ratio is more than offset by LRB's significant miss ratio improvements.

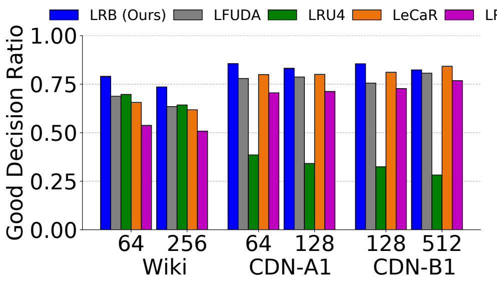

Figure 10: Good decision ratios for different algorithms. Good decision ratio correlates strongly with byte miss ratio.

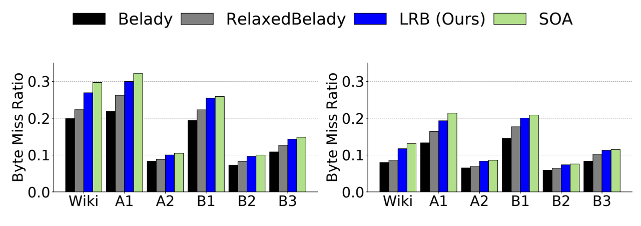
We believe these experimental observations show that LRB is a practical design for today's CDNs and that it can be deployed on existing CDN hardware.

6.4 LRB vs. State-of-the-art Algorithms

We compare the byte miss ratio of LRB to 14 state-of-the-art caching algorithms using simulations with a wide range of cache sizes using the six different traces.

Of the 14 algorithms, nine algorithms (FIFO, Hyperbolic, GDSF, GDWheel, UCB, LFO, AdaptSize, S4LRU, and LHD)



(a) 256 GB (b) 1 TB

Figure 11: Comparison of byte miss ratios for Belady, relaxed Belady, LRB, and the best state-of-the-art (SOA) policy.

achieve a low byte miss ratio on at least one CDN traces. To improve readability, we show only the five best-performing algorithms in the following figures (TinyLFU, LeCaR, LRUK, LFUDA, and LRU). Figure 9 shows the wide-area network traffic reductions of each of these algorithms relative to B-LRU, with different cache sizes using the six traces.

LRB robustly outperforms the best state-of-the-art algorithms. It achieves the lowest byte miss ratio for all 33 CDN trace and cache size combinations. Overall, LRB reduces WAN traffic by 4–25% on average.

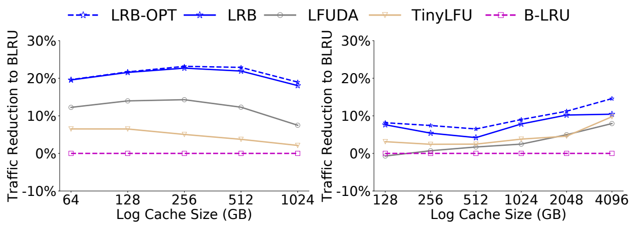
Note that LRB's WAN traffic reduction does not generally decrease with larger cache sizes. For example, on CDN-B2 the traffic reduction steadily increases between 128 GB and 4 TB. Our interpretation is that these traces span a wide range of different CDN request patterns. On average (across all cache sizes), LRB reduces WAN traffic by over 13% compared to B-LRU. Additionally, LRB is robust across all traces whereas no prior caching algorithm consistently improves the performance across traces and cache sizes. For example, LRU4 is the best on Wikipedia, but among the worst on other traces. LFUDA does well on Wikipedia, CDN-A1, but poorly on CDB-B3. TinyLFU does well on CDN-B3 and CDN-A2, but not on Wikipedia. These results indicate that heuristic-based algorithms work well with certain patterns and poorly with others.

To further understand where LRB's improvement comes from, Figure 10 shows the good decision ratio of LRB, the three best-performing state-of-the-art algorithms, and LRU. TinyLFU is not included as its implementation does not allow us to evaluate individual decisions. LRB achieves 74–86% good decision ratios, which are the highest for all but one of six combinations. This implies that LRB learns a better workload representation and is able to leverage its model to make good eviction decisions. Overall, we find that the good decision ratio of an algorithm strongly correlates with its byte miss ratio. One exception is CDN-B1 512 GB, where LeCaR has a higher good decision ratio than LRB, but with a worse byte miss ratio.

6.5 Comparison to Belady

We have seen that LRB provides significant improvements over state-of-the-art algorithms. We now compare LRB with the offline Belady MIN (oracle) and relaxed Belady algorithms. Figure 11 compares their byte miss ratios on three cache sizes. We further compare to the state-of-the-art policy, i.e., best performing policy, on each trace and cache size.

We find that LRB indeed reduces the gap between state-of-the-art algorithms and Belady, e.g., by about a quarter on most traces. While a significant gap still remains to Belady, LRB imitates relaxed Belady, which is thus a better reference point for LRB (Section 2). Relaxed Belady represents an ideal LRB with 100% prediction accuracy. The figure shows that LRB is closer to relaxed Belady, e.g., one third to half the distance on most traces. The remaining gap between LRB and relaxed Belady is due to our model's prediction error. This suggests that improvements in the prediction model are a promising direction for future work.



(a) Wikipedia (b) CDN-B1

Figure 12: Traffic reductions of LRB whose sliding memory window parameter are trained by a small portion of trace vs. LRB-OPT whose parameters are trained by the full trace.

6.6 Sliding Memory Window Size Selection

LRB tunes its memory window on a 20% validation prefix. However, as described in Section 4, the validation prefix is short compared to the optimal sliding memory window choice. To evaluate how much better LRB can do without this restriction, we experimentally determine the best sliding memory window for the full trace. We call the resulting LRB variant "LRB-OPT". LRB-OPT further improves the performance of LRB. Figure 12 shows the traffic reduction over B-LRU for the Wikipedia and CDN-B3 trace. For large cache sizes, LRB-OPT achieves an additional 1–4% traffic reduction compared to LRB. All in all, the ready availability of large amounts of training data in production will be highly beneficial for LRB.

7 Related Work

Although cache design has been studied since 1965 [84], we are only aware of three prior works that have studied how to leverage Belady's MIN [16]. Shepherd Cache [71] used a limited window to the future to emulate Belady's algorithm and defers replacement decisions until reuses occur. Hawkeye and Harmony [47, 48] applied Belady's algorithm to the history of memory accesses to help make better eviction or prefetch decisions. These previous efforts are for hardware caches (in the processor) and do not apply to software cache designs, especially with variable-sized objects.

The rest of the extensive literature can be divided into two major lines of work: caching algorithms and methods to adapt these algorithms to the workload.

Heuristic caching algorithms. We classify these algorithms by the features they use in the eviction decisions (Section 2). The two most widely used features are recency and frequency. Recency is typically measured as variants [3,44,52,68,70] of Delta_1 (as defined in Section 4). Some works also consider static features such as object sizes [4,5,12,24,37,76]. Application ids are commonly considered in shared caches [27,28]. Some algorithms rely entirely on frequency-based features (similar to individual EDCs) [7,11,38,53,63,75].

Another common approach is to combine a recency feature, a frequency feature, and an object's size. This is achieved with either a fixed weighting function between these features [5, 15, 18, 21, 26, 35, 40, 46, 56, 59, 69, 73, 86, 88], or by using a single-parameter adaptation method to dynamically set the weights [13, 19, 34, 49–51, 65, 81].

Two recent proposals consider a larger range of features [17, 55] and are evaluated using simulations. Unfortunately, they are either outperformed [55] or barely match [17] the miss ratio of recency/frequency-heuristics such as GDSF [26].

LRB uses a superset of all these features and introduces a low-overhead implementation in the ATS production system.

Workload adaptation methods. There are three different methods to adapt caching systems and their parameters to changing workloads.

Only a few papers propose to use machine learning as an adaptation method [8, 17, 20, 31, 32, 55, 87]. There are two branches. The first branch uses reinforcement learning [31,32,55,87], where the state-of-the-art is represented by UCB in our evaluation. The second branch uses supervised learning [17,20], where the state-of-the-art is represented by LFO in our evaluation. All of these proposals are evaluated using simulations. Unfortunately, both UCB and LFO perform much worse than simpler heuristics such as GDSF [26] on CDN traces (Section 6). In fact, recent work concludes that caching "is not amenable to training good policies" [55]. LRB overcomes this challenge using a different feature set (Section 4) and shows the feasibility of implementing machine learning in CDN production systems (Section 5).

The most common prior tuning approaches rely on shadow cache and hill climbing algorithms [13,19,28,34,50,52,56,65, 81, 82, 88]. Shadow caches are simulations that evaluate the miss ratio of a few parameter choices in parallel. Hill climbing repeatedly reconfigures the system to use the best parameter seen in these simulations, and restarts the simulations in the neighborhood of the new parameter.

Several caching systems rely on mathematical prediction models [9, 45, 64, 83, 85]. All heuristics-based algorithms and workload adaptation methods share the same fundamental limitation: they work well with certain workloads and poorly with others.

8 Conclusions

In this paper, we have presented the design, implementation, and evaluation of LRB and have shown that it is possible to design a practical ML-based CDN cache that approximates Belady's MIN algorithm and outperforms state-of-the-art approaches over 6 production CDN traces.

The key advantage of using ML to approximate Belady's MIN algorithm over access-pattern specific or heuristics-based approaches is that it can intelligently make cache eviction decisions based on any access pattern.

More importantly, we have introduced the relaxed Belady algorithm, Belady boundary, and good decision ratio as an eviction quality metric, which has enabled us to take a fundamentally new approach to caching that approximates Belady's MIN algorithm. We expect that these concepts can benefit others in the future.

We have shown that LRB's implementation is practical and deployable by replacing the caching component of a production CDN caching system with LRB. Our experiments show that its throughput and latency are on par with the native implementation. LRB requires neither GPUs nor accelerators and, in fact, its additional CPU and memory overheads are moderate and within the constraints of today's CDN server hardware. This deployable design is enabled by key design decisions including our feature selection, sliding memory window, training data selection, and choice of a lightweight machine learning model.

We have also shown that there is a sizable gap between LRB and the relaxed Belady offline algorithm. A promising direction of future work is to further improve the prediction accuracy of ML in LRB.

While we show tuning LRB's hyperparameters can be done on a small validation trace, we plan to further simplify deployment by automating the tuning of the sliding memory window parameter. These improvements will be available from LRB's repository at `https://github.com/sunnyszy/lrb`.

Meaningful Availability

Tamás Hauer *Google*   Philipp Hoffmann *Google*   John Lunney *Google*   Dan Ardelean *Google*   Amer Diwan *Google*

Abstract

High availability is a critical requirement for cloud applications: if a sytem does not have high availability, users cannot count on it for their critical work. Having a metric that meaningfully captures availability is useful for both users and system developers. It informs users what they should expect of the availability of the application. It informs developers what they should focus on to improve user-experienced availability. This paper presents and evaluates, in the context of Google's G Suite, a novel availability metric: windowed user-uptime. This metric has two main components. First, it directly models user-perceived availability and avoids the bias in commonly used availability metrics. Second, by simultaneously calculating the availability metric over many windows it can readily distinguish between many short periods of unavailability and fewer but longer periods of unavailability.

1 Introduction

Users rely on productivity suites and tools, such as G Suite, Office 365, or Slack, to get their work done. Lack of *availability* in these suites comes at a cost: lost productivity, lost revenue and negative press for both the service provider and the user [1, 3, 6]. System developers and maintainers use metrics to quantify service reliability [10, 11]. A good availability metric should be *meaningful*, *proportional*, and *actionable*. By "meaningful" we mean that it should capture what users experience. By "proportional" we mean that a change in the metric should be proportional to the change in user-perceived availability. By "actionable" we mean that the metric should give system owners insight into why availability for a period was low. This paper shows that none of the commonly used metrics satisfy these requirements and presents a new metric, *windowed user-uptime* that meets these requirements. We evaluate the metric in the context of Google's G Suite products, such as Google Drive and Gmail.

The two most commonly used approaches for quantifying availability are *success-ratio* and *incident-ratio*. Success-ratio is the fraction of the number of successful requests to total requests over a period of time (usually a month or a quarter) [5, 2, 9]. This metric has some important shortcomings. First, it is biased towards the most active users; G Suite's most active users are 1000x more active than its least active (yet still active) users. Second, it assumes that user behavior does not change during an outage, although it often does: e.g., a user may give up and stop submitting requests during an outage which can make the measured impact appear smaller than it actually is. Incident-ratio is the ratio of "up minutes" to "total minutes", and it determines "up minutes" based on the duration of known incidents. This metric is inappropriate for large-scale distributed systems since they are almost never completely down or up.

Our approach, *windowed user-uptime* has two components. First, user-uptime analyzes fine-grained user request logs to determine the up and down minutes for each user and aggregates these into an overall metric. By considering the failures that our users experience and weighing each user equally, this metric is meaningful and proportional. Second, windowed user-uptime simultaneously quantifies availability at all time windows, which enables us to distinguish many short outages from fewer longer ones; thus it enables our metric to be actionable.

We evaluate windowed user-uptime in the context of Google's G Suite applications and compare it to success-ratio. We show, using data from a production deployment of G Suite, that the above-mentioned bias is a real shortcoming of success-ratio and that windowing is an invaluable tool for identifying brief, but significant outages. Our teams systematically track down the root cause of these brief outages and address them before they trigger larger incidents.

The remainder of this paper is organized as follows. Section 2 reviews related work. Section 3 motivates the need for *windowed user-uptime* Section 4 describes user-uptime. Section 5 extends user-uptime with windowed user-uptime. Section 6 evaluates our approach and Section 8 concludes the paper.

2 Related Work

Understanding and improving availability of computer systems has been a goal for decades [22] with early work aiming at developing stochastic models based on failure characteristics of individual hardware and software components [30, 20, 27, 21] . A more abstract approach [28] uses mean time to failure (MTTF) and mean time to recovery (MTTR), which are well suited to describe a system that shifts between binary up/down states. An extension to this approach that differentiates between transient failures and short-term downtime can be found in Shao *et al.* [26].

When describing complex distributed systems, however, a binary up/down state is usually not accurate. Brown *et al.* [13] focus on success-ratio instead, describing the availability of a system as the percentage of requests served successfully and understanding it as a spectrum between up and down.

Brevik *et al.*[12] show how to compute confidence bounds for future performance based on collected past performance data. Treynor *et al.* [29] describe error budgets connected to an availability goal and how availability of individual components affects the whole system.

In taking a user-centric approach, Dell'Amico *et al.*[18] explore problems similar to those presented here, but with a focus on prediction and future performance. In a sequel[17], a probabilistic model is used to suggest optimizations to a network application.

A common application for availability and error budgets are contracts for cloud service providers [5, 2, 9]. Patel *et al.* [25] discuss these Service Level Agreements (SLAs) focusing on a framework to define and monitor metrics and goals associated with SLAs while Endo *et al.* [19] describe issues encountered when trying to achieve high availability in cloud computing.

Microsoft Cloud services (such as Office 365) compute and report uptime as the time when the overall service is up divided by total time. [4] As a metric based on time, it is immediately meaningful (e.g., everyone interprets 99.9% uptime as "system will be down for a total of 1 day every 1000 days on average").

Before the work in this paper, Gmail computed and reported availability as the percentage of successful interactive user requests (irrespective of which user the request comes from). Google Cloud Platform computes and reports "downtime" as the error rate and downtime period as consecutive minutes of downtime.

Slack's status page reports that it is "a distributed platform and during any given incident it is rare for all Slack teams to be affected. For this reason, we report our uptime as an average derived from the number of affected users." [7]

Amazon Web Services computes and reports "Error rate" as the percentage of requests that result in errors in a 5 minute interval. The average of these five minute calculations is reported to customers, as "Monthly uptime percentage" - the average of all the 5-minute error rates. [2]

In the following sections, we will look at three desirable properties of an availability metric: meaningful, proportional and actionable. The surveyed systems each satisfy some but not all of these three properties.

3 Motivation

Availability is the ability of a service to perform its required function at an agreed instant or over an agreed period of time [24]. At a high level, all availability metrics have the following form:

$$\text{availability} = \frac{\text{good service}}{\text{total demanded service}} \tag{1}$$

Availability metrics are invaluable to both users and developers [10].

For users, they tell them whether or not a service is suitable for their use case. For some use cases, unavailability translates into lost productivity and a *meaningful* measure can help quantify that.

For developers, availability metrics help prioritize their work to improve their system. For this to be the case, the measure should be *proportional* and *actionable*. A proportional metric enables developers to quantify the benefit of an incremental improvement. An actionable metric enables them to zero in on episodes of worst availability and thus find problems that they need to address.

Broadly speaking, availability metrics fall in two categories: *time based* and *count based*, according to how they quantify the "good service" and "total demanded service" in Eq. (1).

3.1 Time-based availability metrics

Toeroe *et al.* [28] define availability as $\frac{\text{MTTF}}{\text{MTTF+MTTR}}$ where MTTF is the mean-time-to-failure and MTTR is mean-time-to-recovery. This measure is based on the duration when the system is up or down; these concepts are meaningful to users. Thus it is no surprise that many cloud providers, e.g. Microsoft's Office 365 [4], use it. The time between failures is uptime and the time to recover from a failure is downtime, thus we can express this metric as Eq. (1) once we identify uptime and downtime as the measure of good and bad service, respectively [29]:

$$\text{availability} = \frac{\text{uptime}}{\text{uptime} + \text{downtime}}. \tag{2}$$

At a deeper level, this measure depends in a complex way on the precise meanings of "failure" and "recovery". At one extreme we could consider a system to have a failure only when there is an outage that affects *all* users. At the other extreme, we could consider a system to have a failure when there is an outage that affects even a *single* user.

Neither of these definitions are adequate. The first is unsatisfactory because the design and deployment of cloud systems, such as Azure [14], Dynamo [16], or Gmail, actively avoid single points of failure by sharding data across many machines and using replication [23] with failover when problems occur. Consequently, these systems rarely have an outage that affects all users [29]. The other extreme is not suitable, particularly for systems with hundreds of millions of users, because there will always be some that are experiencing failures. The system may not even be at fault for such outages. For example, we once debugged a situation where a user had authorized access to their Gmail account to many third-party services, each of which was repeatedly making extremely large requests against the user's account, inadvertently and collectively causing a denial of service attack, and in turn an outage for that user. It would be unreasonable to consider this as an outage of Gmail.

Consequently, availability in terms of up and down states either require manual labeling of up and down times (e.g., the incident ratio metric) or the use of thresholds, e.g., the G Suite SLA defines downtime as "if there is more than a five percent user error rate" [5]. While such thresholds avoid the extremes above, they do so arbitrarily. Furthermore, availability metrics that use such thresholds are not proportional. For example, the G Suite definition treats a system with 5% error rate the same as a system with 0.0001% error rate; and it treats a system with 5.1% error rate the same as a system with 99% error rate.

Thus, commonly used time-based availability metrics:

- are not proportional to the severity of the system's unavailability (a downtime with 100% failure rate weighs as much as one with 10%).
- are not proportional to the number of affected users (a downtime at night has the same weight as a downtime during peak period).
- are not actionable because they do not, in themselves, provide developers guidance into the source of failures.
- are not meaningful in that they rely on arbitrary thresholds or manual judgments (e.g., incident-ratio).

3.2 Count-based availability metrics

While the most common definitions of availability (including the ones discussed above) are in terms of time, some systems use "success-ratio" instead. Success-ratio is the ratio of successful requests to total requests. Since success-ratio does not use a threshold, it is more proportional than commonly-used time-based metrics.

Success-ratio as an availability measure is popular because it is easy to implement and is a reasonable measure: it accurately characterizes a service, whose (un-)reliability stems solely from a stochastic distribution of failures. Because the computation is based on user requests, it approximates user perception better than if we used some internal instrumentation to reason about the service's health. It is, however, prone to bias: the most active users are often 1000x more active than the least active users and thus are 1000x over-represented in the metric.

Even if we disregard the bias with respect to different users' activity, this metric can fail to proportionally capture changes in availability. Consider, for example, that a service is down for 3 hours and then up for 3 hours. While the system is up, users are active on the system and thus make many (successful) requests to the system. While the system is down, they will periodically probe the system to check if is still down but the inter-arrival time of the requests is likely lower than if the system is in active use. For certain systems, particularly ones that provide a service to other systems, the opposite situation may hold: a client service may flood our system with retries thus inflating failure count. Users ultimately care about time, thus a count-based measure - in contrast to a time-based one - can misrepresent the magnitude of an outage.

In summary, count-based (success-ratio) availability metrics:

- are not meaningful in that they are not based on time.
- are biased by highly active users.
- are biased because of different client behavior during outages.

3.3 Probes

Using synthetic probes may mitigate some of the shortcomings of success-ratio. For example, probing the system automatically at regular intervals can avoid bias. This approach works well for low-level systems with modest business logic, for example, a network which "just" sends and receives packets. In contrast, a cloud application may have hundreds of types of operations and the work required by an operation type depends on the type and the user's corpus (e.g., a search operation for a user with a few documents is fundamentally different, in terms of the work involved, from a search for a user with millions of documents). Consequently, despite years of effort, we have been unable to fully represent real workloads on our system with synthetic probes [8]. Thus, for cloud applications, a metric which uses synthetic probes may not be representative of real-user experience.

In summary, availability metrics based on synthetic probes:

- are not representative of user activity.
- are not proportional to what users experience.

3.4 Actionable metrics

The availability metrics that we have described so far represent different points in the tradeoffs for "proportional" and "meaningful". All of them, however, have a similar weakness when it comes to being "actionable": a single number associated with a reporting period does not allow enough insight into the source or the shape of unavailability.

Indeed, none of the existing metrics can distinguish between 10 seconds of poor availability at the top of every hour or 6 hours of poor availability during peak usage time once a quarter. The first, while annoying, is a relatively minor nuisance because while it causes user-visible failures, users (or their clients) can retry to get a successful response. In contrast the second is a major outage that prevents users from getting work done for nearly a full day every quarter.

In the following section, we describe a new availability measure, user-uptime that is meaningful and proportional. Afterwards, we'll introduce windowed user-uptime, which augments it to be actionable.

4 Proportional and meaningful availability: user-uptime

As discussed in Section 3, prior metrics for availability are not meaningful or proportional. A seemingly straightforward variant of Eq. (2) satisfies both proportionality and meaningfulness:

$$\text{user-uptime} = \frac{\sum_{u \in \text{users}} \text{uptime}(u)}{\sum_{u \in \text{users}} \text{uptime}(u) + \text{downtime}(u)}, \qquad (3)$$

Since this metric is in terms of time, it is meaningful to users. Since it is free from arbitrary thresholds, it is (inversely) proportional to the duration and magnitude of the unavailability. The calculation of this metric, however, is not straightforward as it requires a definition of uptime(u) and downtime(u) *per user*. The remainder of this section describes how we calculate these.

4.1 Events and durations

An obvious approach to uptime and downtime would be to introduce evenly spaced synthetic probes for *each* user (Figure 1) and count the successful and failing probes. In Figure 1 the light green circles are successful events and dark red diamonds are failed ones from a single user's perspective. The green horizontal line at the top marks the period when the user perceives the system to be up (i.e., its length represents uptime) while the red one on the bottom marks the period when the user perceives the system to be down. As discussed in Section 3.1, however, synthetic probes fail to

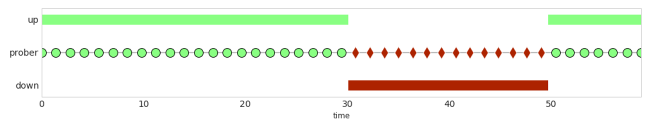

Figure 1: System availability as seen through evenly-spaced prober requests. success-ratio=67%, user-uptime=67%

mimic true user behavior. For example, we may probe certain operations but users may experience unavailability for other operations. In a recent Gmail outage, for example, the failure of the system serving attachments impacted only operations that accessed attachments; but other operations were largely unaffected.

Our key insight, therefore, is to use user requests as probes. A user's perception of a system being up or down depends on the response they get when they interact with it: if the response is successful (unsuccessful) they perceive the system as being up (down). For example, as long as the user can successfully edit a document, she perceives the system to be up; once she experiences a failing operation she perceives the system to be down.

Success versus failure of individual events is not always obvious to the user: for example, if a device's request to synchronize the contents of the user's mailbox fails, the user may not notice that the system is down. Despite this, we want our availability metric to be conservative: if there is *any* chance that a user may perceive a failure (even one as subtle as a longer-than-usual delay in the notification for a new email) we consider it as a failure.

Fig. 2 illustrates this approach. In contrast to Fig. 1, availability is not necessarily the same as success-ratio. Section 4.2 discusses some variations of this approach and the consequences of our choices.

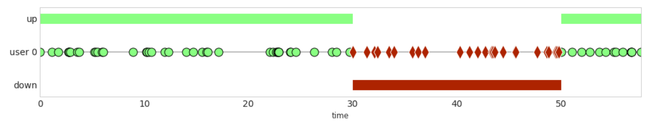

Figure 2: Availability as seen through unevenly spaced requests from a single user. success-ratio=68%, user-uptime=65%

Fig. 3 illustrates a system with four users. Each user experiences an outage of a different duration and generates requests at a different rate from the other users. Thus if we use success-ratio across the users, it will skew availability towards the most prolific user. User-uptime does not suffer from this bias.

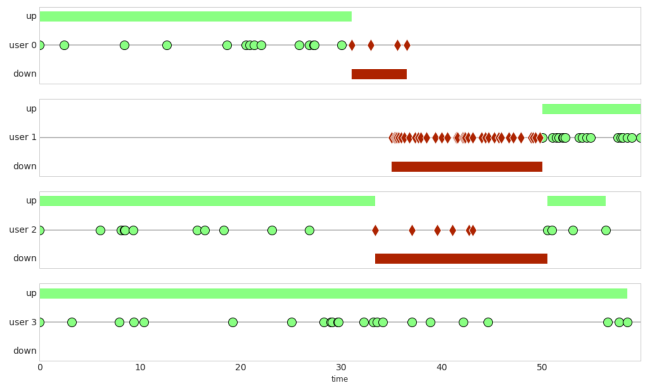

Figure 3: An outage which affects users selectively.

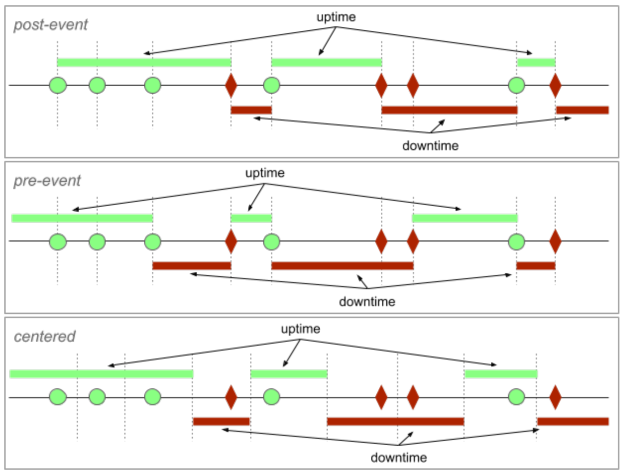

Figure 4: Three choices to extrapolate uptime or downtime from neighboring events

4.2 Challenges with user uptime

While we have illustrated user-uptime using examples, there are two main questions that we have glossed over: (i) how do we label a duration as up or down; and (ii) how do we address users that are inactive. The remainder of this section addresses these challenges.

4.2.1 Labeling durations

As long as back-to-back events are both failures or successes, it is obvious how to label the duration between the two events. But if back-to-back events are different (i.e., one is a failure and one is a success) there are three choices (Fig. 4):

- After a successful (or failing) operation, assume that the system is up (or down) until the user sees evidence to the contrary.
- Before a successful (failing) operation, assume that the system is up (down) until the previous event. Intuitively, this option takes the position that the user request probes the state (up or down) of the system up to the previous operation.
- Split the duration between events (i.e., half the time is uptime and half is downtime).

Assuming that transitions (from up to down or vice versa) occur at random points between the events, the differences between the above three options will be negligible. This is not always the case when the client aggressively retries failing operations. For simplicity, and because it captures user intuition of system availability, we use the first option.

4.2.2 Active and inactive periods

If a user stops all activity for an extended period (e.g., goes on a vacation) they have no perception of the system being up or down: assuming that the system is up or down continuously after the last seen request does not make sense and may even optimistically bias the data: e.g., if a user has an unsuccessful request they may retry until they get success and thus the last request before a vacation is disproportionately likely to be successful.

To this end, we introduce a *cutoff* duration; if a user has been inactive for more than this duration, we consider the user as being inactive on the system and thus do not count uptime or downtime. We pick the cutoff duration as the 99th percentile of the interarrival time of user requests. For Gmail this is 30 minutes. Experiments with multiples of this duration have shown that our availability metric does not change significantly with different values of the cutoff duration.

Now we can define how we label durations as uptime or downtime for each user:

Definition (uptime, downtime): A segment between two consecutive events originating from the same user is:

- *inactive* if the two events are further apart than `cutoff`, otherwise
- *uptime* if the first of the two events was *success*
- *downtime* if the first of the two events was *failure*.

Fig. 5 illustrates this definition.

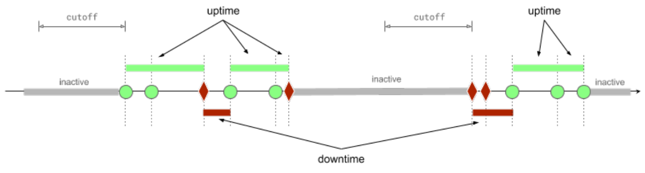

Figure 5: Definition of uptime and downtime segments

For each user u and a measurement period of interest, uptime(u) is the sum of the lengths of the uptime segments and downtime(u) is the sum of the lengths of the downtime segments. We can calculate overall availability for the system by aggregating across all users as in Eq. (3).

4.3 Properties of user-uptime

We now study the properties of user-uptime and success-ratio in synthetic situations where we know the ground truth; later (Section 6) we evaluate them in a production system.

For the first example, we generated synthetic user requests for an hour such that all user requests within a contiguous 15 minute period failed. We simulated this thousands of times for 10,000 synthetic active users. Fig. 6 illustrates what this outage looks like for 2 users.

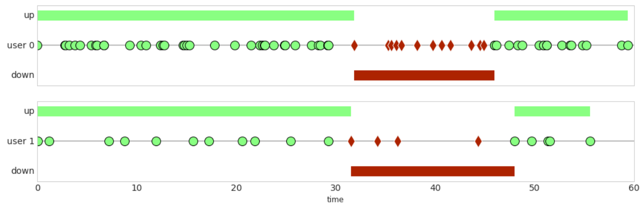

Figure 6: Two users' activity around a hard outage during $30 < t < 45$

Fig. 7 shows the distribution of the success-ratio and user-uptime metrics across the different simulations. We see that both metrics show an availability of around 0.75 but the standard deviation for user-uptime is much smaller indicating that user-uptime more precisely and consistently captures the outage.

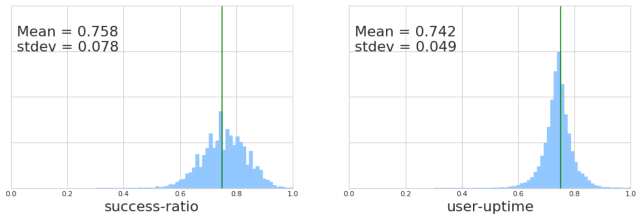

Figure 7: Normalized distribution of success-ratio and user-uptime measurements

For the second example, we incorporated retries: when a request fails, the user retries the request. Fig. 8 shows the distribution for success-ratio and user-uptime for this experiment. We see that user uptime is more accurate than success-ratio: identifying the availability of 0.75 with a tight distribution. Success-ratio, on the other hand, is affected by the retries and indicates a lower availability than what users actually experienced.

In summary, at least with synthetic examples we see that user-uptime better captures availability than success-ratio. Section 6 compares the two metrics using production data.

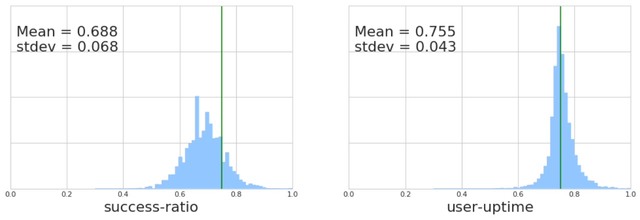

Figure 8: Normalized distribution of success-ratio and user-uptime measurements with automatic retries

5 Actionable availability: windowed user-uptime

Cloud productivity suites commonly define, track, and report monthly or quarterly availability. As Section 3.4 points out, monthly or quarterly availability data is often not actionable. Concretely, monthly availability does not distinguish between a flaky system that routinely fails a small percentage of the requests from a system whose failures are rare but when they happen the system is unavailable for an extended duration.

To distinguish long outages from flakiness, we must look at availability at the timescale of the outages: looking at a timescale of months may average away the unavailability and paints a rosier picture than reality. Our approach, *windowed user-uptime*, addresses this by combining information from all timescales simultaneously. The rest of this section describes windowed user-uptime and explores its properties.

5.1 Calculating windowed user-uptime

Windowed user-uptime iterates over all time windows fully included in the period of interest (e.g., month or quarter) and it computes an availability score for each window size. For example, to calculate windowed user-uptime over the month of January 2019, windowed user-uptime finds the worst period of each window size from 1 minute up to a month. The score for a window size w is the availability of the *worst* window of size w in our period of interest. We calculate the availability for a particular window from t_1 to t_2 as follows:

$$A(t_1, t_2) = \frac{\text{good service between } t_1 \text{ and } t_2}{\text{total service between } t_1 \text{ and } t_2}$$

To obtain the score for a window of size w, we enumerate all windows of duration w, compute the availability for each of them, and take the lowest value. Thus, we end up with one score for each window size. We call this score the minimal cumulative ratio (MCR).

Formally, the *MCR* for a window size w in a period (T_1, T_2) is as follows:

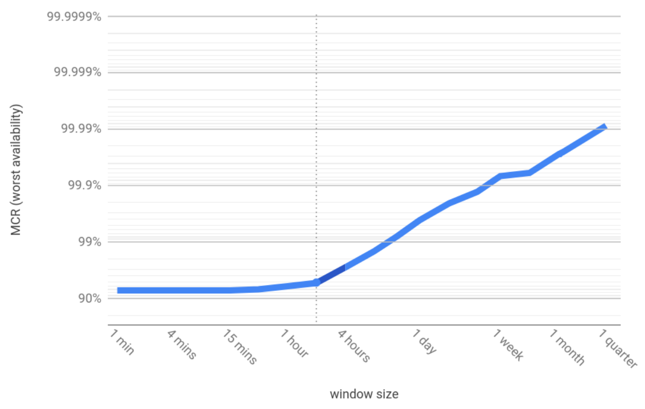

Figure 9: Windowed user-uptime:

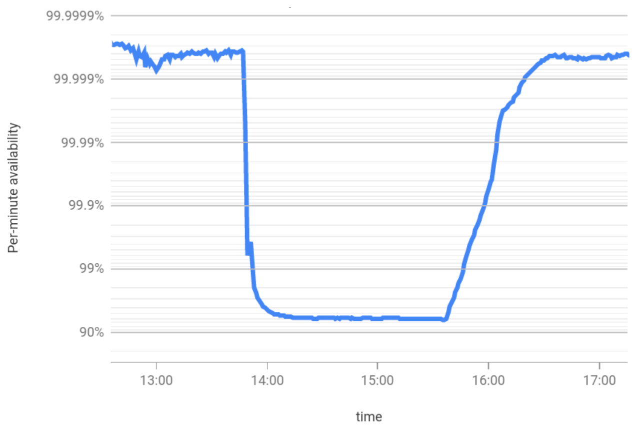

Figure 10: Per-minute availability over time

$$\mathrm{MCR}(w) \equiv \min_{T_1<t_1<t_2<T_2} \{A(t_1,t_2)|t_2-t_1=w\} \tag{4}$$

MCR picks the worst availability for each window size because that is the window that had the most impact on overall availability. Prior work in evaluating real-time garbage collectors and specifically the Minimum-Mutator-Utilization metric [15] inspired our windowing approach.

Fig. 9 shows an example of windowed user-uptime over a period of one quarter; the x-axis gives the window size and the y-axis (in log scale) gives the corresponding MCR. Fig. 9 enables us to readily make the following observations:

- The overall availability for the quarter is 99.991%; this is the rightmost point in the curve.

- There was no window of one minute or longer whose availability was worse than 92%.

- Knees of the curve can give insight into the longest incidents and their distribution for the service. In the example, the knee at about 2 hours indicates that the episode that brought availability down to 92% lasted for two hours; availability rapidly improves for larger windows.

By maintaining a mapping from each window size to the start of the window, we can readily examine the worst window(s) of a particular size in detail (e.g., Fig. 10). We can automatically discover the knee by finding the peak of the 2nd derivative of the windowed graph.

In summary, windowed user-uptime provides us with a rich view into the availability of our services. This data is actionable: it tells us the windows that degrade our overall availability. Our engineers use these graphs to find and fix sources of unavailability.

5.2 Monotonicity with integer-multiple sized windows

Intuitively, we expect windowed user-uptime to be monotonically non-decreasing in the size of the window; i.e., we expect larger windows to have better availability. This section proves that this is the case as long as window sizes are integer multiples of smaller ones.

We use boldface to distinguish windows: $\mathbf{w} = [t_1,t_2]$ from window sizes: $w = t_2 - t_1$. For the remainder of this section a window $\mathbf{w}$ will always be a continuous interval. The availability of a window $\mathbf{w}$ is the ratio of uptime and total time[1] over that window:

$$A(\mathbf{w}) = \frac{u(\mathbf{w})}{t(\mathbf{w})}.$$

Given a period of interest, $[T_1,T_2]$, windowed user-uptime, or the *minimal cumulative ratio* is the least of the availabilities of all windows (Eq. (4)) of *size* w that are fully enclosed within $[T_1,T_2]$:

$$\mathrm{MCR}(w) \equiv \min_{\substack{\mathbf{w}\subseteq[T_1,T_2]\\ |\mathbf{w}|=w}} \left(\frac{u(\mathbf{w})}{t(\mathbf{w})}\right).$$

One expects $\mathrm{MCR}(w)$ to be a monotonic function. Indeed, the availability over a window $\mathbf{w}'$ of size w' is intuitively the mean of a fluctuating time series. Scanning the interval with windows of smaller size $w < w'$, we should find both higher and lower availability values and the minimum of these should be smaller than the mean over the whole window:

$$\mathrm{MCR}(w) \overset{?}{\leq} MCR(w') \qquad w \leq w'. \tag{5}$$

[1]We use user-uptime terminology but windowing can be defined for other availability metrics. Substitute the corresponding concepts for good and total service, for example request count in case of success-ratio.

Eq. (5) indeed holds when we can cover a larger window fully using windows of the next smaller size without overlap. Consider $\mathbf{w}'$ of size w' covered with windows of size w as in Fig. 11

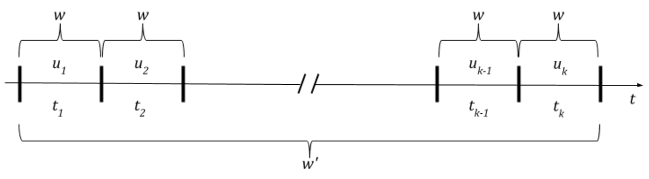

Figure 11: Covering a window with smaller ones: $w' = kw$

We denote the uptime and total time of the i^{th} window as u_i and t_i, respectively. Then the availability of $\mathbf{w}'$ can be written as:

$$A(\mathbf{w}') = \frac{u_1 + u_2 + \ldots + u_k}{t_1 + t_2 + \ldots + t_k}.$$

It is impossible that all of the ratios u_i/t_i are greater than $A(\mathbf{w}')$. Indeed, the above equation can be rearranged to

$$0 = \sum_{i=1}^{k} (u_i - A(\mathbf{w}')t_i)$$

and at least one term in the sum must be non-positive for the sum to yield zero: $u_j \leq A(\mathbf{w}')t_j$. Therefore there is at least one window of size w whose availability is at most that of $\mathbf{w}'$:

$$\frac{u_j}{t_j} \leq A(\mathbf{w}').$$

It follows that every window of length kw contains at least one window of size w with lower availability. Since there exists a window whose availability is MCR(kw), it follows that:

$$\mathrm{MCR}(w) \leq \mathrm{MCR}(kw) \qquad \forall k \in \mathbb{N} \tag{6}$$

5.3 Monotonicity in the general case

For practical purposes, Eq. (6) is “enough”: the worst availability of a day is always better than the worst availability of an hour or of a minute. Curiously, windowed user-uptime is not monotonically non-decreasing in the general case. The Appendix gives a proof that we can bound the extent of this apparent anomaly:

$$\frac{k}{k+1}\mathrm{MCR}(w) \leq \mathrm{MCR}(w') \qquad kw < w'. \tag{7}$$

In practice, we can guard against the apparent anomaly and enforce strict monotonicity by restricting to integer multiples, e.g. compute windowed user-uptime for windows that are powers of two.

6 Evaluation

Since last year, we have used windowed user-uptime for all G Suite applications (Calendar, Docs, Drive, Gmail, etc.). This section presents case studies where this metric provided keen insight into availability especially compared to the success-ratio metric.

We present availability data from production Google servers; in doing so we ignore unavailability due to issues with user devices or mobile networks.

Since the actual availability data is Google proprietary, we linearly scale and shift all curves in our graphs. This transformation preserves the shape of the curves and enables meaningful comparison between them.

6.1 Availability due to hyper-active users

As we have discussed, bias (due to hyper-active users) can negatively affect success-ratio. This section shows a real-life example of this phenomenon.

Fig. 12 shows (scaled) user-uptime and success-ratio for a large user base. One observes a consistent and significant mismatch between success-ratio and user-uptime.

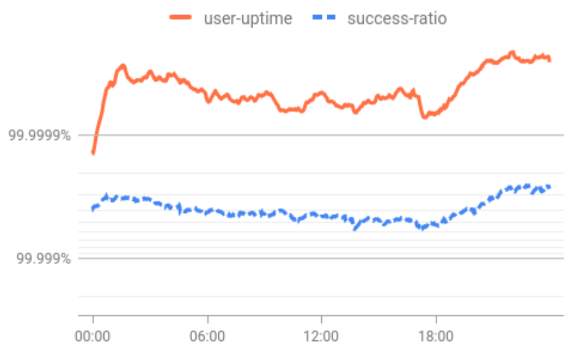

Figure 12: Uptime discrepancy due to mixed use-cases (log scale)

Upon diving into this discrepancy, we discovered that most (99%) active users contribute fewer than 100 events each in the duration of the graph. The remaining (1%) of the users are hyper-active and contribute 62% of all events.

Fig. 13 breaks down the availability data. The “Overall” curves give overall availability, the “Hyperactive users” curves give availability for the most active 1% of the users, and the “Typical users” curves give availability for the rest of them. Success-ratio appears heavily biased towards the availability for hyper-active users even though they make up only 1% of the user base.

Bias due to hyper-active users for success-ratio is, thus, not a theoretical possibility: we see this in production: indeed our most active users are 1000x more active than our

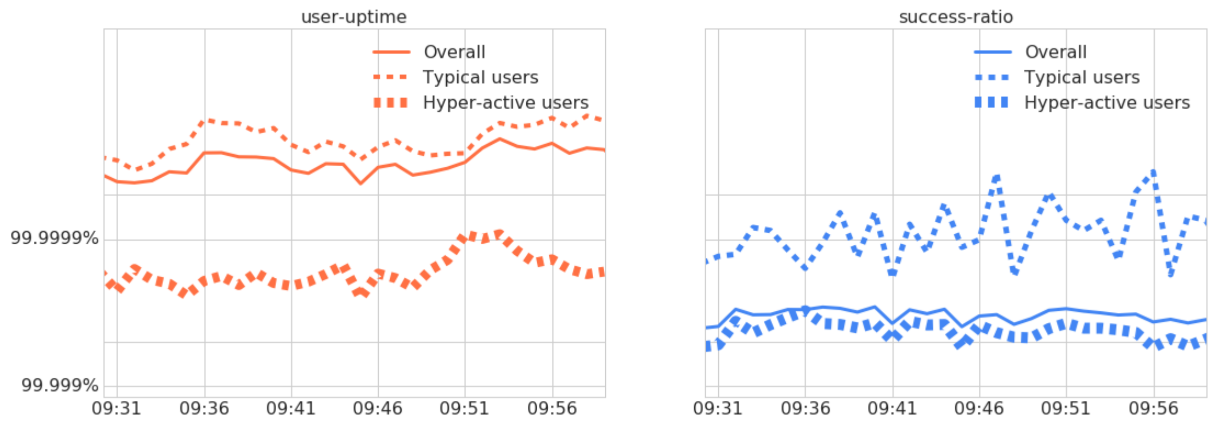

Figure 13: Left: user-uptime for the two clusters of events and the combined user-uptime. Right: success-ratio for the two clusters of events and the combined success-ratio

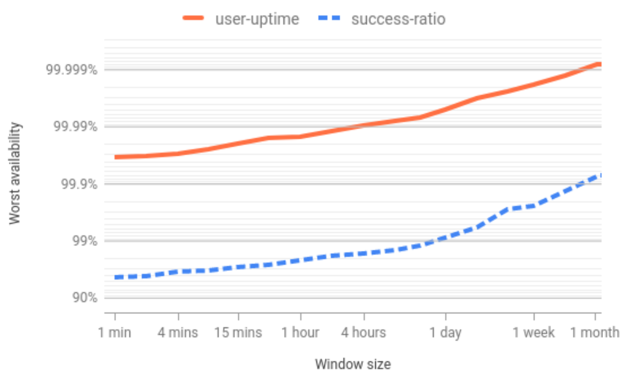

Figure 14: Monthly windowed uptime: success-ratio and user-uptime

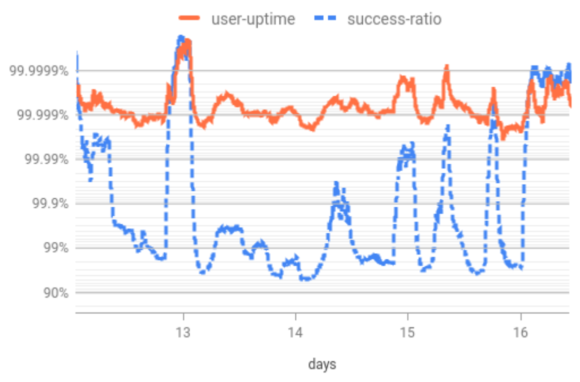

Figure 15: Effect of abusive users

"typical" users which makes this bias a common occurrence. When this bias occurs, success-ratio can mislead us towards thinking that an incident is much more or much less severe than it actually is.

6.2 Availability and hyper-active retries

While so far we have shown availability data for all customers of a G Suite application, we also separately measure availability for large customers since they often have their own unique patterns of usage and thus may experience different availability from other users. From this data we noticed that a particular large customer ($> 100,000$ users) had much poorer success-ratio than other users of Gmail; moreover we noticed a discrepancy between success-ratio and user uptime (Fig. 14). While the curves for user-uptime and success-ratio have the same shape, they are far apart with user-uptime indicating a better availability than success-ratio.

Fig. 15 shows the user-uptime and success-ratio over time. We can see that before and after the incident (i.e., the two ends of the graph) the two metrics were similar, but during the incident the two metrics diverged.

On investigation we uncovered that a small number of users had enabled a third-party application which synced their mailboxes; this external service was unable to handle large mailboxes and for these users it would retry the sync operation repeatedly and without exponential back-off. This generated bursts of failing requests. The event count of these failures drove the success-ratio availability down, even though this impacted only a handful of users and other requests for the users (e.g., to read an email) were successful. User-uptime did not suffer from the bias due to these retries. We were able to resolve this incident by communicating with the third-party vendor.

In summary, users (and the clients they use) can behave differently during incidents than during normal operations. Clients may make many more requests during incidents (our example above) or they may just decide to give up on the

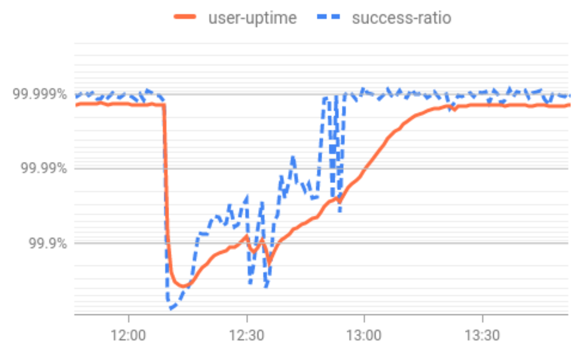

Figure 16: Impact assessment

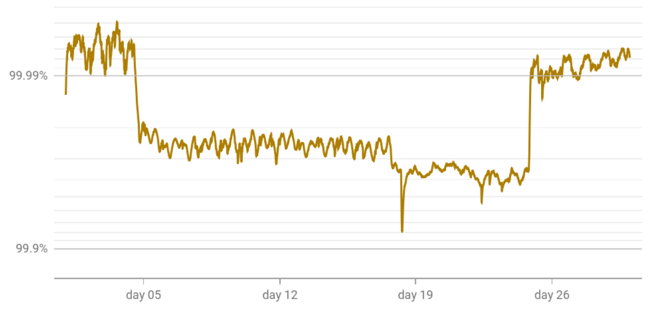

Figure 17: User-uptime analysis of Google Drive traffic, 30 days.

system and try few hours later. In both cases, success-ratio over- or under-estimates the magnitude of an outage while user-uptime matches user perception.

6.3 Quantifying impact of outages

We quantify the impact of every outage on our users. This impact advises the aftermath of the outage: for example, a really severe outage may result in a temporary freeze in deploying new versions until we address all the underlying issues while a less severe outage may require less extreme measures.

When using success-ratio, this quantification is difficult since the metric is not based on time. Concretely, since request patterns (and specifically retry behavior) changes during outages, using success-ratio to derive impact is not meaningful.

Consider, for example Fig. 16 which displays an outage from one of our products. Both success-ratio and user-uptime dip at 12:10 to around 97%, then recover over the course of an hour. What impact did this outage have on our users? Was it the case that $100\% - 97\% = 3\%$ of our users couldn't work for over an hour? Or that the impact was more evenly spread across our users and that automatic retries hid most of the negative impact?

The seconds of downtime, which we compute as part of user uptime, provides more insight. From there we see the minutes of downtime that our users experience. The large number we measured for this indicated that this was clearly a significant outage for some users and the retry behavior was unable to mask this outage from our users.

6.4 Combining user-uptime and success-ratio

The Drive team extensively uses windowed user-uptime to investigate, root-cause and fix sources of unavailability. The proportionality of user-uptime is critical for their use case: they need to be able to make changes and notice a proportional change in the availability metric. Sometimes, combining user-uptime with success-ratio yields valuable insights.

Fig. 17 illustrates this situation. A first analysis of the uptime graph shows a drop on the 4$^{\text{th}}$ day followed by a degradation that reached a plateau on day 18 then was finally fixed on day 26. Looking at success-ratio instead of user-uptime paints the same picture, as can be seen in Fig. 18. Looking at either of these two graphs, it is reasonable to assume that this incident has a single cause.

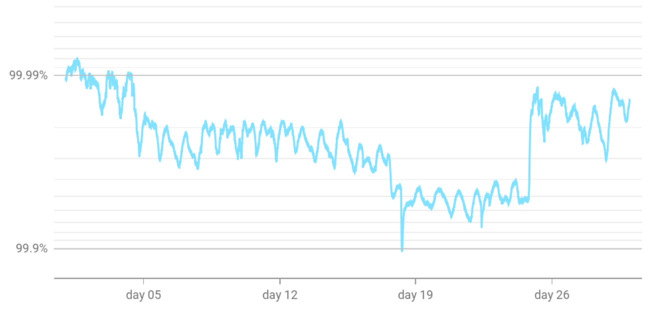

Figure 18: success-ratio of Google Drive, same 30 days as Fig. 17.

But if we plot success-ratio and user-uptime together as in Fig. 19, we see that they diverge on day 18. Indeed, an investigation showed that the period between day 18 and day 26 was caused by a different issue, introduced by an attempted fix for the first problem. It manifests differently in user-uptime compared to success-ratio due to different client behavior for this new issue. This divergence led the engineers to the correct path in fixing the new issue instead of trying to find out why the old issue was still ongoing, and made the path to resolution easier and quicker.

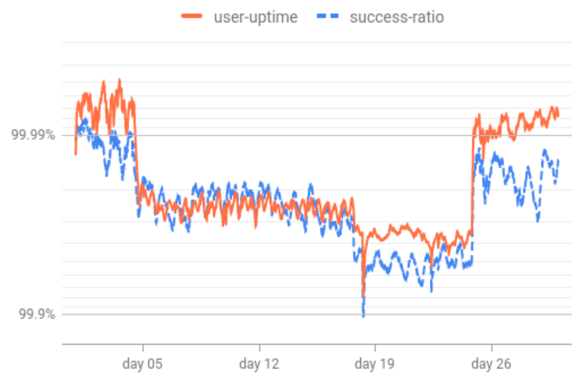

Figure 19: Divergence of user-uptime and success-ratio

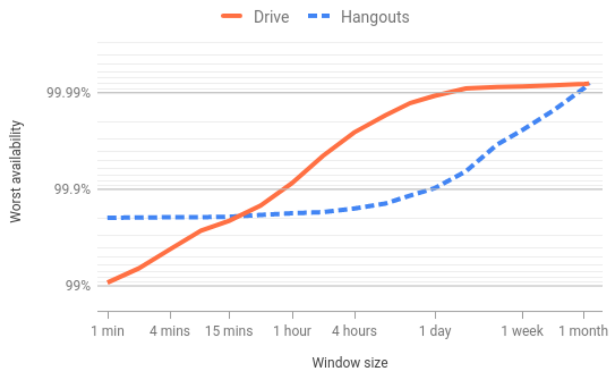

Figure 20: Monthly windowed user-uptime distinguishes between the nature of unavailability

6.5 Windowed uptime indicates burstiness of unavailability

When we look at availability metrics aggregated over a month or a quarter we cannot see short episodes of poor availability. Fig. 20 shows the windowed user-uptime of Drive and Hangouts. The two curves meet at the same point at the 1 month mark; thus they have the same scaled availability (99.972%) over the course of the month. Their windowed user-uptime graphs, however, tell different stories.

Windowed user-uptime reveals that it is a four hour episode (the knee of the curve) that held back Hangouts from having an even higher availability. In a different month without such an episode or if we fix the root cause behind such episodes, this product would have a higher availability.

For Drive, the windowed user-uptime curve has no pronounced knee; this means that rather than a single long episode, there are continuous short episodes which are holding back the service from having a higher availability. Thus, unless we fix their root cause, Drive will continue to suffer from these downtimes month after month.

By exposing shorter episodes of low availability (e.g., Hangouts' four hour episode), windowed user-uptime alerts us to problems that would otherwise be masked by the (commonly-used) monthly aggregation. Our teams consequently use windowed user-uptime to identify, root-cause and then fix the sources of these short episodes, improving overall availability.

7 Applicability of windowed user-uptime

To calculate windowed user-uptime we need fine-grained logs of individual user operation. These logs must include a key that enables us to chain together operations for each user, the timestamp of the operation and the status of each operation (success or failure). In some cases, additional information is invaluable: for example, (i) knowing the type of the operation enables us to determine if different operations have different availability and (ii) knowing the organization of a user enables us to determine if a particular organization is experiencing worse availability compared to other organizations.

In the simplest case we need to retain only the cumulative count of up and down minutes for each minute to calculate windowed user-uptime over any time duration. If we want to slice data along additional dimensions we must maintain the count of up and down minutes for each dimension (organization, operation type, etc.).

It took us about 1 year to deploy windowed user-uptime to all of the G Suite applications. This time included implementation (e.g., to normalize the different log formats so we can use the same pipeline across all of our applications and to build the pipeline for calculating the metric) but the bulk of the time was in determining which operations we should consider in windowed user-uptime and whether or not a given operation's availability could be visible to users. From this experience we are confident that windowed user-uptime is broadly applicable: any cloud service provider should be able to implement it.

8 Conclusion

We have introduced a novel availability metric, *user-uptime* which combines the advantages of per-user aggregation with those of using a time-based availability measure. We have shown that as a result user-uptime avoids multiple kinds of bias: hyper-active users contribute similarly to the metric as regular users, and even behavioral changes during an outage result in a proportional and meaningful measurement that in many cases is even more precise than success-ratio.

We have evaluated our metric against the commonly-used success-ratio metric using production data from G Suite services. We show that the bias in success-ratio is not an academic argument: we actually encounter it in production and that user-uptime avoids this bias.

We have introduced a visualization technique, windowed availability, that allows us to study multiple time-scales from single minutes to a full quarter in an easy to understand graph. Again using production data from G Suite services, we show that windowed user-uptime sheds invaluable and actionable insight into the availability of our services. Specifically, windowed user-uptime enables us to differentiate between many short and fewer but longer outages. This ability focuses our engineering efforts into improvements that will yield the most gains in user-perceived availability.

Appendix: Monotonicity

We prove Eq. (7) which was stated in Section 5 without proof.

$$\frac{k}{k+1}\text{MCR}(w) \leq \text{MCR}(w') \qquad kw < w'. \tag{7}$$

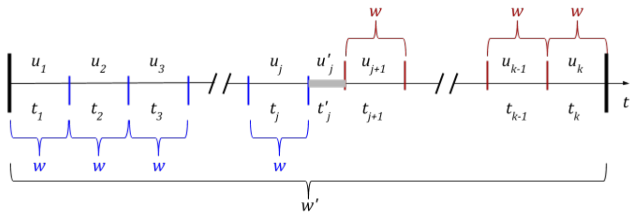

Figure 21: Embedding length-w windows in length-w' one. for $w' \neq kw$

To prove Eq. (7), we cover the larger window of size w' with windows of size w. Pick some $0 \leq j \leq k$ and fill the segment with j windows without a gap from the left and $k-j$ windows from the right, as in Fig. 21. As w' is not an integer multiple of w, this will leave a small segment uncovered in the middle. Like before, we write the availability of $\mathbf{w}'$ in terms of the uptime and total time of the segments as:

$$A(\mathbf{w}') = \frac{U}{T} = \frac{u_1 + \ldots + u_j + u'_j + u_{j+1} + \ldots + u_k}{t_1 + \ldots + t_j + t'_j + t_{j+1} + \ldots + t_k}.$$

The availability of each window of length w is bounded by MCR(w):

$$\frac{u_i}{t_i} \geq \text{MCR}(w).$$

Substituting $u_i \geq \text{MCR}(w)t_i$ and $u'_j \geq 0$ yields:

$$A(\mathbf{w}') \geq \text{MCR}(w)\frac{t_1 + \ldots + t_j + t_{j+1} + \ldots + t_k}{t_1 + \ldots + t_j + t'_j + t_{j+1} + \ldots + t_k}$$

or

$$TA(\mathbf{w}') \geq \text{MCR}(w)(T - t'_j).$$

Depending on how many windows we add on the left or on the right, j can be any integer between 0 (all windows on the right) and k (all windows on the left). Each of these possibilities yields the same inequality as above, they differ only in the respective value of t'_j. Let's add all of these $k+1$ inequalities:

$$(k+1)TA(\mathbf{w}') \geq \text{MCR}(w)(kT + T - \sum_{j=0}^{k} t'_j).$$

Note, however, that

$$T - \sum_{j=0}^{k} t'_j \geq 0$$

because t'_j are total times of non-overlapping intervals, all part of T. Substituting this yields the promised bound:

$$A(\mathbf{w}') \geq \frac{k}{k+1}\text{MCR}(w).$$

We see, therefore, that every window of length $w' > kw$ contains at least one window of size w with lower availability. Since there exists a window whose availability is MCR(w'), Eq. (7) follows.

Understanding, Detecting and Localizing Partial Failures in Large System Software

Chang Lou
Johns Hopkins University

Peng Huang
Johns Hopkins University

Scott Smith
Johns Hopkins University

Abstract

Partial failures occur frequently in cloud systems and can cause serious damage including inconsistency and data loss. Unfortunately, these failures are not well understood. Nor can they be effectively detected. In this paper, we first study 100 real-world partial failures from five mature systems to understand their characteristics. We find that these failures are caused by a variety of defects that require the unique conditions of the production environment to be triggered. Manually writing effective detectors to systematically detect such failures is both time-consuming and error-prone. We thus propose OmegaGen, a static analysis tool that automatically generates customized watchdogs for a given program by using a novel program reduction technique. We have successfully applied OmegaGen to six large distributed systems. In evaluating 22 real-world partial failure cases in these systems, the generated watchdogs can detect 20 cases with a median detection time of 4.2 seconds, and pinpoint the failure scope for 18 cases. The generated watchdogs also expose an unknown, confirmed partial failure bug in the latest version of ZooKeeper.

1 Introduction

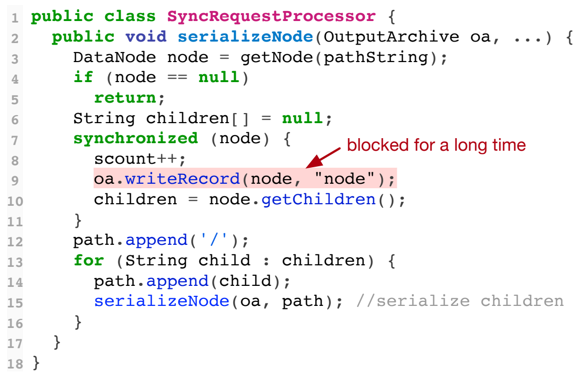
It is elusive to build large software that never fails. Designers of robust systems therefore must devise runtime mechanisms that proactively check whether a program is still functioning properly, and react if not. Many of these mechanisms are built with a simple assumption that when a program fails, it fails completely via crash, abort, or network disconnection.

This assumption, however, does not reflect the complex failure semantics exhibited in modern cloud infrastructure. A typical cloud software program consists of tens of modules, hundreds of dynamic threads, and tens of thousands of functions for handling different requests, running various background tasks, applying layers of optimizations, *etc.* Not surprisingly, such a program in practice can experience *partial failures*, where some, but not all, of its functionalities are broken. For example, for a data node process in a modern distributed file system, a partial failure could occur when a rebalancer thread within this process can no longer distribute unbalanced blocks to other remote data node processes, even though this process is still alive. Or, a block receiver daemon in this data node process silently exits, so the blocks are no longer persisted to disk. These partial failures are *not* a latent problem that operators can ignore; they can cause serious damage including inconsistency, "zombie" behavior and data loss. Indeed, partial failures are behind many catastrophic real-world outages [1, 17, 39, 51, 52, 55, 66, 85, 86]. For example, Microsoft Office 365 mail service suffered an 8-hour outage because an anti-virus engine module of the mail server was stuck in identifying some suspicious message [39].

When a partial failure occurs, it often takes a long time to detect the incident. In contrast, a process suffering a total failure can be quickly identified, restarted or repaired by existing mechanisms, thus limiting the failure impact. Worse still, partial failures cause mysterious symptoms that are incredibly difficult to debug [78], e.g., `create()` requests time out but `write()` requests still work. In a production ZooKeeper outage due to the leader failing partially [86], even after an alert was triggered, the leader logs contained few clues about what went wrong. It took the developer significant time to localize the fault within the problematic leader process (Figure 1). Before pinpointing the failure, a simple restart of the leader process was fruitless (the symptom quickly re-appeared).

Both practitioners and the research community have called attention to this gap. For example, the Cassandra developers adopted the more advanced accrual failure detector [73], but still conclude that its current design *"has very little ability to effectively do something non-trivial to deal with partial failures"* [13]. Prabhakaran *et al.* analyze partial failure specific to disks [88]. Huang *et al.* discuss the gray failure [76] challenge in cloud infrastructure. The overall characteristics of software partial failures, however, are not well understood.

In this paper, we first seek to answer the question, *how do partial failures manifest in modern systems?* To shed some light on this, we conducted a study (Section 2) of 100 real-world partial failure cases from five large-scale, open-source systems. We find that nearly half (48%) of the studied failures



```
 1 public class SyncRequestProcessor {
 2   public void serializeNode(OutputArchive oa, ...) {
 3     DataNode node = getNode(pathString);
 4     if (node == null)
 5       return;
 6     String children[] = null;
 7     synchronized (node) {
 8       scount++;
 9       oa.writeRecord(node, "node");
10       children = node.getChildren();
11     }
12     path.append('/');
13     for (String child : children) {
14       path.append(child);
15       serializeNode(oa, path); //serialize children
16     }
17   }
18 }
```

Figure 1: A production ZooKeeper outage due to partial failure [86].

cause certain software-specific functionality to be stuck. In addition, the majority (71%) of the studied failures are triggered by unique conditions in a production environment, *e.g.*, bad input, scheduling, resource contention, flaky disks, or a faulty remote process. Because these failures impact internal features such as compaction and persistence, they can be unobservable to external detectors or probes.

How to systematically detect and localize partial failures at runtime? Practitioners currently rely on running *ad-hoc* health checks (*e.g.*, send an HTTP request every few seconds and check its response status [3, 42]). But such health checks are too shallow to expose a wide class of failures. The state-of-the-art research work in this area is Panorama [75], which converts various requestors of a target process into observers to report gray failures of this process. This approach is limited by what requestors can observe externally. Also, these observers cannot localize a detected failure within the faulty process.

We propose a novel approach to construct effective partial failure detectors through *program reduction*. Given a program P, our basic idea is to derive from P a reduced but representative version W as a detector module and periodically test W in production to expose various potential failures in P. We call W an *intrinsic watchdog*. This approach offers two main benefits. First, as the watchdog is derived from and "imitates" the main program, it can more accurately reflect the main program's status compared to the existing stateless heartbeats, shallow health checks or external observers. Second, reduction makes the watchdog succinct and helps localize faults.

Manually applying the reduction approach on large software is both time-consuming and error-prone for developers. To ease this burden, we design a tool, *OmegaGen*, that statically analyzes the source code of a given program and generates customized intrinsic watchdogs for the target program.

Our insight for realizing program reduction in OmegaGen is that W's goal is *solely* to detect and localize runtime errors; therefore, it does not need to recreate the full details of P's business logic. For example, if P invokes `write()` in a tight loop, for checking purposes, a W with one `write()` may be sufficient to expose a fault. In addition, while it is tempting to check all kinds of faults, given the limited resources, W should focus on checking faults manifestable only in a production environment. Logical errors that deterministically lead to wrong results (*e.g.*, incorrect sorting) should be the focus of offline unit testing. Take Figure 1 as an example. In checking the `SyncRequestProcessor`, W need not check most of the instructions in function `serializeNode`, *e.g.*, lines 3–6 and 8. While there might be a slim chance these instructions would also fail in production, repeatedly checking them would yield diminishing returns for the limited resource budget.

Accurately distinguishing logically-deterministic faults and production-dependent faults in general is difficult. OmegaGen uses heuristics to analyze how "vulnerable" an instruction is based on whether the instruction performs some I/O, resource allocation, async wait, *etc.* So since line 9 of Figure 1 performs a write, it would be assessed as vulnerable and tested in W. It is unrealistic to expect W to always include the failure root cause instruction. Fortunately, a ballpark assessment often suffices. For instance, even if we only assess that the entire `serializeNode` function or its caller is vulnerable, and periodically test it in W, W can still detect this partial failure.

Once the vulnerable instructions are selected, OmegaGen will encapsulate them into checkers. OmegaGen's second contribution is providing several strong isolation mechanisms so the watchdog checkers do not interfere with the main program. For memory isolation, OmegaGen identifies the *context* for a checker and generates context managers with hooks in the main program which replicates contexts before using them in checkers. OmegaGen removes side-effects from I/O operations through redirection and designs an idempotent wrapper mechanism to safely test non-idempotent operations.

We have applied OmegaGen to six large (28K to 728K SLOC) systems. OmegaGen automatically generates tens to hundreds of watchdog checkers for these systems. To evaluate the effectiveness of the generated watchdogs, we reproduced 22 **real-world** partial failures. Our watchdogs can detect 20 cases with a median detection time of 4.2 seconds and localize the failure scope for 18 cases. In comparison, the best manually written baseline detector can only detect 11 cases and localize 8 cases. Through testing, our watchdogs exposed a new, confirmed partial failure bug in the latest ZooKeeper.

2 Understanding Partial Failures

Partial failures are a well known problem. Gupta and Shute report that partial failures occur much more commonly than total failures in the Google Ads infrastructure [70]. Researchers studied partial disk faults [88] and slow hardware faults [68]. But how software fails partially is not well understood. In this Section, we study real-world partial failures to gain insight into this problem and to guide our solution design.

Scope We focus on partial failure at the process granularity. This process could be standalone or one component in a large service (*e.g.*, a datanode in a storage service). Our studied partial failure is with respect to a process deviating from the functionalities it is supposed to provide *per se*, *e.g.*, store and

Software	Lang.	Cases	Ver.s (Range)	Date Range
ZooKeeper	Java	20	17 (3.2.1–3.5.3)	12/01/2009–08/28/2018
Cassandra	Java	20	19 (0.7.4–3.0.13)	04/22/2011–08/31/2017
HDFS	Java	20	14 (0.20.1–3.1.0)	10/29/2009–08/06/2018
Apache	C	20	16 (2.0.40–2.4.29)	08/02/2002–03/20/2018
Mesos	C++	20	11 (0.11.0–1.7.0)	04/08/2013–12/28/2018

Table 1: Studied software systems, the partial failure cases, and the unique versions, version and date ranges these cases cover.

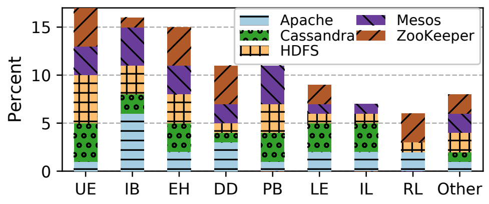


Figure 2: Root cause distribution. *UE*: uncaught error; *IB*: indefinite blocking; *EH*: buggy error handling; *DD*: deadlock; *PB*: performance bug; *LE*: logic error; *IL*: infinite loop; *RL*: resource leak.

balance data blocks, whether it is a service component or a standalone server. We note that users may define a partial failure at the service granularity (*e.g.*, Google drive becomes read-only), the underlying root cause of which could be either some component crashing or failing partially.

Methodology We study five large, widely-used software systems (Table 1). They provide different services and are written in different languages. To collect the study cases, we first crawl all bug tickets tagged with critical priorities in the official bug trackers. We then filter tickets from testing and randomly sample the remaining failures tickets. To minimize bias in the types of partial failures we study, we exhaustively examining each sampled case and manually determine whether it is a complete failure (*e.g.*, crash), and discard if so. In total, we collected 100 failure cases (20 cases for each system).

2.1 Findings

Finding 1: *In all the five systems, partial failures appear throughout release history (Table 1). 54%*[1] *of them occur in the most recent three years' software releases.*

Such a trend occurs in part because as software evolves, new features and performance optimizations are added, which complicates the failure semantics. For example, HDFS introduced a short-circuit local reads feature [30] in version 0.23. To implement this feature, a `DomainSocketWatcher` was added that watches a set of Unix domain sockets and invokes a callback when they become readable. But this new module can accidentally exit in production and cause applications performing short-circuit reads to hang [29].

Finding 2: *The root causes of studied failures are diverse. The top three (total 48%) root cause types are uncaught errors, indefinite blocking, and buggy error handling (Figure 2).*

Uncaught error means certain operation triggers some error condition that is not expected by the software. As an example, the streaming session in Cassandra could hang when the stream reader encounters errors other than `IOException` like `RuntimeException` [6]. Indefinite blocking occurs when some function call is blocked forever. In one case [27], the `EditLogTailer` in a standby HDFS namenode made an RPC `rollEdits()` to the active namenode; but this call was blocked when the active namenode was frozen but not crashed, which prevented the standby from becoming active. Buggy error handling includes silently swallowing errors, empty handlers [93], premature continuing, *etc.* Other common root causes include deadlock, performance bugs, infinite loop and logic errors.

[1]With sample size 100, the percents also represent the absolute numbers.

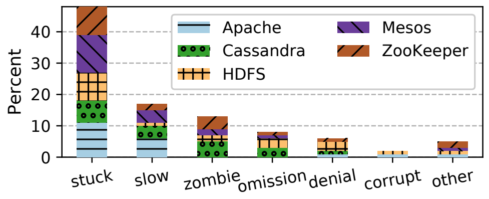

Figure 3: Consequence of studied failures.

Finding 3: *Nearly half (48%) of the partial failures cause some functionality to be stuck.*

Figure 3 shows the consequences of the studied failures. Note that these failures are all partial. For the *"stuck"* failures, some software module like the socket watcher was not making any progress; but the process was not completely unresponsive, *i.e.*, its heartbeat module can still respond *in time*. It may also handle other requests like non-local reads.

Besides "stuck" cases, 17% of the partial failures causes certain operation to take a long time to complete (the *"slow"* category in Figure 3). These slow failures are not just inefficiencies for optional optimization. Rather, they are severe performance bugs that cause the affected feature to be barely usable. In one case [5], after upgrading Cassandra 2.0.15 to 2.1.9, users found the read latency of the production cluster increased from 6 ms/op to more than 100 ms/op.

Finding 4: *In 13% of the studied cases, a module became a "zombie" with undefined failure semantics.*

This typically happens when the faulty module accidentally exits its normal control loop or it continues to execute even when it encounters some severe error that it cannot tolerate. For example, an unexpected exception caused the ZooKeeper listener module to accidentally exit its `while` loop so new nodes could no longer join the cluster [46]. In another case, the HDFS datanode continued even if the block pool failed to initialize [26], which would trigger a `NullPointerException` whenever it tried to do block reports.

Finding 5: *15% of the partial failures are silent (including data loss, corruption, inconsistency, and wrong results).*

They are usually hard to detect without detailed correctness specifications. For example, when the Mesos agent garbage collects old slave sandboxes, it could incorrectly wipe out the persistent volume data [37]. In another case [38], the Apache web server would "go haywire", *e.g.*, a request for a .js file would receive a response of image/png, because the backend connections are not properly closed in case of errors.

Finding 6: *71% of the failures are triggered by some specific environment condition, input, or faults in other processes.*

For example, a partial failure in ZooKeeper can only be triggered when some corrupt message occurs in the `length` field of a record [66]. Another partial failure in the ZooKeeper leader would only occur when a connecting follower hangs [50], which prevents other followers from joining the cluster. These partial failures are hard to be exposed by pre-production testing and require mechanisms to detect at runtime. Moreover, if a runtime detector uses a different setup or checking input, it may not detect such failures.

Finding 7: *The majority (68%) of the failures are "sticky".*

Sticky means the process will not recover from the faults by itself. The faulty process needs to be restarted or repaired to function again. In one case, a race condition caused an unexpected `RejectedExecutionException`, which caused the RPC server thread to silently exit its loop and stop listening for connections [9]. This thread must be restarted to fix the issue. For certain failures, some extra repair actions such as fixing a file system inconsistency [25] are needed.

The remaining (32%) failures are "transient", *i.e.*, the faulty modules could possibly recover after certain condition changes, *e.g.*, when the frozen namenode becomes responsive [27]. However, these non-sticky failures already incurred damage for a long time by then (15 minutes in one case [45]).

Finding 8: *The median diagnosis time is 6 days and 5 hours.*

For example, diagnosing a Cassandra failure [10] took the developers almost two days. The root cause turned out to be relatively simple: the `MeteredFlusher` module was blocked for several minutes and affected other tasks. One common reason for the long diagnosis time despite simple root causes is that the confusing symptoms of the failures mislead the diagnosis direction. Another common reason is the insufficient exposure of runtime information in the faulty process. Users have to enable debug logs, analyze heap, and/or instrument the code, to identify what was happening during the production failure.

2.2 Implications

Overall, our study reveals that partial failure is a common and severe problem in large software systems. Most of the studied failures are production-dependent (finding 6), which require runtime mechanisms to detect. Moreover, if a runtime detector can localize a failure besides mere detection, it will reduce the difficulty of offline diagnosis (finding 8). Existing detectors such as heartbeats, probes [69], or observers [75] are ineffective because they have little exposure to the affected functionalities internal in a process (e.g., compaction).

One might conclude that the onus is on the developers to add effective runtime checks in their code, such as a timer check for the `rollEdits()` operation in the aforementioned HDFS failure [27]. However, simply relying on developers to anticipate and add defensive checks for every operation is unrealistic. We need a *systematic* approach to help developers construct software-specific runtime checkers.

It would be desirable to completely automate the construction of customized runtime checkers, but this is extremely difficult in the general case given the diversity (finding 2) of partial failures. Indeed, 15% of the studied failures are silent, which require detailed correctness specifications to catch. Fortunately, the majority of failures in our study violate liveness (finding 3) or trigger explicit errors at certain program points, which suggests that detectors can be automatically constructed without deep semantic understanding.

3 Catching Partial Failures with Watchdogs

We consider a large server process π composed of many smaller modules, providing a set of functionalities R, *e.g.*, a datanode server with request listener, snapshot manager, cache manager, *etc.* A failure detector is needed to monitor the process for high availability. We target specifically partial failures. We define a partial failure in a process π to be when a fault does not crash π but causes safety or liveness violation or severe slowness for some functionality $R_f \subsetneq R$. Besides detecting a failure, we aim to localize the fault within the process to facilitate subsequent troubleshooting and mitigation.

Guided by our study, we propose an *intersection principle* for designing effective partial failure detectors—construct customized checks that intersect with the execution of a monitored process. The rationale is that partial failures typically involve specific software feature and bad state; to expose such failures, the detector need to exercise specific code regions with carefully-chosen payloads. The checks in existing detectors including heartbeat and HTTP tests are too generic and too *disjoint* with the monitored process' states and executions.

We advocate an **intrinsic watchdog** design (Figure 4) that follows the above principle. An intrinsic watchdog is a dedicated monitoring extension for a process. This extension regularly executes a set of checkers tailored to different modules. A watchdog driver manages the checker scheduling and execution, and optionally applies a recovery action. The key objective for detection is to let the watchdog experience similar faults as the main program. This is achieved through (a) executing *mimic-style* checkers (b) using *stateful* payloads (c) sharing execution environment of the monitored process.

Mimic Checkers. Current detectors use two types of checkers: *probe* checkers, which periodically invoke some APIs; *signal* checkers, which monitor some health indicator. Both are lightweight. But a probe checker can miss many failures because a large program has numerous APIs and partial failures may be unobservable at the API level. A signal checker is susceptible to environment noises and usually has poor accuracy. Neither can localize a detected failure.

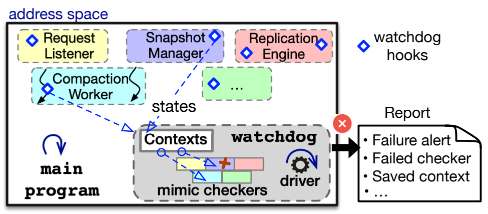

Figure 4: An intrinsic watchdog example.

We propose a more powerful *mimic-style* checker. Such checker selects some representative operations from each module of the main program, imitates them, and detects errors. This approach increases coverage of checking targets. And because the checker exercises code logic similar to the main program in production environment, it can accurately reflect the monitored process' status. In addition, a mimic checker can pinpoint the faulty module and failing instruction.

Synchronized States. Exercising checkers requires payloads. Existing detectors use *synthetic* input (e.g., fixed URLs [3]) or a tiny portion of the program state (e.g., heartbeat variables) as the payload. But triggering partial failures usually entails specific input and program state (§2). The watchdog should exercise its checkers with non-trivial state from the main program for higher chance of exposing partial failures.

We introduce *contexts* in watchdogs. A context is bound to each checker and holds *all* the arguments needed for the checker execution. Contexts are synchronized with the program state through hooks in the main program. When the main program execution reaches a hook point, the hook uses the current program state to update its context. The watchdog driver will not execute a checker unless its context is ready.

Concurrent Execution. It is natural to insert checkers directly in the main program. However, in-place checking poses an inherent tension—on the one hand, catching partial failures requires adding comprehensive checkers; on the other hand, partial failures only occur rarely, but more checkers would slow down the main program in normal scenarios. In-place checkers could also easily interfere with the main program through modifying the program states or execution flow.

We advocate watchdog to run *concurrently* with the main program. Concurrent execution allows checking to be decoupled so a watchdog can execute comprehensive checkers without delaying the main program during normal executions. Indeed, embedded systems domain has explored using concurrent watchdog co-processor for efficient error detection [84]. When a checker triggers some error, the watchdog also will not unexpectedly alter the main program execution. The concurrent watchdog should still live in the same address space to maximize mimic execution and expose similar issues, *e.g.*, all checkers timed out when the process hits long GC pause.

4 Generating Watchdogs with OmegaGen

It is tedious to manually write effective watchdogs for large programs, and it is challenging to get it right. Incautiously written watchdogs can miss checking important functions, alter the main execution, invoke dangerous operations, corrupt program states, *etc.* a watchdog must also be updated as the software evolves. To ease developers' burden, we design a tool, OmegaGen, which uses a novel *program reduction* approach to automatically generate watchdogs described in Section 3. The central challenge of OmegaGen is to ensure the generated watchdog accurately reflects the main program status without introducing significant overhead or side effects.

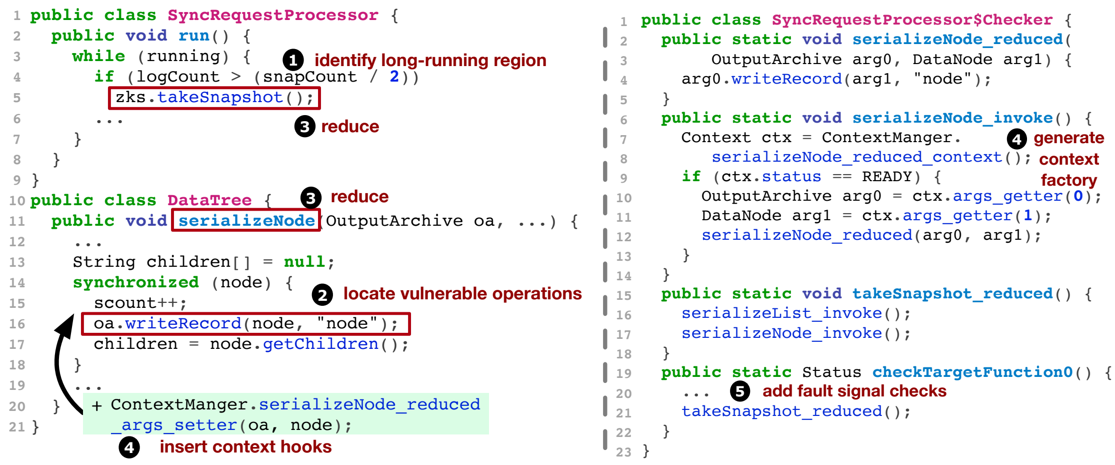
Overview and Target. OmegaGen takes the source code of a program *P* as an input. It finds the long-running code regions in *P* and then identifies instructions that may encounter production-dependent issues using heuristics and optional, user-provided annotations. OmegaGen encapsulates the vulnerable instructions into executable checkers and generates watchdog *W*. It also inserts watchdog hooks in *P* to update *W*'s contexts and packages a driver to execute *W* in *P*. Figure 5 shows an overview example of running OmegaGen.

As discussed in Section 2.2, it is difficult to automatically generate detectors that can catch all types of partial failures. Our approach targets partial failures that surface through explicit errors, blocking or slowness at certain instruction or function in a program. The watchdogs OmegaGen generates are particularly effective in catching partial failures in which some module becomes stuck, very slow or a "zombie" (*e.g.*, the HDFS `DomainSocketWatcher` thread accidentally exiting and affecting short-circuit reads). They are in general ineffective on *silent* correctness errors (*e.g.*, Apache web-server incorrectly re-using stale connections).

4.1 Identify Long-running Methods

OmegaGen starts its static analysis by identifying long-running code regions in a program (step ❶), because watchdogs only target checking code that is continuously executed. Many code regions in a server program are only for one-shot tasks such as database creation, and should be excluded from watchdogs. Some tasks are also either periodically executed such as snapshot or only activated under specific conditions. We need to ensure the activation of generated watchdog is aligned with the life span of its checking target in the main program. Otherwise, it could report wrong detection results.

OmegaGen traverses each node in the program call graph. For each node, it identifies potentially long-running loops in the function body, *e.g.*, `while(true)` or `while(flag)`. Loops with fixed iterations or that iterate over collections will be skipped. OmegaGen then locates all the invocation instructions in the identified loop body. The invocation targets are colored. Any methods invoked by a colored node are also recursively colored. Besides loops, we also support coloring periodic task methods scheduled through common libraries like `ExecutorService` in Java concurrent package. Note that this step may over-extract (*e.g.*, an invocation under a conditional). This is not an issue because the watchdog driver will check context validity at runtime (§4.4).



❶ identify long-running region
❸ reduce
❸ reduce
❷ locate vulnerable operations
❹ insert context hooks
❹ generate context factory
❺ add fault signal checks

```java
public class SyncRequestProcessor {
  public void run() {
    while (running) {
      if (logCount > (snapCount / 2))
        zks.takeSnapshot();
      ...
    }
  }
}
public class DataTree {
  public void serializeNode(OutputArchive oa, ...) {
    ...
    String children[] = null;
    synchronized (node) {
      scount++;
      oa.writeRecord(node, "node");
      children = node.getChildren();
    }
    ...
  }  + ContextManger.serializeNode_reduced
       _args_setter(oa, node);
}
```

```java
public class SyncRequestProcessor$Checker {
  public static void serializeNode_reduced(
      OutputArchive arg0, DataNode arg1) {
    arg0.writeRecord(arg1, "node");
  }
  public static void serializeNode_invoke() {
    Context ctx = ContextManger.
        serializeNode_reduced_context();
    if (ctx.status == READY) {
      OutputArchive arg0 = ctx.args_getter(0);
      DataNode arg1 = ctx.args_getter(1);
      serializeNode_reduced(arg0, arg1);
    }
  }
  public static void takeSnapshot_reduced() {
    serializeList_invoke();
    serializeNode_invoke();
  }
  public static Status checkTargetFunction0() {
    ...
    takeSnapshot_reduced();
  }
}
```

(a) A module in main program **(b)** Generated checker

Figure 5: Example of watchdog checker OmegaGen generated for a module in ZooKeeper.

A complication arises when a method has multiple call-sites, some of which are colored while others are not. Whether this method is long running or not depends on the specific execution. Moreover, an identified long-running loop may turn out to be short-lived in an actual run. To accurately capture the method life span and control the watchdog activation, OmegaGen designs a *predicate*-based algorithm. A *predicate* is a runtime property associated with a method which tracks whether a call site of this method is in fact reached.

For an invocation target inside a potentially long-running loop, a hook is inserted before the loop that sets its predicate and another hook after the loop that unsets its predicate. A callee of a potentially long-running method will have a predicate set to be equal to this caller's predicate. At runtime, the predicates are assigned and evaluated that activates or deactivates the associated watchdog. The predicate instrumentation occurs after OmegaGen finishes the vulnerable operation analysis (§4.2) and program reduction (§4.3).

4.2 Locate Vulnerable Operations

OmegaGen then analyzes the identified long-running methods and further narrows down the checking target candidates (step ❷). This is because even in those limited number of methods, a watchdog cannot afford to check all of their operations. Our study shows that the majority of partial failures are triggered by unique environment conditions or workloads. This implies that operations whose safety or liveness are heavily influenced by its execution environment deserve particular attention. In contrast, operations whose correctness is logically deterministic (*e.g.*, sorting), are better checked through offline testing or in-place assertions. Continuously monitoring such operations inside a watchdog would yield diminishing returns.

OmegaGen uses heuristics to determine for a given operation how *vulnerable* this operation is in its execution environment. Currently, the heuristics consider operations that perform synchronization, resource allocation, event polling, async waiting, invocation with external input argument, file or network I/O as highly vulnerable. OmegaGen identifies most of them through standard library calls. Functions containing complex while loop conditions are considered vulnerable due to potential infinite looping. Simple operations such as arithmetic, assignments, and data structure field accesses are tagged as not vulnerable. In the Figure 5a example, OmegaGen considers the `oa.writeRecord` to be highly vulnerable because its body invokes several write calls. These heuristics are informed by our study but can be customized through a rule table configuration in OmegaGen. For example, we can configure OmegaGen to consider functions with several exception signatures as vulnerable (i.e., potentially improperly handled). We also allow developers to annotate a method with a `@vulnerable` tag in the source code. OmegaGen will locate calls to the annotated method and treat them as vulnerable.

Neither our heuristics nor human judgment can guarantee that the vulnerable operation criteria are always sound and complete. If OmegaGen incorrectly assesses a safe operation as vulnerable, the main consequence is that the watchdog would waste resources monitoring something unnecessarily. Incorrectly assessing a vulnerable operation as risk-free is more concerning. But one nice characteristic of vulnerable operations is that they often propagate [67] – an instruction that blocks indefinitely would also cause its enclosing function to block; and, an instruction that triggers some uncaught error also propagates through the call stack. For example, in a real-world partial failure in ZooKeeper [66], even if OmegaGen misses the exact vulnerable instruction `readString`, a watchdog still has a chance to detect the partial failure if `dserialize` or even `pRequest` is assessed to be vulnerable. On the other hand, if a vulnerable operation is too high-level (*e.g.*, `main` is considered vulnerable), error signals can be swallowed internally and it would also make localizing faults hard.

4.3 Reduce Main Program

With the identified long-running methods and vulnerable operations, OmegaGen performs a top-down program reduction (step ❸) starting from the entry point of long-running methods. For example, in Figure 5a, OmegaGen will try to reduce the `takeSnapshot` function first. When walking the control flow graph of a method to be reduced, if an instruction is tagged as potentially vulnerable, it would be retained in the reduced method. Otherwise, it would be excluded. For a call instruction that is not tagged as vulnerable yet, it would be temporarily retained and OmegaGen will recursively try to reduce the target function. If eventually the body of a reduced method is empty, *i.e.,* no vulnerable operation exists, it will be discarded. Any call instructions that call this discarded method and were temporarily retained are also discarded.

The resulting reduced program not only contains all vulnerable operations reachable from long-running methods but also preserves the original structure, i.e., for a call chain `f` $\hookrightarrow$ `g` $\hookrightarrow$ `h` in the main program, the reduced call chain is `f'` $\hookrightarrow$ `g'` $\hookrightarrow$ `h'` This structure can help localize a reported issue. In addition, when later a watchdog invokes a validator (§4.6), the structure provides information on which validator to invoke.

If a type of vulnerable operation (*e.g.*, the `writeRecord` call in Figure 5a) is included multiple times in the reduced program, it could be redundant in terms of exposing failures. Therefore, OmegaGen will further reduce the vulnerable operations based on whether they have been included already. However, the same type of vulnerable operation may be invoked quite differently in different places, and only a particular invocation would trigger failure. If we are too aggressive in reducing based on occurrences, we may miss the fault-triggering invocation. So, by default OmegaGen only performs intra-procedural occurrence reduction: multiple `writeRecord` calls will not occur within a single reduced method but may occur across different reduced methods.

4.4 Encapsulate Reduced Program

OmegaGen will encapsulate the code snippets retained after step ❸ into watchdogs. But these code snippets may not be directly executable because of missing definitions or payloads. For example, the reduced version of `serializeNode` in Figure 5a contains an operation `oa.writeRecord(node, "node")`. But `oa` and `node` are undefined. OmegaGen analyzes *all* the arguments required for the execution of a reduced method. For each undefined variable, OmegaGen adds a local variable definition at the beginning of the reduced method. It further generates a *context factory* that provides APIs to manage all the arguments for the reduced method (step ❹). Before a variable's first usage in the reduced method, a getter call to the context factory is added to retrieve the latest value at runtime.

To synchronize with the main program, OmegaGen inserts hooks that call setter methods of the same context factory in the (non-reduced) method in the original program at the same point of access. The context hooks are further conditioned on the long-running predicate for this method (§4.1). When the watchdog driver executes a reduced method, it first checks whether the context is ready and skips the execution if the context is not ready. Together, context and predicate control the activation of watchdog checkers—only when the original program reaches the context hooks and the method is truly long-running would the corresponding operation be checked. For example, in the while loop of Figure 5a, if the log count has not reached the snapshot threshold yet, the predicate for `takeSnapshot` is true but the context for the reduced `serializeNode` is not ready so the checking is skipped.

4.5 Add Checks to Catch Faults

After step ❹, the encapsulated reduced methods can be executed in a watchdog. OmegaGen will then add checks for the watchdog driver to catch the failure signals from the execution of vulnerable operations in the reduced methods. OmegaGen targets both liveness and safety violations. Liveness checks are relatively straightforward to add. OmegaGen inserts a timer before running a checker. Setting good timeouts for distributed systems is a well-known hard problem. Prior work [82] argues that replacing end-to-end timeouts with fine-grained timeouts for local operations makes the setting less sensitive. We made similar observations and use a conservative timeout (default 4 seconds). Besides timeouts, the watchdog driver also records the moving average of checker execution latencies to detect potential slow faults.

To detect safety violations, OmegaGen relies on the vulnerable operations to emit explicit error signals (assertions, exceptions, and error codes) and installs handlers to capture them. OmegaGen also captures runtime errors, *e.g.*, null pointer exception, out of memory errors, `IllegalStateException`.

Correctness violations are harder to check automatically without understanding the semantics of the vulnerable operations. Fortunately such silent violations are not very common in our studied cases (§2). Nevertheless, OmegaGen provides a `wd_assert` API for developers to conveniently add semantic checks. When OmegaGen analyzes the program, it will treat `wd_assert` instructions as special vulnerable operations. It performs similar checker encapsulation (§4.4) by analyzing the context needed for such operations and generates checkers containing the `wd_assert` instructions. The original `wd_assert` in the main program will be rewritten as a no-op. In this way, developers can leverage the OmegaGen framework to perform concurrent expensive checks (*e.g.*, if the hashes of new blocks match their checksums) without blocking the main execution.

The watchdog driver records any detected error in a log file. The reported error contains the timestamp, failure type and symptom, failed checker, the corresponding main program location that the failed checker is testing. backtrace, *etc*. The watchdog driver also saves the context used by the failed checker to ease subsequent offline troubleshooting.

4.6 Validate Impact of Caught Faults

An error reported by a watchdog checker could be transient or tolerable. To reduce false alarms, the watchdog runs a validation task after detecting an error. The default validation is to simply re-execute the checker and compare, which is effective for transient errors. Validating tolerable errors requires testing software features. Note that the validator is *not* for handling errors but rather confirming impact. Writing such validation tasks mainly involves invoking some entry functions, *e.g.*, `processRequest(req)`, which is straightforward.

OmegaGen provides skeletons of validation tasks, and currently relies on manual effort to fill out the skeletons. But OmegaGen automates the decision of choosing which validation task to invoke based on which checker failed. Specifically, for a filled validation task T that invokes a function `f` in the main program, OmegaGen searches the generated reduced program structure (§4.3) in topological order and tries to find the first reduced method `m'` that either matches `f` or any method in the `f`'s callgraph. Then OmegaGen generates a hashmap that maps all the checkers that are rooted under `m'` to task T. At runtime, when an error is reported, the watchdog driver checks the map to decide which validator to invoke.

4.7 Prevent Side Effects

Context Replication. To prevent the watchdog checkers from accidentally modifying the main program's states, OmegaGen analyzes *all* the variables (context) referenced in a checker. It generates a replication setter in the checker's context manager, which will replicate the context when invoked. The replication ensures any modifications are contained in the watchdog's state. Using replicated contexts also avoids adding complex synchronization to lock objects during checking. But blindly replicating contexts will incur high overhead. We perform *immutability analysis* [74, 77] on the watchdog contexts. If a context is immutable, OmegaGen generates a reference setter instead, which only holds a reference to the context source.

To further reduce context replication, we use a simple but effective lazy copying approach that, instead of replicating a context upon each set, delays the replication to only when a getter needs it. To deal with potential inconsistency due to lazy replication—*e.g.*, the main program has modified the context after the setter call—we associate a context with several attributes: `version`, `weak_ref` (weak reference to the source object), and `hash` (hash code for the value of the source object). The lazy setter only sets these attributes but does not replicate the context. Later when the getter is invoked, the getter checks if the referent of `weak_ref` is not null. If so, it further checks if the current hash code of the referent's value matches the recorded `hash` and skip replication if they do not match (main program modified context). Besides the attribute checks in getters, the watchdog driver will check if the `version` attributes of each context in a vulnerable operation match and skip the checking if the versions are inconsistent (see further elaboration in Appendix A).

I/O Redirection and Idempotent Wrappers. Besides memory side effects; we also need to prevent I/O side effects. For instance, if a vulnerable operation is writing to a snapshot file, a watchdog could accidentally write to the same snapshot file and affect subsequent executions of the main program. OmegaGen adds I/O redirection capability in watchdogs to address this issue: when OmegaGen generates the context replication code, the replication procedure will check if the context refers to a file-related resource, and if so the context will be replicated with the file path changed to a watchdog test file under the same directory path. Thus watchdogs would experience similar issues such as degraded or faulty storage.

If the storage system being written to is internally load-balanced (*e.g.*, S3), however, the test file may get distributed to a different environment and thus miss issues that only affect the original file. This limitation can be addressed as our write redirection is implemented in a cloning library, so it is relatively easy to extend the logic of deciding the redirection path there to consider the load-balancing policy (if exposed). Besides, if the underlying storage system is layered and complex like S3, it is perhaps better to apply OmegaGen on that system to directly expose partial failures there.

For socket I/O, OmegaGen can perform similar redirection to a special watchdog port if we know beforehand the remote components are also OmegaGen-instrumented. Since this assumption may not hold, OmegaGen by default rewrites the watchdog's socket I/O operation as a ping operation.

If the vulnerable operation is a read-type operation, redirection to read from the watchdog special test file may not help. We design an idempotent wrapper mechanism so that both the main program and watchdog can invoke the wrapper safely. If the main program invokes the wrapper first, it directly performs the actual read-type operation and caches the result in a context. When the watchdog invokes the wrapper, if the main program is in the critical section, it will wait until the main program finishes, and then it gets the cached context. In the normal scenario, the watchdog can use the data from the read operation without performing the actual read. In the faulty scenario, if the main program blocks indefinitely in performing the read-type operation, the watchdog would uncover the hang issue through the timeout of waiting in its wrapper; a bad value from the read would also be captured by the watchdog after retrieving it. For each vulnerable operation of read-type, OmegaGen generates an idempotent wrapper with the above property, replaces the main program's original call instruction to invocation of the wrapper, and places a call instruction to the wrapper in the watchdog checker as well.

5 Implementation

We implemented OmegaGen in Java with 8,100 SLOC. Its core components are built on top of the Soot [90] program analysis framework, so it supports systems in Java bytecode. OmegaGen does not rely on specific JDK features. The Soot version we used can analyze bytecode up to Java 8. We leverage a cloning library [79] with around 400 SLOC of changes to support our selective context replication and I/O redirection mechanisms. OmegaGen's workflow consists of multiple phases to analyze and instrument the program and generate

watchdogs. A single script automates the workflow and packages the watchdogs with the main program into a bundle.

6 Evaluation

We evaluate OmegaGen to answer several questions: (1) does our approach work for large software? (2) can the generated watchdogs detect and localize diverse forms of real-world partial failures? (3) do the watchdogs provide strong isolation? (4) do the watchdogs report false alarms? (5) what is the runtime overhead to the main program? The experiments were performed on a cluster of 10 cloud VMs. Each VM has 4 vCPUs at 2.3GHz, 16 GB memory, and 256 GB disk.

6.1 Generating Watchdogs

To evaluate whether our proposed technique can work for real-world software, we evaluated OmegaGen on six large systems (Table 2). We chose these systems because they are widely used and representative, with codebases as large as 728K SLOC to analyze. OmegaGen uses around 30 lines of default rules for the vulnerable operation heuristics (most are types of Java library methods) and an average of 10 system-specific rules (*e.g.*, special asynchronous wait patterns). OmegaGen successfully generates watchdogs for all six systems.

Table 3 shows the total watchdogs generated. Each watchdog here means a root of reduced methods. Note that these are static watchdogs. Only a subset of them will be activated in production by the watchdog predicates and context hooks (§4.1). We further evaluate how comprehensive the generated checkers are by measuring how many thread classes in the software have at least one watchdog checker generated. Figure 6 shows the results. OmegaGen achieves an average coverage ratio of 60%. For the threads that do not have checkers, they are either not long-running (*e.g.*, auxiliary tools) or OmegaGen did not find vulnerable operations in them. In general, OmegaGen may fail to generate good checkers for modules that primarily perform computations or data structure manipulations. The generated checkers may still contain some redundancy even after the reduction (§4.3).

6.2 Detecting Real-world Partial Failures

Failure Benchmark To evaluate the effectiveness of our generated watchdogs, we collected and reproduced 22 **real-world** partial failures in the six systems. Table 10 in the appendix lists the case links and types. All of these failures led to severe consequences. They involve sophisticated fault injection and workload to trigger. It took us 1 week on average to reproduce each failure. Seven cases are from our study in Section 2. Others are new cases we did not study before.

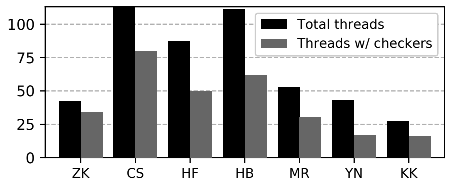

Figure 6: Thread-level coverage by generated watchdog checkers.

Detector	Description
Client (Panorama [75])	instrument and monitor client responses
Probe (Falcon [82])	daemon thread in the process that periodically invokes internal functions with synthetic requests
Signal	script that scans logs and checks JMX [40] metrics
Resource	daemon thread that monitors memory usage, disk and I/O health, and active thread count

Table 4: Four types of baseline detectors we implemented.

Baseline Detectors The built-in detectors (heartbeat) in the six systems cannot handle partial failures at all. We thus implement four types of advanced detectors for comparison (Table 4). The client checker is based on the observers in state-of-the-art work, Panorama [75]. The probe checker presents Falcon [82] app spies (which are also manually written in the Falcon paper). When implementing the signal and resource checkers, we follow the current best practices [15, 42] and monitor signals recommended by practitioners [2, 31, 41, 43].

Methodology The watchdogs and baseline detectors are all configured to run checks *every second*. When reproducing each case, we record when the software reaches the failure program point and when a detector first reports failure. The detection time is the latter minus the former. For slow failures, it is difficult to pick a precise start time. We set the start point using criteria recommended by practitioners, e.g., when number of outstanding requests exceeds 10 for ZooKeeper [31].

Result Table 5 shows the results. Overall, the watchdogs detected 20 out of the 22 cases with a median detection time of 4.2 seconds. 12 of the detected cases are captured by the default vulnerable operation rules. 8 are caught by system-specific rules. In general, the watchdogs were effective for liveness issues like deadlock, indefinite blocking as well as safety issues that trigger explicit error signals or exceptions. But they are less effective for silent correctness errors.

In comparison, as Table 5 shows, the best baseline detector only detected 11 cases. Even the combination of all baseline detectors detected only 14 cases. The client checkers missed 68% of the failures because these failures concern the internal functionality or some optimizations that are not immediately visible to clients. The signal checker is the most effective among the baseline detectors, but it is also noisy (§6.6).

the paper. A network issue caused a ZooKeeper remote snapshot dumping operation to be blocked in a critical section, which prevented update-type request processing threads from proceeding (Figure 1). OmegaGen generates a checker `serializeNode_reduced`, which exposed the issue in 4 s.

CS1 [7]: The Cassandra Commitlog executor accidentally died due to a bad commit disk volume. This caused the uncommitted writes to pile up, which in turn led to extensive garbage collection and the process entering a zombie status. The relevant watchdog OmegaGen generates is `CommitLogSegment_reduced`. Interestingly, this case had negative detection time. This happens because the executor successfully executed the faulty program point prior to the failure and set the watchdog context (log segment path). When the checker was scheduled, the context was still valid so the checker was activated and exposed the issue ahead of time.

HB5 [18]: Users observed some gigantic write-ahead-logs (WALs) on their HBase cluster even when WAL rolling is enabled. This is because when a peer is previously removed, one thread gets blocked for sending a shutdown request to a closed executor. Unfortunately this procedure holds the same lock `ReplicationSourceManager#recordLog`, which does the WAL rolling (to truncate logs). Our generated watchdog mimics the procedure of submitting request and waiting for completion, and experienced the same stalling issue on closed executor.

CS4 [11]: Due to a severe performance bug in the Cassandra compaction module, all the `RangeTombstones` ever created for the partition that have expired would remain in memory until the compaction completes. The compaction task would be very slow when the workloads contain a lot of overwrites to collections. The relevant checker OmegaGen generates is `SSTableWriter#append_reduced`. After the tombstones piles up, this checker reports a slow alert based on the dramatic ($10\times$) increase of moving average of operation latencies.

YN1 [44]: A new application (AM) was stuck after getting allocated to a recently added NodeManager (NM). This was caused by `/etc/hosts` on the ResourceManager (RM) not being updated, so this new NM was unresolvable when RM built the service tokens. RM would retry forever and the AM would keep getting allocated to the same NM. Our watchdogs failed to detect the issue. The reason is that the faulty operation `buildTokenService()` mainly creates some data structure, so OmegaGen failed to consider it as vulnerable.

6.3 Localizing Partial Failure

Detection is only the first step. We further evaluate the localization effectiveness for the detected cases in Table 5. we measure the distance between the error reporting location and the faulty program point. We categorize the distance into six levels of decreasing accuracy. Table 6 shows the result. Watchdogs directly pinpoint the faulty instruction for 55% (11/20) of the detected cases, which indicates the effectiveness of our vulnerable operation heuristics. In case MR1 [35], after noticing the symptom (reducer did not make progress for a long time), it took the user more than two days of careful log analysis and thread dumps to narrow down the cause. With the watchdog error report, the fault was obvious.

For 35% (7/20) of detected cases, the watchdogs either localize to some program point within the same function or some function along the call chain, which can still significantly ease troubleshooting. For example, in case HF2 [24], the balancer was stuck in a loop in `waitForMoveCompletion()` because `isPendingQEmpty()` will return false when no mover threads are available. The generated watchdog did not pinpoint either place. But it caught the error through timeout in executing a `future.get()` vulnerable operation in its checker `dispatchBlockMoves_reduced`, which narrows down the issue.

In comparison, the client or resource detectors can only pinpoint the faulty process. To narrow down the fault, users must spend significant time analyzing logs and code. In case HB4 [21], the client checker even blamed a wrong innocent process, which would completely mislead the diagnosis. The probe checker localizes failures to some internal functions in the program. But these functions are still too high-level and distant from the fault. The signal checker localizes 8 cases.

6.4 Fault-Injection Tests

To evaluate how the watchdogs may perform in real deployment, we conducted a random fault-injection experiment on

	ZK	CS	HF	HB	MR	YN

signal	3.2–9.6	0	0–0.05	0–0.67	0	0

Table 7: False alarm ratios (%) of all detectors in the evaluated six systems. Each cell reports the ratio range under three setups (stable, loaded, tolerable). *watch_v*: watchdog with validators.

the latest ZooKeeper. In particular, we inject four types of faults to the system: *Infinite loop* (modify loop condition to force running forever); *Arbitrary delay* (inject 30 seconds delay in some complex operations); *System resource contention* (exhaust CPU/memory resource); *I/O delay* (inject 30 seconds delay in file system or network). After that, we run a series of workloads and operations (e.g., restart some server). We successfully trigger 16 synthetic failures. Our generated watchdogs can detect 13 out of the 16 triggered synthetic failures with a median detection time of 6.1 seconds. The watchdogs pinpoint the injected failure scope for 11 cases.

6.5 Discovering A New Partial Failure Bug

During our continuous testing, our watchdogs exposed a new partial bug in the latest version (3.5.5) of ZooKeeper. We observe that our ZooKeeper cluster occasionally hangs and new create requests time out while the admin tool still shows the leader process is working. This symptom is similar to our studied bug ZK1. But that bug is already fixed in the latest version. The issue is also non-deterministic. Our watchdogs report the failure in 4.7 seconds. The watchdog log helps us pinpoint the root cause for this puzzling failure. The log shows the checker that reported the issue was `serializeAcls_reduced`. We further inspected this function and found that the problem was the server serializing the `ACLCache` inside a critical section. When developers fixed the ZK1 bug, this similar flaw was overlooked and recent refactoring of this class made the flaw more problematic. We reported this new bug [49], which has been confirmed by the developers and fixed.

6.6 Side Effects and False Alarms

We ran the watchdog-enhanced systems with extensive workloads and verified that the systems pass their own tests. We also verified the integrity of the files and client responses by comparing them with ones from the vanilla systems. If we disable our side-effect prevention mechanisms (§4.7), however, the systems would experience noticeable anomalies, *e.g.*, snapshots get corrupted, system crash; or, the main program would hang because the watchdog read the data from a stream.

We further evaluate the false alarms of watchdogs and baseline detectors under three setups: *stable*: runs fault-free for 12 hours with moderate workloads (§6.7); *loaded*: random node restarts, every 3 minutes into the moderate workloads, switch to aggressive workloads (3× number of clients and 5× request sizes); *tolerable*: run with injected transient errors tolerable by the system. Table 7 shows the results. The false alarm ratio is calculated from total false failure reports divided by the total number of check executions. Watchdogs did *not* report false alarms in the stable setup. But during a loaded period, they incur around 1% false alarms due to socket connection errors or resource contention. These false alarms would disappear once the transient faults are gone. With the validator mechanism (§4.6), the watchdog false alarm ratios (the *watch_v* row) are significantly reduced. Among the baseline detectors, we can see that even though signal checkers achieved better detection, they incur high false alarms (3–10%).

Table 9: System throughput (op/s) w/ different detectors.

6.7 Performance and Overhead

We first measure the performance of OmegaGen's static analysis. Table 8 shows the results. For all but HBase, the whole process takes less than 5 minutes. HBase takes 17 minutes to generate watchdogs because of its large codebase.

We next measure the runtime overhead of enabling watchdogs and the baseline detectors. We used popular benchmarks configured as follows: for ZK, we used an open-source benchmark [16] with 15 clients sending 15,000 requests (40% read); for Cassandra, we used YCSB [61] with 40 clients sending 100,000 requests (50% read); for HDFS, we used built-in benchmark NNBenchWithoutMR which creates and writes 100 files, each file has 160 blocks and each block is 1MB; for HBase, we used YCSB with 40 clients sending 50,000 requests (50% read); for MapReduce and Yarn, we used built-in DFSIO benchmark which writes 400 10MB files.

Table 9 shows that the watchdogs incur 5.0%–6.6% overhead on throughput. The main overhead comes from the watchdog hooks rather than the concurrent checker execution. The probe detectors are more lightweight, incurring 0.2%–3.2% overhead. We also measure the latency impact. The watchdogs incur 9.3%–12.2% overhead on average latency and 8.3%–14.0% overhead on tail (99th percentile) latency. But given the watchdog's significant advantage in failure detection and localization, we believe its higher overhead is justified. For a cloud infrastructure, operators could also choose to activate watchdogs on a subset of the deployed nodes to reduce the overhead while still achieving good coverage.

We measure the CPU usages of each system w/o and w/ watchdogs. The results are 57%→66% (ZK), 199%→212% (CS), 33%→38% (HF), 36%→41% (HB), 5.6%→6.9% (MR), 1.5%→3% (YN). We also analyze the heap memory usages. The median memory usages (in MiB) are 128→131 (ZK), 447→459 (CS), 165→178 (HF), 197→201 (HB), 152→166

(MR), 154→157 (YN). The increase is small because contexts are only lazily replicated every checking interval, compared to continuous object allocations in the main program.

6.8 Sensitivity

We evaluate the sensitivity of our default 4-sec timeout threshold on detecting liveness issues with ZK1 [45] (stuck failure) and ZK4 [48] (slow failure). Under timeout threshold 100 ms, 300 ms, 500 ms, 1 s, 4 s, and 10 s, the detection times for ZK1 are respectively 0.51 s, 0.61 s, 0.70 s, 1.32 s, 4.28 s, and 12.09 s. The detection time generally decreases with smaller timeout, but it is bounded by the checking interval. With timeout of 100 ms, we observe 6 false positives in 5 minutes. For ZK4, when the timeout threshold is aggressive, the slow fault can be detected without the moving average mechanism (§4.5), in particular with detection times of 61.65 s (100 ms), 91.38 s (300 ms), 110.32 s (500 ms). Eventually the resource leak exhausts all available memory before the watchdog exceeds more conservative thresholds.

7 Limitations

OmegaGen has several limitations we plan to address in future work: (1) Our vulnerable operation analysis is heuristics-based. This step can be improved through offline profiling or dynamic adaptive selection. (2) Our generated watchdogs are effective for liveness issues and common safety violations. But they are ineffective to catch silent semantic failures. We plan to leverage existing resources that contain semantic hints such as test cases to derive runtime semantic checks. (3) OmegaGen achieves memory isolation with static analysis-assisted context replication. We will explore more efficient solutions like copy-on-write when porting OmegaGen to C/C++ systems. (4) OmegaGen generates watchdogs to report failures for individual process. One improvement is to pair OmegaGen with failure detector overlays [89] so the failure detector of one process could inspect another process' watchdogs. (5) Our watchdogs currently focus on fault detection and localization but not recovery. We will integrate microreboot [58] and ROC techniques [87].

8 Related Work

Partial failure has been discussed in multiple contexts. Arpaci-Dusseau and Arpaci-Dusseau propose the fail-stutter fault model [56]. Prabhakaran *et al.* analyze the fail-partial model for disks [88]. Correia *et al.* propose the ASC fault model [62]. Huang *et al.* propose a definition for gray failure in cloud [76]. Gunawi *et al.* [68] studies the fail-slow performance faults in hardware. Our study presented in Section 2 focuses on partial failures in modern cloud software. A recent work analyzes failures in cloud systems caused by network partitions [54]. Our work's scope is at the process granularity. A network partition may causes total failures to the partitioned processes (disconnected from other processes). Besides, our work covers much more diverse root causes beyond network issues.

Failure detection has been extensively studied [53, 59, 60, 63, 65, 71, 72, 80–82, 91]. But they primarily focus on detecting fail-stop failures in distributed systems; partial failures are beyond the scope of these detectors. Panorama [75] proposes to leverage observability in a system to detect gray failures [76]. While this approach can enhance failure detection, it assumes some external components happen to observe the subtle failure behavior. These logical observers also cannot isolate which part of the failing process is problematic, making subsequent failure diagnosis time-consuming [32].

Watchdog timers are essential hardware components found in embedded systems [57]. For general-purpose software, watchdogs are more challenging to construct manually due to the large size of the codebase and complex program logic. Consequently, existing software using the watchdog concept [4, 14] only designs watchdogs as shallow health checks (*e.g.*, http test) and a kill policy [42]. Our position paper [83] advocates for the intrinsic watchdog abstraction and articulates its design principles. OmegaGen provides the ability to automatically generate comprehensive, customized watchdogs for a given program through static analysis.

Several works aim to generate software invariants or ease runtime checking. Daikon [64] infers likely program invariants from dynamic execution traces. PCHECK [92] uses program slicing to extract configuration checks to detect latent misconfiguration during initialization. OmegaGen is complementary to these efforts. We focus on synthesizing checkers for monitoring long-running procedures of a program in production by using a novel program reduction technique.

9 Conclusion

System software continues to become ever more complex. This leads to a variety of partial failures that are not captured by existing solutions. This work first presents a study of 100 real-world partial failures in popular system software to shed light on the characteristics of such failures. We then present OmegaGen, which takes a program reduction approach to generate watchdogs for detecting and localizing partial failures. Evaluating OmegaGen on six large systems, it can generate tens to hundreds of customized watchdogs for each system. The generated watchdogs detect 20 out of 22 real-world partial failures with a median detection time of 4.2 seconds, and pinpoint the scope of failure for 18 cases; these results significantly outperform the baseline detectors. Our watchdogs also exposed a new partial failure in latest ZooKeeper.

Acknowledgments

We would like to thank the NSDI reviewers and our shepherd, Aurojit Panda, for their valuable comments that improved the paper. We thank Ziyan Wang for implementing the `wd_assert` API support for OmegaGen. We are grateful to the generous cloud research credits support from Azure, AWS and Google Cloud Platform. This work was supported in part by funding from NSF grants CNS-1755737 and CNS-1910133.

Appendix A Additional Clarifications

Consistency under Lazy Replication Section 4.7 describes that we associate a context with three attributes (`version`, `weak_ref`, and `hash`) to deal with potential inconsistency due to the lazy replication optimization. Here, we give a concrete example to clarify how potential inconsistency could arise and how it is addressed. With lazy replication (essentially "copy-on-get"), a context may be modified or even invalidated after the context setter call; if this occurs, the getter will replicate a different context value. For example,

```
       Main Program                     Watchdog Checker
-----------------------------     --------------------------
void foo() {                      void foo_reduced_invoke() {
  foo_reduced_args_setter(oa);
  write(oa);
  oa.append("test");
                  <---      oa = foo_reduced_ctx.args_getter(0);
}
```

Id.	Root Cause	Conseq.	Sticky?	Study?

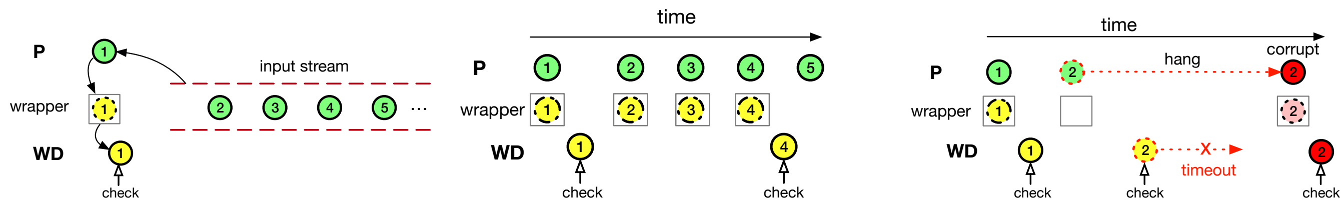
MR4 [33]	Uncaught Error	Zombie	Yes	No
YN1 [44]	Improper Err Handling	Stuck	Yes	No

Table 10: 22 real-world partial failures reproduced for evaluation. *ZK*: ZooKeeper; *CS*: Cassandra; *HF*: HDFS; *HB*: HBase; *MR*: MapReduce; *YN*: Yarn. Sticky?: whether the failure persists forever. Study?: whether the failure is from the studied cases in Section 2.

By the time the context getter is invoked in the checker, `oa` may already be invalidated (garbage collected). But since the getter will check the `weak_ref` attribute, it will find out the fact that the context is invalid (`weak_ref` returns `null`) and hence not replicate. If `oa` is still valid, the context getter will further check the hash code of the current value and skip replication if it does not match the recorded `hash`. This approach is lightweight. But it assumes the hash code contract of Java objects being honored in a program. If this is not the case, *e.g.*, `oa`'s hash code is the same regardless of its content, inconsistency (getter replicates a modified context) could arise. Such inconsistency may or may not cause an issue for the checker. For the above example, the checker's `write` may write `"xxxtest"` instead of `"xxx"` to the watchdog test file, which is still fine. But if another vulnerable operation has a special invariant on `"xxx"`, the inconsistency will lead to a false alarm at runtime. Our low false alarm rates during the 12-hour experiment period suggest that hash code contract violation is generally not a major concern for mature software.

Another consistency scenario to consider is when a checker uses some vulnerable operation that requires multiple context arguments. Since the context retrieval is asynchronous under the lazy replication optimization, a race condition could occur while a getter is retrieving all the arguments. For example,

```
          Main Program                          Watchdog Checker
-----------------------------------    --------------------------
```



(a) Idempotent wrapper for `readRecord` **(b)** Invoking wrapper in normal scenario **(c)** Invoking wrapper in faulty scenario

Figure 7: Illustration of idempotent wrapper

```
// called in a loop
synchronized void foo() {            void foo_reduced_invoke() {
                         <--- arg0 = foo_reduced_ctx.args_getter(0);
  ...
  foo_reduced_args_setter(oa, node);
  oa.writeRecord(node);
                         <---  arg1 = foo_reduced_ctx.args_getter(1);
}
```

After the getter retrieves `oa`, the second argument (`node`) is updated before the getter retrieves it. In this case, both arguments are valid and match their recorded `hash` attributes. However, they are mixed from two invocations of `foo()`. We address this inconsistency scenario with the `version` attributes. A checker will compare if the `version` attributes of all the contexts it needs are the same before invoking the checked operation, and skip the checking if the versions are inconsistent.

Appendix B Implementation Details

Idempotent Wrapper Section 4.7 describes our idempotent wrapper mechanism that allows watchdogs to safely invoke non-idempotent operations, especially `read`-type operations. We further elaborate the details for this mechanism here.

The basic idea is to have both the watchdog and main program invoke the wrapper instead of the original operation in a coordinated fashion. The wrapper distinguishes whether the call is from main program or the watchdog. Take a vulnerable operation `readRecord` as an example. In the fault-free scenario, the main program performs the actual `readRecord` like normal; the watchdog checker would get a cached value. In a faulty scenario, the main program may get stuck in `readRecord`; the watchdog would be blocked outside the critical section of the wrapper so it can detect the hang without performing the actual `readRecord`. Figure 7 illustrates both scenarios.

OmegaGen automatically generates idempotent wrappers for all read-type vulnerable operations. OmegaGen first locates all statements that invoke a read operation in the main program. It extracts the stream objects from these statements. A wrapper is generated for each type of stream object. The watchdog driver maintains a map between the stream objects and the wrapper instances. For the wrapper to later perform the actual operation, OmegaGen assigns a distinct operation number for each read-type method in the stream class, and generates a dispatcher that calls the method based on the op number. Then, OmegaGen replaces the original invocation with a call to the watchdog driver's wrapper entry point using the

		ZK	CS	HF	HB	MR	YN
Disk	Base	3.97	6.04	88.26	1.50	0.10	0.05
(MB/s)	w/ WD	4.04	6.12	89.02	1.53	0.10	0.05
Network	Base	997	2,884	27	993	1.3	1.5
(KB/s)	w/ WD	1,031	2,915	28	1,048	1.7	1.8

Table 11: Average disk and network I/O usages of the base systems and w/ watchdogs.

stream object, operation number, and caller source as the arguments. For example, `buf = istream.read();` in the main program would be replaced with `buf = WatchdogDriver.readHelp(istream, 1, 0);` where 1 is the op number for `read` and 0 means the wrapper is called from the main program.

The other steps in the checker construction for the read-type operations are similar to other types of vulnerable operations. The key difference is that OmegaGen will generate a self-contained checker for the *wrapped* operation instead of the operation. It particular, the checker OmegaGen generates will contain a call instruction to the proper wrapper using source 1 (from watchdog) as the argument.

Appendix C Supplementary Evaluation

Semantic Check API Our experiments in Section 6 did not use semantic checks, `wd_assert` (§4.5), to avoid biased results. But we did test using `wd_assert` on a hard case ZK3. Although the watchdog OmegaGen automatically generates detected this case, it is because the failure-triggering condition (bad disk) also affected some other vulnerable I/O operations in the watchdog. We wrote a `wd_assert` to check if the on-disk transaction records are far behind in-memory records:

```
wd_assert(lastProcessedZxid <= (new
ZKDatabase(txnLogFactory)).loadDataBase()+MISS_TXN_THRESHOLD);
```

OmegaGen handles the tedious details by automatically extracting the necessary context, encapsulating a watchdog checker, and removing this expensive statement from the main program. The resulted semantic checker can detect the failure within 2 seconds and pinpoint the issue.

I/O Usage Overhead We measured the disk I/O usages (using `iotop`) and network I/O usage (using `nethogs`) for the six systems with and without watchdogs under the same setup as our overhead experiment in Section 6.7. Table 11 shows the results. We can see the I/O usage increase incurred by the watchdogs is small (a median of 1.6% for disk I/O and 4.4% for network I/O).

Check before You Change: Preventing Correlated Failures in Service Updates

Abstract

The reliability of cloud services can be significantly undermined by correlated failures due to shared service dependencies, even when the services are already replicated across machines. State-of-the-art failure prevention systems can proactively audit a service before its deployment to detect risks for correlated failures, but their auditing speeds are too slow for frequent service updates. This paper presents CloudCanary, a system that can perform *real-time* audits on service updates to identify the root causes of correlated failure risks, and generate improvement plans with increased reliability.

CloudCanary achieves this with two primitives, SNAPAUDIT and DEPBOOSTER. SNAPAUDIT leverages two insights to achieve high accuracy and efficiency: a) service updates typically affect only a small part of the service stack, allowing the majority of previous auditing results to be reused; and b) structural reliability auditing tasks can be reduced to a Boolean satisfiability problem, which can then be solved efficiently using modern SAT solvers. DEPBOOSTER, on the other hand, can generate improvement plans efficiently by reducing the required reasoning load, using novel techniques such as model counting. We demonstrate in our experiments that CloudCanary can perform audits over large deployments 200× faster than state-of-the-art systems, and that it consistently generates high-quality improvement plans within minutes. Moreover, CloudCanary can yield valuable insights over real-world traces collected from production environments.

1 Introduction

High reliability is an essential requirement for cloud services. To enhance reliability, cloud providers typically replicate states and functionality across multiple servers, under the assumption of failure independence [33, 34, 54].

Reality, however, is more complicated. The complex, multilayered nature of network/software stacks in cloud services may conceal underlying interdependencies between seemingly independent components, such as network switches and software modules. Failures of these common service dependencies can lead to correlated failures *despite replication*, causing service downtime [11, 25, 39, 70]. For example, a faulty top-of-rack (ToR) switch would affect all replicas in the same rack [18], and a buggy software component could propagate failures across all service instances it supports [38]. Such incidents have repeatedly made the headlines: in one of the Rackspace outage events [9], glitches in two core switches caused multiple servers to be inaccessible, leading to significant service disruption; in another incident, a single faulty data collector in Amazon EBS brought down the Relational Database service in an entire availability zone [3].

A number of previous efforts have focused on diagnosing the root causes of correlated failures [14, 23, 47, 58]. While this is useful, post-failure diagnostics typically involves prolonged failure recovery time [12, 64], as even the best of diagnostic tools cannot *prevent* service outages. Such outages can be quite costly: on average, a single datacenter outage can cause an economic loss of $740,357 [4].

More recent proposals aim to proactively prevent correlated failures by auditing the structural reliability of cloud services before deployment [22, 70, 71]. At a high level, these systems collect a comprehensive set of structural dependency data in cloud services, and construct a system-wide fault graph to encode the dependencies. They then identify potential risks for correlated failures from the fault graph.

However, state-of-the-art auditing systems are designed to perform audits at service initialization, not for conducting *real-time* audits throughout the service lifetime. Runtime audits are necessary, because existing work has shown that many dependencies potentially causing correlated failures are introduced by network and software updates (*e.g.*, reconfigurations and upgrades) during service runtime [39]. For example, a Gmail service upgrade configured microservice replicas to share the same vulnerable component, which later rendered user data unavailable for many hours [5]. Existing systems are impractical for real-time audits for two reasons.

- First, they are *too slow* in analyzing cloud-scale deployments in real time. For example, a state-of-the-art system takes ∼35 hours to analyze a 30,528-component service [70], making it only possible to perform a few audits per week. This cannot match the update frequency in today's clouds—for instance, Google reported 58 updates per week, roughly one update every three hours [37].
- Second, these tools can only alert the operator to correlated failure risks, but do not offer further support to find effective *improvement plans*. Thus, the operator needs to either manually reason about improvements to the existing deployment, or use automated tools to generate a plan from scratch [22, 70]. The former is error-prone, and the latter may result in a plan that requires considerable service reconfiguration. Moreover, both are inefficient.

[*] Work done while at Yale University.

In other words, although the operator may have enough lead time to perform audits at service initialization, the high turnaround time of existing systems prohibits their use in real-time auditing during service runtime.

We present CloudCanary, a system that can efficiently and accurately a) alert the operator to the root causes of correlated failure risks introduced by service updates, and b) generate a set of improved deployment plans with higher reliability. CloudCanary achieves this using two primitives—SnapAudit and DepBooster—to help prevent correlated failures during service runtime in a timely manner.

Contribution #1. SnapAudit (§3) can efficiently and accurately identify root causes for correlated failures in a given service snapshot. The design of SnapAudit addresses two challenges. The first is how to rapidly analyze a fault graph representing the service update snapshot. To address this challenge, we propose an *incremental auditing* algorithm to identify a set of *differential fault graphs*, which represents the "delta" between the service snapshots before and after an update. Based on the insight that service updates usually affect a *small* part of service stacks [37, 49, 60], extracting differential fault graphs enables us to avoid the need to re-analyze the entire fault graph from scratch. Second, although differential fault graphs are already smaller than the overall fault graph, analyzing each of them is still NP-hard and time-consuming [63]. We therefore propose an approach that speeds up the fault graph analysis by transforming a differential fault graph into a Boolean formula, and then solving the formula using a high-performance MinCostSAT solver [35].

Contribution #2. DepBooster (§4), on the other hand, helps the operator improve a risk-prone deployment. It allows the operator to specify a reliability goal (*e.g.*, the failure probability needs to be lower than a certain threshold), and then generates a set of alternative improvement plans that meet the specification. DepBooster also addresses two challenges. First, there are infinitely many potential improvement plans to be checked for their capability to satisfy the specified goal. To overcome this challenge, we utilize *network compression* [17]—a technique that can simplify a datacenter network by collapsing symmetric network structures and slicing away irrelevant parts—to significantly reduce the number of states we need to check. Second, even after compression, it still takes a long time to check whether a candidate deployment meets the specified goal. We further propose a novel algorithm based on model counting [20] for efficient checks.

To the best of our knowledge, CloudCanary is the first practical system capable of preventing correlated failure risks in service updates. We have built a CloudCanary prototype and evaluated it with a set of real-world scenarios (§6). Our results show that SnapAudit can identify correlated failure root causes in a 1,183,360-component service within 8 minutes, 200× faster than the state-of-the-art systems, and that DepBooster can find high-quality improvement plans within minutes.

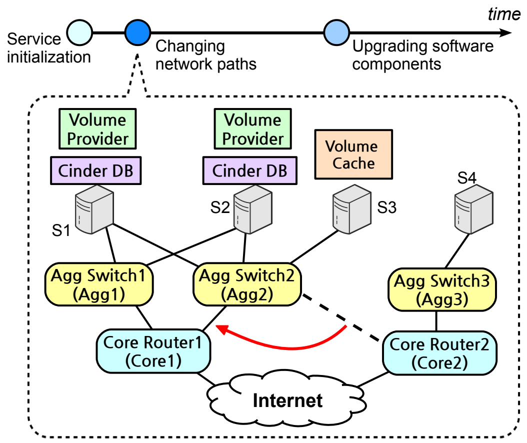

Figure 1: An update that affects the Cinder DB deployment, where the path Agg2→Core2 is shifted to Agg2→Core1 due to an ECMP configuration change.

2 Overview

In this section, we first motivate our problem further (§2.1). Then, we describe the state-of-the-art auditing systems and their limitations (§2.2 and §2.3). Finally, we present the architecture of CloudCanary (§2.4).

2.1 Motivation

Cloud operators ensure service reliability by replicating important state and functionality. Suppose that an operator deploys Cinder DB (a block storage system in OpenStack) in her datacenter, and that she replicates Cinder DB across multiple servers to increase reliability. Unbeknownst to this operator, the replicated Cinder DB instances may share deep dependencies, such as certain network or software components [3, 9]. The failures of such latent common dependencies can lead to a correlated failure across the entire system, undermining the use of replication. Such common dependencies are often called a *risk group*—a (small) number of components whose simultaneous failure results in a correlated failure.

To prevent correlated failures, the operator needs a tool to check for risk groups in a service deployment and generate improvement plans. For instance, if a risk group only contains one element, *e.g.*, a shared switch, it may potentially become a single point of failure. In this case, the operator may want to improve the deployment so that even the smallest risk group contains more than one element. In a similar spirit, if the estimated probability for correlated failures is above a threshold, the operator may want to find a functionally equivalent deployment with a lower failure probability.

Suppose that a service never goes through updates, then the above tasks only need to be performed once at service initialization. However, this is rarely the case in today's clouds, as most services experience frequent updates in their lifetime, and risk groups can be introduced in any of the updates [39]. Figure 1 shows an example: if the network path Agg2→Core2 is shifted to Agg2→Core1 (*e.g.*, due to a change to the ECMP configuration), such an update will introduce a new risk group $\sigma = \{\text{Core1}\}$, the fault of which will result in a correlated failure across both Cinder DB instances. Therefore, checking for risk groups and generating improvement plans need to be performed *continuously in real time*.

2.2 Starting Basis: Fault Graphs

Operators already apply a set of "golden standards" for increasing service reliability, such as rack-aware replica placement [8], geo-replication [1], canary tests [10], but achieving a comprehensive understanding of failure risks is a task that needs to be automated. To this end, several state-of-the-art auditing systems [22, 70, 71] have been proposed to proactively check for correlated failures. They do so using a common abstraction called a *fault graph* [63], which represents the structural dependencies of a service.

Fault graph. A fault graph is a layered DAG representing the logical relationships between component faults within a given system [63]. Figure 2 shows the fault graph of the example service in Figure 1. The fault graph has two types of nodes: *fault events* and *logic gates*. The leaf nodes in a fault graph are *basic faults*, which are the smallest units of failures under consideration, *e.g.*, the failure of a switch or software library. The root node in a fault graph represents a *target service fault*, which indicates the failure of the entire service. The rest of the nodes are *intermediate faults*, which describe how basic faults may cause larger service disruptions.

The fault propagation is encoded by layers of *logic gates* in between. If a component fails, the corresponding fault node outputs a 1 to its parent node, which could be either an `AND` or `OR` gate; otherwise the fault node outputs a 0. For an `OR` gate, if any of its children fail, a fault propagates upwards; for an `AND` gate, it only propagates a fault upwards if all of its children fail. Faulty nodes could be further associated with weights that encode the failure probabilities. Each non-leaf node has an *input gate* that connects its lower-layer faults, but leaf nodes, *i.e.*, basic faults, do not have an input gate.

Fault graph generation. State-of-the-art auditing systems (*e.g.*, INDaaS [70], reCloud [22]) have used existing data acquisition tools to automatically collect the structural dependency data needed for generating fault graphs. These tools cover a variety of dependency data, including network path dependencies [56, 70, 77], software component call flows [69, 73–75], and micro-service execution dependencies [24, 61]. Then, these auditing systems invoke various fault graph synthesis algorithms [51, 70–72] to automatically build fault graphs based on the acquired dependency data. Large-scale fault graph generation has been shown to be efficient—for example, INDaaS generates a 70,656-leaf fault graph within minutes [70].

Commercial data centers also deploy a variety of such profiling tools to track inter-service dependency, although the specific tools would differ from company to company. For instance, the Maelstrom [61] system at Facebook collects

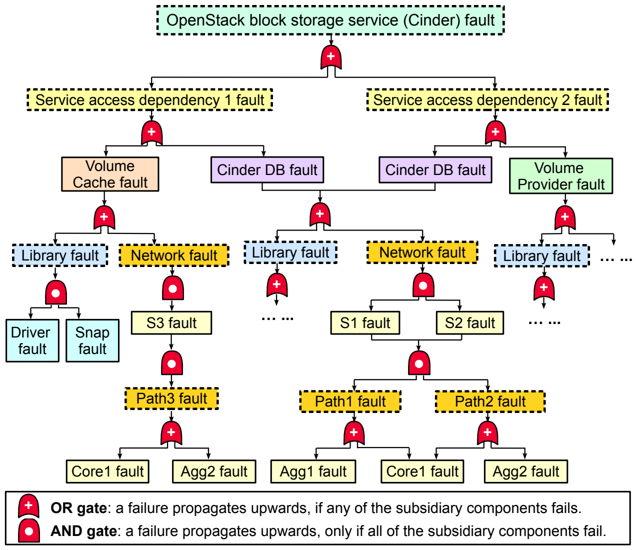

Figure 2: A fault graph representing the post-update service snapshot shown in Figure 1. Path 1, Path 2, and Path 3 represent the links Agg1→Core1, Agg2→Core1, and Agg2→Core1, respectively. Dashed boxes are logical components that do not exist physically.

service dependency data and uses it for failure mitigation. Later in our evaluation, we have also collected dependency data from a production data center using tools that are already in active deployment.

2.3 State of the Art and Limitations

State-of-the-art systems, such as INDaaS [70], reCloud [22], and RepAudit [71], can perform structural reliability audits on fault graphs to detect risk groups. They then output the identified risk groups to the operator to alert her to the risk. For instance, they may identify {Core1} to be a risk group, because its failure would cause the entire service to fail. However, existing systems all focus on *one-shot* audits at service initialization. They cannot handle *real-time* audits during service runtime due to the following two reasons.

Inefficient risk group auditing. Since detecting risk groups is NP-hard [63], existing auditing systems either perform an exhaustive search, which scales poorly to large deployments, or use heuristics, which sacrifices accuracy. For instance, INDaaS [70] takes ∼35 hours to analyze a 30,528-component service. Such speeds cannot match the frequency of network and software updates in today's clouds—for instance, Google reported 58 network updates per week [37].

Lack of support for generating improvement plans. Existing systems offer no support for the operator to automatically generate improvement plans. As a result, even after performing hours-long audits, the operator still needs to reason about improvement plans if the current service snapshot does not meet her reliability requirements. Existing systems such as INDaaS [70] and reCloud [22] can compute deployment plans from scratch, but such plans may differ considerably from

Table 1: Key techniques in CloudCanary.

Objective	Key techniques	Section(s)
Reusing previous audit results	Caching + Cache refreshes	3.1 + 3.4
Avoiding full-blown Cartesian products	Reduction to DNF (Disjunctive Normal Form) conversion	3.1
Incremental auditing	Differential fault graphs	3.2
Efficient auditing	Reduction to minimum-cost SAT	3.3
Avoiding large-scale Markov chains	Reduction to model counting	4.2
Handling non-uniform probabilities	Adding virtual leaf nodes	4.2
Reducing the search space	Network compression + Search heuristics	4.3

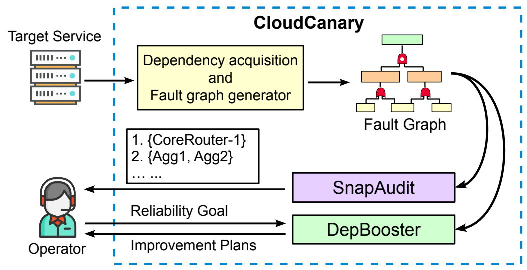

Figure 3: The workflow and architecture of CloudCanary with two novel primitives: SnapAudit and DepBooster.

the current snapshots and require non-trivial reconfiguration. Moreover, these systems are also inefficient to use in service runtime with high update frequency.

Therefore, although the two tasks can be performed with looser time constraints at service initialization, services with frequent updates demand better support for efficient audits and improvements in real time.

2.4 Our Approach: CloudCanary

We propose CloudCanary to achieve the above goals. Figure 3 shows CloudCanary's workflow. For a given service snapshot S, CloudCanary collects its dependency data and constructs a fault graph using existing dependency acquisition and fault graph generation modules [70]. The key innovation in CloudCanary is its two primitives SnapAudit and DepBooster. SnapAudit can extract risk groups from S, and DepBooster can generate improvement plans, both in a matter of minutes. Table 1 highlights the key techniques we have used and the objectives they are designed to achieve.

SnapAudit. To accelerate auditing, SnapAudit uses two insights. First, since service updates typically just affect a small subset of dependencies [37, 49, 60], there is no need to audit from scratch for each update. Rather, SnapAudit performs a complete fault graph analysis at service initialization, and aggressively reuses cached results to perform *incremental auditing* afterwards. Second, we use a novel encoding to reduce fault graph analysis to a *minimum cost Boolean Satisfiability (SAT) solving* problem, and leverage modern SAT solvers for fast auditing. This insight is driven by the fact that modern SAT solvers can solve complex Boolean formulas efficiently with accuracy guarantees.

DepBooster. The second primitive automatically generates improvement plans to meet a reliability goal, *e.g.*, the minimal risk group containing more than k elements, or the failure probability being lower than α. If naïvely done, assessing the failure probability requires solving a long Markov chain [63], and searching through all possible plans further exacerbates the inefficiency. We use a novel reduction to *model counting* to compute the failure probability, as well as a combination of *network compression* and *search heuristics* to reduce the search space.

3 The SnapAudit Design

This section details the design of SnapAudit that identifies the minimal risk groups in a given service snapshot. Figure 4 presents the key algorithms of SnapAudit: FirstAudit is only executed once at service initialization. IncAudit performs incremental auditing for the subsequent snapshots during service runtime. For a given service snapshot, the input of FirstAudit or IncAudit is a fault graph G representing its underlying dependency structure, and the output is Σ_G which contains the top-k *minimal* risk groups of G.

Minimal risk group. A risk group is *minimal* if the removal of any of its constituent elements makes it no longer a risk group. For instance, in Figure 2, there are two minimal risk groups: $\sigma_1 = \{\text{Core1}\}$ and $\sigma_2 = \{\text{Agg1} \wedge \text{Agg2}\}$. On the other hand, $\sigma_3 = \{\text{Agg1} \wedge \text{Core1}\}$ is also a risk group but is not a minimal risk group, because the failure of Core1 alone can cause the entire service to fail. Moreover, we can characterize a risk group's criticality by its cardinality, *e.g.*, σ_1 is more critical than σ_2 because $|\sigma_1| = 1 < |\sigma_2| = 2$—it takes two failures in σ_2 to take down the service but only a single failure in σ_1. The top-k risk groups of a given fault graph G are a ranked list of minimal risk groups by size or by failure probability. *e.g.*, $\Sigma_G = \{\sigma_1, \sigma_2\}$. Extracting minimal risk groups in a fault graph is NP-hard [63, 72].

3.1 The First Audit

At service initialization, we use FirstAudit to compute the risk groups from scratch. FirstAudit not only audits the overall fault graph G, but also *every subgraph* in G, thus enabling subsequent audits (performed by IncAudit) to reuse the results for these subgraphs. All audit results are recorded in a key-value cache Σ, where the key corresponds to a particular subgraph, and the value is its top-k minimal risk groups. FirstAudit builds a unique identifier for each subgraph by constructing a Merkle Hash Tree [53], and uses the root node's hash as the identifier of the entire subgraph. This allows for a

```
function FIRSTAUDIT($G$)
    if isleaf($G$) then
        $\Sigma_G \leftarrow \{G\}$
    for $c \in G.children$ do
        if $\Sigma_c = \emptyset$ then
            $\Sigma_c \leftarrow$ FIRSTAUDIT($c$)
    $\Sigma_G \leftarrow$ MERGE(G)
    return $\Sigma_G$
```

```
function MERGE($G$)
    $c_1, \cdots, c_k \leftarrow G.children$
    if $G.gate = AND$ then
        $\Sigma_G \leftarrow \text{DNF}(\Sigma_{c_1} \wedge \cdots \wedge \Sigma_{c_k})$
    else
        $\Sigma_G \leftarrow \text{DNF}(\Sigma_{c_1} \vee \cdots \vee \Sigma_{c_k})$
    return $\Sigma_G$
```

```
function INCAUDIT($G$)
    $\Pi \leftarrow$ GETBORDER($G$)
    for $t \in \Pi, t.children \notin \Pi$ do
        for $c \in t.children, \Sigma_c = \emptyset$ do
            $\Sigma_c \leftarrow$ MINCOSTSAT($c$)
    $\Sigma_G \leftarrow$ MERGEALL($G$)
    return $\Sigma_G$
```

```
function GETBORDER($G$)
    while $BFS(G)$ with $Q$ do
        $n \leftarrow Q.Pop()$
        if $\Sigma_n = \emptyset$ then
            if $c \in n.child, \Sigma_c \neq \emptyset$ then
                $L.append(n)$
            $Q.Push(n.children)$
    return $L$
```

Figure 4: The key functions in SNAPAUDIT: FIRSTAUDIT and MERGE (§3.1), INCAUDIT and GETBORDER (§3.2).

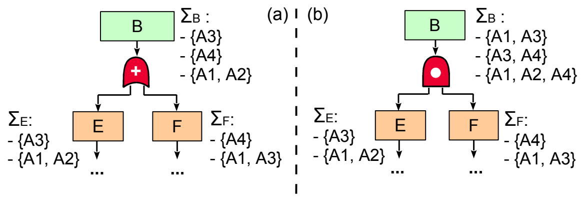

Figure 5: Merging risk groups for AND/OR gates.

more compact encoding of the subgraphs in the cache, given that the number of subgraphs in G is very large. For example, in Figure 5(a), the key of the subgraph rooted at B is $h(B) = h(h(E)||h(F))$, where h is a hash function and $||$ denotes concatenation. Indexing Σ by B's key would return $\Sigma_B = \{\{A3\}, \{A4\}, \{A1 \wedge A2\}\}$.

To generate Σ for both G and its subgraphs, a strawman solution is to directly call existing auditing systems such as INDaaS [70]. However, as discussed in §2.3, these systems are quite slow because their fault graph analysis algorithms scale poorly. Here, any inefficiency would be amplified several times over, because we are computing the minimal risk groups *for each subgraph* in G. To address this problem, we propose a completely different approach to computing the minimal risk groups, using high-performance Boolean formula translation toolchains such as Z3 [27] and Velev [62].

Overall, our FIRSTAUDIT algorithm starts with the leaf nodes, and recursively ascends to upper layers, until it reaches the root node of G. The base case for FIRSTAUDIT is to compute the minimal risk group list Σ_n for a leaf node n, where it simply returns $\Sigma_n = \{\{n\}\}$. In the inductive case, FIRSTAUDIT processes an intermediate node n with children $n_1, \cdots, n_k$ by calling MERGE on n and combining results for all its children. If n's children are connected by an OR gate, we have $\Sigma_n = \Sigma_{n_1} \cup \cdots \cup \Sigma_{n_k}$; otherwise, if n's children are connected by an AND gate we have $\Sigma_n = \Sigma_{n_1} \times \cdots \times \Sigma_{n_k}$, where $\times$ denotes Cartesian product. Figure 5 shows a concrete example.

Reduction to DNF conversion. A naïve MERGE over an AND gate requires a full-blown Cartesian product between risk groups, which leads to state explosion. If the size of each Σ_{n_i} is $|\Sigma|$, merging k of them would result in a set of size $|\Sigma|^k$; after s merges, the size would further grow to $|\Sigma|^{ks}$. To solve this problem, our insight is that MERGE can be achieved by a DNF (Disjunctive Normal Form) conversion, which can be efficiently computed using modern solvers [27]. A Boolean formula is in DNF if it is a disjunction of conjunctive clauses.

Consider the case shown in Figure 5(b), where we have $\Sigma_E = \{\{A3\}, \{A1 \wedge A2\}\}$ and $\Sigma_F = \{\{A4\}, \{A1 \wedge A3\}\}$. We need to compute $\Sigma_B = \Sigma_E \times \Sigma_F$, which can be transformed to a Boolean formula: $\phi = \Sigma_E \wedge \Sigma_F = ((A1 \wedge A2) \vee A3) \wedge ((A1 \wedge A3) \vee A4)$. By using Z3, we can quickly compute the DNF of ϕ, getting $(A1 \wedge A3) \vee (A1 \wedge A2 \wedge A4) \vee (A3 \wedge A4)$. As a result, Σ_B contains three minimal risk groups: $\{A1, A3\}$, $\{A3, A4\}$, and $\{A1, A2, A4\}$. Note that only DNF transformation can output all the minimal risk groups within one-run, and other solvers, *e.g.*, MinCostSAT, do not support such a capability.

3.2 Subsequent Audits

All subsequent audits are performed using INCAUDIT, which reuses the results in Σ generated by FIRSTAUDIT. As shown in Figure 4, INCAUDIT has three steps: GETBORDER, MINCOSTSAT, and MERGEALL. Given a fault graph G, INCAUDIT first uses GETBORDER to identify the differential fault graphs, and then invokes MINCOSTSAT to extract risk groups from each differential fault graph. Finally, INCAUDIT uses MERGEALL to merge the results for the differential fault graphs and those for the unchanged subgraphs, getting the final result Σ_G (*i.e.*, G's minimal risk groups).

GETBORDER. This step identifies a set of special *border nodes* that delineates the changed and unchanged portions of the fault graph. Concretely, a node n with children $n_1, \cdots, n_k$ is called a border node if a) at least one of $n_1 - n_k$'s key has a hit in Σ (*i.e.*, $\Sigma_{n_i} \neq \emptyset$), and b) at least one of them has a miss in Σ (*i.e.*, $\Sigma_{n_j} = \emptyset$). If all n's children have been previously audited, or none of them has been audited, then n is not a border node. For instance, in Figure 6, A and B are border nodes, but C–F are not.

To identify border nodes, we traverse G in a breadth-first order from the root. For each traversed node n, we check whether n has a hit in Σ. If n has a hit, we can reuse its result because 1) n is not a border node, and 2) n's subgraph has not changed. If n misses in Σ (*e.g.*, A in Figure 6), we check its children. If any of n's children has a hit in Σ (*e.g.*, D in Figure 6), we record n as a border node, and recurse and process n's children in order to find more border nodes.

We then extract *differential fault graphs* based on the border nodes and analyze such subgraphs from scratch, starting from the *bottom border node*. A node is a bottom border node if a) it is a border node, and b) none of its subgraphs contains

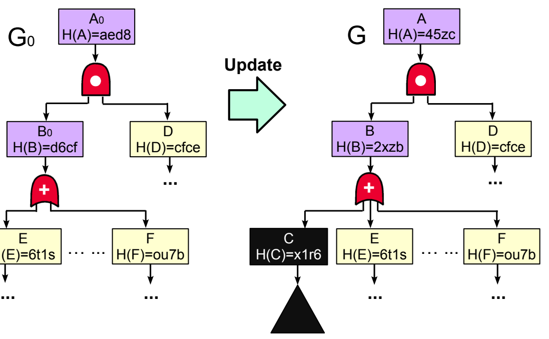

Figure 6: A service update where a subgraph C is added to the fault graph; this changes the keys for subgraphs rooted at A and B. In the updated fault graph, A and B are border nodes, B is the bottom border node, and D–F are unchanged. The subgraph rooted at C is a differential fault graph, which we invoke MINCOSTSAT on to obtain Σ_C. The results for Σ_D, Σ_E, and Σ_F have already been cached in Σ.

more border nodes. For example, in Figure 6, the only bottom border node is B; A is a border node, but not a bottom border node. We identify the bottom border nodes' children who miss in Σ (*e.g.*, C in Figure 6) as the roots of differential fault graphs, and analyze such subgraphs from scratch.

MINCOSTSAT. To analyze a differential fault graph, G_Δ, from scratch, a straightforward approach is to directly invoke FIRSTAUDIT. However, unlike the first audit at service initialization, which could be performed at leisure, INCAUDIT is frequently invoked during service runtime; thus, efficiency is much more critical. Thus, rather than audit all subgraphs in G_Δ, we only audit G_Δ itself. We achieve this by reducing this single audit to a *minimum-cost SAT* problem, which can be efficiently solved using modern SAT solvers. This step is denoted by MINCOSTSAT. For example, in Figure 6, because the subgraph rooted at C is a differential fault graph, we invoke MINCOSTSAT to compute its minimal risk groups, *i.e.*, Σ_C. We detail this MINCOSTSAT reduction in §3.3.

MERGEALL. After we use MINCOSTSAT to compute the risk groups for all differential fault graphs, we need to recompute the risk groups of G. Our insight is that we already have results for the siblings of these differential fault graphs (*e.g.*, D, E, and F in Figure 6), and we could directly use the DNF conversion in MERGE (§3.1), to obtain the risk groups for the entire G. Specifically, we generate a Boolean formula ϕ by only combining all the border nodes' children using their respective logic gates. Then, we transform ϕ into DNF, obtaining Σ_G. For example, in Figure 6, we first generate $\phi = (\Sigma_C \vee \Sigma_E \vee \Sigma_F) \wedge \Sigma_D$, and then transform it into DNF, getting the recomputed Σ_A.

3.3 The MinCostSat Solving

We now detail the design of MinCostSAT function, which can efficiently and accurately extract minimal risk groups from a given fault graph.

At a high level, a minimum-cost SAT problem [35] takes as input a Boolean formula ϕ with n Boolean variables $b_1, b_2, \ldots, b_n$, and a cost vector $\{w_i | w_i \geq 0, 1 \leq i \leq n\}$. The goal is to find a satisfying assignment to these variables such that ϕ evaluates to `True`, and simultaneously minimizing the following value: $W = \sum_{i=1}^{n} w_i b_i$.

We design the MINCOSTSAT function to compute the top-k risk groups. Initially, we transform an input fault graph into a Boolean formula ϕ, and initialize the cost of all the Boolean variables to one. For example in Figure 7, the fault graph at the left-hand can be transformed into (Agg1 $\vee$ Core1) $\wedge$ (Core1 $\vee$ Agg2). We then use a MinCostSAT solver to find the top-k critical risk groups through k rounds. Without loss of generality, for the i-th round, we identify the i-th smallest risk group in three steps: 1) we input the current formula ϕ_i and its cost vector into the MinCostSAT solver to generate the satisfying assignment with the minimal cost, 2) we obtain a risk group by extracting all the `True` literals from the resulting assignment, denoted as ψ. and 3) we use a conjunction to connect the current ϕ_i and the negation of ψ, generating a new $\phi_{i+1} = \phi_i \wedge \neg\psi$ for the next round.

3.4 Further Speedups

Since SNAPAUDIT heavily relies on the cache Σ for efficient audits, we propose two additional techniques to achieve further speedups. First, the results obtained during INCAUDIT can also be cached in Σ, so that Σ would grow over the service lifetime and the hit rate would improve. Second, INCAUDIT does not audit the subgraphs of a G_Δ, but the subgraphs may be needed for subsequent audits. We therefore run a background process that periodically invokes FIRSTAUDIT over the more recent snapshot to refresh the cache. However, we have omitted these techniques from the pseudocode for brevity.

4 The DEPBOOSTER Design

Identifying risk groups is a useful first step, but the operator still needs to reason about ways to increase the service reliability. Rather than ask the operator to achieve this manually, CloudCanary offers a second primitive, DEPBOOSTER, to generate improvement plans in an automated fashion.

4.1 The DEPBOOSTER Workflow

DEPBOOSTER offers the operator an interface to specify "reliability goals", and assesses if the current deployment meets the goals. If not, DEPBOOSTER generates improvement plans with increased reliability. These goals are specified as $spec = req \wedge action \wedge cons$. req is a requirement parameter. It can be a) $rcg > t$, which means the smallest risk groups in the deployment should contain more than t elements, b) $fp < \alpha$, which means the failure probability should be lower than some threshold α, or c) a combination of both. While DEPBOOSTER currently only supports constraints like failure probability and the size of risk groups, more constraints, *e.g.*, key paths, are easily added.

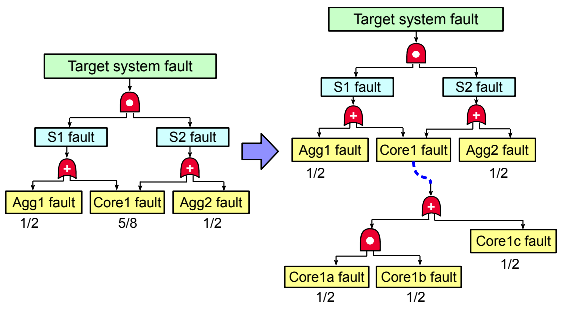

Figure 7: Transforming G by adding virtual leaf nodes.

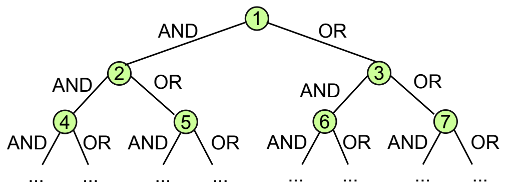

Figure 8: DEPBOOSTER searches through combinations of AND/OR gates to approximate a given probability.

DEPBOOSTER first assesses whether $rcg > t$ and $fp < \alpha$ already hold on the current snapshot. (Computing whether $rcg > t$ is achieved using SNAPAUDIT, which we described in §3; we defer the algorithm for computing whether $fp < \alpha$ to §4.2.) If both predicates hold, DEPBOOSTER reports so and terminates. Otherwise, it uses the strategies in *action* and the constraints in *cons* to generate improvement plans. *action* specifies an extensible set of basic actions to generate improvement plans with. Currently, DEPBOOSTER supports 1) `mov{r, A`$\rightarrow$`B}`, which moves a service replica `r` from a node `A` to another node `B`; 2) `add{r, A}`, which instantiates an additional replica `r` on node `A`; and 3) `link{A, B}`, which adds a network link between network components A and B. DEPBOOSTER then performs a search for improvement plans based on the basic actions. *cons* contains positive and negative constraints which specify that certain components must or must not be used in an improvement plan.

Example. We now provide a concrete example based on the scenario in Figure 1. Here, the operator provides DEPBOOSTER with a goal: $spec = \{rcg > 1 \wedge fp < 0.08\} \wedge \{mov\} \wedge \{Agg3\}$, which specifies that a) the smallest risk groups should contain more than one elements, and b) the failure probability should be lower than 0.08. If the current snapshot does not meet either of these two goals, DEPBOOSTER will generate a set of improvement plans. Moreover, the *spec* requires DEPBOOSTER to generate improvement plans by only moving replicated instances from the current replica servers to other servers. Finally, any improvement plan must still use the switch Agg3, as specified in *cons*. For this specification, DEPBOOSTER has generated two potential plans: a) `mov{CinderDB, S1->S4}`, and b) `mov{CinderDB, S2->S4}`. In other words, if we migrate the Cinder DB instance on S1 or S2 to S4, then new deployment would meet the desired goals.

4.2 Computing Failure Probability

We now describe how DEPBOOSTER computes the failure probability of a service snapshot. A strawman solution would be to derive the failure probability of the root node from these of the leaf nodes step by step, which is equivalent to computing the conditional probability of a Markov chain [63]. As we will show later, this is a time-consuming operation over large deployments, infeasible to be performed in real time. Instead, DEPBOOSTER uses two techniques to address this.

Technique #1: Model counters. DEPBOOSTER sidesteps the need for Markov chain computation by encoding this into a *model counting* problem. Suppose that the Boolean formula of the fault graph G is ϕ. A model counter [20] can find M—the number of satisfying assignments of ϕ. Assuming for now that all leaf nodes have a failure probability of exactly $\frac{1}{2}$, then the failure probability of G is simply $M/2^n$, where n is the number of leaf nodes in G. Since model counting does *not* need to compute the solutions themselves, but only the number of satisfying assignments, this is much more efficient than solving a Markov chain.

Technique #2: Virtual leaf nodes. However, another challenge arises: in practice, not all leaf nodes have the same failure probability, and such a probability is typically much lower than $\frac{1}{2}$. We address this by adding "virtual nodes" in the fault graph and reducing the problem again into the plain version of model counting. At a high level, we achieve this by substituting a node with failure probability of p with a subtree of virtual nodes, where all virtual nodes have a failure probability of $\frac{1}{2}$, and the failure probability of the entire virtual subtree evaluates to p with a user-defined precision ε. For instance, in the example shown in Figure 7, our goal would be to transform the node with $p = \frac{5}{8}$ (*i.e.*, `Core1 fault`) into a virtual subtree.

Figure 8 shows the solution space that DEPBOOSTER searches through to find a combination of gates that approximates a given failure probability. At any point in the search, the path from the root to a node n represents the current combination of gates. These gates further connect virtual nodes of failure probability $\frac{1}{2}$ (not shown in the figure). For instance, the path from the root to node 5 consists of an `AND` gate and then an `OR` gate, so the formula would be `(v1 AND v2) OR v3`, where `v1-v3` are virtual nodes with a failure probability of $\frac{1}{2}$. The failure probability of n_5 can then be computed as $p(n_5) = ((\frac{1}{2} \times \frac{1}{2}) + \frac{1}{2}) - (\frac{1}{2} \times \frac{1}{2}) \times \frac{1}{2} = \frac{5}{8}$. Our algorithm performs a BFS over the solution space, and constructs a combination of gates based on the path from the root to the current node. If $|p(n_j) - p| < \varepsilon$ holds for the current node, the search stops and we use the current combination to approximate a given probability. This transformation converts the fault graph G to a larger fault graph G' with (roughly) the same

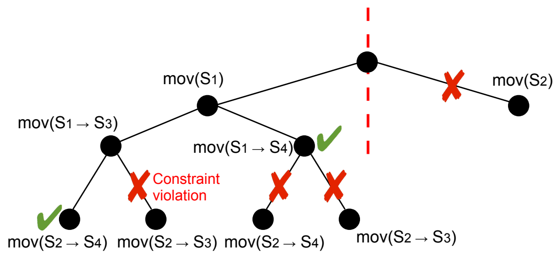

Figure 9: An example state-space tree.

failure probability that can be solved by model counters—*i.e.*, $p = M'/2^{n'}$, where M' is the model counter output for G' and n' is the number of leaf nodes in G'.

4.3 The DepBooster Algorithm

If the current deployment already meets the reliability goals, DepBooster directly terminates. Otherwise, it generates improvement plans by searching through a state-space tree. Each node in this tree represents one concrete move in *action*, and a path from the root to a leaf represents an improvement plan. Since there could be a large number of possible improvement plans, DepBooster uses two techniques to accelerate the search. Below, we use Figure 9 as an example to illustrate how DepBooster generates improvement plans for our running example in §4.1.

Technique #3: Network compression. We use the observation that datacenter network topologies tend to be highly symmetric, and can be "simplified" to equivalent topologies much smaller in size [17]. This enables DepBooster to perform the search on the smaller networks, and then map the solution back onto the original topologies. Driven by this observation, DepBooster transforms the input network topology D to a simplified topology d while preserving its original connectivity and reachability. Briefly, this is achieved by collapsing symmetric network structures (*i.e.*, routers and paths) and slicing away irrelevant structures. For instance, Figure 9 shows how the symmetric branch at S_2 has been pruned. We refer interested readers to the original paper [17] for proofs.

Technique #4: Iterative deepening. DepBooster then generates the state-space tree T_d based on the simplified topology d. It never materializes T_d in its entirety, but only explores it step by step. Concretely, DepBooster performs an Iterative Deepening Depth-First Search (IDDFS) [46] on T_d starting from the root. For each traversed node n, DepBooster checks whether n or any of n's children violates the specified constraints. If any constraint is violated, then the corresponding branches are pruned. For example, in Figure 9, the branch `mov(S2 -> S3)` under `mov(S1 -> S3)` is pruned because moving Cinder DB instances on S1 and S2 to S3 violates the constraint that Agg3 must be used in the new deployment. For the remaining nodes, DepBooster runs IncAudit and the failure probability computation approach (designed in §4.2) to check whether the size of risk groups and failure probability meet the specified goals. For instance, in Figure 9, we do not need to check any branches below the state `mov(S1 -> S4)`, since moving the Cinder DB instance on S1 to S4 has already satisfied the specified goals.

DepBooster can be configured to a) produce improvement plans with the smallest number of actions, b) find the first t improvement plans, and c) run until a timeout occurs. In the running example, we have used b) to find four improvement plans: 1) `mov{CinderDB, S1->S4}`, 2) `mov{CinderDB, S2->S4}`, 3) `mov{CinderDB, S1->S3}`, `mov{CinderDB, S2->S4}`, and 4) `mov{CinderDB, S2->S3}`, `mov{CinderDB, S1->S4}`. The first two plans correspond to those shown in §4.1.

5 Limitations and Discussions

We discuss three high-level limitations of CloudCanary and potential ways to address them.

Quality of inputs. CloudCanary takes two types of inputs as given: a) dependencies, and b) failure probabilities; so it would be limited by the accuracy of the inputs (see §6.5 for a concrete example). For instance, an operator might not know that two upstream ISPs share the same undersea fiber, and that a fiber cut would bring down both networks; or an operator's estimate of the failure probabilities might not be perfectly accurate. In such cases, CloudCanary cannot automatically identify these inaccuracies. However, CloudCanary can benefit from advances in dependency collection systems or failure estimation algorithms: enhancement to CloudCanary's inputs always leads to improved utility.

Dependency granularity. CloudCanary is also limited by the dependency granularity of its data acquisition system; it currently cannot reason about more fine-grained dependencies such as configuration files. If a misconfigured component handles two upper-layer services differently, the current version of CloudCanary would not be able to identify that. This is somewhat akin to the previous limitation, and could benefit from a similar solution—*e.g.*, enhancing the fault graphs to capture configuration files.

Non-deterministic failures. The logic gates in CloudCanary's fault graph are deterministic, which assumes that if two services depend on a common component, the failure of the component would affect both services. This assumption does not capture well non-deterministic and/or partial failures, *e.g.*, when a bit flip in switch TCAM only affects a subset of services but not others. Modeling such behaviors might require extensions to the fault graph abstraction, which we leave as future work.

6 Evaluation

Our evaluation aims to answer three high-level questions: (1) How efficient and accurate is CloudCanary in identifying the risk groups? (2) How quickly can CloudCanary generate improvement plans? and (3) How well can CloudCanary shed light on failure risks in real-world traces?

Table 2: The configuration of our deployments.

	Deploy. A	Deploy. B	Deploy. C
# Switch ports	24	64	128
# Core routers	144	1,024	4,096
# Agg switches	288	2,048	8,192
# ToR switches	288	2,048	8,192
# Virtual machines	3,456	65,536	524,288
# Libraries/Microservices	4,492	79,824	638,592
Total # of components	8,668	150,480	1,183,360

Prototype implementation. We have developed a CloudCanary prototype using a mix of C++, Python, and open-source software libraries. Our system consists of three components: a) fault graph generator, b) SnapAudit, and c) DepBooster. The fault graph generator uses NSDMiner [56] and TS [24] to acquire network and software dependency data, and uses INDaaS [70] to parse and generate fault graphs. Our SnapAudit prototype uses a) a high-performance MinCostSAT solver, Maxino [6], for solving the Boolean formulas that encode the fault graphs, b) the Z3 solver [27] for DNF conversion, and c) a fault graph parser based on pyeda [7] to optimize the encoding and transformation of formulas. Our DepBooster prototype uses a scalable open-source SAT model counter, ApproxMC [2], to compute failure probabilities.

6.1 Experimental Setup

We have emulated a datacenter network with a Clos topology [59], and installed Apache Hadoop 3.2.0 and ZooKeeper 3.4.0 as the cloud services. In the performance experiments, we varied the service size from 8,668 to 1,183,360 software and network components using up to 524 k virtual machines, as shown in Table 2. We also used a real failure probability distribution trace for network devices in our experiments. All machines have an Intel Xeon E5-1620 v2 Quad Core HT 3.7 GHz CPU and 16 GB memory.

Baseline systems. Table 3 presents the three state-of-the-art auditing systems that we have used as the baseline to compare CloudCanary against. Among these systems, INDaaS [70] is more accurate than RepAudit [71] and reCloud [22], but the latter two are faster. This is because the minimal risk group algorithm in INDaaS relies on an exhaustive search, which can produce 100% accurate results but scales poorly. RepAudit and reCloud trade accuracy for efficiency: the former uses a simple MaxSAT solving that cannot guarantee that the identified risk groups are minimal[1], and the latter uses sampling for approximation, which may miss risk groups. Furthermore, we have included a fourth baseline that we call ProbINDaaS [70], which is a randomized version of INDaaS that also relies on sampling for efficiency. We note that reCloud uses a more advanced sampling algorithm (*i.e.*, dagger sampling) than ProbINDaaS (*i.e.*, Monte Carlo), and that reCloud can additionally provide the ability to generate a deployment from scratch to meet a reliability goal. Unlike all these baseline systems, CloudCanary can generate *improvement plans* based on the current deployment, and it performs *incremental auditing while preserving accuracy*. As shown later, CloudCanary achieves 100% accuracy while outperforming all baselines.

[1]MaxSAT solving means: given an SAT formula with weight one to each clause, find truth values for its variables that maximize the combined weight of the satisfied clauses.

Table 3: All evaluated systems and their comparisons.

System	Accurate?	Efficient?	Imp. Plans?
INDaaS [70]	✓	×	×
ProbINDaaS [70]	×	✓✗	×
reCloud [22]	×	✓✗	×
RepAudit [71]	✓✗	✓✗	×
CloudCanary	✓	✓	✓

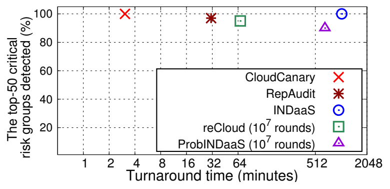
6.2 Performance: SnapAudit

We start by evaluating the performance of SnapAudit using the deployments in Table 2 (A: small, B: medium, C: large). For each deployment, we measured a) the time each system took to audit the service from scratch, and b) the time to audit an updated snapshot when 10% of the hosts and links have been affected. All audits asked for top-50 risk groups.

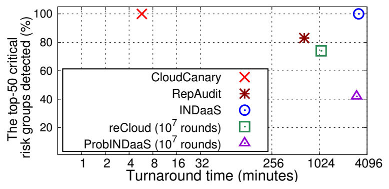
Efficiency. At service initiation, we observe that INDaaS is the slowest, taking up to $\sim$5811 minutes on the largest deployment. The two probabilistic approaches ProbINDaaS and reCloud (both with 10^7 sampling rounds) also perform poorly due to the large search space. RepAudit outperforms other baselines and is slightly ($\sim$1.3$\times$) faster than SnapAudit's FirstAudit. However, this is expected, because RepAudit only audits the overall fault graph, whereas FirstAudit audits *both* the overall fault graph *and* its subgraphs to create reusable results for subsequent audits.

We then updated the three deployments by randomly adding or removing 10% hosts and links, and ran the four auditing systems on the resulting deployments A′–C′. Figure 10 shows the turnaround time (X-axis) versus audit accuracy (Y-axis). As we can see, SnapAudit's IncAudit consistently outperforms INDaaS, ProbINDaas, reCloud, and RepAudit for all subsequent audits. On deployment B, IncAudit is faster than the second fastest system RepAudit by 200$\times$.

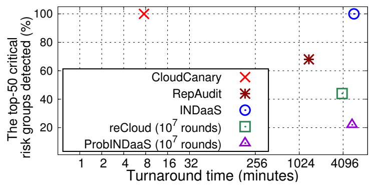
Accuracy. Moreover, SnapAudit always has an accuracy of 100% across deployments—the same with INDaaS—but RepAudit only has 96%, 83%, and 68% in deployment A'–C', respectively. ProbINDaaS and reCloud are even less accurate. Here, an inaccurate audit in RepAudit, reCloud, and ProbINDaaS means that a) some risk groups are missing from the output, and b) some risk groups generated by these systems are not minimal. For instance, SnapAudit outputs $\Sigma = \{\{A\},\{B\},\{C,D\}\}$ as the top-3 risk groups. An inaccurate system, however, may output $\Sigma' = \{\{A,E\},\{C,D,E\},\{C,D,F\}\}$, where $\{B\}$ is missing and the rest of the risk groups are not minimal. Therefore, even a low inaccuracy rate (*e.g.*, 100%−96%=4%) means that human operators need to *manually* inspect the results to identify re-



(a) Deployment A'.



(b) Deployment B'.



(c) Deployment C'.

Figure 10: Performance evaluation of CloudCanary, INDaaS, reCloud (with 10^7 rounds of sampling) and ProbINDaaS (with 10^7 rounds of sampling), and RepAudit in one of the update snapshots.

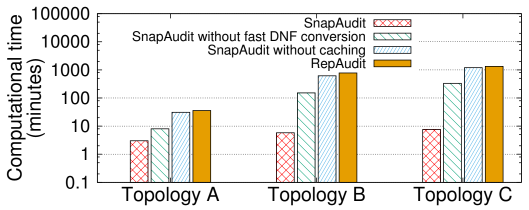


Figure 11: SnapAudit microbenchmarks.

dundancy and reason about the possibility of unidentified risk groups—a task that is time-consuming to perform at runtime.

Microbenchmarks. To further understand the performance improvements of the incremental auditing algorithm in SnapAudit, we have performed a set of microbenchmarks to break down the speedups. We used RepAudit as the baseline, as it performs faster than other systems and is closest to SnapAudit in its use of SAT solvers. For each of the deployments A'–C', we measured the execution times for four scenarios: a) SnapAudit with all optimizations turned on, b) SnapAudit without the fast DNF conversion, c) SnapAudit further without caching previous results, and d) RepAudit. Figure 11 shows that, without any optimization, SnapAudit performs very similarly with RepAudit; the slight speedup comes from the differences in the SAT formulations. The fast DNF conversion led to speedups of $2\times$–$40\times$, and reusing cached results led to speedups of $4\times$–$8\times$. These results demonstrate that the optimization techniques in SnapAudit can significantly accelerate incremental auditing.

Degrees of update. A third observation is that the time INDaaS, ProbINDaas, reCloud, and RepAudit took on each subsequent audit is roughly the same with that on their first audits, because they perform each audit from scratch. SnapAudit's IncAudit, on the other hand, is significantly faster on subsequent audits than its first audit.

To further evaluate how the degree of updates affects the auditing time of SnapAudit, we tested updates that affect 10%–50% of the components in deployment C, and used SnapAudit to audit these five updates. As shown in Figure 12, the turnaround time of CloudCanary increases roughly linearly with the update percentage. This is good news, because a complete overhaul of a deployed service is rare. Most updates only affect a small part of the service, and they can reap the benefits of CloudCanary easily. On the contrary, since RepAudit never used any incremental algorithm, the RepAudit performance in Figure 10 reflects the update that affects the majority of the deployment.

6.3 Performance: DepBooster

We now evaluate the performance of DepBooster for computing failure probabilities and generating improvement plans. For the first task, our baseline systems are INDaaS and RepAudit, both of which solve a Markov chain to obtain the probability. For the second task, our baseline systems are reCloud and RepAudit, although they are not designed to generate improvement plans directly.

Failure probability computation. Figure 13 shows the time DepBooster, reCloud (with 10^7 sampling rounds) and the baseline system (Markov chain computation) took to compute the failure probability of each deployment. For DepBooster, we set the precision per leaf node to be 10^{-4} (defined in §4.2) when adding virtual leaf nodes. As shown in Figure 13, DepBooster achieves a speedup of two to three orders of magnitude compared to reCloud and the baseline. On the largest deployment, DepBooster only took 2.5 minutes, whereas the baseline and reCloud took more than 10 hours. In terms of the failure probability precision, we found that DepBooster approximates the probability of the baseline system (which does not use any approximation) with an error of 10^{-3} for all tested deployments, whereas the error in reCloud is 10^{-2} for all tested deployments.

Improvement plan generation. Next, we evaluate the performance of DepBooster, using reCloud as the baseline. Each deployment hosted the service instances on 50% of the servers, and the query asked for improvement plans to reduce the failure probability to under 0.008 using the `mov` strategy. Figure 14 shows the results. We can see that DepBooster finished within 30 minutes across deployments, and outperforms reCloud and RepAudit by at least one order of magnitude. DepBooster can do better for two reasons. First, the model counter-based failure probability computation (§4.2) speeds up the result checking for each candidate solution. In fact, Figure 13 can also be looked as the microbenchmark evaluation for DepBooster, because the bottleneck operation of DepBooster is failure probability computation. Second, the pruning technique (§4.3) reduces the number of solutions searched; thus, we can observe few failure probability computations are needed.

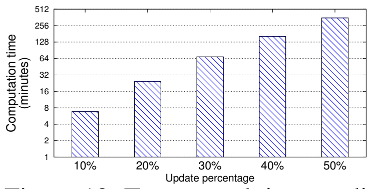

Figure 12: Turnaround time on different degrees of update.

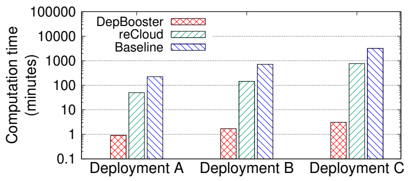

Figure 13: Performance: computing failure probability.

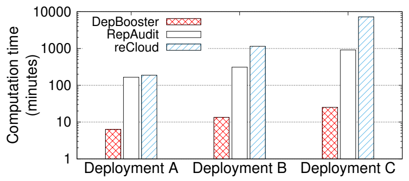

Figure 14: Performance: generating improvement plans.

6.4 Case Study

To better understand how the auditing (in)efficiency affects real-time updates, we have performed a case study that emulates a series of network and software updates. They consisted of 52 updates over the span of one week—we collected the update frequency and distribution from a large-scale cloud provider. We adapted six of these updates from realistic update scenarios [37, 48, 57] and from the Apache issue tracker [13]. All other updates were randomly generated and each of them affected 10% nodes in the deployment. This set of experiments was conducted over a deployment with 576 64-port core routers, 1,152 64-port aggregation switches, 1,152 64-port top-of-rack switches, and 27,648 servers.

Figure 15 shows the results for the first six updates, which we adapted from existing work.

- **Snapshot S0.** At service initialization, the operator set up the entire service, and performed an audit from scratch using the four auditing systems.
- **Snapshot S1: Small updates [48].** The first update changed 1% of network links.
- **Snapshot S2: Large updates [57].** The second update changed 20% servers and 20% links based on a network update trace, and it is designed as "pressure test".
- **Snapshots S3 and S4: Frequent updates [37].** The subsequent two updates occurred within a short interval of seven hours, designed as another pressure test.
- **Snapshots S5 and S6: Software version updates.** The final two updates were to software dependencies, where ZooKeeper was updated from version 3.4.0 to 3.4.6, and then to 3.4.8. They were designed to test the systems' ability to identify software-level risk groups.

Identifying risk groups. Figure 15 shows that existing systems are too inefficient for real-time auditing. INDaaS was only able to finish the auditing for S0 (at service initialization) and S6, but failed for all other updates, because its turnaround time exceeded the intervals between them. RepAudit and reCloud took roughly eight and sixteen hours per snapshot, and they finished S0, S2, and S6, which happened to be spaced out from their previous updates by more than sixteen hours, But they failed to finish for S3–S5, which came close to each other. Recall that, as explained in §6.2, RepAudit and reCloud achieve this speedup by trading accuracy for efficiency, so operators still need to manually reason about missing and non-minimal risk groups after audits.

CloudCanary achieves 100% accuracy in all tested cases, outputting the same results with INDaaS on scenarios where INDaaS was able to finish. However, for each real-time audit, it only took 4.7–6.5 minutes, outperforming INDaaS by 290×, reCloud by 250×, and RepAudit by 150×–200×. The only case where CloudCanary was slightly slower than RepAudit was at service initialization—when auditing S0, CloudCanary needs to audit *all subgraphs* in the fault graph from scratch.

Generating improvement plans. We then ran DEPBOOSTER to generate improvement plans for each snapshot. Since the strategies in CloudCanary do not involve changes to software components, we only evaluated S0–S4, where the reliability can be improved using CloudCanary's `mov` strategy. Our reliability goal was specified as $spec = \{rcg > 5 \wedge fp < 0.008\} \wedge \{mov\}$, and we assigned the failure probability of each switch or server to be 0.002 [36]. For S0–S4, CloudCanary generated improvement plans in 4.87, 2.32, 5.77, 7.12 and 6.29 minutes, respectively. In all cases, CloudCanary finished well before the next update arrived. Furthermore, in order to test the effectiveness of our improvement, we injected errors via a chaos-monkey-like way, randomly killing four components, because our constraints set $rcg > 5$. We observed that the improved deployments never failed.

Overall success rates: We now report results for all 52 update snapshots. Our metric is the *success rate* of a system, defined as $r = \frac{m}{n}$, where m is the number of updates for which the system finished on time, and n is the total number of updates. In other words, $m - n$ is the number of updates that cannot be handled due to an audit system's high turnaround time. Overall, INDaaS failed on almost all cases ($r = 1.92\%$) due to its inefficiency. reCloud and RepAudit are faster, but still only had a success rate of 3.85%. CloudCanary, on the other hand, achieved a success rate of 100%, finishing all audits with an average turnaround time of 5.23 minutes.

6.5 Identifying Real Risk Groups

Finally, we evaluate the usability of CloudCanary using a real-world update trace collected from a major service provider. The trace contains 300+ updates to its infrastructure, including software microservices, power sources, and network switches. The operators that executed these updates have already been trained with best practices for service reliability, but systematically understanding service dependencies is always a challenging task. For each update in this trace, we have used CloudCanary to identify the top-5 risk groups, and obtained

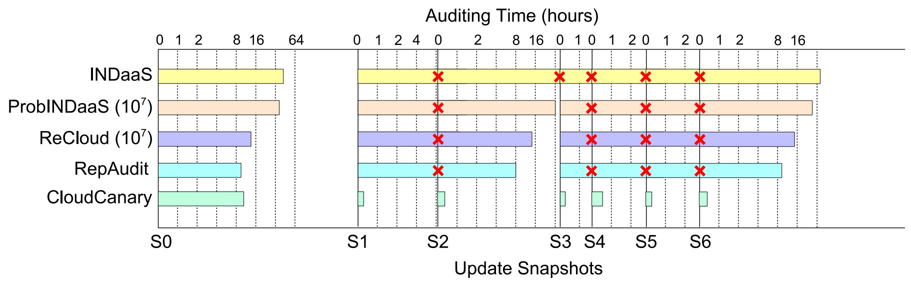

Figure 15: Results on a deployment running Hadoop 3.2.0 and ZooKeeper 3.4.0 in a Clos-topology datacenter with 27,648 hosts and 880 routers. S_i are service updates, which potentially lead to new risk groups.

feedback from the operators. Upon their request, the numbers below are presented as 50+, 10+, and so on, by rounding off their last digits. A key highlight here is that operators have confirmed that 50%+ of these risk groups were previously unknown to them, and that some of them actually caused service downtime in the past.

Microservices. We found 50+ risk groups in the microservice updates. The operators have confirmed that 96% of them could lead to correlated failures; the rest 4% are due to false positives of the dependency collection tool (see §5 for discussion on quality of inputs). One particularly risky example from the operators' feedback is an update that routes all requests to the same authentication service on a single machine. If this machine fails, this would lead to a major outage. The operators can fix this risk group by replicating the authentication service across multiple machines.

Power sources. We found 10+ risk groups in the power sources. Operators have confirmed that all of them could lead to correlated failures, and, in fact, 30%+ of them did trigger service downtime in the past. As a highlight, one of the updates assigned primary and backup power sources in the same cluster to serve several racks hosting a critical service. The cloud provider had experienced multiple hours of downtime due to a failure of these power sources.

Network. CloudCanary reported 30+ risk groups, including ToR/aggregation switches and shared fiber, all of which have been confirmed by the operators. As an example, we found that multiple data centers in the same city shared the same fiber bundles, which presents a risk of correlated failures. These risks can be prevented by adding redundant fiber bundles across different cities.

7 Related Work

Structural reliability auditing. The most relevant to CloudCanary are structural reliability auditing systems, INDaaS [70], reCloud [22], and RepAudit [71], which can construct fault graphs from dependency data and perform audits to prevent correlated failures. INDaaS and CloudCanary have higher accuracy than RepAudit and reCloud, because the latter two use approximate algorithms to trade accuracy for efficiency. Moreover, different from all existing work, CloudCanary is designed to perform *incremental auditing* over service updates.

Network/System verification. Failure prevention can also be achieved by formal analysis, such as configuration verification [16, 19, 31, 32, 50, 55, 60, 68], and synthesis/repair [29, 30, 48, 52, 65]. Some of these systems also use incremental verification for speedup when performing analysis [40, 43, 44]. Compared to these systems, CloudCanary has a very different goal—it aims at preventing correlated failures resulting from common dependencies—and also involves completely different algorithms as a result. On the contrary, network verification and synthesis systems primarily focus on reachability and performance properties, such as host-to-host connectivity. Similarly, software misconfiguration detection tools like PCheck [67] also focused on configuration logic, rather than failures caused by common dependencies.

Post-failure diagnostics. Many diagnostic systems [14, 15, 21, 23, 26, 28, 41, 42, 45, 56, 58] and provenance systems [66, 76, 77] have been proposed for failure troubleshooting. CloudCanary aims at a different goal from these efforts.

8 Conclusion

We have presented CloudCanary, a system that can perform real-time audits to prevent correlated failures in service updates. Our system can compute the risk groups in a service snapshot using cached results from previous audits, and it can generate improvement plans with increased reliability. It achieves this using a set of novel techniques, such as incremental auditing and network pruning. CloudCanary outperforms state-of-the-art systems by 200× and can generate improvement plans for large deployments within several minutes. Moreover, it can yield valuable insights over real-world traces from production environments.

Gryff: Unifying Consensus and Shared Registers

Matthew Burke

Princeton University

Wyatt Lloyd
Princeton University

Abstract

Linearizability reduces the complexity of building correct applications. However, there is a tradeoff between using linearizability for geo-replicated storage and low tail latency. Traditional approaches use consensus to implement linearizable replicated state machines, but consensus is inefficient for workloads composed mostly of reads and writes.

We present the design, implementation, and evaluation of Gryff, a system that offers linearizability and low tail latency by unifying consensus with shared registers. Gryff introduces carstamps to correctly order reads and writes without incurring unnecessary constraints that are required when ordering stronger synchronization primitives. Our evaluation shows that Gryff's combination of an optimized shared register protocol with EPaxos allows it to provide lower service-level latency than EPaxos or MultiPaxos due to its much lower tail latency for reads.

1 Introduction

Large-scale web applications rely on replication to provide fault-tolerant storage. Increasingly, developers are turning to linearizable [32] storage systems because they reduce the complexity of implementing correct applications [2, 13, 17]. Recent systems from both academia [27, 35, 40, 52, 53, 57] and industry [6, 11, 14, 17, 23] demonstrate this trend.

Traditionally, linearizable storage systems for geo-replicated settings are built using state machine replication via consensus [33, 36, 37, 38, 45, 47, 50, 51]. These protocols are safe under the asynchronous network conditions that are common in wide-area networks. Furthermore, they provide the abstraction of a shared command log, which allows for the implementation of arbitrary deterministic state machines. Strong synchronization primitives, such as read-modify-write operations (rmws), can thus be used in applications built on top of these systems, further easing the programming burden on developers.

Linearizability for geo-replicated storage, however, comes with a tradeoff between strong guarantees and low latency. At least one communication delay between replicas is necessary to maintain a legal total order of operations [41], and in the wide-area, this communication incurs a considerable latency cost even in the best case. The tradeoff is starker for tail latency, where adverse conditions such as network delays, slow or failed replicas, and concurrent operations further delay responses to clients.

Tail latency is of particular importance for large-scale web applications, where end-user requests for high-level application objects fan-out into hundreds of sub-requests to storage services [18]. For example, when a user loads a page in a social networking service, an application server typically needs to invoke and wait for the completion of dozens of requests to replicas before returning the page to the client [2]. Only once the client receives the page can it begin loading additional assets and rendering the page. Thus, the median latency experienced by the end-user depends on the maximum of tens or hundreds of operations, which is dictated by the tail of the latency distribution.

Consensus protocols demonstrate the tradeoff between strong guarantees and low tail latency. Fundamentally, no protocol can solve consensus and guarantee termination in an asynchronous system with failures [24]. In practice, this impossibility result manifests as performance inefficiencies, such as serializing operations through a designated leader or delaying concurrent operations. In geo-replicated settings at scale, these inefficiencies impact tail latency.

In contrast, shared register protocols can implement linearizable shared registers, which support simple reads and writes, and guarantee termination in asynchronous systems with failures [5]. This translates to favorable tail latency for real protocols: shared register protocols are typically leaderless and often do not delay reads or writes, even if there are concurrent operations. The reads and writes provided by shared registers are the dominant types of operations in large-scale web applications [9]. Yet, shared registers are fundamentally too weak to directly implement strong synchronization primitives like rmws [31]. To resolve this tradeoff, the solution is to combine the strong synchronization provided by consensus with the favorable read/write tail latency of shared registers in a single protocol.

The idea of unifying consensus and shared registers is not new [8]. However, the only previous attempt of which we are aware is incorrect because it does not safely handle certain interleavings of operations. Our key insight is that protocol-level mechanisms for enforcing the interaction between rmws and reads/writes are difficult to reason about, which can lead to subtle safety violations. Instead, we argue the interaction be enforced at a deeper level, in the ordering mechanism itself, to simplify reasoning about correctness.

We introduce consensus-after-register timestamps, or *carstamps*, a novel ordering mechanism for distributed storage to leverage this insight. Carstamps allow writes and rmws to concurrently modify the same state without serializing through a leader or incurring additional round trips. Reads use carstamps to determine consistent values without interposing on concurrent updates.

Gryff is our system that implements this ordering mechanism to achieve unification.[1] It is the first such system to be proven correct, implemented, and empirically evaluated. Gryff combines a multi-writer variant [43] of the ABD [5] protocol for reads and writes with EPaxos [47] for rmws. In addition to the challenges associated with unifying these protocols, we introduce an optimization to further rein in tail latency by reducing the frequency of reads taking multiple wide-area round trips.

We implemented Gryff in the same framework as EPaxos [47] and MultiPaxos [36] and evaluated its performance in a geo-replicated setting. Our evaluation shows that Gryff reduces the tradeoff between linearizability and low tail latency for workloads representative of large-scale web applications [10, 16, 17]. For moderate contention workloads, Gryff reduces p99 read latency to $\sim$56% of EPaxos, but has $\sim 2x$ higher write latency. This tradeoff allows Gryff to reduce service-level p50 latency to $\sim$60% of EPaxos for large-scale web applications whose requests fan-out into many storage-level requests.

In summary, the contributions of this paper include:

- A novel ordering mechanism, carstamps, that enables efficient unification of consensus with shared registers. (§3)
- The Gryff design that combines a shared register protocol with EPaxos to provide reads, writes, and rmws. (§4, §5)
- The implementation and evaluation of Gryff, which demonstrates its latency improvements. (§6)

2 Consensus vs. Shared Registers

This section covers preliminaries and then compares and contrasts consensus and shared register protocols. It looks at the interfaces they support, the ordering constraints they impose, and the ordering mechanisms they use.

Model and Preliminaries. We study systems comprised of a set P of m processes that communicate with each other over point-to-point message channels. Processes may fail according to the *crash failure model*: a failed process ceases executing instructions and its failure is not detectable by other processes. The system is *asynchronous* such that there is no upper bound on the time it takes for a message to be delivered and there is no bound on the relative speeds at which processes execute instructions.

Linearizability is a correctness condition for a concurrent object that requires (a) operations invoked by processes accessing the object appear to execute in some total order that is consistent with the semantics of the object (i.e., that is *legal*) and (b) the total order is consistent with the order that operations happened in real time [32]. Linearizability is a *local* property, meaning it holds for a collection of objects if and only if it holds for each individual object.

[1]A gryffin is a mythological hybrid creature that combines the power of a lion with the speed of an eagle.

For the remainder of this text, we consider linearizable replication of a single object by omitting object identifiers; it is straightforward to compose instances of such a system to obtain a linearizable multi-object system.

2.1 State Machines and Consensus

State machine replication is the canonical approach to implementing fault-tolerant services [56]. It provides a fault-tolerant *state machine* that exposes the following interface:

- $\textsc{Command}(c(\cdot))$: atomically applies a deterministic computation $c(\cdot)$ to the state machine and returns any outputs

Each command can include zero or more arguments, read local state, perform deterministic computation, and produce output. The state machine approach applies these commands one by one starting from the same initial state to move replicas through identical states. Thus, if some replicas fail, the remaining replicas still have the state and can continue to provide the service.

Applying commands in the same order on all replicas requires an ordering mechanism that is *stable*, i.e., a replica knows when a command's position is fixed and it will never receive an earlier command [56]. In asynchronous systems where processes can fail, consensus protocols [33, 36, 37, 38, 45, 47, 50, 51] are used to agree on this stable ordering.

Figure 1a shows the stable ordering provided by consensus protocols for state machine replication. Commands are assigned positions in a log and a command becomes stable once there are no empty slots preceding its own in the log.

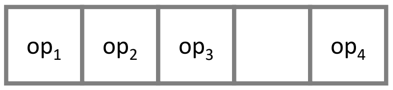
2.2 Shared Registers and Their Protocols

A *shared register* has the following interface:

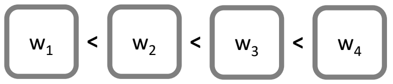
- $\textsc{Read}()$: returns the value of the register
- $\textsc{Write}(v)$: updates the value of the register to v

Shared registers provide a simple interface with read and write operations. They are less general than state machines as they provably cannot be used to implement consensus [31]. Shared register protocols replicate shared registers across multiple processes for fault tolerance [5, 22, 43].

Shared register protocols provide a linearizable ordering of operations. That ordering does not have to be stable, however, because each write operation fully defines the state of the object. Thus, a replica can safely apply a write w_4 even if it does not know about earlier writes. If an earlier write w_3 ever does arrive, the replica simply ignores that write because it already has the resulting state from applying w_3 and then w_4. Figure 1b shows shared register ordering where there is a total order of all writes (denoted by $<$) without stability.

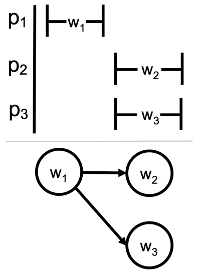


(a) Ordering in consensus protocols. Operations op_1, op_2, and op_3 are stable, but op_4 is not.

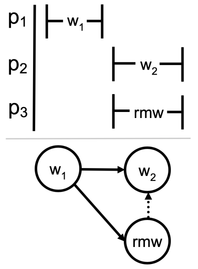


(b) Ordering in shared register protocols. No writes are stable.

Figure 1: Comparison of ordering in consensus and shared register protocols. Shared register protocols provide an unstable ordering where new writes can be inserted between writes that have already completed.



(a) w_2 and w_3 may be arbitrarily ordered.



(b) if rmw reads w_1, it must be before w_2.

Figure 2: Solid arrows are real time ordering constraints. Dashed arrows are operation semantic constraints.

2.3 Shared Objects and Their Ordering

A *shared object* exposes the following interface:

- READ(): returns the value of the object
- WRITE(v): updates the value of the object to v
- RMW($f(\cdot)$): atomically reads the value v, updates the value to $f(v)$, and returns v

The abstraction of a shared object captures an intuitive programming model that is used in real-world systems [12, 15, 23, 44, 54, 55]. Most operations read or write data, but rmws support stronger primitives to synchronize concurrent accesses to data. For example, a conditional write can be implemented with a rmw by using a function $f(\cdot)$ that returns the new value to be written only if some condition is met.

Shared objects and state machines are equivalent in that an instance of one can be used to implement the other [31]. However, the difference is that shared objects expose a more restrictive interface for directly reading and writing state, as do shared registers. These simpler operations can be implemented more efficiently because their semantics impose fewer ordering constraints.

Yet, neither the stable ordering of state machine replication nor the unstable total ordering of shared register protocols is a good fit for shared objects. A stable order, on the one hand, over constrains how reads and writes are ordered and results in less efficient protocols. On the other hand, an unstable total order under constrains how rmws are ordered and results in an incorrect protocol.

Figure 2 demonstrates these different constraints. Consider the execution in Figure 2a where two processes, p_2 and p_3, write concurrently. Linearizability stipulates that w_2 and w_3 be ordered after w_1 because they are invoked after w_1 completes in real time. However, there is no stipulation for how w_2 and w_3 are ordered with respect to each other because the result of a write does not depend on preceding operations. Both $w_1 \to w_2 \to w_3$ and $w_1 \to w_3 \to w_2$ are valid.

Now consider the execution in Figure 2b involving a rmw. Process p_2 writes while p_3 concurrently executes a rmw. The *base update* of a rmw is the operation that writes the value that the rmw reads. Assume that w_1 is the base update of *rmw*. Then, not only does *rmw* need to be ordered after w_1, but no other write may be ordered between w_1 and *rmw*. This additional constraint ensures legality because the semantics of a rmw requires that it must appear to atomically read and update the object based on the value read. Thus, only $w_1 \to rmw \to w_2$ is a valid order.

3 Carstamps for Correct Ordering

Consensus-after-register timestamps, or *carstamps*, precisely capture the ordering constraints of shared objects. They provide the necessary stable order for rmws and the more efficient unstable order for reads and writes. This section describes the requirements of a precise ordering mechanism for shared objects and then describes carstamps.

3.1 Precise Ordering for Shared Objects

An ordering mechanism is an injective function $g : X \to Y$ from a set X of writes and rmws to a totally ordered set $(Y, <_Y)$. A mechanism g produces a total order $<_g$ on X: for all $x_1, x_2 \in X$, $x_1 <_g x_2$ if and only if $g(x_1) <_Y g(x_2)$.

Typically, replication protocols augment an ordering mechanism with protocol-level logic to enforce real time and legality constraints on the total order given by the ordering mechanism to provide linearizability. While the logic for enforcing real time constraints is often straightforward, legality constraints can be more complex.

Protocol-level Legality. For example, consider the Active Quorum Systems (AQS) protocol [7, 8]. AQS is the only prior protocol of which we are aware that attempts to combine consensus and shared registers and it does so with an unstable ordering mechanism. This allows for executions where a rmw *rmw* with base update u is ordered such that there exists a $y \in Y$ with $g(u) <_Y y <_Y g(rmw)$. This can result in an illegal total order when a write w is concurrent with *rmw* because w may be assigned $g(w) = y$. AQS contains no logic at the protocol-level to prevent this subtle scenario. We discuss such an execution in detail in Appendix C and describe how there does not exist a linearizable order of all operations.

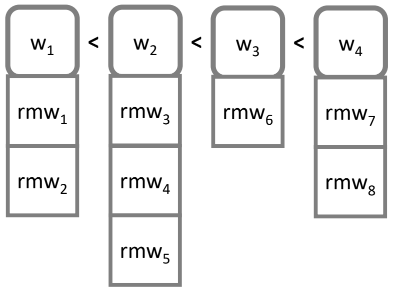


Figure 3: Unified ordering provided by carstamps for writes and rmws. Writes are unstably ordered while rmws are stably ordered with their base updates.

Ordering-level Legality. Our key insight is that the legality constraints of linearizability can be encoded in the ordering mechanism itself. An ordering mechanism that does this must ensure that for all $rmw \in X$ such that u is the base update of rmw, $g(u) <_Y g(rmw)$ and $g(u)$ is a *cover* of $g(rmw)$. This means that there is no $y \in Y$ such that $g(u) <_Y y <_Y g(rmw)$. With such an ordering mechanism, there is no need for protocol-level logic to prevent other writes in X from being assigned an illegal position in the total order between $g(u)$ and $g(rmw)$.

3.2 Carstamps

Our solution which leverages this insight is called *carstamps*. A carstamp is a triple $cs = (ts, id, rmwc)$ with three fields: a logical timestamp ts, a process identifier id, and a rmw counter $rmwc$. The logical timestamp and process identifier can be used by a write protocol to form an unstable order of writes. A rmw rmw with base update u whose carstamp is cs_u is assigned a carstamp $cs_{rmw} = (cs_u.ts, cs_u.id, cs_u.rmwc + 1)$. The fields encode ordering constraints between operations via a lexicographical comparison such that $cs_1 < cs_2$ if and only if $cs_1.ts < cs_2.ts$ or $cs_1.ts = cs_2.ts$ and $cs_1.id < cs_2.id$ or $cs_1.ts = cs_2.ts$ and $cs_1.id = cs_2.id$ and $cs_1.rmwc < cs_2.rmwc$.

By incrementing the lowest order field of the carstamp, each carstamp assigned to a base update of a rmw is guaranteed to cover its rmw. This stable ordering of rmws with their base updates is visualized in Figure 3. Writes are assigned to carstamps in the first row as part of an increasing unstable order. RMWs are assigned to carstamps in the column to which their base update belongs immediately below their base update.

Consider the example from Figure 2b and assume that w_1 is assigned carstamp $cs_{w_1} = (1,1,0)$ by p_1. Then, since rmw reads w_1, it will be assigned carstamp $cs_{rmw} = (1,1,1)$. Based on the lexicographical ordering of carstamps, there does not exist a carstamp cs such that $cs_{w_1} < cs < cs_{rmw}$, so w_2 cannot be arbitrarily re-ordered between w_1 and rmw.

4 Gryff Protocol

Gryff unifies shared registers with consensus using carstamps. It implements a linearizable shared object (§2) that tolerates the failure of up to f out of $n = 2f + 1$ replicas. We divide its description into three components. First, we provide additional background including the shared register protocol and consensus protocol upon which its read, write, and rmw protocols are built (§4.1). Second, we describe how Gryff adapts these protocols with carstamps (§4.2,§4.3). Third, we describe an optimization to the base Gryff protocol that improves read latency in geo-replicated settings (§5).

In addition, in Appendix B we prove Gryff implements a shared object with linearizability. Appendix B also proves read/write wait-freedom—every read or write invoked by a correct process eventually completes—and rmw wait-freedom with partial synchrony—if there is a point in time after which the system is synchronous, every rmw invoked by a correct process eventually completes.

4.1 Background

Section 2 provides background on our model, linearizability, and state machines and shared registers in general. This subsection adds useful definitions and then describes the two specific protocols that Gryff adapts, a multi-writer variant [43] of ABD [5] and EPaxos [47].

Definitions. A subset of processes $R \subseteq P$ are *replicas* that store the value of the object. We assume reliable message delivery, which can be implemented on top of unreliable message channels via retransmission and deduplication.

Replicas are often deployed across a wide-area network such that inter-replica message delivery latency is on the order of tens of milliseconds. This is commonly done so that replica or network failures correlated by geographic region do not immediately cause the system to become unavailable. We say that a process p is *co-located* with a replica r if the message delivery latency between p and r is much less than the minimum inter-replica latency. Client processes running applications are typically co-located with a single replica, for example, within the same datacenter.

A *quorum system* $\mathcal{Q} \subseteq \mathcal{P}(R)$ over R is a set of subsets of R with the *quorum intersection property*: for all $Q_1, Q_2 \in \mathcal{Q}$, $Q_1 \cap Q_2 \neq \emptyset$. We use *quorum* both to mean a set of replicas in a particular quorum system and the size of such a set. Gryff can use any quorum system, but for liveness with up to f replica failures, we assume the use of the majority quorum system $\mathcal{Q}_{maj}$ such that $\forall Q \in \mathcal{Q}_{maj}. |Q| = f + 1$.

A *coordinator* is a process that executes a read, write, or rmw protocol when it receives such an operation from an application. In shared register protocols, the coordinators are typically the client processes on which the application is running. In consensus protocols, the coordinators are typically one of the replicas to which client processes forward their requests. We assume all processes possess a unique *identifier* that can be used when coordinating an operation to distinguish the coordinator from other processes.

Multi-Writer ABD. The multi-writer variant [43] of ABD [5] is a shared register protocol that requires two phases for both reads and writes. To provide a linearizable order of reads and writes, it associates a *tag* $t = (ts, id)$ with each write where *ts* is a logical timestamp and *id* is the identifier of the coordinator. Writes are ordered lexicographically by their tags. Each replica stores a value v and an associated tag t.

Reads and writes have two phases. A read begins with the coordinator reading the current tag and value from a quorum. Once it receives these, it determines the value that will be returned by the read by choosing the value associated with the maximum tag from the tags returned in the quorum. Then, the coordinator propagates this maximum tag and value to a quorum and waits for acknowledgments. We say that a replica *applies* a value v' and tag t' when it overwrites its v and t with v' and t' if $t' > t$. After a replica receives the propagated tag and value, it applies them and sends an acknowledgment to the coordinator.

A coordinator for a write follows a similar two-phase protocol, except instead of propagating the maximum tag t_{max} and associated value received in the first phase, it generates a new tag $t = (t_{max}.ts + 1, id)$ to associate with the value to be written where *id* is the identifier of the coordinator. In the second phase, the coordinator propagates this new tag and value to a quorum and waits for acknowledgments.

EPaxos EPaxos [47] is a consensus protocol that provides optimal commit latency in the wide-area. It has three phases in failure-free executions: PreAccept, Accept, and Commit. If a command commits on the *fast path*, the coordinator returns to the client after the PreAccept phase and skips the Accept phase. Otherwise, the command commits on the *slow path* after the Accept phase. Commands that do not read state complete at the beginning of the Commit phase; commands that do read state complete after a single replica, typically the coordinator, executes the command to obtain the returned state. The purpose of the PreAccept and Accept phases is to establish the *dependencies* for a command, or the set of commands that must be executed before the current command. The purpose of the Commit phase is for the coordinator to notify the other replicas of the agreed-upon dependencies.

PreAccept phase. The coordinator of a command constructs the preliminary dependency set consisting of all other commands of which the coordinator is aware that interfere (i.e., access the same state machine state) with it. It sends the command and its dependencies to a fast quorum of replicas. When replicas receive the proposed dependencies, they update them with any interfering commands of which they are aware that are not already in the set and respond to the coordinator with the possibly updated dependencies. If the leader receives a fast quorum of responses that all contain the same dependencies, it proceeds to the Commit phase.

v - value of shared object
cs - carstamp of shared object
prev - value and carstamp generated by the previously executed rmw
i - next unused instance number
cmds - two-dimensional array of instances indexed by replica id and instance number each containing:

- *cmd* - command to be executed
- *deps* - instances whose commands must be executed before this one
- *seq* - approximate sequence number of command used to break cycles in dependency graph
- *base* - possible base update for rmw
- *status* - status of instance

Figure 4: State at each replica.

Accept phase. Otherwise, the coordinator continues to the Accept phase where it builds the final dependencies for the command by taking the union of all the dependencies that it received in the PreAccept phase. It sends these to a quorum and waits for a quorum of acknowledgments before committing. Regardless of whether the command is committed after the first or second phase, once it is committed, a quorum store the same dependency set for the command.

Execution. Dependency sets for distinct commands define a dependency graph over all interfering commands. The EPaxos execution algorithm, separate from the commit protocol, executes all commands in the deterministic order specified by the graph. Cycles may exist in the graph, in which case a total order is determined by a secondary attribute called an approximate sequence number. We refer the reader to the EPaxos paper for more details [47].

4.2 Read & Write Protocols

The read and write protocols are based on multi-writer ABD. Figure 4 summarizes the state that is maintained at each replica. Algorithms 1 and 2 show the pseudocode for the coordinators and replicas. The key difference from multi-writer ABD is that replicas maintain a carstamp associated with the current value of the shared object instead of a tag so that rmws are properly ordered with respect to reads and writes.

Reads. We make the same observation as Georgiou et al. [26] that the second phase in the read protocol of multi-writer ABD is redundant when a quorum already store the value and associated carstamp chosen in the first phase. In such cases, the coordinator may immediately complete the read (Line 6 of Algorithm 1). Otherwise, it continues as normal to the second phase in order to propagate the observed value and carstamp to a quorum.

Writes. When generating a carstamp after the first phase of a write, the coordinator chooses the *ts* and *id* fields as

Algorithm 1: Read and write coordinator protocols.

```
procedure Coordinator::READ() at $p \in P$
    send $Read1$ to all $r \in R$
    wait to receive $Read1Reply(v_r, cs_r)$ from all $r \in Q \in \mathcal{Q}$
    $cs_{max} \leftarrow \max_{r \in Q} cs_r$
    $v \leftarrow v_r : cs_r = cs_{max}$
    if $\forall r \in Q : cs_r = cs_{max}$ then
        return $v$
    send $Read2(v, cs_{max})$ to all $r \in R$
    wait to receive $Read2Reply$ from all $r \in Q' \in \mathcal{Q}$
    return $v$
procedure Coordinator::WRITE($v$) at $p \in P$
    send $Write1$ to all $r \in R$
    wait to receive $Write1Reply(cs_r)$ from all $r \in Q \in \mathcal{Q}$
    $cs_{max} \leftarrow \max_{r \in Q} cs_r$
    $cs \leftarrow (cs_{max}.ts + 1, id, 0)$
    send $Write2(v, cs)$ to all $r \in R$
    wait to receive $Write2Reply$ from all $r \in Q' \in \mathcal{Q}$
```

Algorithm 2: Read and write replica protocols.

```
when replica $r \in R$ receives a message $m$ from $p \in P$ do
    case $m = Read1$ do
        send $Read1Reply(v, cs)$ to $p$
    case $m = Read2(v', cs')$ do
        APPLY($v', cs'$)
        send $Read2Reply$ to $p$
    case $m = Write1$ do
        send $Write1Reply(cs)$ to $p$
    case $m = Write2(v', cs')$ do
        APPLY($v', cs'$)
        send $Write2Reply$ to $p$
procedure Replica::APPLY($v', cs'$)
    if $cs' > cs$ then
        $cs \leftarrow cs'$
        $v \leftarrow v'$
```

in multi-writer ABD. The *rmwc* field is reset to 0 (Line 15 of Algorithm 1). While not strictly necessary, this curbs the growth of the *rmwc* field in practical implementations.

4.3 Read-Modify-Write Protocol

Gryff's rmw protocol uses EPaxos to stably order rmws as commands in the dependency graph. Figure 4 summarizes the replica state. Algorithms 3 and 4 show the pseudocode for a rmw coordinator and replica message handling excluding the recovery procedure. Appendix B includes the pseudocode for the recovery procedure. The highlighted portions of the pseudocode show the changes from canonical EPaxos. We denote by I_{cmd} the set of commands of which the local replica is aware that interfere with *cmd*.

We make three high-level modifications to canonical EPaxos in order to unify its stable ordering with the unstable ordering of Gryff's read and write protocols.

1. A base update attribute, *base*, is decided by the replicas during the same process that establishes the dependencies and the approximate sequence number for a rmw.
2. A rmw completes after a quorum execute it.
3. When a rmw executes, it chooses its base update from between its *base* attribute and the result of the previously executed rmw *prev*. The result of the executed rmw is applied to the value and carstamp of the executing replica.

The first change adapts EPaxos to work with the unstable order of writes by fixing the write upon which it will operate. The second change adapts it to work with reads that bypass its execution protocol and directly read state. The third change ensures that concurrent rmws that choose the same initial base update are stably ordered using the ordering and execution protocols of EPaxos. We next discuss each of these changes in more detail.

Base Attribute. The *base* attribute associated with a rmw represents a possible base update on which the rmw will execute. Initially, the coordinator sets this to what it believes are the current value and carstamp of the shared object (Line 6 of Algorithm 3). When a replica receives a *PreAccept* message, it merges what it believes is the correct base update with the base update proposed by the coordinator (Line 5 of Algorithm 4). The fast path condition remains essentially unchanged: the coordinator commits the command if it receives *PreAcceptOK* responses from a fast quorum indicating that all replicas in the quorum agree on the attributes for the command. Otherwise, the coordinator merges all attributes it has received in the PreAccept phase and sends out the final attributes in the Accept phase.

Quorum Execute. In canonical EPaxos, a rmw completes after a single replica executes it because reads are executed through the same consensus protocol. Since Gryff's read protocol circumvents consensus and reads the state of the shared object directly from a quorum, a rmw must be executed at a quorum so that it is visible to reads that come after it in real time. This guarantees the rmw will be visible to future reads by the quorum intersection property.

Execution. The algorithm for determining the execution order of commands is unchanged from canonical EPaxos. The EXECUTE procedure in Algorithm 4 is called when a rmw *rmw* in the dependency graph committed at position (i, j) in the *cmds* array is ready to be executed.

In the procedure, the final base update for *rmw* is chosen to be the value and carstamp pair with the larger carstamp

Algorithm 3: RMW coordinator protocol.

```
procedure Coordinator::RMW($f(\cdot)$) at $c \in R$
    PreAccept Phase:
    $i \leftarrow i+1$
    $cmd \leftarrow f(\cdot)$
    $seq \leftarrow 1+\max(\{cmds[j][k].seq | (j,k) \in I_{cmd}\} \cup \{0\})$
    $deps \leftarrow I_{cmd}$
    $base \leftarrow (v,cs)$
    $cmds[id][i] \leftarrow (cmd, seq, deps, base,$ pre-accepted$)$
    send $PreAccept(cmd, seq, deps, base, id, i)$ to all $r \in F \setminus \{c\}$ where $F \in \mathscr{F}$
    wait to receive $PreAcceptOK(seq'_r, deps'_r, base'_r)$ from all $r \in F \setminus \{c\}$
    if $\forall r_1, r_2 \in F \setminus \{c\} : seq'_{r_1} = seq'_{r_2} \wedge deps'_{r_1} = deps'_{r_2} \wedge base'_{r_1} = base'_{r_2}$ then
        $deps, seq, base \leftarrow deps'_r, seq'_r, base'_r : r \in F \setminus \{c\}$
        goto Commit Phase
    Accept Phase:
    $deps \leftarrow \cup_{r \in F} deps_r$
    $seq \leftarrow \max_{r \in F} seq_r$
    $base \leftarrow base_r : \forall r' \in F.base_r.cs \geq base_{r'}.cs$
    $cmds[id][i] \leftarrow (cmd, seq, deps, base,$ accepted$)$
    send $Accept(cmd, seq, deps, base, id, i)$ to all $r \in Q \setminus \{c\}$ where $Q \in \mathscr{Q}$
    wait to receive $AcceptOK$ from all $r \in Q \setminus \{c\}$
    Commit Phase:
    $cmds[id][i] \leftarrow (cmd, seq, deps, base,$ committed$)$
    send $Commit(cmd, seq, deps, base, id, i)$ to all $r \in R \setminus \{c\}$
    wait to receive $Executed(v)$ from all $r \in Q' \in \mathscr{Q}$
    return $v$
```

Algorithm 4: RMW replica protocol.

```
when replica $r \in R$ receives a message $m$ from $c \in R$ do
    case $m = PreAccept(cmd, seq, deps, base, id_c, i)$ do
        $seq' \leftarrow \max(\{seq\} \cup \{1+cmds[j][k].seq | (j,k) \in I_{cmd}\}$
        $deps' \leftarrow deps \cup I_{cmd}$
        $base' \leftarrow$ if $cs > base.cs$ then $(v,cs)$ else $base$
        $cmds[id_c][i] \leftarrow (cmd, seq', deps', base',$ pre-accepted$)$
        send $PreAcceptOK(seq', deps', base')$ to $c$
    case $m = Accept(cmd, seq, deps, base, id_c, i)$ do
        $cmds[id_c][i] \leftarrow (cmd, seq', deps', base',$ accepted$)$
        send $AcceptOK$ to $c$
    case $m = Commit(cmd, seq, deps, base, id_c, i)$ do
        $cmds[id_c][i] \leftarrow (cmd, seq', deps', base',$ committed$)$

procedure Replica::EXECUTE$(j,k)$
    $base \leftarrow cmds[j][k].base$
    if $cmds[j][k].base.cs < prev.cs$ then
        $base \leftarrow prev$
    $v' \leftarrow cmds[j][k].cmd(base.v)$
    $cs' \leftarrow (base.cs.ts, base.cs.id, base.cs.rmwc+1)$
    $prev \leftarrow (v', cs')$
    APPLY$(v', cs')$
    send $Executed(base.v)$ to replica $j$
```

between the result *prev* of the previously executed rmw and the *base* attribute of *rmw* (Line 15 of Algorithm 4). The *prev* variable is the most recent state of the shared object produced by the execution of a rmw whereas the *base* attribute is the most recent state of the shared object that the coordinator observed after *rmw* was invoked. In the absence of concurrent updates, these states are equivalent, so it is safe for the *rmw* to choose the state as the base update.

However, when rmws are concurrent, *prev* may be more recent than the *base* attribute of *rmw* because concurrent rmws were ordered and executed before *rmw*. In such cases, *rmw* must remain consistent with the stable order of rmws provided by EPaxos by executing on the most recent state.

The resulting value and carstamp of *rmw* are decided by executing the modify function $f(\cdot)$ on the value of the base update and incrementing the *rmwc* of the carstamp of the chosen base update. The replica finishes by applying the new value and carstamp and notifying the coordinator that the rmw has been executed.

5 Proxying Reads

The base Gryff read protocol, as described in the previous section, provides reads with single round-trip time latency from the coordinator to the nearest quorum including itself (1 RTT) when there are no concurrent updates. Otherwise, reads have at most 2 RTT latency. We discuss how read latency can be further improved in deployments across wide-area networks.

Because the round-trip time to the replica that is co-located with a client process is negligible relative to the inter-replica latency, replicas can coordinate reads for their co-located clients and utilize their local state in the read coordinator protocol to terminate after 1 RTT more often. When using this optimization, we say that the coordinating replica is a *proxy* for the client process's read.

Propagating Extra Data in Read Phase 1. The proxy includes in the *Read1* messages its current value *v* and carstamp *cs*. Upon receiving a *Read1* message with this additional information, a replica applies the value and carstamp before returning its current value and carstamp. This has the effect of ensuring every replica that receives the *Read1* messages will have a carstamp (and associated value) at least as large as the carstamp at the proxy when the read was invoked.

When this is the most recent carstamp for the shared object, the read is guaranteed to terminate after 1 RTT. This is because every *Read1Reply* that the coordinator receives will contain this most recent carstamp and associated value.

Updating the Proxy's Data. The proxy also applies the values and carstamps that it receives in *Read1Reply* messages as it receives them and before it makes the decision of whether or not to complete the read after the first phase. If every reply contains the same carstamp, then the read completes after 1 RTT even if the carstamp at the proxy when the read was invoked is smaller than the carstamp contained in every reply.

Given our assumption that each quorum contains $f+1$ replicas, these two modifications ensure that reads coordinated by a proxy r only take 2 RTT during normal operation when there is a concurrent update that arrives at the f nearest replicas to r in an order that interleaves with the *Read1* messages from r. Algorithm 7 in Appendix B describes the read proxy changes to base Gryff in pseudocode. Appendix B also contains a brief argument for why the read proxy optimization maintains the correctness of base Gryff.

Always Fast Reads When $n = 3$. This optimization increases the likelihood that a read completes in 1 RTT because the proxy replica is privy to more information—i.e., the number of replicas that contain the same value and carstamp—than a client process. Moreover, it allows Gryff to always provide 1 RTT reads when $n = 3$ since the proxy and any single other replica comprise a quorum. This optimization is, in some sense, the dual of the optimization that EPaxos [47] uses to always provide 1 RTT writes when $n = 3$. In both cases, the coordinator and the other replica in the quorum adopt each other's state so that the quorum always has the same state at the end of the first phase.

6 Evaluation

Gryff unifies consensus with shared registers to avoid the overhead of consensus for reads and writes. To quantify the benefits and drawbacks of this approach for storing data in geo-replicated, large-scale web applications, we ask:

- Do Gryff's shared register read and write protocols reduce read tail latency relative to the state-of-the-art? (§6.3)
- How do the read/write/rmw latency and throughput of Gryff compare to state-of-the-art protocols? (§6.4,§6.5)
- Does Gryff improve the median service-level latency for large scale web applications? (§6.6)

We find that, for workloads with moderate contention, Gryff reduces p99 read latency to ∼56% of EPaxos, but has ∼2x higher write latency. This tradeoff allows Gryff to reduce service-level p50 latency to ∼60% of EPaxos for large-scale web applications whose requests fan-out into many storage-level requests. Gryff and EPaxos each achieve a slightly higher maximum throughput than MultiPaxos due to their leaderless structure.

	CA	VA	IR	OR	JP
CA	0.2				
VA	72.0	0.2			
IR	151.0	88.0	0.2		
OR	59.0	93.0	145.0	0.2	
JP	113.0	162.0	220.0	121.0	0.2

Figure 5: Round trip latencies in ms between nodes in emulated geographic regions.

6.1 Baselines and Implementation

We evaluate Gryff against MultiPaxos and EPaxos. MultiPaxos [36], VR [50], Raft [51] and other protocols with leader-based architectures are used in commercial systems to provide linearizable replicated storage [14, 17, 23, 52]. While leader-based protocols have drawbacks in geo-replicated settings, their extensive use in real systems provides a practical measuring stick. EPaxos [47] is the state-of-the-art for geo-replicated storage.

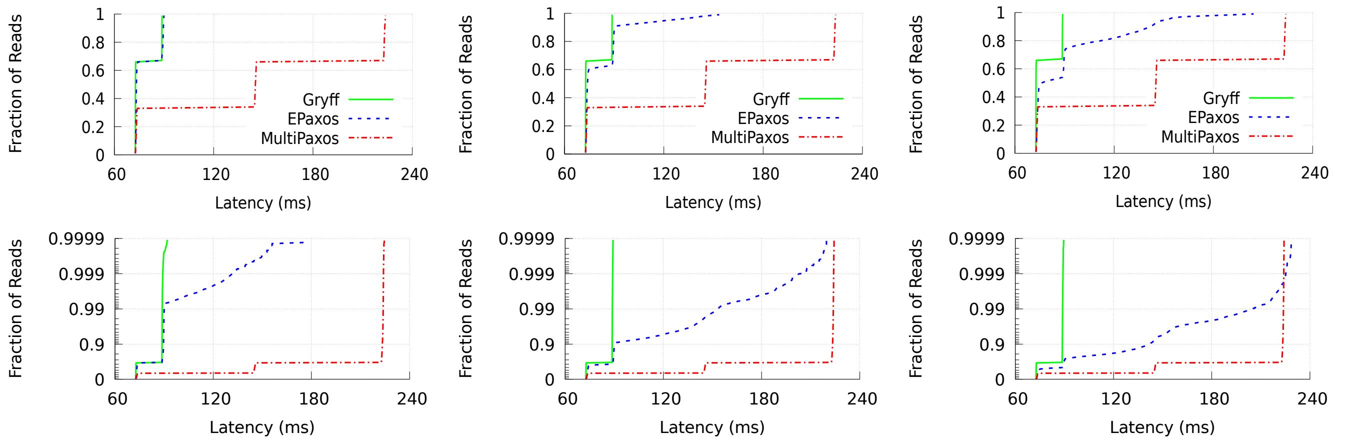
We implemented Gryff in Go using the framework of EPaxos to facilitate apples-to-apples comparisons between protocols. Our implementation is a multi-object storage system that uses the protocols as described in this paper with the addition of object identifiers to messages and state. Our code and experiment scripts are available online [29]. We use the existing implementation of MultiPaxos in the framework for our experiments. All of our experiments use the thrifty optimization for EPaxos, MultiPaxos, and Gryff. We use the read proxy optimization for Gryff.

6.2 Experimental Setup

Testbed. We run our experiments on the Emulab testbed [61] using pc3000 nodes. These node types have 1 Dual-Core 3 GHz CPU, 2 GB RAM, and 1 Gbps links to all other nodes. For three replica latency experiments, we emulate replicas in California (CA), Virginia (VA), and Ireland (IR). In five replica latency experiments, we add replicas in Oregon (OR) and Japan (JP). In all experiments, we place the MultiPaxos leader in CA.

We emulate wide-area network latencies using Linux's Traffic Control (tc) to add delays to outgoing packets on all nodes. Table 5 shows the configured round-trip times between nodes in different regions. We choose these numbers because they are the typical round-trip times between the corresponding Amazon EC2 availability regions.

Clients. For all experiments, we use 16 clients co-located with each replica. This number of clients provides enough load on the evaluated protocols to observe the effects of concurrent operations from many clients, but only moderately saturates the system. We avoid full saturation in order to isolate the protocol mechanisms that affect tail latency from hardware and software limitations at various levels in our stack. Clients perform operations in a closed loop.



(a) 2% conflicts. (b) 10% conflicts. (c) 25% conflicts.

Figure 6: Gryff's reads always complete in 1 RTT when $n = 3$. 99th percentile read latency is between 0 ms and 115 ms lower than EPaxos and 134 ms lower than MultiPaxos.

Measurement. Each experiment is run for 180 seconds and we exclude results from the first 15 seconds and last 15 seconds to avoid artifacts from start-up and cool-down. The latency for an individual operation is measured as the time between when a client invokes the operation and when it is notified of the operation's completion.

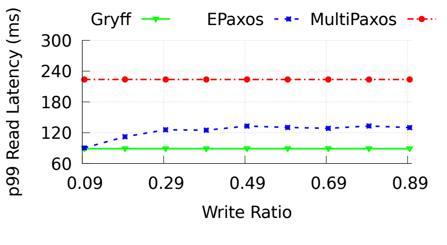
Conflicting Operations. When two operations target the same object in a storage system, we say the operations *conflict*. We use *conflict percentage* as a parameter in our workloads to control the percentage of operations from each client that target the same key. Workloads are highly skewed if and only if their conflict percentage is high.

6.3 Tail Latency

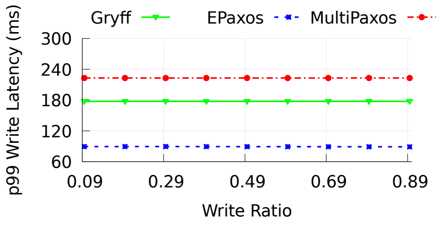
Gryff is designed to reduce the latency cost of linearizability for large scale web applications. Tail latency is of particular importance for these applications because end-user requests for high-level application objects typically fan-out into hundreds of sub-requests to storage services [2, 18]. The object can only be returned to the end-user once all of these sub-requests complete, so the median latency experienced by the end-user is dictated by the tail of the latency distribution for operations to these storage services.

6.3.1 Varying Conflict Percentage

To understand the read tail latency of Gryff and the baselines, we use a variant of the YCSB-B [16] workload that contains 94.5% reads, 4.5% writes, and 1.0% rmws. We examine a read-heavy distribution of operations because most large-scale web applications are read-heavy. For example, more than 99.7% of operations are reads in Google's advertising backend, F1 [17], 99.8% of operations in Facebook's TAO system are reads [10], and 3 out of 5 of YCSB's core workloads contain over 95% reads [16].



(a) Read operations.

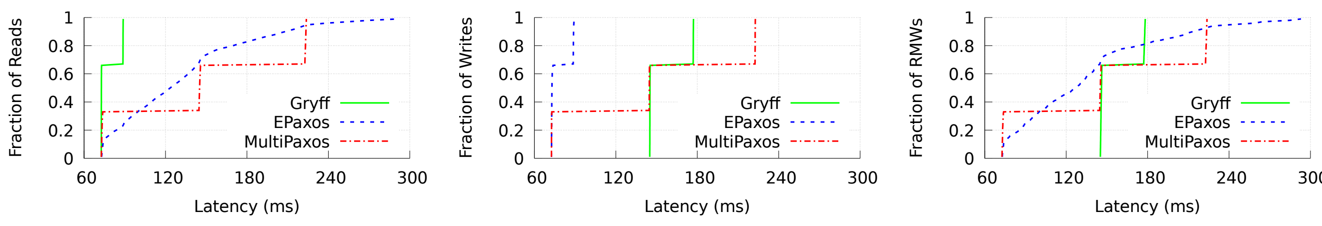


(b) Write operations.

Figure 7: Gryff reduces p99 read latency between 1 ms and 44 ms relative to EPaxos and 134 ms relative to MultiPaxos for varying write percentages. EPaxos' p99 write latency is 89 ms lower than Gryff's p99 write latency regardless of write percentage and conflicts.

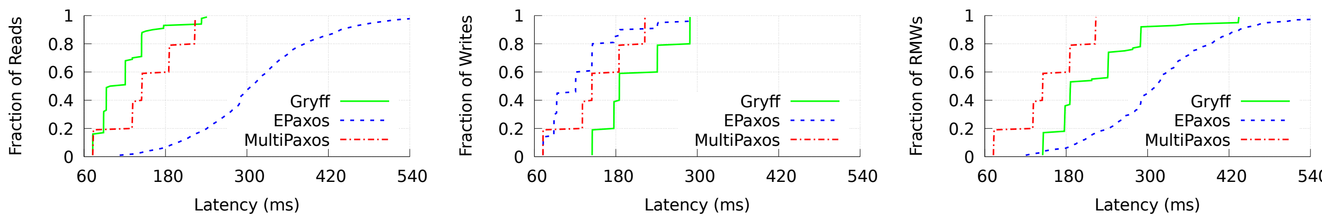
Figure 6a shows the results for three different conflict percentages with $n = 3$. In each sub-figure, a log-scale CDF up to p99.99 is shown below the normal-scale CDF.

1 RTT Reads for Gryff. For $n = 3$ replicas, Gryff always completes reads in 1 RTT due to the read proxy optimization (§5). Figure 6 shows that clients in each region receive responses to their read requests after 1 RTT to the nearest quorum regardless of conflict percentage. Clients in CA are closest to the replicas in CA and VA and vice versa for clients in VA. This results in 66% of the reads completing in the round-trip time between CA and VA (72 ms). Clients in IR



(a) Reads. **(b) Writes.** **(c) RMWs.**

Figure 8: Gryff's writes take 2 RTT, which is always more than EPaxos when $n = 3$. MultiPaxos writes can be faster or slower than Gryff depending on client location and geographic setup.



(a) Reads. **(b) Writes.** **(c) RMWs.**

Figure 9: Gryff trades off worse write latency for better read and rmw latency relative to EPaxos when $n = 5$.

are closest to the replicas in IR and VA, so 33% of the reads complete in the round-trip time between IR and VA (88 ms).

Execution Dependencies Delay EPaxos. EPaxos always commits in 1 RTT for $n = 3$. However, a read cannot complete until a replica executes it and a replica can only execute it after receiving and executing its dependencies. This increases latency when a locally committed read has dependencies on operations that have not yet arrived at the local replica from other replicas. As shown in Figure 6a, these delays do not affect the p99 read latency of EPaxos when there are few conflicts. However, the log-scale CDF shows that a small number of reads are, in fact, delayed.

MultiPaxos has Client-dependent Stable Latency. The MultiPaxos leader can always commit and execute operations in 1 RTT to the nearest quorum. However, clients must also incur a 1 RTT delay to the leader. For clients co-located with the leader (in CA), this delay is negligible, so the latency experienced by these clients with MultiPaxos is less than or equal to the latency experienced with the other protocols. This is demonstrated in the 33rd percentile latencies in Figure 6. For clients not co-located with the leader, the latency is roughly 2 RTT.

Gryff improves 99th percentile read latency between 0 ms and 115 ms relative to EPaxos for low and high conflict percentages and 134 ms relative to MultiPaxos.

6.3.2 Varying Write Percentage

While Gryff's read tail latency is low for read-heavy workloads, we also quantify the tail latency under balanced and write-heavy workloads. To do so, we fix the conflict percentage at 2% and measure the 99th percentile latency of read and write operations for workloads containing 1% rmws and varying ratios of reads and writes. We vary the write percentage from 9.5% to 89.5% and the read percentage from 89.5% to 9.5%. Figure 7 shows the results for $n = 3$ replicas.

Gryff and MultiPaxos Unaffected. The write percentage does not affect Gryff's write latency because its write protocol arbitrarily orders concurrent writes. Similarly, MultiPaxos commits writes through the same path regardless of conflicting operations.

EPaxos Reads Slowdown. With increasing write percentage, the chance that a read obtains a dependency increases even with a fixed conflict percentage (Figure 7a). Unlike reads, writes do not need to be executed before they complete, so they still complete as soon as they are committed. This only takes 1 RTT in EPaxos when $n = 3$. EPaxos dominates Gryff and MultiPaxos for p99 write latency.

Five Replica Varying Write Ratio. We run the same workload with $n = 5$ and show the results in Figure 12 in Appendix A. Gryff can no longer always complete reads in 1 RTT, but due to the low conflict percentage it still achieves a p99 read latency of 1 RTT regardless of write percentage. EPaxos can no longer always commit in 1 RTT. This especially impacts EPaxos' p99 write latency, which becomes approximately the same as Gryff (290 ms).

6.4 Read/Write/RMW Latency

We also quantify the latency distributions of write and rmws in Gryff relative to that of the baselines. For these experiments, we use a variant of the YCSB-A workload with 49.5%

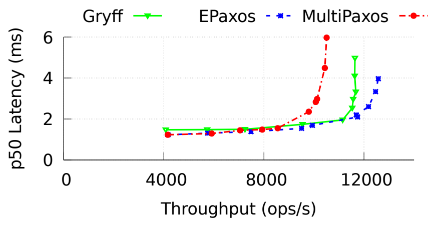


Figure 10: Gryff's throughput at saturation is within 7.5% of EPaxos and is higher than MultiPaxos.

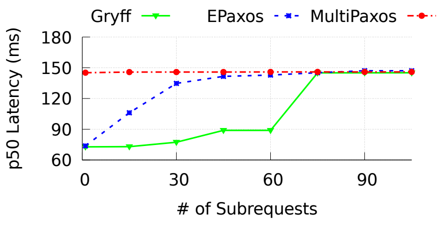

Figure 11: Gryff improves service-level p50 latency when the expected tail-at-scale request contains many reads.

reads, 49.5% writes, and 1.0% rmws with 25% conflicts. The balance between reads and writes allows us to observe the effects that interleavings of operations with different semantics have on the performance of the evaluated protocols. Similarly, the high conflict percentage reveals performance when concurrent operations to the same object interleave.

Figure 8 shows the cumulative distribution functions of the latencies for each operation type for $n = 3$ replicas. Figure 9 shows the same for $n = 5$.

1 RTT Reads for Gryff. For $n > 3$, Gryff often completes reads in 1 RTT, but sometimes takes 2 RTT. Figure 9a demonstrates this behavior as the tail surpasses the 1 RTT latency for any region.

EPaxos Writes are Fast, Reads are Slower. EPaxos dominates Gryff and MultiPaxos for write latency because it always commits in a single round trip for $n = 3$ (Figure 8b) and often commits in a single round trip for $n = 5$ (Figure 9b). As discussed in Section 6.3.1, reads cannot complete until they are executed, so when there are more replicas and more concurrent writes, EPaxos' read latency increases due to the increased likelihood that reads acquire dependencies on updates from other regions.

2 RTT Writes for Gryff. Writes in Gryff takes 2 RTT to complete. Figure 8b demonstrates the gap between EPaxos and Gryff for $n = 3$. When $n > 3$ replicas (Figure 9b), EPaxos still typically completes writes faster than Gryff because it only takes 2 RTT when conflicting concurrent operations arrive at replicas in the intersections of their fast quorums in different orders.

Less Blocking for RMWs in Gryff. Gryff achieves 2 RTT rmws when there are no conflicts and 3 RTT when there are. While Gryff must still block the execution of rmws until all dependencies have been received and executed, Gryff experiences significantly less blocking than EPaxos. This is because EPaxos needs to have dependencies on writes, but Gryff's rmw protocol does not.

EPaxos dominates Gryff for write latency. For $n = 3$, the p50 write latency of Gryff is 72 ms higher and the p99 write latency is 89 ms higher than EPaxos.

6.5 Throughput

We measure median latency at varying levels of load in a local-area cluster. Again, we use the variant of YCSB-A with 49.5% reads, 49.5% writes, and 1.0% rmws with 25% conflicts. Figure 10 shows the results for $n = 3$. We find that Gryff's throughput at saturation is about 11,600 ops/s, within 7.5% of EPaxos. This is also about 1,200 ops/s higher than the maximum throughput of MultiPaxos. Like EPaxos, Gryff does not require a single replica to be involved in the execution of every operation, so it achieves better scalability and load-balancing than leader-based protocols.

Gryff Scales Better. We run the same workload with $n = 5$ and show the results in Figure 13 in Appendix A. Gryff's maximum throughput is higher than EPaxos because EPaxos can no longer always commit on the fast path. Each operation that commits on the slow path on EPaxos requires an additional quorum of messages and replies, which causes the system to more quickly saturate.

6.6 Tail at Scale

Our primary experiments show that Gryff improves read latency relative to our baselines. However, p50 write and p50 rmw latency are lower in EPaxos for $n = 3$. For other parts of the distributions and for MultiPaxos, the latency tradeoff is not comparable. To understand how these tradeoffs with EPaxos and MultiPaxos affect the performance of large-scale web applications whose structure resembles the common structure discussed in Section 6.3, we ran experiments that emulate end-user requests.

We emulate the request pattern of an application preparing a high-level object for an end-user. The object is composed of m sub-requests to the storage system that are drawn from a fixed distribution of reads, writes, and rmws. For example, in order to display a profile page in a social network, dozens of requests to the storage systems that store profile information must be initiated simultaneously [10]. The latency of one of these *tail at scale requests* is the maximum latency of all of its sub-requests. Thus, the median latency of tail at scale requests depends on the tail latency of the sub-requests.

The large-scale web applications whose workloads we emulate are typically read-heavy (§6.3). Moreover, they are often highly skewed. Facebook engineers report that a small set of objects account for a large fraction of total read and write operations in the social graph [2]. This experiment uses a 99%/0.9%/0.1% read/write/rmw workload with 25% conflicts. We vary the number of sub-requests m from 1 to 105 in increments of 15. Figure 11 summarizes the results.

Fast Reads Improve Median End-to-end Latency. Gryff's median latency is lower than that of EPaxos and MultiPaxos when fewer than half of the tail at scale requests are expected to contain a write or rmw operation. Compared to EPaxos' p50 latency, Gryff's is up to 57 ms lower for $n = 3$.

Five Replica Tail-at-scale. We run the same workload with $n = 5$ and show the results in Figure 14 in Appendix A. All protocols follow trends similar to the $n = 3$ case. However, Gryff cannot always complete reads in 1 RTT, so the longer tail of the read latency distribution causes the median latency of these tail at scale requests to increase at a smaller number of sub-requests. Similarly, EPaxos can no longer always commit in 1 RTT, so its tail latency is 2 RTTs plus the delay from blocking for dependencies.

7 Related Work

We review related work in geo-replicated storage systems and combining consensus with shared registers.

EPaxos. EPaxos [47] is the state-of-the-art for linearizable replication in geo-replicated settings. Our evaluation shows that EPaxos dominates Gryff for blind write latency. On the other hand, Gryff dominates EPaxos for read latency and its rmw latency ranges from higher to lower as the contention in the workload increases. This tradeoff is possible because Gryff only uses consensus for operations that require it.

Read Leases. Read leases allow clients to read replicated state from leaseholders by requiring updates to the replicated state be acknowledged by the leaseholders before completing [28, 49]. While this enables reads that need only communicate with a single replica, it sacrifices write availability when a leaseholder fails until the lease expires. Furthermore, to implement read leases safely, clocks at each process must have bounded skew, which is not satisfied by current commodity clocks [25]. Given these difficult availability and safety tradeoffs, we do not consider read leases in the context of Gryff or the baseline systems, but we believe they can be adapted to Gryff's write and rmw protocols.

Other Linearizable Protocols. Paxos [36], VR [50], Fast Paxos [38], Generalized Paxos [37], Mencius [45], Raft [51], Flexible Paxos [33], CAESAR [4], and SD Paxos [62] are consensus protocols that are used to implement linearizable replicated storage systems by ensuring the Agreement property for state machine replication [56]. Other systems, such as Sinfonia [1] and Zookeeper [34], use similarly expensive coordination protocols (2PC and atomic broadcast respectively) to provide strong consistency. CURP [53], Chain Replication [59], and other primary-backup protocols [3] achieve good performance when failures are detectable. Gryff guarantees linearizability in systems with undetectable failures for reads, writes, and rmws and only incurs expensive coordination overhead when needed.

ABD [5] provides linearizable reads and writes with guaranteed termination in asynchronous settings. Subsequent work has established the conditions under which linearizable shared register protocols can provide fast—i.e., complete in 1 RTT—reads [20] or writes [22]. Gryff maintains the performance benefits of these protocols for reads and writes and incorporates rmws for when application developers need stronger synchronization primitives.

Weaker Semantics for Lower Latency. Other geo-replicated systems eschew strong consistency for weaker consistency models that support lower latency operations. PNUTS [15] provides per-timeline sequential consistency, OCCULT [46], COPS [42], and GentleRain [19] provide causal consistency. ABD-Reg [60] provides regularity. Moreover, some systems provide hybrid consistency: Pileus [58], Gemini [39], and ICG [30] allow some operations to be strongly consistent and other operations to be weakly consistent. Gryff provides linearizability to free developers from reasoning about complex consistency models.

Consensus and Shared Registers. Active Quorum Systems (AQS) [7, 8], to our knowledge, was the first attempt to combine consensus with shared registers. We found that AQS allows for non-linearizable executions because its ordering mechanism is unstable for rmws (Appendix C). In contrast, Gryff uses carstamps to stably order rmws with their base updates while allowing for efficient reads and writes with an unstable order. In addition, Gryff is implemented and empirically evaluated.

Cassandra [44] provides reads and writes with tunable consistency and implements a compare-and-swap for applications that occasionally need stronger synchronization. Unlike Gryff, Cassandra's reads and writes are not linearizable by default and its compare-and-swap is not consistent when operating on data also accessed via reads and writes.

8 Conclusion

Gryff unifies consensus and shared registers with carstamps. This reduces latency by avoiding the cost of consensus for the common case of reads and writes. Our evaluation shows that the reduction in latency for individual operations reduces the median service-level latency to $\sim$60% of EPaxos for large-scale web applications.

Acknowledgments We thank our shepherd, Patrick P. C. Lee, and the anonymous reviewers for their helpful comments. A Additional Experiments

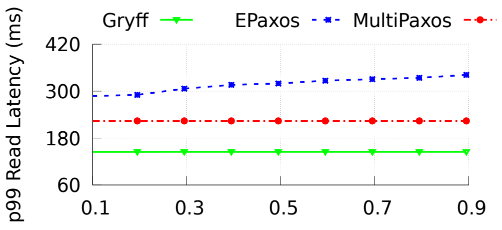
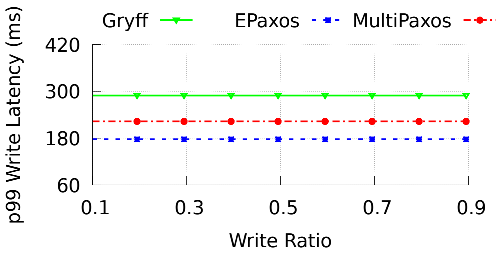
This appendix contains figures for experiments run with $n = 5$ replicas. Discussions of these results are in the main body of the paper in Section 6.

B Proof of Correctness

The proof of correctness for Gryff is presented in five parts. First, we define our model and introduce definitions (§B.1). Second, we describe the remainder of the rmw protocol (§B.2). Third, we prove safety for the base protocol (§B.3).



(a) Read operations.



(b) Write operations.

Figure 12: Gryff has better p99 read latency for $n = 5$ because, even though reads sometimes complete in 2 RTT, enough still complete in 1 RTT that the p99 latency is determined by 2 RTT in a region (CA) where the nearest quorum are relatively close (72 ms per RTT). EPaxos cannot always commit reads or writes in 1 RTT, so its latency increases relative to $n = 3$.

Fourth, we prove liveness for the base protocol (§B.4). Fifth, we argue that the read proxy optimization maintains the desired correctness properties (§B.5).

B.1 Preliminaries

We introduce the system model (§B.1.1) and define a shared object (§B.1.2).

B.1.1 Model

The system is comprised of a set P of *processes* $\{p_1, ..., p_m\}$. A subset $R \subseteq P$ of processes are *replicas* $\{r_1, ..., r_n\}$. Processes communicate with each other over point-to-point message channels. We assume *reliable message delivery*. This abstraction can be implemented on top of unreliable message channels that guarantee eventual delivery via retransmission and deduplication.

Processes may fail according to the *crash failure model*: a failed process ceases executing instructions and its failure is not detectable by other processes. The system is *asynchronous* such that there is no upper bound on the time it takes for a message to be delivered and there is no bound on relative speeds at which processes execute instructions.

Processes are state machines that deterministically transition between states when an *event* occurs. A process interacts with its environment via a set of objects O. The process may

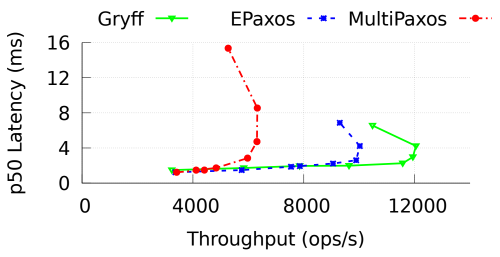


Figure 13: Gryff's throughput at saturation is higher than both EPaxos and MultiPaxos when $n = 5$.

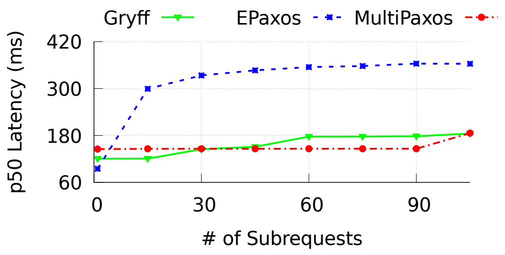

Figure 14: For $n = 5$, the difference in service-level p50 latency is larger because reads in EPaxos suffer from more blocking with more replicas and clients executing operations.

receive an operation op for an object via an invocation event $inv(op)$. The process indicates the result of the operation by generating a response event $resp(op)$. Internal events are the modification of local state at a process, the sending or receipt of a message, and the failure of process. We denote the process associated with an event e by $process(e)$.

An *execution* is an infinite sequence of events generated when the processes run a distributed algorithm. A *partial execution* is a finite prefix of some execution. A process is *correct* in an execution if there are infinite number of events associated with it. Otherwise, the process is *faulty*. Given a set of processes P and an execution e, we denote the set of correct processes in P by $alive(e,P)$, and the set of faulty processes in P by $faulty(e,P)$.

We borrow histories and related definitions from Herlihy and Wing [32]. A *history* h of an execution e is an infinite sequence of operation invocation and response events in the same order as they appear in e. A history may also be defined with respect to a partial execution e'; such a history is a finite sequence. A *subhistory* of a history h is a subsequence of the events of h.

We denote by $ops(h)$ the set of all operations whose invocations appear in h. An invocation is *pending* in a history if no matching response follows the invocation. If h is a history, $complete(h)$ is the maximal subsequence of h consisting only of invocations and matching responses. A history h is *complete* if it contains no pending invocations.

A history h is *sequential* if (1) the first event of h is an invocation and (2) each invocation, except possibly the last, is immediately followed by a matching response and each response is immediately followed by an invocation.

A *process subhistory*, $h|i$, of a history h is the subsequence of all events in h which occurred at p_i. An object subhistory h/o is similarly defined for an object $o \in O$. Two histories h and h' are *equivalent* if $\forall 1 \leq i \leq m. h|i = h'|i$. A history h is *well-formed* if $\forall 1 \leq i \leq m. h|i$ is sequential. We assume all histories are well-formed.

A set S of histories is *prefix-closed* if, whenever h is in S, every prefix of h is also in S. A *single-object* history is one in which all events are associated with the same object. A *sequential specification* for an object $o \in O$ is a prefix-closed set of single-object sequential histories for o. A sequential history h is *legal* if $\forall o \in O. h/o$ belongs to the sequential specification for o.

A history induces an irreflexive partial order on $ops(h)$, denoted $<_h$, as $op_1 <_h op_2$ if and only if $resp(op_1) < inv(op_2)$ in h.

A *quorum system* $\mathcal{Q} \subseteq \mathcal{P}(R)$ over R is a set of subsets of R with the *quorum intersection property*: for all $Q_1, Q_2 \in \mathcal{Q}$, $Q_1 \cap Q_2 \neq \emptyset$. We use *quorum* both to mean a set of replicas in a particular quorum system and the size of such a set.

B.1.2 Shared Objects

A shared object is a data type that supports the following operations:

- READ(): returns the value of the object
- WRITE(v): updates the value of the object to v
- RMW($f(\cdot)$): atomically reads the value v of the object, updates the value to $f(v)$, and returns v

We use $reads(h)$, $writes(h)$, and $rmws(h)$ to denote the set of all operations that are reads, writes, and rmws in $ops(h)$ respectively. We use $updates(h) = writes(h) \cup rmws(h)$ to denote the set of operations which update the state of a shared object in $ops(h)$. We use $observes(h) = reads(h) \cup rmws(h)$ to denote the set of operations which observe the state of a shared object in $ops(h)$.

Definition B.1. *(Shared Object Specification) A sequential object subhistory h/o belongs to the* sequential specification of a shared object *if for each $op \in observes(h/o)$ such that $resp(op) \in h/o$, $resp(op)$ contains the value of the latest preceding operation $u \in updates(h/o)$ or if there is no preceding update, then $resp(op)$ contains the initial value of o.*

B.2 Recovery for RMW Protocol

Algorithms 5 and 6 show the modifications to the basic EPaxos recovery protocol. In addition to the replica state in Figure 4, each replica also maintains *epoch*, the current epoch used in generating ballot numbers, and b, the highest ballot number seen in the current epoch. Each instance in the

Algorithm 5: Recovery coordinator protocol for rmws.

```
1  when replica $r \in R$ suspects replica $c \in R$ failed while committing instance $j$ do
2      $ballot \leftarrow (epoch, (b+1), id_r)$
3      send $Prepare(ballot, id_c, j)$ to all $r \in R$
4      wait to receive $PrepareOK(cmd_r, seq_r, deps_r, base_r, status_r, ballot_r)$ from all $r \in Q \in \mathcal{Q}$
5      $\mathcal{R} \leftarrow \{(cmd_r, seq_r, deps_r, base_r, status_r) \mid \forall r' \in Q : ballot_r \geq ballot_{r'}\}$
6      if $(cmd, seq, deps, base, \textit{committed}) \in \mathcal{R}$ then
7          run Commit Phase for $(cmd, seq, deps, base)$ at $(id_c, j)$
8      else if $(cmd, seq, deps, base, \textit{accepted}) \in \mathcal{R}$ then
9          run Accept Phase for $(cmd, seq, deps, base)$ at $(id_c, j)$
10     else if $\exists S \subseteq \mathcal{R}$ : $(cmd_c, seq_c, deps_c, base_c, status_c) \notin S) \wedge$ $(|S| \geq \lfloor \frac{n}{2} \rfloor) \wedge$ $(\forall reply_1, reply_2 \in S. reply_1 = reply_2 \wedge reply_1.status = \textit{pre-accepted})$ then
11         run Accept Phase for $(cmd_r, seq_r, deps_r, base_r) \in S$ at $(id_c, j)$
12     else if $(cmd, seq, deps, base, \textit{pre-accepted}) \in \mathcal{R}$ then
13         run PreAccept Phase for $cmd$ at $(id_c, j)$, avoid fast path
14     else
15         run PreAccept Phase for $no\text{-}op$ at $(id_c, j)$, avoid fast path
```

cmds array also contains a *ballot* number that is only used during recovery.

Note that the only change Gryff makes is that the *base* attribute is recovered along with the *deps* and *seq* attributes. To support optimized EPaxos, similar changes must be made to the optimized recovery protocol. We refer the reader to the optimized recovery protocol description in the EPaxos technical report [48] and our implementation of Gryff [29] for more details.

B.3 Proof of Linearizability

More Definitions. A *consistency condition* is specified by a particular set of schedules. Linearizability [32] is a strong consistency condition that reduces the complexity of building correct applications.

Definition B.2 (Linearizability)**.** *A complete history h satisfies* linearizability *if there exists a legal total order τ of $ops(h)$ such that $\forall op_1, op_2 \in ops(h). op_1 <_h op_2 \implies op_1 <_\tau op_2$.*

Algorithm 6: Recovery replica protocol for rmws.

```
1  when replica $r \in R$ receives a message $m$ from $x \in R$ do
2      case $m = Prepare(ballot, j, k)$ do
3          if $ballot > cmds[j][k].ballot$ then
4              $cmds[j][k].ballot = ballot$
5              send $PrepareOK(cmds[j][k])$ to $x$
6          else
7              send $NACK$ to $x$
```

Given a particular consistency condition, we are interested in whether a system enforces the condition for all possible partial executions.

Definition B.3. *The system* provides consistency condition *C if, for every partial execution e of the system, the history h of e can be extended to some history h' such that $complete(h')$ is in C.*

Unless otherwise noted, the rest of this section considers a complete history h produced by the distributed algorithm specified in Algorithms 1, 2, 3, and 4 in the main body of the paper and Algorithms 5 and 6 in this appendix.

The *coordinator* of a read or write is the invoking process. For rmws, the coordinator is the replica that notifies the invoking process its rmws has been executed. We assume that each $u \in updates(h)$ writes a unique value.

Definition B.4. *A complete operation $op \in observes(h)$* observes *an update $u \in updates(h)$ if the value returned in $resp(op)$ was written by u.*

Definition B.5. *The* carstamp cs_{op} *assigned to a complete operation $op \in ops(h)$ is:*

- *If $op \in writes(h)$, cs_{op} is the carstamp determined on Line 15 of Algorithm 1.*
- *If $op \in rmws(h)$, cs_{op} is the carstamp determined by Property B.4.*
- *If $op \in reads(h)$, cs_{op} is the carstamp cs_u assigned to the update u that op observes.*

Structure. We abstract the implementation details of the rmw protocol into four sufficient properties. The proofs of the subsequent lemmas and theorem assume that the rmw protocol provides these properties. At the end of this subsection, we prove that Gryff's rmw protocol does exactly this.

Property B.1. *(Freshness) Every complete $rmw \in rmws(h)$ is assigned a carstamp such that $\forall Q \in \mathcal{Q}. cs_{rmw} > \min_{r \in Q} cs_r$ where cs_r is the carstamp at r when rmw is invoked.*

Property B.2. *(Propagation) For every complete $rmw \in rmws(h)$ there exists a $Q \in \mathcal{Q}$ such that $\forall r \in Q. cs_r \geq cs_{rmw}$ where cs_r is the carstamp at r when rmw completes.*

Property B.3. *(Uniqueness) For all complete $rmw_1, rmw_2 \in rmws(h)$, $cs_{rmw_1} \neq cs_{rmw_2}$.*

Property B.4. *(Assignment) Every complete $rmw \in rmws(h)$ is assigned the carstamp $cs_{rmw} = (cs_u.ts, cs_u.id, cs_u.rmwc + 1)$ where u is the update that rmw observes.*

The linearizability proof follows a linear structure. We first prove that the carstamps assigned to each operation respect the real time order of h in Lemmas B.1-B.5. These proofs leverage the quorum intersection property. Then, we prove that a partial order on operations induced by their carstamps respects both the real time order of h and the legality condition for shared objects in Lemmas B.6-B.10. Finally, we connect these lemmas in Theorem B.1 to show that a total order of this partial order satisfies linearizability.

Lemma B.1. *After a replica $r \in R$ executes the* APPLY *function with tuple (v, cs) and before it executes any other instruction, $cs_r \geq cs$ where cs_r is the carstamp at r.*

Proof. By the condition on Line 13 of Algorithm 2. □

Lemma B.2. *$\forall r \in R, cs_r$ monotonically increases where cs_r is the carstamp at r.*

Proof.

1. cs_r is only modified via the APPLY function.

   PROOF: By the fact that, out of all of the replica pseudocode in Algorithms 2, 3, 4, 5, and 6, the APPLY function in Algorithm 2 is the only place that cs_r is assigned a value.

2. Q.E.D.

   PROOF: By Lemma B.1 and 1. □

Lemma B.3. *If an operation $op \in ops(h)$ is complete, then after $resp(op)$ there exists a $Q \in \mathcal{Q}$ such that $\forall r \in Q. cs_r \geq cs_{op}$ where cs_r is the carstamp at r.*

Proof.

1. Let op be an operation in $ops(h)$
2. CASE: $op \in writes(h)$

   2.1. Let $Q \in \mathcal{Q}$ be the quorum from which the coordinator of op receives *Write2Reply* messages.

   PROOF: By the hypothesis that op is complete and the requirement that the coordinator of op waits to receive *Write2Reply* messages from a quorum before completing op (Line 17 of Algorithm 1).

   2.2. Each $r \in Q$ received a *Write2* message for op containing (v, cs_{op}) where v is the value written by op.

   PROOF: By 2.1 and that a replica sends a *Write2Reply* message for op to the coordinator of op only if it receives a *Write2* message for op containing (v, cs_{op}).

   2.3. Each $r \in Q$ applied (v, cs_{op}) before sending a *Write2Reply* message for op.

   PROOF: By 2.1, 2.2, and the requirement that a replica sends a *Write2Reply* message after it applies the tuple it received in a *Write2* message (Line 10 of Algorithm 2).

   2.4. Q.E.D.

   By Lemma B.1, Lemma B.2, and 2.3.

3. CASE: $op \in reads(h)$

   3.1. CASE: op completed after Read Phase 1 (Line 7 of Algorithm 1).

   3.1.1. Let $Q \in \mathcal{Q}$ be the quorum from which the coordinator of op receives *Read1Reply* messages.

   PROOF: By the hypothesis that op is complete and the requirement that the coordinator of op waits to receive *Read1Reply* messages from a quorum before completing op (Line 3 of Algorithm 1).

   3.1.2. When each $r \in Q$ sent their *Read1Reply* message, $cs_r = cs_{op}$ where cs_r is the carstamp at r.

   PROOF: By 3.1.1, Definition B.5, the case 3.1 assumption, and the fast read condition (Line 6 of Algorithm 1).

   3.1.3. Q.E.D.

   PROOF: By Lemma B.2 and 3.1.2.

   3.2. CASE: op completed after Read Phase 2 (Line 10 of Algorithm 1).

   3.2.1. Let $Q \in \mathcal{Q}$ be the quorum from which the coordinator of op receives *Read2Reply* messages.

   PROOF: By the hypothesis that op is complete, the case 3.2 assumption, and the requirement that the coordinator of op waits to receive *Read2Reply* messages from a quorum before completing op in Read Phase 2 (Line 9 of Algorithm 1).

   3.2.2. Each $r \in Q$ received a *Read2* message for op containing (v, cs_{op}) where v is the value written by op.

   PROOF: By 3.2.1 and that a replica sends a *Read2Reply* message for op to the coordinator of op only if it receives a *Read2* message for op containing (v, cs_{op}).

   3.2.3. Each $r \in Q$ applied (v, cs_{op}) before sending a *Read2Reply* message.

   PROOF: By 3.2.1, 3.2.2, and the requirement that a replica sends a *Read2Reply* message after it applies the tuple it received in a *Read2* message (Line 5 of Algorithm 2).

3.2.4. Q.E.D.

By Lemma B.1, Lemma B.2, and 3.2.3.

4. CASE: $op \in rmws(h)$

PROOF: By Property B.2.

5. Q.E.D.

PROOF: By 1, 2, 3, and 4. □

Lemma B.4. *For all operations $op \in ops(h)$ and updates $u \in updates(h)$, $op <_h u \implies cs_{op} < cs_u$.*

Proof.

1. Let $Q_{op} \in \mathcal{Q}$ be a quorum such that $\forall r \in Q_{op}. cs_r \geq cs_{op}$ where cs_r is the carstamp at r when u is invoked.

PROOF: By the hypothesis that *op* completed before *u* was invoked and Lemma B.3.

2. Let u be an update in $updates(h)$.
3. CASE: $u \in writes(h)$

3.1. Let $Q_u \in \mathcal{Q}$ be the quorum from which the coordinator of u receives *Write1Reply* messages and cs_{max} be the largest carstamp contained in these messages.

PROOF: By the hypothesis that u is complete and the requirement that the coordinator of u waits to receive *Write1Reply* messages from a quorum before completing u (Line 13 of Algorithm 1).

3.2. Let $r \in Q_{op} \cap Q_u$ be a replica.

PROOF: By 1, 3.1, and the Quorum Intersection property.

3.3. *op* completed before r received a *Write1* message for u.

PROOF: By the hypothesis that *op* completed before u was invoked and 3.2.

3.4. The *Write1Reply* message that r sent for u contains a carstamp $cs_r \geq cs_{op}$.

PROOF: By 1 and 3.3.

3.5. The coordinator for u assigns u the carstamp $cs_u = (cs_{max}.ts + 1, id, 0)$ where $cs_{max} \geq cs_r$ and id is the id of the coordinator for u.

PROOF: By 3.1 and the assignment of a carstamp to u (Lines 14 and 15 of Algorithm 1).

3.6. Q.E.D.

PROOF: By 3.4, and 3.5.

4. CASE: $u \in rmws(h)$

PROOF: By 1 and Property B.1.

5. Q.E.D.

PROOF: By 2, 3, and 4. □

Lemma B.5. *For all operations $op \in ops(h)$ and reads $\rho \in reads(h)$, $op <_h \rho \implies cs_{op} \leq cs_\rho$.*

Proof.

1. Let u be the update that ρ observes.

PROOF: By the hypothesis that ρ is complete and Definition B.4.

2. CASE: $u = op$

2.1. $cs_\rho = cs_u = cs_{op}$

PROOF: By the assumption of case 2, 1, and Definition B.5.

2.2. Q.E.D.

PROOF: By 2.1.

3. CASE: $u \neq op$

3.1. Let $Q_{op} \in \mathcal{Q}$ be a quorum such that $\forall r \in Q_{op}. cs_r \geq cs_{op}$ where cs_r is the carstamp at r when ρ is invoked.

PROOF: By the hypothesis that *op* completed before ρ was invoked and Lemma B.3.

3.2. Let $Q_\rho \in \mathcal{Q}$ be the quorum from which the coordinator of ρ receives *Read1Reply* messages and cs_{max} be the largest carstamp contained in these messages.

PROOF: By the hypothesis that ρ is complete and the requirement that the coordinator of ρ waits to receive *Read1Reply* messages from a quorum before completing ρ (Line 3 of Algorithm 1).

3.3. Let $r \in Q_{op} \cap Q_\rho$ be a replica.

PROOF: By 3.1, 3.2, and the Quorum Intersection property.

3.4. *op* completed before r received a *Read1* message for ρ.

PROOF: By the hypothesis that *op* completed before u was invoked and 3.3.

3.5. The *Read1Reply* message that r sent for ρ contains a carstamp $cs_r \geq cs_{op}$.

PROOF: By 3.1 and 3.4.

3.6. The coordinator for ρ chooses u to be the update corresponding to cs_{max}.

PROOF: By 3.2 and the selection of an update to observe for ρ (Lines 4 and 5 of Algorithm 1).

3.7. Q.E.D.

PROOF: By 3.5 and 3.6.

4. Q.E.D.

PROOF: By 1, 2, and 3. □

We define the relation $<_\psi$ on $ops(h)$ as follows:

- $\forall op_1, op_2 \in ops(h).\, cs_{op_1} < cs_{op_2} \implies op_1 <_\psi op_2$.
- $\forall \rho \in reads(h)$ such that ρ observes an update $u \in updates(h)$, $u <_\psi r$. $\forall u' \in updates(h)$ such that $u <_\psi u'$, $r <_\psi u'$.
- $\forall \rho_1, \rho_2 \in reads(h)$ such that ρ_1 and ρ_2 observe the same update u, $inv(\rho_1) < inv(\rho_2) \implies \rho_1 <_\psi \rho_2$.
- $\forall op_1, op_2, op_3 \in ops(h).\, op_1 <_\psi op_2 \land op_2 <_\psi op_3 \implies op_1 <_\psi op_3$.

Less formally, $<_\psi$ orders operations by their carstamps and inserts reads in between the updates that the reads observe and subsequent updates.

Lemma B.6. *For all $u_1, u_2 \in updates(h)$, $u_1 <_h u_2 \implies u_1 <_\psi u_2$.*

Proof.

1. $cs_{u_1} < cs_{u_2}$.

PROOF: By the hypothesis that $u_1 <_h u_2$ and Lemma B.4.

2. Q.E.D.

PROOF: By 1 and the definition of $<_\psi$. □

Lemma B.7. *For all $u \in updates(h)$ and $\rho \in reads(h)$, $u <_h \rho \implies u <_\psi \rho$.*

Proof.

1. $cs_u \le cs_\rho$.

PROOF: By the hypothesis that $u <_h \rho$ and Lemma B.5.

2. CASE: $cs_u < cs_\rho$.

PROOF: By the definition of $<_\psi$.

3. CASE: $cs_u = cs_\rho$.

3.1. ρ observes u

PROOF: By the assumption of case 3 and Definition B.4.

3.2. Q.E.D.

PROOF: By 3.1 and the definition of $<_\psi$.

4. Q.E.D.

PROOF: By 1, 2, and 3. □

Lemma B.8. *For all $\rho \in reads(h)$ and $u \in updates(h)$, $\rho <_h u \implies \rho <_\psi u$.*

Proof.

1. $cs_\rho < cs_u$.

PROOF: By the hypothesis that $\rho <_h u$ and Lemma B.4.

2. Q.E.D.

PROOF: By 1 and the definition of $<_\psi$. □

Lemma B.9. *For all $\rho_1, \rho_2 \in reads(h)$, $\rho_1 <_h \rho_2 \implies \rho_1 <_\psi \rho_2$.*

Proof.

1. $cs_{\rho_1} \le cs_{\rho_2}$.

PROOF: By the hypothesis that $\rho_1 <_h \rho_2$ and Lemma B.5.

2. CASE: $cs_{\rho_1} < cs_{\rho_2}$

PROOF: By the definition of $<_\psi$.

3. CASE: $cs_{\rho_1} = cs_{\rho_2}$

3.1. $resp(\rho_1) < inv(\rho_2)$

PROOF: By the hypothesis that $\rho_1 <_h \rho_2$.

3.2. $inv(\rho_1) < inv(\rho_2)$

PROOF: By 3.1.

3.3. Q.E.D.

PROOF: By 3.2 and the definition of $<_\psi$.

4. Q.E.D.

PROOF: By 1, 2, and 3. □

Lemma B.10. *If τ is a topological sort of $<_\psi$, τ is a legal total order of $ops(h)$.*

Proof.

1. Let $op \in observes(h)$ be an operation that observes an update $u \in updates(h)$.

PROOF: By the hypothesis that op is completed.

2. CASE: $op \in reads(h)$.

2.1. There is no u' such that $u <_\psi u' <_\psi op$.

PROOF: By the assumption of case 2 and the definition of $<_\psi$.

2.2. There is no u' such that $u <_\tau u' <_\tau op$.

PROOF: By the hypothesis thatτ is a topological sort of $<_\psi$ and 2.1.

2.3. Q.E.D.

PROOF: By 2.2, the definition of legal, and Definition B.1.

3. CASE: $op \in rmws(h)$.

PROOF: By 1, 2, 3, 4, 5, and 7. □

RMW Properties. In order to prove that Gryff's rmw protocol provides the aforementioned properties, we rely on the correctness of EPaxos [48]. Because replicas act as coordinators for a rmw invoked by other processes, the failure of a replica during a rmw before the invoking process learns of the result may cause the invoking process to submit its rmw to another replica. Replicas must be able to recognize duplicates, only execute the rmw once, and store the result until the invoking process generates a response event.

This issue affects all protocols that rely on a subset of processes to coordinate the execution of operations on behalf of other processes. In Gryff, if a process learns that a pending rmw has been executed by at least one replica, it must ensure that a quorum have executed the rmw before completing it. A replica can ensure this by sending *Commit* messages with the appropriate attributes to all replicas. Replicas that receive *Commit* messages for a rmw they have already executed can immediately reply with an *Executed* message. For brevity, we omit the duplicate execution check for a replica receiving a rmw in Algorithm 3 and assume that if a replica has already executed a rmw, it will skip to Line 20 of Algorithm 3.

We assume the use of the majority quorum system $\mathcal{Q}_{maj}$ such that $\forall Q \in \mathcal{Q}_{maj} \cdot |Q| = \lfloor \frac{n}{2} \rfloor + 1$. This assumption implies each quorum is a subset of a fast quorum and equivalent to a slow quorum in canonical EPaxos.

Definition B.6. *A command γ is* committed *at a replica $r \in R$ if the cmds array at r contains an instance with γ as the command and* **committed** *as the status.*

Lemma B.11. *The system provides Property B.1.*
Proof. Let *rmw* be an operation in *rmws*(h) and $Q \in \mathcal{Q}$ be a quorum.

1. *rmw* committed with attributes that are the union of the attributes computed by each $r \in S$ where $S \supseteq Q'$ for some $Q' \in \mathcal{Q}$.

 1.1. *rmw* commits with basic EPaxos or with optimized EPaxos.

 1.2. CASE: *rmw* commits with basic EPaxos.

 PROOF: By Step 1.1 of the proof of Theorem 4 in the EPaxos technical report, which states that *rmw* is committed with the union of attributes from $\lfloor \frac{n}{2} \rfloor + 1$ replicas, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

 1.3. CASE: *rmw* commits with optimized EPaxos.

 There are two sub-cases:

 1.3.1. CASE: *rmw* commits without running the recovery procedure.

 PROOF: By 1.2 and that a fast quorum in optimized EPaxos is larger than a majority quorum because this case reduces to 1.2 with the fast quorum size reduced from $n-1$.

 1.3.2. CASE: *rmw* commits through the optimized recovery procedure.

 1.3.2.1. CASE: *rmw* commits before step 7 of the optimized recovery procedure, or after exiting one of the Else branches in step 7.

 PROOF: By Step 2.1 of Theorem 7 of the EPaxos technical report, which states that *rmw* must have been pre-accepted by a majority of replicas, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

 1.3.2.2. CASE: *rmw* committed after exiting the optimized recovery procedure on the If branch in step 7.

 PROOF: By Step 2.2.2 of Theorem 7 of the EPaxos technical report, which states that *rmw* must have been pre-accepted by a majority of replicas, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

 1.3.2.3. Q.E.D.

 PROOF: By 1.3.2.1 and 1.3.2.2.

 1.3.3. Q.E.D.

 PROOF: By 1.3.1 and 1.3.2.

 1.4. Q.E.D.

 PROOF: By 1.1, 1.2, and 1.3.

2. The *base* attribute of *rmw* is chosen such that $base.cs \geq \max_{r \in S} cs_r \geq \max_{r \in Q'} cs_r$ where cs_r is the carstamp at r when *rmw* is invoked.

 2.1. *rmw* committed after the PreAccept Phase or the Accept Phase. Note that the basic recovery procedure and optimized recovery procedure always exit by running the PreAccept, Accept, or Commit phase. Each of these is reducible to committing after the PreAccept phase or Accept phase.

 2.2. CASE: *rmw* committed after the PreAccept Phase (Line 12 of Algorithm 3).

 2.2.1. When each $r \in S$ sent their *PreAcceptOK* message, $cs_r = base.cs$ where cs_r is the carstamp at r.

 PROOF: By 1, the case 2.2 assumption, and the fast path condition (Line 10 of Algorithm 3).

 2.2.2. Q.E.D.

 PROOF: By Lemma B.2 and 2.2.1.

 2.3. CASE: *rmw* committed after the Accept Phase.

 2.3.1. CASE: The Accept phase is run during normal processing.

 PROOF: By Lemma B.2 and the selection of *base* in the Accept Phase (Line 15 of Algorithm 3).

 2.3.2. CASE: The Accept phase is run during recovery (either basic or optimized).

 PROOF: By the fact that the recovery procedures exit directly to the Accept phase only if *rmw* has previously been pre-accepted by a majority.

 2.4. Q.E.D.

PROOF: By 2.1, 2.2, and 2.3.

3. $base.cs \geq \min_{r \in Q} cs_r$.

PROOF: By 2 and the Quorum Intersection property ($\max_{r \in Q'} cs \geq \min_{r \in Q \cap Q'} cs_r \geq \min_{s \in Q'} cs_r$).

4. $cs_{rmw} > base.cs$.

PROOF: By the generation of the carstamp of *rmw* (Line 18 of Algorithm 4).

5. Q.E.D.

PROOF: By 3 and 4. □

Lemma B.12. *The system provides Property B.2.*

Proof. Let *rmw* be an operation in $rmws(h)$.

1. After *rmw* completes, $\exists Q \in \mathcal{Q}$ such that each $r \in Q$ has executed *rmw*.

PROOF: By the hypothesis that *rmw* is complete and the requirement that the coordinator only completes *rmw* when it has received *Executed* messages from a quorum (Line 21 of Algorithm 3).

2. Each $r \in Q$ applied cs_{rmw}.

PROOF: By 1 and that a replica only sends an *Executed* message for *rmw* if it has applied the carstamp and value of *rmw* (Line 20 of Algorithm 3).

3. Q.E.D.

PROOF: By 2, Lemma B.1, and Lemma B.2. □

Lemma B.13. *The system provides Property B.3.*

Proof. Let rmw_a and rmw_b be operations in $rmws(h)$.

1. Either rmw_a is executed before rmw_b or vice versa.

PROOF: By Theorem 4 and Theorem 7 from the EPaxos technical report, that the logic for determining the *deps* and *seq* attributes of a command remains unchanged from EPaxos, and that the logic for determining the execution order of commands remains unchanged from EPaxos.

2. CASE: rmw_a is executed before rmw_b.

2.1. $cs_{rmw_a} < cs_{rmw_b}$.

2.1.1. For any two interfering commands rmw_a and rmw_b, there is a sequence of zero of more interfering commands that are executed between rmw_a and rmw_b. Let this sequence be $rmw_a = rmw_1, ..., rmw_k = rmw_b$.

PROOF: By Theorem 4 and Theorem 7 from the EPaxos technical report.

2.1.2. Proof by induction on the sequence $rmw_1, ..., rmw_k$.

2.1.2.1. Base case: $k = 2$ (rmw_2 immediately follows rmw_1).

2.1.2.1.1. $prev.cs = cs_{rmw_1}$.

PROOF: By the assumption of the base case 2.1.2.1 and that *prev* is only modified when a rmw is executed (Line 19 of Algorithm 4).

2.1.2.1.2. $cs_{rmw_2} > prev.cs$.

PROOF: By the generation of cs_{rmw_2} to be larger than *prev* at the time that rmw_2 is executed (Lines 15, 16, and 18 of Algorithm 4).

2.1.2.1.3. Q.E.D.

PROOF: By 2.1.2.1.1 and 2.1.2.1.2.

2.1.2.2. ASSUME: $cs_{rmw_1} < cs_{rmw_i}$.
PROVE: $cs_{rmw_1} < cs_{rmw_{i+1}}$.

2.1.2.2.1. $prev.cs = cs_{rmw_i}$.

PROOF: By the assumption that rmw_i was the last rmw to be executed and that *prev* is only modified when a rmw is executed (Line 19 of Algorithm 4).

2.1.2.2.2. $cs_{rmw_{i+1}} > prev.cs$

PROOF: By the generation of $cs_{rmw_{i+1}}$ to be larger than *prev* at the time that rmw_{i+1} is executed (Lines 15, 16, and 18 of Algorithm 4).

2.1.2.2.3. Q.E.D.

PROOF: By 2.1.2.2.1 and 2.1.2.2.2.

2.1.3. Q.E.D.

PROOF: By 2.1.1 and 2.1.2.

2.2. Q.E.D.

PROOF: By 2.1.

3. CASE: rmw_2 is executed before rmw_1.

PROOF: By symmetry with case 2.

4. Q.E.D.

PROOF: By 1, 2, and 3. □

Lemma B.14. *The system provides Property B.4.*

Proof. Let *rmw* be an operation in $rmws(h)$.

1. Let $u \in updates(h)$ be the update that *rmw* observes.

PROOF: By the assumption that *rmw* is complete.

2. Let cs_u be the carstamp chosen on Lines 14 and 16 of Algorithm 4.

PROOF: By 1 and Definition B.4.

3. Q.E.D.

PROOF: By 2, Definition B.5, and the generation of cs_{rmw} (Line 18 of Algorithm 4). □

Lemmas B.11, B.12, B.13, and B.14 imply that Gryff's rmw protocol satisfies the assumptions needed to prove Theorem B.1.

B.4 Proof of Wait-Freedom

More Definitions. Wait-freedom is a strong liveness property that guarantees a correct process can always make progress regardless of concurrent operations invoked by other processes.

Definition B.7. *(Wait-Freedom) A subset $S \subseteq ops(h)$ of operations are* wait-free *in a history h with execution e if $\forall op \in S. process(inv(op)) \in alive(e,P) \implies resp(op) \in h$.*

Unless otherwise noted, the rest of this section considers an execution e with history h produced by the distributed algorithm specified in Algorithms 1, 2, 3, and 4 in the main body of the paper and Algorithms 5 and 6 in this appendix.

We assume that there are $n = 2f + 1$ replicas and that up to f replicas may fail and any number of other processes may fail in e. Thus, we assume the use of the majority quorum system $\mathcal{Q}_{maj}$ such that $\forall Q \in \mathcal{Q}_{maj}. |Q| = f + 1$.

Structure. We first prove that Gryff's reads and writes are wait-free in Theorems B.2 and B.3. To prove wait-freedom for rmws, we discuss why the synchrony assumption must be strengthened from asynchrony to partial synchrony. With this stronger assumption, we restate the liveness property of EPaxos and use this to prove that Gryff's rmws are wait-free in Theorem B.5.

Theorem B.2. *The system provides read wait-freedom.*

Proof. 1. Let op be an operation in $reads(h)$.

2. The coordinator of op is correct.

PROOF: By the definition of a coordinator of a read and by the hypothesis that $process(inv(op)) \in alive(e,P)$.

3. $|alive(e,R)| \geq f + 1$

PROOF: By the assumption that at most f out of $2f + 1$ replicas can fail in any execution.

4. The coordinator sends a *Read1* message for op to every replica $r \in R$.

PROOF: By 2 and Line 2 of Algorithm 1.

5. Each $r \in alive(e,R)$ delivers a *Read1* message for op.

PROOF: By 4, the assumption that $r \in alive(e,R)$, and the assumption that the network guarantees eventual reliable message delivery.

6. Each $r \in alive(e,R)$ sends a *Read1Reply* message for op to the coordinator.

PROOF: By 5, the assumption that $r \in alive(e,R)$, and that the message handler for a *Read1* message contains no blocking instructions or conditional branches (Algorithm 2).

7. The coordinator delivers *Read1Reply* messages from a quorum $Q \in \mathcal{Q}$.

PROOF: By 2, 3, 6, the assumption that the network guarantees eventual reliable message delivery, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

8. CASE: $\forall r \in Q. cs_r = cs_{max}$

PROOF: By 7, the assumption of the case and that the coordinator generates $resp(op)$ when this assumption holds (Lines 6 and 7 of Algorithm 1).

9. CASE: $\exists r \in Q : cs_r \neq cs_{max}$

9.1. The coordinator sends a *Read2* message for op to every replica $r \in R$.

PROOF: By 2, the assumption of the case, and Line 8 of Algorithm 2.

9.2. Each $r \in alive(e,R)$ delivers a *Read2* message for op.

PROOF: By 9.1, the assumption that $r \in alive(e,R)$, and the assumption that the network guarantees eventual reliable message delivery.

9.3. Each $r \in alive(e,R)$ sends a *Read2Reply* message for op to the coordinator.

PROOF: By 9.2, the assumption that $r \in alive(e,R)$, and that the message handler for a *Read2* message contains no blocking instructions or conditional branches on sending a reply (Algorithm 2).

9.4. The coordinator delivers *Read2Reply* messages from a quorum $Q \in \mathcal{Q}$.

PROOF: By 2, 3, 9.3, the assumption that the network guarantees eventual reliable message delivery, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

9.5. Q.E.D.

PROOF: By 7, 9.4, and the fact that the coordinator generates a $resp(op)$ after receiving a quorum of *Read2Reply* messages (Line 10 of Algorithm 1).

10. Q.E.D.

PROOF: By 7, 8, and 9. □

Theorem B.3. *The system provides write wait-freedom.*

Proof. 1. Let *op* be an operation in $writes(h)$.

2. The coordinator of *op* is correct.

PROOF: By the definition of a coordinator of a write and by the hypothesis that $process(inv(op)) \in alive(e,P)$.

3. $|alive(e,R)| \geq f+1$

PROOF: By the assumption that at most f out of $2f+1$ replicas can fail in any execution.

4. The coordinator sends a *Write1* message for *op* to every replica $r \in R$.

PROOF: By 2 and Line 12 of Algorithm 2.

5. Each $r \in alive(e,R)$ delivers a *Write1* message for *op*.

PROOF: By 4, the assumption that $r \in alive(e,R)$, and the assumption that the network guarantees eventual reliable message delivery.

6. Each $r \in alive(e,R)$ sends a *Write1Reply* message for *op* to the coordinator.

PROOF: By 5, the assumption that $r \in alive(e,R)$, and that the message handler for a *Write1* message contains no blocking instructions or conditional branches (Algorithm 2).

7. The coordinator delivers *Write1Reply* messages from a quorum $Q \in \mathcal{Q}$.

PROOF: By 2, 3, 6, the assumption that the network guarantees eventual reliable message delivery, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

8. The coordinator sends a *Write2* message for *op* to every replica $r \in R$.

PROOF: By 2, 7, and Line 16 of Algorithm 2.

9. Each $r \in alive(e,R)$ delivers a *Write2* message for *op*.

PROOF: By 8, the assumption that $r \in alive(e,R)$, and the assumption that the network guarantees eventual reliable message delivery.

10. Each $r \in alive(e,R)$ sends a *Write2Reply* message for *op* to the coordinator.

PROOF: By 9, the assumption that $r \in alive(e,R)$, and that the message handler for a *Write2* message contains no blocking instructions or conditional branches on sending a reply (Algorithm 2).

11. The coordinator delivers *Write2Reply* messages from a quorum $Q \in \mathcal{Q}$.

PROOF: By 2, 3, 10, the assumption that the network guarantees eventual reliable message delivery, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

12. Q.E.D.

PROOF: By 11 and the fact that the coordinator generates a $resp(op)$ after receiving a quorum of *Write2Reply* messages (Algorithm 1). □

Note that Theorems B.2 and B.3 rely on our weak network assumption that messages are eventually delivered and do not require any stronger assumptions about the synchrony of the system. Eventual message delivery only precludes infinitely long partitions in the network, which is unlikely to occur in any practical system.

RMW Wait-Freedom. The FLP impossibility result implies that no consensus protocol can provide both safety and liveness in asynchronous systems where processes can fail [24]. Because rmw can solve consensus [31], this also implies that no rmw protocol can provide both.

The rest of this section shows that Gryff's rmw protocol provides wait-freedom if we relax the system model from asynchrony to partial synchrony [21]. In the partial synchrony model, there are two bounds Δ and Φ such that after some unknown point in time during an execution of the system, all messages are delivered within Δ time of when they are sent and all correct processes take at most Φ time between the execution of instructions.

As in the proof of linearizability, we rely on the correctness of EPaxos in the partial synchrony model [48].

Theorem B.4. *EPaxos guarantees with high probability that every proposed command will eventually be committed by every $r \in alive(e,R)$ as long as messages eventually reach their destination before their recipient times out.*

Lemma B.15. *With high probability, every $r \in alive(e,R)$ executes every rmw that commits.*

Proof. Let r be a correct replica, *rmw* be an operation in $rmws(h)$, and D be the transitive closure of the set of dependencies for *rmw* determined by the commit protocol.

1. With high probability, every $rmw' \in D$ eventually commits at r.

PROOF: By Theorem B.4.

2. With high probability, every $rmw' \in D$ is executed at r. Proof by generalized induction on D.

2.1. Base case: $rmw_0 \in D$ is the first rmw committed in e.

PROOF: By the assumption that r is correct, the assumption of the base case 2.1, and that the EPaxos execution algorithm contains no blocking instructions for commands with no dependencies.

2.2. ASSUME: For any $rmw'' \in D$ such that rmw'' is before rmw' in the EPaxos execution order, rmw'' is executed at r.
PROVE: rmw' is executed at r

PROOF: By the assumption that r is correct, the induction hypothesis 2.2, and that the EPaxos execution algorithm only blocks the execution of a command until all of its dependencies have executed.

2.3. Q.E.D.

By 1, 2.1, and 2.2.

3. With high probability, after all $rmw' \in D$ have executed, rmw will be executed.

3.1. CASE: rmw is in its own strongly connected component in the dependency graph.

PROOF: By the execution order specified by the EPaxos execution algorithm, which requires every dependency of a command to be executed before the command is executed.

3.2. CASE: rmw is in a cycle in the dependency graph.

PROOF: By the execution order specified by the EPaxos execution algorithm, which requires that cycles be broken in order of *seq*, and the fact that rmw may be executed before some of its dependencies within the same cycle.

3.3. Q.E.D.

PROOF: By 3.1 and 3.2.

4. Q.E.D.

PROOF: By 2 and 3. □

Theorem B.5. *If there is a point in time after which the system is synchronous with bounds Δ and Φ, the system provides rmw wait-freedom with high probability.*

Proof. Let op be an operation in $rmws(h)$.
1. $|alive(e,R)| \geq f+1$

PROOF: By the assumption that at most f out of $2f+1$ replicas can fail in any execution.

2. With high probability, every $r \in alive(e,R)$ commits an instance containing op.

PROOF: By the hypothesis that there is a finite time after which all messages are delivered within Δ time of when they are sent and Theorem B.4.

3. With high probability, every $r \in alive(e,R)$ executes op.

PROOF: By 2 and Lemma B.15.

4. With high probability, every $r \in alive(e,R)$ sends an *Executed* message for op to the coordinator.

By 3 and that there are no blocking instructions or conditional branches on sending an *Executed* message in the EXECUTE function.

5. With high probability, the coordinator delivers an *Executed* message for op from a quorum $Q \in \mathcal{Q}$.

PROOF: By 1, 4, the assumption that the network guarantees eventual reliable message delivery, and the assumption that the majority quorum system $\mathcal{Q}_{maj}$ is used.

6. Q.E.D.

PROOF: By 5 and the fact that the coordinator generates a $resp(op)$ after receiving a quorum of *Executed* messages. □

B.5 Read Proxy Correctness

Algorithm 7: The modified read coordinator protocol and *Read1* message handler for using the read proxy optimization.

```
1  procedure Coordinator::READ($(v, cs)$) at $p \in P$
2      send $Read1(v, cs)$ to all $r \in R$
3      wait to receive $Read1Reply(v_r, cs_r)$ from all
         $r \in Q \in \mathcal{Q}$
4      for $r \in Q$ do
5          APPLY($(v_r, cs_r)$)
6      $cs_{max} \leftarrow \max_{r \in Q} cs_r$
7      $v \leftarrow v_r : cs_r = cs_{max}$
8      if $\forall r \in Q : cs_r = cs_{max}$ then
9          return $v$
10     send $Read2(v, cs_{max})$ to all $r \in R$
11     wait to receive $Read2Reply$ from all $r \in Q' \in \mathcal{Q}$
12     return $v$
13 when replica $r \in R$ receives a message $m$ from $p \in P$ do
14     case $m = Read1(v', cs')$ do
15         APPLY($(v', cs')$)
16         send $Read1Reply(v, cs)$ to $p$
```

The pseudocode for the read proxy optimization described in Section 5 is in Algorithm 7. We briefly argue that the optimization does not change the correctness proofs.

The optimization changes the definition of the coordinator of a read from the invoking process to the replica that notifies the invoking process of the result of the read. Neither the definition change nor the added logic for the optimization affect the proof of linearizability because the value that a read observes is still chosen to be the one associated with the maximum carstamp on a quorum. Reads can be executed multiple times without affecting the state of the shared object, so it is safe for a client to timeout after a finite time t and forward its read to another replica if it suspects the initial coordinator failed.

The proof of wait-freedom for reads remains the same, but needs a small clarification in the proof of Step 2. Since at most f replicas can fail, a client will eventually forward its read to a correct replica that will complete the read coordinator protocol. This will happen after at most $f \cdot t$ time, which is finite.

C Non-Linearizable AQS Execution

AQS [8] attempts to exploit the same observation that Gryff does about the relationship between shared register and consensus protocols to improve performance under the Byzantine failure model. In Figure 15, we demonstrate an explicit execution of AQS that exhibits non-linearizable behavior.

Here, process p_1 first issues and completes w_1 with $ts = (1,1)$ that is seen by all replicas (Figure 15.1). After this write has completed, process p_2 begins w_2 and sees w_1 with $ts = (1,1)$, so it chooses $ts = (2,2)$ for w_2 (Figure 15.2). This write then pauses, and process p_3 issues rmw_3 to primary s_4. The primary gathers state from all replicas and picks $base\_state = \langle w_1, ts = (1,1)\rangle$ (Figure 15.3). The primary then generates an updated state v_l based on w_1 and sends PRE-PREPARE messages to all replicas. These messages are accepted by all replicas because w_1 is the most recent state they have observed (Figure 15.4). All replicas then broadcast PREPARE messages to all other replicas, and the messages are received and accepted. All replicas then broadcast COMMIT messages (Figure 15.5) and rmw_3 pauses. Process p_2 now finishes w_2 by sending out a second round of messages with $ts = (2,2)$, and all replicas accept and apply this write (Figure 15.6). Shortly after, replicas receive COMMIT messages from all other replicas for rmw_3, forming a commit certificate. All replicas generate $ts_l = succ(ts = (1,1), s_4) = (2,4)$ and apply rmw_3 (Figure 15.7). Process p_4 now issues a read ρ_4, and the read completes in one round, returning $ts = (2,4)$ from rmw_3 (Figure 15.8).

There is no legal total order for this execution because rmw_3 must follow w_1 with no writes in between because rmw_3 picks $base\_state = \langle w_1, ts = (1,1)\rangle$. Thus, rmw_3 must be ordered before w_2. We also must have ρ_4 ordered after both rmw_3 and w_2 because it begins in real time after both operations have finished. The read ρ_4 sees rmw_3, so rmw_3 must be ordered after w_2. Thus, there is no legal total order of operations and linearizability is not satisfied.

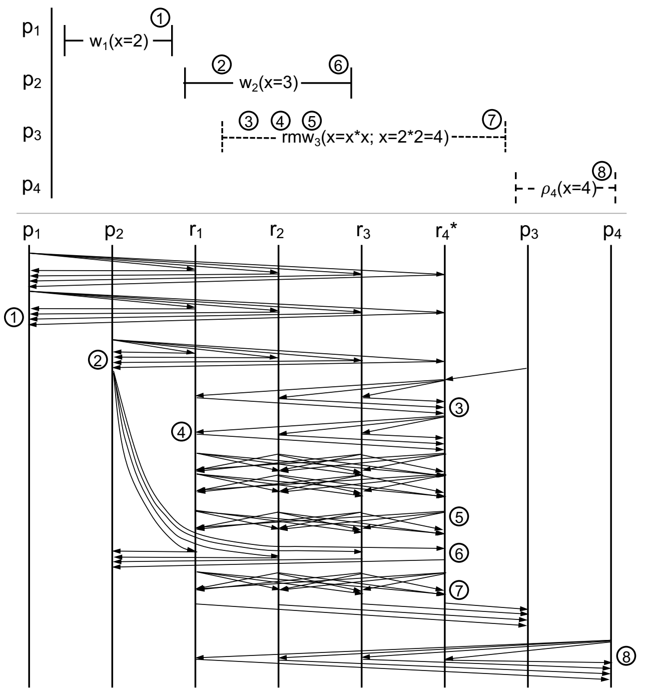

Figure 15: Labeled numbers represent the following events: 1. p_1 issues and completes w_1 with $ts = (1,1)$. 2. p_2 issues w_2 and gets back $ts = (1,1)$; the process then picks $ts = (2,2)$ for w_2. 3. The primary s_4 picks $base\_state = \langle w_1, ts = (1,1)\rangle$. 4. All replicas accept PRE-PREPARE messages because w_1 is the most recent state observed. 5. All replicas broadcast COMMIT messages to all other replicas. 6. All replicas apply w_2 because $ts = (2,2) > ts = (1,1)$. 7. All replicas apply rmw_3 because $ts = (2,4) > ts = (2,2)$. 8. p_4 issues and completes ρ_4 in 1 round, returning rmw_3 with $ts = (2,4)$.

CableMon: Improving the Reliability of Cable Broadband Networks via Proactive Network Maintenance

Abstract

Cable broadband networks are one of the few "last-mile" broadband technologies widely available in the U.S. Unfortunately, they have poor reliability after decades of deployment. Cable industry proposed a framework called Proactive Network Maintenance (PNM) to diagnose the cable networks. However, there is little public knowledge or systematic study on how to use these data to detect and localize cable network problems. Existing tools in the public domain have prohibitive high false-positive rates.

In this paper, we propose CableMon, the first public-domain system that applies machine learning techniques to PNM data to improve the reliability of cable broadband networks. CableMon uses statistical models to generate features from time series data and uses customer trouble tickets as hints to infer abnormal thresholds for these generated features. We use eight-month of PNM data and customer trouble tickets from an ISP to evaluate CableMon's performance. Our results show that 81.9% of the abnormal events detected by CableMon overlap with at least one customer trouble ticket. This ticket prediction accuracy is four times higher than that of the existing public-domain tools used by ISPs. The tickets predicted by CableMon constitute 23.0% of the total network-related trouble tickets, suggesting that if an ISP deploys CableMon and proactively repairs the faults detected by CableMon, it can preempt those customer calls. Our current results, while still not mature, can already tangibly reduce an ISP's operational expenses and improve customers' quality of experience. We expect future work can further improve these results.

1 Introduction

Broadband access networks play a crucial role in modern life. They help narrow digital divide, enable e-commerce, and provide opportunities for remote work, study, and entertainment. In the US, cable networks are one of the few available infrastructures that can provide broadband Internet access to US homes. In many rural areas, they are often the only broadband choice. According to a study in 2016 [6], cable broadband is available to 93% of US homes, far more than the two alternative choices: high bitrate digital subscriber line (VDLS) (43%) and Fiber-to-the-Premises (FTTP) (29%).

However, cable networks are prone to reliability problems, partly due to their Hybrid Fiber-Coaxial (HFC) architecture. This architecture uses both optical fibers and coaxial cables to deliver a mixed bundle of traffic, including video, voice, and Internet data. Unlike fiber optics, coaxial cables are vulnerable to radio frequency (RF) interference. Many parts of the cable networks are now decades old [1]. Aging can lead to problems such as cable shielding erosion, loose connectors, and broken amplifiers. All those problems can manifest themselves as poor application-layer performance, e.g., slow web responses or low-quality video streaming. Much measurement study has shown that broadband networks have poor reliability [3,12,17,22,23,28]. A recent one [3] shows that the average availability of broadband Internet access is at most two nines (99%), much less than the minimum FCC's requirement (four nines 99.99%) for the public switched telephone network (PSTN) [20]. Admittedly, if ISPs replace the last-mile coaxial cables with fiber optics, many of these problems may disappear. However, due to the prohibitive cost of FTTP, cable broadband networks are likely to remain as one of the few broadband choices in rural America for the next decade or two. Therefore, it is critically important that the cable Internet services remain robust during emergencies, especially as more and more subscribers migrate their landline phones to VoIP phones.

The cable industry has long recognized this problem and developed a platform called Proactive Network Maintenance (PNM) to improve the reliability of their networks [7]. PNM enables a cable ISP to collect a set of performance metrics from each customer's cable modem. We refer to this set of data as PNM data. One example of a PNM metric is a cable

[*] Jiyao Hu and Zhenyu Zhou, placed in alphabetic order, are the lead student authors and contributed equally to this work.

channel's signal-to-noise ratio. PNM aims to enable an ISP to proactively detect and fix network faults before they impact services and customers.

Although PNM has been incorporated into DOCSIS since 2005 [7], how to use PNM data to improve network reliability remains an open challenge. The best current practice recommended by CableLabs[1] [7] and the tools used by some ISPs [22] use a set of manually configured thresholds to flag a faulty network condition. The feedback from deploying ISPs is that these thresholds are often too conservative, leading to high false positives.

This work aims to improve the reliability of cable broadband networks. We speculate that the challenge of using PNM data is due to the lack of expert knowledge or ground truth on what PNM values warrant a proactive network repair. In an RF system like a cable network, network conditions may degrade gradually, making it challenging to define a static threshold that separates what is faulty from what is not. We develop a system called CableMon, which uses machine learning techniques to infer network faults that demand immediate repair. CableMon couples PNM data with customer trouble tickets to identify the ranges of PNM values that are likely to lead to a customer's trouble call. Our hypothesis is that if a network fault impacts an ISP's customers, then some customer is likely to call to report the problem. Therefore, we can use customer trouble tickets as hints to learn what network conditions are likely to lead to customer trouble calls. It is desirable for an ISP to prioritize its effort to repair those problems, because if they persist, they are likely to reduce customer satisfaction and increase the cost for customer support.

A key technical challenge we face is that both customer tickets data and PNM data contain much noise. Customer tickets are not reliable indicators of network faults. A customer may or may not call when there is an underlying network problem, and vice versa. PNM data, by its nature, describe cable channels' conditions as well as environmental noises. Therefore, if we use customer tickets to label PNM data as normal or faulty, and apply an off-the-shelf machine learning technique to detect network faults, we may not have good detection results. In addition, manual labeling is not practical in this context, because there lacks expert knowledge and the dataset is too large.

In CableMon's design, we use three techniques to address the above challenges (§ 4). First, to reduce noise in customer tickets, we filter customer tickets according to the ticket descriptions and only choose the tickets that suggest network problems as hints. Second, to reduce noise in PNM data, we treat a modem's PNM data as time series data and use its time series features (e.g., expected moving average or variance) for fault detection. Third, we develop a customized classification method that is robust to both noise in tickets and noise in PNM data.

[1]CableLabs is a research and development lab founded by American Cable operators in 1988 and led the development of DOCSIS and PNM.

With the support of CableLabs, we have obtained eight months of anonymized PNM data and the corresponding customer trouble tickets from a mid-size U.S. ISP. We use five months of data to train CableMon, and use the next three months data following the training set as the test set to evaluate how well CableMon detects network faults. CableMon takes the PNM data in our test set as input and detects when a network fault occurs and when it ends. Due to the lack of ground truth, we evaluate CableMon's performance using customer trouble tickets in the test set. When CableMon detects a network anomaly, if a customer who experiences the anomaly reports a ticket, we consider the detection a success. We compare CableMon with a tool currently used by our collaborating ISP, which we refer to as AnonISP, and with a tool developed by Comcast [22]. Our results show that 81.9% of the anomalies detected by CableMon lead to a customer trouble ticket. In contrast, only 10.0% of the anomalies detected by AnonISP's tool lead to a trouble ticket; and 23.5% of the anomalies detected by Comcast's tool lead to a customer ticket. In addition, CableMon predicts 23.0% of all network-related tickets, while AnonISP's tool predicts 25.3% and Comcast's tool predicts less than 3%. The trouble tickets predicted by CableMon on average last 32.5 hours (or 53.3%) longer than those predicted by other tools, suggesting that those tickets are more likely to require repair efforts. The median time from the beginning of a fault detected by CableMon to the reporting time of a ticket is 164.1 hours (or 29.3%) shorter than that of a fault detected by other tools, suggesting that the faults detected by CableMon require more immediate repair.

To the best of our knowledge, this work is the first large-scale public study that couples PNM data with customer trouble tickets to improve the reliability of cable networks. Our main contribution is CableMon, a system that detects network faults more reliably than the existing public-domain work. It serves as a starting point to unleash the full potential of PNM data. We are working with an ISP and the CableLabs to deploy CableMon in practice and we expect the feedback from practice can further improve the performance of CableMon. One general lesson we learn is that one can use customer trouble tickets as hints to learn what values of network performance metrics indicate customer-impacting problems, despite the presence of noise in both the ticket data and the network performance data. We believe this lesson is applicable to proactive network maintenance in other types of networks, including cellular networks, WIFI access networks, and data-center networks.

2 Background and Datasets

In this section, we briefly introduce the cable Internet architecture and describe the datasets we use in this work.

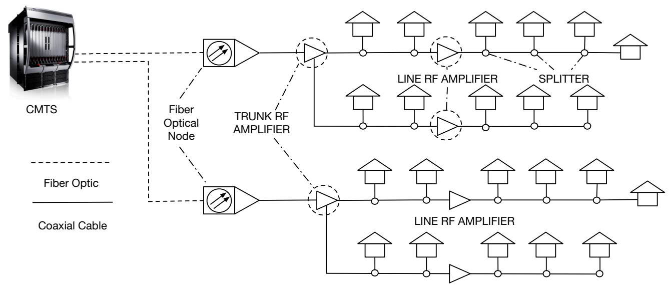

Figure 1: **An overview of the Hybrid Fiber Coaxial (HFC) architecture.**

2.1 Cable Network Architecture

Figure 1 shows a high-level overview of a cable broadband network. A cable broadband network is an access network. It provides the "last-mile" Internet connectivity to end users. A customer connects to the cable network via a cable modem residing in her home. The cable access network terminates at a device called a Cable Modem Termination System (CMTS), which is a router with one port connecting to the Internet and many other ports connecting to customers' cable modems.

At the IP level, there is only one hop between a customer's cable modem/home router and the CMTS. Underlying this single IP hop, there is a complicated link-level structure that consists of different types of physical links and devices. The "last-mile" links that connect to the customer premises are often made of copper coaxial cables. These cables terminate at a device called a fiber node (FN). A fiber node connects to the CMTS via optical fibers. It converts the incoming optically modulated signals into electrical signals and sends the signals towards the customers' homes, and vice versa. Due to signal attenuation, cable networks deploy radio frequency (RF) amplifiers between a fiber node and a residential home. Along the way to a customer's home, new branches may split from the main cable by the line splitters. All these devices could introduce signal distortion and noise.

Historically, cable TV networks divide radio frequency into multiple channels, each of 6MHz width. Cable broadband networks use a subset of these channels as data carriers. A cable ISP typically uses three or four of these channels at the lower end of the spectrum to carry data from a user's cable modem to CMTS. We refer to this direction as the *upstream* direction. An ISP may use sixteen or more of the channels at the higher end of the spectrum to carry data from a CMTS to a modem. We refer to this direction as the *downstream* direction.

2.2 Datasets

We have obtained two types of anonymized modem-level data from a U.S. cable ISP for this study. They include (1) PNM data and (2) customer trouble ticket data. We have a total of eight months of data dating from 01/06/2019 to 08/31/2019. Next, we describe each dataset in turn. [2]

PNM data: The PNM data we obtained were collected by a common standard built into DOCSIS. A CMTS can query a DOCSIS-compliant cable modem (CM) to obtain certain performance data. DOCSIS standardizes how a CM or CMTS stores these performance data in a local Management Information Base (MIB) [7]. A remote process can use the Simple Network Management Protocol (SNMP) to query the MIBs of each CM or a CMTS to obtain performance data [36].

Currently, we only have PNM data from the upstream channels. DOCSIS 3.0 gives a cable operator the ability to collect the full spectrum view of a cable modem's RF channels. It is our future work to investigate whether this type of data may further improve our detection accuracy.

A record in the PNM data we obtain has the following fields:

- *Timestamp*: The time when a PNM query is sent.
- *Anonymized MAC*: The hashed MAC address of the queried CM.
- *Anonymized Account Number*: The hashed user account number. This field is used to link a customer ticket with the corresponding PNM data from the customer's CM.
- *Channel Frequency*: This field identifies which upstream channel this record is about.
- *SNR*: The upstream signal-to-noise ratio of this channel.
- *Tx Power*: A CM's signal transmission power.
- *Rx Power*: The received signal power at the CMTS.
- *Unerrored*: The number of unerrored codewords received at the CMTS.
- *Corrected*: The number of errored but corrected codewords received at the CMTS.
- *Uncorrectable*: The number of errored but uncorrected codewords.
- *T3 Timeouts*: The number of DOCSIS T3 timeouts [5] the CM has experienced since its last reboot. A DOCSIS T3 timeout occurs when there is an error in a CM's ranging process, which we will soon explain.
- *T4 Timeouts*: The number of DOCSIS T4 timeouts [5] the CM has experienced since its last reboot. Similarly, a T4 timeout occurs when there is a ranging error.
- *Pre-Equalization Coefficients*: The set of parameters a CM uses to compute how to compensate for channel distortions during a ranging process.

A CM uses a process called *ranging* to compute a set of parameters called *pre-equalization coefficients* for mitigating channel distortions. When RF signals travel along a coaxial cable, they may be distorted as different frequencies attenuate at different speeds and noise may be added to the channel. To mitigate the channel distortions, a CM adds correction signals to the data signals it transmits. Ideally, the correction signals will cancel out the distortions when the signals arrive at the CMTS. A CM and a CMTS exchange messages periodically

[2]We note that we have discussed this work with our institute's IRB. And they consider it does not involve human subjects.

to compute the correction signals. This process is called ranging. And the set of parameters used to compute the correction signals are called pre-equalization coefficients.

The PNM data we obtain are collected every four hours from several of an ISP's regional markets. There are around 60K unique account numbers in our datasets.

Customer Ticket Data: We have also obtained the records of customer trouble tickets from the same ISP. The relevant fields in each record include the hashed customer's account number, the ticket creation time, the ticket close time (if it was closed), a brief description of the actions taken to resolve the ticket, and a possible diagnosis.

3 Overview

In this section, we motivate the design of CableMon by describing the limitations of existing work. We then describe the design rationale of CableMon, its design goals, and the design challenges we face.

3.1 Limitations of Existing Work

The existing PNM work in the public domain [7, 17, 22] use a set of PNM metrics and manually-set thresholds to detect network faults. If the value of a metric is below or above a threshold, it indicates a fault. This approach has several limitations. First, it is challenging to set the right thresholds. If the thresholds were set too conservatively, they might flag too many faults for an ISP to fix. In contrast, if they were set too aggressively, an ISP might miss the opportunities for proactive maintenance. There lacks a systematic study on how to set the threshold values to achieve the best tradeoff. Second, the existing work mostly uses the instantaneous values of PNM data for fault detection. However, due to the inherent noise in PNM data, using the instantaneous values may lead to instability in detection results. In addition, it may fail to detect faults that can only be captured by abnormalities in a PNM metric's statistical values, e.g., variations.

For ease of explanation, we use one threshold value recommended in the CableLabs' PNM best practice document [7] to illustrate the limitations. CableLabs' recommendation uses a variable called Main Tap Ratio (MTR) computed from a modem's pre-equalization coefficients. It specifies that when the MTR value of a modem is below a threshold (<18dB), there is a fault in the network that needs immediate repair.

We sample the MTR values in one of the ISP's markets. There are more than 60K modems in this market. We choose five random days' records during an eight-month period in 2019 and measure the MTR values of all modems during the sampled days. Table 1 shows the percentage of modems that have a channel whose MTR value is below the recommended threshold. If an ISP used the recommended MTR threshold, at any sampled day, there would be more than 24% of cable modems that require immediate repair. We also measure the MTR values among all PNM records during this eight-month period. In more than 26% of the records, a modem's MTR value is below 18dB.

3.2 Design Goals

CableMon aims to enable an ISP to detect network problems that demand immediate repair. Specifically, it aims to accurately detect the set of network conditions that adversely impact customer experience. We refer to these network conditions as network anomalies or faults in this work. Its design goals include the following:

- High ticket prediction accuracy, and moderate ticket coverage. Ideally, we would like to use precision (the set of true positives detected over all detected positives) and recall (the set of true positives detected over all true positives) to measure the performance of CableMon. However, because we do not know ground truth, we instead use customer tickets as indications of true positives. We define *ticket prediction accuracy* as the ratio between the number of anomalies detected by CableMon that lead to one or more customer tickets and the number of total anomalies CableMon detects. Similarly, we define *ticket coverage* as the ratio between the number of tickets CableMon predicts and the total number of network-related customer tickets. It is desirable that CableMon has high ticket prediction accuracy because an ISP is often limited by the number of technicians it has to repair network faults, avoiding false alarms is practically more important than repairing all faults proactively. What we learned from AnonISP is that even a 10% reduction in customer calls can reduce their operational costs significantly. Therefore, as a starting point, we aim for a high ticket prediction accuracy and a moderate ticket coverage.

- No manual labeling. One approach to detect network anomalies is to train a supervised learning classifier on labeled data. The labels tell what PNM metrics indicate network anomalies and what do not. However, we do not have such labeled data. And due to lack of ground truth and the large size of the data, manual labeling is also practically challenging. Therefore, we aim to design CableMon without requiring manual labeling.

- No extensive parameter tuning. We aim to release CableMon as an off-the-shelf-tool at cable ISPs. Therefore, we require that CableMon's fault detection methods work effectively without much parameter tuning on the ISP side.

- Efficient. We require that CableMon can detect whether there is a network fault or not in real time. This is because an ISP can deploy CableMon as a diagnosis tool in

	03/13/2019	04/09/19	06/25/19	07/15/19	08/15/19	Eight-month
MTR $<$ 18dB	24.95 %	25.45 %	27.16 %	27.07 %	27.38 %	26.15 %

Table 1: **The percentage of cable modems that need to be repaired if an ISP were to follow one of the CableLabs' recommendations.**

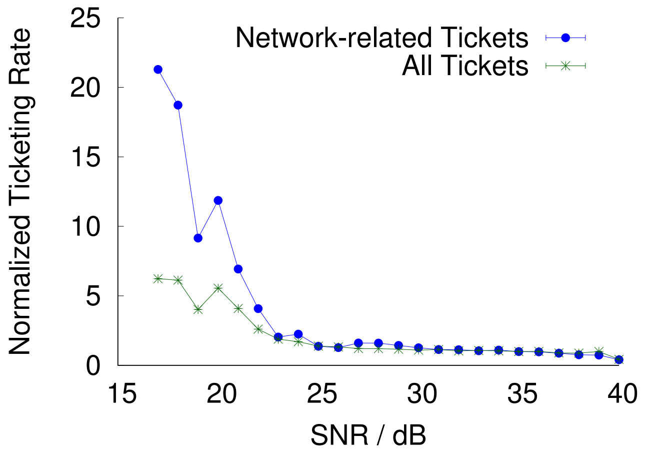

Figure 2: **This figure shows how the customer ticketing rate varies with the values of SNR. Ticketing rate tends to increase when SNR values are low.**

addition to using it for proactive network management. When an ISP receives a customer trouble call, it is often challenging to diagnose what has caused the customer's problem. An ISP can use CableMon to help diagnose whether the problem is caused by a network fault.

3.3 Design Rationale

To meet CableMon's design goals, we use customer trouble tickets as hints to train a customized classifier to detect network faults. We hypothesize that the occurrences of customer trouble tickets should correlate with those of network faults. When a customer-impacting fault occurs, some customers are likely to call the ISP to fix it. Each call creates a trouble ticket. If the values of PNM data can indicate network faults, then the values of PNM data should correlate with how frequently customer trouble tickets are created. In this paper, we define the average number of customer tickets created in a unit time as the *ticketing rate*.

To validate this hypothesis, we measure how ticketing rate changes with different values of a PNM metric. For a PNM metric m (e.g., SNR), we sort the values of m in an ascending order. Each pair of adjacent values define a bin b. For each bin b, we measure the number of tickets N_b that occur in the time periods where the value of m falls within the bin, and the total length of those time periods T_b. We then divide N_b by T_b to obtain the ticketing rate for bin b. We note that a PNM record is collected at discrete time points (roughly four hours apart in our datasets). We assume that a PNM value remains unchanged between its collection points.

As an example, we show how the ticketing rate varies with the values of SNR in Figure 2. We normalize this value by the baseline ticketing rate, which we obtain by dividing the total number of customer tickets in our dataset by the total collection period. The line marked by the legend "All Tickets" shows how the ticketing rate varies with the values of SNR if we consider all tickets; and the line marked by "Network-related Tickets" shows how the ticketing rate of network-related tickets varies with SNR. As can be seen, when the values of SNR are low, both the network-related ticketing rate and the all-ticket ticketing rate tend to increase, suggesting that low SNR values signal network faults.

In practice, customer tickets do not always indicate network faults. On the one hand, many customers may call an ISP for non-network related problems. The customer ticket data we obtain includes a ticket action field and a ticket description field, which provide the information on how an ISP deals with a ticket. We observe that nearly 25% of tickets are resolved via"Customer Education" or "Cancelled", suggesting that they are not caused by networking problems. On the other hand, customers may not report tickets when network outages indeed take place. In our ticket dataset, when an outage affects an entire region, all tickets caused by that outage are labeled as "part of primary," grouped and pointed to a primary ticket, which is a representative ticket of the outage. We manually checked an outage that affected more than 200 customers' PNM data and observed that only $\approx 6.1\%$ of the customers have a "part of primary" tickets and the rest $\approx 93.9\%$ of the customers did not report anything.

To reduce noise in tickets, we select a subset of customer tickets that are likely to be caused by network problems. We select the tickets based on both a ticket's action field and the ticket's description field. From the action field, we select tickets that lead to a "Dispatch" action. We assume that the tickets that caused an ISP to dispatch a technician are likely to be triggered by network-related problems. From the description field, we select tickets whose ticket description keywords suggest networking problems. Examples of such keywords include "Data Down", "Noisy Line" and "Slow Speed". In the rest of this paper, we refer to those selected tickets as "network-related tickets."

Figure 2 compares how the ticketing rate of network-related tickets and all tickets vary with SNR values. As can be seen, network-related tickets have higher ticketing rates when SNR is low, suggesting that the occurrences of those tickets are better indicators of network faults.

We note that according to the ISP who provided us the datasets, network-related tickets may also contain non-networking tickets due to human errors. A human operator who fills a ticket action or description field may make a mistake. And a technician may be dispatched when there is no network fault due to an erroneous diagnosis.

Challenges: A key question we need to answer is how to use customer tickets as hints for detecting network faults. Ideally, if a customer calls only when a network fault occurs, we could label the PNM records collected around the ticket creation time as abnormal, and apply supervised learning to learn the PNM thresholds that suggest a network fault. We have tried several such machine learning algorithms when we started this project, but found that that this approach did not work well with our datasets. First, customer calls are unreliable fault indicators. A customer may or may not call when there is a fault and vice versa. Second, PNM data contain noise. During a faulty period, some PNM metrics may occasionally show normal values due to the added noise. Similarly, even when there is no fault, some PNM metrics may show instantaneous abnormal values. Thus, if we use the tickets to label PNM data, it may introduce many false positives as well as many false negatives. We found it challenging to tune a machine learning algorithm with this labeling method. It is even harder to explain the results when we change a parameter. Next, we describe how we design CableMon to use a simple and customized classifier to address these challenges.

4 Design

In this section, we describe the design of CableMon. We first describe how we reduce the noise in customer tickets and the noise in PNM data. We then describe a customized classifier that aims to robustly classify PNM values as normal and abnormal despite the presence of noise. Finally, we describe how an ISP can use the classification results to detect network faults and to help diagnose a customer's trouble call.

4.1 Reducing Noise in PNM data

PNM data measure the instantaneous state of cable's RF channels and contain noise. An added noise may make a PNM metric take an abnormally low or high instantaneous value. To address this problem, we treat PNM data as time-series data and apply statistical models to smooth the noise and generate additional features for fault detection.

Table 2 summarizes all the statistical models we use to process PNM data. For each PNM metric collected at timestamp i with value V_i, we calculate its average, its weighted moving average (WMA), exponentially weighted moving average (EWMA), the difference between the current value and its WMA (WMA Diff), and its variance. We note that the average, WMA, WMA Diff, and variance values all require a window size as a hyper-parameter. Because we do not have any prior knowledge on how to set this parameter, we try a series of window sizes, ranging from *1 day* to *7 days*, incrementing by 1 day at each step. For the λ parameter required by EWMA, we vary the value of λ from *0.1* to *0.9*, incrementing by 0.1 at each step. For each PNM metric, we generate 37 time-series features. We apply this approach to all nine PNM metrics and totally generate 333 time-series features. We refer to them as time-series features.

Model	Equation
Average	$AVG_i = \frac{V_i+V_{i-1}+\cdots+V_{i-win+1}}{win}$
WMA	$WMA_i = \frac{win \cdot V_i+(win-1)\cdot V_{i-1}+\cdots+1\cdot V_{i-win+1}}{win\cdot(win-1)/2}$
EWMA	$EWMA_1 = V_1$ $EWMA_i = \lambda \cdot V_i + (1-\lambda)EWMA_{i-1}$
WMA Diff	$V_i - WMA_i$
Variance	$VAR_i = \frac{1}{win}\sum_{k=i-win+1}^{i}(V_k - AVG_i)^2$

Table 2: **This table summarizes the statistical models we use to generate the time-series features. (WMA: Weighted Moving Average, EWMA: Exponentially Weighted Moving Average.)**

4.2 Determining A Fault Detection Threshold

After we reduce noise in both the customer tickets and the PNM data, we aim to determine a threshold for each PNM metric that indicates network faults. We note that there is no explicit definition of what a network fault is. Instead, we choose to use the network conditions that are likely to cause a trouble call to approximate a network fault. With this approximation, we may not detect minor issues that do not warrant a trouble call. We argue that this design is advantageous, because it allows an ISP to prioritize its resources to fix the customer-impacting problems.

In the case of SNR, if we choose too high a value as a fault detection threshold, an ISP may become too proactive, fixing minor problems that many customers may not care, which we refer to as false positives. If we choose too low a value, an ISP may miss opportunities to proactively repair a problem before a customer calls, which we refer to as false negatives.

We aim to design an algorithm that minimizes both false positives and false negatives. From our investigation in § 3.3, we see that different values of a PNM metric have different likelihood to concur with a trouble ticket. Inspired by this observation, we use the ticketing rate as a metric to help choose a fault detection threshold. Our intuition is that the customer ticketing rate during a faulty period should be higher than a normal period when there is no fault. Therefore, for each feature f generated from a PNM metric, we determine a threshold value thr_f such that thr_f maximizes the ratio between the ticketing rate in the time periods when a network fault exists and the time periods when there is no fault. We refer to this ratio as the ticketing rate ratio.

Specifically, we search through the range of values of a feature f in small steps. At each step s, we consider the value of the feature $f_s \in [f_{min}, f_{max}]$, as a candidate for the threshold.

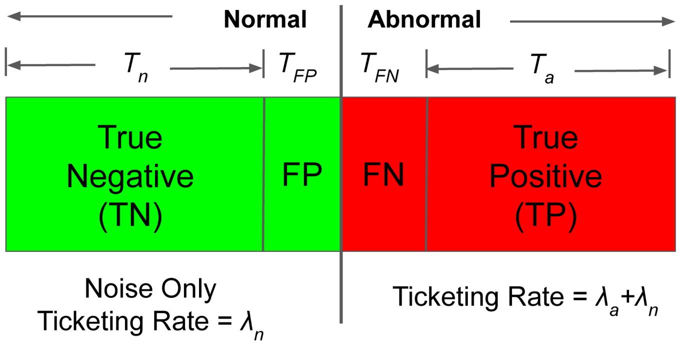

Figure 3: **Analysis of ticketing rate ratio.**

We then compare the value of f at a PNM data collection point with f_s, and label the collection time period as abnormal or normal, based on whether the value of f is below or above the candidate threshold value f_s. For some features such as the average SNR, below the threshold is abnormal. For other features, the opposite is true. After determining each collection period as normal or abnormal, we count the number of network-related tickets occurred in the normal and abnormal periods respectively and divide them by the normal and abnormal time periods determined by f_s. We then compute the ticketing rate ratio: $TRR(f_s)$. The threshold value thr_f is chosen as the value of f_s that maximizes the ticketing rate ratio $TRR(f_s)$.

We also note that for features following a normal distribution such as Rx Power, we choose to use two threshold values to determine whether a collection period is normal or abnormal. The pseudo code can be found at §A.

We now explain why choosing a threshold that maximizes the ticketing rate ratio may help minimize the false positives and false negatives. The entire time line can be divided into two subspaces: the normal (no fault) and the abnormal (with fault) periods. Ideally, the normal sub-space should not receive any trouble ticket. In practice, there is always a ticketing noise. We assume a uniformly distributed ticketing noise with the rate λ_n spreads the whole space. Similarly, we assume an additional uniformly distributed ticketing rate that occurs only in the abnormal sub-space and denote it as λ_a.

A threshold value thr_f of a feature also divides the time line into two subspaces: normal and abnormal. The first subspace includes a true negative part T_n and a false negative part T_{FN}, where an abnormal period is erroneously considered as normal. The second subspace includes a true positive part T_a and a false positive part T_{FP}, where a normal period is considered abnormal. The ticketing rate ratio determined by the threshold thr_f can be computed as follows:

$$D(T_n, T_{FP}, T_{FN}, T_a) = \frac{\frac{\lambda_n T_{FP} + (\lambda_a + \lambda_n) T_a}{T_a + T_{FP}}}{\frac{\lambda_n T_n + (\lambda_a + \lambda_n) T_{FN}}{T_n + T_{FN}}}$$

Both the numerator and denominator can be regarded as a weighted average of λ_n and $\lambda_a + \lambda_n$, with the time period lengths as the weights. Because $\lambda_a + \lambda_n > \lambda_n$ always holds, we can show that the derivatives of D over the false positives T_{FP} and the false negatives T_{FN} are non-increasing:

$$\frac{\partial D}{\partial T_{FP}} < 0 \text{ and } \frac{\partial D}{\partial T_{FN}} < 0$$

Therefore, because T_{FP} and T_{FN} are non-negative, the ticket rate ratio is maximized when both false positives and false negatives are zero:

$$D_{max} = \lim_{\substack{T_{FP} \to 0 \\ T_{FN} \to 0}} D = \frac{\lambda_a}{\lambda_n} + 1$$

4.3 Feature Selection

We have a total of more than three hundred time-series features and it is unlikely they are all useful indicators of network faults. To find the relevant features, we only select the features with high ticketing rate ratios from each PNM metric. Specifically, among the same type of features derived from a PNM metric with different hyperparameters, we choose the one with the highest ticketing rate ratio as the representative feature. For each representative feature derived from the same PNM value, we choose the top two with the highest ticketing rate ratios. Finally, among the remaining candidates, we choose the top N features that have the highest ticketing rate ratios. We determine the number of features N based on the desired ticketing rate ratios, ticket prediction accuracy, and ticket coverage as we soon describe in § 5.1.

Features	Ticketing Rate Ratio
snr-var-2	14.49
uncorrected-var-1	7.66
rxpower-wma-diff-4	5.31
t3timeouts-wma-diff-1	4.93
t4timeouts-var-1	4.18

Table 3: **Top 5 features and their ticketing rate ratio.**

Table 3 shows the top five features we used and their ticketing rate ratios calculated from our training sets (Section 5.2). The name of each feature consists of the raw PNM metric, the statistical model we apply to the metric, and the parameter. For example, the *snr-var-2* means the variance of SNR with a *2-days* window size. We note that all features have a high ticketing rate ratio and we expect them to effectively detect network faults.

4.4 Combining Different Features

Different PNM features may detect different types of network faults. Therefore, we build the final classifier by combining the detection results of all selected features. As long as one selected feature considers a PNM collection period abnormal, we classify the collection period as abnormal. For each

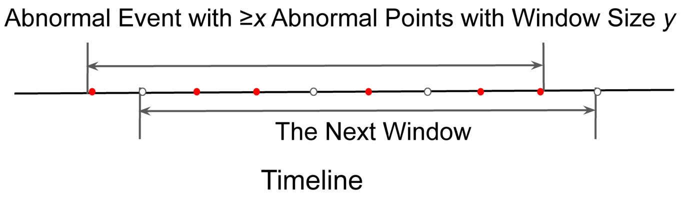

Figure 4: **This figure explains the sliding window algorithm. When the number of abnormal points within a sliding window exceeds a threshold, the window is considered to be abnormal. An abnormal event is given by merging the abnormal windows.**

selected feature, we have already chosen a threshold that maximizes the ticketing rate ratio. Therefore, we expect that combining the results of all selected features will also provide a high ticketing rate ratio. We evaluate the results of our classifier in § 5.1.

4.5 ISP Deployment

An ISP can use CableMon in two ways: proactive network maintenance for predicted trouble tickets and diagnosing the root cause of a trouble ticket when receiving a call. In this section, we describe the algorithms for an ISP to decide when to send out a repair technician proactively and how to diagnose the root cause.

CableMon's classifier can monitor an ISP's network continuously. It can output a normal and abnormal decision when a PNM record is collected from a customer's modem. However, due to the existence of noise and the intermittent nature of some faults, if an ISP makes a dispatch decision whenever it observes an abnormal PNM data point, it may lead to many false positives. To address this problem, we design a sliding window algorithm for an ISP to make a dispatch decision. The high-level idea of this algorithm is that an ISP should only dispatch a technician after a fault persists.

Figure 4 explains this algorithm. The algorithm takes two parameters: y and x, where y is the size of the window, and x is the number of abnormal data points detected in the window. When an ISP collects a new PNM record, it looks back to a window size y of collection points. If x out of y data points are considered as abnormal, then the ISP should dispatch a technician to examine and repair the network.

An ISP can determine the parameters x and y based on the false positives and false negatives it is willing to tolerate. The ISP can estimate the values of false positives and false negatives from its historic PNM data and ticket data. Therefore, choosing those parameters only requires an ISP to train CableMon using its own PNM and ticket data and does not require tuning. In § 5.1, we use our datasets to show how an ISP can effectively choose the parameters x and y.

Similarly, an ISP can use CableMon to help diagnose the root cause of a call. When it receives a trouble call, if the customer complains about a performance problem, and the ISP sees that in the past collection window of size y, there exists x abnormal collection points, the ISP can conclude that the trouble is likely to be caused by a network problem.

5 Evaluation

In this section, we describe how we evaluate CableMon's performance.

5.1 Establishing Evaluation Metrics

Ideally, we would like to deploy CableMon on a real cable ISP and measure how it reduces the number of trouble tickets over a long term. It is our future work to conduct such a real-world experiment. In this work, we aim to estimate how many trouble tickets CableMon would reduce were it deployed on our collaborating ISP.

To do so, we emulate the sliding window algorithm described in § 4.5 using our test dataset. We start from the beginning of the test dataset. If there are x abnormal points detected in a window size of y, we mark it as the beginning of a fault. We then move the window to the next data point. When the number of abnormal points falls below x, we mark it as the end of a fault. If there is a trouble ticket occurred during a fault, we consider this fault detection as a true fault. We note that if we detect a fault simultaneously within multiple customers, as long as one customer reports a ticket, we consider it a true fault. We assume that if an ISP dispatched a repair technician when it detected the onset of the fault, it could have avoided the trouble ticket. We define *ticket prediction accuracy* as the number of true faults divided by the total number of detected faults. We define *ticket coverage* as the number of trouble tickets occurred during a detected fault divided by the total number of network-related trouble tickets.

It is not sufficient to use only ticket prediction accuracy and ticket coverage to gauge CableMon's performance. This is because if CableMon detects the entire time period that spans the test dataset as a faulty period, it will achieve 100% ticket coverage and ticket prediction accuracy. To avoid this pitfall, we also use the normalized ticketing rate, which is defined as the ticketing rate in all faculty periods normalized by the ticketing rate of the time period that spans the test dataset. If CableMon erroneously detects the entire time period as abnormal, it will achieve a low normalized ticketing rate close to 1.

How an ISP chooses the sliding window parameters: In practice, an ISP can use a training set to determine the threshold values of CableMon's classifier. It can use the ticket prediction accuracy, ticket coverage, and the normalized ticketing rate obtained from a validation set to choose the combination of the sliding window parameters.

We show an example in Figure 5. In this example, we choose a window size of 12 data points (y = 12), which is roughly two days long. We then measure the ticket prediction accuracy, ticket coverage, and the normalized ticketing rate

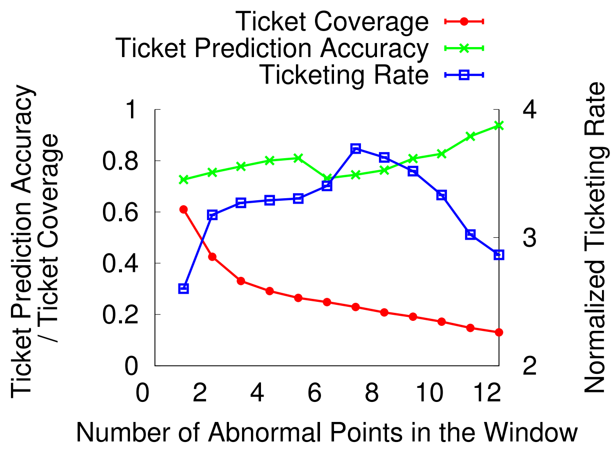

Figure 5: **This figure shows the ticket detection accuracy, the ticket coverage, and the normalized ticketing rate of the sliding window algorithm with different parameters.**

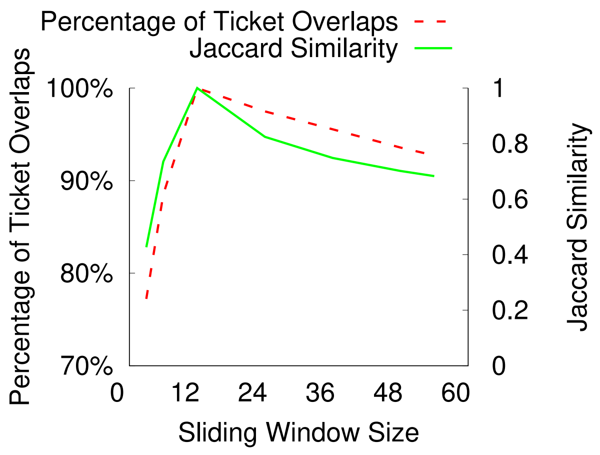

Figure 6: **This figure shows what percentage of tickets detected by different window sizes overlap with those detected by a window size of 12 and the Jaccard similarity between the faulty periods detected by different window sizes and those detected by a window size of 12.**

when the number of abnormal points x varies from 0 to 12. As can be seen, when x is around 8, the sliding window algorithm achieves a high normalized ticketing rate, a relatively high ticket prediction accuracy 80%, and a ticket coverage around 20%. Since avoiding false dispatches is more important than predicting all trouble tickets, an ISP can choose (8, 12) as its sliding window parameters for fault detection.

We have tried different sizes of the sliding window, ranging from one to 60 data points. For each window size, we use the above method to choose the parameter x such that both the ticket prediction accuracy and the normalized ticketing rate are high, and the ticket coverage is above a minimum threshold 15%. We compare the tickets and the faulty periods detected by different window parameters. We use the Jaccard similarity metric [25] to measure the overlaps of faulty periods detected by different window parameters. As can be seen in Figure 6, 90% of the tickets detected by windows larger than 12 overlap; and the faulty periods detected by them have a Jaccard similarity larger than 60%. This result suggests that different window parameters are likely to detect the same sets of faults, and the performance of CableMon is not sensitive to the window parameters.

5.2 Experiment Setup

After we establish the evaluation metric, we train and evaluate CableMon on a 50-machine Linux cluster with 40 $\sim$ 512 GB RAM and 8 $\sim$ 48 core running Ubuntu 18.04. CableMon is trained on five-month data from 01/06/2019 to 05/30/2019 and tested with three-month data from 06/01/2019 to 08/31/2019.

Comparing with the existing work: We compare CableMon's performance with two existing methods. One is from our collaborating ISP, AnonISP, which uses a visualization tool that colors different ranges of PNM values for an operator to manually monitor its networks' conditions. AnonISP's tool has two manually configured thresholds for several raw PNM values and therefore has three fault indication levels: normal (green), marginal (yellow), and abnormal (red). We compare AnonISP's tool against CableMon with these thresholds and regard both yellow and red levels as network fault, as the ISP's experts usually do.

Another tool from industry uses Comcast's scoreboard method [22]. Comcast is considered as the leading company in the area of PNM research. They developed a method that compares a PNM metric to a threshold and assigns a score to each comparison result. If the sum of the comparison scores exceeds a threshold value, then the method considers there is a fault in the network.

Since both AnonISP and Comcast's tool detects a fault using a single PNM data record, we apply the sliding window algorithm to both tools for a fair comparison.

Comparing with Machine Learning Techniques: We also compare the performance of CableMon with three classical machine learning algorithms: Decision Tree (DT) [34], Random Forest (RF) [4] and Support Vector Machine (SVM) [14]. Since these algorithms require labeled data, we label the PNM data with tickets. Each ticket has a creation time and a closed time. We label the PNM data collected between this time interval as positive samples and other data as negative samples. We generate 47,518 positive samples and the same number of abnormal samples as our training set to train the machine learning models and evaluate them with the same evaluation metrics.

Table 4 shows the ticket prediction accuracy, the ticket coverage, and the normalized ticketing rate of different methods. As can be seen, CableMon achieves the highest ticket prediction accuracy and the highest normalized ticketing rate

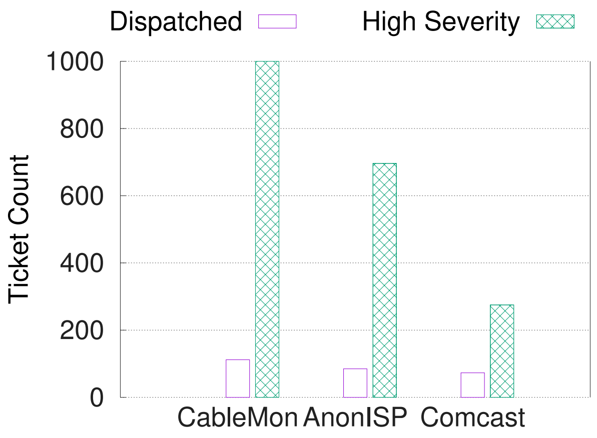

Figure 7: **This figure shows the number of different types of tickets detected by different methods.**

among all methods. Its ticket coverage is lower than that of AnonISP. However, this is because AnonISP detects too many false faults, as shown by its low ticket prediction accuracy. We note that all three machine learning algorithms require a long training time, as each has multiple parameters to tune. The results we present here are the best ones after many rounds of tuning. When we started this project, we started with those algorithms, but abandoned them due to the challenges to tune them and to explain the results when certain parameters are changed.

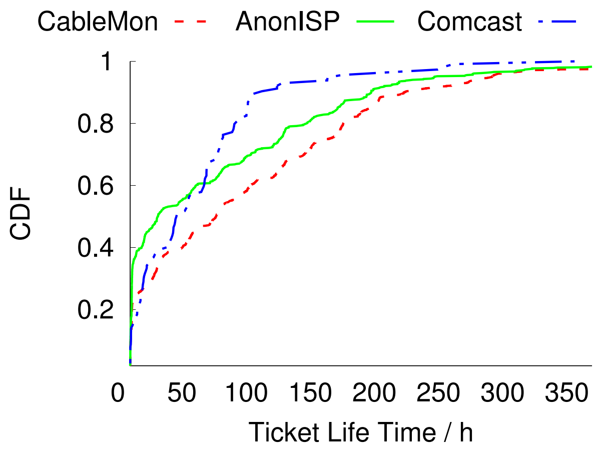
Methods	Ticket Prediction Accuracy	Ticket Coverage	Normalized Ticketing Rate
CableMon	81.92%	22.99%	3.55
Decision Tree	68.93%	15.53%	2.52
SVM	75.64%	12.54%	2.02
Random Forest	73.14%	14.21%	2.24
Comcast	23.48%	2.21%	1.18
AnonISP's tool	10.04%	25.13%	0.98

Table 4: **Performance of different methods**

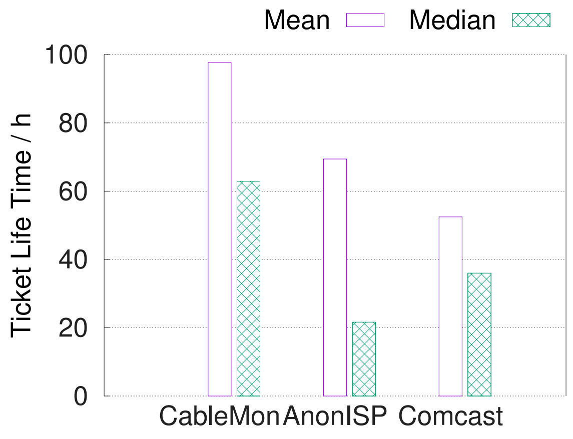
5.3 Detected Tickets Statistics

To further analyze the detected tickets, we examine the tickets detected by CableMon and existing ISP tools according to the ticket action and description fields. We omit the results of the machine learning algorithms for clarity. The characteristics of the tickets detected by those algorithms are similar to those of CableMon, but they have lower ticket detection accuracy and coverage. Figure 7 shows the number of different types of tickets detected by different methods. As can be seen, CableMon can detect a significantly more number of dispatched and high severity tickets than the two existing ISP tools.

Figure 8(a) shows the distribution of a detected ticket's life time, and figure 8(b) shows the average and median life time



(a) CDF



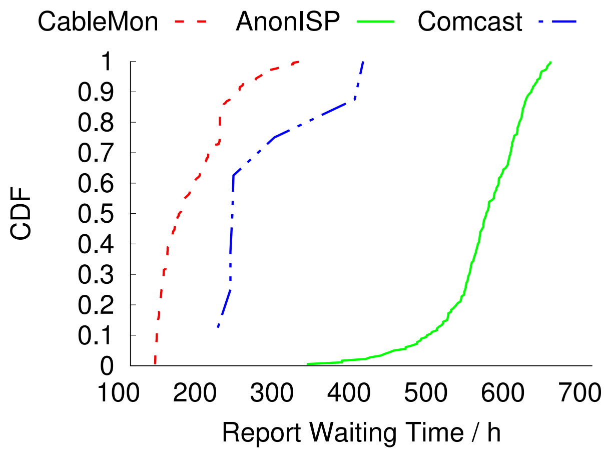
(b) Mean and Median

Figure 8: **The figures show the CDF, mean, and median of the life time of tickets predicted by different methods. A longer ticket life time indicates that the problem that triggered the ticket takes a longer time to fix.**

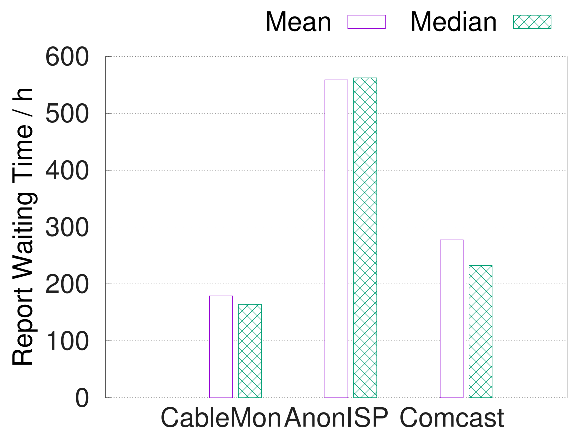
of a detected ticket. A ticket's life time is defined as the time between a ticket is created to the time a ticket is closed. As can be seen, the tickets detected by CableMon have longer life times, suggesting that CableMon detects the problems that take longer to resolve.

We also measure the time elapsed from when a fault is detected to when a ticket is created. We refer to this time as "Report Waiting Time." Figure 9(a) shows the cumulative distribution of the report waiting time of different methods, and figure 9(b) shows the average and median report waiting time of different methods. As can be seen, CableMon's report waiting time is also significantly shorter that that of other methods, indicating that its detected faults lead to customer trouble tickets faster than those detected by other methods.

Finally, we measure the distribution of a fault detected by different methods. Figure 10 shows the PDF of the length of a fault detected by different methods. As can be seen,



(a) CDF



(b) Mean and Median

Figure 9: **The figures show the CDF, mean, and median of the report waiting time of tickets predicted by different methods. A shorter report waiting time indicates that the problem triggered by the ticket is more urgent.**

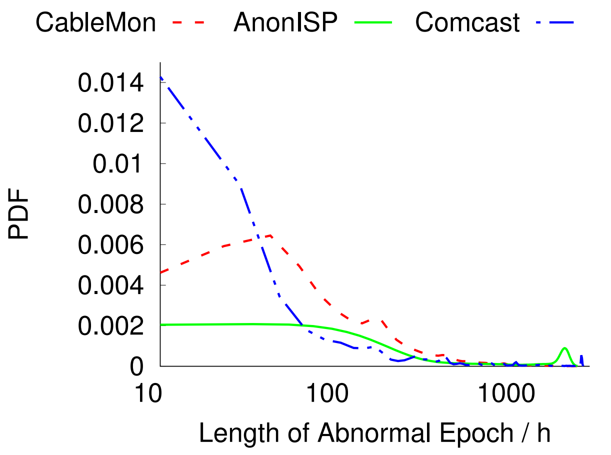


Figure 10: **This figure shows the PDF of the length of a detected fault.**

CableMon detected faults tend to last a moderate period of time. The highest probability density is slightly less than 100 hours (roughly four days). Comcast's tool detects many faults that last less than one day, shorter than what a typical network repair action takes. This result suggests that many of the detected faults could be false positives. The faults detected by AnonISP's tool have a wide range of life span, from very short faults to very long faults (>500 hours), which are outside the normal range of repair actions. Again, this result suggests that many of the detected faults could be false positives.

6 Related Works

Previous work measured the reliability of broadband networks. The Federal Communications Commission launched the Measuring Broadband America (MBA) project [10] since 2010. Bischof et al. [3] showed that poor reliability will heavily affect user traffic demand. Padmanabhan et al. [28] demonstrated that the outages of broadband networks tend to happen under bad weather conditions. Baltrunas et al. [2] also measured the reliability of mobile broadband networks.

Network fault diagnosis has attracted much attention from the community for a long time. Many approaches from industry, especially the cable industry, set manual thresholds for certain measured metrics to detect network outages. Amazon [11] used a fixed threshold to monitor the condition for its cloud services. Zhuo et al. [41] treated packet loss as a fault indicator and showed the correlation between Tx/Rx Power and packet loss rate. They again use manually set thresholds to detect network faults. Lakhina et al. [21] proposed the first framework that applied Principal Component Analysis (PCA) to reduce the dimension of network traffic metrics. Huang et al. [16] showed that Lakhina's framework works well with a limited number of network devices, but has performance issues on larger datasets. Moreover, Ringberg et al. [35] pointed out that using PCA for traffic anomaly detection is much more tricky than it appears. Besides PCA, many other statistical models are applied to network anomaly detection. Gu et al. [13] measured the relative entropy of the metrics and compared them to the baseline. Subspace [26] is introduced to deal with high-dimensional and noisy network monitoring data. Kai et al. [19] used Expectation–Maximization (EM) algorithm to estimate the parameters of their model and obtain the upper or lower bound of the common metric values. Independent Component Analysis [30], Markov Modulated Process [32], and Recurrence Quantification Analysis [29] are also introduced to find the anomaly points in time series data. These methods aim to detect sudden changes in data. Differently, CableMon uses customer ticket as hints to label the input data and uses the ticketing rate ratio to select relevant features.

Recently, machine learning has been used for network anomaly detection. Leung et al. [24] designed a networking anomaly detection system using a density-based clustering algorithm, which obtained the accuracy as 97.3%. Dean et al. [9] presented an Unsupervised Behavior Learning framework based on the clustering algorithm. However, cluster-based approaches do not work well with sparse data, which is the case of our PNM data where abnormal events are rare. Sung et al. [37] deployed Support Vector Machines (SVMs) to estimate the actual crucial features. According to our evaluation, SVMs do not perform as well as CableMon. Liu et al. [27] adopted more than twenty statistics models to obtain more features from the original data. They used all generated features in Random Forest and achieved high accuracy and effectiveness. However, they still require manual labeling to train the Random Forest model. PreFix [39] predicts switch failures with high precision and recall. However, it also requires significant manual efforts for labeling, while our work does not. Pan et al. [31] also used the tickets as the hints to select potential network faults. However, they still asked experts to manually label network faults and use this labelled data to train a Decision Tree model. In contrast, CableMon does not use any manual label.

Previous researches have also focused on processing customer report tickets. LOTUS [38] deploys Natural Language Processing (NLP) techniques to understand the tickets. Potharaju et al. [33] built a system that automatically processes the raw text of tickets to infer the networking faults and find out the resolution actions. Jin et al. [18] studied the tickets in cellular networks and categorized the types of customer trouble tickets. Chen et al. [8] and Hsu et al. [15] use both customer trouble tickets and social media postings to determine network outages. This work combines an ISP's customer trouble tickets and PNM data to infer network faults.

7 Discussion

CableMon uses customer trouble tickets as network fault indicators to build a classifier without manual labeling. We plan to focus on the following directions to improve the performance of CableMon:

- When there lacks a large set of labeled data, semi-supervised learning [40] combines a small set of labeled data and a large set of unlabeled data to improve classification accuracy. We plan to investigate whether semi-supervised learning approach as well as other machine learning methods such as deep learning can improve the performance of CableMon.

- Presently, we use network-related tickets to train the classifier. We have discovered that customers tend to report tickets at weekdays rather than on weekends and during the day rather than at night. From this pattern, one may infer that if a customer reports a ticket at an "atypical" time, it is more likely to indicate a customer-impacting problem. If we place a higher weight for such "outlier" tickets in a classification algorithm, we may increase both the ticket prediction accuracy and coverage.

- ISPs desire to differentiate failures that affect a group of customers from those that affect a single customer. We refer to faults that affect multiple customers as "maintenance issues." If there is a maintenance issue, it is also desirable to locate the place where this issue has happened. It is possible to infer maintenance issues by clustering customers' PNM data, and to infer the location of a maintenance issue by combining the geographical location of each modem with the topology of HFC network. It is our future work to study these problems.

- When detecting network faults, CableMon outputs whether there is an abnormal event and how long it exists. It is desirable to rank the severity of abnormal events so that an ISP can prioritize its repair actions. It is our future work to explore such ranking algorithms.

8 Conclusion

Cable broadband networks are widely deployed all around U.S. and serve millions of U.S. households. However, cable networks have poor reliability. Although the cable industry has developed a proactive network maintenance (PNM) platform to address this issue, cable ISPs have not fully utilized the collected data to proactively detect and fix network faults. Existing approaches rely on instantaneous PNM metrics with manually set thresholds for fault detection and can introduce an unacceptably high false positive rate. We design CableMon, a system that learns the fault detection criteria from customer trouble tickets. Our design overcomes the noise from both PNM data and customer trouble tickets and achieves a nearly four times higher ticket prediction accuracy than the existing tools in the public domain. This is a first step toward enabling an ISP to use PNM data to proactively repair a failure before a customer calls and to diagnose whether a customer trouble call is caused by a network fault.

Abstract

Data flow graphs are a popular program representation in machine learning, big data analytics, signal processing, and, increasingly, networking, where graph nodes correspond to processing primitives and graph edges describe control flow. To improve CPU cache locality and exploit data-level parallelism, nodes usually process data in batches. Unfortunately, as batches are split across dozens or hundreds of parallel processing pathways through the graph they tend to fragment into many small chunks, leading to a loss of batch efficiency.

We present Batchy, a scheduler for run-to-completion packet processing engines, which uses controlled queuing to efficiently reconstruct fragmented batches in accordance with strict service-level objectives (SLOs). Batchy comprises a runtime profiler to quantify batch-processing gain on different processing functions, an analytical model to fine-tune queue backlogs, a new queuing abstraction to realize this model in run-to-completion execution, and a one-step receding horizon controller that adjusts backlogs across the pipeline. We present extensive experiments on five networking use cases taken from an official 5G benchmark suite to show that Batchy provides 2–3× the performance of prior work while accurately satisfying delay SLOs.

1 Introduction

One near-universal technique to improve the performance of software packet processing engines is batching: collect multiple packets into a single burst and perform the same operation on all the packets in one shot. Processing packets in batches is much more efficient than processing a single packet at a time, thanks to amortizing one-time operational overhead, optimizing CPU cache usage, and enabling loop unrolling and SIMD optimizations [7,8,11,22,26]. Batch-processing alone often yields a 2–5× performance boost. Fig. 1 presents a series of micro-benchmarks we performed in BESS [14] and FastClick [3], two popular software switches, showing that executing an ACL or a NAT function is up to 4 times

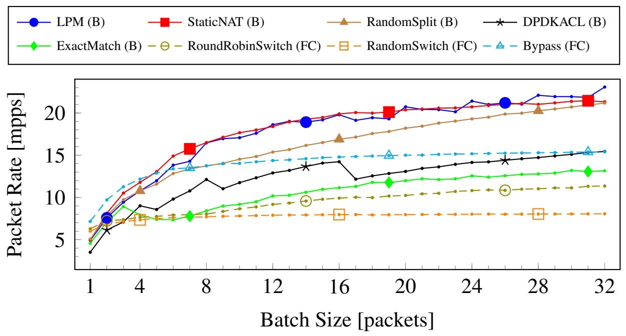

Figure 1: Maximum packet rate (in millions of packets per second, mpps) over different packet processing micro-benchmarks in BESS [14] (marked with B) and in FastClick [3] (FC) when varying the input batch size.

as efficient on batches containing 32 packets compared to single-packet batches. Prior studies provided similar batch-processing profiles in VPP [2,22], [27, Fig. 3]. Accordingly, batching is used in essentially all software switches (VPP [2, 27], BESS [14], FastClick [3], NetBricks [36], PacketShader [15], and ESwitch [30]), high-performance OS network stacks and dataplanes [3,6,8,11], user-space I/O libraries [1,16], and Network Function Virtualization platforms [19,21,42,45,50].

Unfortunately, even if the packet processing engine receives packets in bursts [1,2,6,27,29,41,50], batches tend to break up as they progress through the pipeline [20]. Such *batch-fragmentation* may happen in a multi-protocol network stack, where packet batches are broken into smaller per-protocol batches to be processed by the appropriate protocol modules (e.g., pure Ethernet, IPv4, IPv6, unicast/multicast, MPLS, etc.) [8,11]; by a load-balancer that splits a large batch into smaller batches to be sent to different backends/CPUs for processing [19]; in an OpenFlow/P4 match-action pipeline where different flow table entries may appoint different next-stage flow tables for different packets in a batch [30,38], or in essentially any packet processing engine along the branches of the data flow graph (splitters) [3,14,16,31,47]. In fact, any operation that involves *matching* input packets against a lookup

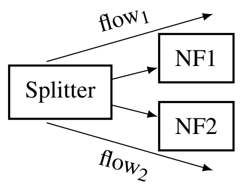

Figure 2: A sample packet processing data flow graph: a two-way splitter with two network functions (NFs). Both NFs incur one unit of execution cost per each processed batch and another one unit per each packet in the batch; the splitter incurs negligible cost. There are two service chains (or flows), one taking the upper and one taking the lower path.

table and *distributing* them to multiple next-stage processing modules may cause packet batches to fragment [20]. Worse still, fragmentation at subsequent match-tables combine multiplicatively; e.g., VRF-splitting on 16 VLANs followed by an IP lookup on 16 next-hops may easily break up a single batch of 256 packets into 256 distinct batches containing one packet each. Processing packets in the resultant small chunks takes a huge toll on the compute efficiency of the pipeline, which was designed and optimized for batch-processing in the first place [2, 11, 27]. We stress that batch-fragmentation is quite dynamic, depending on the input traffic profile, the offered load, the packet processing graph, the NFs, and flow table configuration; therefore, modeling and quantifying the resultant performance loss is challenging [22].

Trivially, *fragmented batches can be "de-fragmented" using queuing*, which delays the execution of an operation until enough packets line up at the input [1, 6, 15, 50]. This way, processing occurs over larger batches, leading to potentially significant batch-processing gains. However, queuing packets, thereby artificially slowing down a pipeline in order to speed it up, is tricky [8, 11]; a suboptimal queuing decision can easily cause delay to skyrocket. Fig. 2 shows a motivating example: if two batches containing 2 packets each enter the pipeline then unbuffered execution incurs 8 units of execution cost, as the splitter breaks up each batch into two batches containing one packet each. Placing a queue at the NF inputs, however, enables recovery of the full batches, bringing the execution cost down to 6 units (1 unit per the single batch processed and 2 units per the 2 packets in the batch) but increasing delay to 2 full turnaround times. For a k-way splitter the cost of an unbuffered execution over k batches including k packets each would be $2k^2$, which buffering would reduce to $k+k^2$; about $2\times$ batch-processing gain at the cost of $k\times$ queuing delay.

Of course, packet processing cannot be delayed for an arbitrarily long time to recover batches in full, since this may violate the service level objectives (SLOs) posed by different applications. A typical tactile internet and robot control use case requires 1–10 msec one-way, end-to-end, 99th percentile latency [28]; the 5G radio access/mobile core requires 5–10 msec; and reliable speech/video transport requires delay below 100-200 msec. At the extreme, certain industry automation, 5G inter-base-station and antenna synchronization, algorithmic stock trading, and distributed memory cache applications limit the one-way latency to 10-100 μsec [12, 25].

The key observation in this paper is that *optimal batch-scheduling in a packet processing pipeline is a fine balancing act to control queue backlogs, so that processing occurs in as large batches as possible while each flow traversing the pipeline is scheduled just fast enough to comply with the SLOs*. We present Batchy, a run-to-completion batch-scheduler framework for controlling execution in a packet-processing pipeline based on strict service-level objectives. Our contributions in Batchy are as follows:

Quantifying batch-processing gain. We observe that batch-processing efficiency varies widely across different packet-processing functions. We introduce the *Batchy profiler*, a framework for quantifying the batched service time profile for different packet-processing functions.

Analytical model. We introduce an expressive mathematical model for SLO-based batch-scheduling, so that we can reason about the performance and delay analytically and fine tune batch de-fragmentation subject to delay-SLOs. We also fix the set of basic assumptions under which the optimal schedule is well-defined (see earlier discussion in [6, 15, 50]).

Batch-processing in run-to-completion mode. Taking inspiration from Nagle's algorithm [32], we introduce a new queuing abstraction, the fractional buffer, which allows us to control queue backlogs at a fine granularity even in run-to-completion scheduling, which otherwise offers very little control over when particular network functions are executed.

Design, implementation, and evaluation of Batchy. We present a practical implementation of our batch-scheduling framework and, taking use cases from an official 5G NFV benchmark suite (L2/L3 gateway with and without ACL, NAT, VRF, a mobile gateway, and a robot-control pipeline), we demonstrate that Batchy efficiently exploits batch-processing gain consistently across a wide operational regime with small controller overhead, bringing 1.5–3$\times$ performance improvement compared to outliers and earlier work [21], while satisfying SLOs. Batchy is available for download at [4].

The rest of the paper is structured as follows. In Section 2 we introduce the Batchy profiler, Section 3 presents the idealized mathematical model and introduces fractional buffers, Section 4 discusses our implementation in detail, and Section 5 describes our experiments on real-life use cases. Finally, Section 6 discusses related work and Section 7 concludes the paper. A detailed exposition of the algorithms used in our implementation is given in the Appendix.

2 Profiling Batch-processing Gain

There are many factors contributing to the efficiency of batch-processing; next, we highlight some of the most important

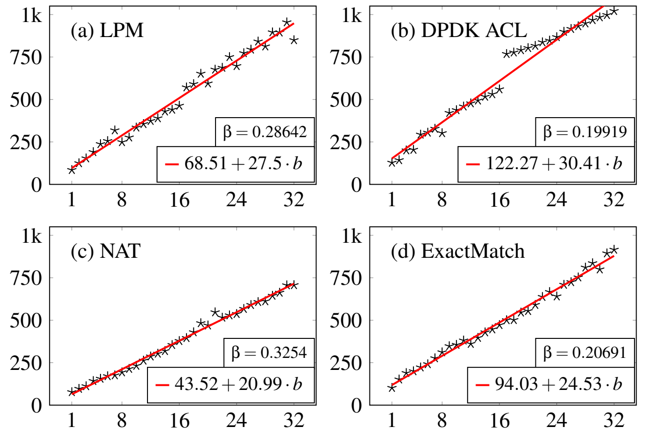

Figure 3: Service-time profile: execution time [nsec] for different modules as the function of the input batch size, averaged over 10 runs at 100,000 batches per second. The inset gives the batchiness β_v and the linear regression $T_{v,0} + T_{v,1}b_v$. Observe the effects of quad-loop/SIMD optimization for the ACL module at batch size 4, 8, and 16.

ones [26,47]. First, executing a network function on a batch incurs non-negligible computational costs independent from the number of packets in it, in terms of CPU-interrupt, scheduling, function call, I/O, memory management, and locking overhead, and *batching amortizes this fixed-cost component* over multiple packets [8, 26]. Second, executing an operation on multiple packets in one turn *improves CPU cache usage*: packets can be prefetched from main memory ahead of time and data/code locality improves as CPU caches are populated by the first packet and then further processing happens without cache misses. For example, VPP modules are written so that the entire code fits into the instruction cache, reducing icache misses [2, 27]. Third, *loop unrolling*, a compiler optimization to rewrite loops into dual- or quad-loops [26] to improve branch predictor performance and keep the CPU pipeline full, is effective only if there are multiple packets to process in one shot. Batch-processing also opens the door to exploit data-level parallelism, whereby the CPU performs the same operation on a batch of 4–32 packets in parallel for the cost of a single SIMD instruction (SSE/AVX) [16].

Intuitively, different packet-processing functions may benefit differently from batch-processing; e.g., a module processing packets in a tight loop may benefit less than a heavily SIMD-optimized one. This will then affect batch-scheduling: reconstructing batches at the input of a lightweight module might not be worth the additional queuing delay, as there is very little efficiency gain to be obtained this way.

Fig. 3 provides a *service time profile* as the execution time for some select BESS modules [14] as the function of the batch size [22]. We observe two distinct execution time components. The *per-batch cost component*, denoted by $T_{v,0}$ [sec] for a module v, characterizes the constant cost that is incurred just for calling the module on a batch, independently from the number of packets in it. The *per-packet cost component* $T_{v,1}$, [sec/pkt], on the other hand, models the execution cost of each individual packet in the batch. A linear model seems a good fit for the service time profiles: accordingly we shall use the linear regression $T_v = T_{v,0} + T_{v,1}b_v$ [sec] to describe the execution cost of a module v where b_v is the batch-size, i.e., the average number of packets in the batches received by module v. The coefficient of determination R^2 is above 96% in our tests, indicating a good fit for the linear model.

The per-batch and per-packet components determine the potential batch-processing gain on different packet processing modules. We quantify this gain with the *batchiness* measure β_v, the ratio of the effort needed to process B packets in a single batch of size B through v compared to the case when processing occurs in B distinct single-packet batches:

$$\beta_v = \frac{T_{v,0} + B * T_{v,1}}{B(T_{v,0} + T_{v,1})} \sim \frac{T_{v,1}}{T_{v,0} + T_{v,1}} \text{ for large } B \quad . \tag{1}$$

Batchiness varies between 0 and 1; small β_v indicates substantial processing gain on v and hence identifies a potential control target. The relatively small batchiness measures in Fig. 3 suggest that most real-world packet-processing functions are particularly sensitive to batch size.

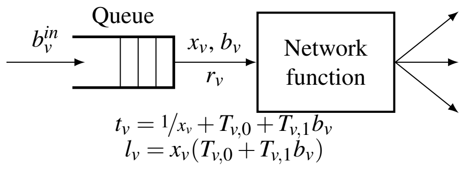
Batchy contains a built-in profiler that runs a standard benchmark on the system under test at the time of initialization, collects per-batch and per-packet service-time components for common NFs, and stores the results for later use.

3 Batch-scheduling in Data Flow Graphs

Next, we present a model to describe batch-based packet processing systems. The model rests on a set of simplifying assumptions, which prove crucial to reason about such systems using formal arguments. We adopt the terminology and definitions from BESS, but we note that the model is general enough to apply to most popular data flow graph packet-processing engines, like VPP [47], Click/FastClick [3, 31], NetBricks [36], or plain DPDK [16]; match-action pipelines like Open vSwitch [38] or ESwitch [30]; or to data flow processing frameworks beyond the networking context like TensorFlow [10] or GStreamer [43].

3.1 System model

Data flow graph. We model the pipeline as a directed graph $\mathcal{G} = (V, E)$, with modules $v \in V$ and directed links $(u, v) \in E$ representing the connections between modules. A *module* v is a combination of a (FIFO) *ingress queue* and a *network function* at the egress connected back-to-back (see Fig. 4). *Input gates* (or ingates) are represented as in-arcs $(u, v) \in E$: $u \in V$ and *output gates* (or outgates) as out-arcs $(v, u) \in E$:



Queue
b_v^{in}
x_v, b_v
r_v
Network function
$t_v = 1/x_v + T_{v,0} + T_{v,1} b_v$
$l_v = x_v(T_{v,0} + T_{v,1} b_v)$

Figure 4: A Batchy module.

$u \in V$. A batch sent to an outgate (v,u) of v will appear at the corresponding ingate of u at the next execution of u. Modules never drop packets; we assume that whenever an ACL module or a rate-limiter would drop a packet it will rather send it to a dedicated "drop" gate, so that we can account for lost packets. A normal queue is a module with an empty network function.

Batch processing. Packets are injected into the ingress, transmitted from the egress, and processed from outgates to ingates along data flow graph arcs, in batches [2, 14, 16, 27, 30]. We denote the maximum batch size by B, a system-wide parameter. For the Linux kernel and DPDK $B = 32$ or $B = 64$ are usual settings, VPP sets the batch size to 256 packets by default [27], while GPU/NIC offload often works with $B = 1024$ or even larger to maximize I/O efficiency [40, 50].

Splitters/mergers. Any module may have multiple ingates (merger) and/or multiple outgates (splitter), or may have no ingate or outgate at all. An IP Lookup module would distribute packets to several downstream branches, each performing group processing for a different next-hop (splitter); a NAT module may multiplex traffic from multiple ingates (merger); and an IP Checksum module would apply to a single datapath flow (single-ingate–single-outgate). Certain modules are represented without ingates, such as a NIC receive queue; we call these *ingress modules* S. Similarly, a module with no outgates (e.g., a transmit queue) is an *egress module*.

Compute resources. A *worker* is an abstraction for a CPU core, where each worker $w \in \mathcal{W}$ is modeled as a connected subgraph $\mathcal{G}_w = (V_w, E_w)$ of $\mathcal{G}$ with strictly one ingress module $S_w = \{s_w\}$ executing on the same CPU. We assume that when a data flow graph has multiple ingress modules then each ingress is assigned to a separate worker, with packets passing between workers over double-ended queues. A typical setup is to dedicate a worker to each receive queue of each NIC and then duplicate the entire data flow graph for each worker. Each worker may run a separate explicit scheduler to distribute CPU time across the modules in the worker graph, or it may rely on run-to-completion; see Appendix A for an overview.

Flows. A flow $f = (p_f, R_f, D_f), f \in \mathcal{F}$ is our abstraction for a service chain, where p_f is a path through $\mathcal{G}$ from the flow's ingress module to the egress module, R_f denotes the offered packet rate at the worker ingress, and D_f is the delay-SLO, the maximum permitted latency for any packet of f to reach the egress. What constitutes a flow, however, will be use-case specific: in an L3 router a flow is comprised of all traffic destined to a single next-hop or port; in a mobile gateway a flow is a complex combination of a user selector and a bearer selector; in a programmable software switch flows are completely configuration-dependent and dynamic. Correspondingly, flow-dissection in a low-level packet processing engine cannot rely on the RSS/RPS function supplied by the NIC, which is confined to VLANs and the IP 5-tuple [6, 19]. Rather, in our framework flow dispatching occurs *intrinsically* as part of the data flow graph; accordingly, we presume that match-tables (splitters) are set up correctly to ensure that the packets of each flow f will traverse the data flow graph along the path p_f associated with f.

3.2 System variables

We argue that at multiple gigabits per second it is overkill to model the pipeline at the granularity of individual packets [22]. Instead, in our model variables are continuous and differentiable, describing system *statistics* over a longer period of time that we call the *control period*. This is analogous to the use of standard (continuous) network flow theory to model packet routing and rate control problems. We use the following variables to describe the state of the data flow graph in a given control period (dimensions indicated in brackets).

Batch rate x_v [$1/s$]: the number of batches per second entering the network function in module v (see again Fig. 4).

Batch size b_v [pkt]: the average number of packets per batch at the input of the network function in module v, where $b_v \in [1, B]$ and, recall, B is the maximum allowed batch size.

Packet rate r_v [pkt/s]: the number of packets per second traversing module v: $r_v = x_v b_v$.

Maximum delay t_v [sec]: delay contribution of module v to the total delay of packets traversing it. We model t_v as

$$t_v = t_{v,\text{queue}} + t_{v,\text{svc}} = 1/x_v + (T_{v,0} + T_{v,1} b_v) \quad , \tag{2}$$

where $t_{v,\text{queue}} = 1/x_v$ is the queuing delay by Little's law and $t_{v,\text{svc}} = T_{v,0} + T_{v,1} b_v$ is the service time profile (see Section 2).

System load l_v (dimensionless): the network function in module v with service time $t_{v,\text{svc}}$ executed x_v times per second incurs $l_v = x_v t_{v,\text{svc}} = x_v(T_{v,0} + T_{v,1} b_v)$ system load in the worker.

Turnaround-time T_0 [sec]: the maximum CPU time the system may spend pushing a single batch through the pipeline. The turnaround time typically varies with the type and number of packets in each batch, the queue backlogs, etc.; correspondingly, we usually consider the time to execute *all* modules on maximum sized batches as an upper bound:

$$T_0 \le \sum_{v \in V} (T_{v,0} + T_{v,1} B) \quad . \tag{3}$$

3.3 Assumptions

Our aim is to define the simplest possible batch-processing model that still allows us to reason about flows' packet rate and maximum delay, and modules' batch-efficiency. The below assumptions will help to keep the model at the minimum; these assumptions will be relaxed later in Section 4.

Feasibility. We assume that the pipeline runs on a single worker and this worker has enough capacity to meet the delay-SLOs. In the next section, we show a heuristic method to decompose a data flow graph to multiple workers in order to address SLO violations stemming from inadequate resources.

Buffered modules. We assume that all modules contain an ingress queue and all queues in the pipeline can hold up to at most B packets at any point in time. In the next section, we show how to eliminate useless queues in order to remove the corresponding latency and processing overhead.

Static flow rate. All flows are considered constant-bit-rate (CBR) during the control period (usually in the millisecond time frame). This assumption will be critical for the polynomial tractability of the model. Later on, we relax this assumption by incorporating the model into a receding-horizon optimal control framework.

3.4 Optimal explicit batch-schedule

Workers typically run an *explicit scheduler* to distribute CPU time across the modules in the worker graph. Common examples include Weighted Fair Queueing (WFQ) and Completely Fair Scheduling (CFS); here, the user assigns integer weights to modules and the scheduler ensures that runtime resource allocation will be proportional to modules' weight [46]. For simplicity, we consider an *idealized* WFQ/CFS scheduler instead, where execution order is defined in terms per-module *rates* and not weights; rates will be converted to weights later.

The idealized scheduler runs each module precisely at the requested rate. When scheduled, the modules' network function dequeues at most a single batch worth of packets from the ingress queue, executes the requested operation on all packets of the batch, forms new sub-batches from processed packets and places these to the appropriate outgates.

In this setting, we seek for a set of rates x_v at which each module $v \in V$ needs to be executed in order to satisfy the SLOs. If multiple such rate allocations exist, then we aim to choose the one that minimizes the overall system load.

Recall, executing v exactly x_v times per second presents $l_v = x_v t_{v,\text{svc}} = x_v(T_{v,0} + T_{v,1}b_v)$ load to the system. The objective function, correspondingly, is to find rates x_v that minimize the total system load $\sum_{v \in V} l_v$, taken across all modules:

$$\min \sum_{v \in V} x_v(T_{v,0} + T_{v,1}b_v) \ . \tag{4}$$

Once scheduled, module v will process at most $b_v \in [1,B]$ packets through the network function, contributing $t_{v,\text{svc}} = T_{v,0} + T_{v,1}b_v$ delay to the total latency of each flow traversing it. In order to comply with the delay-SLOs, for each flow f it must hold that the total time spent by any packet in the worker ingress queue, plus the time needed to send a packet through the flow's path p_f, must not exceed the delay requirement D_f for f. Using that the ingress queue of size B may develop a backlog for only at most one turnaround time T_0 (recall, we assume there is a single worker and each queue holds at most B packets), and also using (2), we get the following *delay-SLO constraint*:

$$t_f = T_0 + \sum_{v \in p_f} \left({}^{1}\!/_{x_v} + T_{v,0} + T_{v,1}b_v\right) \le D_f \qquad \forall f \in \mathcal{F} \ . \tag{5}$$

Each module $v \in V$ must be scheduled frequently enough so that it can handle the *total offered packet rate* $R_v = \sum_{f: v \in p_f} R_f$, i,e., the sum of the requested rate R_f of each flow f traversing v (recall, we assume flow rates R_f are constant). This results the following *rate constraint*:

$$r_v = x_v b_v = \sum_{f: v \in p_f} R_f = R_v \qquad \forall v \in V \ . \tag{6}$$

Finally, the backlog b_v at any of the ingress queues across the pipeline can never exceed the queue size B and, of course, all system variables must be non-negative:

$$1 \le b_v \le B, \ x_v \ge 0 \qquad \forall v \in V \ . \tag{7}$$

Together, (4)–(7) defines an optimization problem which provides the required static scheduling rate x_v and batch size b_v for each module v in order to satisfy the SLOs while maximizing the batch-processing gain. This of course needs the turnaround time T_0; one may use the approximation (3) to get a conservative estimate. Then, substituting $b_v = \sum_{f: v \in p_f} {}^{R_f}\!/_{x_v} = {}^{R_v}\!/_{x_v}$ using (6), we get the following system, now with only the batch-scheduling rates x_v as variables:

$$\min \sum_{v \in V} x_v\left(T_{v,0} + T_{v,1}\frac{R_v}{x_v}\right) \tag{8}$$

$$t_f = T_0 + \sum_{v \in p_f} \left(\frac{1}{x_v} + T_{v,0} + T_{v,1}\frac{R_v}{x_v}\right) \le D_f \quad \forall f \in \mathcal{F} \tag{9}$$

$${}^{R_v}\!/_{B} \le x_v \le R_v \qquad \forall v \in V \tag{10}$$

Since the constraints and the objective function are convex, we conclude that (8)–(10) *is polynomially tractable and the optimal explicit batch-schedule is unique* [5]. Then, setting the scheduling weights proportionally to rates x_v results in the optimal batch-schedule on a WFQ/CFS scheduler [46].

3.5 Run-to-completion execution

WFQ/CFS schedulers offer a plausible way to control batch de-fragmentation via the per-module weights. At the same time, often additional tweaking is required to avoid head-of-line blocking and late drops along flow paths [21], and even running the scheduler itself may incur non-trivial runtime overhead. *Run-to-completion execution*, on the other hand, eliminates the explicit scheduler all together, by tracing the entire input batch though the data flow graph in one shot without the risk of head-of-line blocking and internal packet drops [6,14]. Our second batch-scheduler will therefore adopt run-to-completion execution.

The idea in run-to-completion scheduling is elegantly simple. The worker checks the input queue in a tight loop and, whenever the queue is not empty, it reads a single batch and injects it into pipeline at the ingress module. On execution, each module will process a single batch, place the resulting packets at the outgates potentially breaking the input batch into multiple smaller output batches, and then recursively schedule the downstream modules in order to consume the sub-batches from the outgates. This way, the input batch proceeds through the entire pipeline in a single shot until the last packet of the batch completes execution, at which point the worker returns to draining the ingress queue. Since upstream modules will *automatically* schedule a downstream module whenever there is a packet waiting to be processed, run-to-completion execution does not permit us to control when individual modules are to be executed. This makes it difficult to enforce SLOs, especially rate-type SLOs, and to delay module execution to de-fragment batches.

Below, we introduce a new queuing abstraction, the *fractional buffer*, which nevertheless lets us exert fine-grained control over modules' input batch size. The fractional buffer is similar to Nagle's algorithm [32], originally conceived to improve the efficiency of TCP/IP networks by squashing multiple small messages into a single packet. The backlog is controlled so as to keep end-to-end delay reasonable. Indeed, Nagle's algorithm exploits the same batch-efficiency gain over the network as we intend to exploit in the context of compute-batching, motivating our choice to apply it whenever there is sufficient latency slack available.

A fractional buffer maintains an internal FIFO queue and exposes a single parameter to the control plane called the *trigger* b, which enables tight control of the queue backlog and thereby the delay. The buffer will enqueue packets and suppress execution of downstream modules until the backlog reaches b, at which point a packet batch of size b is consumed from the queue, processed in a single burst through the succeeding module, and execution of downstream modules is resumed. Detailed pseudocode is given in Appendix C.

We intentionally define the trigger in the batch-size domain and not as a perhaps more intuitive timeout [32], since timeouts would re-introduce an explicit scheduler into the otherwise "schedulerless" design. Similarly, we could in theory let the buffer to emit a batch larger than b whenever enough packets are available; we intentionally restrict the output batch to size b so as to tightly control downstream batch size.

What remains is to rewrite the optimization model (8)–(10) from explicit module execution rates x_v to fractional buffer triggers. Interestingly, *jumping from rate-based scheduling to the run-to-completion model is as easy as substituting variables*: if we replace the ingress queue with a fractional buffer with trigger b_v in each module v, then the subsequent network function will experience a batch rate of $x_v = {R_v}/{b_v}$ at batch size b_v. Substituting this into the optimization problem (4)–(7) yields the *optimal batch-schedule for the run-to-completion model* with variables $b_v : v \in V$:

$$\min \sum_{v \in V} \frac{R_v}{b_v}(T_{v,0} + T_{v,1} b_v) \tag{11}$$

$$t_f = T_0 + \sum_{v \in p_f} \left(\frac{b_v}{R_v} + T_{v,0} + T_{v,1} b_v \right) \le D_f \quad \forall f \in \mathcal{F} \tag{12}$$

$$1 \le b_v \le B \quad \forall v \in V \tag{13}$$

Again, the optimization problem is convex and the optimal setting for the fractional buffer triggers is unique. In addition, the feasible region is linear, which makes the problem tractable for even the simplest of convex solvers. Since the substitution $x_v = {R_v}/{b_v}$ can always be done, we find that for *any* feasible batch-rate $x_v : v \in V$ in the explicit scheduling problem (8)–(10) there is an equivalent set of fractional buffer triggers $b_v : v \in V$ in the run-to-completion problem (11)–(13) and *vice versa*; put it another way, *any system state (collection of flow rates and delays) feasible under the explicit scheduling model is also attainable with a sufficient run-to-completion schedule*. To the best of our knowledge, this is the first time that an equivalence between the two crucial data flow-graph scheduling models is shown. We note however that the assumptions in Section 3.3 are critical for the equivalence to hold. For instance, explicit scheduling allows for a "lossy" schedule whereas a run-to-completion schedule is lossless by nature; under the "feasibility" assumption, however, there is no packet loss and hence the equivalence holds.

4 Implementation

We now describe the design and implementation of Batchy, our batch-scheduler for data flow graph packet-processing engines. The implementation follows the model introduced above, extended with a couple of heuristics to address practical limitations. We highlight only the main ideas of the implementation below; a detailed description of the heuristics with complete pseudocode can be found in the Appendix.

Design. To exploit the advantages of the simple architecture and zero scheduling overhead, in this paper we concentrate on the run-to-completion model (11)–(13) exclusively and we leave the implementation of the explicit scheduling model (8)–(10) for further study. This means, however, that currently we can enforce only delay-type SLOs using Batchy. In our design, the control plane constantly monitors the data plane and periodically intervenes to improve batch-efficiency and satisfy SLOs. Compared to a typical scheduler, Batchy interacts with the data plane at a coarser grain: instead of operating at the granularity of individual batches, it controls the pipeline by periodically adjusting the fractional buffer triggers and then it relies entirely on run-to-completion scheduling to handle the fine details of module execution.

Receding-horizon control. A naive approach to implement the control plane would be to repeatedly solve the convex program (11)–(13) and apply the resulting optimal fractional-buffer triggers to the data plane. Nevertheless, by the time the convex solver finishes computing the optimal schedule the system may have diverged substantially from the initial state with respect to which the solution was obtained. To tackle this difficulty, we chose a *one-step receding-horizon control* framework to implement Batchy. Here, in each control period the optimization problem (11)–(13) is bootstrapped with the current system state and fed into a convex solver, which is then is stopped *after the first iteration*. This results a coarse-grain control action, which is then immediately applied to the data plane. After the control period has passed, the system is re-initialized from the current state and a control is calculated with respect to this new state. This way, the controller rapidly drives the system towards improved states and eventually reaches optimality in steady state, automatically adapting to changes in the input parameters and robustly accounting for inaccuracies and failed model assumptions without having to wait for the convex solver to fully converge in each iteration.

Main control loop. Upon initialization, Batchy reads the data flow graph, the flows with the SLOs, and per-module service time profiles from the running system. During runtime, it measures in each control period the execution rate $\tilde{x}_v$, the packet rate $\tilde{r}_v$, and the mean batch size $\tilde{b}_v^{in}$ at the *input* of the ingress queue for each module $v \in V$, plus the 95th percentile packet delay $\tilde{t}_f$ measured at the egress of each flow $f \in \mathcal{F}$. (The overbar tilde notation is to distinguish *measured* parameters.) The statistics and the control period are configurable; e.g., Batchy can be easily re-configured to control for the 99th percentile or the mean delay. Due to its relative implementation simplicity and quick initial convergence, we use the gradient projection algorithm [5] to compute the control but in each run we execute only a *single* iteration. The algorithm will adjust triggers so as to obtain the largest relative gain in total system load and, whenever this would lead to an SLO violation, cut back the triggers just enough to avoid infeasibility.

Insert/short-circuit buffers. An unnecessary buffer on the packet-processing fast path introduces considerable delay and incurs nontrivial runtime overhead. In this context, a buffer is "unnecessary" if it already receives large enough batches at the input (Batchy detects such cases by testing for $\tilde{b}_v^{in} \geq 0.7B$); if it would further fragment batches instead of reconstructing them ($b_v \leq \tilde{b}_v^{in}$); or if just introducing the buffer already violates the delay-SLO ($1/x_v > D_f$ for some $v \in p_f$). If one of these conditions hold for a module v, Batchy immediately short-circuits the buffer in v by setting the trigger to $b_v = 0$: the next-time module v is executed the ingress queue is flushed and subsequent input batches are immediately fed into the network function without buffering. Similar heuristics allow Batchy to inject buffers into the running system: at initialization we short-circuit all buffers ("null-control", see below) and, during runtime, we install a buffer whenever *all* flows traversing a module provide sufficient delay-budget.

Recovering from infeasibility. The projected gradient controller cannot by itself recover from an infeasible (SLO-violating) state, which may occur due to packet rate fluctuation or an overly aggressive control action. A flow f is in SLO-violation if $\tilde{t}_f \geq (1-\delta)D_f$ where δ is a configurable parameter that allows to trade off SLO-compliance for batch-efficiency. Below, we use the setting $\delta = 0.05$, which yields a rather aggressive control that strives to maximize batch size with a tendency to introduce relatively frequent, but small, delay violations. Whenever a flow $f \in \mathcal{F}$ is in SLO violation and there is a module v in the path of f set to a non-zero trigger ($b_v > \tilde{b}_v^{in}$), we attempt to reduce b_v by $\left\lceil \frac{D_f - t_f}{\partial t_f / \partial b_v} \right\rceil$. If possible, this would cause f to immediately recover from the SLO-violation. Otherwise, it is possible that the invariant $b_v \geq \tilde{b}_v^{in}$ may no longer hold; then we repeat this step at as many modules along p_f as necessary and, if the flow is still in SLO-violation, we short-circuit all modules in p_f.

Pipeline decomposition. Batchy contains a pipeline controller responsible for migrating flows between workers to enforce otherwise unenforceable delay-SLOs. Consider the running example in Fig. 2, assume a single worker, let the processing cost of NF1 be 1 unit and that of NF2 be 10 units, and let the delay-SLO for the first flow be 2 units. This pipeline is inherently in delay-SLO violation: in the worst case a packet may need to spend 10 time units in the ingress queue until NF2 finishes execution, significantly violating the delay-SLO for the first flow (2 units). This inherent SLO violation will persist as long as NF1 and NF2 share a single worker. Batchy uses the analytical model to detect such cases: a worker w is in inherent delay-SLO violation if there is a flow $f \in \mathcal{F}$ for which $\sum_{v \in V_w}(T_{v,0} + T_{v,1}B) \geq D_f$ holds, using the conservative estimate (3). Then Batchy starts a flow migration process: first it packs flows back to the original worker as long as the above condition is satisfied and then the rest of the flows are moved to a new worker. This is accomplished by decomposing the data flow graph into multiple disjunct connected worker subgraphs. Note that flows are visited in the ascending order of the delay-SLO, thus flows with restrictive delay requirements will stay at the original worker with a high probability, exempt from cross-core processing delays [19].

Implementation. We implemented Batchy on top of BESS [14] in roughly 6,000 lines of Python/BESS code. (Batchy is available at [4].) BESS is a high-performance packet processing engine providing a programming model and interface similar to Click [31]. BESS proved an ideal prototyping platform: it has a clean architecture, is fast [24], provides an efficient scheduler, exposes the right abstractions and offers a flexible plugin infrastructure to implement the missing ones. The distribution contains two built-in controllers. The *on-off controller* ("Batchy/on-off") is designed for the case when fractional buffers are not available in the data plane. This controller alters between two extremes (bang-bang control): at each module v, depending on the delay budget it either disables buffering completely ($b_v = 0$) or switches to full-batch buffering ($b_v = B$), using the above buffer-insertion/deletion and feasibility-recovery heuristics. On top of this, the *full-fledged Batchy controller* ("Batchy/full") adds fractional buffers and fine-grained batch-size control using the projected gradient method.

5 Evaluation

Batchy is a control framework for packet-processing engines, which, depending on flows' offered packet rate and delay-SLOs, searches for a schedule that balances between batch-processing efficiency and packet delay. In this context the following questions naturally arise: *(i)* how much do batches fragment in a typical use case (if at all) and how much efficiency is there to gain by reconstructing these? how precisely does Batchy enforce SLOs?; *(ii)* which is the optimal operational regime for Batchy and what is the cost we pay?; *(iii)* does Batchy react quickly to changes in critical system parameters?; and finally *(iv)* can Batchy recover from inherent SLO-violations? Below we seek to answer these questions.

Evaluation setup. To understand the performance and latency-related impacts of batch control, we implemented two baseline controllers alongside the basic Batchy controllers (Batchy/on-off and Batchy/full): the *null-controller* performs no batch de-fragmentation at all ($b_v = 0 : v \in V$), while the *max-controller* reconstructs batches in full at the input of all modules ($b_v = B : v \in V$). Both baseline controllers ignore SLOs all together. The difference between performance and delay with the null- and max-controllers will represent the maximum attainable efficiency improvement batching may yield, and the price we pay in terms of delay. We also compared Batchy to NFVnice, a scheduling framework originally defined for the NFV context [21]. NFVnice is implemented in a low-performance container-based framework; to improve performance and to compare it head-to-head, we re-implemented its core functionality within BESS. Our implementation uses WFQ to schedule modules with equal weights and enables backpressure. All controllers run as a separate Python process, asserting *real-time control* over the BESS data plane via an asynchronous gRPC channel.

The evaluations are performed on 5 representative use cases taken from an official industry 5G benchmark suite [24]. The L2/L3(n) pipeline implements a basic IP router, with L2 lookup, L3 longest-prefix matching, and group processing for n next-hops; the GW(n) use case extends this pipeline into a full-fledged gateway with NAT and ACL processing for n next-hop groups; and the VRF(m,n) pipeline implements m virtual GW(n) instances preceded by an ingress VLAN splitter (see Fig. 5). The MGW(m,n) pipeline is a full 4G mobile gateway data plane with m users and n bearers per

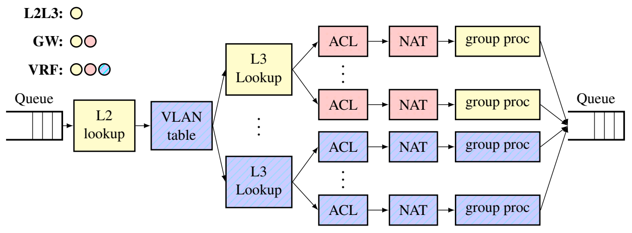


Figure 5: The VRF pipeline. The GW pipeline is identical to the VRF pipeline with only a single VRF instance, and the L2/L3 pipeline is a GW pipeline without a NAT and ACL on the next-hop branches.

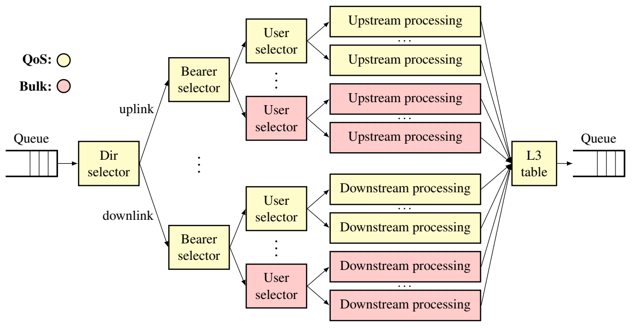

Figure 6: The mobile gateway (MGW) pipeline.

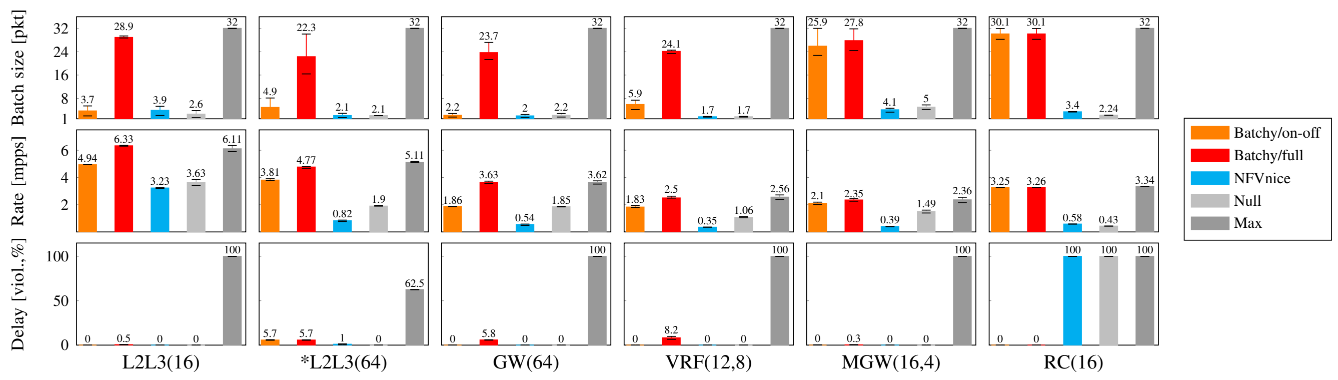
user, with complete uplink and downlink service chains (see Fig. 6). Finally, the RC(n) pipeline models a 5G robot control use case: RC(n) corresponds to the running example in Fig. 2 with n branches, with the upper branch representing an ultra-delay-sensitive industry automation service chain and the rest of the branches carrying bulk traffic. We obtained test cases of configurable complexity by varying the parameters m and n and installing a flow over each branch of the resultant pipelines; e.g., in the VRF(2,4) test we have a separate flow for each VRF and each next-hop, which gives 8 flows in total.

Each pipeline comes with a traffic source that generates synthetic test traffic for the evaluations. For the L2/L3 pipeline, we repeated the tests with a real traffic trace taken from a CAIDA data set [9], containing 1.85 million individual transport sessions of size ranging from 64 bytes to 0.8 Gbytes (18 Kbyte mean) and maximum duration of 1 min (5.4 sec mean); the results are marked with the label *L2L3. Unless otherwise noted, the pipelines run on a single worker (single CPU core), with the traffic generator provisioned at another worker. The maximum batch size is 32, the control period is 100 msec, and results are averaged over 3 consecutive runs.

Each evaluation runs on a server equipped with an Intel Xeon E5-2620 v3 CPU (12 cores total, 6 isolated, power-saving disabled, single socket) with 64GB memory (with 12 $\times$ 1GB allocated as hugepages), installed with the Debian/GNU operating system, Linux kernel v4.19, a forked version of BESS v0.4.0-57-g43bebd3, and DPDK v17.11.

Batch-scheduling constant bit-rate flows. In this test round, we benchmark the static performance of the Batchy con-



Common parameters. test time: 200 periods, warmup: 100 periods, control period: 0.1sec, $\delta = 0.05$, SLO-control: 95th percentile delay, burstiness: 1. Measure params (bucket/max): 5μsec/250msec. L2L3: FIB: 500 entries. CAIDA trace: `equinix-nyc.dirA.20190117-130600.UTC.anon`. GW: ACL: 100 entries, NAT: static NAT. MGW: FIB: 5k entries, 4 users on bearer0, upstream/downstream processing $T_{0,v} = 2000, T_{1,v} = 100$.

Figure 7: Static evaluation results (mean, 1st and 3rd quartile) with the null-controller, max-controller, NFVnice, Batchy/on-off and Batchy/full on different pipelines: average batch-size, cumulative packet rate, and delay-SLO statistics as the percentage of control periods when an SLO-violation was detected for at least one flow.

trollers against the baselines and NFVnice over 6 representative 5G NFV configurations. The null-controller, the max-controller, and NFVnice do not consider the delay-SLO, while for Batchy/on-off and Batchy/full we set the delay-SLO to 80% of the average delay measured with the max-controller; this setting leaves comfortable room to perform batch de-fragmentation but sets a firm upper bound on triggers. (Without an SLO, Batchy controllers degrade into a max-controller.)

After a warmup (100 control periods) we ran the pipeline for 100 control periods and we monitored the batch size statistics averaged across modules, the cumulative packet rate summed over all flows, and the delay-SLO statistics as the percentage of control periods when an SLO violation occurs for *at least* one flow. Fig. 7 highlights the results for 6 select configurations and Appendix B details the full result set. Our observations are as follows.

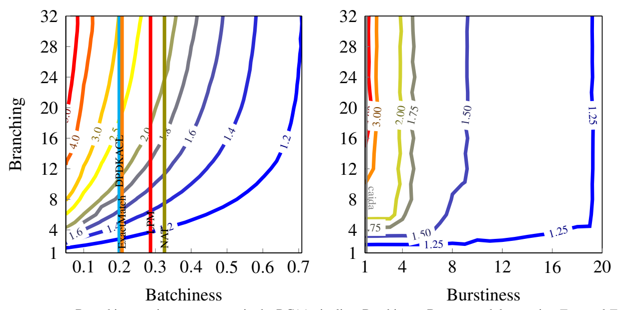
First, *the full-fledged Batchy controller (Batchy/full) can successfully reconstruct batches* at the input of network functions, achieving 70–80% of the average batch size of the max-controller in essentially all use cases (same proportion as the delay-SLO constraints). *Batch-fragmentation gets worse as the number of branches increases* across which batches may be split (the *branching* factor), to the point that when there are 16–64 pathways across the data flow graph the null-controller works with just 2–3 packets per batch. The simplified controller (Batchy/on-off) produces mixed results: whenever there is enough delay-budget to insert full buffers it attains similar de-fragmentation as Batchy/full (MGW(16,4), RC(16)), while in other cases it degrades into null-control (GW(64)).

Second, *batch de-fragmentation clearly transforms into considerable efficiency improvement*. Batchy/full exhibits 1.5–2.5× performance compared to the case when we do no batch de-fragmentation at all (null-control), and Batchy/on-off shows similar, although smaller, improvements. In the robot-control use case we see 7.5× throughput margin. This experiment demonstrates the benefits of selective per-module batch-control: there is only one highly delay-sensitive flow but this alone rules out any attempt to apply batching *globally* (even at the I/O); Batchy can, however, identify this chain and short-circuit all buffers along just this chain while it can still buffer the remaining bulk flows, yielding a dramatic performance boost. Despite the firm upper bound on the delay, and on the maximum attainable batch size, Batchy performs very close to the max-controller and in some tests even outperforms it (e.g., for L2L3(16)). This is because the max-controller buffers all modules unconditionally while Batchy carefully removes unnecessary buffers, and this helps in terms of valuable CPU cycles saved. The results are consistently reproduced over both the synthetic and the real traffic traces.

Third, despite the rather aggressive controller settings ($\delta = 0.05$, see the previous Section), *Batchy controllers violate the delay-SLO at most* 9% *of time* for at least one out of the possibly 64 flows, and even in these cases the relative delay violation is always below 1–2% (not shown in the figures). We believe that this is a price worth paying for the efficiency gain; manually repeating a failed test with a less aggressive control ($\delta = 0.2$) eliminated delay-SLO violations all together, at the cost of somewhat lower throughput.

Finally, we see that the Batchy/on-off controller is already useful in its own right in that it produces substantial batch-performance boost in certain configurations, but it hardly improves on null-control in others. It seems that discrete on-off control is too coarse-grained to exploit the full potential of batch de-fragmentation; to get full advantage we need finer-grained control over batch sizes, and the ensuing delay, using fractional buffers and the Batchy/full controller.

Optimal operational regime and runtime overhead. Next, we attempt to obtain a general understanding of the efficiency improvements attainable with Batchy, and the cost we pay in



Branching: setting parameter n in the RC(n) pipeline. Batchiness: Bypass module, varying $T_{0,v}$ and $T_{1,v}$.
Burstiness: varying mean burst size. Fixed parameters: first plot: burstiness=1; second plot: $\beta = 1/11$ for all modules.

Figure 8: Batchiness and burstiness vs. branching: Batchy/full packet rate normalized to the maximally fragmented case.

terms of controller overhead. For this, we first define a set of meta-parameters that abstract away the most important factors that shape the efficiency and overhead of Batchy, and then we conduct extensive evaluations in the configuration space of these meta-parameters.

The meta-parameters are as follows. Easily, it is the complexity of the underlying data flow graph that fundamentally determines Batchy's performance. We abstract pipeline complexity using the *branching* meta-parameter, which represents the number of distinct control-flow paths through the data flow graph; the higher the branching the more batches may break up inside the pipeline and the larger the potential batch de-fragmentation gain. Second, *batchiness*, as introduced in Section 2, determines each module's sensitivity to batch size; small batchiness usually indicates huge potential de-fragmentation gain. Finally, the specifics of the input traffic pattern is captured using the *burstiness* meta-parameter, which measures the average size of back-to-back packet bursts (or flowlets [37]) at the ingress of the pipeline. Indeed, burstiness critically limits batch-efficiency gains: as packet bursts tend to follow the same path via the graph they are less prone to fragmentation, suggesting that the performance margin of de-fragmentation may disappear over highly bursty traffic.

To understand how these factors shape the efficiency of Batchy, Fig. 8 shows two contour plots; the first one characterizes the speedup with Batchy/full compared to null-control in the branching–batchiness domain and the second one measures branching against burstiness. The plots clearly outline the optimal operational regime for Batchy: *as the number of branches grows beyond* 4–8 *and batchiness remains under* 0.5 *we see* 1.5–4× *speedup, with diminishing returns as the mean burst size grows beyond* 10. These gains persist with realistic exogenous parameters; batchiness for real modules is between 0.2–0.3 (see Fig. 3) and the CAIDA trace burstiness is only 1.13 (see the vertical indicators in the plots). But even for very bursty traffic and/or poor batch sensitivity, Batchy consistently brings over 1.2× improvement and never worsens performance: for workloads that do not benefit from batch de-fragmentation Batchy rapidly removes useless buffers and falls back to default, unbuffered forwarding.

Branching (n)	Response time	Stats	Gradient	Control
1	2.4 msec	66%	31%	3%
2	3.5 msec	61%	37%	2%
4	6.9 msec	65%	32%	3%
8	11.6 msec	65%	32%	3%
16	21.9 msec	66%	30%	4%
32	34.8 msec	68%	28%	4%
64	89.1 msec	72%	22%	6%

Table 1: Batchy/full runtime overhead on increasingly more complex RC(n) pipelines: branching, total controller response time, and contribution of each phase during the control, i.e., monitoring (Stats), gradient control (Gradient), and applying the control (Control).

Table 1 summarizes the controller runtime overhead in terms of the "pipeline complexity" meta-parameter (branching). The profiling results indicate that *the performance gains come at a modest resource footprint*: depending on pipeline complexity the controller response time varies between 2–90 milliseconds, with roughly two thirds of the execution time consumed by marshaling the statistics out from the data-plane and applying the new triggers back via gRPC, and only about one third taken by running the gradient controller itself.

System dynamics under changing delay-SLOs. We found the projected gradient controller to be very fast in the static tests: whenever the system is in steady state (offered load and delay-SLOs constant), Batchy usually reaches an optimal KKT point [5] in about 5–10 control periods. In the tests below, we evaluated Batchy under widely fluctuating system load to get a better understanding of the control dynamics.

First, we study how Batchy reacts to changing delay-SLOs (see the `conf/l2l3_vd.batchy` config file in the Batchy source distribution [4]). The results are in Fig. 9a. In this experiment, we set up the VRF(4, 8) pipeline and vary the delay-SLO between 60 μsec and 300 μsec in 6 steps; see the blue dotted "square wave" in Fig. 9a/Delay panel. The SLOs were set so that we test abrupt upwards ("rising edge") and downwards ("falling edge") delay-SLO changes as well. The figure shows for each control period the value of the trigger at the ACL module of the top branch (first VRF, first next-hop), the total delay and the delay-SLO for the flow provisioned at the top branch, and the normalized cumulative packet rate with the null-controller, the max-controller, and Batchy/full.

The results suggest that *Batchy promptly reacts to "bad news"* (SLO-reduction, falling edge, Fig. 9a/Delay) and instantaneously reduces fractional buffer triggers (Fig. 9a/Control), or even completely short-circuits buffers to recover from SLO-violations, whereas it is much more *careful to react to "good news"* (increasing SLO, rising edge). Overall, the packet delay closely tracks the SLO dynamics. Meanwhile, whenever there is room to perform batch de-fragmentation Batchy rapidly reaches the efficiency of the max-controller, *delivering* 2–3× *the total throughput of the null-controller*.

System dynamics with variable bitrate traffic. Next, we

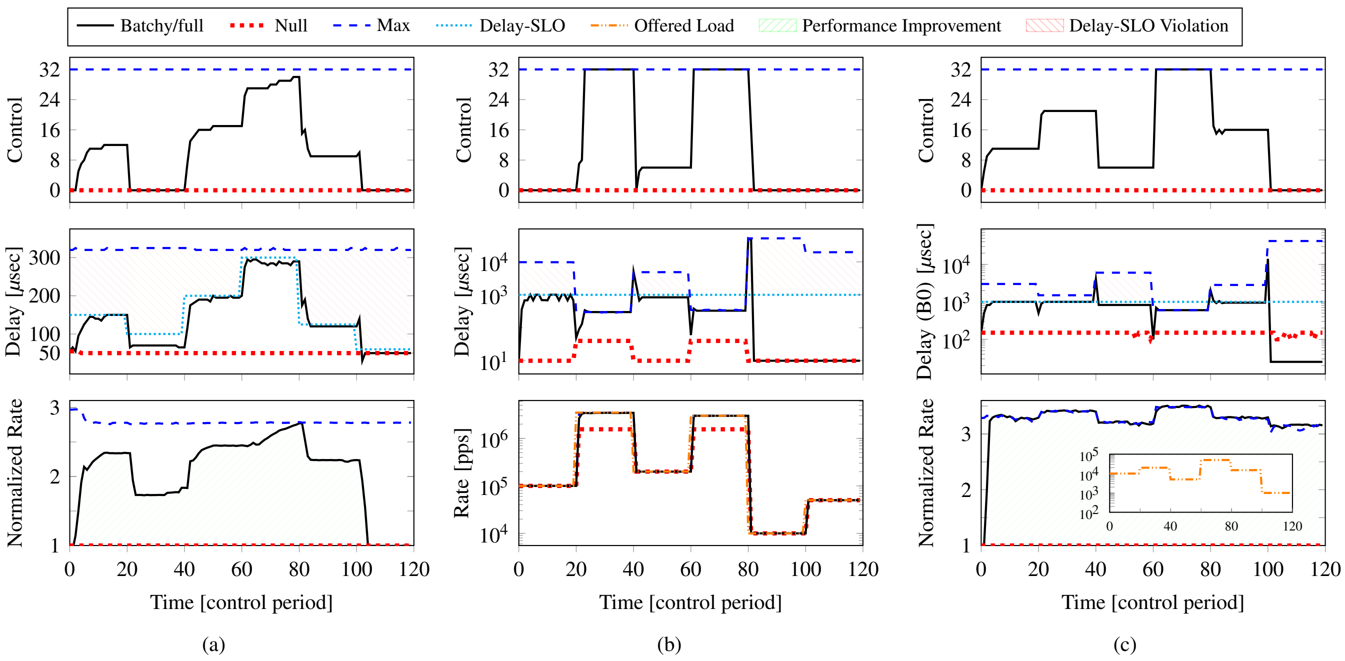


Figure 9: System dynamics with changing SLOs and variable bit-rate traffic: (a) control and delay for the first flow, and cumulative packet rate in the VRF(4,8) pipeline when the delay-SLO changes in the range 60–300 μsec; (b) control and delay for the first flow, and cumulative packet rate in the VRF(4,8) pipeline with the delay-SLO of all flows fixed at 1 msec and varying the total offered load between 50 kpps to 3 mpps; and (c) control, delay, and packet rate for the first user's bearer-0 (B0) flow in the MGW(2,16) pipeline, delay-SLO fixed at 1 msec, bearer-0 rate varying between 1 kpps and 50 kpps for all users.

test Batchy with variable bitrate flows. Intuitively, when the offered load drops abruptly it suddenly takes much longer for a buffer to accumulate enough packets to construct a batch, which causes delay to skyrocket and thereby leads to a grave delay-SLO violation. In such cases Batchy needs to react fast to recover. On the other hand, when the packet rate increases and queuing delays fall, Batchy should gradually increase triggers across the pipeline to improve batch-efficiency.

To understand the system dynamics under changing packet rates, we conducted two experiments. First, we fire up the VRF(4,8) pipeline and we fix the delay-SLO for all flows at 1 msec and vary the total offered load between 50 kpps to 3 mpps in 6 steps; this amounts to a dynamic range of 3 orders of magnitude (see `conf/l2l3_vbr.batchy` in [4]). Second, we set up the MGW(2,16) pipeline (2 bearers and 16 users, see `conf/mgw_vbr.batchy` in [4]), but now only bearer-0 flows (B0, the "QoS" bearer) vary the offered packet rate (between 1 kpps and 50 kpps) and set a delay-SLO (again, 1 msec). The results are in Fig. 9b and Fig. 9c, respectively.

Our observations here are similar as before. Even in the face of widely changing packet rates, Batchy keeps delay firmly below 1 msec except under transients: it *instantaneously recovers from SLO violations and rapidly returns to operate at full batch-size whenever possible*. Meanwhile, the max-controller causes a 100× SLO violation at small packet rates. In the second experiment we again see significant improvement in the total throughput with Batchy, compared to the null-controller (recall, only bearer-0 rate is fixed in this case).

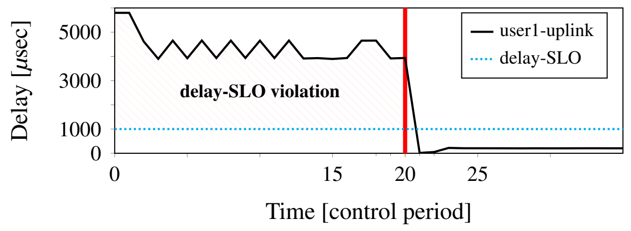

Figure 10: Recovery from inherent delay-SLO violations: MGW(2,8) test case with two users at bearer-0, delay-SLO set to 1 msec. The pipeline controller is started manually at the 20-th control period, moving bulk bearer-1 uplink and downlink traffic to a new worker each. (Downlink traffic and the other user's traffic exhibit similar performance.)

Resource-(re)allocation when SLOs cannot be satisfied. Finally, we study the effects of inherent delay-SLO violations, which occur when the turnaround time grows prohibitive at an over-provisioned worker and ingress queue latency exceeds the delay-SLO even before packets would enter the pipeline. Batchy implements a pipeline controller to detect inherent delay-SLO violations and to heuristically re-allocate resources, decomposing the data flow graph to multiple subgraphs to move delay-insensitive traffic to new workers.

Fig. 10 shows the pipeline controller in action (see `conf/mgw_decompose.batchy`) in [4]). Again we set up the

MGW(2,8) pipeline but now only two users open a flow at bearer-0, with delay-SLO set to 1 msec both in the uplink and downlink direction. The rest of the users generate bulk traffic at bearer-1 with no delay-SLO set. In addition, the service time of the bearer-1 uplink/downlink chains is artificially increased, which causes the turnaround time to surpass 1 msec and the latency for the delay-sensitive bearer-0 flows to jump to 4 msec. The pipeline controller kicks in at the 20-th control period and *quickly recovers the pipeline from the inherent delay-SLO violation*: by decomposing the data flow graph at the output of the `Bearer selector` splitter module, it moves all bearer-1 traffic away to new workers. The delay of bearer-0 flows quickly falls below the SLO, so much so that from this point Batchy can safely increase buffer sizes across the pipeline, leading to more than 10× improvement in the cumulative throughput (not shown in the figure).

6 Related Work

Batch-processing in data-intensive applications. Earlier work hints at the dramatic performance improvement batch-processing may bring in data-intensive applications and in software packet I/O in particular [1,6,7,20,29,41,50]. Consequently, batch-based packet-processing has become ubiquitous in software network switches [2,3,14,15,20,27,30,36], OS network stacks and dataplanes [3,6,8,11], user-space I/O libraries [1,16], and Network Function Virtualization [19,21,42,45,50]. Beyond the context of performance-centric network pipelines, batch-processing has also proved useful in congestion control [37], data streaming [18], analytics [44], and machine-learning [10].

Dynamic batch control. Clearly, the batch size should be set as high as possible to maximize performance [1,6,8,11,16,20,27,29,41,50]; as long as I/O rates are in the range of multiple million packets per second the delay introduced this way may not be substantial [16]. Models to compute the optimal batch size *statically* and *globally* for the entire pipeline, subject to given delay-SLOs, can be found in [6,22,41,50]; [41] presents a discrete Markovian queuing model and [22] presents a discrete-time model for a single-queue single-server system (c.f. Fig. 4) with known service-time distribution. *Dynamic* batch-size control was proposed in [29], but again this work considers packet I/O only. Perhaps the closest to Batchy is IX [6], which combines run-to-completion and batch-size optimization to obtain a highly-efficient OS network data-plane, and NBA [20], which observes the importance avoiding "the batch split problem" in the context of data flow graph scheduling. Batchy extends previous work by providing a unique combination of dynamic *internal batch de-fragmentation* (instead of applying batching only to packet I/O), analytic techniques for *controlling queue backlogs* (using a new abstraction, fractional buffers), and *selective SLO-enforcement* at the granularity of individual service chains (extending batching to bulk flows even in the presence of delay-sensitive traffic).

Data flow graph scheduling. Data flow graphs are universal in data-intensive applications, like multimedia [43], machine learning [10], and robot control [39]. However, most of the previous work on graph scheduling considers a different context: in [23,33] the task is to find an optimal starting time for the parallel execution of processing nodes given dependency chains encoded as a graph, while [13] considers the version of the scheduling problem where graph-encoded dependencies exist on the input jobs rather than on the processing nodes. Neither of these works takes batch-processing into account.

Service chains and delay-SLOs. With network function virtualization [26] and programmable software switches [24,38] becoming mainstream, scheduling in packet-processing systems has received much attention lately. Previous work considers various aspects of NF scheduling, like parallel [42] implementation on top of process schedulers [21], commodity data-centers [19,35], and run-to-completion frameworks in an isolated manner [36], or in hybrid CPU–GPU systems [15,20,48,49]. Recent work also considers SLOs: [45] uses CPU cache isolation to solve the noisy neighbor problem while [50] extends NFV to GPU-accelerated systems and observes the importance of controlling batch-size to enforce delay-SLOs. Apart from complementing these works, Batchy also contributes to recent effort on network function performance profiling (BOLT [17]), efficient worker/CPU resource allocation for enforcing delay-SLOs (Shenango [34]), and avoiding cross-CPU issues in NF-scheduling (Metron [19]).

7 Conclusions

In this paper we introduce Batchy, the first general-purpose data flow graph scheduler that makes batch-based processing a first class citizen in delay-sensitive data-intensive applications. Using a novel batch-processing profile and an analytic performance modeling framework, Batchy balances batch-processing efficiency and latency and delivers strict SLO-compliance at the millisecond scale even at multiple millions of packets per seconds of throughput. As such, Batchy could be used as a central component in 5G mobile cores (e.g., the MGW use case) and industry-automation (e.g., the robot-controller use case) applications and latency-optimized network function virtualization (e.g., the VRF use case). It may also find use outside the networking context, as the batch-scheduler in streaming, analytics, machine learning, or multimedia and signal processing applications. In these applications, however, the default run-to-completion execution model adopted in Batchy may not provide sufficient workload isolation guarantees; future work therefore involves implementing a WFQ controller based on the model (8)–(10) to incorporate Batchy into an explicit process-scheduling model.

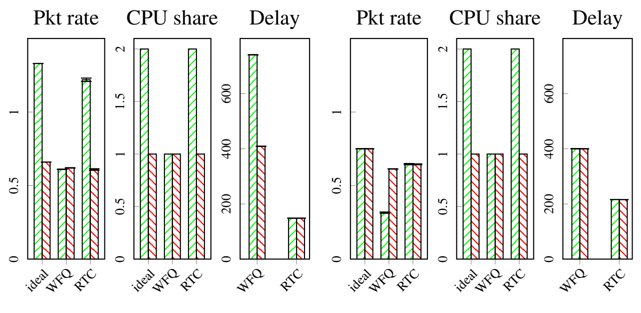
Appendix

A Data Flow Graph Scheduling

Scheduling in the context of data flow graphs means to decide which module to execute next. The goal of the scheduler is to provide efficiency and fairness: efficiency is ultimately determined by the amount of load the system can process from the ingress modules to the egress modules and fairness is generally measured by the extent to which the eventual resource allocation is *rate-proportional* [21]. Here, limited CPU resources need to be allocated between competing modules based on the combination of the offered load (or arrival rate) for the module and its processing cost. Intuitively, if either one of these metrics is fixed then the CPU allocation should be proportional to the other metric. Consider the example in Fig. 2; if the two modules have the same CPU cost but NF1 has twice the offered load than NF2, then we want it to have twice the CPU time allocated, and hence twice the output rate, relative to NF2. Alternatively, if the NFs have the same offered load but NF1 incurs twice the processing cost then we expect it to get twice as much CPU time, resulting in both modules having roughly the same output rate.

Explicit scheduling. In explicit scheduling there is a standalone mechanism that runs side-by-side with the pipeline and executes modules in the given order. A typical example is Weighted Fair Queueing (WFQ) or Completely Fair Scheduling (CFS), where the user assigns integer *weights* to



(a) Asymmetric rate (b) Asymmetric cost

Figure 11: Rate-proportional fairness in WFQ and run-to-completion scheduling in the *asymmetric rate* case (NF1 receives twice the offered load of NF2 and CPU costs are equal) and *asymmetric cost* case (same offered load but NF1 needs twice as much CPU time to process a packet as NF2). Packet rate is in mpps and delay is in μsec, and 🟩 denotes the first flow while 🟥 denotes the second flow as in Fig. 2.

Table 2: Static evaluation results with the null-controller, max-controller, NFVnice, Batchy/on-off and Batchy/full on different pipelines: number of modules, average batch-size over the pipeline, packet rate, and delay statistics in terms of the percentage of control periods when a delay-SLO violation was detected for at least one flow.

modules and the scheduler ensures that the runtime resource allocation will be proportional to modules' weight. WFQ does not provide rate-proportional fairness out of the box; e.g., in the example of Fig. 2 NF1 will *not* receive more CPU time neither when its offered load (asymmetric rate) or processing cost (asymmetric cost) is twice that of NF2 (see Fig. 11). Correspondingly, WFQ schedulers need substantial tweaking to approximate rate-proportional fairness, and need further optimization to avoid head-of-line blocking and late drops along a service chain [21]. Even running the scheduler itself may incur non-trivial runtime overhead. Worse still, packets may get dropped *inside* the pipeline when internal queues overflow; this may be a feature (e.g., when we want to apply rate-limitation or traffic policing via the scheduler) or a bug (when useful traffic gets lost at an under-provisioned queue).

Run-to-completion execution. This model eliminates the explicit scheduler and its runtime overhead all together. In run-to-completion execution the entire input batch is traced though the data flow graph in one shot, by upstream modules automatically scheduling downstream modules whenever there is work to be done [6, 14]. As Fig. 11 shows, this model introduces much smaller delay vs. explicit scheduling, as it needs no internal queues. In addition, run-to-completion provides rate-proportional fairness out-of-the-box, even without additional tweaking and without the risk of head-of-line blocking and internal packet drops. This yields an appealingly simple "schedulerless" design. On the other hand, since module execution order is automatically fixed by the pipeline and the scheduler cannot by itself drop packets, the share of CPU time a module gets is determined by the offered load only. This makes enforcing rate-type SLOs through a run-to-completion scheduler difficult. In our example, if NF2 receives twice the packet rate of NF1 then it will receive twice the CPU share, and hence the second flow will have twice the output rate, even though we may want this to be the other way around.

B Static Evaluations: Detailed Results

The detailed static performance results are given in Table 2. The table specifies the number of modules in each pipeline, the batch size statistics averaged across each module in time, the throughput as the cumulative packet rate summed over all flows, and the delay-SLO violation statistics as the percentage of control periods when we detected an SLO violation for at least one flow, for each of the 5G NF use cases, varying pipeline complexity using different settings for the parameters n and m.

C The Fractional Buffer

The below algorithm summarizes the execution model of a fractional buffer. Here, *queue* means the internal queue of the fractional buffer, b is the trigger, *q.pop(x)* dequeues x packets from the beginning of queue q, and $q.push(batch)$ appends the packets of $batch$ to the queue q.

```
procedure FRACTIONALBUFFER::PUSH($batch$)
    while $queue.size \leq b$ AND $batch.size > 0$ do
        $queue.push(batch.pop(1))$
    end while
    if $queue.size = b$ then
        $new\_batch \leftarrow queue.pop(b)$
        process $new\_batch$ through the network function
        put $v$'s downstream modules to the run queue
        $queue.push(batch.pop(batch.size))$
    end if
end procedure
```

D The Projected Gradient Controller

Below, we discuss the high-level ideas in the projected gradient controller implemented in Batchy and then we give the detailed pseudocode.

First, we compute the objective function gradient $\nabla l =$

$[\partial l/\partial b_v : v \in V]$, which measures the sensitivity of the total system load $l = \sum_{v \in V} l_v$ as of (11) to small changes in the trigger b_v for each module:

$$\frac{\partial l}{\partial b_v} = -\frac{\tilde{r}_v T_{0,v}}{b_v^2} = -\frac{\tilde{x}_v T_{0,v}}{b_v} \quad .$$

The delay-gradients $\nabla t_f = [\partial t_f/\partial b_v : f \in \mathcal{F}]$ are as follows:

$$\frac{\partial t_f}{\partial b_v} = \begin{cases} \frac{1}{\tilde{r}_v} + T_{1,v} & \text{if } v \in p_f \\ 0 & \text{otherwise} \end{cases}$$

Note that the delay t_f of a flow f is affected only by the modules along its path p_f, as long as the turnaround time is considered constant as of (3).

Second, project the objective gradient ∇l to the feasible (i.e., SLO-compliant) space. For this, identify the flows f that may be in violation of the delay-SLO: $\tilde{t}_f \geq (1-\delta)D_f$.

Third, let M be a matrix with row i set to ∇t_f if f is the i-th flow in delay violation and compute the projected gradient $\Delta b = -(I - M^T(MM^T)^{-1}M)\nabla l$. Note that if M is singular or the projected gradient becomes zero then small adjustments need to be made to the projection matrix [5].

Fourth, perform a line-search along the projected gradient Δb. If for some module v the corresponding projected gradient component Δb_v is strictly positive (it cannot be negative) then calculate the largest possible change in b_v that still satisfies the delay-SLO of *all* flows traversing v:

$$\lambda_v = \min_{f \in \mathcal{F}: v \in p_f} \frac{D_f - \tilde{t}_f}{\Delta b_v} \quad .$$

Finally, take $\lambda = \min_{v \in V} \lambda_v$ and adjust the trigger of each module v to $b_v + \lceil \Delta b_v \lambda \rceil$. Rounding the trigger up to the nearest integer yields a more aggressive control.

The below pseudo-code describes the projected gradient controller in detail. Vectors and matrices are typeset in bold in order to simplify the distinction from scalars. We generally substitute matrix inverses with the Moore-Penrose inverse in order to take care of the cases when **M** is singular.

```
procedure ProjectedGradient($\mathcal{G}, \mathcal{F}, D, f$)
    M is a matrix with row $i$ set to $\nabla t_f = \left[\frac{\partial t_f}{\partial b_v} : f \in \mathcal{F}\right]$, where $f$
is the $i$-th flow in $\mathcal{F}$ with $\tilde{t}_f \geq (1-\delta)D_f$
    ▷ Gradient projection
    while True do
        $\mathbf{P} = \mathbf{I} - \mathbf{M}^T(\mathbf{M}\mathbf{M}^T)^{-1}\mathbf{M}$
        $\Delta\mathbf{b} = \mathbf{P}\nabla\mathbf{l}$
        if $\Delta\mathbf{b} \neq 0$ then break
        $\mathbf{w} = -(\mathbf{M}\mathbf{M}^T)^{-1}\mathbf{M}\nabla\mathbf{l}$
        if $\mathbf{w} \geq 0$ then return          ▷ Optimal KKT point reached
        delete row for $f$ from M for some $f \in \mathcal{F} : w_f < 0$
    end while
    ▷ Line search
    for $v \in V, f \in p_v$ do
        if $\Delta b_v > 0$ then
            $\lambda_v = \min_{f \in \mathcal{F}: v \in p_f} \left\lceil \frac{D_f - \tilde{t}_f}{\Delta b_v} \right\rceil$
        end if
    end for
    $\lambda = \min_{v \in V} \lambda_v$
    for $v \in V$ do SetTrigger($v$, $b_v + \Delta b_v \lambda$)
end procedure
```

E The Feasibility-recovery Algorithm

The projected gradient controller cannot by itself recover from situations when a fractional buffer at some module is triggered at a too small rate to deliver the required delay-SLO to each flow traversing the module. The below pseudo-code describes the feasibility recovery process implemented in Batchy, which is implemented to handle such situations.

```
procedure FeasibilityRecovery($\mathcal{G}, \mathcal{F}, D, f$)
    for $f \in \mathcal{F}$ do $t_f \leftarrow \tilde{t}_f$
    ▷ Recover from SLO violation
    for $v \in V : b_v \geq \tilde{b}_v^{in}$ do
        if $\exists f \in \mathcal{F} : v \in p_f$ AND $t_f \geq (1-\varepsilon)D_f$ then
            $\Delta b_v = \max_{f \in \mathcal{F}: v \in p_f \wedge t_f \geq (1-\varepsilon)D_f} \left\lceil \frac{D_f - t_f}{\partial t_f/\partial b_v} \right\rceil$
            if $\Delta b_v > b_v - \tilde{b}_v^{in}$ then $\Delta b_v \leftarrow b_v - \tilde{b}_v^{in}$
            for $f \in \mathcal{F} : v \in p_f$ do $t_f \leftarrow t_f - \frac{\partial t_f}{\partial b_v}\Delta b_v$
            $b_v \leftarrow b_v - \Delta b_v$
        end if
    end for
    ▷ Injecting a buffer
    for $v \in V : b_v = 0$ do
        if $\forall f \in \mathcal{F} : v \in p_f$ it holds that $t_f < (1-\varepsilon)D_f$ then
            $\Delta b_v = \min_{f \in \mathcal{F}: v \in p_f \wedge t_f < (1-\varepsilon)D_f} \left\lceil \frac{t_f - D_f}{\partial t_f/\partial b_v} \right\rceil$
            if $\Delta b_v > \tilde{b}_v^{in}$ then $\Delta b_v \leftarrow \tilde{b}_v^{in}$
            for $f \in \mathcal{F} : v \in p_f$ do $t_f \leftarrow t_f + \frac{\partial t_f}{\partial b_v}\Delta b_v$
            $b_v \leftarrow \Delta b_v$
        end if
    end for
    for $v \in V$ do SetTrigger($v$, $b_v$)
end procedure
```

F The Data Flow Graph Decomposition Algorithm

Pipeline decomposition is initiated in Batchy whenever an inherent delay-SLO violation is detected. This occurs when a worker is overprovisioned and the turnaround time grows beyond the SLO for a delay-sensitive flow; in such cases Batchy migrates delay-insensitive traffic to new workers to address SLO violations. The below pseudo-code describes the pipeline decomposition procedure implemented in Batchy.

```
procedure DecomposePipeline($\mathcal{G}, \mathcal{F}, D, f$)
    $V_t \leftarrow \emptyset$
    $F_t \leftarrow \emptyset$
    $\tau_t \leftarrow \emptyset$
    for $f \in (F$ in ascending order of $D_f)$ do
```

```
        if CHECK_DELAY_SLO($V_t, F_t, \tau_t, f$) then
            $F_t \leftarrow F_t \cup f$
            $V_t \leftarrow V_t \cup p_f$
            $\tau_t \leftarrow \tau_t + \sum_{v \in P_f, v \notin V_t} (T_{0v} + T_{1v} B)$
        else
            $M \leftarrow \emptyset$
            MIGRATEFLOWS($V_t, F_t, M, \mathcal{F}$)
        end if
    end for
end procedure
procedure MIGRATEFLOWS($V_t, F_t, M, \mathcal{F}$)
    for $g \in (\mathcal{F} \setminus F_t)$ do
        for $v \in p_g$ do
            if $v \notin V_t$ and $v \notin M$ then
                create new worker
                add a queue before $v$
                attach queue to new worker
                $M \leftarrow M \cup v$
            end if
        end for
    end for
end procedure
procedure CHECKDELAYSLO($V_t, F_t, \tau_t, f$)
    for $g \in (F_t \cup f)$ do
        if $(\tau_t + \sum_{v \in P_f, v \notin V_t} (T_{0v} + T_{1v} B) + \sum_{v \in P_g} (T_{0v} + T_{1v})) > D_g$
then
            return False
        end if
        return True
    end for
end procedure
```

Adapting TCP for Reconfigurable Datacenter Networks

Abstract

Reconfigurable datacenter networks (RDCNs) augment traditional packet switches with high-bandwidth reconfigurable circuits. In these networks, high-bandwidth circuits are assigned to particular source-destination rack pairs based on a schedule. To make efficient use of RDCNs, active TCP flows between such pairs must quickly ramp up their sending rates when high-bandwidth circuits are made available. Past studies have shown that TCP performs well on RDCNs with millisecond-scale reconfiguration delays, during which time the circuit network is offline. However, modern RDCNs can reconfigure in as little as 20 μs, and maintain a particular configuration for fewer than 10 RTTs. We show that existing TCP variants cannot ramp up quickly enough to work well on these modern RDCNs. We identify two methods to address this issue: First, an in-network solution that dynamically resizes top-of-rack switch virtual output queues to prebuffer packets; Second, an endpoint-based solution that increases the congestion window, `cwnd`, based on explicit circuit state feedback sent via the `ECN-echo` bit. To evaluate these techniques, we build an open-source RDCN emulator, Etalon, and show that a combination of dynamic queue resizing and explicit circuit state feedback increases circuit utilization by 1.91× with an only 1.20× increase in tail latency.

1 Introduction

Modern datacenter applications need high-bandwidth, high–port-count, low-latency, low-cost networks to connect their hosts. Unfortunately, traditional packet switches are hitting CMOS manufacturing limits and are unable to simultaneously provide both high bandwidth and large numbers of ports [43]. Thus, researchers have proposed augmenting datacenter networks with reconfigurable circuit switches (e.g., optical or wireless) that provide high bandwidth between racks *on demand* [6, 16, 20, 25, 26, 32, 38, 42, 47, 51, 57].

However, it can be challenging for endpoints to extract the full potential of *reconfigurable datacenter networks* (*RDCNs*) that combine both circuit and packet networks. Circuit switches incur non-trivial reconfiguration delays while they adjust the high-bandwidth topology, and portions of the circuit network may be unavailable during these periods. Hence, such hybrid designs often result in fluctuations between periods of high bandwidth—when a circuit is provisioned—and low bandwidth—when the packet network is in use. While periods of higher bandwidth are attractive in principle, recent proposals suggest adjusting the topology frequently. The resulting bandwidth fluctuations pose a problem for end-host applications: their active TCP connections must rapidly increase transmission rates to use the available bandwidth and then slow down again to avoid massive queuing. In this paper, we explore these adverse interactions between TCP and RDCNs, and techniques to mitigate their performance impacts.

To amortize the cost of reconfiguration, circuits must be provisioned for a long period of time relative to the reconfiguration delay of the switch. TCP interactions with RDCNs were initially explored in the context of switches with *millisecond*-scale reconfiguration delays [16, 51]. Given the sub-millisecond propagation delays found in modern datacenters, circuits in millisecond-scale reconfiguration networks are enabled for many, many round-trip times (RTTs). These early studies found that TCP was able to adapt to the link speed changes over these time periods. However, modern reconfigurable switches that can change link state on the scale of *microseconds* [20, 38, 47] have redefined these problems. At first glance, these lower reconfiguration delays result in lower overheads and allow more rapid provisioning of bandwidth to where it is needed. However, when circuit uptimes are only a few (e.g., <10) RTTs long, TCP's ramp-up is too slow to utilize the large (e.g., 10×), temporary bandwidth increase before the circuit disappears, leading to low circuit utilization (Section 3). This raises the question of whether an RDCN can employ the rapid reconfigurations needed to meet changing traffic demands while also providing good performance.

The performance issues arise from a broken assumption made by end-hosts about the network: congestion control algorithms generally assume that bandwidth does not fluctuate at short timescales. We explore the consequences of this broken assumption for TCP, and identify two methods, at different levels in the network stack, for ramping up TCP in the environment of rapid bandwidth fluctuation.

First, we build on the insight that in RDCNs, bandwidth fluctuation is not arbitrary; it is part of a known schedule. Therefore, we can proactively modify the network to transparently influence end-host behavior. In this case, we entice TCP to ramp up earlier by eliminating packet drops due to full top-of-rack (ToR) switch virtual output queues (VOQs), thereby triggering end-hosts to increase their sending rates. We accomplish this by dynamically increasing the size of ToR VOQs in advance of provisioning a circuit (Section 5.2). Dynamic VOQ resizing does not require modifying end-hosts and, thus, works with existing TCP implementations.

Our second technique involves minor modifications to the end-host TCP stack to enable further performance improvements. At sending end-hosts, we increase the congestion window, `cwnd`, based on explicit circuit state feedback sent by the reconfigurable switch (Section 5.3). For some rack pair (S, D), we configure our emulated switch to set the `ECN-echo` (ECE) bit in the TCP headers of ACKs sent by D if there is currently a circuit enabled from S to D . The sender monitors the ECE stream, explicitly expanding and contracting `cwnd` when circuits begin and end, respectively.

To evaluate our solutions, we design and implement an open-source RDCN emulator, *Etalon*[1], for use on public testbeds (Section 4). Experiments on 3-rack (48-host) and 8-rack (128-host) emulated testbeds show that dynamic buffer resizing and explicit circuit state feedback increase circuit utilization by 1.91× while increasing 99th percentile tail latency by 1.20× (Sections 6.1 and 6.3).

Ultimately, datacenters must adapt to reap the benefits of RDCNs. In-network changes yield impressive improvements, and if modifying end-hosts is an option, then even higher performance is feasible. We make three contributions:

1. We characterize the critical challenge of rapid bandwidth fluctuation in RDCNs. We use a combination of experimental results and simulations to identify the range of reconfiguration delays that impact TCP performance, and show that a wide range of TCP congestion control algorithms suffer from poor performance in these settings.
2. We propose two solutions, at different layers of the network stack, to ramp up TCP under rapid bandwidth fluctuation: dynamic buffer resizing and explicit circuit state feedback. Our evaluation of these techniques shows the benefits that modifying higher network layers can have for RDCNs.
3. We design and implement an emulation platform, Etalon, for evaluating hybrid networks end-to-end with real applications, and use it to demonstrate the efficacy of our proposed techniques. Etalon is open source [15].

[1]Named after an optical filter used for solar observation.

2 Background

To better understand the challenges and solutions presented in this paper, we first examine RDCNs in detail in Figure 1. While we use optical circuit switching [16, 38, 47, 51] as an illustrative example for the rest of the paper, the results generalize to other reconfigurable technologies, such as free-space optics [20, 26] and 60-GHz wireless [25, 32, 57]). We eschew older millisecond-scale reconfigurable switches [16, 51] for modern microsecond-scale switches [20, 38, 42, 47], as the nature of the challenges and solutions differ with timescale.

2.1 Hybrid Network Model

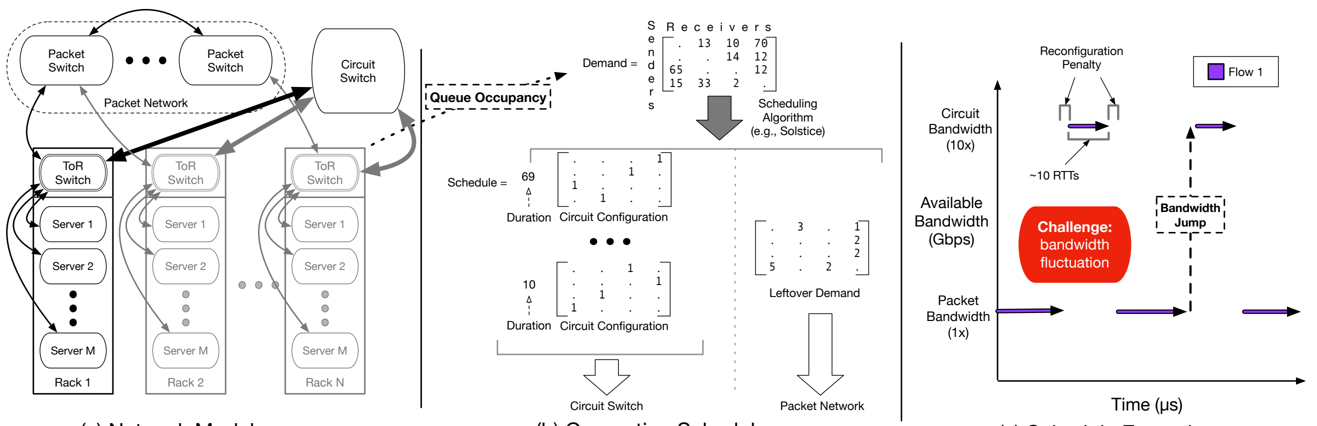
We consider an RDCN of N racks of M servers, with each rack containing a ToR switch (Figure 1(a)). ToRs connect racks to an arbitrarily-complex packet network (one or more switches) and a circuit network composed of a single, central circuit switch. The packet network is low bandwidth (e.g., 10 Gb/s), but can make forwarding decisions for individual packets. The circuit network is high bandwidth (e.g., 80-100 Gb/s), but makes forwarding decisions for many packets on much longer timescales to amortize its reconfiguration penalty.

Reconfiguration time is an inherent trade-off in circuit-switched networks. Instead of providing continuous connectivity between all endpoints, like in a packet network, a circuit network establishes exclusive, but temporary, connections between *pairs* of endpoints. Here, the endpoints are the ToRs. To expand this design to provide full connectivity, the network periodically changes which pairs of endpoints are spanned by a circuit. The physical limits of the specific underlying technology determine how long this reconfiguration takes.

Following prior work [38, 39, 47], we make the pessimistic assumption that, during circuit reconfiguration, no circuit links can be used. This allows us to apply our results to a broader set of technologies. The packet network, on the other hand, can be used at all times. Both switches source packets from $N \times N$ virtual output queues (VOQs) on the ToRs. The circuit switch itself is queue-less: It functions as a crossbar, only allowing configurations that form perfect matchings [2, 16, 38, 39, 47, 51]. I.e., a given sender is connected to exactly one receiver, and vice-versa. Thus, at any point in time, the circuit switch can drain at most one VOQ on each ToR, whereas the packet switch may drain multiple VOQs on each ToR simultaneously.

2.2 Computing Circuit Schedules

The circuit scheduler is tasked with estimating demand on the network and then computing a set of configurations that best satisfies this demand (Figure 1(b)). During reconfiguration, the circuit network is unavailable. Therefore, the circuit scheduler must balance the competing objectives of (1) servicing demand from many different rack pairs by reconfiguring



(a) Network Model (b) Computing Schedules (c) Schedule Execution

Figure 1: Overview of RDCNs.

frequently and (2) achieving high circuit uptime by allowing a configuration to persist for a (relatively) long time. To achieve a high relative uptime of 90%, schedules typically hold a particular circuit state for 9× the duration of a reconfiguration.

Network scheduling in most RDCNs entails mapping rack-level demand to a set of circuit configurations (port-matchings) with corresponding time duration[2]. Any "leftover" demand is handled by the lower-bandwidth packet switch. Borrowing terminology from prior work [47], we refer to a single circuit uptime as a *day* and the reconfiguration period, during which the circuit switch is offline, as a *night*. Night length is determined by switch technology and is generally 10-30 μs [20,38,39,47]. To allow for at least 90% link uptime, the average day length must be ≥9× greater than the night length, or ~90-270 μs. A series of one or more day/night pairs that implement a set schedule is a *week*. Weeks should be sufficiently long (e.g., 2 ms) to amortize schedule computation.

Scheduling is a three-step loop: 1) Demand for the next week is estimated (e.g., through ToR VOQ occupancy); 2) An algorithm computes the schedule for the next week; 3) The schedule is disseminated to the switch. Scheduling algorithms for RDCNs (e.g., Solstice [39] and Eclipse [2]) use skew and sparsity in demand to minimize the number of configurations. Prior work on circuit scheduling informs, but is orthogonal to, our investigation into the resulting bandwidth fluctuations.

2.3 Schedule Execution

Once a schedule is disseminated to the circuit switch, it runs the circuit configurations for their respective duration (Figure 1(c)). After reconfiguration, a flow may transition from using the packet network to using the circuit network and vice versa. Because of the short day length, flows likely spend only a few (e.g., <10) RTTs on the circuit network each day. Therefore, transport protocols must cope with large (e.g., 10×) bandwidth variations based on which network a flow traverses.

[2]A major exception being RotorNet [42], which uses a predetermined schedule. It still suffers from the same bandwidth fluctuations.

Prior work has avoided the bandwidth fluctuation problem by segregating traffic into mice and elephant flows and routing them exclusively over the packet and circuit networks, respectively [16,38]. Each flow encounters one bandwidth regime, albeit the elephant flows must pause during circuit downtime. However, recent work has proven that such segregation is sub-optimal [19]. We adopt a non-segregated approach, treating the hybrid network as indivisible and routing all traffic over available circuit links, thus trading off reduced network complexity for bandwidth fluctuation.

3 TCP in RDCNs: Trends and Challenges

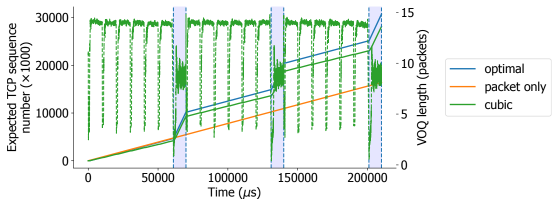
This section investigates how TCP's interactions with RDCNs are evolving with the underlying hardware trends.

3.1 Evolving Reconfiguration Delays

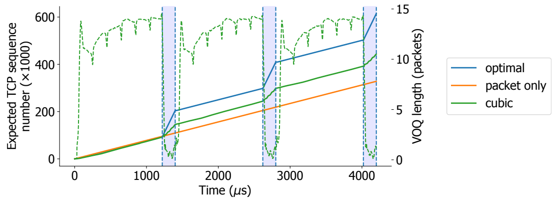
Circuit networks are characterized by their inherently high bandwidth. However, that comes at the cost of flexibility. With the exception of pathological examples, switching flexibility enables the circuit network to better serve diverse workloads. Improving flexibility by reducing the reconfiguration time has been an ongoing challenge for hardware designers, with the hope that circuit technologies will eventually be capable of approximating packet switching.

A decade ago, the best MEMS (Micro-Electro-Mechanical Systems) optical switches, which reconfigure by physically rotating laser-directing mirrors, changed paths on the order of a few milliseconds. If we generously assume that such a switch can reconfigure in 1 ms, our 90% uptime target implies that each configuration will persist for 9 ms. On network timescales, this is an eternity: Assuming a conservative RTT of 60 μs, 9 ms is 150 RTTs.

To understand how TCP behaves on RDCNs, we use an emulator, described in Section 4, and analyze the expected TCP sequence number of flows over time. We run an 8-rack schedule with 1 ms nights and 9 ms days, using the CUBIC [24]



(a) A decade ago: 1-ms reconfiguration delays and 9-ms circuit uptimes give TCP time to saturate the link.



(b) Today: TCP struggles to fill the link for circuits with short 20 μs reconfiguration delays and 180 μs uptimes.

Figure 2: TCP CUBIC performance, then and now. Circuit days are shaded in blue. Dotted lines are the corresponding VOQ length.

variant of TCP. 16 emulated hosts on rack 1 each send a flow to a counterpart host on rack 2. In this experiment, we consider a circuit switch that delivers 8× higher bandwidth than the packet network. The ToR VOQ capacity is 16 packets. The expected sequence number is measured as packets leave the hybrid switch, as described in Section 4.2, and then averaged across experimental runs.

Figure 2a shows the results of this experiment. Circuit uptimes are delineated by the blue vertical shaded regions. Since the sequence number represents the number of bytes transferred, the slope of a line corresponds directly to a flow's achieved bandwidth. We always compare to two baselines: (1) *optimal*, which is calculated based on the line rate of the packet and circuit links (taking into account that the network is offline during reconfigurations), and (2) *packet only*, which is calculated assuming that flows always use the packet network only (and that the packet network is always available). Intuitively, circuit utilization is how well the slope of a line matches that of *optimal* during the blue shaded regions. Experimental results can never exceed *optimal*, and any improvement over *packet only* illustrates the benefit of the hybrid network over a purely packet network. Throughout our analysis, we use the length of the ToR VOQs, described further in Section 4.2, to understand TCP's behavior. For a particular line on a sequence number graph, the dotted line in the same color reports the corresponding average VOQ length.

We can see that TCP roughly keeps up with the optimal throughput of the hybrid network, saturating the link. During the circuit days, which are shaded in blue, the VOQs contain approximately 8 packets. Since the VOQs never empty except for a brief moment when the days begin, there are always

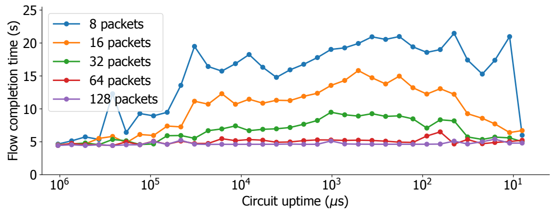


Figure 3: Simulated flow completion time for transferring 25 GB of data using 10 flows, for various buffer sizes.

packets to send over the network, resulting in high utilization.

Let us consider how hybrid networks have evolved over the past decade. Figure 2b shows the same results for a modern schedule with 20 μs nights and 180 μs days. The ratio of circuit uptime is the same, 90%, but TCP performs differently. Because the number of RTTs in a day has decreased from ~150 to ~3, TCP does not ramp up before the circuit ends. For TCP CUBIC, 3 RTTs is simply not enough time to increase the congestion window (`cwnd`) [24]. Moreover, packet drops during the subsequent reconfiguration period and the transition to the packet network cut TCP's sending rate. While TCP does recover while using the packet network, the process repeats at the next cycle, with TCP unable to ramp up to use the circuit network's full bandwidth regardless of how many periods elapse. We can also see this manifested in the VOQ length: When a day begins, the VOQs drain immediately to fill the larger bandwidth-delay product (BDP) of the circuit network, but there are insufficient outstanding packets to do so completely and insufficient time for TCP to ramp up, so the VOQs stay empty throughout the day.

To extend these results to a wider range of circuit uptimes, we ran a simulation that transfers 25 GB of data from one rack to another using 10 TCP CUBIC flows[3]. Figure 3 shows the resulting flow completion times (FCTs) for five orders of magnitude of circuit uptimes, where each line corresponds to a different amount of queuing at the ToR switch. In all cases, the RTT is 60 μs. The takeaways here are twofold: First, considering the smaller queue sizes (8-32 packets), the FCTs are low for short (e.g., 10 μs) and long (e.g., 10 ms) days, yet degrade by $2-4\times$ for moderate values (e.g., 1 ms). For short circuits, the network is effectively approximating packet switching, whereas for long circuits, the uptime is sufficient that fluctuating bandwidth is not an issue. Unfortunately, today's RDCNs fall in the middle region. Techniques to adapt TCP for RDCNs, like those presented in this paper, are necessary as long as circuit reconfiguration and propagation delays place us in a regime similar to this. We predict that the order-of-magnitude improvement in underlying circuit technology that is required to reach the "short circuits" region, where the network approximates packet switching and TCP ramp-up is no longer a problem, is still many years away.

[3]The simulator uses 1500B packets while the Etalon emulator uses 9000B packets. For the experiment in Figure 3, we scale the buffer size by 6× for easier comparison. I.e., for "8 packets", the buffer was $8 \times 6 = 48$ packets.

We find inspiration, however, from a second takeaway: With larger queue sizes (e.g., 64 and 128 packets), the flows complete quickly regardless of the circuit uptime. This indicates that large buffers build up enough excess in-flight data to burst packets quickly when more bandwidth becomes available. We discuss this further in Section 5.1, and this realization become the basis for the dynamic buffer resizing technique that we propose in Section 5.2.

3.2 Categorizing TCP Variants

Before diving into our technical solutions, it is important to remember that TCP comes in many shapes and sizes. The experiments above use TCP CUBIC, a common loss-based variant, but there are dozens of other variants designed for a plethora of network contexts, from low latency to high bandwidth to frequent loss, and more. This section gives an overview of the broad classes of TCP variants and demonstrates that no existing variant works well for hybrid networks.

At the highest level, the goal of TCP congestion control is to maximize the sending rate while fairly sharing the available bandwidth between flows and avoiding overloading the network. Determining the sending rate involves looking at signals from the network to infer its current state. The efficacy of a congestion control algorithm depends on how well it gleans information from such signals. Below, we discuss the three main categories of signals that TCP variants use to detect congestion (packet loss, network delay, and explicit network feedback), and discuss how they are effected by RDCNs.

3.2.1 Loss-based Congestion Control

Packet loss is the most commonly used congestion signal. The intuition here is that when the sender determines that packets are being lost, it assumes that the losses are a result of network congestion. Examples include TCP CUBIC [24], Reno [31], BIC [54], Illinois [40], and Highspeed [18]. In the absence of loss, these protocols increase their transmission rates to probe for available bandwidth, until a loss occurs. Different protocols choose different approaches for this probing, but all of them limit the aggressiveness of their probing to coexist reasonably with other TCP variants. This results in poor performance in RDCNs since these protocols cannot ramp up quickly enough to make use of the high-bandwidth circuits.

3.2.2 Delay-based Congestion Control

Another technique is to use measurements of the packet RTT in the congestion control protocol. Such protocols use RTT increases as an indicator of queue buildup in the network, and therefore congestion. Examples include BBR [5], TCP Vegas [4], and TIMELY [45]. Vegas and BBR are both rate-based protocols that use the difference between the offered load and the achieved throughput to detect queue buildup. TIMELY uses high-fidelity NIC timers to measure the RTT and then paces transmission based on delay gradients.

Like other TCP variants, delay-based variants are typically conservative in their probing for available bandwidth to ensure fair coexistence. An additional interaction with RDCNs is that, due to topology differences, the circuit and packet networks typically have different propagation delays (as discussed in Section 4.4: 30 μs vs. 10 μs, respectively). This poses a challenge for TCP variants that use changes in RTT as an indication of queuing.

3.2.3 Explicit Feedback–based Congestion Control

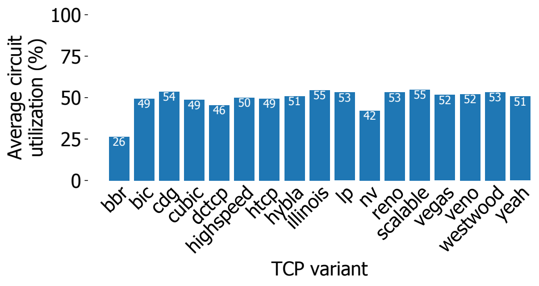
Finally, some TCP variants rely on explicit feedback from the network to detect congestion. Two manifestations of this are XCP [33] and DCTCP [1]. DCTCP responds to switch signals sent when a switch is likely to drop packets soon. If the act of a switch accepting a packet would increase its internal buffer length beyond a threshold (which is set to be lower than the total capacity of the queue), then the switch accepts the packet but sets the ECN flag in its TCP header. This flag is then communicated back to the sender via the packet's ACK. The sender monitors this stream of ECN marks to estimate when the network is close to being congested.

For domains where a single entity controls the senders and the network, coordination in this manner is a direct technique for improving performance. In Section 5.3, we propose a similar technique for adapting to bandwidth fluctuations in RDCNs that uses the ECE bit in ACKs to notify a sender when one of its flows transitions between the packet network and a high-bandwidth circuit.

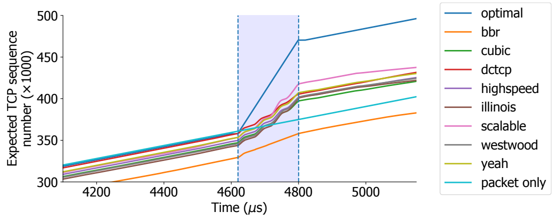
3.2.4 A Common Underlying Issue

We repeat the experiment in Section 3.1 with the 17 TCP variants pre-installed on Ubuntu 18.04. Figure 4a shows the average circuit utilization, which does not exceed 55%. Figure 4b visualizes the expected TCP sequence number over time for a selection of 8 of the 17 variants. Most perform slightly better than CUBIC, with BBR and NV falling behind, but no variant is aggressive enough to overcome the limitation that 3 RTTs is insufficient time to ramp up.

These results demonstrate that the challenge of TCP not ramping up quickly enough is not isolated to CUBIC, and cannot be solved by simply choosing a more appropriate TCP variant. Instead, we need a technique that more-directly interacts with the basic properties of TCP. Furthermore, the fact that all of the (sometimes quite) different TCP variants perform similarly (i.e., with surprisingly little variation, given their technical differences) suggests that they are all hampered in a similar way. If we address this common issue, then we have the potential to improve circuit utilization across the board, for all of these TCP variants.



(a) Circuit utilization vs. TCP variant.



(b) Expected TCP seq. num. vs. time, for many TCP variants. Circuit days are shared in blue.

Figure 4: With 20 μs reconfiguration delays and 180 μs circuit days, no TCP variant performs well.

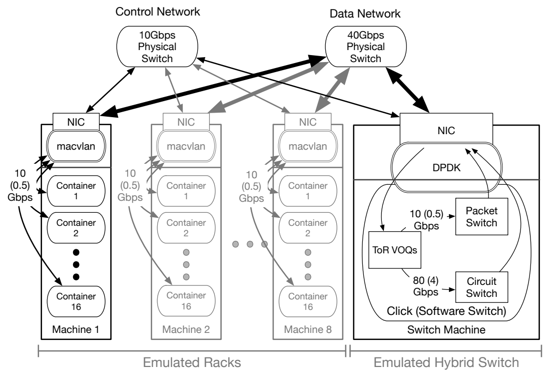


Figure 5: Etalon emulating 8 racks of 16 servers.

4 The Etalon Emulator

One of the key challenges in understanding TCP performance on RDCNs is performing repeatable experiments at scales appropriate for modern distributed cloud applications (i.e., across dozens or hundreds of hosts). In this section, we present our open-source emulator, Etalon [15], which measures the end-to-end performance of *real applications and end-host stacks* on emulated RDCNs in public testbeds.

4.1 Overview

Figure 5 presents an overview of Etalon. Each of the N physical machines emulates a rack of M servers using Docker containers [11, 44]. Containers are connected to the physical NIC using macvlan [12], which virtualizes a physical NIC into multiple virtual NICs, connecting them with a lightweight layer-2 software switch. `tc` [49] controls link bandwidths between the containers and the virtual switch, emulating a host-to-ToR link.

A separate physical machine emulates the reconfigurable datacenter network, as described in Section 4.2. Therefore, a cluster of $N+1$ physical machines can emulate $N \times M$ virtual hosts. For convenience, each physical host is connected to separate control and data networks, but this is not necessary. The experiment harness communicates with the testbed using RPyC [48]. Section 4.3 explains how time dilation enables Etalon to emulate many hosts with high-bandwidth links on a small testbed.

4.2 Click Software Switch

The $(N+1)^{\text{st}}$ machine emulates the RDCN itself, namely the ToR VOQs and the hybrid switch. This host runs a Click [34] software switch that uses DPDK [13] to process packets at line rate. We choose to emulate ToR VOQs in the software switch to make circuit and packet link emulation straightforward.

Figure 6 shows the software switch's internals. Packets enter the switch via DPDK [13] and are sent to an emulated ToR VOQ based on their *(source rack, destination rack)* pair. To achieve line rate, Etalon uses the Click elements `FromDPDKDevice` [7] and `ToDPDKDevice` [8] to exchange packets with the NIC. Packets are pulled from each VOQ by either the packet switch or the circuit switch. In Figure 6, packet uplink i is connected to the N VOQs in ToR i, pulling packets from these VOQs in a *round-robin fashion*. A packet pulled by a packet uplink enters the packet switch, where it is multiplexed over a packet downlink and transmitted using DPDK. If a packet would be dropped in the packet switch, it is held at the ToR VOQ (similar to PFC [28]). Circuit link i is connected to the ith VOQ of each of the N ToRs via a *pull switch*. A settable "input" value on pull switch i connects circuit link i to exactly one VOQ at a time. After packets traverse the circuit link, they are transmitted using DPDK. Before releasing a packet, the Click hybrid switch logs its IP and TCP headers, the current circuit state, and timing information. These logs are used offline to analyze the expected sequence number over time. The experiment harness communicates with the software switch using Click's control socket.

Our software switch contains three control elements (shown in gray in Figure 6): a demand estimator, a scheduler, and a schedule executor. The demand estimator estimates rack-to-rack demand using ToR VOQ occupancy. The scheduler computes a schedule from this demand, which is then run by the schedule executor by modifying the circuit link pull switches' "input" value (as described above). Our scheduler element is pluggable: We implement Solstice [39] as an example, but modify its objective to schedule maximal demand within a set window W (like Eclipse [2]), rather than scheduling all demand in unbounded time. We integrate Solstice, however, purely for implementation completeness. For our evaluation, a simple fixed strobe schedule, as described in

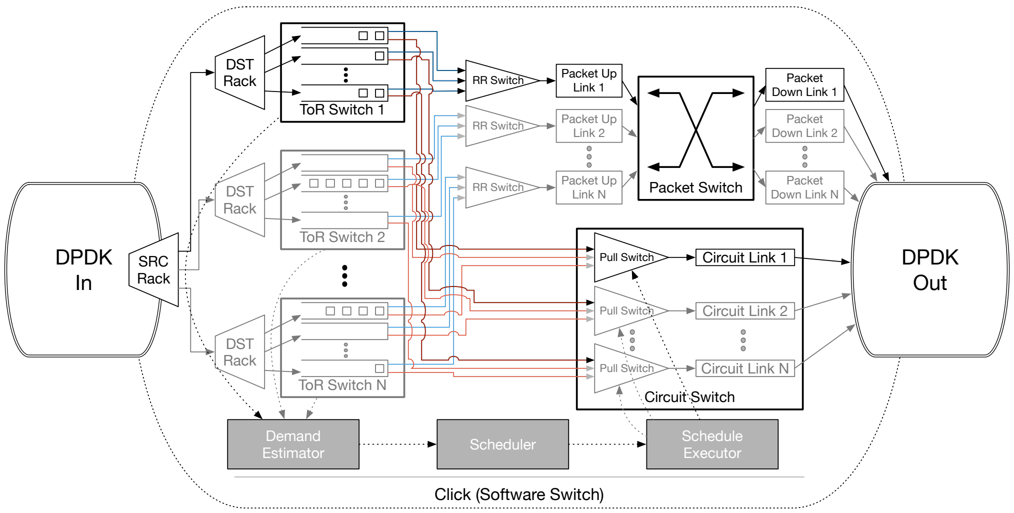

Figure 6: The Click software switch emulates the ToRs, the packet and circuit networks, and scheduling elements.

Section 4.5, is sufficiently illustrative.

4.3 Time Dilation

As the goal of Etalon is to emulate RDCNs on public testbeds, the machine emulating the hybrid network likely has only a single high-speed NIC. However, we wish to emulate a switch with N high-speed ports. We solve this problem with *time dilation (TD)*. Originally proposed for VMs [21, 22, 50] and recently containers [35, 55, 56], TD provides accurate emulation of higher-bandwidth links by "slowing down" the rest of the machine. We refer to the constant factor by which time is dilated as the *time dilation factor (TDF)*. We implement an open-source interposition library called LibVirtualTime (LibVT) [37], which applies TD to many common syscalls without requiring applications changes. We catch: `clock_gettime()`, `gettimeofday()`, `sleep()`, `usleep()`, `alarm()`, `select()`, `poll()`, and `setitimer()`. Extending LibVT to other syscalls is trivial. We verify that common network benchmarks (iperf [29], iperf3 [30], netperf [27], sockperf [41], flowgrind [58, 59], ping [46]) perform correctly with TD. We also limit CPU time for containers with respect to TD. Using time dilation to emulate high-speed links is one of Etalon's main advantages.

4.4 Etalon Testbeds

We use two testbeds for our experiments: a CloudLab cluster emulating 8 racks (128 hosts) and a local cluster emulating 3 racks (48 hosts). We use the large CloudLab cluster to validate the Etalon emulator, and run our experiments on the small local cluster. For the contributions in this paper, we do not require a large cluster or complex workload.

The local testbed uses four servers to emulate three racks of 16 machines plus the hybrid switch, as described in Section 4.2 and Figure 5. Each physical machine has 2 × 20-core 2.8 GHz Intel Xeon E5-2680v2 and is connected to a 40 Gb/s Ethernet data network (with jumbo frames). We also use Etalon on the public CloudLab APT cluster [9, 14], where nine R320 machines emulate eight racks of 16 hosts each and the hybrid switch. Each APT machine has an 8-core 2.1 GHz Intel Xeon E5-2450 and is connected to a 40 Gb/s Ethernet data network (with jumbo frames). At the time of our experiments, the CloudLab APT cluster was configured for 56 Gb/s InfiniBand, so we manually reconfigured the switches into 40 Gb/s Ethernet mode.

We use a TDF of 20× across our experiments. For example, in our 3-rack cluster, we emulate a 3-port 10 Gb/s (0.5 Gb/s)[4] packet switch and a 3-port 80 Gb/s (4 Gb/s) circuit switch. Outside of TD, the network can produce 3×0.5 Gb/s $+ 3 \times 4$ Gb/s = 13.5 Gb/s of total traffic, far below our data network's 40 Gb/s physical link speed. Each per-container link (i.e., each intra-rack link between the ToR and a host) is limited to 10 Gb/s (0.5 Gb/s).

Packet switch up/down links have 5 μs (100 μs with TDF) of delay each. Prior work assumes that the circuit network consists of ToRs connected to a pod-level central circuit switch, thus requiring long fibres (in the case of an optical network) [16]. To model this, we conservatively configure the circuit delay as 30 μs (600 μs), or 3× higher than the total packet link delay (5 $\mu s \times 2$ = 10 μs total). To avoid out-of-order packet delivery, if there is a circuit scheduled between racks S and D, then we disable the packet switch for rack pair (S, D) both during the reconfiguration leading up to a circuit and during the circuit period itself. Therefore, between S and D there exists exactly one connection: either packet or circuit. This is an example of non-segregated routing: Mice and elephant flows traverse the same links.

[4]Values in parenthesis represent bandwidth/delay outside of TD, i.e., actual bandwidth and delay values.

4.5 Schedule and Workload

This paper focuses specifically on congestion control mechanisms, and therefore we believe that a simple traffic pattern is sufficient. With a couple of exceptions, we use the following schedule and workload for all experiments. Extending this investigation to complex workloads is future work.

Schedule We use a strobe schedule that, for a cluster with R racks, creates a circuit from a rack to each other rack $\frac{1}{R-1}$ of the time[5]. Figure 7 shows how, for an 8-rack schedule, a rack connects to each other rack in turn, repeating after a week. Solstice [39] would produce this schedule for an all-to-all workload such as a MapReduce shuffle [10]. For our experiments, a 25-rack cluster (described next) with 20 μs nights and 180 μs days (90% uptime) yields a week of duration $(20\ \mu s + 180\ \mu s) \times (25-1) = 4800\ \mu s$. The time between circuit days is $4800 - 180 = 4620\ \mu s$.

Workload The 16 emulated hosts on rack 1 each use flowgrind [58, 59] to send a TCP flow to their counterpart host on rack 2. The other racks are idle. We choose a flow duration of 3000 weeks, or 14.4 seconds for a 25-rack strobe schedule with 4800 μs per week. Each set of three weeks is treated as one experimental run, and the 1000 runs are averaged when reporting expected sequence number and VOQ length.

To better illustrate our contributions, we take advantage of our simple workload, described above, to emulate a larger testbed. Since our workload involves only racks 1 and 2, from the perspective of either of those racks, the cluster size effects only the duration between circuits. Therefore, we mimic a larger cluster by artificially lengthening this duration. We use this technique to run a 25-rack strobe schedule on our 3-rack local testbed.

4.6 Validating Etalon

We validate Etalon on the 8-rack CloudLab cluster using a strobe schedule while sending TCP traffic between pairs of racks for 2 seconds. ACKs are diverted around the switch for this one experiment to avoid ACK loss. By bypassing the hybrid switch, ACKs are transported instantly across the core of the emulated network, enticing TCP to ramp up faster, thus nullifying the bandwidth fluctuation described in Section 3. This is, of course, an unrealistic technique for actual networks, but we employ it to validate the Etalon emulator. We present timing and bandwidth results in Table 1. These results demonstrate that the emulator is sufficiently accurate to achieve the desired circuit schedule times (night and day lengths) and packet and circuit bandwidths.

[5] A rack need not connect to itself, so there are $R-1$ days in a week.

	Expected	Experimental Mean	Std. Dev.
Circuit day	180μs	180.25μs	0.04μs
Week length	1400μs	1400.02μs	0.05μs
Packet utilization	10 Gbps	9.93 Gbps	0.75 Gbps
Circuit utilization	80 Gbps	79.99 Gbps	1.60 Gbps

Table 1: Validating Etalon's timing and throughput.

5 Overcoming Rapid Bandwidth Fluctuation

As discussed in Section 3, the short uptimes (e.g., < 3 RTTs) of modern reconfigurable datacenter networks create bandwidth fluctuations such that TCP is unable to fully utilize the available bandwidth. This section describes two distinct techniques, implemented at different network layers, that adapt TCP to this challenge: 1) dynamic VOQ resizing that transparently prebuffers packets at the ToR before a circuit activates, and 2) explicit circuit state feedback to end-hosts that directly triggers a `cwnd` increase. Before introducing our techniques, however, we first consider a simpler, static-buffer approach that illustrates the bandwidth and latency trade-off that our solutions must navigate.

Section 3.2 presented the general signals that TCP variants use to infer network congestion. Increasing switch buffer sizes masks packet loses caused by queue overflows. For loss-based TCP variants like CUBIC and New Reno, removing this congestion signal triggers ramp-up. However, this technique is not appropriate for delay-based variants such as TIMELY or Vegas. We demonstrate in Section 6.2 that for variants which rely at least partially on loss as a congestion signal, hiding congestion-based drops is effective at increasing circuit utilization. Our second technique, explicit circuit state feedback via the `ECE-echo` bit, is more general since it provides a direct signal to end-hosts, but of course has the trade-off that it requires modifying end-hosts.

5.1 Leveraging VOQs to Increase Bandwidth

It is well understood that switch buffer sizing presents a trade-off between high bandwidth and low latency [5, 17]. The more traffic that can be queued up in the network, the better it will be able to saturate links in the presence of transient demand—or, in our case, capacity variations—because packets will be available to burst immediately in the event of a capacity increase. However, when packets incur queuing latency, the effective round-trip time increases. Because latency (and tail latency in particular) impacts short flow—and potentially job—completion times, much work on datacenter transport protocols has focused on achieving high bandwidth while keeping queues short [1,5]. As a starting point toward mitigating the effects of bandwidth fluctuation in RDCNs, we experiment with various sizes of static ToR VOQs and demonstrate that loading the network with excess traffic does help saturate the high-bandwidth circuits, but, as expected, at the cost of high latency.

Using the schedule and workload described in Section 4.5, we configure the hosts to run TCP CUBIC, vary the size of the ToR VOQs from 4 to 128 packets, and examine the impact on circuit utilization. Figure 8a. shows utilization measured as the aggregate achieved bandwidth of all of a rack's flows versus the maximum bandwidth the flows should have been able to achieve, averaged over all of the circuit periods in an experiment. For small buffers, circuit utilization is low. Large buffers fare better, with 64 packets building up a sufficient "backlog" of packets to absorb the bandwidth fluctuations.

Figure 8b shows the expected TCP sequence number during the lead-up to a circuit day, for various queue sizes, as measured by the software switch (Section 4.2). The slope of each line is a flow's achieved bandwidth. The *optimal* and *packet only* baselines are computed as in Figure 2. Larger buffers yield a steady convergence to *optimal*. While TCP grows at a rate of one packet per RTT, regardless of buffer size, larger switch buffers allow flows to queue up a packet backlog which then drains during circuit uptime, as shown by the dotted VOQ lines. The VOQ length is level throughout the packet network period.

Finding the "proper" VOQ size for a hybrid switch is difficult. Common wisdom is to use the bandwidth-delay product (BDP) of the network, but the BDP is different for the packet network and the circuit network: ~2 and ~34 packets, respectively. A time-weighted average based on the schedule suggests ~8 packets may be appropriate. As shown in Figure 8a, however, none of these values provide full circuit utilization: 64+ packets are needed[6]. However, we cannot simply adopt queues this large because of their high latency. In a datacenter, where link lengths are short, queuing delay impacts tail latency, which in turn directly impacts distributed applications [1]. Figure 8c shows 99th percentile tail latency for the various ToR VOQ sizes, measured as each packet enters and leaves the software switch. As expected, the packet and circuit latencies both grow as we increase the buffer size.

We want the best of both worlds: Can we achieve full circuit utilization while simultaneously not incurring a latency penalty? No static buffer configuration achieves this. The following subsections describe two techniques to meet this goal: *dynamic* buffer resizing (Section 5.2) and explicit circuit state feedback to end-hosts (Section 5.3).

[6]Our later experiments show that ~45 packets may suffice.

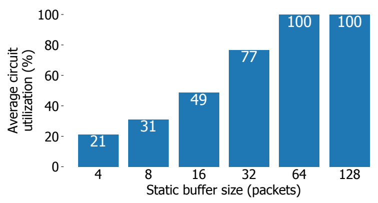
5.2 Dynamic Buffer Resizing

We propose dynamically resizing ToR VOQ capacity to remedy the effects of rapid bandwidth fluctuations on TCP. This is an entirely *in-network* solution, which, to our knowledge, has not been explored in the context of network scheduling. In this section, we focus specifically on loss-based variants of TCP, such as CUBIC.

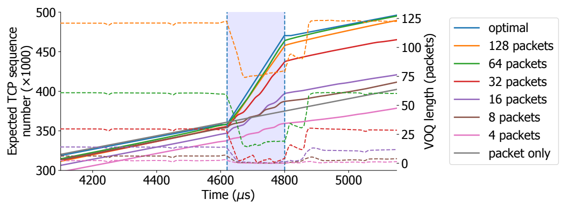
Our key insight is that bandwidth fluctuation within RDCNs is not arbitrary: It is part of a schedule and is known in advance. With this knowledge, we can align in-network buffer sizes with either the packet switch or the circuit switch in real time. By itself, a packet switch can effectively achieve full throughput with a very small buffer (e.g., 4 packets), whereas large buffers cause queuing delay, as shown in Figure 8c. The previous section demonstrated that a circuit switch needs larger buffers (e.g., 64+ packets) to achieve full utilization due to bandwidth fluctuations. With dynamic buffer resizing, we take a step in the right direction by keeping buffers shallow when the packet switch is in use and deep when a circuit is active. Doing this naïvely (i.e., resize buffers when the circuit comes up) provides little benefit; there is simply not enough time in one day for TCP to grow to fill the circuit link, regardless of how large the buffer. Data needs to be available *immediately* at circuit start (either buffered or via a high TCP sending rate); ramping up *ex post facto* means that circuit time has already been wasted.

Instead, we dynamically resize ToR VOQs for a *(source, destination)* rack pair *in advance* of a circuit starting for that pair. This implies that if the circuit schedule dictates that this rack pair should spend most of the time using the packet switch, then small buffers will be used to avoid incurring additional latency. Increasing a rack pair's VOQ size provides two benefits: 1) Packets build up in the queue and are then drained immediately when the circuit activates, creating a momentary burst of traffic, and 2) When the buffered packets drain at circuit start, they generate a surge of ACKs that increase the sender's congestion window (`cwnd`) and sending rate. Exactly how quickly `cwnd` grows depends on the TCP variant in use.

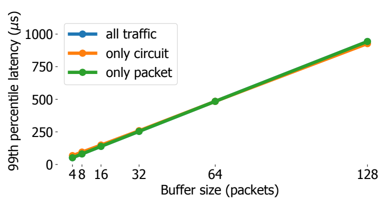
Our buffer resize function has three parameters: `resize`(s, b, τ), where s and b are the small and large buffer sizes in packets, respectively, and τ is how early a buffer should be resized in advance of the circuit start. For the rest of the paper, we use $s = 16$ and $b = 50$. τ is a trade-off: Resizing too late means low circuit utilization, but resizing too early increases latency. We vary τ in experiments in Section 6.1. While the value of τ impacts the circuit utilization/latency trade-off, we find that waiting to resize the buffer back to s after a circuit stops (and thus retaining large buffers for a short time while the packet network comes back into use) has no benefit. Thus, we always reset buffers back to s immediately after circuit teardown.



(a) Circuit utilization vs. static buffer size.



(b) Expected TCP sequence number vs. time, for various static buffer sizes. Circuit days are shaded in blue. Dotted lines are the corresponding VOQ length.



(c) 99th percentile tail latency vs. static buffer size.

Figure 8: Tradeoffs of various static VOQ sizes. Larger buffers improve utilization at the cost of latency.

5.3 Incorporating Explicit Network Feedback

Dynamically resizing ToR VOQs is a transparent, in-network technique that raises circuit utilization without harming latency and does not require end-host modifications. However, this approach is intended for loss-based congestion control schemes and does entail additional latency and buffering. In this section, we propose a direct form of circuit state feedback that applies to more TCP variants (e.g., delay and explicit-feedback–based schemes) and ultimately mitigates this latency penalty. Of course, the trade-off is that techniques involving explicit feedback require modifying the TCP congestion control algorithm running at the sender, making them non-transparent and more difficult to deploy.

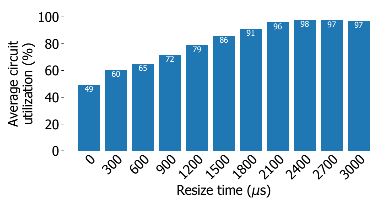
The idea behind explicit network feedback is simple: Notify the sender when a flow is traversing a circuit and should ramp up. However, the delay in this feedback reaching the sender is crucial. Since circuits are live for as few as 3 RTTs, a signal that requires 1 RTT to propagate to the sender (e.g., marking ECN bits of outgoing flows), provides limited benefit. We tighten the feedback loop by instead marking ACKs as they return to the sender. For some rack pair (S,D), we modify our software switch to set the `ECN-echo` (ECE) bit in the TCP headers of ACKs sent by D, if there is currently a circuit enabled from S to D. The hybrid switch examines the circuit state and marks ACKs *after* they traverse the circuit link, so the "freshness" of the feedback signal is equal to the propagation delay of a single packet link between the ToR and the sending end-host, S.

We create a pluggable TCP congestion control module for Linux called reTCP (REconfigurable datacenter network TCP) which looks at this stream of ECE bits, multiplicatively increasing its `cwnd` by $\alpha \geq 1$ on $0 \rightarrow 1$ transitions and decreasing it by $0 \leq \beta \leq 1$ on $1 \rightarrow 0$ transitions. reTCP is an edge detector: It modifies `cwnd` on ECE-bit state *transitions*, not for every packet. We set $\alpha = 2$ and $\beta = 0.5$, based on the results of a parameter sweep. Intuitively, this provides higher circuit utilization because TCP will immediately have a higher sending rate when a circuit starts.

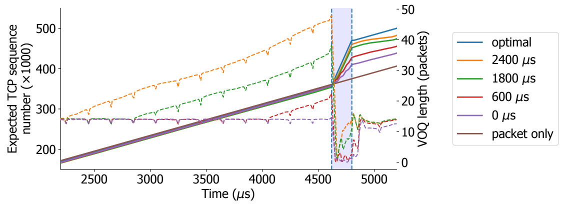
Our reTCP implementation is based on TCP New Reno [23] and relies on its congestion control algorithm, in addition to the above-mentioned technique. reTCP also requires a single-line kernel change, as the kernel only passes ECE flags to congestion control modules if ECN is enabled. Enabling ECN shrinks `cwnd` upon receiving an ECE-marked packet (because ECE bits typically convey congestion information), so we leave ECN disabled and instead modify the kernel to always pass the ECE flag to reTCP.

reTCP is beneficial on its own by increasing the TCP sending rate when a circuit begins, but in combination with dynamic buffer resizing, its benefits multiply. As a starting point, consider the period when the packet network is active, operating with static VOQs (not dynamic buffer resizing). The sender ramps up to a steady state that saturates the packet network bandwidth and VOQ capacity. Suppose that we trigger a reTCP `cwnd` increase during this regime. The network would drop the additional packets and the sender would slow back down, with no benefit. However, dynamic buffer resizing is specifically designed to provide extra VOQ capacity to flows before circuit start, but the usefulness of this capacity and for how long it must be available is determined by the sender's ramp-up rate. The two techniques play to each other's strengths: Combining them, dynamic buffer resizing provides more capacity for flows, and then reTCP fills it. When used in this way, we modify reTCP to mark ACKs not at the start of a circuit, but at the start of the dynamic buffer resizing period. By increasing `cwnd` at the same time that the VOQs grow, reTCP quickly fills the larger capacity, dramatically reducing the duration of prebuffering required to achieve full utilization. Bringing the collaboration full-circle, reTCP's ramp-up burst reduces the prebuffering duration, which in turn lessens the time fraction during which the network experiences deep buffers, thus mitigating the ensuing tail latency spike. Section 6.3 visualizes how dynamic buffer resizing and reTCP jump-start the TCP sender just in time for the circuit network.

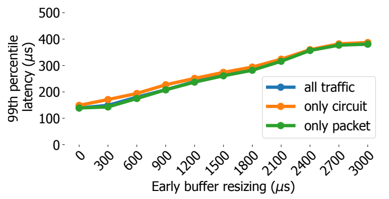
Instead of communicating circuit state on-demand via ACKs and their ECE bits, an alternative design is to inform end-hosts directly using control plane messages, similar to how the ToRs are notified to increase their VOQ capacity prior to circuit start. This would allow the sender to increase its `cwnd` exactly when desired, instead of after the first marked ACK arrives. However, this requires invasive modifications to the end-hosts, since the sender TCP stack would need to communicate with the central scheduler. Our approach is



(a) Circuit utilization vs. prebuffering duration.



(b) Expected TCP sequence number vs. time, for various prebuffering durations. Circuit days are shaded in blue. Dotted lines are the corresponding VOQ length.



(c) 99th percentile latency vs. prebuffering duration.

Figure 9: Dynamic buffer resizing improves circuit utilization at the expense of tail latency.

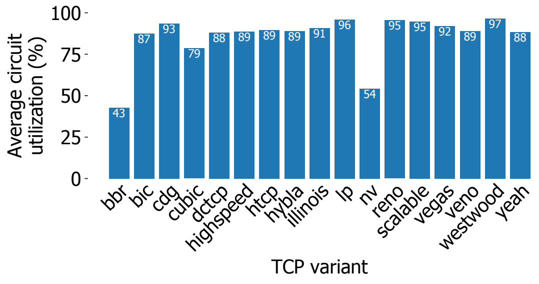


Figure 10: Circuit utilization vs. TCP variant.

less reactive but more practical because it uses existing TCP header fields, modifies only a few lines of code, and avoids distributed control challenges like time synchronization.

6 Evaluation

This section demonstrates that our two proposed techniques, dynamic buffer resizing and explicit circuit state feedback, overcome the challenge of bandwidth fluctuation in RDCNs and enable TCP to take advantage of high-bandwidth circuits when they become available. Additionally, we demonstrate that dynamic buffer resizing provides a general benefit to many TCP variants (beyond CUBIC).

6.1 Evaluating Dynamic Buffer Resizing

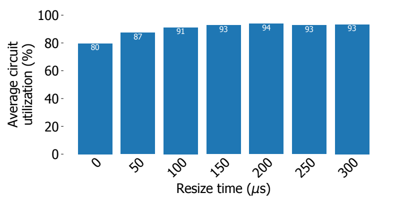
To test the efficacy of dynamic in-network buffer resizing, we repeat the experiments from Section 5.1, but with dynamic instead of static ToR VOQs. Using the schedule and workload described in Section 4.5, we configure the hosts to run TCP CUBIC and vary how early buffer resizing takes place, τ, from 0 μs to 3000 μs, in intervals of 300 μs. Buffers switch between a short capacity of 16 packets and a large capacity of 50 packets. Figure 9a shows average circuit utilization for the various τ. The earlier we resize, the higher utilization flows achieve. With $\tau = 1800$ μs, circuit utilization increases by 1.87× (48.6% → 91.1%), compared to 16-packet static queues.

Figure 9b shows a graph of the expected TCP sequence number and the VOQ length during the lead-up to a circuit day, for selected τ. VOQ length hovers at the small buffer size until dynamic buffering takes effect, then grows steadily, and finally drains sharply when the higher bandwidth circuit activates. For situations that see high utilization, sufficiently many ACKs return and ramp up the sending rate before the VOQs drain completely, which, for TCP CUBIC, is effectively achieved at $\tau = 1800$ μs.

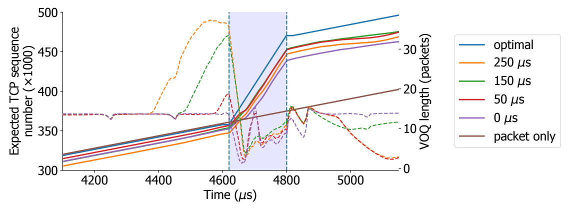
The queue length required for high utilization is a function of the BDPs of the packet (10 Gb/s × 2 × 5 μs = 100 Kb) and circuit (80 Gb/s × 30 μs = 2.4 Mb) networks. These BDPs differ by ~32 9000 B packets. Assuming a few extra packets due to store-and-forward delays, between 35 and 40 packets must be in the VOQs before circuit start to keep the network fully utilized. The matches the growth of the VOQ line for $\tau = 1800$ μs (91% utilization) in Figure 9b.

The remaining question is whether this high utilization comes at the cost of high latency, as it did for static buffers. Median latency does not increase until $\tau = 2700$ μs; we omit the results for brevity. Figure 9c shows how dynamic resizing affects 99th percentile tail latency. Tail latency depends on the length of the VOQs, which increases with the prebuffering duration. The 1.87× circuit utilization increase is paired with a tail latency growth of 2.33× (123 μs → 286 μs). These results can be compared to static VOQs in two ways: (1) Comparing $\tau = 1800$ μs to a static buffer with similar throughput (64 packets), dynamic buffering improves tail latency by 0.59× (484 μs → 286 μs); (2) Comparing to a static buffer with similar tail latency (32 packets), the circuit utilization increases by 1.19× (76.7% → 91.1%). Ultimately, this experiment demonstrates that dynamic buffer resizing has the potential to meet our goal of achieving full circuit utilization with less of an impact on latency than large static buffers, but its latency penalty, especially at the tail, is still unreasonably high for distributed applications.

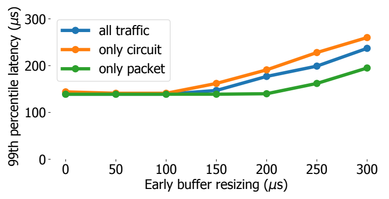
Given that resizing provides large buffers to flows for a significant amount of time (e.g., 41% of the schedule for $\tau = 1800$ μs) it is surprising that tail latency is not as bad as static buffers for comparable circuit utilization. We can use large buffers for a large fraction of time because when circuits are torn down and flows transition back to the packet network, the resulting bandwidth reduction (8× in these experiments) causes TCP to dramatically scale back its sending rate at



(a) Circuit utilization vs. prebuffering duration.



(b) Expected TCP sequence number vs. time, for various prebuffering durations. Circuit days are shaded in blue. Dotted lines are the corresponding VOQ length.



(c) 99th percentile latency vs. prebuffering duration.

Figure 11: reTCP achieves high utilization with much lower tail latency than dynamic buffers alone.

the same moment when the VOQs shrink. In effect, switching back to the packet network resets TCP and the networks experiences a period of short queues while TCP recovers.

However, a 2.33× tail latency increase is unacceptable for many latency-sensitive applications. We have not yet met our goal of achieving the "best of both worlds" of high throughput without the corresponding latency penalty. Section 6.3 demonstrates how reTCP completes the picture, achieving high utilization with only a 1.20× tail latency increase.

6.2 Benefits for all TCP Variants

In Section 3.2.4, we demonstrated that the problem of bandwidth fluctuation impacts many TCP variants we tested. Returning to the experiment in Figure 4, we evaluate the variants' performance with dynamic buffer resizing, with $\tau = 1200$ μs. Figure 10 shows the utilization achieved by the 17 variants. The variants experience an average utilization improvement of 36%, compared to static 16-packet buffers, without any modifications to the end-hosts. Resizing earlier (e.g., $\tau = 1800$ μs) yields still-higher utilization, but we present $\tau = 1200$ μs to better illustrate how the TCP variants respond differently. BBR [5] and TCP NV [3], being delay-based protocols that seek to keep buffer occupancy low, naturally do not take advantage of dynamic buffer resizing and realize only 43% and 54% utilization, respectively. Note that DCTCP [1] relies on explicit congestion feedback from network switches in the form of a stream of ECN marks set if adding a packet to a switch queue would cause the queue's capacity to pass a threshold. To accurately support DCTCP in the Etalon emulator, we modify the hybrid switch to mark packets in this way, at 10 packets when using small queues (16 packets) and 31 packets when using large queues (50 packets).

6.3 Evaluating Explicit Network Feedback

Conveying circuit state information to end-hosts provides an explicit signal that TCP can use to adapt to bandwidth fluctuations in RDCNs. In isolation, reTCP yields higher average circuit utilization than static buffers alone, with an average improvement of 2.65% across the static buffer capacities in Figure 8a. An improvement of 6% with 32-packet buffers is the most significant. For 64 and 128–packet queues, both static buffers and reTCP achieve full utilization. We omit the graphs for brevity.

When used in combination with dynamic buffer resizing, reTCP achieves high circuit utilization with a shorter prebuffering duration and, in turn, lower tail latency. Figure 11 repeats the experiments from Section 6.1, but with both dynamic buffer resizing and reTCP, and instead varies τ from 0 μs to 300 μs, in intervals of 50 μs. Note that the x-axis range in Figure 11b is different than in Figure 9b to better visualize the range of τ values during which reTCP ramps up. Figure 11a shows that the two techniques working together achieve a 1.91× (48.7% → 92.7%) circuit utilization improvement compared to 16-packet static buffers, but with lower τ than dynamic buffers alone: at $\tau = 150$ μs instead of $\tau = 1800$ μs. The impact of this order-of-magnitude decrease in prebuffering duration manifests itself in lower tail latency in Figure 11c: an only 1.20× increase (123 μs → 147 μs), compared to 2.33× for dynamic buffer resizing alone.

Comparing Figures 9b and 11b, the steady VOQ growth is replaced by a jump as `cwnd` doubles, sending more packets into the network. At $\tau = 150$ μs, the sender injects sufficiently many packets to grow the VOQ large enough to saturate the higher BDP of the circuit network, when it becomes active. The rate of growth is quick: It keeps the required prebuffering duration short, which reduces tail latency. Overall, dynamic buffer resizing and reTCP overcome the challenge of bandwidth fluctuation in RDCNs, increasing circuit utilization by 1.91× with an only 1.20× tail latency penalty.

6.4 Limitations

Increasing the VOQ size does not, on its own, lead to higher circuit utilization. The TCP sender must ramp up to fill the additional capacity. Section 6.1 shows that this ramp-up may take milliseconds, posing a challenge for schedules that allocate circuits between some rack pairs frequently: The circuit downtime period may be too short to support this lengthy ramp-up. E.g., the time between circuits for a 3-rack cluster with a strobe schedule (week length = 400 μs) is 220 μs, far lower than the $\tau = 1800$ μs deemed necessary by Section 6.1. Investigating this case revealed that as the prebuffer start time approaches the end of the previous circuit, the residual high sending rate quickly fills the VOQs, causing the network to enter a mode similar to using large static buffers, with high tail latency. reTCP ameliorates this problem.

7 Related Work

Research into RDCN design [6,16,20,25,26,32,38,47,51,57] and scheduling [2,36,39] has yet to examine TCP-related challenges for modern RDCNs. c-Through [51] proposes resizing end-host network buffers, but for the purpose of traffic batching, which is necessary to ensure that senders have enough data to fill a circuit when it becomes available. This is only an issue for circuits with long (e.g., millisecond-scale) uptimes, not the microsecond-scale technologies we address in this paper. Other work avoids the bandwidth fluctuation problem by segregating traffic to use either the packet or circuit networks exclusively [16, 38]. Our techniques simplify the network design by not segregating traffic.

Many of the TCP variants in Section 3.2 are tailored for high-bandwidth networks, but they assume that the bandwidth does not change on short timescales. Prior work [52] has examined how TCP reacts to bandwidth fluctuations in wireless networks, but these networks are fundamentally different than RDCNs. Wireless networks have lower bandwidths and BDPs than RDCNs, and unlike in wireless networks, bandwidth fluctuations in RDCNs are not random: They are part of a schedule that is known in advance. This insight enables proactive techniques like dynamic VOQ resizing.

8 Conclusion

With new advances in RDCN technology comes the need to reexamine the protocols running on top of these networks. This paper proposes two techniques to adapt TCP to the rapid bandwidth fluctuation inherent in microsecond-scale reconfigurable datacenter networks: 1) In the network, we transparently resize ToR VOQ buffers prior to circuit activation to help TCP ramp up, but at the cost of higher tail latency; 2) Involving the end-hosts opens the door for high utilization without a latency penalty by incorporating explicit circuit state signals sent from the hybrid switch. Etalon provides opportunities for future work, e.g., exploring multicast-enabled optical circuit switching (e.g., Blast [53]), providing a cross-cutting evaluation of different RDCN designs, and investigating challenges in future sub-μs RDCNs. While this paper focuses on TCP specifically, our investigation into implicit and explicit techniques for adapting the sending rate to the state of the network applies to congestion control in general. We believe that our experiences speak to the need for an end-to-end evaluation of future RDCN designs.

A High-Speed Load-Balancer Design with Guaranteed Per-Connection-Consistency

Tom Barbette Chen Tang Haoran Yao Dejan Kostić

KTH Royal Institute of Technology

Abstract

Large service providers use load balancers to dispatch millions of incoming connections per second towards thousands of servers. There are two basic yet critical requirements for a load balancer: *uniform load distribution* of the incoming connections across the servers and *per-connection-consistency* (PCC), *i.e.*, the ability to map packets belonging to the same connection to the same server even in the presence of changes in the number of active servers and load balancers. Yet, meeting both these requirements at the same time has been an elusive goal. Today's load balancers minimize PCC violations at the price of non-uniform load distribution.

This paper presents CHEETAH, a load balancer that supports uniform load distribution and PCC while being scalable, memory efficient, resilient to clogging attacks, and fast at processing packets. The CHEETAH LB design guarantees PCC for *any* realizable server selection load balancing mechanism and can be deployed in both a stateless and stateful manner, depending on the operational needs. We implemented CHEETAH on both a software and a Tofino-based hardware switch. Our evaluation shows that a stateless version of CHEETAH guarantees PCC, has negligible packet processing overheads, and can support load balancing mechanisms that reduce the flow completion time by a factor of $2-3$x.

1 Introduction

The vast majority of services deployed in a datacenter need load balancers to spread the incoming connection requests over the set of servers running these services. As almost half of the traffic in a datacenter must be handled by a load balancer [41], the inability to uniformly distribute connections across servers has expensive consequences for datacenter and service operators. The most common yet cost-ineffective way of dealing with imbalances and meet stringent Service-Level-Agreements (SLAs) is to over-provision [13].

Existing LBs rely on a simple hash computation of the connection identifier to distribute the incoming traffic among the servers [3, 13, 15, 20, 37, 41, 53]. Recent measurements on Google's production traffic showed that hash-based load balancers may suffer from load imbalances up to 30% [13].

A natural question to ask is why existing load balancers do not rely on more sophisticated load balancing mechanisms, *e.g.*, weighted round robin [51],"power of two choices" [33], or least loaded server. The answer lies in the extreme dynamicity of cloud environments. Services and load balancers "*must be designed to gracefully withstand traffic surges of hundreds of times their usual loads, as well as DDoS attacks*" [3]. This means that the number of servers and load balancers used to provide a service can quickly change over time. Guaranteeing that packets belonging to existing connections are routed to the correct server despite dynamic reconfigurations requires *per-connection-consistency* (PCC) [32] and has been the focus of many previous works [3, 13, 15, 20, 32, 37, 41]. When only the number of load balancers change, hash-based load balancing mechanisms guarantee PCC as packets reach the correct server even when hitting a different LB [3, 37]. To deal with changes in the numbers of servers, existing LBs either store the "connection-to-server" mapping [13, 20, 32, 41] or let the servers reroute packets that were misrouted [3, 37]. In both cases, a hash function helps mitigate PCC violations, though it cannot completely avoid them (more details in Sect. 2). To summarize, existing load balancers cannot uniformly distribute connections across the servers as they rely on hash functions to mitigate (but not avoid) PCC violations.

This paper presents the design and evaluation of CHEETAH, a load balancer (LB) system with the following properties:

- ***dynamicity***, the number of LBs and servers can increase or decrease depending on the actual load;
- ***per-connection-consistency*** (PCC), packets belonging to the same connection are forwarded to the same server;
- ***uniform load distribution***, by supporting advanced load balancing mechanisms that efficiently utilize the servers;
- ***efficient packet processing***, the LB should have minimal impact on communication latency; and
- ***resilience***, it should be hard for a client to "clog" the LB

and the servers with spurious traffic.

CHEETAH takes a different approach compared to existing LBs. CHEETAH stores information about the connection mappings into the connections themselves. More specifically, when a CHEETAH LB receives the first packet of a connection, it encodes the selected server's identifier into a *cookie* that is permanently added to all the packet headers exchanged within this connection. Unlike previous work, which relies on hash computations to mitigate PCC violations, the design of CHEETAH completely *decouples* the load balancing logic from PCC support. This in turn allows an operator to guarantee PCC regardless of the "connection-to-server" mapping produced by the chosen load balancing logic. The goal of this paper is not the design of a novel load balancing mechanism for uniformly spreading the load but rather the design of CHEETAH as a building block to support PCC for *any* realizable load balancing mechanisms *without* violating PCC. As for resilience, we cannot expose the server identifiers to users as this would open the doors to clogging a targeted server. CHEETAH is designed with resilience in mind, thwarting resource exhaustion and selective targeting of servers. To this end, CHEETAH generates "opaque" cookies that can be processed fast and can only be interpreted by the LB.

We present two different implementations of CHEETAH, a stateless and a stateful version. Our stateless and stateful CHEETAH LBs carefully encode the connection-to-servers mappings into the packet headers so as to guarantee levels of resilience that are no worse (and in some cases even stronger) than existing stateless and stateful LBs, respectively. For instance, our stateful LB increases resilience by utilizing a novel and fast stack-based mechanism that dramatically simplifies the operation of today's cuckoo-hash-based stateful LBs, which suffer from slow insertion times.

In summary, our contributions are:

- We quantify limitations of existing stateless and stateful LBs through large-scale simulations. We show that the quality of the load distribution of existing LBs is 40 times worse than that of an ideal LB. We also show stateless LBs (such as Beamer and Faild) can reduce such imbalances at the price of increasing PCC violations.
- We introduce CHEETAH, an LB that guarantees PCC for any realizable load balancing mechanisms. We present a stateless and a stateful design of CHEETAH, which strike different trade-offs in terms of resilience and performance.
- We implement our stateless and stateful CHEETAH LBs in FastClick [5] and compare their performance with state-of-the-art stateless and stateful LBs, respectively. We also implement both versions of CHEETAH with a weighted round-robin LB on a Tofino-based switch [6].
- In our experiments, we show the potential benefits of CHEETAH with a non-hash-based load balancing mechanism. The number of processor cycles per packet for *both* our stateless and stateful implementation of CHEETAH is comparable to existing stateless implementations and 3.5x less than existing stateful LBs.

2 Background and Motivation

Internet organizations deploy large-scale applications using clusters of servers located within one or more datacenters (DCs). We provide a brief background on DC load balancers, discuss related work, and show limitations of the existing schemes. We do not discuss geo-distributed load balancing across DCs. Further, we distinguish between *stateless* LBs, which do not store any per-connection state, and *stateful* LBs, which store some information about ongoing connections.

Multi-tier load balancing architectures. Datacenter operators assign a *Virtual IP* (VIP) address to each operated service. Each VIP in a DC is associated with a set of servers providing that service. Each server has a *Direct IP* (DIP) address that uniquely identifies the server within the DC.

A LB inside the DC is a device that receives incoming connections for a certain VIP and selects a server to provide the requested service. Each connection is a Layer 4 connection (typically TCP or QUIC). For each VIP, a LB partitions the space of the connection identifiers (*e.g.*, TCP 5-tuples) across all the servers (*i.e.*, DIPs) associated with that VIP. The partitioning function is stored in the LB and is used to retrieve the correct DIP for each incoming packet.

A large-scale DC may have tens of thousands of servers and hundreds of LBs [13, 15, 32]. These LBs are often arranged into different tiers (see Fig. 1). The 1st-tier of LBs are faster and less complex than those in subsequent tiers. For example, a typical DC would use BGP routers using ECMP forwarding at the 1st-tier, followed by Layer 4 LBs, in turn followed by Layer 7 LBs and applications [20]. Similar to previous work on DC load balancing, we consider Layer 7 LBs to be at the same level as the services [13, 20, 41]. Any 1st tier LB receiving a packet directed to a VIP, performs a look up to fetch the *set* of 2nd tier LBs responsible for that VIP. It then forwards the packet towards any of these LBs. The main goal of the 1st-tier is demultiplexing the incoming traffic at the per VIP level towards their dedicated 2nd tier LBs. The 2nd-tier LBs perform two crucial operations: *(i)* guaranteeing (PCC) [32] and *(ii) load balancing* the incoming connections.

2.1 Limits of Stateless Load Balancers

Traditional stateless LBs cannot guarantee PCC. A stateless LB partitions the space of connection identifiers among the set of servers. The partitioning function is stored in the LB and does not depend on the number of active connections. Most stateless LBs, *e.g.*, ECMP [9, 19] & WCMP [53], store this partitioning in the form of an *indirection table*, which maps the output of a hash function modulo the size of the table to a specific server [3, 19, 37, 53].

Figure 1: A traditional datacenter load balancing architecture.

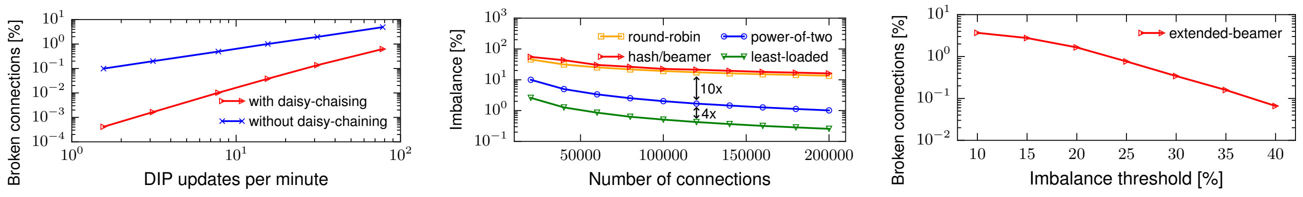
A *uniform hash* scheme maps each server to an equal number of entries in the indirection table. When a LB receives a packet, it extracts the connection identifier from the packet and feeds it as input to a hash function. The output of the hash modulo the size of the indirection table determines the index of the entry in the table where the LB can find to which server the packet should be forwarded. If the number of servers changes, the indirection table must be updated, which may cause some *existing* connections to be rerouted to the new (and wrong) server that is now associated with an entry in the table, *i.e.*, a PCC violation.

Advanced stateless LBs cannot always guarantee PCC. Beamer [37] and Faild [3] introduced *daisy-chaining* to tackle PCC. They encapsulate in the header of the packet the address of a "backup" server to which a packet should be sent when the LB hits the wrong server. This backup server is selected as the last server that was assigned to a given entry in the indirection table before the entry was remapped. PCC violations are prevented as long as *(i)* one does not perform two reconfigurations that change the same entry in the table twice (as only one backup server can be stored in the packet) and *(ii)* one can *simultaneously* reconfigure all the LBs (see [37] for an example).

Fig. 2a shows the percentage of broken connections (*i.e.*, PCC violations) with and without daisy chaining in our large-scale simulations. We used the same parameters, traffic workloads, and cluster reconfiguration events derived from previous work on real-world DC load balancing, *i.e.*, SilkRoad [32]. Namely, we simulated a cluster of 468 servers and we generated a workload using the same traffic distribution of a large web server service. We performed *DIP updates*, *i.e.* removal or additional of servers from the cluster, using different frequency distributions. SilkRoad reports that 95% of their clusters experience between 1.5 and 80 DIP updates/minute and provide distributions for the update time. We define the number of *broken connections* as the number of connections that have been mapped to *at least two* different servers during their starting and ending times. Fig. 2a shows that Beamer and Faild (plotted using the same line) still break almost 1% of the connections at the highest DIP update frequency, which may lead to an unacceptable level of service level agreement (SLA) violations [32].

Hash-based LBs cannot uniformly spread the load. We now investigate the ability of different load balancing mechanisms to uniformly spread the load across the servers for a single VIP. Similarly to the Google Maglev work [13], we define the *imbalance* of a server as the ratio between the number of connections active on that server and the average number of active connections across all servers. We also define the *system imbalance* as the maximum imbalance of any server. The imbalance of a simulation run is the *average* imbalance of the system during the entire duration of the simulation. We discuss different load metrics in Sect. 4. Using the same simulation settings as described above, we compare *(i)* Beamer [37]/Faild [3], which use a uniform hash, *(ii)* Round-Robin [50], which assigns each new connection to the next server in a list, *(iii)* Power-Of-Two [33], which picks the least loaded among two random servers, and *(iv)* Least-Loaded [50], which assigns each new connection to the server with fewest active connections. We note that Round-Robin, Power-Of-Two, and Least-Loaded require storing the connection-to-server mapping, hence they cannot be supported by Beamer/Faild. In this simulation, we do not change the size of the cluster but rather vary only the number of connections that are active at the same time in the cluster between 20K and 200K. We choose this range of active connections to induce the same imbalances (15%-30%) observed for uniform hashes in Google Maglev [13]. Fig. 2b shows the results of our simulations. We note that Beamer-like hash-based LBs outperform consistent hashing by a factor of 2x. Round-Robin outperforms a Beamer-like LB by a factor of 1.2x. When comparing these schemes with Power-Of-Two, we observe a reduction in imbalance by a factor of 10x. Finally, Least-Loaded further reduces the imbalance by an additional factor of 4*x*. These results show that a more uniform distribution of loads can be achieved by storing the mapping between connections and servers, though one still has to support PCC when the LB pool size changes. We note that today's stateful LBs [13,20,32,41] rely on different variations of uniform-hash, thus suffer from imbalances similarly to Beamer.

Beamer can reduce imbalance at the cost of a greater number of PCC violations. We tried to reduce the imbalances in Beamer by monitoring the server load imbalances and modify the entries in the indirection table accordingly. We extended Beamer with a dynamic mechanism that gets as input an imbalance threshold and remove a server from the indirection table whenever its load is above this threshold. The server is



(a) Impact of daisy-chained during DIP updates. (b) Load imbalance. (c) Dynamic Beamer imbalance.

Figure 2: Analysis of PCC-violations and load imbalances of state-of-the-art load balancers. To ease visibility, points are connected with straight lines along the x-axis.

re-added to the table when its number of active connections drops below the average. Note that, if an entry in the indirection table changes its server mapping twice, Beamer will break those existing connections that were relying on the initial state of the indirection table. Fig. 2c shows the percentage of broken connections for increasing imbalance thresholds. We set the number of active connections to 70K (corresponding to an *average* 30% imbalance in Fig. 2b). We note that guaranteeing an imbalance of at most 10% would cause 3% of all connections to break. Even with an imbalance threshold of 40% one would still observe 0.1% broken connections because of micro-bursts. Hence, even this extended Beamer cannot guarantee PCC and uniform load balancing at the same time.

2.2 Limits of Stateful Load Balancers

Stateful LBs store the connection-to-server mapping in a so-called `ConnTable` for two main reasons: *(i)* to preserve PCC when the number of servers changes and *(ii)* to enable fine-grain visibility into the flows.

Today's stateful LBs cannot guarantee PCC. Consider Fig. 1 and the case in which we add an additional stateful LB for a certain VIP. The BGP routers, which rely on ECMP, will reroute some connections to a LB than does not have the state for that connection. Thus, this LB does not know to which server the packet should be forwarded unless all LBs use an identical hash-based mechanism (and therefore experience imbalances). Therefore, existing LBs (including Facebook Katran [20], Google Maglev [13], and Microsoft Ananta [41]) rely on hashing mechanisms to mitigate PCC violations. However, this is not enough if the number of servers also changes, then some existing connections will be routed to an LB without state, hence it will hash the connection to the wrong server, thus breaking PCC.

Today's stateful LBs rely on complex and slow data structures. State-of-the-art LBs rely on cuckoo-hash tables [40] to keep per-connection mappings. These data structures guarantee constant time lookups but may require non-constant insertion time [43]. These slow insertions may severely impact the LB's throughput, *e.g.*, a throughput loss by 2x has been observed on OpenFlow switches when performing ~ 60 updates/second [34].

2.3 Service Resilience and Load Balancers

Load balancers are an indispensable component against clogging Distributed Denial of Service (DDoS) attacks, *e.g.*, bandwidth depletion at the server and memory exhaustion at the LB. Dealing with such attacks is a multi-faceted problem involving multiple entities of the network infrastructure [30], *e.g.*, firewalls, network intrusion detection, application gateways. This paper does not focus on how the LB fits into this picture but rather studies the resilience of the LB itself and the resilience its design provides to the service operation.

LBs shield servers from targeted bandwidth depletion attacks. An LB system should guarantee that the system absorb sudden bursts due to DDoS attacks with minimal impact on a service's operation. Today's LB mechanisms rely on hash-based load balancing mechanisms to provide a first pro-active level of defense, which consists in spreading connections across all servers. As long as an attacker does not reverse engineer the hash function, multiple malicious connections will be spread over the servers. A system should not allow clients to target specific servers with spurious traffic.

Stateful LBs support per-connection view at lower resilience. Stateful LBs provide fine-grained visibility into the active connections, providing resilience to the service operation, *e.g.*, by selectively rerouting DDoS flows. At the same time, stateful LBs are a trivial target of resource depletion clogging DDoS attacks: incoming spurious connections add to the connection table rapidly exhaust the limited LB memory (*e.g.*, [37]) or grow the connection table aggressively, rapidly degrading performance even with ample memory [34]. Stateless LBs can inherently withstand clogging DDoS, sustaining much higher throughput, but can only offer per-server statistics visibility to the service operation.

Having analyzed the above limitations of existing load balancers, we conclude this section by asking the following question: *"Is it possible to design a DC load balancing system that guarantees PCC, supports any realizable load balancing mechanism, and achieves similar levels of resiliency of today's state-of-the-art LBs?"*

3 The CHEETAH Load Balancer

In this section, we present CHEETAH, a load balancing system that supports arbitrary load balancing mechanisms and guarantees PCC without sacrificing performance. CHEETAH solves many of the today's load balancing problems by encoding information about the connection into a *cookie* that is added to all the packets of a connection.[1] CHEETAH sets the cookie according to any chosen and realizable load balancing mechanism and relies on that cookie to *(i)* guarantee future packets belonging to the same connection are forwarded to the same server and *(ii)* speed up the forwarding process in a stateful LB, which in turn increases the resilience of the LB. Understanding what information should be encoded into the cookie, how to encode it, and how to use this information inside a stateless or stateful LB is the goal of this section. We start our discussion by introducing the stateless CHEETAH LB, which guarantees PCC and preserves the same resilience and packet processing performance of existing stateless LBs. We then introduce the stateful CHEETAH LB, which improves the packet processing performance of today's stateful LBs, and present an LB architecture that strikes different tradeoffs in terms of performance and resilience. We stress the fact that CHEETAH does not propose a novel LB mechanism but is a building block for supporting arbitrary LB mechanisms without breaking PCC (we show the currently implemented LB mechanisms in Sect. 4).

A naïve approach. We first discuss a straightforward approach to guarantee PCC that would not work in practice because of its poor resiliency. It entails storing the identifier of a server (*i.e.*, the DIP) in the cookie of a connection. In this way, an LB can easily preserve PCC by extracting the cookie from each subsequent incoming packet. We note that such naïve approaches are reminiscent of several previous proposals on multi path transport protocols [10, 39], where the identifiers of the servers are explicitly communicated to the clients when establishing multiple subflows within a connection. There is at least one critical resiliency issue with this approach. Some clients can wait to establish many connections to the same server and then suddenly increase their load. This is highly undesired as it leads to cascade-effect imbalances and service disruptions [47].

3.1 Stateless CHEETAH LB

The stateless CHEETAH LB: encoding an opaque offset into the cookie. We now discuss how we overcome the above issues in CHEETAH. We aim to achieve the same resiliency levels[2] of today's production-ready stateless LBs (*e.g.*, Faild [3]/Beamer [37, 47]) while supporting arbitrary load balancing mechanisms and guaranteeing PCC. We

[1] We discuss legacy-compatibility issues in Sect. 4

[2] See Sect 2.3 for details of stateless/stateful load balancing resiliency.

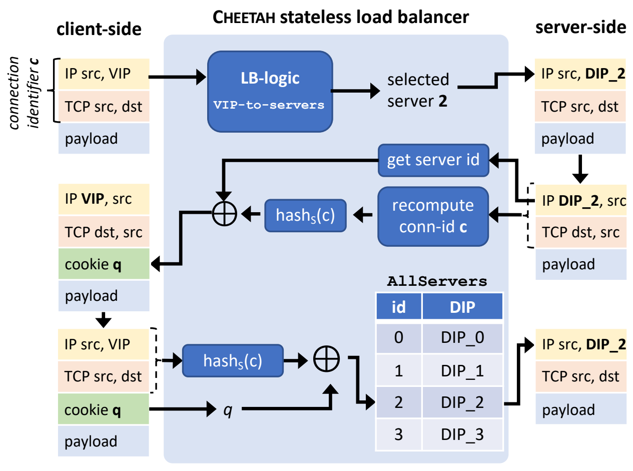


Figure 3: CHEETAH stateless LB operations.

assume a single tier LB architecture and defer the discussion of multi-tier architectures to later in this section.

The CHEETAH stateless LB keeps two different types of tables (see Fig. 3): an `AllServers` table that maps a server identifier to the DIP of the server and a `VIPToServers` table that maps each VIP to the set of servers running that VIP. The `AllServers` table is mostly static as it contains an entry for each server in the DC network. Only when servers are deployed in/removed from the DC is the `AllServers` table updated. The `VIPToServers` table is modified when the number of servers running a certain service increases/ decreases, a more common operation to deal with changes in the VIP current demands.

When the LB receives the first packet of a connection (top part of Fig. 3), it extracts the set of servers running the service (*i.e.*, with a given VIP) from the `VIPToServers` table, selects one of the servers according to any pre-configured load balancing mechanism, and forwards the packet.[3] For every packet received from a server (middle part of Fig. 3), the LB encodes an "opaque" identifier of the server mapping into the cookie for this connection. To do so, CHEETAH computes the hash of the connection identifier with a salt S (unknown to the clients), XORs it with the identifier of the server, and adds the output of the XOR to the packet header as the cookie. The salt S is the same for all connections. When the LB receives any subsequent packet belonging to this connection (bottom part of Fig. 3), it extracts the cookie from the packet header, computes the hash of the connection identifier with the salt S, XORs the output of the hash with the cookie, and uses the output of the XOR as the identifier of the server. The LB then looks up the DIP of the server in the `AllServers` table.

Stateless CHEETAH guarantees PCC. CHEETAH relies on two main design ideas to avoid breaking connections:

[3] How to implement different LB mechanisms in programmable hardware and software LBs is shown in Sect. 4.

(i) moving the state needed to preserve the mapping between a connection and its server into the packet header of the connection and *(ii)* using the more dynamic `VIPToServers` table only for the 1st packet of a connection. Subsequently, the static `AllServers` table is used to forward packets belonging to any existing connection. This trivially guarantees PCC. We defer discussion of multi-path transport protocols to Sect. 6.

Compared to existing stateless LBs Stateless CHEETAH achieves similar resiliency. Binding the cookie with the hash of the connection identifier brings one main advantage compared to the earlier naïve scheme, as an attacker must first reverse engineer the hash function of the LB in order to launch an attack targeting a specific server. This makes CHEETAH as resilient as other production-ready stateless LBs. We note that CHEETAH is orthogonal to DDoS mitigation defence mechanisms, especially when deployed in reactive mode. We further discuss CHEETAH resilience, including support for multi path transport protocols, in Sect. 6.

Stateless CHEETAH supports arbitrary load balancing mechanisms. All the reviewed state-of-the-art LBs (even stateful ones) are restricted to uniform hashing when it comes to load balancing mechanisms — as any other mechanism would break an unacceptable number of connections when the number of servers/LBs changes. In contrast, whenever a new connection arrives at a stateless CHEETAH LB, CHEETAH selects a server among those returned from a lookup in the `VIPToServers` table. The selected server may depend upon the specific load balancing mechanism configured by the service's operator. We note that the selection of the server may or may not be implementable in the data-plane. The CHEETAH LB guarantees that once the mapping connection-to-server has been established by the LB logic (not necessarily at the data-plane speed), all the subsequent packets belonging that that connection will be routed to the selected server. Since the binding of the connection to the server is stored in the packet header, CHEETAH can support LB mechanisms that go well beyond uniform hashing. For instance, an operator may decide to rely on "power of two choices" [33], which is known to reduce the load imbalance by a logarithmic factor. Another service operator may prefer a weighted round-robin load balancing mechanism that uses some periodically reported metrics (*e.g.*, CPU utilization) to spread the load uniformly among all the servers.

Lower bounds on the size of the cookie. In CHEETAH, the size of the cookie has to be at least $\log_2 k$ bits, where k is the maximum number of servers stored in the `AllServers` table. Therefore, the size of the cookie grows logarithmically in the size of the number of servers. One question is whether PCC can be guaranteed using a cookie whose size is smaller than $\log_2(k)$ and the memory size of the LB is constant. We defer proof of the following theorem to App. A.

Theorem 1. Given an arbitrarily large number of connections, any load balancer using $O(1)$ memory requires cookies of size $\Omega(\log(k))$ to guarantee PCC under any possible change in the number of active servers, where k is the overall number of servers in the DC that can be assigned to the service with a given VIP.

In App. A, we generalize the above theorem to show a certain class of advanced load balancing mechanisms, including round-robin and least-loaded, requires cookies with a size of at least $\log_2(k)$ bits even in the absence of changes in the set of active servers.

While the above results close the doors to any sublogarithmic overhead in the packet header; in practice, operators may decide to trade some PCC violations and load imbalances for a smaller sized cookie. We refer the reader to App. B for a discussion about how to implement CHEETAH with limited size cookies.

3.2 Stateful CHEETAH LB

We also designed a stateful version of CHEETAH to support a finer level of visibility into the flows than that offered by stateless LBs. A stateful LB can keep track of the behaviour of each individual connection and support complex network functions, such as rate limiters, NATs, detection of heavy-hitters, and rerouting to dedicated scrubbing devices (as in the case of Microsoft Ananta [41] and CloudFlare [30]). In contrast to existing LBs, our stateful LB guarantees PCC (inherited from the stateless design) and uses a more performant `ConnTable` that is amenable to fast data plane implementations. In the following text we say that PCC is guaranteed if a packet is routed to the correct server as long as an LB having state for its connection exists.

The stateful CHEETAH load balancer: encoding table indices in the packet header. As discussed in Sect. 2, today's stateful LBs rely on advanced hash tables, *e.g.*, cuckoo-hashing [40], to store per-connection state at the LB [32]. Such data structures offer constant-time data-plane lookups but insertion/modification of any entry in the table requires intervention of the slower control plane or complex & workload-dependant data structures (*e.g.*, Bloom filters [32], Stash-based data structures [43]), which are both complex and hard to tune for a specific workload.

We make a simple yet powerful observation about stateful tables that any insertion, modification, or deletion of an entry in a table can be greatly simplified if a packet carries information about the index of the entry in the table where its connection is stored. Since datacenters may have tens of billions of active connections, we need to devise a stateful approach where the size of the cookie is explicitly given as input. In a stateful CHEETAH LB (see Fig. 4), we store a set of m `ConnTable` tables that keep per-connection statistics and DIP mappings. We also use an equal number of `ConnStack` stacks of indices, each storing the unused entries in its corresponding `ConnTable`.

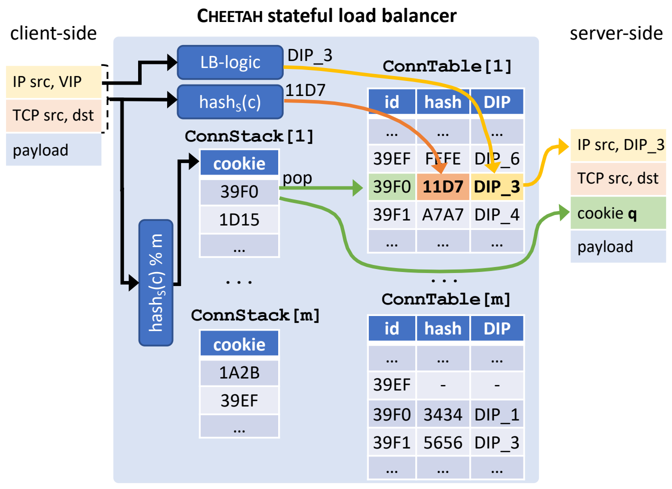

Figure 4: CHEETAH stateful LB operations for the 1st packet of a connection. We do not show the stateless cookie for identifying the stateful LB. The `VIP-to-servers` is included within the LB-logic and not shown. The server performs Direct Server Return (DSR) so the response packet does not traverse the load balancers. Subsequent packets from the client only access their index in the correspoding `ConnTable`.

For the sake of simplicity, we first assume there is only one LB and one `ConnTable` with its associated `ConnStack`, *i.e.*, $m = 1$. Whenever a new connection state needs to be installed, CHEETAH pops an index from `ConnStack` and incorporates it as part of the cookie in the packet's header. It also stores the selected server and the hash of the connection identifier with a salt S into the corresponding table entry. This hash value allows the LB to filter out malicious attempts to interfere with legitimate traffic flows, similarly to SilkRoad [32]. Whenever a packet belonging to an existing connection arrives at the LB, CHEETAH extracts the index from the cookie and uses it to quickly perform a lookup only in the `ConnTable`. Note that insertion, modification, and deletion of connections can be performed in constant time entirely in the data plane. We explain details of the implementation in Sect. 4.

The number of connections that we can store within a single `ConnTable` is equal to 2^r, where r is the size of the cookie. In practice, the size of the cookie may limit the number of connections that can be stored in the LB. We therefore present a hybrid approach that uses a hash function to partition the space of the connection identifiers into m partitions. As for any stateful table, m should be chosen high enough so the total number of entries $m * 2^r$ is suitable. The same cookie can be re-used among connections belonging to distinct partitions.

A hybrid datacenter architecture. Stateful LBs are typically not deployed at the edge of the datacenter for two reasons: they are more complex and slower compared to stateless LBs. As such, they are a weak point that could compromise the entire LB availability. Therefore, we propose a 2-tier DC architecture where the first tier consists of stateless CHEETAH LBs and the second tier consists of stateful CHEETAH LBs. The stateless LB uses the first bytes of the cookie to encode the identifier of a stateful load balancer, thus guaranteeing a connection always reaches the same LB regardless of the LB pool size. The stateful load balancer uses the last bytes of the cookie to encode per-connection information as described above.

4 Implementation

The simplicity of our design makes CHEETAH amenable to highly efficient implementations in the data-plane. We implemented stateful and stateless CHEETAH LBs on FastClick [5], a faster version of the Click Modular Router [26] that supports DPDK and multi-processing. Previous stateless systems, such as Beamer [37], have also relied on FastClick for their software-based implementation. We also implemented stateless and stateful versions of the CHEETAH LB with a weighted round-robin LB on a Tofino-based switch using P4 [6].[4] We can only make a general P4 implementation available due to Tofino-related NDAs. Both implementations are available at [4]. We first discuss the critical question of where to actually store the cookie in today's protocols and then describe the FastClick and P4-Tofino implementations.

Preserving legacy-compatibility. Our goal is to limit the amount of modifications needed to deploy CHEETAH on existing devices. Ideally, we would like to use a dedicated TCP option for storing the CHEETAH cookie into the packet header of all packets in a connection. However, this would require modifications to the clients, which would be infeasible in practice. We therefore identified three possible ways to implement cookies within existing transport protocols *without* requiring any modifications to the clients' machines: *(i)* incorporate the cookie into the `connection-id` of QUIC connections, *(ii)* encode the cookie into the least significant bits of IPv6 addresses and use IPv6 mobility support to rebind the host's address (the LB acts as a home agent), and *(iii)* embed the cookie into part of the bits of the TCP timestamp options. In this paper, we implemented a proof-of-concept CHEETAH using the TCP timestamp option as explained in App. C.[5] . We note that similar encodings of information into the TCP timestamp have been proposed in the past but require modifications to the servers [39]. The stateless CHEETAH LB can transparently translates the server timestamps with the encoded timestamps without interfering

[4]Detailed performance benchmarking of CHEETAH on the Tofino switch is subject to an NDA. The Tofino implementations follow the description of the mechanisms presented in Sect. 3, use minimal resources, and incur neither significant performance overheads nor require packet recirculation.

[5]We verified in App. C that the latest Android, iOS, Ubuntu, and MacOS operating systems support TCP timestamp options but not Windows.

with TCP timestamp related mechanisms (*i.e.*, RTT estimation and protections against wrapped sequences [8]). Therefore, no modifications are required to the servers for stateless mode unless the datacenter operator wants to guarantee Direct Server Return (DSR), *i.e.*, packets from the servers to the client do not traverse any load balancer. In that case, the server must encode the cookie into the timestamp itself. The cookie must also be sent back by the server for stateful mode, as the load balancer would not be able to find the stack index for returning traffic. Server modifications are described in C.2. We leave the implementation of CHEETAH on QUIC and IPv6 as future work. We note that a QUIC implementation would be easier and more performant since parsing TCP options is an expensive operation in both software and hardware LBs.

Table 1: TCP Options pattern

SYN packets	
MSS SAckOK Timestamp [NOP WScale]	49.86%
MSS NOP WScale NOP NOP Timestamp [SAckOK EOL]	44.49%
MSS NOP WScale SAckOK Timestamp	4.53%
Slow path	1,12%
SYN-ACK packets	
MSS SAckOK Timestamp [NOP WScale]	76.85%
MSS NOP WScale SAckOK Timestamp	18.79%
MSS NOP NOP Timestamp [SAckOK EOL]	1.69%
MSS NOP WScale NOP NOP Timestamp [SAckOK EOL]	1.55%
Slow path	1,12%
Other packets	
NOP NOP Timestamp	98.46%
NOP NOP Timestamp [NOP NOP SAck]	1.49%
Slow path	0,05%

4.1 FastClick implementation

The FastClick implementation is a fully-fledged implementation of CHEETAH that supports L2 & L3 load balancing and multiple load balancing mechanisms (*e.g.*, round-robin, power-of-2 choices, least-loaded server). The LB supports different load metrics including number of active connection and CPU utilization. The LB decodes cookies for both stateless and stateful modes using the TCP timestamp as described above, and can optionally fix the timestamp in-place if the server is not modified to do it.

Parsing TCP options. Each TS option has a 1-byte identifier, 1-byte length, and then the content value. Options may appear in any order. This makes extracting a specific option a non-trivial operation [10]. We focus on extracting the timestamp option TS_{ecr} from a packet. To accelerate this parsing operation, we performed a statistical study over 798M packets headers from traffic captured on our campus.

Table 1 shows the most common patterns observed across the entire trace for packets containing the timestamp option. The Linux Kernel already implements a similar fast parsing technique for non-SYN(/ACK) packets. We first consider non-SYN packets (*i.e.*, "Other packets" in the table). Our study shows that 99.95% of the packets have the following pattern: NOP (1B) + NOP (1B) + TimeStamp (10B) possibly followed by other fields. When a packet arrives, we can easily determine whether it matches this pattern by performing a simple 32-bit comparison and checking that the first two bytes are NOP identiers and the third one is the Timestamp id. We process the remaining 0.05% of the traffic in the slow path. We now look at SYN packets. Consider the first row in the table, *i.e.*, MSS (4B) + SAckOK (2B) + TimeStamp (10B) + SAck + EOL. To verify if a packet matches this pattern, we perform a 64-bit wildcard comparison and check that the first byte is the MSS id, the fifth byte is the SAckOK id, and the seventh byte is the TimeStamp id. We can apply similar techniques for the remaining patterns matchable with 64 bits. Some types of hosts generate packets whose patterns are wider than 64 bits, which is the limit of our x86_64 machine. We then rely on one SSE 128bit integer wildcard comparison to verify such patterns. The remaining 2.24% of patterns are handled through a standard hop-by-hop parsing following the TCP options Type-Length-Value chain. Finally, we note that we can completely avoid the more complex parsing operations for SYNs and SYN/ACKs if servers use TCP SYN cookies [12] (see App. C for more details).

Load balancing mechanisms. CHEETAH supports any realizable LB mechanisms while guaranteeing PCC. We implemented several load balancing mechanisms that will be evaluated using multiple workloads in Sect. 5.2. Among the load-aware LB mechanisms, we distinguish between metrics that can be tracked with or without coordination. Without any coordination, the LB can keep track of the number of packets/bytes sent per server and an estimate of the number of open connections based on a simple SYN/FIN counting mechanism.[6] For LB approaches that require coordination with the servers, our implementation supports load distribution based on the CPU utilization of the servers. Note that using a least-loaded server for coordination-based approaches is a bad idea as a single server will receive all the incoming connections until its load metric increases and is reported to the LB, ultimately leading to instabilities in the system. Therefore, we decided to implement the following two load-aware balancing mechanisms, which we introduced in Sect. 2: *(i)* power-of-2 choices and *(ii)* a weighted round robin (WRR). For WRR, we devised a system where the weights of the servers change according to their relative (CPU) loads. We increase the weights for servers that are underutilized depending on the difference between their load and the average server load. More formally, the number of buckets N_i assigned to server i is computed as $N_i = round(10\frac{L_{avg}}{(1-\alpha)*L_i+\alpha*L_{avg}})$ where L_i is the load of a server, and α is a factor that tunes the speed of the convergence, which we set to 0.5. A perfectly balanced system would give $N = 10$ buckets to each server. An underutilized server gets more than

[6] We envision an ad-hoc mechanism to signal closed connection between the LB and the server would make the estimate reliable in the future.

N buckets (in practice limited to $3N$) while an overloaded server gets less than N buckets (lower bounded by 2).

4.2 P4-Tofino prototype

The stateless CHEETAH LB follows exactly the description from Sect. 3.1. We store the `all-servers` and the `VIP-to-servers` tables using exact-match tables. We rely on registers, which provide per-packet transactional memories, to store a counter that implements the weighted-round-robin LB. We note that implementing other types of LB mechanisms such as least-loaded in the data-plane is non trivial in P4 since one would need to extract a minimum from an array in $O(1)$. This operation will likely requires to process the packet on the CPU of the switch. The insertion/deletion of the cookie on any subsequent non-SYN packet can be performed in the data-plane. The stateful CHEETAH LB adheres to the description in Sect. 3.2. We use P4 registers to enable the insertion of connections into the `ConnTable` at the speed of the data-plane. We store the elements of the `ConnStack` stack in an array of registers, the `ConnTable` into an array of registers, and the pointer to the head of the stack in another register.

5 Evaluation

The CHEETAH LB design allows datacenter operators to unleash the power of arbitrary load balancing mechanisms while guaranteeing PCC, *i.e.*, the ability to grow/shrink the LB and DIP pools without disrupting existing connections. In this section, we perform a set of experiments to assess the performance achievable through our stateless and stateful LBs. We focus only on evaluating the performance of the FastClick implementation.[7] All experiments scripts, including documentation for full reproducibility are available at [4].

We pose three main questions in this evaluation:

- *"How does the **cost of packet processing** in* CHEETAH *compare with existing LBs?"* (Sect. 5.1)
- *"Can we reduce **load imbalances** by implementing more advanced LB mechanisms in* CHEETAH*?"* (Sect. 5.2)
- *"How does the **PCC support** in* CHEETAH *compare with existing stateless LBs?"* (Sect. 5.3)

Experimental setting. The LB runs on a dual-socket, 18-core Intel®Xeon®Gold 6140 CPU @ 2.30GHz, though only 8 cores are used from the socket attached to the NIC. Our testbed is wired with 100G Mellanox Connect-X 5 NICs [48] connected to a 32x100G NoviFlow WB5000 switch [36]. All CPUs are fixed at their nominal frequency.

Workload generation. To generate load, we use 4 machines with a single 8-core Intel®Xeon®Gold 5217 CPU @ 3.00GHz with hyper-threading enabled using an enhanced version of WRK [17] to generate load towards the LB. We also use four machines to run up to 64 NGINX web servers (one per hyper-thread), isolated using Linux network namespaces. Each NGINX server has a dedicated virtual NIC using SRIOV, allowing packets to be switched in hardware and directly received on the correct CPU core. We generate requests from the clients using uniform and bimodal distributions, as well as the large web server service distributions already used in the simulations of Sect. 2.

[7]We argue that our Tofino implementation would perform similarly in terms of ability to uniformly distribute the load.

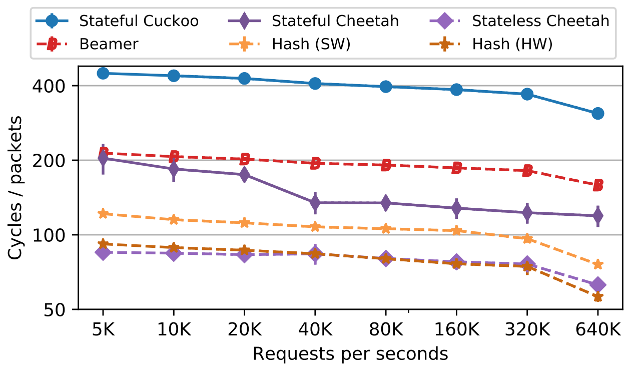

Figure 5: CPU cycles/packets for various methods. CHEETAH achieves the same load balancing performance as stateful LBs with 5x fewer cycles and only a minor penalty over hashing.

Metrics. We evaluate the imbalance among servers using both the variance of the server loads and the 99th percentile flow completion times (FCTs), where the latter one is key for latency-sensitive user applications. We measure the LB packet processing time in CPU cycles per second. Each point is the average of 10 runs of 15 seconds unless specified otherwise.

5.1 Packet Processing Analysis

We first investigate the cost in terms of packet processing time for using stateless CHEETAH. We compare it against stateful CHEETAH, a stateful LB based on per-core DPDK cuckoo-hash tables, and two hashing mechanisms, one using the hash computed in hardware by the NIC for RSS [21], and one computed in software with DPDK [29]. We also compare with a streamlined version of Beamer [38], without support for bucket synchronization, UDP, and MPTCP, thus representing a lower-bound on the Beamer packet processing cost.

Stateless CHEETAH incurs minimal packet processing costs. Fig. 5 shows the number of CPU cycles consumed by different LBs divided by the number of forwarded packets for increasing number of requests per second. We tune the request generation for a file of 8KB so that none of the clients or servers were overloaded. The main result from this experiment is that stateless CHEETAH consumes almost the same number of CPU cycles per packet as the most optimized, hardware assisted hash-based mechanism and significantly fewer cycles than stateful approaches. Beamer consumes more cycles than both CHEETAH LBs, still without bringing PCC

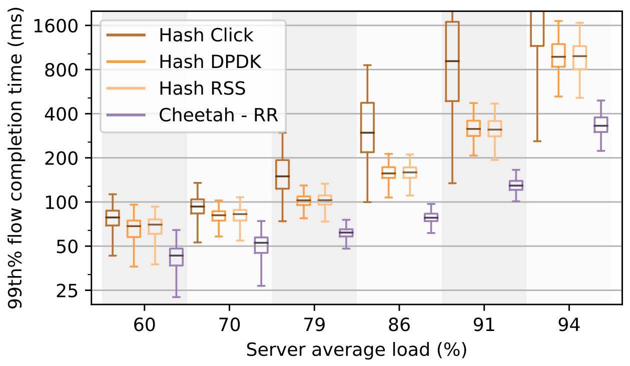

Figure 6: 99th-perc. FCT for the increasing average server load. CHEETAH achieves 2x−3x lower FCT than Hash RSS.

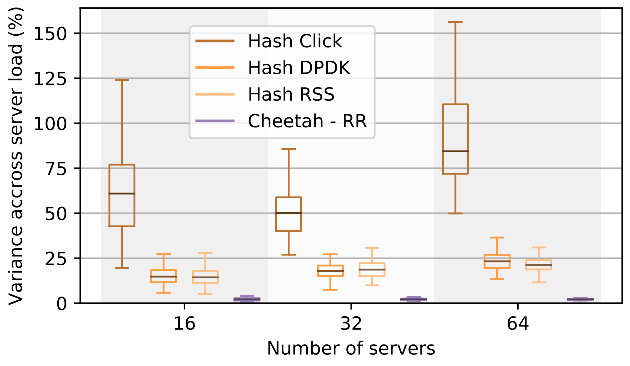

Figure 7: Variance among servers' load of various methods for an increasing number of servers. The average requests/s is 100 per server. CHEETAH, though stateless, allows a near-perfect load spreading.

guarantee (see Sect. 5.3). This is mainly due to the operation of encapsulating the backup server into the packet header and the more compute-intensive operations needed by Beamer to lookup into a bigger "stable hashing" table. Finally, we note that, with the web service requests size distribution, each methods only need 4 CPU cores to saturate the 100Gbps link.

Stateful CHEETAH outperforms cuckoo-hash based LBs. We also note in Fig. 5 the improvements in packet processing time of stateful CHEETAH (which uses a stack-based `ConnTable` table) compared to the more expensive stateful LBs using a cuckoo-hash table. Stateful CHEETAH achieves performance close to a stateless LB and a factor of $2-3$x better that cuckoo-hash based LBs.

Dissecting stateless CHEETAH performance. The key insight into the extreme performance of CHEETAH is that the operation of obfuscating the cookie only adds less than a 4-cycle hit. We in fact rely on the network interface card hardware to produce a symmetric hash (*i.e.*, using RSS). We expect the advent of SmartNICs as well as QUIC and IPv6 implementations, which have easier-to-parse headers, to perform even better. We note that our stateless CHEETAH implementation uses server-side TCP timestamp correction (see Sect. 4), which only imposes a 0.2% performance hit over the server processing time. If we were to use LB-side timestamp correction, we observe that the stateless CHEETAH modifies the timestamp MSB on the LB in just 30 cycles per packet performance hit. To summarize, stateless CHEETAH brings the same benefits as stateful LBs (in terms of load balancing capabilities) in addition to PCC guarantees at basically the same cost (and resilience) of stateless LBs.

5.2 Load Imbalance Analysis

We now assess the benefits of running CHEETAH using a non-hash-based load balancing mechanism and compare it to different uniform hash functions (similarly to those implemented in Microsoft Ananta [41], Google Maglex [13], Beamer [37], and Faild [3]). We stress that we do not propose novel load balancing mechanisms but rather showcase the potential benefits of a load balancer design that supports any realizable load balancing mechanisms. We only evaluate stateless CHEETAH as the load imbalance does not depend on the stored state (and would result in similar performance).

In this experiment, each server performs a constant amount of CPU-intensive work to dispatch a 8KB file. The generator makes between 100 and 200 requests per server per second on average depending on our targeted system load. Given this workload and service type, we expect an operator to choose a uniform round-robin LB mechanism to distribute the load.

CHEETAH significantly improves flow completion time. Fig. 6 compares CHEETAH with round-robin and hash-based LB mechanisms with 64 servers. We consider three hash functions: Click [26], DPDK [29], and the hardware hash from RSS. We stress the fact that these hash-based functions represent the quality of load balancing achievable by existing stateless (*e.g.*, Beamer [37]) and stateful LBs (*e.g.*, Ananta [41]) LBs. We measure the 99th percentile flow completion time (FCT) tail latency for the increasing average server load. We note that CHEETAH reduces the 99th percentile FCT by a factor of $2-3$x compared to the best performing hash-based mechanism, *i.e.*, Hash RSS.

CHEETAH spreads the load uniformly. To understand why CHEETAH achieves better FCTs, we measure the variance of the servers' load over the experiment for an average server load of 60% and 16, 32, and 64 servers. Fig. 7 shows that (as expected) the variance of RR is considerably smaller than hash-based methods. This is because the load balancer iteratively spreads the incoming requests over the servers instead randomly spreading them. In this specific scenario, CHEETAH allows operators to leverage RR, which would otherwise be impossible with today's load balancers. Fig. 7 also shows that the quality of the hash function is important

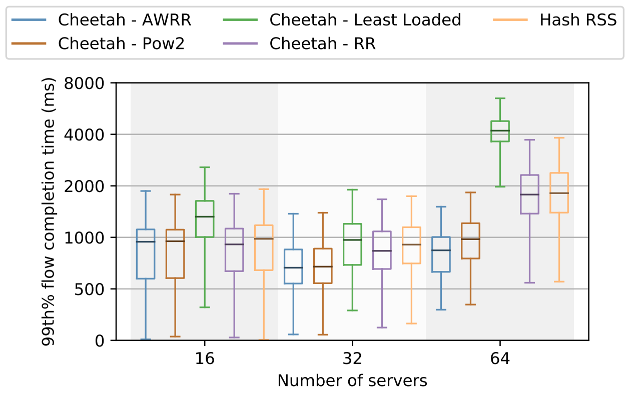

Figure 8: Evaluation of multiple load balancing methods for a bimodal workload. Both AWRR and Pow2 outperform Hash RSS by a factor of 2.2 and 1.9 respectively with 64 servers.

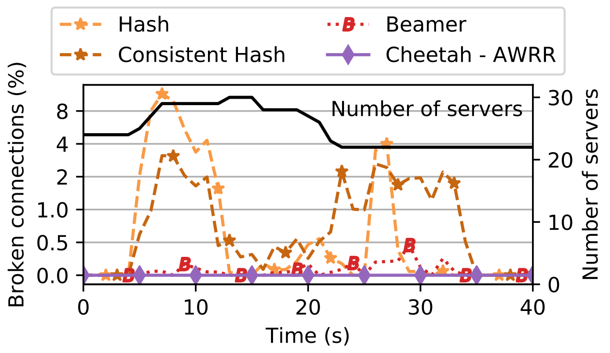

Figure 9: Percentage of broken requests while scaling the number of servers. Cheetah guarantees PCC whereas hashing breaks up to 11% of the connections, consistent hashing 3% and Beamer up to 0.5%.

as the default function provided in Click does not perform well. In contrast, the CRC hash function used by DPDK is comparable to the Toeplitz based function used in RSS [28]. Moreover, the RSS function has the advantage of being performed in hardware.

CHEETAH improves FCT even with non-uniform workloads. Fig. 8 shows the tail FCT for a bimodal workload, where 10% of requests take 500ms to be ready for dispatching and the remaining ones take a few hundred microseconds. In this scenario, some servers will be loaded in an unpredictable way thus creating a skew that requires direct feedback from the servers to solve. We can immediately see that RR with 64 servers leads to very high FCTs. We evaluate three ways to distribute the incoming requests according to the current load (see Sect. 4.1): automatic weighted round robin (AWRR), power of two choices (Pow2), and the least loaded server. Each server piggybacks its load using a monitoring Python agent on the server that reports its load through an HTTP channel to the LB at a frequency of 100Hz, though experimental results showed similar performance at 10Hz. Least loaded performs poorly since it sends all the incoming requests to the same server for 10ms, overloading a single server. Pow2 and AWRR spread the load more uniformly as the LB penalizes those servers that are more overloaded. Consequently, both methods reduce the FCT by a factor of two compared to Hash RSS with 64 servers. These experiments demonstrate the potential of deploying advanced load balancing mechanisms to spread the service load.

5.3 PCC Violations Analysis

We close our evaluation by demonstrating the key feature of the stateless CHEETAH LB, *i.e.*, its ability to avoid breaking connections while changing the server and/or LB pool sizes. We compare CHEETAH against Hash RSS, consistent hashing, and Beamer. We start our experiment with a cluster consisting of 24 servers. We tune a python generator [4] to create 1500 requests/s, increasing following a sinusoidal load to 2500 requests/s and descending back to 1500 over the 40 seconds of the experiment. The size and duration of the requests are served using the web server distribution. We iteratively add 7 servers to the pool as the load increases. We then drain 8 servers when the rate goes down. Fig. 9 shows the percentage of broken requests over completed requests every second over time. Some connections gets accounted as broken dozen of seconds later as clients continue sending retransmission before raising an error. Compared to Beamer, Cheetah not only achieves better load balancing with AWRR (Sect. 5.2), but it also does not break any connection.

6 Frequently Asked Questions

Does CHEETAH preserve service resilience compared to existing LBs? Yes. We first discuss whether a client can clog a server. A client generating huge amounts of traffic using the same connection identifier can be detected and filtered out using heavy-hitter detectors [41]. This holds for any stateless LBs, *e.g.*, Beamer [37]. A more clever attack entails reverse engineering the salted hash function and deriving a large number of connection identifiers that the LB routes to the same (specific) server, possibly with spoofed IP addresses. To do so, an attacker needs to build the $(conn.id, cookie) \mapsto server$ mapping. This requires performing complex measurements to verify whether two connection IDs map to the same server. Given that CHEETAH uses the same hash function of any existing LB (which is not cryptographic due to their complexity [3]), reverse engineering this mapping will be as hard as reverse engineering the hash of the existing LBs. As for the resilience to resource depletion, we note from Fig. 5 that stateless (stateful) CHEETAH has similar (better) packet processing times of today's stateless (stateful) LBs. Thus, we argue that CHEETAH achieves the same levels of resilience of today's existing LB systems.

Does CHEETAH make it easy to infer the number of servers? Not necessarily. A 16-bit cookie permits at least an order of magnitude more servers than the number of servers used to operate the largest services [32]. If this is still a concern, one can hide the number of servers by reducing the size of the cookie and partitioning the connection identifier space similarly to our stateful design of CHEETAH.

Does CHEETAH support multipath transport protocols? Yes. In multipath protocols, different sub-connection identifiers must be routed to the same DIP. Previous approaches exposed the server's id to the client [10, 39]; however, this decreases the resilience of the system decreases. CHEETAH can use a different permutation of `AllServers` for each additional *i*'th sub-connection. Clients inform the server of the new sub-connection identifier to be added to an existing connection. The server replies with the cookie to be used using the *i*'th `AllServers` table. This keeps the resilience of the system unchanged compared to the single path case.

7 Related Work

There exists a rich body of literature on datacenter LBs [2, 7, 11, 13, 16, 18–20, 22–25, 32, 37, 41, 52, 53]. We do not discuss network-level DC load balancers [2, 7, 16, 18, 22, 24, 25, 52], whose goal is to load balance the traffic within the DC network and do not deal with per-connection-consistency problems.

Stateless LBs. Existing stateless LBs rely on hash functions and/or "daisy chaining" techniques to mitigate PCC violations (2), *e.g.*, ECMP [19], WCMP [53], consistent hashing [23], Beamer [37], and Faild [3]. The main limitation of such schemes is the suboptimal balancing of the server loads achieved by the hash function, which is known to grow exponentially in the number of servers [49]. Shell [42] proposed a similar use of the timestamp option as a reference to an history of indirection tables, which comes at both the expense of memory and low-frequency load rebalancing.

QUIC-LB [11] is a high-level design proposal at the IETF for a stateless LB that leverages the `connection-id` of the QUIC protocol for routing purposes. While sharing some similarities to our approach, QUIC-LB *(i)* does not present a design of a stateful LB that would solve cuckoo-hash insertion time issues, *(ii)* does not evaluate the performance obtainable on the latest generation of general-purpose machines, *(iii)* relies on the modulo operation with an odd number to hide the server from the client, an operation that is not supported in P4, and *(iv)* does not discuss multi path protocols. We note that our cookie can be implemented as the 160-bit `connection-id` in QUIC, which is also easier to parse than the TCP timestamp option. Encoding the connection-to-server mapping has recently been briefly discussed in an editorial note without discussing LB resilience, stateful LBs, or implementing and evaluating such a solution [31].

Several stateless load balancers that support multi path transport protocols have been proposed in the past. Such load balancers guarantee all the subflows of a connection are routed to the same server by explicitly communicating an identifier of the server to the client [10, 39]. These approaches may be exploited by malicious users to cause targeted imbalances in the system, which is prevented in CHEETAH thanks to using distinct hashes for the subflows (see Sect. 6).

Stateful LBs. Existing stateful LBs store the connection-to-server mapping in a cuckoo-hash table [13, 15, 20, 32, 41] (see Sect. 2). These LBs still rely on hash-based LB mechanisms — as these lead to fewer PCC violations when changing the number of LBs. In contrast, CHEETAH decouples PCC support from the LB logic, thus allowing operators to choose any realizable LB mechanism. Moreover, cuckoo-hash tables suffer from slow (non-constant) insertion time. FlowBlaze [43] and SilkRoad [32] tackled this problem using a stash-based and bloom-filter-based implementations, respectively. Yet, both solutions cannot guarantee insertions in constant-time: FlowBlaze relies on a stash that may be easily filled by an adversary while SilkRoad is limited by both the size of the Bloom Filter and the complexity of the implementation. CHEETAH uses a constant-time stack that is amenable to fast implementation in the dataplane. Existing stateful LBs also suffer from the fact that the 1st-tier of stateless ECMP LBs reshuffle connections to the wrong stateful LB when the number of LBs changes. In contrast, 1st-tier stateless CHEETAH guarantees connections reach the correct stateful LB regardless of changes in the LB pool size.

8 Conclusions

We introduced CHEETAH, a novel building block for load balancers that guarantees PCC and supports any realizable LB mechanisms. We implemented CHEETAH on both software switches and programmable ASIC Tofino switches. We consider this paper as a first step towards unleashing the power of load balancing mechanisms in a resilient manner. We leave the question of whether one can design novel load balancing mechanisms tailored for Layer 4 LBs as well as deployability with existing middleboxes as future work.

APPENDIX

A Proof of Theorem 1

Theorem 1. Given an arbitrarily large number of connections, any load balancer using $O(1)$ memory requires cookies of size $\Omega(\log(k))$ to guarantee PCC under any possible change in the number of active servers, where k is the overall number of servers in the DC that can be assigned to the service with a given VIP.

Proof sketch. We prove the statement of the theorem in the widely adopted Kolmogorov descriptive complexity model [27]. We leverage similar techniques used in the past to demonstrate a variety of memory-related lower bounds for shortest-path routing problems [14].

Let R be the set of all the possible connection identifiers. Let C be the set of all possible cookies. Let $S = \{s_1, \dots, s_k\}$ be the set of servers. We assume $|R| \gg |S|$, which is the most interesting case in real-world datacenters. Suppose, by contradiction, that there exists an LB which uses $O(1)$ memory with cookies of size smaller than $\log(k)$ bits that guarantees under any arbtirary number of changes in the subset of active servers $A \subseteq S$. For any possible set of active servers A, the LB maps a new incoming connection identifier $r \in R$ to a certain server $s \in S$, *i.e.*, the LB logic maps incoming connections using an arbitrarily function $f : R \times 2^A \to S$.

Let us now restrict our focus to the $|S|$ distinct sets of active servers in which only a single server is active, *i.e.*, $A_1 = \{s_1\}, \dots, A_k = \{s_k\}$. Depending on the time instance when a connection $r \in R$ arrives, the connection may be mapped to any of these servers. The mapping must be preserved for the entire duration of the connection, which means the LB must be able to forward any future packet belonging to r regardless of the current set of active servers. Therefore, the LB must be able to distinguish among $|R| \times |S|$ distinct possible mappings between connections and servers. Consider our cookie with l bits, where $l < |S| = \log(k)$. This information allows us to distinguish among $|R| \times l$ possible mappings, which leaves $|R| \times (|S| - l) = O(|R||S|)$ mappings to the LB memory. This is a contradiction since we assumed the LB uses a memory of $O(1)$. □

It is trivial to verify that the above theorem holds even if one wants to implement an advanced LB mechanism, *e.g.* round-robin, least-loaded, even without allowing any changes in the number of servers.

B Constant-size cookies

Minimizing PCC violations with constant-size cookies: keeping a history at the LB. A simple way to deal with changes in the number of active servers when using a uniform-hash load balancing mechanism is to encode in the cookie a *tag* that can be used by the LB to uniquely identify a previous configuration of active servers. The LB stores the last n configurations of active servers and identifies them using $\log_2(n)$ bits, which are encoded into the cookie. Thus, as long as a connection is mapped to a server that existed in any of the last n configurations, the connection will be unbroken. The LB can modify the cookie associated with a connection to use "fresher" cookies. [8]. Clearly, if an operator drains a server, *i.e.*, purposely does not assign new connections to it, any remaining connections will be broken after n changes in the tag.

Minimizing load imbalances using constant-size cookies: adding a hash function index to the cookie. A common technique to reduce load imbalances in a system is to rely on "power-of-two" choices mechanisms to map a request to a server. When the LB receives a new incoming connection, it computes the hash of the connection identifier using two different hash functions h_1 and h_2, whose outputs are used to select two servers. The LB then compares the load of the two selected servers and maps the incoming connection to the least loaded server among these two (according to some definition of "load"). The main issue in the DC context with power-of-two choice load balancing mechanisms is that the LB needs to remember for each connection, which of the two servers was used to serve the connection, that is, the LB must be stateful. CHEETAH can support a power-of-two choices LB mechanism simply by storing in the cookie a single bit that identifies which of the two hash functions is to be used for that connection. Similarly, multiple hashes could be supported by increasing the size of the cookie logarithmically in the number of hash functions. We note that when the number of servers change, connections may break. We refer the reader to the previous paragraph on how to deal with PCC violations with constant-size cookies.

C TCP timestamp encoding

We decided to encode the CHEETAH cookie into the 16 most significant bits of the TCP timestamp. We acknowledge that alternative ways to encode information into the TCP timestamps are possible [39] but require modifications to the servers.

Encoding cookies in the TCP timestamp option. TCP end-hosts use TCP timestamp options to estimate the RTT of the connection. The timestamp consists of a 64-bit pair (TS_{val}, TS_{ecr}), where TS_{val} and TS_{ecr} are the 32-bit timestamps set by the sender and receiver of the packet, respectively. When an end-host receives a packet, it echoes the TS_{val} back to the other end-host by copying it into the TS_{ecr}. We leverage the TS_{val} to carry the CHEETAH cookie on every packet directed towards the client, which will echo it back as the TS_{ecr}. We encode the cookie in the 16 most significant bits of the 32-bit TS_{val} for every packet directed towards a client.[9] We must therefore fix the original 16 most significant bit of the TS_{ecr} before it is processed by the TCP stack of the server. This can be done in the load-balancer or on the server itself. Our measurements of the top 100 ranked Alexa websites [1] reported in App. D shows that the minimal unit of a timestamp is 1 millisecond. This means that the least significant 16 bits of the timestamp would wrap up every 2^{16}ms.

TCP timestamps are mostly supported in today's OSes. We ran a small experiment to verify whether today's client devices support the echoing of TCP timestamp options back to the servers. We tested the latest OSes available in both recent smartphones and desktop PCs: Google Android 9, iOS 13, Ubuntu 18.04, Microsoft Windows 10, and MacOS 10.14. We observed that all except Microsoft Windows correctly negotiate and echo the TCP timestamp option when the server requires to use it. Based on some recent measurements, more than 98% of the smartphone and tablet devices are either using Android or iOS [46]. Smartphone devices are the most common type of devices, representing 53% of all devices [45]. For desktop devices, Windows is the predominant OS with over 75% of the desktop share whereas MacOS represent a 16% of this share [44]. For Windows desktop devices, a cloud operator can either encode the cookie in the QUIC header (69% of the Windows users use Google Chrome, compatible with QUIC [35]), IPv6 address, or install stateful information into the LB for these devices.

C.1 Fixing the timestamp in the load balancer

For each server, we keep in memory two versions of the 16 most significant bits (MSB) replaced by our cookie: the current one and the previous one. We use one bit of the cookie to remember the version of the original MSB for every given packet sent to the client. When a wrap up of the timestamp happens, we set the oldest MSB bucket to the new MSB timestamp of the server, and we change the version bit of outgoing packets to designate that one. When a packet is received, the cookie is read, then the original MSB given by the version bit found in the packet reader is rewritten back in

[8]This operation requires a bit more than one Round-Trip-Time (RTT) to update the client from the LB (the packet must first be processed by the server, which has to send an acknowledgment to the client with the updated cookie

[9]Timestamp options have already been used in the past for protecting against SYN flood attacks, *e.g.*, TCP SYN cookies [12]. We note that several large cloud networks completely disable TCP SYN cookies and rely on different mechanisms to handle SYN flood attacks [30], thus CHEETAH would not cause deployment issues. We note that an alternative implementation of CHEETAH, in which the mapping with the server is only performed at the end of the 3-way handshake does not prevent the cloud provider from using TCP SYN cookies. This solution requires all the servers to use exactly the same parameters when generating the TCP SYN cookies and is left as a minor future work extension.

the timestamp of the packet. To avoid having clients sending very old cookies, we rely on TCP keepalives set to 25 seconds, which allows us to both detect timestamp wraps at the LB[10] and deal with TCP PAWS packet filters[11].

C.2 Fixing the timestamp on the server

We modified the Linux Kernel 5.1.5 (available at [12]) to enable the same mechanism directly on the server. Doing so increase the server packet processing time by only 0.2%, as the timestamp is parsed in any cases on the server. This enables the server to keep the value of the cookie, and directly encode the cookie in the TS_{val}. Such returning packet do not need to go through the load balancer and allows the use of DSR. Having the cookie on both sides of the load-balancer is also needed for the stateful implementation.

D Alexa Top100 Timestamp Measurements

We ran a comprehensive set of measurements to determine the granularity of the TCP timestamp unit utilized by the largest service providers according to the Alexa Top100 ranking [1]. We downloaded large files from each the top 15 ranked web sites and extracted both the TCP timestamp TS_{val} options and the client side timestamp. We then computed the difference between the TCP last and first timestamps and divided this amount by the different between the client measured last and first (non-TCP) timestamps. The result is the granularity of the server-side TCP timestamp unit. We report the results in Table 2. All the service providers using TCP timestamps have a granularity of at least 1ms. This means the timestamp wraps every $2^{16} \approx 65$ seconds when using CHEETAH to support these services.

Table 2: Measured TCP timestamp granularity for different websited. Some service providers do not use TCP timestamp options.

Web site	**TS granularity**	**Method**
drive.google.com	1ms	gdown
dropbox.com	1ms	wget
twitch.tv	1ms	watch video
weobo.com	1ms	watch video
bilibili.com	N.A.	-

imdb.com	10ms	watch video

[10]Detecting a wrap at the server is a straightforward operation. To detect a wrap at the LB, we need to guarantee the server sends a packet at least once every 2^{15}ms$\approx$ 33s.This would typically be the case for every real-world Internet service.

[11]We note that flipping the MSB of the timestamp (*i.e.* the version bit) every time a wrap is detected may create problems with PAWS [8]. PAWS is a TCP mechanism that discards packets with TCP timestamps that are not "fresh", *i.e.*, a timestamp is considered *old* if the difference between the latest received timestamp and the newest received timestamp is smaller than 2_{31}. To avoid enabling this condition, it is sufficient to guarantee the server keeps a TCP keep-alive timer of $(2^{15} - \max RTT)$ milliseconds. Assuming a $\max RTT$ of 5 seconds, we set the keep-alive to a conservative value of 25 seconds. With 100K connections, the bandwidth overhead is just 0.00002% on a 100Gbps server interface.

Programmable Calendar Queues for High-speed Packet Scheduling

Naveen Kr. Sharma[*] *Chenxingyu Zhao*[*] *Ming Liu*[*] *Pravein G Kannan*[†] *Changhoon Kim*[‡]
Arvind Krishnamurthy[*] *Anirudh Sivaraman*[§]

Abstract

Packet schedulers traditionally focus on the prioritized transmission of packets. Scheduling is often realized through coarse-grained queue-level priorities, as in today's switches, or through fine-grained packet-level priorities, as in recent proposals such as PIFO. Unfortunately, fixed packet priorities determined when a packet is received by the traffic manager are not sufficient to support a broad class of scheduling algorithms that require the priorities of packets to change as a function of the time it has spent inside the network. In this paper, we revisit the Calendar Queue abstraction and show that it is an appropriate fit for scheduling algorithms that not only require prioritization but also perform dynamic escalation of packet priorities. We show that the calendar queue abstraction can be realized using either dataplane primitives or control-plane commands that dynamically modify the scheduling status of queues. Further, when paired with programmable switch pipelines, we can realize programmable calendar queues that can emulate a diverse set of scheduling policies. We demonstrate the power of this abstraction using three case studies that implement variants of LSTF, Fair Queueing, and pFabric in order to provide stronger delay guarantees, burst-friendly fairness, and starvation-free prioritization of short flows, respectively. We evaluate the benefits associated with these scheduling policies using both a custom simulator and a small-scale testbed.

1 Introduction

Many network scheduling algorithms today require a notion of *dynamic priority*, where the priority of individual packets within a flow varies over the lifetime of the flow. These packet priorities generally change with either the amount of bytes sent by the flow, how fast the flow is transmitting, or time spent by the packet inside the network. Such scheduling algorithms enable richer application-level prioritization and performance guarantees, such as shortest-job first to minimize average flow completion time, earliest deadline first to enable timely delivery of all messages, or fair-queueing, as illustrated by a long list of proposed scheduling algorithms (e.g., pFabric [4], PIAS [5], WFQ [14], FIFO+ [13], LSTF [17], and EDF [18]).

Switch-level support for multiple fine-grained priority levels (as in PIFO [28], pHeap [7]) can aid the realization of these scheduling algorithms. However, there are still several challenges in faithfully implementing these algorithms efficiently and at line rate. First, implementing strict and fine-grained priority levels is expensive, especially at scale involving high bandwidths and hundreds or thousands of unique flows at multiple terabits per second. Second, and more crucially, existing switch support for priorities does not allow for dynamic changes to the priority of a packet during its stint inside the switch buffer. Fixed packet priorities cannot effectively emulate the *ageing* property required by many of the scheduling algorithms, wherein the priority of a packet increases with the time it spends inside a queue.

Consider, for instance, the Least Slack Time First (LSTF [17]) scheduling discipline wherein each packet maintains a delivery deadline, and the switch emits from its buffer the packet with the least slack at a given instant. LSTF cannot be realized using fixed packet priorities that are determined when the packets are inserted into a priority queue. Notably, given a packet that has a deadline of $current\_time + slack$, a switch scheduler that maps this deadline to a priority level would quickly exhaust a *finite* number of priority levels. As long as there are packets buffered inside the switch, packets received with later deadlines would have to be progressively assigned lower priority levels, and the switch will eventually run out of priority levels to use for incoming packets.

In this paper, we argue that what is needed is a scheduling mechanism that supports both prioritization and implicit escalation of a packet's priority as it spends more time inside the switch buffer. We observe that a mechanism similar to Calendar Queues [10] would be a more appropriate fit for implementing these scheduling algorithms. Calendar Queues allow events (or packets) to be enqueued at a priority level or rank corresponding to a future time, and this rank gradually changes as time moves forward. A scheduling algorithm simply decides how far in the future a packet must be processed and then controls how time is advanced, say based on the switch's physical clock (i.e., *physical time*) or the number of communication rounds across flows (i.e., *logical time*).

Calendar queues have certain properties that make them amenable to efficient hardware realization, especially on upcoming programmable switch hardware. A calendar queue consists of multiple physical switch queues, and at any point in time, only one of the queues in a calendar queue is active. Further, a calendar queue imposes a fixed rotation order for activating queues. We describe how the activation of queues in a fixed order can be achieved by periodically modifying the priority and active status of queues, either through dataplane primitives expected in future programmable switches or through today's control-plane operations, albeit at a higher

[‡]Barefoot Networks
[§]NYU

latency. When combined with the stateful and flexible packet processing capabilities of a programmable switch (such as Barefoot's Tofino and Cavium's Xpliant), we can customize the calendar queue abstraction to realize a broad class of scheduling algorithms that capture both physical and logical notions of time.

We demonstrate the power and flexibility of the calendar queue abstraction using three case studies. First, we use a calendar queue to perform deadline-aware scheduling of aggregate flows (or co-flows) and further use the same underlying calendar queue to implement fair queuing for the background traffic. The programmable switch pipeline performs the accounting operations required to keep track of the slack available for a packet and computes its rank as it traverses a network path. In our second case study, we use calendar queues to implement fair queueing and its variants that can tolerate a limited amount of burstiness, thereby providing a configurable balance between fairness and burst-friendliness. Here, the programmable switch pipeline maintains the flow state to perform the accounting operations required for scheduling. For our third case study, we realize pFabric and its variant that can provide a configurable amount of starvation prevention. We use a programmable pipeline to ensure the in-order transmission of packets even as the switch attributes higher priorities to later packets transmitted within a flow. We use a small-scale testbed comprising of Barefoot Tofino switches and a custom event-driven simulator to evaluate the benefits of these different scheduling algorithms.

2 Background

In this section, we discuss background material related to reconfigurable switches, the structure of the traffic manager (which is the same for both fixed-function and today's reconfigurable switches), and prior work on programmable packet scheduling.

2.1 Reconfigurable Switches

In this work, we assume that this programmable scheduling is used in conjunction with a reconfigurable switch, such as the Reconfigurable Match Table (RMT) model described in [8, 9]. A reconfigurable switch can operate at terabits/s by providing a restricted match+action (M+A) processing model: match on arbitrary packet header fields and perform simple packet processing actions. When a packet arrives at the switch, relevant headers fields are extracted via a user-defined parser and passed into a pipeline of user-defined M+A stages. Each stage matches on a subset of extracted headers and performs simple processing primitives or actions on any header. After traversing the ingress pipeline stages, packets are deposited in one of the multiple queues, typically 32–64, associated with the egress port for future transmission. On transmission, the packet goes through a similar egress pipeline undergoing further modifications.

In addition to a programmable parser and pipeline stages, these switches provide several hardware features to implement more complex use-cases: (1) a limited amount of stateful memory, such as counters and meters, which can be read and updated to maintain state across packets, (2) computation primitives, such as simple arithmetic operations and hashing, which can perform a limited amount of processing on header fields and data retrieved from stateful memory, and (3) the ability to recirculate or generate special datapath packets using *timers* that can be used to modify Traffic Manager status as well as synchronize the ingress and egress pipelines. Further, switch metadata, such as queue lengths, congestion status, and bytes transmitted, can also be used in packet processing. The complete packet processing, including parsing and match+action stages, can be configured using a high-level language, such as P4 [8]. A number of such switches, e.g., Cavium XPliant [11], Barefoot Tofino [6] and Intel Flexpipe [20], are available today.

A single pipeline's throughput is limited by the clock frequency achievable using today's transistor technology (typically about 1 GHz). To scale to higher packet-processing rates, which is required for switches with aggregate switch capacity in the Tbit/s range, the switch consists of multiple identical pipelines where the programmable stateful memory is local to each pipeline.

2.2 Traffic Manager

We now briefly describe the architecture of the traffic manager (TM) on merchant-silicon switches (e.g., Barefoot's Tofino and Broadcom's Trident series). The TM is responsible for two tasks: (1) buffering packets when more than one input port is trying to send packets to the same output port simultaneously, and (2) scheduling packets at each output port when the link attached to the port is ready to accept another packet.

Buffering: The TM is organized as a fixed number of first-in, first-out (FIFO) queues per output port. The ingress pipeline of the switch is responsible for determining both the FIFO queue and the output port that the packet should go to. Once the packet exits the ingress pipeline, the TM checks if there is sufficient space in the packet buffer to admit the new packet. Once the packet has been admitted to the buffer, it can not be dropped later because dropping a previously enqueued packet requires additional memory accesses to the packet buffer, which is expensive at line rate.

Scheduling: Packets are eventually dequeued from the buffer when the link attached to an output port goes idle and requests a new packet. During dequeue, the TM has to pick a particular FIFO at that output port, remove the earliest packet at that queue, and transmit it. The TM uses a combination of factors to determine which queue to dequeue from. First, each queue has a priority; queues with higher priority are strictly preferred to those with lower priorities. Next, within a priority level, the queues are scheduled in weighted round-round robin order (using an algorithm like DRR [26]). Lastly, each queue can be limited to a maximum rate and is paused and removed from consideration for scheduling if it has exceeded this rate over some time interval. Queues can also be paused because of a PFC [16] pause frame from a downstream switch.

To perform buffering and scheduling, the TM maintains a per-queue priority level, a per-queue pause status flag, and counters that track buffer occupancy on a per-input-port, per-PFC-class, per-output-port, and per-output-FIFO basis. These are required both to decide when and whether to admit packets and which queues to schedule. Because the status flag and counters support limited operations (e.g., toggling or increment/decrement), they can be implemented very efficiently in hardware, allowing simultaneous access from multiple ingress and egress switch pipelines in a single clock cycle (unlike state within the pipeline that can only be accessed once per clock cycle). It is important to note that these hardware mechanisms appear in traffic managers in both fixed-function and programmable switches.

2.3 Programmable Scheduling

The discussion above focused on a fixed-function TM that supports a small menu of scheduling algorithms (typically priorities, weighted round-robin, and traffic shaping). Recent proposals for programmable scheduling [2, 19, 23, 27–29] propose additional switch hardware in the TM to make the scheduling decision programmable, assuming the existence of a programmable ingress and egress switch pipeline like RMT. Of the proposals for programmable scheduling, we describe the PIFO work because it targets a switch similar to our paper, and it is representative of the hardware considerations associated with programmable scheduling. We defer a detailed comparison of both expressiveness and feasibility with prior work to later sections.

PIFOs enable programmable scheduling by using a programmable priority queue to express custom scheduling algorithms. Some external computation (either on the end host or a programmable switch's ingress pipeline) sets a rank for the packet. This rank determines the packet's order in the priority queue. By writing different programs to compute different kinds of packet ranks (e.g., deadlines or virtual times), different scheduling algorithms can be expressed using PIFOs.

While PIFOs are flexible, they have two shortcomings. PIFOs not only require the development of new hardware blocks that can scale with line rate (as we discuss below), but they are also limited given their support for a finite priority range (as we discuss in the next section). The scaling challenge arises out of needing to maintain a priority queue. The PIFO paper assumes that ranks within flows are naturally in strictly increasing order (i.e., flows are FIFOs), requiring the switch to only find the minimum rank among the head packets across all flows. While this reduces the sorting/ordering requirement of PIFO, sorting the total number of flows in the buffer is still challenging. The PIFO work provides a custom hardware primitive, the flow scheduler, which maintains a sorted array of a few thousand flows and can process tens of flows per output port across about 64 output ports on a single pipeline for an aggregate throughput of 640 Gbit/s. Scaling this primitive to higher speeds and a multi-pipeline switch can be challenging. Thus, a key goal of our programmable scheduling proposal is that it should be realized without increasing the temporal and spatial complexity of existing TM implementations.

3 Packet Scheduling using Programmable Calendar Queues

In this section, we begin by describing the Calendar Queue concept as introduced by Randy Brown in 1988 [10]. We then consider the abstraction of a Programmable Calendar Queue that combines the calendar queue scheduling mechanism with programmable packet processing pipelines. This combination allows for flexibility and extensibility, and we show how we can instantiate different variants of Programmable Calendar Queues to emulate different scheduling algorithms that appear in the literature.

3.1 Motivating Calendar Queues

Calendar Queues: The Calendar Queue was first introduced for organizing the pending event set in a discrete event simulation. It is a type of priority queue implementation that has low insertion and removal costs for certain priority distributions. Calendar Queues (CQs) are analogous to desk calendars used for storing future events for the next year in an ordered manner. A CQ consists of an array of buckets or queues, each of which stores events for a particular *day* in sorted order. Events can be scheduled for a future date by inserting the event in the bucket corresponding to the date. At any point, events are dequeued and processed from the current day in sorted order. Once all events are processed from the current day, we stop processing events for the current day and move onto the next day. The emptied bucket is then used to store tasks that need to be performed a year from now.

Drawbacks of existing priority queueing schemes: Prior work has made the observation that, scheduling algorithms make two decisions: in what order packets should be scheduled (in the case of work-conserving algorithms) or when they should be scheduled (in the case of non-work-conserving algorithms). For most scheduling algorithms, these decisions can be made at packet enqueue time. Comparison-based fine-grained priority queueing schemes, such as pHeap [7] or PIFO [28], can realize some of these algorithms by computing an immutable *rank* for a packet at packet enqueue time and dequeuing packets in increasing rank order. Eiffel [23] further observes that packet ranks often have a specific range (which can be expressed as integers) and that a large number of packets share the same rank. These characteristics make a bucket-based priority queue an efficient and feasible solution for implementing various scheduling algorithms.

We observe that many scheduling algorithms cannot be realized using fine-grained priority queuing schemes if the

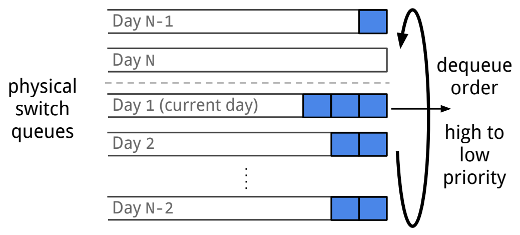

Figure 1: Example of a Programmable Calendar Queue.

computed rank needs to fall within a finite range. Consider the example of fair queuing (as in WFQ or STFQ), where for each arriving packet, a finishing round is computed based on the current round number and the finishing round of the previous packet in that packet's flow. Packets are then transmitted in order of increasing finishing round numbers. Further, the algorithm periodically increases the current round number. One could attempt to realize fair queuing using a fine-grained priority queuing scheme by mapping a packet's finishing round number to an immutable rank. Since the ranks of buffered packets cannot be changed, the mapping function needs to be monotonic, i.e., it needs to map higher finishing rounds to higher ranks. The mapping function would then exhaust any finite range of ranks, and the switch would then not be able to attribute a meaningful rank for incoming packets.

Similarly, in the case of the earliest deadline first (EDF), each packet in a flow is associated with a wall-clock deadline, and packets need to be scheduled in increasing order of deadlines. If one were to compute the rank of a packet as a monotonic function of the packet's deadline, the switch would exhaust the rank space as the wall-clock time progresses.

It is worth noting that, when the switch has no buffered packets, the mapping function could execute a "reset" and start reusing lower ranks. However, an implementation cannot assume that the switch would ever enter such a state, let alone periodically (i.e., within a bounded period of time before the rank space is exhausted).

Utility of Calendar Queues: We propose to use the Calendar Queues abstraction as a mechanism to realize scheduling algorithms such as EDF and fair queuing. A CQ is an attractive option for implementing these algorithms as it allows for implicit and en-masse escalation of the priorities of buffered packets when the CQ moves from one day to another. For instance, when a CQ completes processing the events for Day k and performs a *rotation* to Day $k+1$, it implicitly increases the priority of all days except Day k, which now occupies the lowest priority in the priority range. This rotation mechanism allows scheduling algorithms to escalate the priorities of buffered packets with time (as is the case with EDF and fair queuing) and reuse emptied buckets for incoming packets with low priority.

3.2 Programmable Calendar Queues (PCQs)

We now describe Programmable Calendar Queues in the context of reconfigurable switches. The programmable packet processing pipelines on these switches allow us to customize not only the rank computation but also the CQ rotation process. Just like a calendar has 365 days, we assume our Calendar Queue abstraction has a fixed number of buckets or FIFO queues, say N, each of which stores packets scheduled for next N periods (see Figure 1). Any network scheduling algorithm using CQs must then make the following key decisions. First, the scheduling algorithm must decide how far in the future the incoming packet should be scheduled, i.e., choose a future period from [0, N-1] to enqueue the packet into. This is similar to rank computation in PIFO. Second, it must periodically decide when and how to advance time, i.e., decide when a period is over and move onto the next period. This stops the enqueueing of packets in the current period and allows the reuse of the corresponding queue resource for the period that is *N* periods into the future. Third, when the CQ advances to the next period, the pipeline state has to be suitably modified to ensure the appropriate computation of ranks for incoming packets.

The advancing of time can be done using a physical clock, i.e., the CQ moves onto the next queue after a fixed time interval periodically; we call this a *Physical* Calendar Queue. Alternatively, the CQ can advance to the next queue whenever the current queue is empty, i.e., it happens logically depending on metrics such as bytes sent or number of communication rounds; we call this a *Logical* Calendar Queue. A Physical Calendar Queue lets us implement both work-conserving schemes, such as EDF, and non-work-conserving schemes, such as Leaky Bucket Filter, Jitter-EDD, and Stop-and-Go, whereas a Logical Calendar Queue can implement work-conserving schemes, such as LSTF, WFQ, and SRPT.

We now list the interface methods exposed to the packet processing pipelines that enable these forms of customization.

- **CQ.enqueue(n)**: Used by the ingress pipeline to schedule the current packet *n* periods into the future.
- **CQ.dequeue()**: Used by the egress pipeline to obtain a buffered packet, if any, for the current period.
- **CQ.rotate()**: Used by the pipelines to advance the CQ so that it can start transmitting packets for the next period.

We observe that PCQs have certain properties that allow for efficient implementations. (In Section 3.4, we describe how to realize this abstraction in hardware.) When individual CQ periods are mapped to separate physical switch queues, a CQ scheduler needs to maintain state only at the granularity of switch queues (e.g., the queue corresponding to the current period). The scheduler does not require expensive sorting or comparisons to determine packet transmission order. More importantly, a CQ rotation involves a deterministic and predictable transition from one switch queue to another at the end of each period. This transition can be realized either using data-plane primitives in upcoming reconfigurable hardware (as we discuss in Section 3.4) or through the switch's control plane (as is the case with our prototype).

3.3 Programmable Scheduling using PCQs

We now show how various scheduling algorithms can be realized using Calendar Queues in conjunction with a programmable packet processing pipeline. We describe three different algorithms, each of which differs in the way it utilizes CQs. First, an approximate variant of WFQ that uses a *Logical* CQ. Next, we implement approximate EDF using LSTF scheduling that uses a work-conserving *Physical* CQ. Finally, we realize a Leaky Bucket Filter that utilizes a non-work-conserving *Physical* CQ.

3.3.1 Weighted Fair Queueing

Weighted Fair Queueing (WFQ) scheduling achieves max-min fair allocation among flows traversing a link by emulating a bit-by-bit round-robin scheme where each active flow transmits a single bit of data each round. This emulation is realized at packet granularity by assigning each incoming packet a departure *round number* based on the current round number and the total bytes sent by the flow. All buffered packets are dequeued in order of increasing departure round numbers.

Packet State
```
 weight : Packet flow’s weight
```
Switch State
```
 bytes[f] : Number of bytes sent by flow f
 round    : Current round number
 BpR      : Bytes sent per round for each flow
```
Rank Computation & Enqueueing
```
 bytes[f] = max(bytes[f], round * BpR * weight)
 n = (bytes[f] + pkt.size) / (BpR * weight) - round
 CQ.enqueue(n)
```
Queue Rotation
```
 if CQ.dequeue() is null
   CQ.rotate()
   round = round + 1
```

Figure 2: WFQ implementation using a Logical CQ.

We implement WFQ using Logical CQs closely following the round number approximation described in [25]. We use coarse-grain rounds that are only incremented after all active flows have transmitted a configurable quantum of bytes. The rank computation is done in such a way that each fair queuing round is mapped to a day (queue) in the Calendar Queue and, whenever a day finishes (i.e., the queue is drained completely), the round number is incremented by one. The complete switch state and computation required is shown in Figure 2. Note that this is an approximation of the WFQ algorithm where the round numbers are not as precise or faithful to the original algorithm, and there can be situations in which packets are transmitted in an *unfair* order. However, this *unfairness* has an upper-bound and is controlled by the BpR variable in the rank computation. As we show later in the evaluation, this approach closely approximates ideal fair queueing.

3.3.2 Earliest Deadline First

In Earliest Deadline First (EDF) scheduling, each packet from a flow is assigned a deadline or expected time of reception. At each network hop, the packet with the closest deadline is transmitted first. We implement EDF using Least Slack Time First scheduling, where each packet carries a *slack* value of the time remaining till its deadline. The slack is initialized to `deadline-arrivalTime` at the source and updated at each hop along the way (i.e., each switch subtracts the time spent at the hop from the slack). The implementation uses a Physical CQ, as shown in Figure 3, which we describe next.

Packet State
```
 slack : Initialize to flow_deadline - arrival_time
```
Switch State
```
 dT      : Time interval of each queue
 delta   : Skew between ideal and measured time
 lastRot : Timestamp of last rotation
```
Rank Computation & Enqueueing
```
 n = (slack - delta + (currentTime - lastRot)) / dT
 CQ.enqueue(n)
```
Queue Rotation
```
 if CQ.dequeue() is null
   CQ.rotate()
   delta = delta + (dT - (currentTime - lastRot))
   lastRot = currentTime
```

Figure 3: EDF using a work-conserving Physical CQ.

We choose a fixed time interval for each *day* or queue for our Physical CQ, say dT. Packets with an effective slack of $0 - dT$ are assigned to queue 1, slack of $dT - 2 \cdot dT$ are assigned to queue 2, and so on. This assignment ensures that packets with closer deadlines are prioritized. Queue rotation occurs when the current queue becomes empty. Since we can spend a longer or shorter time than dT in any queue depending on the traffic pattern, we require some additional state to ensure that new packets are inserted in the correct queue with respect to the deadlines of already enqueued packets. The `delta` variable keeps track of how far ahead the CQ is compared to the ideal time. If we spend less than dT for a queue, *delta* increases, and if we spend more than dT, it decreases. The *delta* is then incorporated in the rank computation and is reset to 0 whenever there are zero buffered packets. Note that the programmable switch pipeline allows us to perform not only the rank computation but also decide when to perform the CQ rotation and how to update switch state after a rotation.

3.3.3 Leaky Bucket Filter

A Leaky Bucket Filter (LBF) is a non-work-conserving scheduling algorithm that rate limits a flow to a specified bandwidth and a maximum backlog buffer size. An LBF can be realized using a Physical Calendar Queue by storing a fixed quantum of bytes per flow in each queue and rotating

Packet State

```
rate : Output rate limit
size : Maximum bucket size
```

Switch State

```
dT       : Time interval size of each queue
bytes[f] : Bytes sent by flow f
round    : Current round number
```

Rank Computation & Enqueueing

```
bytes[f] = max(bytes[f], round * rate * dT)
n = bytes[f] / (rate * dT) - round
if n > size / (rate * dT)
  drop packet
else
  CQ.enqueue(n)
```

Queue Rotation

```
if dT time has elapsed
  CQ.rotate()
  round = round + 1
```

Figure 4: A Leaky Bucket Filter using a non-work-conserving Physical CQ.

queues at fixed time intervals, very similar to the WFQ example discussed earlier. However, we do not dequeue packets from the next queue even if the current queue is empty, which gives us the desired non-work-conserving behavior. The byte quantum depends on the rate limit set for the flow and the configured time interval dT of each queue. If the number of enqueued bytes for a flow exceeds the bucket size, we simply drop the packet. This scheme lets us realize multiple filters using the same underlying CQ, as shown in Figure 4.

We assume the configured `rate` and `size` parameters for the filter are in the packet header, but they can be stored at the switch as well. For each flow, we keep track of bytes sent so far and compute the queue id by dividing it with the quantum, which is the configured filter rate times the queue interval dT. We assume that the cumulative rate of all flows does not exceed the line rate at the switch; if that happens, all flows will be slowed down in proportion to their configured rates equally.

3.4 Implementing PCQs in Hardware

We now describe how Calendar Queues can be implemented on programmable switches. We assume an RMT model switch (as described in Section 2) with an ingress pipeline, followed by the traffic manager, which maintains multiple packet queues, and finally an egress pipeline. Implementing a CQ in this model is non-trivial because the packet enqueue decision (i.e., which queue to insert the packet into) is made in the ingress pipeline, but the queue status (i.e., occupancy, depth) is available in the egress pipeline after the packet traverses the traffic manager. Since these modules are implemented as separate hardware blocks, we need to *synchronize* state among them to achieve the CQ abstraction.

We can realize CQs on programmable switches using mutable switch state, multiple FIFO queues, the ability to create and recirculate packets selectively, and the ability to pause/resume queues or alter queue priorities directly in the data plane. All these capabilities are either already available in today's programmable switches except for the data-plane-based queue pausing, resuming, and priority updating. However, we confirmed with experts in switching ASIC design that adding such a capability is relatively straightforward because doing so doesn't change the order of temporal or spatial complexity of existing TM implementations. Existing TMs already support several per-packet metadata to expose controllable features or statistics. Moreover, PFC already requires a similar queue pausing/resuming capability triggered by certain protocol messages in the data plane anyway. This new feature exposes a similar functionality only in a programmatic way by exposing such knobs to the programmable pipeline. Moreover, even in the absence of data-plane support for priority changes, we can still approximate this functionality using the control plane (as we do in our testbed).

Implementation Overview: We first provide a high-level description of our scheme. Each *period* in the CQ is mapped to a single FIFO queue within a set of queues associated with the outgoing port. The ingress pipeline computes which *period* or queue each incoming packet is enqueued into. We assume a TM that allows the pipeline to enqueue incoming packets into any of the available FIFO queues. At any given time, the queue settings satisfy the following properties: (a) The queue corresponding to the current period has the highest priority level, so that its packets can be transmitted immediately. We refer to this queue as the head queue. (b) The queue corresponding to the next period has a lower priority level and is active/unpaused. (c) All other queues corresponding to future periods are at the lowest priority level and are paused. This specific configuration has two desirable properties. First, since the next period's queue is also active, the switch can start transmitting packets from the next period's queue as soon as the head queue becomes empty. Second, when we perform a CQ rotation, we need to perform only a small number of changes to queue priorities and active statuses.

The CQ cycles or rotates through available queues one at a time, making each queue the head queue. The rotation is triggered when the head queue is empty (in case of a logical CQ) or the CQ time interval has elapsed (in case of a physical CQ). When a rotation happens, we need to make sure all packets from the head queue are drained completely and that it is empty before changing its priority to lowest. Once the priority is set, the head queue can be reused to store packets for future periods.

Implementation Details: We break down the implementation of CQs into the following three steps. Appendix A provides additional details.

Step 1 - Initiate Rotation: This step detects when a rotation needs to happen and initiates the rotation by informing the ingress pipeline using a recirculation packet. In the case of a logical CQ, we initiate rotation when the head queue is empty. This can be detected in two ways. First, in some

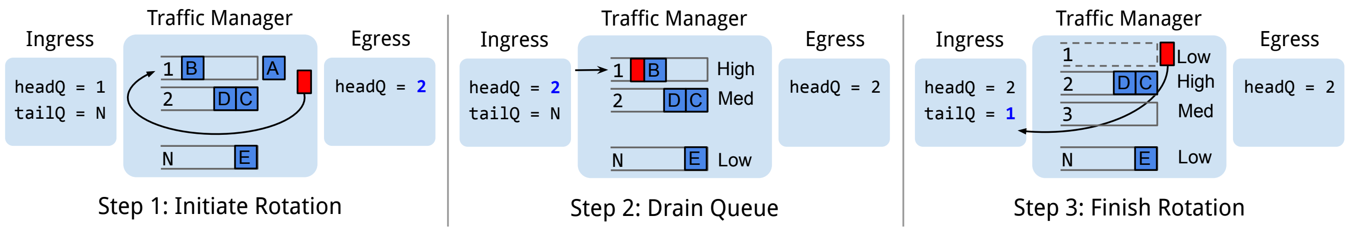

Figure 5: Step 1, the egress pipeline tries to dequeue from the current headQ, and if it is the last packet, it initiates rotation by creating and recirculating a `rotate` (red packet) to the ingress pipeline. Step 2, the ingress pipeline on receiving this packet, updates the headQ and enqueues a `marker` packet as the last packet into the old headQ. Finally in Step 3, when the egress pipeline receives the `marker` packet, it updates the queue priority and notifies the ingress pipeline that it is safe to reuse the queue for future packets by updating the tailQ.

programmable switches, the traffic manager metadata could provide the egress pipeline information regarding the depth of the queue from which the packet was dequeued. If it is zero, this is the last packet from the head queue, and we initiate rotation. Second, we can check the queue id from which the packet was dequeued to infer whether the head queue is empty. Since the successor head queue is also unpaused with a lower priority, a packet dequeued from it implies the head queue is empty. We use the latter method in our prototype as it imposes fewer requirements on the traffic manager metadata available to the switch pipeline. In the case of a physical CQ, the rotation happens at fixed time intervals and is configured through timers or packet generators. When a rotation begins, we recirculate a special `rotate` packet to the ingress pipeline so that it stops enqueuing packets in the head queue and begins draining it, which happens in Step 2.

Step 2 - Drain Queue: This step ensures that the head queue is completely drained, and no more packets are enqueued into it till the rotation finishes. On receiving the `rotate` recirculation packet, the ingress pipeline advances the head queue pointer, essentially stopping any new packets from being enqueued into it. But, there could still be some packets in the pipeline currently making their way into the head queue. To make sure these are transmitted in the right order, the ingress enqueues a special `marker` packet into the head queue after updating the head of the calendar queue. This packet is the last packet to be enqueued into the head queue, and its arrival at the egress pipeline means the queue is completely drained, and we can proceed with finishing the rotation described in Step 3.

Step 3 - Finish Rotation: The `marker` packet is recirculated back to the ingress pipeline, and this informs the ingress pipeline that it is safe to reuse the queue for future periods. The ingress changes the priority of the just emptied queue to lowest and also pauses it, essentially pushing the queue to the end of the CQ. The ingress also unpauses the queue associated with the next period to ensure that there are no transmission stalls after the current period ends. The queue configuration change can be achieved in two ways depending on the underlying hardware support. The `marker` packet can be pushed up to the control plane CPU, which can alter the queue configurations using traffic manager APIs. This approach incurs a latency overhead before the drained queue can be used for packets associated with future periods. Alternatively, if the hardware supports priority change in the datapath, the processing of the `marker` packet with the appropriate metadata tags affects the configuration change almost immediately.

We now briefly highlight some of the attributes of PCQ that aid in efficient hardware realization. First, CQs maintain state at the granularity of physical switch queues instead of individual packets or flows. Second, at any given point in time, there is a designated head queue that is responsible for providing the packets that are to be transmitted. Third, the rotation operation involves changing just the metadata of queue and that too of at most three queues. This combination of factors allows us to bolt-on the PCQ abstraction on to a traditional TM.

3.5 Analysis and Extensions

We now analyze our PCQ abstraction and compare it to both fine-grained priority queuing schemes and an ideal Calendar Queue along different dimensions. We also provide an extension that expands the scheduling capability of the PCQ.

Expressiveness: From a theoretical perspective, a static priority mechanism (e.g., PIFO) with infinite priority levels is equivalent to a Calendar Queue with infinite buckets, and most scheduling algorithms can be expressed in both these hypothetical schemes. However, a practical PIFO has finite priority levels, and a practical CQ has finite buckets, which affects the feasibility and the fidelity of scheduling algorithms. An algorithm can be implemented using PIFOs if all packets throughout the "lifetime" of the algorithm have ranks strictly in the priority queue range. This is true for algorithms like pFabric where packet rank is solely a function of flow size, but not true for WFQ or EDF where packet ranks are computed based on a round number or current time, which is monotonically increasing. As discussed earlier, the priority-level space will roll over eventually, and the ordering of enqueued packets will be violated. On the other hand, our realization of PCQs requires that the enqueued packets' ranks at any instant fit within the available buckets or queues, which makes it challenging to implement algorithms that require both a large packet rank range as well as high fidelity in distinguishing between the packet ranks; we can extend the range of a CQ by bucketing several packet ranks together, but that introduces approximations which we discuss next.

Approximations: There are two sources of approximations that arise in a PCQ. First, inversions within a FIFO queue. The original Calendar Queue [10] maintains events in a single bucket in sorted order, whereas we simply use a FIFO queue. This can lead to inversions if multiple ranks are assigned to the same bucket, i.e., a higher priority packet is scheduled after a lower priority packet. This presents a feasibility vs. accuracy trade-off for the scheduling algorithm, and if the bucket intervals are chosen carefully, the approximation is acceptable as we show later in the evaluation. It is worth noting that one could borrow some of the mechanisms from the SP-PIFO work [2] to reduce rank inversions, but we leave that to future work. Second, the PCQ imposes a limit on the range of the CQ. Since the number of FIFO queues is limited, there is a possibility that packets will arrive with a rank beyond the range of the CQ. One can theoretically increase the bucket size to include a larger priority schedule such packets that are very far in the future. However, this will lead to an increase in inversions and reduce the accuracy of the priority queuing mechanism. Another option is to store overflowing packets into a separate queue and recirculate them into their appropriate queue when they get close to their service time. Furthermore, the range of a CQ can be significantly increased by employing a hierarchical structure, and we describe this next.

Hierarchical Calendar Queues: One way to extend the range of a CQ is to employ a hierarchical structure among the available FIFO queues, similar to hierarchical timing wheels, at the cost of recirculating some data packets. To create a 2-level hierarchical calendar queue (HCQ), we split the N FIFO queues into two groups of sizes n_1 and n_2, respectively. The two groups run independent calendar queues CQ_1 and CQ_2 on top of them, however with different bucket intervals: CQ_1 having an interval of one time period and CQ_2 having an interval of n_1 time periods, as shown in Figure 6. The idea is that a single queue of CQ_2 has an interval equivalent to the full rotation of all n_1 queues of CQ_1. A packet with a scheduled time between 1 to n_1 is inserted into the appropriate queue in CQ_1, packets with time between n_1+1 to $2\times n_1$ are inserted into the first queue of CQ_2, packets with $2\times n_1+1$ to $3\times n_1$ are inserted into the second queue of CQ_2, and so on. This approach provides a total range of $n_1\times n_2$ time periods, whereas just using a single CQ over N queues would give a range of just n_1+n_2.

However, this comes at the cost of recirculating any data packet that is enqueued in CQ_2. When a full rotation of all n_1 queues in CQ_1 finishes, all packets from the head queue of CQ_2 are recirculated and deposited into appropriate queues in CQ_1. Note that this approach is still significantly better

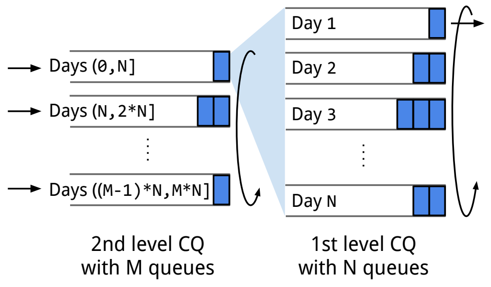

Figure 6: Example of a 2-level Hierarchical CQ. Packets are enqueued into the higher level CQ if they are too far into the future and recirculated into the finer level CQ periodically.

than the approach described in [10], where packets scheduled too far in the future are simply enqueued in the scheduled queue *modulo N*, and recirculated if the scheduled time has not arrived; Brown's scheme can recirculate a packet multiple times, whereas an HCQ recirculates a packet only once leading to more efficient use of bandwidth. Implementing HCQs also requires storing and managing extra state for both CQs and more complex computations when determining the destination queue for a packet. With 32 FIFO queues, a 2-level HCQ can be implemented with 16×16 queues to achieve a reach of 256 time periods or a 3-level HCQ with $16\times8\times8$ queues with a total reach of 1024, which is significantly larger than 32.

Limitations: Similar to PIFOs, CQs compute the enqueue rank only on packet arrival. Therefore, the relative order of already buffered packets cannot be changed after enqueuing. This limitation prevents CQs from realizing mechanisms such as pFabric's starvation prevention technique [4], where the dequeue order of multiple previously received packets changes on an enqueue; a later packet within a flow would signal that there are fewer remaining bytes within the flow and, thereby, increase the priority of the flow's previously enqueued packets. CQs do allow us to realize other, arguably stronger, forms of starvation prevention, as we will see in Section 4.5. Another limitation of CQs is that we can schedule packets only in the future. If the computed rank is before the current CQ time, the resulting packet schedule will be different from the desired ordering. Essentially, this means that CQs cannot correctly order packets that have ranks in the past. One could address this limitation by not immediately reusing a queue for a future period as soon as we perform a CQ rotation and allowing some number of queues from the past to be active. Finally, CQs have an upper limit on the range of ranks they can enqueue at a time. If a scheduling algorithm requires a large range, it cannot be implemented accurately using CQs; the hierarchical scheme outlined above can increase a CQ's range, but it comes with an approximation cost.

4 Evaluation

We evaluate the practical feasibility, expressiveness, and performance of Calendar Queues by implementing them on a

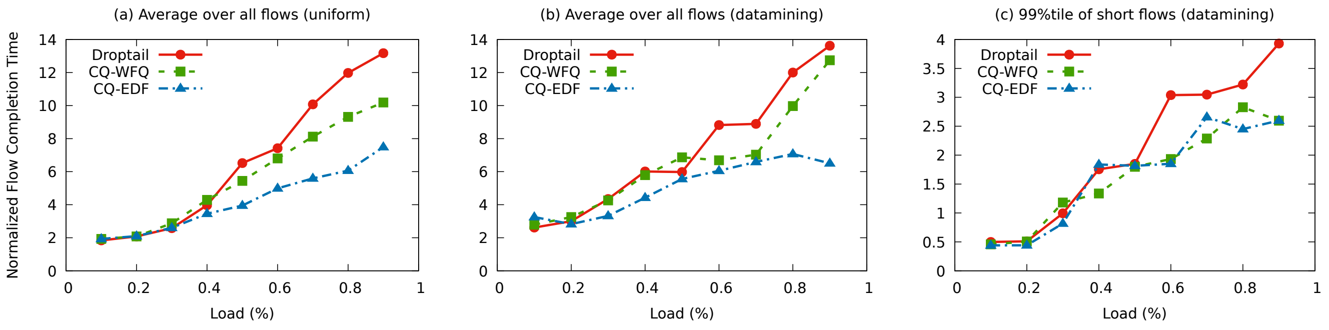

Figure 7: Average and tail latencies for both synthetic and datamining workloads with WFQ and EDF policies implemented using Calendar Queues on top of Barefoot Tofino switch in the hardware testbed.

programmable Barefoot Tofino switch and realizing two classical scheduling algorithms using CQs. Next, using large scale packet-level simulations, we demonstrate the flexibility of the Calendar Queue abstraction with three case studies. First, we instantiate a physical calendar queue that performs deadline-aware scheduling of both aggregate flows (or coflows) and individual flows. Second, we instantiate a logical calendar queue that implements a variant of fair-queueing that can tolerate a limited amount of burstiness, thereby providing a configurable balance between fairness and flow completion time for short flows. Finally, we implement a variant of pFabric that prevents long flows from starving by gradually increasing the priority of all enqueued packets. None of these scheduling algorithms can be realized using traditional priority queuing schemes such as PIFO.

4.1 Hardware Prototype Implementation

We implement and evaluate programmable calendar queues on the Barefoot Tofino 100BF-32X switch. As the current Tofino switch does not support updating a queue's priority on the datapath, we implement CQs using a combination of in-built packet generator, packet re-circulation, and control plane operations to drain packets in the correct order.

First, we use the in-built packet generator on the switch to periodically generate probe packets and detect when a queue rotation needs to be performed. The egress pipeline tracks the current head of the CQ, and when a packet is dequeued from the next queue (signifying the current queue is empty), it re-circulates the probe packet back to the ingress to initiate a rotation. Next, the ingress pipeline updates the current head of the CQ and enqueues the probe packet into the queue being rotated out to drain it fully, and no more packets are inserted into it. When the egress pipeline receives the probe packet again, it is safe to update the priority of the drained queue, and we achieve this by setting a flag in the egress pipeline. Finally, the control CPU polls on this flag variable, and when set, it makes an API call to update the queue's priority and notifies the ingress pipeline that it is safe to use this queue to store the future packets.

Testbed and Workload We implement two scheduling algorithms, WFQ [14] and EDF [18] using Calendar Queues and compare them against standard FIFO droptail scheduling in a 2-level fat-tree topology, consisting of 2 ToR switches, 2 aggregation switches, and 4 servers by using loopback links with ingress-port based virtualization to divide the 32 physical ports into multiple switches. All links in the network are 40Gbps with 80µs end-to-end latency. Each server opens 80 concurrent long-running connections to other servers and generates flows according to a Poisson process at a rate configured to achieve the desired network load. We tested a synthetic workload that draws flow sizes at uniform with a max size of 12.5 MB and the data mining workload from [4].

Performance Figure 7 shows the average and 99th percentile latencies. Across both workloads, we can see the WFQ and EDF implementations performing better than simple droptail queues. The difference is more significant at higher network load when queues build up at the switch due to bursty arrivals. This is when the prioritization and correct scheduling of packets leads to a visible difference in FCTs. However, the important point here is that we were able to realize these scheduling policies at a line-rate of 40 Gbps without being limited by the number of flows. We further measured the extra physical switch resources consumed by our implementation of WFQ and EDF using CQs, and report them in Appendix B.

4.2 Packet-level Simulations

We study our use-cases in a large-scale cluster deployment using an event-driven, packet-level simulator. We extend the mptcp-htsim simulator [21] to implement Calendar Queues and several other comparison schemes. The simulation consists of 256 servers connected in a 3-level fat-tree topology consisting of 8 ToR switches, 8 aggregation switches, and 4 core switches. Each ToR switch is connected to 32 servers using 10 Gbps links, and all other switches are connected to each other using 40 Gbps links. Next, we describe each case-study and evaluate them.

4.3 Use Case 1: Coflow scheduling using Least Slack Time First (LSTF) scheduling

Distributed applications running inside datacenters generate network traffic patterns that require optimizing the perfor-

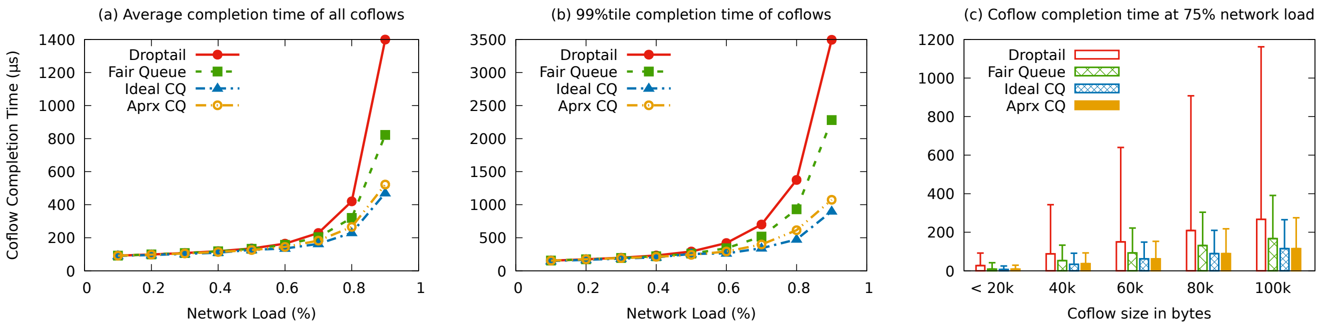

Figure 8: Coflow completion time when running a mix of background and coflow traffic with coflows prioritized over background flows. (a) average CCT for all coflows, (b) 99th percentile CCT for all coflows, and (c) average and 99th percentile (using error bar) for various coflow size buckets at 75% network load.

mance on a collection of flows [12], called coflows, rather than individual flows, e.g., partition-aggregate or bulk synchronous programming tasks such as multi-get Memcached queries and MapReduce jobs. The performance of such applications depends on the last finishing flow among the collection and prior work [1] has shown that near-optimal performance can be achieved by ordering coflows using a Shortest Remaining Processing Time (SRPT) first mechanism and ensuring that any packet from any flow of a coflow X ordered before coflow Y is transmitted before any packet from coflow Y.

We implement the above approach using LSTF scheduling on top of Calendar Queues to optimize coflow completion times (CCT). However, instead of using the complex BSSI algorithm in [1], which decides priorities based on other coflows in the system, we choose a much simpler heuristic to order coflows as they arrive. We compute a deadline for the whole coflow, assuming the largest sub-flow in the coflow is the bottleneck and will be the last to finish. Therefore, the deadline is simply the largest sub-flow size divided by endhost link speed. All we need to do is assign this deadline to all packets of all flows in the coflow and ensure that packets with the earliest deadline are transmitted first at each switch.

We calculate each packet's *slack* as the time remaining until the deadline of its corresponding coflow. The slack is initialized in the packet header at the endhost, and as the packet traverses the network, each switch enqueues the packet in the Calendar Queue based on this slack value. The higher the slack value, the farther in future the packet is scheduled for transmission. On departure, the switch deducts the time spent at the switch from the slack and updates the packet header. As a result, critical flows with lower slack values and closer deadlines are dynamically prioritized over non-critical flows with larger slack values and farther deadlines. Note that this scheme could have been implemented using an exact priority queue (such as PIFO) with absolute deadlines embedded in the packet header, but that would require clocks to be synchronized. More importantly, the switch would run out of priority levels eventually and would not be able to enforce deadlines. We, therefore, implement the scheme using LSTF on top of Calendar Queues.

We measure the performance of the above coflow scheduling mechanism using event-driven simulations and compare it with the following queueing schemes:

- **Droptail**: Traditional switch with a single FIFO queue that drops packets from the tail when full.
- **Fair Queue**: Bit-by-bit round-robin algorithm from [14] that achieves max-min fairness.
- **Ideal Calendar Queue**: A CQ with *infinite* buckets that also transmits packets in sorted order within each bucket.
- **Approx Calendar Queue**: Our implementation of CQs that uses 32 FIFO queues and 10µs round interval.

In all the above schemes, we use the same end-host flow control protocol, DCTCP, with the additional embedding of *slack* value based on the coflow deadline.

Workload and Performance Metric We use a mix of background traffic, which is the enterprise workload in [3] and a synthetic coflow workload derived from a Facebook trace [1]. Coflows, on average, have ten sub-flows and a total size of 100 KB. The ratio of background traffic to coflow traffic is 3:1. Flows and coflows arrive according to a Poisson process at randomly and independently chosen source-destination server pairs with an arrival rate chosen to achieve the desired level of utilization in the aggregation-core switch links. We evaluate the performance in terms of flow completion time (FCT) or, in case of coflows, the coflow completion time (CCT), which is the maximum FCT of comprising sub-flows and report both mean and 99th percentile numbers.

Since we have a mix of background flows and coflows, we must decide how they co-exist together and are scheduled inside the network. One trivial way is to treat background traffic as a separate class with a lower priority than coflow traffic. This configuration is evaluated in Setup 1. Another option made possible by CQs is to treat background traffic as fair-queued and coflow traffic as deadline-aware using the same underlying CQ to schedule packets belonging to both classes. This demonstrates the flexibility of CQs in realizing multiple scheduling policies at once, and we evaluate this configuration in Setup 2.

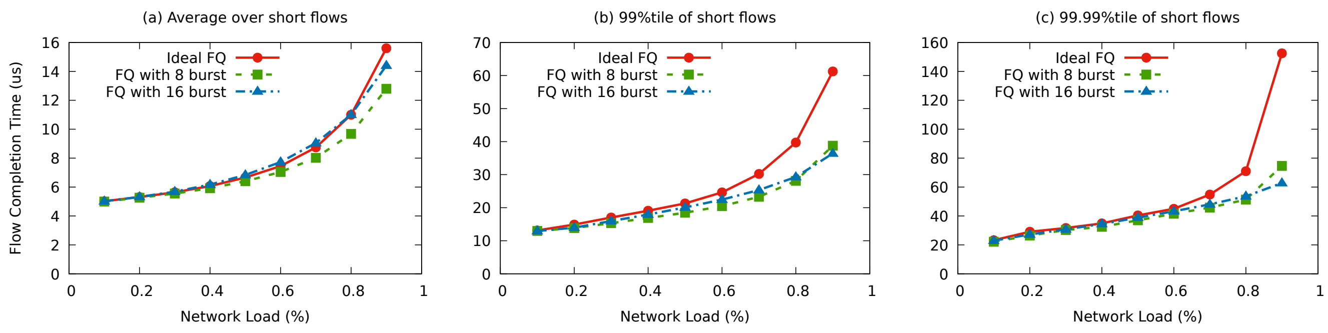

Figure 9: Average and percentile flow completion times for short flows with varying network load and permissible burst size.

Setup 1: Coflows have priority over background traffic. We treat background flows as a different traffic class with lower priority than coflows by using a separate queue with strictly lower priority. As a result, the background traffic performance is not affected by the coflow scheduling policy, and we report coflow completion times in Figure 8. The average CCT improves by up to 3x and 99th percentile CCT by 5x at high network loads. This improvement is both because we are emulating an SRPT policy as well as because we de-prioritize shorter sub-flows within a coflow over other more critical flows. Both droptail and fair-queuing finish short flows within a coflow quickly, although they have a significant *slack* till the deadline. Moreover, our CQ implementation is able to accurately emulate an ideal calendar queue mechanism using a limited number of FIFO queues, and the gap between ideal CQ and our CQ is fairly negligible.

We present the results for Setup 2 in Appendix C.

4.4 Use Case 2: Weighted Fair Queueing with Burst Allowance

First, we implement Fair Queueing using calendar queues as described in Section 3.3.1, which emulates a round-robin scheme wherein each active flow transmits a fixed number of bytes each round (*BpR*). The departure round computed for each packet is mapped to a future day (or queue) in the CQ, which transmits the packets in the correct order. This scheme has been shown to emulate Fair Queuing accurately [25] and while it implements Start Time Fair Queueing at a coarse granularity, it is often desirable to allow a burst of packets from a single flow to be transmitted back-to-back to achieve a better latency for short flows and improve tail latency [13]. This only affects fairness at very short timescales while maintaining fairness at larger timescales.

We modify WFQ to allow short bursts to go through using a simple modification to the enqueuing logic at the ingress. In addition to maintaining a byte counter per flow and computing a packet's round number as byte counter divided by *BpR*, we maintain a permitted *burst size*. While our original WFQ implementation allows a flow to send at most *BpR* bytes per round, the burst-friendly variant lets a flow enqueue up to a fraction of available burst size into a single round, allowing it to exceed its fair share allocation temporarily.

More precisely, instead of computing the round number as `R = bytes[f]/BpR`, where `bytes[f]` is the amount of bytes enqueued by flow `f`, we incorporate burst size into the calculation as follows,

```
R = bytes[f]/max(BpR, BurstSize - bytes[f])
```

where `BurstSize` is the configured permissible burst size. This essentially lets `BurstSize/2` bytes to be enqueued in the current round, `BurstSize/4` in the next round, and so on, as show in Figure 10. Any enqueued bytes exceeding the burst size are assigned the same round number as before.

We implement this burst-friendly fair-queuing scheme with configured burst sizes of 8 and 16 packets (denoted by FQ-8 and FQ-16), along with ideal fair-queueing on top of our Calendar Queues and measure the impact on flow completion times using simulations. We use the same 3-level fat-tree topology and enterprise workload for this use case.

Figure 9 shows the flow completion times of short flows as we increase the network load. At higher network loads, allowing a burst of bytes to go through leads to up to 2-3x reduction in higher percentile latencies. Figure 11 breaks down the latency improvement across different flow size buckets, and it confirms that short flows in the region of burst size show the most improvement. More importantly, larger flows are unaffected by this temporary burst allowance.

4.5 Use Case 3: pFabric with Starvation Prevention

pFabric [4] is a transport layer designed to provide near-optimal flow completion time by essentially emulating Shortest Remaining Processing Time (SRPT) first scheduling at each switch. Each flow packet carries a single number that encodes its priority – in this case, it is set to the remaining flow size when the packet is transmitted. All switches forward the packet with the shortest remaining flow size at any given time. This simple scheme can be implemented using a static fine-grained priority scheme such as PIFO, as it does not require the gradual priority escalation. However, this leads to potential starvation of long flows, which are always deprioritized compared to shorter flows, making it impractical to run in real environments. This is shown in Table 1, where we simulated the same 3-level fat-tree topology and ran the enterprise workload at 80% network load. As flow size increases,

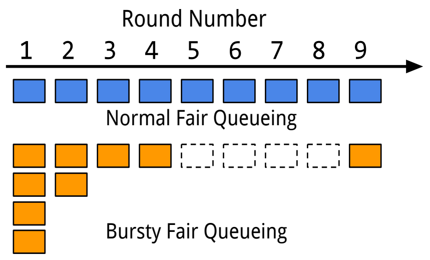

Figure 10: Packet enqueuing behavior of normal fair queueing vs bursty fair queueing.

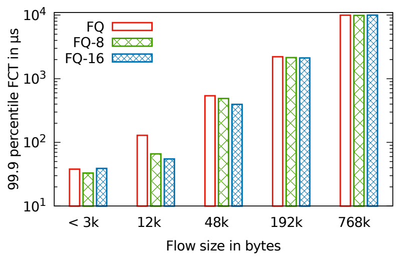

Figure 11: 99.9 percentile latency for various flow size buckets at 90% network load in micro-seconds.

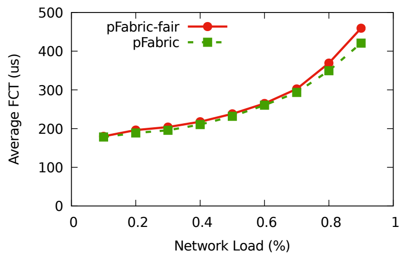

Figure 12: Average FCT for pFabric and pFabric-fair for enterprise workload in our testbed.

Flowsize	10k	100k	1M	10M	100M
pFabric	679	651	670	524	265
pFabric-fair	650	642	638	543	442

Table 1: Average bandwidth in MBps achieved by flows in various bucket sizes.

the average transmission rate decreases resulting in reduced bandwidth available for longer flows.

If we were to think of fair queuing and pFabric as ends of the spectrum, calendar queues would provide us with options in the middle. We implement a fairer version of pFabric, called pFabric-fair, by slightly altering the enqueuing mechanism. A packet with k bytes remaining in the flow is enqueued $f(k)$ periods into the future, where $f(k)$ is a log function. Thus, higher rounds are exponentially bigger, and the CQ can accommodate large flow sizes. Whenever the current head queue is empty, we rotate to the next queue, which ensures that low priority packets from larger flows are not permanently starved, merely deprioritized at enqueue time, and their priorities increase with time. However, we need some additional state to ensure that we do not enqueue a later packet from a flow ahead of the flow's previously received packets, which we achieve by keeping track of the highest queue for each flow.

Figure 12 shows the average and 99th percentile FCT for all flows with varying network loads for pFabric and pFabric-fair. Although pFabric-fair has a slightly higher average FCT at higher network loads, it also provides higher bandwidth to large-sized flows, preventing them from starving.

5 Related Work

Packet schedulers available in switching hardware today are fixed function, supporting specific primitives such as strict priority, rate limits, round-robin fairness, although a vast number of richer scheduling algorithms that provide stronger guarantees exist in the literature, such as WFQ [14], pFabric [4], STFQ [15], SRPT [24], EDF [18].

Several recent proposals aim to provide a programmable packet scheduler that can implement these scheduling algorithms while operating at line rate of terabits per second, such as PIFO [28], PIEO [27], and SP-PIFO [2]. All of these proposals provide the abstraction of *static* and *finite* priority levels, which we argue is insufficient to implement several scheduling algorithms that require monotonically escalating priorities. pHeap [7], PIFO and PIEO provide fine-grained priority levels, which makes it challenging for them to scale to large packet buffers and multi-pipeline switches. SP-PIFO is similar to Calendar Queues as it also provides coarse-grained priority levels using only FIFO queues, and can scale to current line-rate switches. SP-PIFO dynamically adjusts the priority range of individual queues by changing queueing thresholds, which can be explored further in the context of Calendar Queues as well.

Another chain of work proposes efficient packet scheduling in software such as Carousel [22], Loom [29], and Eiffel [23]. These approaches rely on timing wheel data structures or bucketed integer priority queue-like data structures for efficient operation. Calendar Queue borrows ideas from similar data structures while targeting switching hardware that can support today's large buffer and multi-pipeline routers.

6 Conclusion

We propose a flexible packet scheduler designed for line-rate hardware switches, called Programmable Calendar Queues, that enables the efficient realization of several classical scheduling algorithms. It relies on the observation that most algorithms require both prioritization and implicit escalation of a packet's priority. We show how they can be implemented efficiently on today's programmable switches by dynamically changing the priority of queues using either dataplane primitives or control-plane operations. We demonstrate that PCQs can be used to realize interesting variants of LSTF, Fair Queueing, and pFabric to provide stronger delay guarantees, burst-friendly fairness, and starvation-free prioritization of short flows, respectively.

A Detailed Implementation Notes for Realizing PCQs in Hardware

We now present the traffic manager API and how it is invoked by the different steps involved in transitioning a CQ from one period to another.

Traffic Manager API

- `tm_enqueue(packet, queue)`: Enqueues a packet in the given queue.
- `tm_pause(queue)`: Stop or pause queue from transmitting any packets until unpause is called on the same queue.
- `tm_unpause(queue)`: Resume queue, allowing it to send out packets until pause is called.
- `tm_setPriority(queue, p)`: Set priority of queue to `p` (one of different levels supported by the TM)
- `tm_dequeue()` (called from egress): Returns a packet from the highest priority unpaused queue, along with the queue id from which it was dequeued.

The exact details of enqueue/dequeue and rotation are described in the pseudocode below. In addition, we store the following state at ingress and egress to keep track of Calendar Queue status and perform queue rotations. The special recirculation packets also contain metadata regarding which queue is being rotated out.

Ingress State

```
currQ: queueId currently at the head of the CQ
prevQ: queueId that was just rotated out and is draining
nextQ: queueId that will be unpaused next
```

Egress State

```
currQ: queueId at the head of the CQ (egress)
```

Packet Enqueue Function

```
packet_enqueue(pkt, X) (called from ingress)
  // According to desired scheduling algorithm.
  x = compute_rank(pkt)
  // Enqueue packet in queue (currQ + x) % N
  tm_enqueue(pkt, (currQ + x) % N)

  // process initiate rotate packet
  if packet == rotate:
     ingress.prevQ = ingress.currQ
     ingress.currQ = ingress.nextQ
     ingress.nextQ = (ingress.nextQ + 1) % N
     tm_enqueue(marker, ingress.prevQ)
     tm_setPriority(prevQ, High)
     tm_setPriority(currQ, Medium)

  // process marker packet
  if packet == marker:
     tm_pause(marker.queueId)
     tm_unpause(nextQ)
     tm_setPriority(nextQ, Low)
```

Packet Dequeue Function

```
packet_dequeue() (called from egress)
  // Returns the highest priority packet
  pkt, queueId = tm_dequeue()

  // Need to initiate rotation
  if queueId != egress.currQ:
     create and circulate a rotate packet on egress.currQ
     egress.currQ++

  // Normal packet dequeue
  if queueId == egress.currQ:
     perform normal packet processing

  if pkt == marker:
     recirculate marker back to ingress
```

Note that, if no more packets remain to be transmitted, then rotate packet is never sent out and currQ remains the same. This avoids unnecessary rotations when the link traffic is less than the link bandwidth.

B Resource Overhead of Implementing CQs

Table 2 shows the additional overhead of implementing CQs along with various scheduling policies, as reported by the P4 compiler. First, since we were able to compile CQs directly onto the Tofino hardware, we can support an arbitrary number of flows at the configured line-rate of 40 Gbps, and are not scale limited in any way. We do require some additional state that is proportional to the number of CQs instantiated across all ports and the number of queues in each CQ. Each scheduling policy also keeps extra state for rank computation, which takes extra resources, e.g., keeping flow byte counters for WFQ results in 50% increase in SRAM usage.

Resource	Baseline	CQ w/ EDF	CQ w/ WFQ	CQ w/ EDF+WFQ
Pkt Header Vector	356	356	356	356
Pipeline Stages	9	9	12	12
Match Crossbar	50	54	63	68
Hash Bits	113	124	140	150
SRAM	27	29	46	48
TCAM	2	2	2	2
ALU Instruction	11	12	13	14

Table 2: Summary of resource usage for a Calendar Queue implementation with 32 physical queues on top of P4 switch.

C Scheduling Deadline-aware and Background Traffic using the same CQ

In Setup 2 described in Section 4.3, we use the same underlying Calendar Queue to schedule background flows as fair-queued traffic and coflows as deadline or slack based traffic. For a background flow packet, which is fair-queued, we compute its departure queue based on bytes enqueued by the flow using the WFQ implementation described in Section 3.3.1. For a deadline-aware coflow packet, we calculate

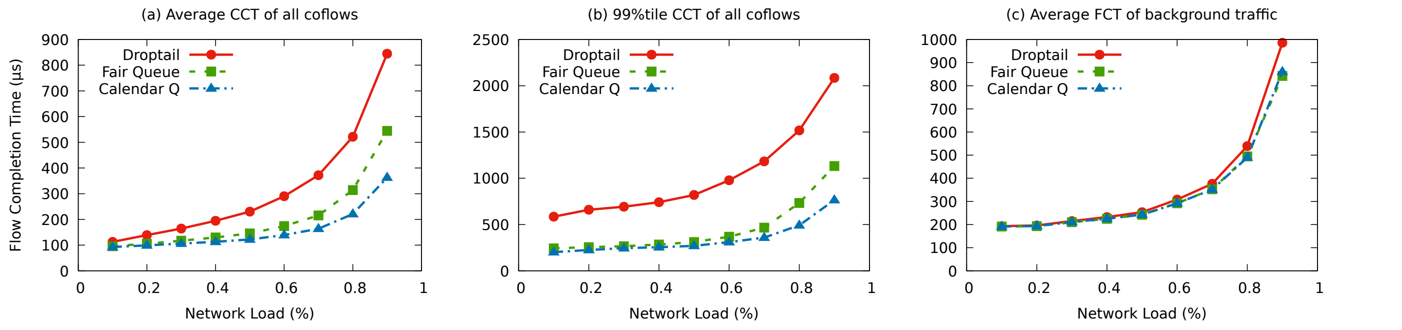

Figure 13: CCT and FCT when scheduling background traffic as fair-queued and coflow traffic as deadline-aware using the same Calendar Queue.

its departure queue using the slack inside the packet header by dividing it with the configured bucket interval as described in Section 3.3.2. We can control the relative priority of background vs. coflow traffic by changing the bucket interval. A higher bucket interval will accommodate more bytes from deadline traffic compared to fair-queued traffic. We use a default value of 10µs as the bucket interval and 1 MSS as the bytes quantum per round for fair queueing.

Figure 13 shows the coflow completion times and FCT of background flows in this setup. The average CCT shows up to 2.5x and 1.5x improvement compared to droptail and fair queuing, respectively. This benefit again comes from the fact that we are able to schedule shorter coflows before longer coflows, as well as de-prioritize shorter sub-flows within a coflow over other more critical sub-flows. The 99th percentile shows a similar improvement of 3x over droptail queues. Moreover, the average FCT of background flows stays roughly the same and is unaffected by the coflow scheduling being done by the Calendar Queue.

Contra: A Programmable System for Performance-aware Routing

Abstract

We present Contra, a system for performance-aware routing that can adapt to traffic changes at hardware speeds. While point solutions exist for a fixed topology (e.g., a Fattree) with a fixed routing policy (e.g., use least utilized paths), Contra can operate seamlessly over any network topology and a wide variety of sophisticated routing policies. Users of Contra write network-wide policies that rank network paths given their current performance. A compiler then analyzes such policies in conjunction with the network topology and decomposes them into switch-local P4 programs, which collectively implement a new, specialized distance-vector protocol. This protocol generates compact probes that traverse the network, gathering path metrics to optimize for the user policy dynamically. Switches respond to changing network conditions by routing flowlets along the best policy-compliant paths. Our experiments show that Contra scales to large networks, and that in terms of flow completion times, it is competitive with hand-crafted systems that have been customized for specific topologies and policies.

1 Introduction

Configuring a network to achieve a diverse range of objectives, such as routing constraints (*e.g.*, traffic should go through a series of middleboxes), and traffic engineering (*e.g.*, minimize latency and maximize throughput), is a challenging task. To handle this complexity, one approach has been to use SDN solutions, which have a centralized point for management [25, 26]. However, centralized controllers are inherently too slow to respond to fine-grained traffic changes, such as short traffic bursts. In fact, even the software control planes locally on the switches are often limited in their ability to select new routes fast enough.

Recent work has developed load-balancing mechanisms that operate entirely in the data plane to enable real-time adaptation [11, 30]. By making use of fine-grained performance information on hardware timescales, these systems can deliver considerable performance benefits over static load-balancing mechanisms like ECMP. Unfortunately, existing systems, such as Conga [11] and Hula [30], are point solutions that only work under specific assumptions about the network topology, routing constraints, and performance objectives—they only support a "least utilized shortest path" policy on a data center topology. It is not obvious how to adapt them for other kinds of topologies or policies.

In this paper, we describe Contra, a general and programmable system for performance-aware routing. Network operators configure Contra by describing the network topology as well as a high-level policy that defines routing constraints and performance objectives. Contra then generates P4 programs for switches in the network, which execute in a fully distributed fashion. Collectively, they implement a specialized version of a distance-vector protocol that forwards traffic based on routing constraints and optimizes for the user-defined performance objectives. This protocol operates by generating periodic probes that traverse policy-compliant paths and collect user-defined performance metrics. Switches analyze the incoming probes and rank paths in real time, storing the current best next hop to reach any given destination. Since the programs run in the data plane, switches can react to performance changes quickly. Overall, Contra is designed to achieve the following objectives:

- General – operates over a wide range of policies
- Reusable – works correctly for any topology
- Distributed – does not require central coordination
- Responsive – adapts to changing metrics quickly
- Implementable – on today's programmable data planes
- Policy-compliant – packets only use allowed paths
- Loop-free – mitigates persistent/transient loops
- Optimal – converges to best paths under stable metrics
- Stable – mitigates oscillation under changing metrics
- Efficient – avoids undue traffic and switch overhead
- Ordered – limits out-of-order packet delivery

To achieve these objectives, we need to address several challenges. First, to operate over arbitrary topologies, Contra requires new techniques to search the set of possible paths for optimal routes. State-of-the-art solutions, such as Conga [11] and Hula [30], assume a tree-based data center topology, which makes exploring possible paths, avoiding forwarding loops, and finding optimal routes straightforward. Second, link and path metrics can change constantly, which may

cause unsynchronized views at different switches. Making forwarding decisions based on inconsistent views may lead to forwarding loops or paths that violate the routing policy. Third, a naïve solution that constantly changes routes can cause transient or even persistent chaos. We draw inspirations from wireless network routing [16, 38, 39], and design mechanisms that leverage programmable data planes to address this. Finally, we develop policy-aware flowlet switching, which routes flowlets to mitigate out-of-order packet delivery while ensuring policy compliance.

Summary. We make several contributions in the design of Contra, and Figure 1 summarizes the key ideas.

- We define a new programming abstraction that views policies as path-ranking functions, and generalizes existing languages by allowing operators to specify path constraints and dynamic metrics simultaneously.
- We design a new configurable, performance-aware, distance-vector routing protocol.
- We develop compilation algorithms that generate switch-local P4 programs that implement a particular configuration of the protocol based on user policy.
- We have built a system prototype, and conducted thorough experiments to demonstrate that Contra is competitive with state-of-the-art systems that are customized for a specific topology and routing policy.

Non-goals. There has been abundant recent research on efficient load-balancing strategies, especially in data centers. The goal of this work is not to outperform such strategies in the contexts for which they have been manually optimized. Rather, our goal is to facilitate the deployment of such techniques on a much broader set of networks and with a broader collection of optimization criteria, and to do so without asking network operators to take the time, or acquire the expertise necessary, to write "assembly-level" P4 programs.

2 Policy language

Contra includes a high-level language that can express a wide range of user policies, which are functions that rank network paths. Our compiler then ensures that switches always use the best policy-compliant paths. Users can combine regular expressions, which express hard constraints on the allowed paths, with performance metrics to express dynamic preferences. As a concrete example, consider the following policy:

```
minimize( if A .* then path.util else path.lat )
```

It first classifies paths using a regular expression (`A .*`), and then based on the classification, it defines the rank to be either path utilization or latency. Each node will separately choose its best paths according to this function. So node A will always choose the least utilized path, while all other nodes will select the path with the lowest latency.

The Contra language can also capture static policies in existing systems that are not related to performance. For instance, FatTire [40] uses regular expressions to classify legal and illegal paths (though it says nothing about the *performance* of such paths). To route packets through a waypoint `W`, a FatTire policy would be `(.* W .*)`, which allows any path through `W` but no other paths. Contra can represent this by mapping all legal paths to 0 and illegal paths to ∞:

```
minimize( if .* W .* then 0 else ∞ )
```

This policy will ensure that every node always selects a path through `W` if one exists in the network, and drops traffic otherwise; no path is preferred to a path with rank ∞.

As another example, Propane [14] allows users to write policies about failover preferences. A Propane policy `(A B D) >> (A C D)` indicates a preference for sending traffic through path `A B D` and only using `A C D` if the first path is not available (*e.g.*, a link has failed). In Contra, we can achieve the same effect by ranking paths statically as below.

```
minimize( if A B D then 0 else if A C D then 1 else ∞ )
```

In Contra, it is also possible to rank paths based on multiple metrics. For example, suppose we prefer that A reaches D via B instead of via C, and we also prefer shorter, less utilized paths. This can be achieved by lexicographically ranking paths, *e.g.*, prefer paths through B first, then shortest paths, and finally, least utilized paths.

```
minimize( if A .* B .* D then (0, path.len, path.util)
      else if A .* C .* D then (1, path.len, path.util)
      else ∞ )
```

Ranking paths using regular expressions defines strict, inviolate preferences; however, operators may have softer constraints based on path performance: *e.g.*, one path may be preferred up to a point, but if the utilization is too high then some traffic should be shunted along another path instead. For example, to prefer least-utilized paths when the network load is light (utilization of the path is less than 80%), even if those paths are long, but to prefer shortest paths when network load is heavy (and hence to save bandwidth globally), one might use the following policy.

```
minimize( if path.util < .8
            then (1, 0, path.util)
            else (2, path.len, path.util) )
```

Policy

$$\begin{array}{lll} pol & ::= & \mathsf{minimize}(e) \qquad\qquad\qquad \textit{optimization} \end{array}$$

Expressions

$$\begin{array}{llll} e & ::= & n & \textit{constant numeric rank} \\ & \mid & \infty & \textit{infinite rank} \\ & \mid & \mathsf{path.attr} & \textit{path attribute} \\ & \mid & e_1 \circ e_2 & \textit{binary operation} \\ & \mid & \mathsf{if}\ b\ \mathsf{then}\ e_1\ \mathsf{else}\ e_2 & \textit{if statement} \\ & \mid & (e_1, \ldots, e_n) & \textit{tuple} \end{array}$$

Boolean Tests

$$b \ ::= \ r \mid e_1 \leq e_2 \mid \mathsf{not}\ b \mid b_1\ \mathsf{or}\ b_2 \mid b_1\ \mathsf{and}\ b_2$$

Regular Paths

$$r \ ::= \ \mathsf{node\_id} \mid . \mid r_1 + r_2 \mid r_1\ r_2 \mid r^*$$

Figure 2: Syntax for Contra policies.

Finally, to steer traffic towards or away from particular links, one may add or subtract weights. For instance, the following policy demonstrates how to add weight to costly links AB and CD while otherwise using simple shortest paths.

```
minimize( (if .* AB .* then 10 else 0) +
          (if .* CD .* then 20 else 0) + path.len )
```

Figure 2 presents the full language syntax, and Table 1 presents selected policy examples taken from the literature. The key novelty of the language is that it can capture many of the *static* conditions expressed by earlier work such as Fat-Tire [40] or NetKAT [13] as well as the *relative* preferences of Propane [14], and yet it also augment such policies with *dynamic* preferences based on current network conditions.

Policy	Implementation
P1. Shortest path routing [24]	path.len
P2. Minimum utilization [30]	path.util
P3. Widest shortest paths [32]	(path.len, path.util)
P4. Waypointing [13]	if .*(F_1+F_2).* then path.util else ∞
P5. Link preference [14]	if .*XY.* then path.util else ∞
P6. Weighted link [19]	(if .*XY.* then 10 else 0) + path.len
P7. Source-local preference [12]	if X.* then path.util else path.lat
P8. Congestion-aware routing [27]	if path.util < .8 then (1, 0, path.util) else (2, path.len, path.util)

Table 1: Selected Contra policies.

Policy analysis and guarantees. Contra requires user policies to be *monotonic* (metrics do not improve for longer paths) and *isotonic* (switches have consistent preferences). If a policy is non-isotonic (*e.g.*, P8), Contra will attempt to decompose it into multiple isotonic subpolicies that can be processed separately. Contra can do this for many conditional policies (*e.g.*, P8), but it will not always succeed, e.g., for "shortest widest paths"; see Appendix A for more discussion. These algebraic constraints guarantee that when metrics are stable, new flows will be sent along globally optimal paths [22]. Our system also guarantees that hard constraints expressed by regular expressions are never violated. Under changing metrics, when switches make distributed decisions based on their local views, routes may be suboptimal [11].

3 Selected Challenges

Contra addresses three key challenges. To illustrate these challenges, we first describe a simple strawman solution designed for a specific topology (data center networks) and specific policy (use least utilized paths). Consider the simple leaf-spine topology in Figure 3(a), where switch S wants to send traffic to switch D over the least-utilized path:

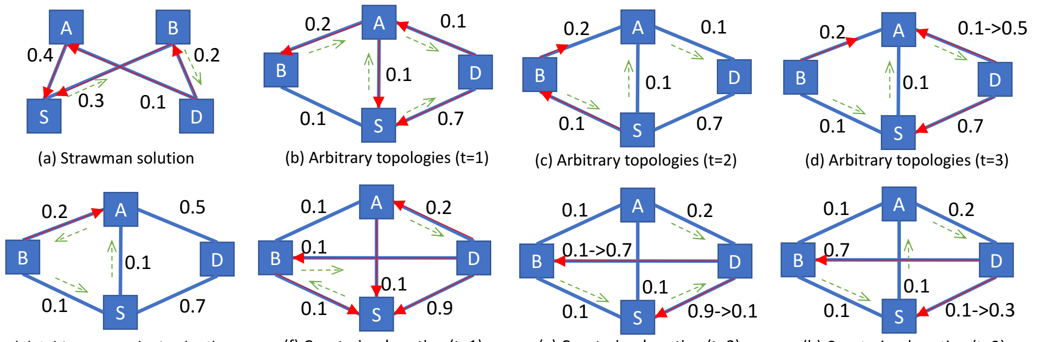
```
minimize( if S.*D then path.util else ∞)
```

One strawman solution is to use a distance-vector protocol, where each switch propagates link metrics (*i.e.*, utilization) to its neighbors via periodic probes, and builds up a local forwarding table of "best next hops" to reach other switches.

Concretely, at time 1, D sends two probes to A and B carrying utilizations u(A-D)=0.1 and u(B-D)=0.2, respectively. Upon receiving a probe, a spine switch updates its metric, and then disseminates the probe to its downstream neighbors. The updated probe metric is the maximum of a) the original probe metric, and b) the utilization of the inbound link from the switch's neighbor, so the probe always carries the utilization of the bottleneck link on its traversed path. For instance, when B receives the probe from D, it updates the utilization to 0.3, which is the maximum of a) the original probe metric, u(B-D)=0.2, and b) the utilization u(S-B)=0.3; when A receives the probe from D, it updates the utilization in the probe to be 0.4, which is the maximum of u(A-D)=0.1 and u(S-A)=0.4. At time 2, both A and B disseminate the updated probes to S. Now, S has received probes on both paths S-A-D (u=0.4) and S-B-D (u=0.3), and it chooses B as the best next hop to reach D due to its lower utilization. Changes in link metrics are then propagated by the next round of probes. In fact, this describes Hula [30], a state-of-the-art solution for utilization-aware routing in data centers.

Challenge #1: Arbitrary topologies. On a tree topology, simple mechanisms (*e.g.*, defining a set of "downstream" and "upstream" neighbors for each switch) suffice to explore paths and prevent forwarding loops [30], but on a non-hierarchical topology, it is insufficient.

Consider the sequence of events in Figures 3(b)-(e), where S prefers the least-utilized path to D. Suppose that at time 1, D sends out probes to A and S, and A propagates D's probe to B and S, with the utilizations shown in Figure 3(b); now, both B and S prefer to reach D via A. At time 2, S propagates A's probe to B about S-A-D (u=0.1), so B changes its preference to go through S; B then propagates S's probe to A (u=0.2), but it gets delivered only at time 4. At time 3, u(A-D) increases to 0.5, which is discovered by a new periodic probe from D to A and S. From A's perspective, the best path to reach D is still A-D, except that now the utilization is 0.5 instead. At time 4, when B's (old) probe to A arrives with u=0.2, A mistakenly thinks that it should instead reach D via B, not knowing that A is itself on B's best path to reach D. As a result, a forwarding loop S-A-B-S would form, and it will *persist* as long as the link utilizations remain stable.



(a) Strawman solution (b) Arbitrary topologies (t=1) (c) Arbitrary topologies (t=2) (d) Arbitrary topologies (t=3)
(e) Arbitrary topologies (t=4) (f) Constrained routing (t=1) (g) Constrained routing (t=2) (h) Constrained routing (t=3)

Figure 3: Supporting sophisticated policies over arbitrary topologies is challenging. (Solid, red arrows represent probes, and dotted, green arrows represent packet forwarding. Links are labeled with performance metrics.)

It might seem that path-vector protocols would address this problem, where probes record their traversed paths, and switches avoid picking paths that involve themselves. However, the root cause of transient loops is the inconsistent views during network convergence; so transient loops can still form even with path-vector protocols [37]. Carrying the path traversed by the probe would also increase traffic overheads and the complexity for processing probes.

Solution. Our solution is inspired by DSDV [39] and a more recent proposal Babel [16], which were originally developed for wireless mesh networks. At a high level, switches assign version numbers to probes, so that they can identify and avoid using outdated probes. In addition, Contra uses flowlet switching [44] to pin traffic to particular paths and avoid out-of-order packet delivery. Still, because flowlet entries expire at different times, it is possible for transient loops to form on rare occasions. Contra quickly detects and breaks such loops by monitoring hop counts.

Challenge #2: Constrained routing. Supporting routing policies with path constraints leads to additional challenges. Consider the scenario in Figure 3(f), where the policy is not only to prefer least-utilized paths, but also that traffic should never first go through B and then A due to security concerns:

```
minimize(if .*B.*A.* then ∞ else path.util)
```

Under this policy, S can only send traffic to D via a) S-D, b) S-A-D, c) S-B-D, or d) S-A-B-D; initially, S prefers c) (u=0.1). Now consider the sequence of events shown in Figures 3(f)-(h). Suppose that at time 1, the traffic from S arrives at B. At time 2, the u(B-D) increases to 0.7, and u(S-D) decreases to 0.1, so B updates its best next hop (to reach D) to be S, preferring the path B-S-D. At time 3, B sends the traffic back to S, which already forms a loop. But things can get even worse: at time 3, u(S-D) increases to 0.3, so S changes its preference to be S-A-D (u=0.2). So the traffic has been forwarded along a path S-B-S-A-D, which not only contains a loop but also violates the intended policy.

Solution. Contra compiles the regular expression constraints in the user policy into automata, and intersects these automata with the network topology to obtain a *product graph* [45, 14], which specifies a probe and packet tagging scheme for each switch. Intuitively, tags represent states of the user-defined automata; by checking that probes and packets carry the right state when arriving at a switch, it is possible to enforce the global user policy in a distributed fashion. This tagging scheme guarantees that no packet ever deviates from a user's regular expression constraints in the policy.

Challenge #3: Custom performance metrics. Supporting custom performance metrics also introduces new challenges. As discussed earlier, a switch only propagates the probe with the *best* metric to its neighbors. However, such local decisions do not always give rise to globally optimal results, unless the policy is *isotonic* [22] (*i.e.*, roughly speaking, downstream nodes respect the preferences of upstream nodes). Unfortunately, some useful policies, such as some congestion-aware routing schemes, are not isotonic [27].

Solution. Contra analyzes the user policy to determine if it is isotonic. If not, Contra decomposes the non-isotonic policy into multiple isotonic subpolicies. Information about each subpolicy is propagated separately in different classes of probe and the best probe from each class is chosen locally. The classes are recombined and a route corresponding to the best current path is chosen only at a traffic source. Hence, if metrics are stable, then new flows will be sent along globally optimal paths. To avoid packet reordering due to unstable metrics, we follow Conga and Hula's strategy and use flowlet switching, which trades the fact that packets in pinned flowlets may follow suboptimal paths for stability.

4 Compilation: Stable metrics

The goal of the compiler is to generate a particular configuration of the Contra protocol that efficiently implements the desired policy in the data plane. We describe compilation in two phases. First, in this section, we describe an algorithm that operates *as if link metrics do not change*, so probes only need to be propagated once. The next section explains how this algorithm is extended to handle changing metrics.

Challenge. One key challenge during compilation involves

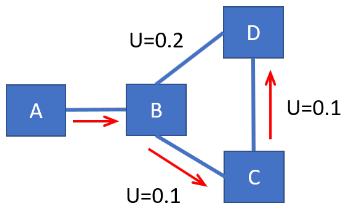


Figure 4: Naïve solutions may lead to suboptimal paths. Node `A` uses `ABCD` even though a better path `ABD` exists.

policies with conditional regular expression matches, such as `(if r then m1 else m2)`, because nodes may rank paths differently based on the branch of the conditional they use. In fact, conditional regular expression matches are one source of non-isotonicity: if every node selects the best next hop according to its own preferences alone, other nodes might wind up with suboptimal routes. For example, consider the following policy when applied to the topology in Figure 4:

```
minimize( if (A B D) then 0 else path.util)
```

In this example, `A` prefers path `ABD`, but `B` prefers the least utilized path `BCD`. The correct behavior in this scenario would be for `B` to carry `A`'s traffic along path `ABD` while simultaneously sending its own traffic along path `BCD`.

However, a naïve (and erroneous) implementation may disseminate probes along the paths `DB` and `DCB`[1] and ask `B` to decide which path is best. In this case, `B` would use the probe from `DCB` and discard the one from `DB`. However, if the latter probe is discarded, `A` will not receive information about its preferred route! To avoid this, another naïve solution would be to propagate probes along all possible paths in the network to avoid missing good paths. For instance, `B` might send every probe it receives to `A`. However, this would lead to far too many probes, as the number of paths in a graph may be exponential in the number of nodes.

Solution. Instead, for a conditional `(if r then m1 else m2)`, if one could determine the path with minimal metric `m1` that matches `r` using one probe, and separately determine the path with minimal metric `m2` that does not match `r` using another probe, then nodes could delay choosing their best path until both probes have been received and only then combine the information to make a decision. This is one concrete instance where Contra needs to decompose the non-isotonic policy (due to regular expressions) into multiple isotonic subpolicies. Contra achieves this by creating an efficient data structure that combines all regular expressions appearing in a policy with the network topology, and by sending separate probes for different regular expression matches.

4.1 Finding policy-compliant paths

Inspired by Merlin [45] and Propane [14], Contra constructs a data structure called a *product graph* (PG), which compactly represents all paths allowed by the policy.

[1]Recall that probes travel in the opposite direction to actual traffic.

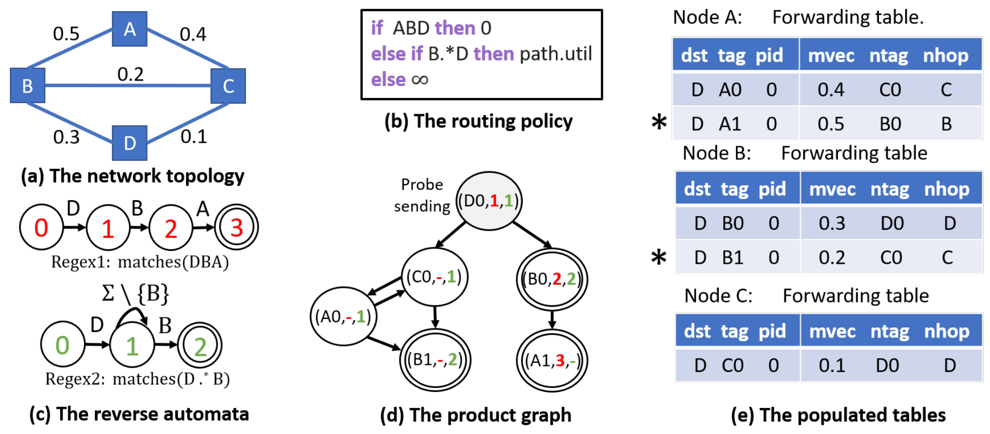
Policy automata. A policy's regular expressions define the different ways the shape of a path can affect its ranking. To process a policy, we first convert all such regular expressions into finite automata. Because probes disseminate information starting from the destination, but policies describe the direction of traffic that flows in the opposite direction, we actually construct an automaton for the reverse of each regular expression. Each automaton is a tuple $(\Sigma, Q_i, F_i, q_{0_i}, \sigma_i)$. Σ is the alphabet, where each character represents a switch ID in the network. Q_i is the set of states in automaton i. The initial state is q_{0_i}. F_i is the set of accepting / final states. $\sigma_i: Q_i \times \Sigma \to Q_i$ is the transition function. Consider the example policy in Figure 5(b), which a) allows A to reach D via the path A-B-D, b) allows B to reach D via any path with the least utilization, and c) disallows all other paths. The Contra compiler would generate the automata in Figure 5(c).

Network topology. The construction of the automata has not considered the actual network topology, so not all automaton transitions are legitimate. For instance, although the automaton for `D.*B` could in principle accept a sequence of transitions `D-A-B`, this sequence would never happen on the network shown in Figure 5(a), simply because `D` is not directly connected to `A`. Therefore, our compiler merges the topology with the automata and prunes invalid transitions.

Product graph (PG). If there are k automata (one for each regular expression used in the policy), then each state in the PG would have $k+1$ fields, $(X, s_1, \cdots, s_k)$, where the first field X is a topology location, and s_i is a state in the i-th automaton; there is a directed edge from $(X, s_1, \cdots, s_k)$ to $(X', s'_1, \cdots, s'_k)$, if a) $X - X'$ is a valid link on the topology, and b) for each automaton i, we have $\sigma_i(s_i, X') = s'_i$.

Concretely, in the PG in Figure 5(d), every edge represents both valid transitions on the two policy automata and a valid forwarding action on the topology. As examples, no edges exist from any `(D,*,*)` state to `(A,*,*)` state, because they have been eliminated due to topology constraints; also, there is a transition between node `D0` and `B0` because a) the topology connects `D` and `B`, and b) applying `B` to each automaton from state 1 leads to state 2. We use the symbol "–" to denote the special "garbage" state—the state from which there is no valid transition in an automaton.

Virtual nodes. We distinguish PG nodes ("virtual nodes") from topology locations ("physical nodes"). A physical node X may have multiple virtual nodes, because probes could arrive via different paths, and reach different automaton states as a result. For instance, the physical node `B` has two virtual nodes `(B0,-,2)` and `(B1,2,2)`; we have labeled their location fields as `B0`, `B1` to capture this, and we call them *tags*. If multiple virtual nodes exist, then probes must be duplicated to traverse paths that satisfy different constraints. For instance, `B` will receive a probe for `B0` representing a path on the way to matching regex `ABD`, and a second probe for `B1` representing a path on the way to matching regex `B.*D`.



Node A: Forwarding table.

	dst	tag	pid	mvec	ntag	nhop
	D	A0	0	0.4	C0	C
∗	D	A1	0	0.5	B0	B

Node B: Forwarding table

	dst	tag	pid	mvec	ntag	nhop
	D	B0	0	0.3	D0	D
∗	D	B1	0	0.2	C0	C

Node C: Forwarding table

dst	tag	pid	mvec	ntag	nhop
D	C0	0	0.1	D0	D

Figure 5: A running example of the compilation algorithm.

Probe sending states. If a physical node X is a valid destination allowed by the policy, then exactly one of its virtual nodes is a *probe sending* state. This state has the form $(X0, \sigma_0(q_{0_0}, X), \cdots, \sigma_k(q_{0_k}, X))$; all probes that originate from X initially carry this state. This is because, when probes start at the originating node, they have only traversed the first hop "X" from the initial automata states q_{0_i}.

Policy compliance. Any path in the PG from an accepting state to a probe sending state is a policy-compliant path. All policy-compliant physical paths also exist in the PG.

4.2 Packet forwarding

Before describing the protocol itself, we first describe the structure of the forwarding (`FwdT`) tables on each switch. The compiler only generates the table layout, and then actual entries are populated at runtime based on link metrics, which we describe in the next subsection.

An entry in the forwarding table has the form `[dst`*`,tag`*`,pid`*`,mv,ntag,nhop]`, where the star fields are table lookup keys. Each row of the table indicates where the given switch will send packets destined for `dst` when those packets carry a PG node `tag` and probe number id `pid`. The sender of packets will set the initial tag and the probe number based on its best path. At each intermediate hop, when a packet with a given `dst`, `tag`, and `pid` matches an entry in `FwdT`, the switch looks up the next tag (`ntag`) and replace the packet's tag with it; it also forwards the packet to the next hop (`nhop`). The metrics vector (`mv`) is not used for packet forwarding, but for populating the entries. A property of `FwdT` is that any `tag`-`ntag` pair in this table corresponds to a PG edge, and when a `ntag` is written into a packet it is then forwarded out the `nhop` port that leads to a topology node corresponding to that `ntag`. This process implies that forwarding will always follow edges in the PG.

As an example, consider the `FwdT` table for switch `B`: the policy allows `B` to reach `D` either through a) `B-D`, satisfying (part of) the regular expression `ABD`, or through b) the best of `B-D`, `B-C-D`, and `B-A-C-D`, satisfying the regular expression `B.*D`. The former corresponds to the virtual node `B0` in the PG, and the latter is implemented by a combination of both `B0` and `B1`. Hence, the reader may observe that it is possible for nodes of the product graph to contribute to the implementation of more than one regular expression in the policy—this sharing improves algorithm performance as a single probe can contribute to uncovering information useful in more than one place in the policy.

Ignoring for now how the forwarding entries were populated, consider the first entry in `B`'s table in Figure 5(e). The entry is generated from the virtual node `B0`: if a packet is at `B` with `tag=B0` and a destination `D`, then either that packet was sent from `A`, and traveled to `B` or it was sent directly from `B`. In either case, the current best path is through the next hop `nhop=D` with a metric `mv=0.3`. Moreover, before `B` sends the packet to `D`, it should update the tag to the new virtual node's tag `D0`. The second entry in `B`'s table is generated from `B1`. When packets are tagged with `B1`, there are two paths they could take to `D`: `B-C-D` and `B-A-C-D`. Currently, the least utilized path is `B-C-D`, so `nhop=C` and `mv=0.2`. The updated tag will then be `C0`. For this policy, only one probe is needed (carrying utilization), so there is only a single probe id (`pid`) of 0. The asterisk next to the `B1` entry indicates that `B` prefers `B-C-D` over `B-D`, which is determined after evaluating the user policy on both paths. Hence, traffic sourced from `B` will choose `B-C-D`. Note that each source can determine its own preference: although `B` prefers `C`, `A` can still use `A-B-D` since `A`'s traffic will be forwarded using the `B0` entry.

Function SwiForwardPkt in Figure 6 summarizes the packet forwarding logic. When a packet first arrives at the switch from a host, it is treated differently. In this case, this first switch must determine the preferred path for the packet (with each path having a representative destination, PG start node and probe id), which is stored in the `BestT` table.

4.3 Sending probes

While the forwarding tables compactly encode how devices should forward traffic in a policy-compliant way, we have yet to describe how these tables are populated. To this end,

```
function InitProbe(PGNode n, ProbeId pid)
    if n.isPrbSendingState then
        p.origin ← ToTopoNode(n)
        p.pid ← pid
        p.tag ← n.tag
        p.mv ← InitMVec
        MulticastProbe(n, p)

function MulticastProbe(PGNode n, Probe p)
    pg_neighbors ← GetPgOutNeighbors(n)
    topo_neighbors← ToTopoNodes(pg_neighbors)
    Multicast(p→topo_neighbors)
```

```
function ProcessProbe(Switch S, Probe p)
    n ← NextPGNode(S, p.tag)
    p.mv ← UpdateMVec(p.inport)
    key ← (p.origin, n.tag, p.pid)
    (mv, ntag, nhop) ← FwdT[key]
    if f(p.pid, p.mv) < f(p.pid, mv) then
        FwdT[key] ← (p.mv, p.tag, p.inport)
        oldKey ← BestT[p.origin]
        if s(key) < s(oldKey) then
            BestT[p.origin] ← key
        p.tag ← n.tag
        MulticastProbe(n, p)
```

```
function SwiForwardPkt(Packet p, Switch S)
    key ← (p.dst, p.tag, p.pid)
    if fromHost(p.inport) then
        key ← BestT[S]
        p.pid ← key.pid
    (mv, ntag, nhop) ← FwdT[key]
    p.tag ← ntag
    SendPkt(p, nhop)
```

Figure 6: Pseudocode for the synthesized switch-local programs. Underlined variables are PG states.

the Contra compiler generates protocol logic for propagating probes from probe sending states in order to populate the tables with the best paths to each destination.

At a high level, each node in the PG propagates probes to its neighbors. For instance, a probe starts at `D0` (`D` with tag 0) and is sent to `B0` and `C0`. `C0` updates the utilization to be 0.1 and adds this entry to its forwarding table before sending a new probe to `A0` and `B1`. Similarly, `B0` adds an entry for the probe it received from `D0` with utilization now 0.3 before sending a new probe to `A1`. `A1` receives a probe from `B0` and adds an entry with utilization 0.5, etc. `A0` receives a probe from `C0` with metric now 0.4 and adds this entry to its table before sending the probe to `C0` and `B1`. Probes will continue to propagate through the PG so long as they decrease the best available metric for that probe type and PG node. Since a static analysis ensures that policy metrics are monotonically increasing, probes will not be propagated endlessly in loops.

To determine which entry to use for forwarding local traffic, switches compute the best path by keeping a pointer to their overall best entry (the asterisks in Figure 5(e)). For example, consider the node `A`. Evaluating the policy on `A0` results in ∞ because `A0` is not an accepting state for regex `ABD` or `B.*D`. On the other hand, evaluating the policy in `A1` results in 0 (the best rank) because `A1` is an accepting state for regex `ABD`. Hence, the asterisk appears by `A1`.

Probe generation. Probes are generated from initial PG states (*e.g.*, `(D0,1,1)` in our example). These sending states use the procedure in InitProbe to initiate probes, and use MulticastProbe to multicast the probes along the outgoing PG edges to all downstream neighbors. Each probe carries four fields: (1) *origin* denotes the topology location of the sending switch (*i.e.*, `D` for the state `(D0,1,1)`); (2) `pid` is the probe id, as obtained from the policy decomposition; (3) `mv` denotes the metrics vector used in the policy (*i.e.*, utilization in the example, which is initialized to a default value 0); and (4) *tag* denotes the id of the PG node the probe is at.

Probe dissemination. The ProcessProbe algorithm describes how a switch processes a probe from its neighbor. It first obtains the PG node for the neighbor (n). Next, it updates the metrics in the probe based on the port at which the probe arrived, *e.g.*, the maximum of the probe's carried utilization and the local port's utilization. If this probe (with id *i* and tag *t*) contains a better metric according to *f* than what is currently associated with *i* and *t*, then it updates its `FwdT` table with the new `nhop`, `ntag`, and `mv` based on this probe. The switch also checks if an update affects its overall best choice (*i.e.*, where the asterisk points to), as recorded in the `BestT`. The switch looks up the existing value and compare it to the current probe using the function *s* that checks the overall value of the probe (not just per tag / probe id). Finally, the probe tag is updated to the correct value for n, and the probe is multicast to all PG neighbors.

5 Compilation: Unstable metrics

Consider using the same solution as described in Section 4, but instead of sending just one probe, sending many probes periodically, one per time interval. This introduces new complications due to the lack of synchronization; certain parts of the network may be working with outdated information. In fact, the example sequence from Section 3, Figure 3(b)-(f) demonstrates exactly how a problem can arise—the example culminates with the forwarding loop S-A-B-S. Notice also that this loop is technically policy-compliant because any path from S to D is allowed, so the packet tagging mechanism would not prohibit it.

The key issue is that when switches use old probes to make decisions, loops can form. In Figure 3(b), the probe *p* from B to A took a long time to propagate; by the time *p* arrived at A, the metrics had already changed again. Concretely, *p* was computed using an old metric u(A-D)=0.1, which had since changed to 0.5; but A still used this outdated probe and thought D was a better next hop.

5.1 Preventing persistent loops

To prevent loops, we draw on ideas from Babel [16], which distinguishes outdated probes from new ones using a version number, and discards outdated probes. In our scenario, this suggests A should discard *p* because it has an older version number, and should continue to use D as the next hop, thereby avoiding the loop. When a round of probes is still in propagation, switches may have temporarily inconsistent views, so a packet may experience a transient (yet policy-compliant) loop. However, versioned probes would guarantee that persistent loops would not form [16].

We note that there is a long body of work on loop prevention in routing protocols with tradeoffs being made in terms of space overhead and convergence time. Contra's compilation algorithm can potentially be integrated with different loop prevention techniques. For example one could prevent loops by adding a bit vector to each probe to record visited nodes (*i.e.*, a path-vector protocol) at the cost of greatly increased probe overhead (one bit for every router). We opt for our approach to limit the space overhead of probes.

Refinement (Versioned probes). *As before, except that a) switches attach version numbers to the probes, which increase for each round; b) the* `FwdT` *table records the version number of the probe that was used to compute each entry; and c) before a switch updates an entry with version* v *with a probe of version* v'*, it needs to check that* $v' \geq v$.

5.2 Probe frequency

Versioning the probes, however, leads to an additional complexity: a node may not always be able to pick the best path. Consider a case where D sends probes to S every 0.2 ms along two available paths: a) p_1 with utilization of 0.4 and a latency of 0.1 ms, and b) p_2 with utilization of 0.1 but a latency of 0.2 ms. Due to the higher latency of p_2, whenever S receives a probe from this path, it would find the probe to be outdated, since newer probes had arrived from p_1. As a result, S ends up always using p_1 which has a higher utilization, even if the policy prefers the least-utilized path p_2.

We observe that this problem can be addressed by ensuring (with high probability) that old probes are fully propagated throughout the network before new probes are sent out. In the above scenario, if we set the probe period to be 0.2 ms or larger, then S would instead pick p_2 to be the better path after both probes have been received.

Refinement (Limited probe frequency). *As before, except that the probe period needs to be larger than or equal to* $0.5 \times RTT$*, where* RTT *is the highest round-trip time between any pair of switches in the network.*

5.3 Policy-aware flowlet switching

Since Contra can spread traffic in the same flow across multiple paths, it is important to mitigate the potential out-of-order packet delivery. One classic approach is *flowlet switching* [44], where packets in the same flow are grouped in bursts/flowlets and the same forwarding decision is applied to the entire flowlet. By doing so, the first packet in the flowlet is always forwarded to the best path, and subsequent packets in the same flowlet would inherit this (slightly outdated) forwarding decision. This also increases network stability: although each switch's best path is constantly fluctuating, at any given point, much of the current network traffic is pinned to a particular path. Only new flowlets will make use of the current path information.

(b) Flowlet switching may lengthen the duration of temporary loops

Figure 7: Challenges due to flowlet switching.

A first attempt to implement flowlet switching in Contra would be to have each switch maintains a table of the form `[fid*,nhop,t]`, where `fid` is the flowlet ID (from hashing a packet's five tuple), `nhop` is the temporarily "pinned" next hop, and `t` is the timestamp of the last packet in `fid`. When the next packet in `fid` arrives, the switch computes the gap between its timestamp and `t`: if the gap is small, this packet will use the current `nhop`; otherwise, the switch expires this entry and starts a new flowlet. Perhaps surprisingly, deploying such a flowlet switching mechanism with Contra may result in policy violations. Consider the example in Figure 7(a), where the policy prefers the least utilized of the upper or lower paths, but avoids the "zigzag" path.

```
if SCEFD + SAEBD then path.util else ∞
```

Suppose that at t=1, S sends traffic to D via the lower path due to its lower utilization; using flowlet switching, all switches temporarily pin this flowlet to their respective next hops along the path when they receive the first packet in the flowlet (*e.g.*, A pins to E at t=1.1, which expires at t=2.1; E pins to B at t=1.2, which expires at t=2.2; and so forth). At t=2, S discovers that the utilization of the upper path has improved, and changes its preference to D instead. However, if the packets from S arrive at E before t=2.2, which is its flowlet switching expiration time, E will continue to forward these packets to the lower path, causing a policy violation.

The fundamental reason for this is that flowlet switching is oblivious to routing constraints. Our solution makes it *policy-aware* by adding PG tags to flowlet entries. Concretely, policy-aware flowlet switching extends the table format to be `[tag*,pid*,fid*,nhop,t]`, where `tag` and `pid` are obtained from the probe that created the forwarding entry, and `tag`, `pid`, and `fid` are match keys. This enables flowlet switching *within each policy constraint and probe type*. Now, when E processes the packet at t=2.2, it would see that the packet was constrained to traverse the upper path and use the flowlet entry for that path.

Refinement (Policy-aware flowlet switching). *As before, except that switches perform policy-aware flowlet switching by maintaining multiple entries for the same flowlet, each for a different path constraint/tag and probe type.*

5.4 Handling failures

Switches also need to discover new best paths when links or switches fail. Suppose that the best path for S to reach D is S-A-D, but the link A-D goes down at some point. We need to ensure that S will learn about the failure and change to another available path if one exists. Our solution is to first detect failed links, and then to expire flowlet entries when their next hop is along a link that is believed to be failed.

Refinement (Expiration). *As before, except that a flowlet entry is expired when a packet arrives at a switch and is going to be forwarded by the flowlet entry, and the next hop is along a failed link.*

Handling failures, of course, requires the existence of a failure detection mechanism. The specific link failure detection methods are beyond the scope of Contra; the above approach merely ensures that switch routes around detected failures for future flowlets. In our implementation of Contra, a switch marks a link as failed when there have been no probes along the link for *k* probe periods, where *k* is a parameter that determines how fast failures should be discovered.

5.5 Breaking transient loops

As we discussed, transient loops may still occur when probes are in propagation. Figure 7(b) is a concrete example. At t=1, the best path for S to reach D is S-B-A-D. Then, at t=2, A receives a probe from D carrying a worse metric, so it propagates the probe to S and B. Before this probe arrives at S and B, A learns of the better path through S, and traffic that is already in flight will be forwarded along a transient loop S-B-A-S; this loop will be broken once S and B receive the new probe because it has a higher version number.

Interestingly, flowlet switching may lengthen the duration of transient loops because flowlet switching decisions may expire at different times across hops. Suppose that A's timer expires at t=3, and it starts using the new best next hop S to reach D; however, the timers at S and B do not expire until t=4. Then the traffic would continue to be forwarded in the loop S-B-A-S regardless of the newer probe, until S and B have updated their flowlet switching decisions.

We address this by detecting loops lazily and flushing the offending flowlet switching entries upon detection. Concretely, each switch maintains a *loop detection* table {`flow_hash`*,`maxttl`,`minttl`}, which maps a flow's CRC hash to the maximum and minimum TTL values seen at this switch. δ=`maxttl-minttl` should be stable in the absence of loops: it is the difference between the longest and the shortest paths packets could have traversed to reach the current switch. However, when there is a loop, δ would continue to grow. Therefore, switch detects a potential loop (with false positives) when its δ exceeds a threshold. When this happens, the switch expires its flowlet switching decision, and starts a new flowlet using the latest metric in the `FwdT` table. Hence, we arrive at our final solution below.

Final solution. *As before, except that switches use loop detection tables to detect and break loops by refreshing their flowlet switching decisions using the latest metrics.*

6 Evaluation

We aim to answer three main questions in our evaluation: a) How well does Contra scale to large networks? b) How competitive is Contra compared to hand-crafted systems? and c) How well does Contra work on general topologies? Due to space constraints, some results appear in the Appendix.

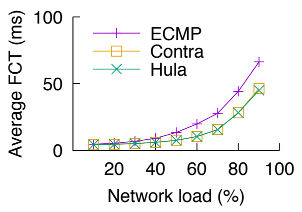
6.1 Prototype implementation and setup

Our prototype [3] consists of 7485 lines of code in F# [6], which processes policy and topology descriptions, and generates switch-local P4 programs. The compilation also minimizes the number of tags and forwarding table sizes.

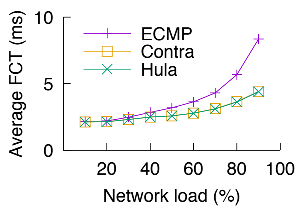
Experimental setup. We have used three types of topologies: a) data center topologies, b) random graphs, and c) real-world topologies (e.g., Abilene [1] and those from Topology Zoo [7]). Our baseline systems for data center networks are ECMP and Hula [30], load-balancing schemes for a Fattree topology. ECMP balances traffic randomly without considering network load, and Hula is load-aware and always chooses the least-utilized path among all shortest paths. Our baseline system for arbitrary graphs is SPAIN [35], which statically (*i.e.*, independently of network load) selects multiple paths to route traffic. We used two workloads obtained from production networks for our evaluation: a web search workload [12], and a cache workload [43].

Simulation vs. Emulation. For simulation, we have used a customized version of ns-3 [4] that implements P4 switches using the `bmv2` model, and it runs on a Dell server with six Intel i7-8700 CPU cores and 16 GB of RAM. For emulation, we have used the `bmv2` switches in a Mininet [34] cluster on 15 CloudLab [17] servers, each with eight cores and 128 GB of RAM. The simulation allows us to conduct experiments at high link speeds (up to 40 Gbps), as traffic forwarding is simulated in an idealized environment. The emulation, on the other hand, generates and forwards real network traffic across machines. This allows us to evaluate the systems in a high-fidelity environment [34], albeit with lower link speeds (50 Mbps) to avoid causing bottlenecks in the software switches.

We have replicated the emulation setup (45 switches in a 6-ary Fattree) in our simulator, and measured for eight setups (workloads+policies) the Pearson correlation coefficient (PCC) [42] between the emulated and simulated results. Seven of the setups produced PCC values of 0.99+, and the other produced 0.98 (1.0 means perfect correlation). This "meta" experiment confirms that the simulation and emulation results closely mirror each other, and that our observations are consistent across setups. Below, after presenting compiler results (§6.2), we first describe our simulation results (§6.3-§6.5), and then the high-fidelity emulation (§6.6).

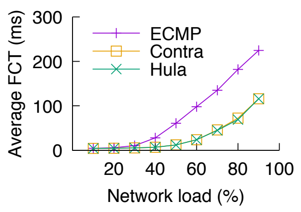


(a) The web search workload

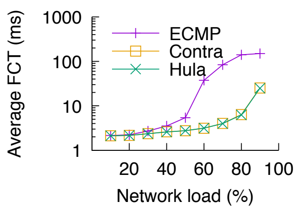


(b) The cache workload

Figure 8: Contra achieves a similar FCT as Hula, outperforming ECMP considerably.



(a) The web search workload



(b) The cache workload

Figure 9: Contra achieves a significantly shorter FCT than ECMP on an asymmetric topology with a failed link.

6.2 Compiler scalability

To test the scalability of our compiler, we used topologies of varying sizes from 20 to 500 nodes. For each topology, we evaluated three different policies: a) minimum utilization (MU: no regular expressions, single performance metric), b) waypointing (WP: three regular expressions, single performance metric), and c) congestion-aware routing (CA: no regular expression, non-isotonic policy with two performance metrics). The concrete numbers are included in Figure 14 in Appendix C, and we summarize the key takeaways here: The compiler scales roughly linearly with topology size, and completes in seconds on topologies with hundreds of nodes. Use of regular expressions increases product graph size and hence compilation time. Non-isotonic policies add some overhead due to the additional policy analysis.

We have also measured the switch state used by the generated P4 programs (Figure 15 in Appendix C). At a high level, WP and CA require more state than MU: WP's regular expressions require tracking automaton states. and CA's non-isotonic policy requires a separate table for each metric in the decomposed policy (*i.e.*, separate entries for different `pid` values). However, no more than 70 kB of switch state was necessary in any experiment—a tiny fraction of the available memory on modern switches (tens of megabytes) [2].

6.3 Performance: Data center topology

We compare Contra with ECMP and Hula in terms of their flow completion time (FCT) in simulation. In our topology (Figure 13a), we used 32 hosts with 10 Gbps links, with 10 Gbps links between switches, and an oversubscription ratio of 4:1. Half of these hosts were configured as senders, and the other half receivers. We set the probe period to 256μs and flowlet timeout to 200μs for both Contra and Hula. All links have a queue buffer size of 1000 MSS by default. Moreover, we tuned the desired network load from 10% to 90% by adjusting the flow arrival times, and obtained the FCT for each setting. The policy used in Contra is widest shortest paths (WSP; policy P3 in Table 1), which picks the least-utilized shortest paths and is equivalent to Hula; we found that the performance of Contra with the MU policy (P2 in Table 1) is similar to WSP in this setup.

Symmetric Fattrees. Figure 8 shows that both Contra and Hula outperform ECMP considerably because they balance traffic based on network load. At 90% load, they reduce the average FCT by 30% for the web search dataset and by 47% for the cache dataset. Hula outperforms Contra slightly, by 0.33% on average across different datasets and network loads. This is because Hula knows statically what paths are shortest paths (and hence what ports to send probes from), whereas Contra has to discover this information dynamically (*i.e.*, by carrying the path length as well as the utilization, and also by sending probes both "up" and "down" at each level in the datacenter)—hence Contra sends more probes than Hula in order to achieve generality over different topologies and policies. Further compiler optimizations could likely reduce this gap further (*e.g.*, by identifying shortest paths statically). We also refer interested readers to Appendix I for detailed breakdown of probe and tag overheads.

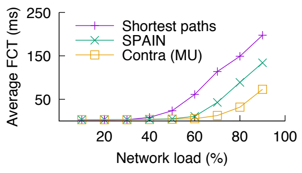
Asymmetric Fattrees. Next, we ran the same experiment after injecting a failure on a link between an aggregation switch and a core switch, so that the topology became asymmetric. Figure 9 shows the FCT for this setting. In this case, we found that ECMP incurred heavy traffic loss beyond 50% network load, even though 75% of all capacity remains after the link failure. The average FCT increased by 3.18$\times$ for the web search dataset and 8.72$\times$ for the cache dataset. In contrast, Contra and Hula only had an increase of 1.80$\times$ for the web search dataset and 1.67$\times$ for the cache dataset, relative to the FCTs on the symmetric topology.

We further measured the queue growths under ECMP and Contra with 60% workload on the web search dataset without bounding the maximum queue sizes (see Figure 16 in Appendix D). We found that Contra's queue lengths never exceeded 1000 MSS, whereas ECMP saw queue lengths larger than 1000 MSS more than 97% of the time, which can cause heavy traffic loss when the queues are full.

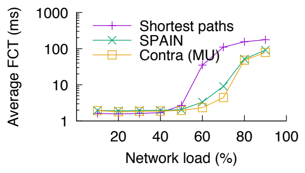
In order to measure Contra's response time to link failures, we sent UDP workloads at 4.25 Gbps rate, and brought down an aggregate-core link. Contra successfully detected the link failure after 800μs, which is close to the failure detection threshold (3$\times$probe period=768μs) that we used. Upon detection, Contra routed around the failure and recovered the throughput within 1 ms. We found that Hula performs similarly as Contra (Figure 17 in Appendix D).

6.4 Performance: Arbitrary topologies

We now evaluate the performance of Contra on general topologies. We modeled our network after the Abilene [1] topology, configured all links to be 40 Gbps, and randomly chose four pairs of senders/receivers. Since Hula is specialized to a Fattree topology and will not work outside of this context, and since ECMP will not load balance when there is only a single shortest path, we have used two other baselines: a) shortest path routing (SP), which simply sends traffic to the shortest paths, and b) SPAIN [35], which precomputes all paths using (static) heuristics that avoid overlap, and then load balances between these paths.



(a) The web search workload



(b) The cache workload

Figure 10: Contra outperforms SPAIN in FCT.

Figure 10 shows the FCT for these different systems. A naïve strategy that simply chooses shortest paths performs the worst. Since SPAIN can utilize multipath routing, it outperforms SP by 32.5% on average for the web search workload and 26.9% on for the cache workload. Contra achieves the best performance among the three: it evenly distributes traffic based on path utilization, and reduces FCT relative to SPAIN by 31.3% on average for the web search workload and 13.8% for the cache workload.

6.5 Protocol dynamics

Next, we study the network dynamics of performance-aware routing. The high-level note here is that, if a policy uses `m` as the metric, then paths with better `m` values may not necessarily be shorter and have lower end-to-end latency. The MU policy is a case in point, because 1) a least-utilized path could be a non-shortest path; and 2) compared to a slightly more utilized shortest path, the non-shortest path may also have higher end-to-end delay if its extra propagation delay offsets its lower queueing delay. Finally, when nodes are temporarily out of sync (§5.5), transient loops may arise.

Transient loops. We first quantify the amount of packets forwarded in transient loops. Under the MU policy on the Fattree and Abilene topologies at 60% load, only tiny fractions of traffic (0.024% and 0.021%, respectively) experienced loops. Compared to the shortest paths, these packets traversed 3.15 more hops on average for the Fattree, and 3.09 for Abilene. They also experienced an increase in end-to-end latency by 72.4μs (Fattree) and 65.2μs (Abilene). Our loop detection mechanisms successfully broke these loops.

Non-shortest paths. Packets could also traverse non-shortest paths without experiencing loops. We observed that the fractions of such packets are 16.6% for Fattree and 39.8% for Abilene. These packets also experienced latency increases of 42.3μs (Fattree) and 39.3μs (Abilene). An interesting observation here is that the application performance (in terms of FCT) depends on the tradeoff between propagation delay and queueing delay. In other words, if least-utilized paths happen to have high propagation delays, then the MU policy may not always lead to FCT improvement. We have observed both cases in our experiments with different topologies, path latencies, and number of shortest paths.

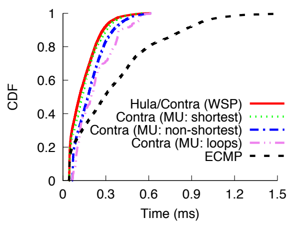
Contra, Hula, ECMP. Figure 11a shows the end-to-end latency packets experienced in Contra for two policies (WSP and MU) on the Fattree, and shows the breakdown for the MU policy (shortest paths, non-shortest paths, and transient loops). As expected, packets never experienced loops under WSP, which routes traffic to the least utilized of shortest paths. For Contra (MU), packets forwarded in loops took more time than those on non-shortest paths, and both took longer than those on shortest paths; they experienced slightly higher latency than in Hula. Nevertheless, Contra (MU) still outperforms ECMP significantly, because shortest paths with high utilization in ECMP have higher queuing delays than non-shortest paths with low utilization. (Results for Abilene are similar; see Figure 19a in Appendix E.)

Network loads. We also found that more packets tend to traverse longer paths as the network load increases (Figures 19b and 19c; in Appendix E). Across all scenarios, 12%-16% traffic took longer paths in the Fattree; within such traffic, 93%-98% took 2 extra hops and the rest took 4 extra hops. On Abilene, where shortest paths are fewer, 32%-50% traffic took longer paths; within this, 97%-99% took fewer than 4 extra hops and the longest path had 9 extra hops.

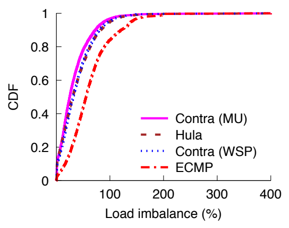
Load imbalance. Next, we focus on understanding the load imbalance over small timescales in ECMP, Hula, and Contra. Figure 11b shows the CDF of load imbalance of the four aggregate-core links on the Fattree topology at 70% load. We measured the throughput of these links for each 100μs interval for 1 second; we then computed the throughput differences between the most and least loaded links, and normalized them by the average throughput across the links. As we can see, Contra and Hula perform similarly, and they both balance the load much more evenly than ECMP. In particular, this shows that packets traversing non-shortest paths or transient loops in Contra do not lead to notable load imbalance even at small timescales.

6.6 High-fidelity emulation

We have set up a high-fidelity emulator on 15 CloudLab [17] servers using a distributed cluster of Mininet [34]. Our topology is a 6-ary Fattree with 45 switches running P4 `bmv2` [5] and 57 end-hosts with 1:1 oversubscription. We have set the link speeds to be 50 Mbps and verified that this is the highest link speed achievable in our testbed without causing bottle-



(a) End-to-end latency



(b) Load imbalance

Figure 11: Packets that experience transient loops or non-shortest paths spent more time in the network (a); but they do not lead to notable load imbalance (b).

necks in the software switches. As discussed before, we have mirrored the same setup in simulation and conducted experiments in both settings. The highest-level takeway is that we observed similar results on both setups. Below, we summarize the key findings, and note that the full set of figures (Figures 20-25) are in Appendix F.

Symmetric Fattree. Contra and Hula outperform ECMP considerably in FCT, and they perform similar to each other. At 90% load for the web search workload, they improve the performance of small flows (<100 kB) by 21%, large flows (>10 MB) by 12.7%, and 13.7% across flows.

Asymmetric Fattree. We then re-ran the FCT experiments, after bringing down three out of 27 aggregate-core links (11.1% reduction to overall capacity). Compared to the topology without failures, at 90% load, the average FCT increased by 15% for the web search dataset and 23% for the cache dataset in ECMP. Contra, on the other hand, only increased by 6% (web search) and 9% (cache), respectively.

Arbitrary topologies. We have also set up the Abilene topology in emulation and compared Contra with SPAIN, and note again that Hula only works on a tree topology. We found that at 90% load, Contra reduces FCT by 22.0% (web search) and 45.7% (cache) under the MU policy. For the web search (cache) dataset, it achieves 11.0% (36.5%) speedup for small flows, and 20.9% (46.1%) speedup for large flows.

7 Related Work

Traffic engineering and load balancing. Contra is different from centralized TE solutions, such as B4 [26], SWAN [25], Hedera [9], MicroTE [15], and Gvozdiev [23], as well as distributed TE solutions, such as TeXCP [28], MATE [18], and Halo [33], in that Contra performs fine-grained load balancing in the data plane. Contra borrows a similar load balancing mechanism from Hula [30] and Conga [11], so their characteristics are similar in terms of dynamics and performance benefits. The main novelty of Contra over all of these systems is to generalize point solutions to a wide range of policies and arbitrary topologies.

Routing. Existing work has studied loop prevention in distance-vector routing [21, 36, 10, 39, 16, 38] with different overhead, convergence, and stability tradeoffs. Contra is most related to DSDV [39], AODV [38], and Babel [16], which use sequence numbers on route updates for convergence. The novelty of Contra lies in its use of programmable data planes to implement a wide array of distance-vector protocols in the presence of unstable metrics, and its design of policy-aware flowlet switching mechanisms.

Regular languages for networking. NetKAT [13], Merlin [45], FatTire [40], and Propane [14] all use regular expressions to specify path constraints, but none of them supports dynamic preferences based on network conditions.

8 Discussion

Correctness guarantees. Contra guarantees that traffic always follows policy-compliant paths even in the presence of unstable metrics. In terms of performance, previous work has shown that when switches make distributed decisions, the resulting mechanism is not globally optimal [11]. However, as demonstrated in our experiments as well as previous work [11, 30], performance-aware routing still leads to FCT improvements compared to static routing.

Policy changes. Policy changes can be handled by recompilation, which would generate new switch programs. As we demonstrated in the experiments, policy compilation is fast and scales to large networks. We expect policy changes to happen infrequently and only on a larger timescale. In order to implement the updates, Contra may be able to borrow existing work on consistent update algorithms [41].

Traffic classes. Contra currently does not support traffic classes. Adding such support would require extending the language with header predicates [20, 13], and designing new mechanisms to prioritize one traffic class over another.

9 Conclusion

We have presented Contra, a system for specifying and enforcing performance-aware routing policies. Policies in Contra are written in a declarative language, and compiled to switch programs that run on the data plane to implement a variant of distance-vector protocols. These programs generate probes to collect path metrics, and dynamically choose the best paths along which to forward traffic. Our evaluation shows that Contra scales well to large topologies, and that the synthesized switch programs can achieve performance competitive with hand-crafted solutions that are specialized to particular topologies and hard-coded policies. Contra is also substantially more general, supporting a wide range of policies over arbitrary topologies.

A Policy analysis and decomposition

At a high level, the Contra compiler implements the policies in a distance-vector protocol, where switches propagate periodic probes and compute a best next hop for each destination using the path metrics. To avoid flooding the network with probes, a switch will only disseminate the best probe in a batch and discard the rest. Moreover, if a policy uses multiple metrics, each probe will carry all metrics to further reduce traffic. However, these techniques are not always safe—the policy needs to be *isotonic*, because otherwise downstream switches can wind up with suboptimal paths. The policy also needs to be *monotonic*, because otherwise loops may form.

Monotonicity. A policy f is monotonic iff. extending a path p by an additional link l does not result in a better ranked path, i.e., $f(p) \le f(p \cdot l)$; f is *strictly* monotonic if $f(p) < f(p \cdot l)$. Strict monotonicity ensures that loops will not form in distance-vector protocols (assuming static metrics that do not change), because a path's rank only degrades as it gets longer [22]. In principle, one could write a policy that is not monotonic, such as `minimize (- path.len)`, but in practice, we are not aware of such policies actually in use. On the other hand, there are practical policies such as `minimize (path.util)` that are not *strictly* monotonic. To ensure safety, the Contra compiler implements a conservative monotonicity analysis and alerts a programmer of a potential error if the policy is non-monotonic. But our compiler accepts non-strict monotonic programs: our probe propagation mechanism associates an "age" with each probe stored in a switch, and break ties by rejecting more recent probes if they have the same value as the currently used metric, because they may have traversed zero-weight cycles.

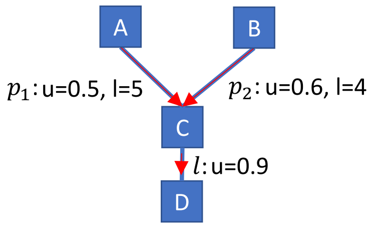

Figure 12: Contra requires (sub)policies to be isotonic.

Isotonicity. A policy f is isotonic iff. for any paths p_1, p_2, and any link l, extending both paths by l preserves the original relative ranking, *i.e.*, $f(p_1) \le f(p_2) \iff f(p_1 \cdot l) \le f(p_2 \cdot l)$. Isotonicity guarantees convergence to the best paths [22] even if a switch discards suboptimal probes. Figure 12 demonstrates the idea: if C prefers the probe from path p_1 over that from p_2 and discards the latter, then its downstream neighbor D must have the same preference, or else it would miss a path with a better metric. However, there are some useful policies that are non-isotonic, such as the following congestion-aware routing policy [27] that switches between metrics depending on the network condition.

$$\texttt{if } \texttt{path.util} < .8 \texttt{ then } (1, \texttt{path.util}) \texttt{ else } (2, \texttt{path.len})$$

To see why the policy is non-isotonic, consider the switch C in Figure 12 that receives two probes with metrics {`u=0.5,l=5`} and {`u=0.6,l=4`}. C prefers the first probe because `path.util < 0.8` evaluates to true for both probes and the two probes will be ranked based on utilization. However, C cannot simply discard the second probe, because all paths to its downstream neighbor D may be highly congested (e.g., u(D-S)=0.9). In this case, `path.util < 0.8` evaluates to false at D for both probes, causing D's preference to be inverted.

Policy decomposition. The Contra compiler tries to decompose non-isotonic policies into multiple isotonic (and monotonic) subpolicies, and generates different types of probes to propagate each subpolicy. If such a decomposition is impossible, then it rejects the policy. For instance, the compiler decomposes the previous policy as follows:

$$\texttt{if } \boxed{\texttt{path.util}}^{0} < .8 \texttt{ then } (1, \boxed{\texttt{path.util}}^{0}) \texttt{ else } (2, \boxed{\texttt{path.len}}^{1})$$

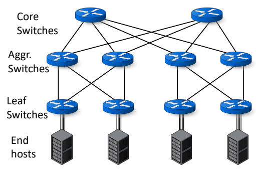
where type-0 probes carry `path.util`, and type-1 probes carry `path.len`. Switches can discard suboptimal probes within each type, but must propagate both types of probes. The complete policy is only evaluated at source nodes. We only attempt this analysis on conditional policies, such as the one above. There remain non-isotonic policies such as "shortest widest paths" (path.util, path.len) that the Contra compiler is unable to implement.

More generally, our compiler performs an analysis to try to decompose f to a collection of subpolicies $(s, f_1, \ldots, f_n)$, where each f_i is monotonic and isotonic, and s combines the subpolicies such that $f(p) = s(f_1(p), \ldots, f_n(p))$. For this decomposition to be correct, s needs to be strictly increasing in each of its arguments, i.e., for any $x_i \le x'_i$, we need to have $s(x_1, \ldots, x_{i-1}, x_i, x_{i+1}, x_n) \le s(x_1, \ldots, x_{i-1}, x'_i, x_{i+1}, x_n)$. Intuitively, this condition allows a switch to safely discard any non-minimum x_i values of each probe type.

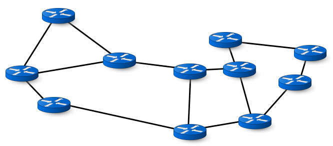
Limitations. Currently, Contra does not support traffic classification, but extending the language with header predicates as in prior work [20, 13] should not present any significant intellectual challenge. A more notable limitation involves policies that prioritize one traffic class over another. For instance, B4 [26] prioritizes small, latency-sensitive user requests over large, latency-insensitive bulk transfers. Currently, Contra ranks paths and selects the best path for each flowlet, but does not compare different types of traffic in order to prefer one over the other. We leave integration of such policies into our framework to future work.

B Key topologies for experimental evaluation

We briefly talked about our experimental setups in Section 6.1. Here, we provide more details of topologies we



(a) The Fattree topology



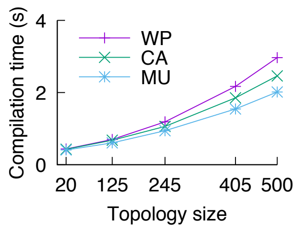
(b) The Abilene topology

Figure 13: The topologies we have used in the simulation environment.

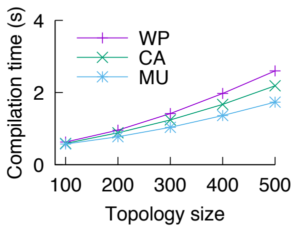
have used. We conducted our experiments in simulation (ns-3) and emulation (bmv2 in Mininet) using two topologies—a Fattree network and the Abilene network. Figure 13 shows topologies we used in simulation setup. The links between switches in both topologies operate at high speed: 10 Gbps in Fattree and 40 Gbps in Abilene . The emulation environment, on the other hand, uses a 6-ary Fattree with 45 switches (not shown, see [8] for more details), as well as the Abilene topology (Figure 13b). In both emulated topologies, the links operate at lower speed (50 Mbps) to avoid causing bottlenecks in the software switches.

C Compiler scalability

We tested Contra compiler scalability (more details in Section 6.2) using topologies of varying sizes from 20 to 500 nodes. Figure 14 shows the time to compile P4 programs from high-level policies as topology size increases. Figure 15 shows the amount of resources used by the P4 programs compiled for different policies.



(a) Fattree topologies



(b) Random networks

Figure 14: The Contra compiler scales well to large network sizes and sophisticated policies (unit: seconds).

D Link failure

To understand the degree of congestion when topology becomes asymmetric due to link failures, we injected a link failure between aggregation and core switches, and then measured queue lengths of other links. Figure 16 shows the CDF of queue lengths for Contra (under the WSP policy: widest shortest paths) and ECMP when there is a link failure. As we can see, Contra has much shorter queues than ECMP, and Contra queue length is less than 1000 MSS. Note that we have not bounded to queue sizes in order to study the queue growths in different systems. Figure 17 shows the aggregate throughput before and after a link failure. Contra successfully detected this failure in 800 μs and recovered its throughput in 1 ms.

E Protocol dynamics

Previously, in Section 6.5 we have summarized the results of network dynamics experiments. Here, we present the full results across network loads. Figures 18a and 19a show the end-to-end latency packets experience in the Fattree topology and the Abilene topology at 60% network load (dataset: web search). For MU policy, we further break down the number of extra hops in transient loops and non-shortest paths for both topologies: Figures 18b and 19b show number of extra hops in non-shortest paths as network load increases; Figures 18c and 19c show the number of extra hops in transient loops.

F High-fidelity emulation

In the main paper, Section 6.6 already summarized the key FCT results obtained in our emulation testbed. Here, we show the full results across workloads, network loads, and Contra policies. All results are obtained over four runs. Figure 20 and Figure 22 show the FCT results for web search and cache workloads in 6-ary symmetric Fattree topology. Figure 21 and Figure 23 show the FCT results for web search and cache workloads in 6-ary asymmetric Fattree topology. Figure 24 and Figure 25 show the FCT results for web search and cache workloads in the Abilene topology.

G Comparison with the FMCF solution

Although the experiments on flow completion times already demonstrate that Contra can boost application performance, we would like to further investigate how Contra performs when compared to an *idealized* solution for which we can derive an optimal bound. To this end, we use a *Fractional Multi-Commodity Flow* problem (FMCF) [29] to model this scenario, and note that similar formulations have been used in other projects [31, 47]. An MCF problem takes as input the (fixed) demand for sender/receiver pairs and the network topology, and computes the optimal traffic splitting across paths in order to minimize the utilization of the most congested link. The *fractional* version of MCF simply means that a flow can be split across different paths as well. This formulation makes several simplifying assumptions, which require minor modifications to the tested systems. Nevertheless, we believe that the results we obtain are still illustrative, as these assumptions make it possible to derive an optimal solution to compare against. The policy we have used in Contra is WSP (widest shortest paths) for Fattree, and MU (Minimum Utilization) for Abilene.

G.1 The FMCF formulation

We have used the same formulation as the Linear Programming Formulation (LPF) in [46]. This formulation models the physical network as $G(V,E)$, where V denotes the set of switches and E denotes the set of links. For each link (i,j), c_{ij} represents its link capacity. $X_{ij}^k \in [0,1]$ is the percentage

Figure 25: FCT results for cache workload in Abilene topology.

of traffic a solution sends to link (i,j) for a given commodity flow from the source s_k to the destination t_k, where $k \in K$ represents a commodity flow chosen from the set K of flows to be sent. The total demand for a flow k is d_k. Our goal is to minimize the maximum link utilization $\alpha \in [0,1]$ across the network.

The problem can then be formulated as follows:

$$\min(\alpha) \tag{1}$$

s.t.

$$\sum_{j:(i,j)\in E} X_{ij}^k - \sum_{j:(j,i)\in E} X_{ji}^k = 0, \qquad k \in K, i \neq s_k, t_k \tag{2}$$

$$\sum_{j:(i,j)\in E} X_{ij}^k - \sum_{j:(j,i)\in E} X_{ji}^k = 1, \qquad k \in K, i = s_k \tag{3}$$

$$\sum_{k\in K} d_k X_{ij}^k \leq c_{ij}\alpha, \qquad (i,j) \in E \tag{4}$$

$$0 \leq X_{ij}^k \leq 1, \alpha \geq 0.$$

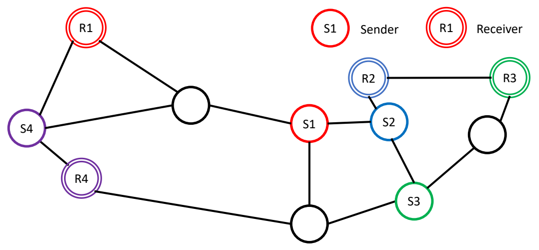
Equations 1 and 4 define α as the maximum link utilization and set the objective function to minimize this. Equation 2 encodes the flow conservation principle, which specifies that all nodes should have the same amount of incoming and outgoing traffic, except for the sources and destinations. Equation 3 specifies the source switch of each flow.

Simplifying assumptions: We note that this formulation makes several simplifying assumptions when testing the systems. In order to ensure that the created demands are static, we used UDP instead of TCP to avoid its flow control algorithm, and we artificially made the buffers deep enough to avoid packet loss. Given that the FMCF formulation does not have the notion of flowlets (which requires reasoning with timing behaviors), we have configured ECMP, SPAIN, and Contra to perform per-packet load balancing to emulate the problem that FMCF models. This configuration significantly disadvantages Contra, because unlike ECMP, SPAIN, which are inherently multipath, Contra is designed to spread traffic per-flowlet over time, and it only changes paths based on periodic probes. Since this feature is disabled, we instead measured the utilization of all systems at a coarser timescale over multiple RTTs, so that Contra is given an opportunity to balance the load. Despite the above simplifications, we believe that the results we obtain are still illustrative, as these assumptions make it possible to derive an optimal solution that we can compare the actual systems against.

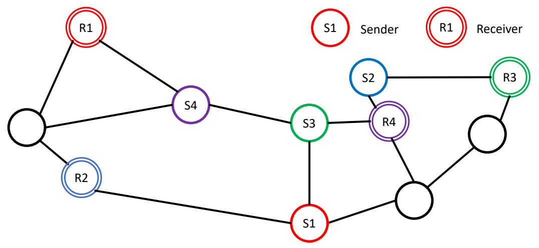
G.2 Experimental results for FMCF

Figures 27 and 28 show three setups where the optimal solutions returned by our solver are 20%, 40%, and 60%, respectively. For each setup, we have tested the systems on a Fattree topology and on Abilene. On a Fattree, both ECMP and Contra are very close to the optimum: they are 0.049% and 0.16% higher than optimum on average. Since ECMP splits traffic on a per-packet basis, it is expected to achieve almost perfect load balancing; Contra underperforms slightly since it only changes forwarding decisions based on periodic probes, but it performs close to ECMP and the optimum.

On a general topology, the performance of SPAIN is highly dependent on the locations of senders and receivers, as its load balancing mechanism precomputes non-overlapping paths when possible. We found that, when alternative paths in SPAIN do not overlap, it performs very close to optimum (worse only by 2.53%), but when paths overlap, SPAIN could underperform by as much as 6.55%. Contra, on the other hand, has consistent performance, and achieves similar performance with the same scenarios used to evaluate SPAIN. Compared to the optimum, the results for Contra are 2.41% and 2.36% higher, respectively. Figure 26 shows the two setups we have used for the experiments with SPAIN.



(a) Abilene setup 1



(b) Abilene setup 2

Figure 26: Selection of sender/receiver pairs on Abilene.

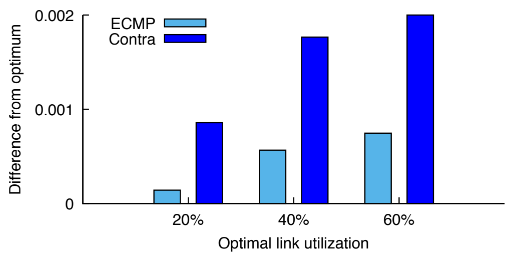


Figure 27: The performance of Contra is close to the optimum in the FMCF formulation (Fattree topology).

H Waypoint policy

The performance evaluation in our main paper has focused on policies that do not involve regular expressions, because regular expressions constrain paths rather than optimize for performance. Nevertheless, we have conducted a set of ex-

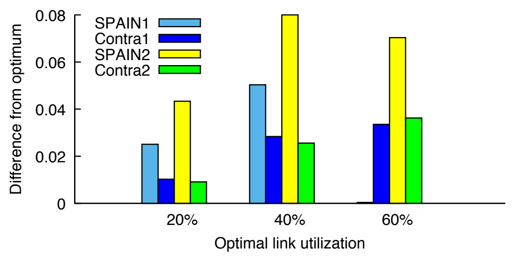

Figure 28: The performance of Contra is close to the optimum in the FMCF formulation (Abilene topology).

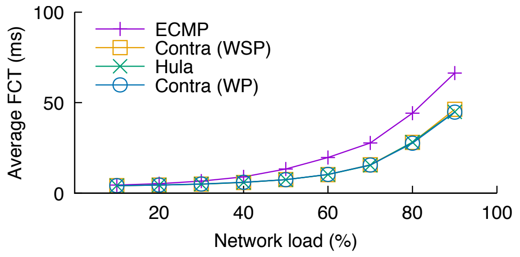

Figure 29: FCT for the waypoint policy (workload: web search)

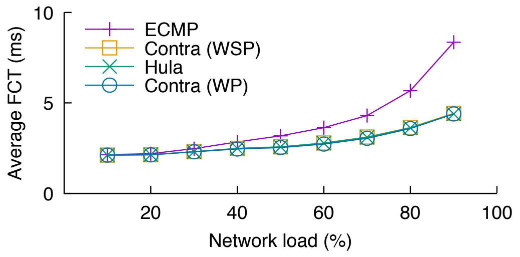

Figure 30: FCT for the waypoint policy (workload: cache)

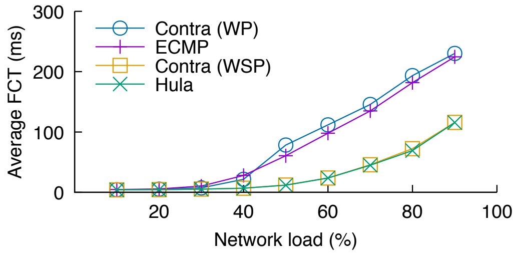

Figure 31: FCT for the waypoint policy on an asymmetric topology (workload: web search)

periments on such policies, and report the key findings in this section. We have used the waypoint policy (WP) with one regular expression, and measured the performance and protocol overhead in different workloads.

Flow completion time. Figures 29 and 30 show the FCT achieved by the WP policy on a symmetric data center topology, on the web search and cache datasets, respectively. As we can see, on the symmetric topology, WP performs similarly to Hula and WSP on both workloads. Figures 31 and 32 show the FCT results for the asymmetric topology, where we have injected a failed link. When the topology is asymmetric, WP performs worse than ECMP. This is expected, as WP imposes additional path constraints.

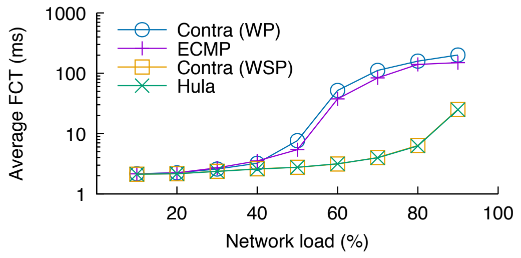

Figure 32: FCT for the waypoint policy on an asymmetric topology (workload: cache)

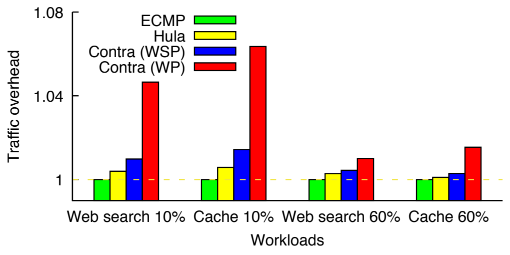

Figure 33: The tags in the waypoint (WP) policy introduce more traffic overhead.

Protocol overhead. Figure 33 shows the traffic overhead of the WP policy. As we can see, WP sends more traffic than WSP because it tags packets with policy states and creates separate probes for different regular expression matches. At 10% load, 92% of the traffic overhead is due to probes and 8% due to tags; at 60% load, 70% of the traffic overhead is due to probes and 30% due to tags.

I Traffic overhead

To evaluate the traffic overhead incurred by Contra due to additional probes (the policies below do not require tags), we measured the amount of traffic sent over the network by Contra, Hula, and ECMP at 10% and 60% network load. Figure 34 shows the results a normalized by the traffic sent by ECMP (i.e., no extra tags or probes). Across workloads, Contra incurred 0.79% more traffic than ECMP, and 0.44% more than Hula, which seems to be reasonable.

We also evaluated the traffic overhead of SPAIN and Contra on the Abilene network, at 10% and 60% network load. Figure 35 shows the results. We found that only 0.54% of traffic is due to the extra probes in Contra. Interestingly, al-

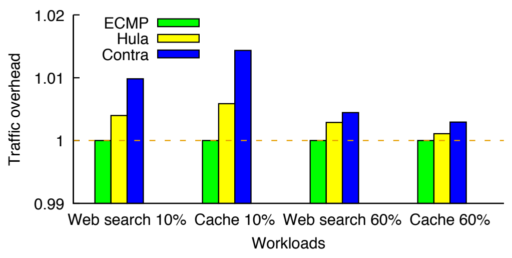

Figure 34: The traffic overhead of Contra is low.

though SPAIN did not use any extra probes, the amount of traffic SPAIN sent across the network is higher than that of Contra, and even higher than the total traffic of Contra. This is because SPAIN's paths are on average longer than these used in Contra. As a result, Contra requires 6.65% less network bandwidth than SPAIN.

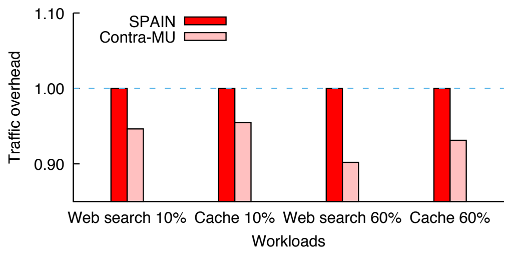

Figure 35: The traffic overhead of Contra and SPAIN on the Abilene network

FLAIR: Accelerating Reads with Consistency-Aware Network Routing

Hatem Takruri, Ibrahim Kettaneh, Ahmed Alquraan, Samer Al-Kiswany
University of Waterloo, Canada

Abstract

We present FLAIR, a novel approach for accelerating read operations in leader-based consensus protocols. FLAIR leverages the capabilities of the new generation of programmable switches to serve reads from follower replicas without compromising consistency. The core of the new approach is a packet-processing pipeline that can track client requests and system replies, identify consistent replicas, and at line speed, forward read requests to replicas that can serve the read without sacrificing linearizability. An additional benefit of FLAIR is that it facilitates devising novel consistency-aware load balancing techniques.

Following the new approach, we designed FlairKV, a key-value store atop Raft. FlairKV implements the processing pipeline using the P4 programming language. We evaluate the benefits of the proposed approach and compare it to previous approaches using a cluster with a Barefoot Tofino switch. Our evaluation indicates that, compared to state-of-the-art alternatives, the proposed approach can bring significant performance gains: up to 42% higher throughput and 35-97% lower latency for most workloads.

1. Introduction

Replication is the main reliability technique for many modern cloud services [1, 2, 3] that process billions of requests each day [3, 4, 5]. Unfortunately, modern strongly-consistent replication protocols [6] – such as multi-Paxos [7], Raft [8], Zab [9], and Viewstamped replication (VR) [10] – deliver poor read performance. This is because these protocols are leader-based: a single leader replica (or leader, for short) processes every read and write request, while follower replicas (followers for short) are used for reliability only.

Optimizing read performance is clearly important; for instance, the read-to-write ratio is 380:1 in Google's F1 advertising system [11], 500:1 in Facebook's TAO [5], and 30:1 in Facebook memcached deployments [12]. Previous efforts have attempted to accelerate reads by giving read leases [13] to some [14] or all followers [1, 15, 16], While holding a lease, a follower can serve read requests without consulting the leader; each lease has an expiration period. Unfortunately, this approach complicates the system's design, as it requires careful management of leases, affects the write operation – as all granted leases need to be revoked before an object can be modified – and imposes long delays when a follower holding a lease fails [1, 14].

Alternatively, many systems support a relaxed consistency model (e.g., eventual [2, 17, 18, 19, 20, 21] or read-your-write [5, 21, 22]), in exchange for the ability to read from followers, albeit the possibility of reading stale data.

In this paper, we present the fast, linearizable, network-accelerated client reads (FLAIR), a novel protocol to serve reads from follower replicas with minimal changes to current leader-based consensus protocols without using leases, all while preserving linearizability. In addition to improving read performance, FLAIR improves write performance by reducing the number of requests that must be handled by the leader and employing consistency-aware load-balancing.

FLAIR is positioned as a shim layer on top of a leader-based protocol (§3). FLAIR assumes a few properties of the underlying consensus protocol: the operations are stored in a replicated log; at any time, there is at most one leader in the system that can commit new entries in the log; reads served by the leader are linearizable; and after committing an entry in the log, the leader knows which followers have a log consistent with its log up to that entry. These properties hold for all major leader-based protocols (Raft [8], VR [10], DARE [23], Zookeeper [2], and multi-Paxos [24, 25, 26]).

FLAIR leverages the power and flexibility of the new generation of programmable switches. The core of FLAIR is a packet-processing pipeline (§4) that maintains compact information about all objects stored in the system. FLAIR tracks every write request and the corresponding system reply to identify which objects are stable (i.e., not being modified) and which followers hold a consistent value for each object, then uses this information to forward reads of stable objects to consistent followers. Followers optimistically serve reads and the FLAIR switch validates read replies to detect stale values. If the switch suspects that a reply from a follower is stale, it will drop the reply and resubmit the read request to the leader.

An additional benefit of FLAIR is that it facilitates the building of novel consistency-aware load balancing techniques. In systems that grant a lease to followers [1, 14, 15, 16], clients send read requests to a randomly selected follower. If the follower does not hold a lease, it blocks the request until it obtains a lease, or it forwards the request to the leader; either way, this approach adds additional delay. FLAIR does not incur this inefficiency as FLAIR load balances read requests only among followers that hold a consistent value for the requested object. In this paper we design three consistency-aware load balancing techniques (§6): random, leader avoidance, and load awareness.

Unlike other systems that use switch's new capabilities [27, 28, 29], FLAIR does not rely on the controller to update the switch information after every write operation, as this approach would add unacceptable delays. Instead, FLAIR piggybacks control messages on system replies, and the switch extracts and processes them.

Despite its simplicity, implementing this approach is complicated by the limitations of programmable switches (§2) and the complexity of handling switch failures, network partitioning, and packet loss and reordering (§4).

To demonstrate the powerful capabilities of the proposed approach, we prototyped FlairKV (§6), a key-value store built atop Raft [8]. We made only minor changes to Raft's implementation [30] to enable followers to serve reads, make the leader order write requests following the sequence numbers assigned by the switch, and expose leader's log information to the FLAIR layer. The packet-processing pipeline was implemented using the P4 programming language [31]. We implemented the three aforementioned load-balancing techniques (§6).

Our evaluation of FlairKV (§7) on a cluster with a Barefoot Tofino switch shows that FLAIR can bring sizable performance gains without increasing the complexity of the leader-based protocols or the write operation overhead. Our evaluation with different read-to-write ratios and workload skewness shows that FlairKV brings up to 2.8 times higher throughput than an optimized Raft implementation, at least 4 times higher throughput compared to Viewstamped replication, Raft, and FastPaxos, and up to 42% higher throughput and up to 35-97% lower latency for most workloads compared to state-of-the-art leases-based design [1, 16].

The performance and programmability of the new generation of switches opens the door for the switches to be used beyond traditional network functionalities. We hope our experience will inform a new generation of distributed systems that co-design network protocols with systems operations.

2. Background

In this section, we present an overview of leader-based consensus protocols, followed by a look at the new programmable switches and their limitations.

2.1. Leader-based Consensus

Leader-based consensus (LC) protocols [8, 9, 10, 23, 24, 25] are widely adopted in modern systems [2, 3, 4, 16]. The idea of having a leader that can commit an operation in a single round trip dates back to the early consensus protocols [7, 32]. Having a leader reduces contention and the number of messages, which greatly improves performance [7, 24].

LC protocols divide time into terms (a.k.a. views or epochs). Each term has a single leader; if the leader fails, a new term starts and a new leader is elected.

Clients send write requests to the leader (1 in Figure 1). The leader appends the request to its local log (2) and then sends the request to all follower replicas (3). A follower appends the request to its log (4) before sending an acknowledgment to the leader (5). If the leader receives an acknowledgment from a majority of its followers, the operation is considered *committed*. The leader *applies* the operation to its local state machine (e.g., in memory key-value store in Figure 1) in (6), then acknowledges the operation to the client (7). The leader will asynchronously inform the followers that it committed the operation. Followers maintain a *commit_index*, a log index pointing to the last committed operation in the log; when a follower receives the commit notification, it advances its *commit_index* and applies the write to its local store.

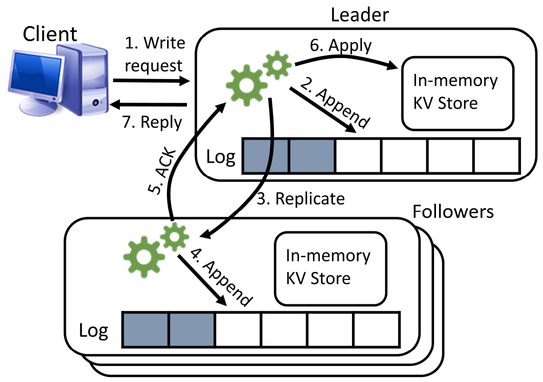

Figure 1. The path for a write operation.

The replicated log has two properties that make it easy to reason about: it is guaranteed that if an operation at index *i* is committed, then every operation with an index smaller than *i* is committed as well; and if a follower accepts a new entry to its log, it is guaranteed that its log is identical to the leader's log up to that entry.

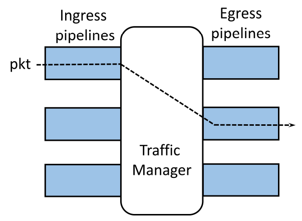
Client read requests are also sent to the leader. In Raft, the leader sends a heartbeat to all followers to make sure it is still the leader. If a majority of followers reply, the leader serves the read form its local store: it will check that all committed operations related to the requested object are applied to the local store before serving the request.

A common optimization is the leader lease optimization. Instead of collecting a majority of heartbeats for every read request, a majority of the followers can give the leader a lease [8, 24]. While holding a lease, the leader serves reads locally without contacting followers. Unfortunately, even with this optimization, the performance of the leader-based protocols is limited to a single-node performance.

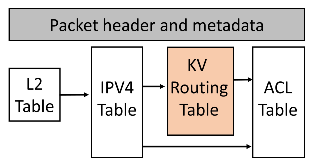
2.2. Programmable Switches

Programmable switches allow the implementation of an application-specific packet-processing pipeline that is deployed on network devices and executed at line speed. A number of vendors produce network-programmable ASICs, including Barefoot's Tofino [33], Cavium's XPliant [34], and Broadcom Trident 3 [35].

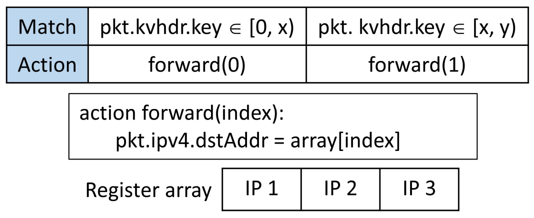
Figure 4(a) illustrates the basic data plane architecture of modern programmable switches. The data plane contains three main components: ingress pipelines, a traffic manager,



(a) Switch data plane.



(b) Pipeline for routing based on a hash-based key



(c) Simple match-action stage for routing based on a hash-based key for the KV routing table in subfigure (b)

Figure 4. Switch data plane.

and egress pipelines. A packet is first processed by an ingress pipeline before it is forwarded by the traffic manager to the egress pipeline that will finally emit the packet.

Each pipeline is composed of multiple stages. At each stage, one or more tables match fields in the packet header or metadata; if a packet matches, the corresponding action is executed. Programmers can define custom headers and metadata as well as custom actions. Each stage has its own dedicated resources, including tables and register arrays (a memory buffer). Figure 4(b) shows a simple example of a pipeline that routes a request to a key-value store based on the key, and Figure 4(c) shows the details of the KV routing stage. The stage forwards the request based on the key in the packet's custom L4 header. The programmer implements a forward() action that accesses the register array holding nodes' IP addresses. An external controller can modify the register array and the table entries.

Stages can share data through the packet header and small per-packet metadata (a few hundred bytes in size) that is propagated between the stages as the packet is processed throughout the pipeline (Figure 4(b)). The processing of packets can be viewed as a graph of match-action stages.

Programmers use domain-specific languages like P4 [36] to define their own packet headers, define tables, implement custom actions, and configure the processing graphs.

Challenges. While programmable ASICs and their domain-specific languages significantly increase the flexibility of network switches, the need to execute custom actions at line speed restricts what can be done. To process packets at line speed, P4 and modern programmable ASICs have to meet strict resource and timing requirements. Consequently, modern ASICs limit (1) the number of stages per pipeline, (2) the number of tables and registers per stage, (3) the number of times any register can be accessed per packet, (4) the amount of data that can be read/written per-packet per register, (5)

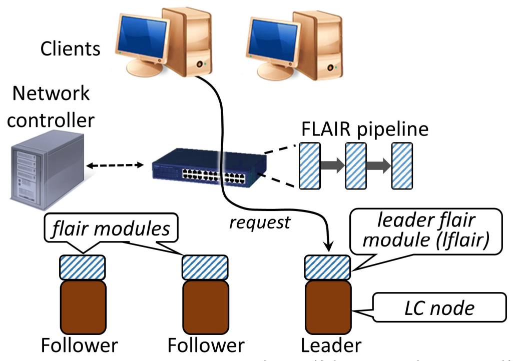


Figure 2. System architecture. The solid arrow shows a client request, while the dashed arrow show control messages.

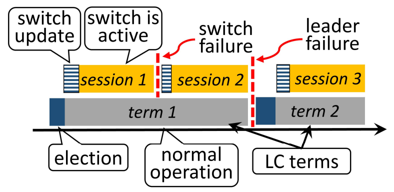

Figure 3. FLAIR sessions. Time is divided into terms. Each term starts with a leader election. Each term has one or more sessions that start with updating the switch data.

the size of per-packet metadata that is passed between stages. Finally, modern ASIC's lack support of loops or recursion.

3. FLAIR Overview

FLAIR is a novel protocol that targets deployments in a single data center. Figure 2 shows the system architecture, which consists of a programmable switch, a central controller, and storage nodes. Typically, multiple FLAIR instances are deployed with each serving a disjoint set of objects. For simplicity, we present a FLAIR deployment with one replica set (i.e., one leader and its followers).

FLAIR is based on the following assumptions; the network is unreliable and asynchronous, as there are no guarantees that packets will be received in a timely manner or even delivered at all, and there is no limit on the time a node or switch takes to process a packet. Finally, FLAIR assumes a non-byzantine failure model in which nodes and switches may stop working but will never send erroneous messages.

FLAIR divides time into sessions (Figure 3). During a session the leader is bonded to a single switch that runs the FLAIR pipeline. Each session has a unique id that is assigned in a strictly increasing order. A session ends when a leader fails or the leader suspects that the switch has failed. An LC term may have one or more sessions, but a session does not span multiple terms.

A session starts with the FLAIR module at the leader (dubbed the *lflair* module) incrementing the session id, committing it to the LC log, updating the switch information about the objects in the system, then activating the session at the switch. *lflair* module keeps the switch's information up to date while in an active session. If the switch does not have an active session it drops all FLAIR packets.

Clients. FLAIR is accessed through a client library with a simple read/write/delete interface. Read (get) and write (put) read or write entire objects. The library adds a special FLAIR packet header to every request, that contains an operation code (e.g., read) and a key (a hash-based object identifier).

Controller. Our design targets data centers that use a SDN network following a variant of the multi-rooted tree topology [37, 38]. A central controller uses OpenFlow [39] to manage the network by installing per-flow forwarding, filtering, and rewriting rules in switches.

As with previous projects that leverage SDN capabilities [27, 29, 40, 41], the controller assigns a distinct address for each replica set. The controller installs forwarding rules to guarantee that every client request for a range of keys served by a single replica set is passed through a specific switch (dubbed FLAIR switch); that switch will run the FLAIR logic for that range of keys. The controller typically selects a common ancestor switch of all replicas and installs rules to forward system replies through the same switch. Only client request/replies are routed through the FLAIR switch, leader-follower messages do not have the FLAIR header nor are necessarily routed through the FLAIR switch.

While this approach may create a longer path than traditional forwarding, the effect of this change is minimal. Li et al. [40] reported that for 88% of cases, there is no additional latency, and the 99th percentile had less than 5 μs of added latency. This minimal added latency is due to the fact that the selected switch is the common ancestor of target replicas and client packets have to traverse that switch anyway.

On a switch failure, the controller selects a new switch and updates all the forwarding rules accordingly. The controller load balances the work across switches by assigning different replica sets to different switches.

Storage Nodes. The storage nodes run the FLAIR and LC protocols. For read requests, before serving a read, followers verify that all committed writes to the requested object have been applied to the follower's local storage.

Write requests are processed by the leader. After a successful write operation, the leader passes to the *lflair* module the log index at which the write was committed and the list of followers that accepted the write operation and have a consistent log up to that log index. The *lflair* encodes this list into a compact bitmap and uploads it and the log index to the switch (piggybacked on the write reply).

Programmable Switch. The switch is a core component of FLAIR: it tracks every write request and the corresponding reply to identify which objects are stable (not being modified) and which replicas have a consistent value of each object (encoded in the bitmap provided by the *lfair* module). If a read is issued while there are outstanding writes for the target object (i.e., writes without corresponding replies), the read is forwarded to the leader. If a read request is processed by the switch when there are no outstanding writes to the requested object, the switch forwards the request to one of the followers included in the last bitmap for the object sent by the *lflair* module. Followers optimistically serve read requests. The switch inspects every read reply; if it suspects that a follower returned stale data (Section 4.4), it will conservatively drop the reply and forward the request to the leader. FLAIR forwards all writes to the leader.

FLAIR also includes techniques to handle multiple concurrent writes to the same object (Section 4.3), packets reordering (Section 4.6), and tolerating switch, node, and network failures (Section 4.6).

4. System Design

4.1. Network Protocol

Packet format. FLAIR introduces an application-layer protocol embedded in the L4 payload of packets. Similar to many other storage systems [27, 29, 40], FLAIR uses UDP to issue client requests in order to achieve low latency and simplify request routing. Communication between replicas uses TCP for its reliability. A special UDP port is reserved to distinguish FLAIR packets; for UDP packets with this port, the switch invokes the FLAIR custom processing pipeline. Other switches do not need to understand the FLAIR header and will treat FLAIR packets as normal packets. In this way, FLAIR can coexist with other network protocols.

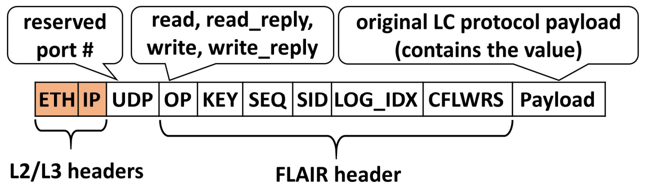
Figure 5 shows the main fields in the FLAIR header. We briefly discuss the fields here (a detailed discussion of the protocol is presented next):

- `OP`: the request type. Clients populate this field in the request packet (e.g., read, or write); replicas populate this field in the reply packets (e.g., read_reply, write_reply).
- `KEY`: hash-based object identifier.
- `SEQ`: a sequence number added by the switch. The switch increments the sequence number on every write operation.
- `SID`: a unique session id. The <`SID`, `SEQ`> combination represents a unique identifier for every write request.
- `LOG_IDX`: a log index. In a write_reply, the log index indicates the index at which the write was committed. For reads, the switch populates `LOG_IDX` to make sure the followers' logs are committed and applied up to that index.
- `CFLWRS`: In write_reply, the `CFLWRS` is a map of the followers that have a consistent log up to `LOG_IDX`.

Following the FLAIR header is the original LC protocol payload, which includes the value for read/write operations.

4.2. Switch Data Structures

To process a read request, the switch performs two specific tasks (Section 4.4). First, it forwards read requests to consistent followers while balancing the load among them. Second, it verifies the read replies to preserve safety. To perform these tasks, the switch maintains two data structures: a session array and a key group array.



reserved port #
read, read_reply, write, write_reply
original LC protocol payload (contains the value)
ETH
IP
UDP
OP
KEY
SEQ
SID
LOG_IDX
CFLWRS

Figure 5. FLAIR packet format.

```
SessionArrayEntry {                 KGroupArrayEntry {
  bit<1>  is_active;                  bit<1>  is_stable;
  bit<32> session_id;                 bit<64> seq_num;
  bit<32> leader_ip;                  bit<64> log_idx;
  bit<64> session_seq_num;            bit<8>  consistent_followers;
  bit<48> heartbeat_tstamp; }       }
```

Listing 1. Session and kgroup entries. The numbers indicate the field size in bits.

Session array. A single switch typically supports multiple replica sets (i.e., FLAIR+LC instances) with each set storing a disjoint set of keys. Each entry in the session array maintains the session status for a single replica set. An entry contains an is_active flag, session id, leader IP address, current session sequence number, and the timestamp of the last heartbeat received from the *lflair* module (Listing 1). When is_active is true, we say the session is *active*, which indicates that the session entry and kgroup array are consistent with the leader's information. The switch processes packets using the FLAIR custom pipeline only if the session is active; otherwise, it will drop all FLAIR packets, rendering the system unavailable to clients until the switch can reach the *lflair* module and sync its session entry and key group array.

Key group (KGroup) array. To decide if followers can serve a certain read request, the switch needs to maintain information about which followers have the latest committed value of every object. Maintaining such information in the switch ASIC's memory is not feasible; instead, FLAIR groups objects based on their key and maintains aggregate information per group. We use the most significant *k* bits of the key to map an object to a key group (kgroup).

Every FLAIR+LC instance has a dedicated kgroup array. Each entry in the array (Listing 1) contains the status of a single kgroup, including an is_stable flag that indicates if all objects in the kgroup are stable. If a kgroup is not stable (is_stable is false), this indicates that at least one object in the kgroup is being modified (i.e., has an outstanding write in the system). The array entry also includes the sequence number (seq_num) of the last write request processed by the switch for any object in the kgroup, the log index (log_idx) of the last successful write to any object in the kgroup, and the consistent_followers bitmap pointing to all followers that have a consistent log up to log_idx.

4.3. Handling Write Requests

To issue a write request, a client populates the OP and KEY fields of the FLAIR packet header and puts the value in the payload, then sends the request.

When the switch receives the request, it will mark the corresponding kgroup entry as unstable. The switch will increment the session_seq_num in the session array and use it to populate the sequence number (seq_num) in the kgroup entry and the sequence number (SEQ) in the request header. Finally, the switch populates the session id (SID) field in the header and forwards the request to the leader.

The *lflair* module will verify that the session id is valid, and will pass the write request to the leader. The leader verifies that the <SID, SEQ> combination is larger than the <SID, SEQ> number of any previous write request it ever received, else it will drop the packet. The LC leader will process the write request following the LC protocol (Section 2.1): it will replicate the request to all followers, and when a majority of followers acknowledge the operation, the write operation is considered committed. A follower will acknowledge a write operation only if its log is identical to the leader's log up to that entry.

For the write reply, the leader will pass the following to the *lflair* module: the LC protocol payload for the write_reply, the log index at which the write was committed, and the list of followers that acknowledged the write. The *lflair* module will create the write reply packet with the leader provided payload, and will populate the LOG_IDX and the bitmap of the consistent followers (CFLWRS) using the information provided by the leader. *lflair* module populates the sequence number (SEQ) in the write_reply header using the SEQ of the corresponding write request. The *lflair* module then sends the write_reply packet.

The switch will process the write_reply header and verify its session id. The switch will compare the sequence number (SEQ) of the reply to the sequence number (seq_num) in the kgroup entry; if they are equal, this signifies that no other write is concurrently being processed in the system for any object in the kgroup. Consequently, it will update the log_idx and the consistent_followers fields in the kgroup entry using the values in the write reply. Then it will mark the kgroup stable and forward the reply to the client.

If the sequence number in the reply is smaller than the sequence number in the kgroup entry, this indicates that a later write to an object in the same kgroup has been processed by the switch. In this case, the switch forwards the write reply to the client without modifying the kgroup entry. The kgroup entry remains unstable until the last write to the kgroup (with a SEQ number in the write_reply equal to the seq_num in the kgroup entry) is acknowledged by the leader.

In a nutshell, the switch acts as a look-through metadata cache. Write requests invalidate the switch metadata related to the accessed kgroup, and write replies update the kgroup metadata at the switch. As we see next, the kgroup metadata is used to consistently load balance reads.

4.4. Handling Read Requests

Clients fill the OP and KEY fields of the FLAIR header and send the request. When the switch receives the request, it will check the kgroup entry. If the entry is stable, the switch will fill the sequence number (SEQ) and log index (LOG_IDX) header fields using the values in the kgroup entry. Then it will forward the request to one of the followers indicated in the consistent_followers bitmap. Section 6.2 details our load balancing techniques.

If the kgroup entry is not stable, the switch forwards the read request to the leader. We note that there is a chance for false positives in this design, as a single write will render all the objects in the same kgroup unstable. This is a drawback of maintaining information per group of keys. This inefficiency is incurred by leases-based protocols as well, as they maintain a lease per group of objects.

When a follower receives a read request, the follower's FLAIR module validates the request, then calls advance_then_read(LOG_IDX, key) routine, which compares the follower's commit_index to LOG_IDX. If the commit_index is smaller, the follower advances its commit_index to equal LOG_IDX, apply all the log entries to the local store, then serve the read request. The FLAIR module will populate the read_reply header; for the SEQ and SID fields, it will use the values found in the read request header.

We note that it is safe to advance the follower's commit_index to match the LOG_IDX in the read request, as the switch forwards read requests to a follower only if the leader indicates that all entries in the log up to that log index are committed, and that this specific follower is one of the replicas that have a log consistent to the leader's log up to that index. We discuss FLAIR correctness in Section 5.

When the switch receives a read_reply from a follower, it validates the session id, then verifies that the SEQ number of the read_reply equals the seq_num of the kgroup entry. If the sequence numbers are not equal, this signifies that a later write request was processed by the switch and there is a chance the follower has returned stale value. In this case, the switch drops the read_reply, generates a new read request using the KEY field from read_reply packet, and submits the read request to the leader. If the sequence number of the read_reply equals the sequance number in the kgroup entry, the switch forwards the reply to the client.

If a read request is forwarded to the leader, the *lflair* module verifies the session id, then calls advance_then_read(LOG_IDX, key). The switch verifies that the leader reply is valid (i.e., has the correct session id) before forwarding it to the client, without checking the seq_num in the kgroup entry.

4.5. Session Start Process

On the start of a new session, the *lflair* module reads the last session id from the LC log, increments it, and commits the new session id to the LC log. Then the *lflair* module asks the central controller for a new switch. The central controller neutralizes the old switch (making it drop all FLAIR packets) and reroutes FLAIR packets to a new switch, then confirms the switch change to the *lflair* module. This step guarantees that at any time at most one FLAIR switch is active. The *lflair* module updates the session entry (Listing 1) at the switch with the current leader IP and session id. For each new session, session_seq_num is reset to zero.

Populating the kgroup array. The *lflair* module maintains a copy of the kgroup array similar to the one maintained by the switch. If the leader did not change between sessions (e.g., the session change is due to switch failure), the kgroup array at the *lflair* module is up to date. The *lflair* module will set the seq_num entry in all kgroup entries to zero (equal to the session_seq_num in the session entry)., and upload it to the switch.

If the kgroup array at the *lflair* module is empty – for instance, after electing a new leader – the *lflair* module will query the leader for three pieces of information: its commit_index, the list of followers with the same commit_index, and a list of all uncommitted operations in the log (i.e., the operations after the commit_index in the log). The list of uncommitted operations is typically small, as it only includes operations that were received before the end of the last term but were not committed yet. The *lflair* module will traverse the list of uncommitted writes and mark their target kgroup entries unstable. For all other kgroup entries, the *lflair* module will mark them stable and set their seq_num to zero, log_idx to the leader's commit_index, and consistent_followers to include all the followers that have the same commit_index as the leader's. After updating the session entry and the kgroup array at the switch, the *lflair* module activates the switch session (sets is_active to true).

4.6. Fault Tolerance

Follower Failure. We rely on the LC protocol to handle follower failures. To avoid sending read requests to a failing follower, the leader notifies the *lflair* module when it detects the failure of a follower. The *lflair* module removes the follower from the switch-forwarding table (Section 3).

Leader Failure. On leader failure, a new leader is elected and a new term starts. The new leader informs the *lflair* module of the term change; and the *lflair* module starts a new session (Section 3).

The *lflair* module sends periodic heartbeats to the switch. Upon receiving a heartbeat, the switch determines whether it is from the current session. If the heartbeat is valid, the switch updates the heartbeat_timestamp in the session array and replies to the *lflair* module.

Switch Failure. If the *lflair* module misses the switch heartbeats for a *switch_stepdown* period of time (3 heartbeats in our prototype), the *lflair* module will suspect that the switch has failed and will start a new session. For efficiency (i.e. does not affect safety), if the switch misses three heartbeats from the leader, it will deactivate the session.

Network Partitioning. If a network partition isolates the switch from the leader, the leader treats it as a failed switch, as detailed above. If a network partition isolates the switch from a follower, read requests forwarded to the follower will time out and the client will resubmit the request. This failure affects performance, but not correctness. Upon determining that a follower is not reachable, the leader removes it from the forwarding table, as in the case of the failed follower described above.

Packet Loss. If a read or write request is lost, the client times out and resubmits the request. If a write reply is lost before reaching the switch, the kgroup entry will remain unstable until a new write operation to any key in the kgroup succeeds. While the kgroup entry is not stable, all read requests are forwarded to the leader.

Packet Reordering. It is critical for FLAIR correctness that the leader processes write requests in the same order that they are processed by the switch. Every write operation gets a unique <SID, SEQ> number. The switch marks a kgroup entry unstable until the leader replies to the last write issued for a key in the kgroup. Consequently, if the leader processes the requests out of order, the switch will incorrectly mark a kgroup stable while the out-of-order writes are modifying its objects. To prevent this scenario, the leader keeps track of the largest <SID, SEQ> it has ever processed and drops any write request with a smaller number. While session numbers (SIDs) are maintained in the log, the largest processed sequence number is retained in memory. If the leader fails, the new leader starts a new session, increments the session id (SID), and sets the session sequence number (SEQ) to zero.

5. Correctness

FLAIR guarantees linearizability, which means that concurrent operations must appear to be executed by a single machine. FLAIR relies on the LC protocol for any operation that updates the log and for reads from the leader.

FLAIR only adds the ability to serve reads from followers. In this section, we sketch out the proof of FLAIR correctness when the read is served by a follower. A full and detailed proof is available in the technical report [42]. Further, we used the TLA+ model checking tool [43] to verify the FLAIR correctness. We started from Raft's TLA+ specification [44] and extended it with a formal specification for our protocol and new invariants to validate the linearizability of reads. The TLA+ specification is in our technical report [42].

Safety. FLAIR guarantees that all read replies are linearizable. FLAIR trusts that the leader's read replies are linearizable and forwards them to the client. For reads served by followers, FLAIR guarantees that the read reply returns an identical value, as if the read was served by the leader. This is guaranteed using the following two steps:

First, when the switch receives a read request, the switch forwards that request to followers only when the switch has an active session and the kgroup entry is stable. This signifies that the switch information is up-to-date with the *lflair* module's information. Identifying a kgroup entry as stable signifies that there are no current writes to any object in the kgroup and that the last leader-provided consistent_followers bitmap points to followers that have the last committed value for every object in the kgroup. Consequently, any of the consistent followers will return a value identical to the leader's value.

Second, after forwarding a read request to a follower (say, flwrA), the switch may receive a write request that modifies the object. The leader may replicate the write request to a majority of nodes that does not include flwrA. If the leader processes the write request before flwrA serves the read request, flwrA will return stale data. To avoid this case, the switch performs a safety check on every read reply coming from followers: it verifies that the kgroup is still stable, and that the sequence number in the read_reply is equal to the sequence number in the kgroup entry. If the sequence numbers do not match (which indicates that there are later writes to objects in the kgroup), the switch conservatively drops the read reply and forwards the request to the leader. *At all times, reads are linearizable in FLAIR.*

6. Implementation

To demonstrate the benefits of the new approach, we prototyped FlairKV, a FLAIR-based key-value store built atop Raft [30]. We chose Raft due to its adoption in production systems [45, 46, 47, 48, 49], and the availability of standalone production-quality implementations [50].

6.1. Storage System Implementation

We have implemented FlairKV, including all switch data plane features, the FLAIR module, leaders' and followers' modifications, and the client library. We extended the Raft's follower code to implement an advance_then_read() function. We extended the leader to notify the *lflair* module as soon as it gets elected, and to extract its commit_index, the list of followers with a commit_index equal to the leader's commit_index, and the list of uncommitted writes. We extended the write reply with the list of followers which acknowledged the write. We implemented the leader lease optimization [8, 24] and modified Raft's client library to add the FLAIR header to client requests.

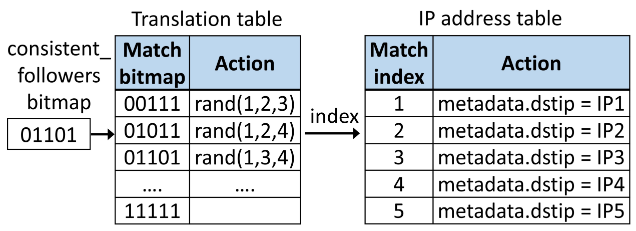
6.2. Switch Data Plane Implementation

The switch data plane is written in P4 v14 [31] and is compiled for Barefoot's Tofino ASIC [33], with Barefoot's P4Studio software suite [51]. Our P4 code defines 30 tables and 12 registers: six for the session array and six for the kgroup array. The kgroup array has 4K entries. Larger number of kgroups had negligible effect on performance. In total, our implementation uses less than 5% of the on-chip memory available in the Tofino ASIC, leaving ample resources to support other switch functionalities or more FlairKV instances. The rest of this section discusses optimizations implemented in FlairKV to cope with the strict timing and memory constraints of P4 and switch ASIC.

Heartbeats implementation. The leader and the switch exchange periodic heartbeats. If the switch_stepdown period passes without receiving a leader heartbeat, the switch deactivates the session. Instead of running a process in the controller to continuously track heartbeats, the switch monitors missed heartbeats as part of the validation step in the processing pipeline. The switch keeps track of the timestamp of the last heartbeat received in the session array (Listing 1). When processing any FLAIR packet, the switch computes the difference between the current time and the last heartbeat timestamp; if the difference is larger than switch_stepdown, the switch deactivates the session, making the system unavailable until the leader starts a new session.

Forwarding logic translates the consistent followers' bitmap to follower IP addresses. Storing the IP addresses of consistent followers for every entry in the kgroup array significantly increases the memory footprint. Moreover, randomly selecting a follower from the list while avoiding inconsistent ones is tricky given the P4 and current ASIC challenges (Section 2.2). Instead, the FlairKV leader encodes the follower status in a one-byte `consistent_followers` bitmap (Listing 1). Replicas are ordered in a list. If the least significant bit in the `consistent_follower` bitmap is set, this indicates that the first replica in the list is consistent, and so forth.

When forwarding a read request, the switch translates the encoded bitmap of consistent followers to select one follower; Figure 6 shows the translation process. The `consistent_followers` bitmap is used as an index to the translation table. Each entry in the table has an action that randomly selects a number that is then used as an index to the IP addresses table.



Match bitmap	Action
00111	rand(1,2,3)

2	metadata.dstip = IP2
3	metadata.dstip = IP3
4	metadata.dstip = IP4
5	metadata.dstip = IP5

Figure 6. Logical view of the forwarding logic. The stability bitmap matches an entry in the translation table and executes the corresponding action, generating an index of the selected destination's IP address. Using the index, the IP address table sets the destination's IP address in the metadata.

This design has two benefits: it significantly reduces the memory footprint of the kgroup array, and it can be accelerated using P4 "action profiles" [52].

Load balancing. In addition to the aforementioned random load-balancing technique (Figure 6), we implemented two load-aware techniques:

- *Leader avoidance*. Our benchmarking revealed that the write operation takes 35 times longer than a read operation; most of this overhead is borne by the leader. Consequently, this load-balancing technique avoids sending read requests to the leader for stable kgroups if there are any writes in the system. The aim is to reduce the leader load, as it is already busy serving writes and serving reads for unstable kgroups.
  To implement this technique, we compare the sequence number of a write_reply with the `session_seq_num`. If they are not equal, then there are pending writes in the system and the leader should not be burdened with any reads to stable kgroups.

- *Follower load awareness*. This technique distributes the load across followers proportionally to their load in the last *n* seconds. This technique is especially useful for deployments that use heterogeneous hardware, experience workload variations, or deploy more than one replica (i.e., replicas for different ranges of keys) on the same machine. In our design, followers report the length of the request queue in every heartbeat. Every second, the leader calculates the average queue length for each follower and assigns proportional weights to each follower. The leader updates the translation table to reflect these weights. For instance, if follower 1 should receive double the load of any other replica, the action for a bitmap 00111 will be `rand`(1, 1, 2, 3), doubling the chance replica 1 is selected.

Register access logic. Each stage has its own dedicated registers, and a register can be accessed only once in a stage. This restriction complicates FlairKV's logic, as different packet types (e.g., read and write_reply) must access the same registers at different stages in the pipeline. To cope with this restriction, FlairKV adds a dedicated table to access each register. Figure 7 shows an example of an action table for accessing register *r1*. Our code aggregates the information about all possible modes of accessing *r1* in the packet's metadata, including the access type (read or write), the index, and which data should be written or where the value should be read to. We then use a dedicated match-action table (Figure 7) to perform the actual read or write operation to/from the register in a single stage with a single invocation of the table. This approach has the additional benefit of reducing the number of stages.

Processing concurrent requests. The switch processes packets sequentially in a pipeline. Each pipeline stage processes one packet at a time. The switch may have multiple

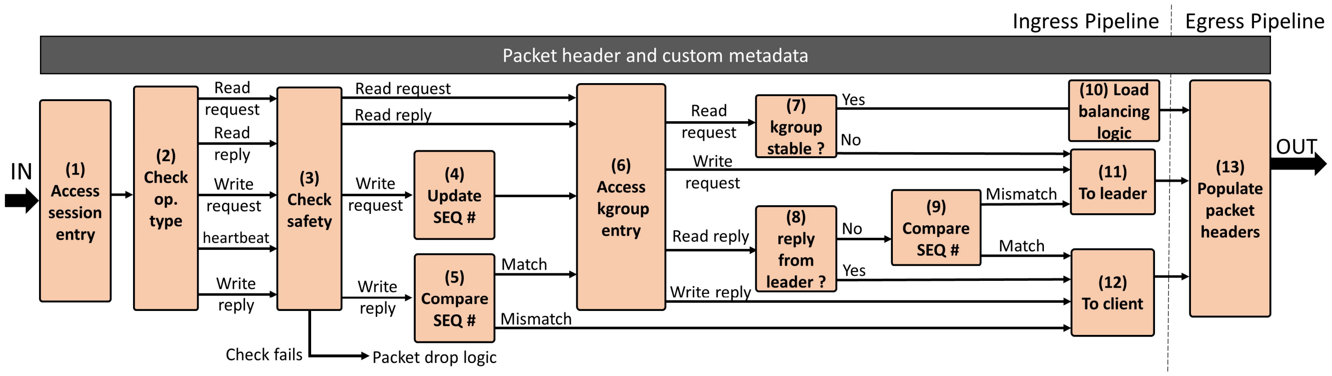

Figure 8. Logical view of the FlairKV switch data plane.

pipelines, each serving a subset of switch ports. FLAIR uses a single ingress pipeline and all egress pipelines. If a FLAIR packet is received on a different ingress pipeline, the packet is recirculated [52] to the FLAIR pipeline.

6.3. Putting the Switch Pipeline Together

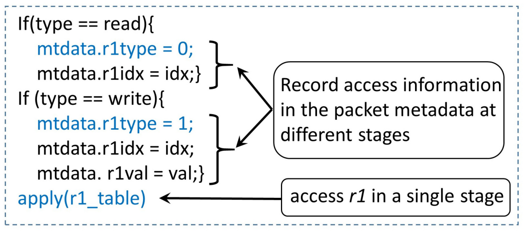
Figure 8 shows the pipeline layout in the switch data plane and the flow for a FlairKV packet. The pipeline starts by reading the session information (1 in Figure 8) and adding it to the packet metadata. Then the it extracts the operation type (2) and validates the request (3) by verifying the session id. If the packet has an older session id the packet is dropped. Further, in the validation stage the switch confirms that it did not miss leader heartbeats in the last switch_stepdown period (Section 4.6), else it deactivates the session.

Read requests access the kgroup array (6), and if the group is stable, the request is forwarded to a load-balancing logic (10) that implements the forwarding logic (Section 6.2); otherwise, it is sent to the leader.

If a read reply is from the leader, it is forwarded to the client (12). If it is from a follower, the pipeline performs the safety check (9) and, if it suspects the reply is stale, drops the reply, then resubmits the read request to the leader (11).

Write requests update the session_seq_num (4) and the kgroup entry (6), then are sent to the leader (11).

Write replies compare the sequence number of the reply to the one in the kgroup entry (5); if they match, the kgroup



```
If(type == read){
   mtdata.r1type = 0;
   mtdata.r1idx = idx;}
If (type == write){
   mtdata.r1type = 1;
   mtdata.r1idx = idx;
   mtdata. r1val = val;}
apply(r1_table)
```
Record access information in the packet metadata at different stages
access *r1* in a single stage

Match	Action
mtdata.r1type == 0	mtdata.r1val = reg1[mtdata.r1idx]
mtdata.r1type == 1	reg1[mtdata.r1idx] = mtdata.r1val

Register r1 access table (**r1_table**)

Figure 7. Register access table. P4 code aggregates access information that is used by a dedicated register access table.

entry is updated (6) and the pipeline forwards the reply to the client (12).

The egress pipeline (13) has one logical stage that populates the header fields (e.g., SEQ number, SID, etc.) using the data available in the packet's metadata.

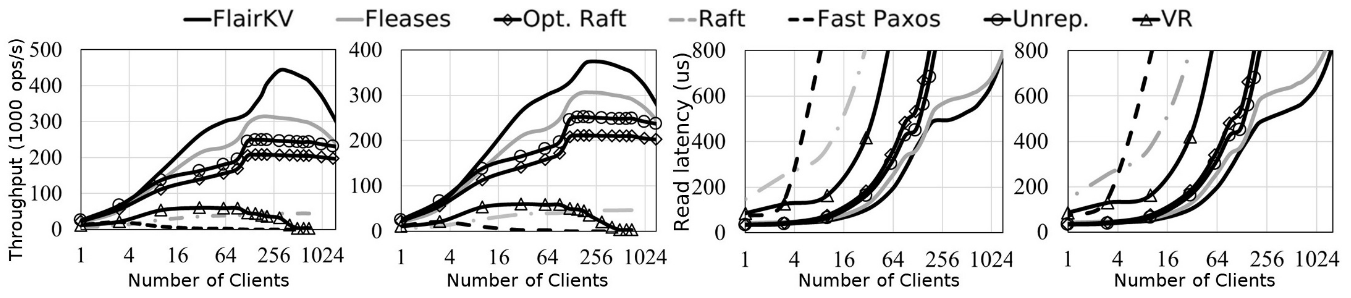
7. Evaluation

We compare our prototype with previous approaches in terms of throughput and latency (§7.1) with different workload skewness (§7.2) and read/write ratios (§7.3).

Testbed. We conducted our experiments using a 13-node cluster. Each node has an Intel Xeon Silver 10-core CPU, 48GB of RAM, and 100Gbps Mellanox NIC. The nodes are connected to an Edgecore Wedge 100 ×32BF switch with 32 100Gbps ports. The switch has Barefoot's Tofino ASIC, which is P4 programmable. Unless otherwise specified, three machines ran the server code, while the other 10 machines generated the workload.

Alternatives. We compare the throughput and latency of the following designs and optimizations:

- **Leader-based**. We used two leader-based protocol implementations: LogCabin, the original implementation of Raft (**Raft**), and an implementation of Viewstamped replication (**VR**) [26]. Raft and VR implement a batching optimization which batches and replicates multiple log entries in a single round trip.
- **Optimized Leader-based (Opt. Raft).** Our benchmarking revealed that the original Raft implementation could not utilize the resources of our cluster. We implemented two main optimizations: first, we changed the request-processing logic from an event-driven to a thread-pool design, as our benchmarking indicated a thread-pool performs better; second, we implemented the leader-lease optimization. These changes significantly improved Raft's performance.
- **Quorum-based reads (Fast Paxos).** An alternative to the leader-based design is the quorum design [40, 41, 53]. Typically, client read requests are sent to all followers, and each follower responds directly to the client. The client waits for a reply from a supermajority [53] before



(a) Throughput - Uniform (b) Throughput -Zipf (c) Latency-Uniform (d) Latency-Zipf

Figure 9. Throuhgput and Latency while varying the number of clients. The figures show the throughput and the average latency for different number of clients for workload B for the uniform distribution (a, c), and for the Zipf distribution (b, d).

completing a read. We used a Fast Paxos implementation that implements only the normal case [26].

- **Follower-lease optimization (FLeases).** Similar to MegaStore [1], the leader grants read leases to all followers. Before serving a write, the leader revokes all leases, processes the write operation, and then grants a new lease to followers. The lease's grant/revoke messages are piggybacked on the consensus protocol messages. However, writes should be processed by *all* followers before replying to the client. In our experiments, if a follower receives a read request for an object for which it does not have an active lease, it forwards the request to the leader. MegaStore applications typically partition the keys into thousands of groups, each group contains logically-related keys [1] (e.g., a key group per blog [1]). We partitioned the keys into 4K groups (the same number of kgroups in FlairKV), and followers get a lease per group. Clients randomly select a follower for each read request and send the request directly to it.
- **Unreplicated/NOPaxos (Unrep.).** As a baseline, the unreplicated configuration deploys Optimized-Raft (discussed above) on a single node. The single node stores the data set and serves all operations without replication.

  This configuration also represents the best possible performance of the network-optimized NOPaxos [40] protocol. NOPaxos uses a network switch to order and multicast read and write operations to all replicas. An operation is successful if the majority accepts a write or returns the same value for a read. Consequently, NOPaxos read performance is limited by the slowest node in the majority of nodes. NOPaxos evaluation shows that the best throughput and latency the protocol can achieve are within 4% that of an unreplicated system [40].
- **FlairKV.** Unless otherwise specified, we used FlairKV with the leader-avoidance load-balancing technique.

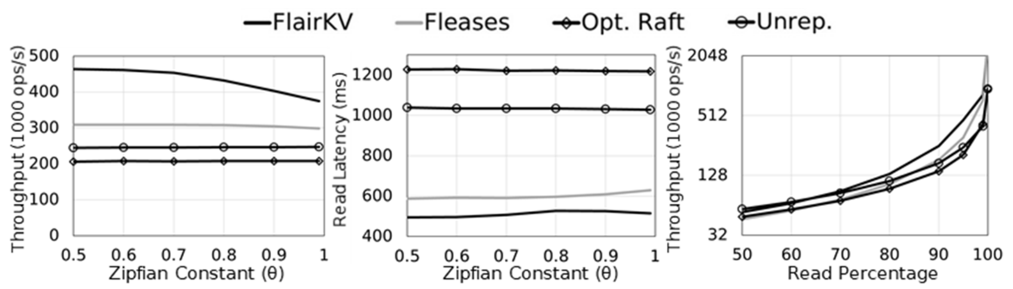
We benchmarked every system and selected a configuration that maximized its performance. We stored all data in memory. In all experiments, all systems' performance (with the exception of FastPaxos) was stable with a standard deviation less than 1%.

Workload. We used synthetic benchmarks and the YCSB benchmark [54] to evaluate the performance of all systems. In our evaluation, we considered both uniform and skewed workloads. The skewed workload follows the Zipf distribution with a skewness parameter of 0.99. We also used the YCSB benchmark. We experimented with 100,000 and 1 million keys. We present the results with 100,000 keys as, in skewed workloads, the fewer number of hot keys increased the chance of having concurrent requests accessing the same key (i.e. is less favorable for FlairKV). FlairKV brings slightly higher performance benefit when using 1 million keys than 100,000 keys. The key size is 24 bytes and the hash of the key string is used as the key in the FLAIR protocol. The value size is 1KB.

7.1. Performance Evaluation

We compared the seven systems using YCSB workload B (95:5 read:write ratio) while varying the number of clients, with uniform and skewed workload distribution. Figure 9 shows the throughput and average latency with a uniform and skewed distributions. With the uniform distribution (Figure 9 (a) and (c)), FlairKV achieves up to 42% higher throughput and 23.7% lower average latency than FLeases, and 1.3 to 2.1 times higher throughput and 1.5 to 2.4 times lower latency compared to optimized Raft and unreplicated setup. Fast Paxos, Raft, and VR, achieve the lowest throughput and highest latency as these systems contact the majority of nodes for every read.

FlairKV achieved better performance than FLeases for three reasons. First, FlairKV uses the leader-avoidance load-balancing technique, which reduces the load on the leader when there are writes, thereby accelerating writes and shortening the time period in which kgroups are marked unstable. This approach is effective as writes take almost 35 times longer than reads in Opt.Raft, and 30 times longer in the unreplicated setup. We recorded the number of read requests served by the leader. For instance, with 300 clients (Figure 9.a) the leader served 2% of the reads in FlairKV (those are reads to unstable kgroups), while it served 34% of the reads in FLeases. We note that the leader-avoidance technique cannot be applied to FLeases which tasks the clients



(a) Throughput (b) Read latency

Figure 10. Throughput and Latency while varying skewness. The figures show the throughput (a) and the average latency (b) for different zifpian constants for a uniform workload B with 300 clients.

Figure 11. Throughput while varying the read ratio. Using uniform workload B.

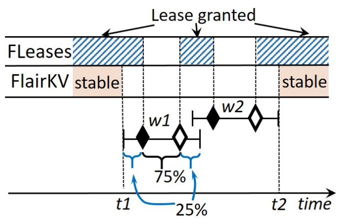


Figure 12. Subtle effect of FLAIR. FLeases may grant leases for up to 25% more time compared to FlairKV. Bars mark the time from the moment a switch receives a write request (w1 or w2) until it receives a corresponding reply.

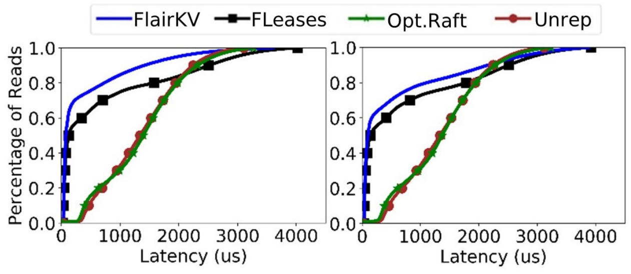
with selecting a follower to send the read request to. This technique requires accurate information about the current load of the leader and which followers are stable which are not available to clients.

Second, in FLeases, when an object is not stable, if a client sends a request to a follower, the follower will redirect the request to the leader, increasing overhead and incurring extra latency. Unlike FLeases, FlairKV switch knows if an object is not stable and forwards read requests for that object directly to the leader. The third reason which had a minor impact when using 3 replicas is that the write operation in FLeases need to reach all followers, while FlairKV writes only need a majority.

Optimized-Raft's performance is better than that of Raft, VR, and FastPaxos. The unreplicated deployment slightly improves throughput and latency over Optimized-Raft by avoiding the replication overhead for write operations. These two systems still lag behind FlairKV as they only utilize a single node (the leader) for serving all reads and writes.

Figure 9 (b) and (d) show the throughput and average latency with a skewed workload (Zifpian constant of 0.99). The skewed workload results in higher contention and an increased frequency at which a read request finds a kgroup unstable. This contention reduces the chances of reading from followers. FlairKV leader served 21% of reads of which 1% are redirected from followers, while FLeases leader served 37% of reads. Even under the skewed workload, FlairKV still achieves the highest performance, up to 26% higher throughput and 18.1% lower latency than FLeases, and 1.5 to 1.8 times higher throughput and 2 to 2.4 times lower latency than optimized Raft and the unreplicated setup.



(a) B-Uniform (b) B-Zipf

Figure 13. Latency CDF. The figures show the latency CDF for reads under workload B using 300 clients with a uniform distribution (a), and a Zipf distribution with skewness of 0.99 (b). The lines for Opt. Raft and Unrep. almost overlap.

Latency evaluation. Figure 13.a shows the latency CDF of FlairKV, FLeases, OptRaft, and Raft. Under the uniform workload B with 300 clients (other workloads had similar results). FlairKV lowered the latency for the slowest 40% requests by at least 38% relative to FLeases. Under the Zipf workload (Figure 13.b), FlairKV lowered the slowest 50% of request by up to 35% relative to FLeases.

FLeases has higher latency as it incurs extra delay due to the load imbalance between nodes (e.g., the leader serves 41% of requests for workload B with Zipf distribution) and due to followers redirecting 4% of requests to the leader.

Under all workloads, FlairKV significantly improved operation's latency relative to OptRaft and Raft. The median latency of FlairKV is 2% of Raft's latency and 2-8% of OptRaft's latency.

7.2. Workload Skewness

We measured the impact of the workload skewness on throughput (Figure 10.a) and average latency (Figure 10.b) by varying the Zipfian constant from 0.5 to 0.99. FlairKV consistently achieves better performance: 1.26 to 2.25 times higher throughput and 1.13 to 2.48 times lower average latency compared to all other systems. We notice that as the skewness increases FlairKV and FLeases performance decreases as higher skewness increases contention on the few popular kgroups, making them unstable for longer time, and increases the number of requests the leaders have to process. Other systems performance is not noticeably affected by skewness.

We noticed high workload skewness affects FlairKV's performance more than FLeases. This is due to a subtle side effect of FlairKV. When there are concurrent writes to the same kgroup, FlairKV will mark a group unstable from the moment the first request is processed by the switch until the last request to the kgroup is replied to ([*t1*, *t2*] in Figure 12). In FLeases, the lease revocation is piggybacked on the write replication step (black diamonds in Figure 12). Once the leader commits a write, it sends a commit notification and grants a new lease to the followers (white diamonds). Hence, FLeases may grant a lease between concurrent writes, creating more opportunity for serving reads from followers.

To further understand this effect, we tracked leases and the stability of kgroups under the skewed (factor of 0.99) write heavy YCSB workload A (1:1 read:write ratio). We noticed that while 29% of reads found the kgroup unstable in FlairKV, only 4% of reads in FLeases reached a follower that did not have a lease. We further profiled the write operation path and found that FLeases revokes leases for 75% of the write operation time (Figure 12), 25% shorter than the period FlairKV marks a kgroup unstable. Despite this subtle effect FlairKV leader still has lighter load, it served 29% of reads compared to 37% served by the FLeases leader. Notwithstanding this effect FlairKV still brings 17% to 26% performance improvement even under skewed workloads.

7.3. Read/Write Ratio

Figure 11 shows the effect of the ratio of reads to writes on systems' performance with a uniform workload B. Compared to FLeases, FlairKV has up to 1.5 times higher throughput for all read to write ratios, with the exception of the read-only workload in which their performance is comparable. FlairKV has 1.25 to 2.8 times higher throughput compared to the Opt. Raft. Compared to the unreplicated setup, FlairKV has up to 2.8 times higher throughput for workloads with 70% reads or more and a comparable performance under write heavy workloads (read ratio 50-70%).

8. Related Work

Network-accelerated systems. Recent projects have utilized SDN capabilities to provide load balancing [55, 56, 57], access control [58], seamless virtual machine migration [59], and improving system security, virtualization, and network efficiency [60]. SwitchKV [29] uses SDN capabilities to route client requests to the caching node serving the key. A central controller populates the forwarding rules to invalidate routes for objects that are being modified and installs routes for newly cached objects. NetCache [28] proposes using the limited switch memory as a look-through cache for key-value stores.

Network-accelerated consensus. A number of recent efforts leverage SDN's capabilities to optimize consensus protocols. Speculative Paxos [41] builds a mostly ordered multicast primitive and uses it to optimize the multi-Paxos consensus protocol. Network-ordered Paxos (NOPaxos) [40] leverages modern network capabilities to order multicast messages and add a unique sequence number to every client request. NOPaxos uses these sequence number to serialize operations and to detect packet loss. Speculative Paxos and NOPaxos are optimized for operations that update the log but not for read operations. NetChain [61] and NetPaxos [62] implement replication protocols on a group of switches. These protocols are suitable for systems that store only a few megabytes of data (e.g., 8MB in the NetChain prototype). Unlike FLAIR, these efforts do not optimize for read operations. Reads are still served by the leader or a quorum of replicas.

Consensus protocols optimized for the WAN. A number of consensus protocols are optimized for WAN deployments. Quorum leases [14] proposes giving a read lease to some of the followers; Unlike Megastore leases, when an object is modified, only the followers that have the lease are contacted. Quorum leases has a better performance than Megastore leases in WAN setups, but do not bring benefits when deployed in a single cluster [14]. Mencius [63] is a multi-leader protocol in which each leader controls part of the log. EPaxos [64] is a leaderless protocol where clients can submit request to any replica. Non-conflicting write can commit in one round trip, while conflicting writes will be resolved using Paxos.

CURP [65] optimizes the write operation through exploiting commutativity between concurrent writes. In data center deployments, CURP reads are served by the leader and hence are limited to a single node performance, in WAN deployment CURP applies a technique similar to FLeases.

9. Conclusion

We present FLAIR, a novel protocol that leverages the capabilities of the new generation of programmable switches to accelerate read operations without affecting writes or using leases. FLAIR identifies, at line rate, which replicas can serve a read request consistently, and implements a set of load-balancing techniques to distribute the load across consistent replicas. We detailed our experience building FlairKV and presented a number of techniques to cope with the restrictions of the current programmable switches. We hope our experience informs a new generation of systems that co-design network protocols with system operations.

Acknowledgment

We thank the anonymous reviewers and our shepherd, Amin Vahdat, for their insightful feedback. We thank Ali Mashtizadeh, Bernard Wong, and Ken Salem for their insightful feedback on early versions of this paper. We thank Lori Paniak for his help in running the experiments. Towards Logically Centralized Interdomain Routing

Shahrooz Pouryousef, Lixin Gao, and Arun Venkataramani

University of Massachusetts Amherst

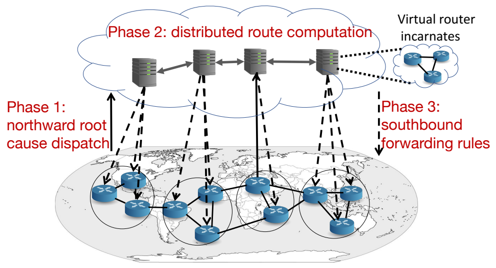
Abstract

In this paper, we present the design and implementation of CIRCA, a logically centralized architecture and system for interdomain routing that enables operators to offload BGP-style route computation to the cloud while preserving the confidentiality of proprietary information. To this end, our work presents the first provably safe, live, and fully distributed convergence detection algorithm for decentralized policy routing and, somewhat surprisingly, shows that long MRAI timers can likely be completely eliminated while significantly improving convergence delays with logical centralization. Our experiments with a Quagga-based CIRCA prototype and the Internet's AS topologies suggest that CIRCA can improve interdomain routing convergence delays and transient route inconsistencies by over an order of magnitude and offers non-trivial incremental deployability benefits with modest changes to widely deployed routing infrastructure.

1 Introduction

Logical centralization of control and management for enterprise networks has proven successful in recent years. However, this trend has minimally, if at all, affected interdomain routing in the Internet that has seen little fundamental change in over two decades of operation and continues to suffer from long convergence delays, lack of control-data separation, poor management knobs, lack of evolvability, etc.

Logical centralization or cloud-assisted interdomain route computation holds the promise of alleviating these longstanding problems but is not easy to accomplish. Unlike enterprise networks, a key stumbling block is the need to maintain the confidentiality of proprietary routing policies. Recent research [2, 17] has attempted to attack this problem by employing secure multiparty computation, but its inherently computationally-expensive nature poses a scaling challenge, so it has been demonstrated only at small scales with restrictive assumptions on the expressiveness of routing policies. Cloud-assisted interdomain route computation has therefore



Phase 2: distributed route computation
Virtual router incarnates
Phase 1: northward root cause dispatch
Phase 3: southbound forwarding rules

Figure 1: CIRCA: northward root cause dispatch, cloud-driven route computation, and southbound forwarding rules.

been limited to narrower contexts such as software-defined exchange points [15, 16], engineering traffic across multiple ASes owned by a single enterprise [18, 53], or compromising on either or both of scale and policy confidentiality [26].

In this paper, we present the design and implementation of CIRCA, the first logically centralized interdomain routing control architecture and system enabling operators to offload BGP-style route computation *as-is* to the cloud while preserving the confidentiality of proprietary policies. The CIRCA service makes the following assurances to network operators: (1) forwarding entries computed by CIRCA will be *equivalent* (as formalized in §3.4.1) to what their routers are computing today; (2) CIRCA will quickly return forwarding entries reflecting a converged state of the network circumventing BGP's long tail of convergence delays (tens of seconds to minutes); and (3) CIRCA does not require an AS to disclose proprietary policy information to any third party except to the extent that it can already be inferred by its eBGP peers.

The high-level design of the baseline CIRCA system, as illustrated in Figure 1, is simple: each router speaking BGP (or *ground router*) has a virtual router incarnate (or *avatar*) in the CIRCA cloud. Upon detecting a root cause event, a ground router dispatches it cloudward to its avatar; the virtual routers in the cloud thereafter simply replay the same BGP protocol as ground routers but in a significantly "fast-forwarded" manner; and upon convergence, cloud routers dispatch modified forwarding entries to their ground incarnates.

A natural question is why this simple, perhaps even seemingly naive, high-level design can enable the cloud to compute routes faster than the ground if it's replaying the same protocol. The answer is threefold: (1) the cloud can easily afford orders of magnitude more control bandwidth, e.g., tens or even hundreds of Gbps of LAN bandwidth, compared to the ground; (2) propagation delays in the cloud ($<$ 1 ms or even just a few microseconds [21, 33, 35, 55]) are several orders of magnitude lower than the delay diameter of the Internet ($\approx$ hundreds of ms); (3) the (cloud) control plane is physically isolated from and can not interfere with the (ground) data plane. Thus, the cloud has the luxury of doing away with long route advertisement timers that in ground-BGP today are believed necessary to mitigate the risk of super-exponential message complexity [9, 28, 29, 36, 37] and conservatively set to high values (e.g., 30s is a common vendor default).

The deceptively simple exposition above hides a number of research questions that must be answered to translate the high-level design to a deployable system in practice. Can the cloud really compute stable routing outcomes an order of magnitude faster than the ground? Can (and how?) cloud routers quickly detect that the distributed processing of a root event has converged? Can CIRCA guarantee consistency of computed routes and ensure that its computed routing outcomes will match those of BGP despite component or network failures? Can CIRCA coexist with BGP and is it incrementally deployable for incremental benefit?

Tackling the above questions and answering them in the affirmative aided by an implemented prototype of CIRCA is our primary contribution comprising the following parts:

1. *Distributed convergence detection*: Design and implementation of the first fully distributed BGP convergence detector that is provably safe, i.e., no false positives, and live, i.e., detection incurs a modest bounded delay (§3.3).

2. *Quick end-to-end convergence*: Large-scale prototype-driven experiments showing that CIRCA can ensure predictably quick convergence reducing BGP's tail convergence delays by over an order of magnitude, in part by eliminating unnecessary long timers (§3.2, §4.1).

3. *Route computation equivalence*: A design that provably ensures that its computed routing outcomes are equivalent to those of any *convergent* (formalized in §3.4) distributed policy-based ground routing protocol.

4. *Incremental deployability*: Design and evaluation of mechanisms to deploy CIRCA *co-existent* (§3.5.1) with BGP as well as in an *incremental* manner (§3.5.2).

2 Background and lineage

Logical centralization of network control and management, including for interdomain routing, has a long scientific lineage. We overview what prior work has accomplished on that front to position how CIRCA builds upon that work.

In intradomain routing, a line of work seemingly starting with calls for "routing as a service" [30] or "separating routing from routers" followed by works such as RCP [4], 4D [52], Ethane [5] etc. spurred what is now known as software-defined networking (SDN), a term that commonly means logical centralization of control and management for enterprise networks. Much follow-on SDN research as well as widespread embrace by industry firmly attests to its benefits such as cleaner control and data separation, ease of management with a global view, hardware-software decoupling, etc.

Interdomain routing on the other hand, since BGP's creation in the late 80s and progressive standardization through the 90s, has remained largely untouched by the logical centralization trend as BGP4 continues to be the de facto interdomain routing protocol. Recent research however has begun to explore extending SDN approaches to the interdomain context [1, 41, 44, 54]. For example, SDX by Gupta et al. [16] is a software-defined Internet exchange point (IXP) that enables more sophisticated packet processing rules to engineer interdomain traffic. Kotronis et al. [10, 24–27] also advocate a logically centralized “multi-domain SDN" approach as an alternative to BGP, introduce a publicly available (single-node) Mininet-based emulation platform for experimenting with hybrid BGP-SDN routing, and show modest improvements in convergence delays because of centralization. Gupta et al. [2, 17] advocate using secure multiparty computation (SMPC) so as to combine the benefits of logical centralization with confidentiality of proprietary routing policies, and argue that SMPC may be computationally feasible for BGP with some policy restrictions. Recent research has developed approaches for preserving the privacy of ISP policies at Internet exchange points [6, 7, 14].

Consensus routing [20] advocates a consistency-first (in contrast to the Internet's longstanding allegiance to soft-state) approach to interdomain routing. It works by periodically capturing a consistent snapshot of global network state—e.g., by having a small number of say tier-1 ASes engage in a consensus protocol to agree upon globally in-propagation updates—so as to enable computation of so-called *stable forwarding tables* that are guaranteed to be loop-free while relying on *transient* routing heuristics in the forwarding plane to re-route packets encountering blackholes. Consensus routing can be viewed as logically centralizing the snapshotting of network state but continuing to rely on distributed BGP for computation of the stable forwarding tables; the snapshots simply slow down FIB changes making routers jump from one set of consistent FIBs to another.

The above body of prior work informs the design of CIRCA, a logically centralized, scalable, and fault-tolerant architecture to offload interdomain route computation as-is to the cloud without requiring ASes to reveal any additional proprietary policy information while ensuring predictably quick convergence delays, a combination of goals that to our knowledge has not been achieved before.

3 CIRCA design and implementation

CIRCA is driven by the following key design goals.

1. *Limited disclosure*: CIRCA should not require ASes to disclose proprietary policies or topology to any entity.
2. *Quick convergence*: CIRCA should ensure quick convergence unlike BGP's high tail latencies (§3.2).
3. *High availability*: CIRCA should ensure high availability despite component or network failures (§3.4.2).
4. *Route computation equivalence*: CIRCA's computed routes should match those computed by BGP or any desired decentralized and safe routing protocol (§3.4.1).
5. *BGP interoperability*: CIRCA should gracefully coexist with BGP and be incrementally deployable (§3.5).

3.1 Design overview

BGP route computation, even given centralized global topology and policy information, is a computationally hard problem [13] unless restrictive assumptions are made, e.g., under Gao-Rexford (GR) conditions, the complexity is linear in the size of the network. To our knowledge, in the absence of more restrictive assumptions than safety of routing policies, previously proposed approaches for BGP route computation are not qualitatively more efficient than simulating BGP's path exploration process, i.e., some sequence of receive/import/adopt/export activations until convergence. Even logically centralized approaches based on SMPC [17], that in addition to GR constraints restrict policies to be next-hop-based and routes to be uniquely determined by the source-destination pair, compute BGP routes by simulating BGP's path exploration. Algebraic formulations of the problem can potentially compute BGP routing outcomes more efficiently than asynchronously simulating path exploration, e.g., via a generalized Dijkstra-like algorithm [46] or iterative matrix methods that synchronously simulate generalized Bellman-Ford's [45, 46] path exploration, but only under restrictive assumptions that BGP in practice is not known to satisfy, e.g., non-neighbor-based policies like "prefer customer but disprefer routes containing AS X" are neither *left-distributive* nor *monotonic* (also known as *strictly increasing* [8]), each of which is known to be a sufficient condition for computing destination-based forwarding routes efficiently.

CIRCA's high-level design based on virtual routers replaying BGP in the cloud is naturally dictated by two premises: (1) we need to limit disclosure of proprietary policy information to no more than what is shared between ASes in today's BGP (also referred to as *ground-BGP*); (2) even with centrally disclosed policy information, without more restrictive assumptions than just safety, we don't know of a qualitatively more efficient way to compute BGP's routing outcomes other than to simulate its path exploration. Accordingly, CIRCA maps virtual router incarnates (or *avatars*) in the cloud to each *ground router*. In what follows, we first describe unreplicated CIRCA (deferring CIRCA's replication mechanisms for ensuring high availability amidst failures to §3.4.2) wherein each ground router is one-one mapped to a cloud avatar and the cloud avatars execute a protocol derived from the underlying distributed ground routing protocol.

CIRCA operates incrementally in response to *root cause events*, i.e., external events such as a node or link up/down event, link cost change, or an operator-induced policy or configuration change. CIRCA operates in three phases— (1) detection and cloudward dispatch of a root event by a ground router; (2) route computation by cloud routers; (3) adoption of forwarding outcomes dispatched by cloud routers groundward—a high-level design also shared by several prior works [2, 4, 17, 26, 41].

3.1.1 CIRCA north-south protocol

The CIRCA north-south protocol consists of three phases.

Phase I: Upon detecting a root event, a ground router R:

1. Assigns a unique label $E = [seqn, R]$ to the event, where *seqn* is a sequence number incremented by exactly one for each locally detected root cause event;
2. Appends $\langle E, iface, etype, eval \rangle$ to a local persistent log, where *iface* identifies the interface affected by the event and *etype* and *eval* are respectively the event type and value, e.g., *etype* may denote a link cost change and *eval* the value of the new link cost;
3. Sends the ground root cause (GRC) message $\langle \text{GRC}, E, iface, etype, eval \rangle$ to its cloud avatar(s) $\mathbf{v}(R)$.

Phase II: CIRCA cloud routers then take these steps:

1. Upon receiving $\langle \text{GRC}, E = [seqn, R], iface, etype, eval \rangle$, the cloud avatar $v(R)$ initiates a distributed route computation algorithm (in §3.3) for that event after it has sequentially completed the execution for all root events $\langle [k, R] \rangle$ for $k < seqn$;
2. When a cloud router $v(Q)$ impacted by E eventually receives the termination notification (as guaranteed by the liveness property in §3.3.2) for E, it
   (a) appends the FIB entries updated as a result of E to a local persistent log;
   (b) dispatches the FIB entries to ground incarnate Q;

Phase III: A ground router Q receiving FIB entries for E:

1. Appends the FIB entries to a local persistent log;
2. Applies the FIB entries for $E = [seqn, R]$ iff it has applied all FIB entries for root events $[k, R]$ for $k < seqn$;

The high-level protocol above can be optimized as follows.

Garbage collection: A ground router Q informs its cloud avatar $v(Q)$ to garbage collect its log entries for any root cause event E for which Q has already applied (in step III.2 above) the updated FIB entries. The ground router only persists $O(1)$

state per prefix. For each prefix p, it persistently maintains only the FIB entries corresponding to the root event E that it most recently applied in step III.2. §3.4 explains why this preserves Route Computation Equivalence even amidst faults.

Concurrent execution: Step II.1 can be executed in parallel for two or more root events while preserving key safety and liveness properties (as explained in §3.3.3).

Virtual router consolidation: The one-one mapping of ground to virtual routers in CIRCA can be optimized by using a single, more complex route computation server per AS that emulates the receipt/sending of eBGP updates from/to adjacent ASes. Our focus on one-one router mapping in this paper is driven by our goal to show a proof-of-concept design and implementation that works *at all* and at scale, so we defer approaches to optimize cloud resources to future work.

The rest of this section §3 describes how CIRCA achieves its design goals starting with the first limited disclosure goal.

Limited disclosure: CIRCA's threat model assumes that ASes trust the cloud hosting provider to provide the physical infrastructure in a non-curious manner, an assumption consistent with standard IaaS cloud computing industry practice. From a practical standpoint, there is a significant difference between an AS trusting a cloud provider to not peek into its virtual machines versus that AS explicitly submitting all of its proprietary policy information to the cloud provider. Limiting overt leakage of proprietary information further requires that virtual routers belonging to a single AS be hosted within a virtual LAN (VLAN) within the CIRCA cloud so that IGP, iBGP, or other intradomain messages are physically confined within the VLAN. §5 discusses state-of-the-art secure computing techniques to extend CIRCA to work even with a *honest-but-curious* cloud provider in the future.

3.2 MRAI: Unnecessary evil in the cloud

An important reason interdomain routing suffers from long convergence delays is the presence of MRAI (min route advertisement interval) timers [3, 28, 31, 36, 43, 49]. A nontrivial body of prior work suggests that MRAI timers are a necessary evil to tame BGP's message complexity. Early work by Labovitz et al. [28] suggests that without such timers, BGP's message complexity may be superexponential (or $O(n!)$). Although the gadgets exemplifying the superexponential message complexity in that work are somewhat contrived in that their policy configuration does not satisfy Gao-Rexford (GR) conditions that are believed to hold commonly in practice, subsequent work [9] has shown that BGP's message worst-case complexity can be exponential even in GR topologies.

Our position is that MRAI timers even in ground-BGP today are overly conservative and are set to high values (e.g., 30s is a commonly recommended default value [31,50,51]) in part because the relationship between MRAI timers, message complexity, and overall convergence delay is poorly understood. Classical work on this topic [12] suggests that convergence delay exhibits a nonmonotonic relationship to MRAI timers, i.e., there is a minima or a sweet spot setting for the timer below which operators risk worsening convergence delay because of prohibitive message complexity and above which the timers themselves are too conservative exacerbating delay. There isn't universal agreement on what value of the timer is optimal; some have suggested that the common default of 30s is too high [12, 19, 31] while others have noted the risks of heterogeneous timer values further exacerbating message complexity [9], so conventional operational wisdom has been to err on the conservative side.

3.2.1 Why the cloud is different

There are three critical differences between the cloud and ground-BGP with implications for MRAI and other timers.

1. *Control bandwidth*: The CIRCA cloud can be easily provisioned with 2-3 orders of magnitude more control bandwidth (e.g., tens of Gbps) compared to typical control traffic provisioning in ground-BGP today.
2. *Propagation delay*: The propagation delay diameter of the CIRCA cloud is 2-3 orders of magnitude less than the hundreds of milliseconds in ground-BGP today.
3. *Control-data isolation*: Interference between control and data is a non-concern in the CIRCA cloud, so it can afford to be much more wasteful than ground-BGP.

Accordingly, we pick an aggressive point in the design space for CIRCA, namely, no MRAI timers at all! The justification for this design choice is as follows. First, MRAI timers, when they help, intuitively work by limiting spurious path exploration by making each node wait long enough to hear from its neighbors about their reaction to earlier routing messages. However, these very timers can make nodes unnecessarily wait for several MRAI rounds even when there is no possibility of excessive spurious path exploration. Worse, some (admittedly contrived) choices of heterogeneous timer values even in GR settings can actually *cause* exponential message complexity [9] even though overall convergence delay in GR settings is determined by the speed of information propagation along the customer-provider chain and back. Eliminating MRAI timers altogether propagates information as quickly as possible while naturally slowing down node reaction times because of message queuing delays in the rare cases that message processing is indeed a bottleneck.

Second, message processing delays in commodity routers as well as processing delays in well provisioned cloud environments are an order of magnitude lower than the numbers used in prior simulation-based work [12, 43]. Third, we hypothesize that reasonable values of MRAI timer values when useful are positively correlated with propagation delays, i.e., the higher the propagation delays, the higher the timer values needed, all else being equal. This hypothesis is consistent with (but not strictly implied by) the simple model in [37].

Our prototype-driven experiments in §4.1 validate the hypotheses above showing both that MRAI timers are unnecessary in reasonably provisioned cloud settings and that our results do not qualitatively contradict the nonmonotonic behavior reported in previous works when compute provisioning is artificially limited to unrealistically low levels.

3.3 Distributed convergence detection

The description thus far has side-stepped a critical question: *How do* CIRCA *cloud routers replaying a distributed protocol like BGP know when the processing of a root cause event has converged?* A convergence detector is necessary for a cloud router to initiate transmission of the corresponding updated FIB entries to its ground incarnate. The distributed BGP protocol as executed by Internet routers today does not have any such indicator of convergence (other than, trivially, the absence of any routing updates for a sufficiently long time).

To appreciate why detecting convergence in CIRCA is not easy, consider the strawman strategy of each virtual router periodically, say once every τ seconds, reporting the most recent time when it processed a message for a root cause event e to a centralized monitor that declares convergence when no router has processed any message for e in its most recent reporting interval. For $\tau = 5$s and a total of say 10^6 routers, this reporting traffic alone for each root event is 200K pkts/s. A hierarchical convergence detector that employs a per-AS detector with 50K ASes will still incur a reporting traffic of 10K pkts/s per root event, which is prohibitively expensive especially given that many root events may have only a localized impact affecting the forwarding behavior of a small number of ASes if at all. More importantly, a centralized monitor will incur a convergence delay of at least τ seconds per root event, not to mention poor fault tolerance. Finally, a centralized monitor by design observes more information than can be observed or easily inferred by any AS in BGP today, thwarting CIRCA's limited disclosure goal (§3.0).

We present a completely distributed convergence detector that is provably safe, i.e., no false positives, and live, i.e., it will detect convergence provably within at most 3× the actual convergence delay—and in practice within a much smaller factor (§4.2)—and the number of BGP messages as observed by a (theoretical) global monitor. The distributed convergence detection algorithm works in three phases as explained below. For ease of exposition, we first assume failure-free execution (deferring fault tolerance to §3.4). The algorithm is bootstrapped with a set of path updates generated by simulating the root event at the "root" cloud router receiving the corresponding ground root cause message.

Figure 2 illustrates the three phases of the convergence detection algorithm. In the first exploration phase, for each root event e processed by a virtual router, the router maintains state about the event by adding it to a set of unconverged events. When a virtual router R processes a BGP message m related to e and it induces no change to R's FIB (and consequently no new announcements to its neighbors), we say that message m "fizzled" at R. For each fizzled message, R back-propagates

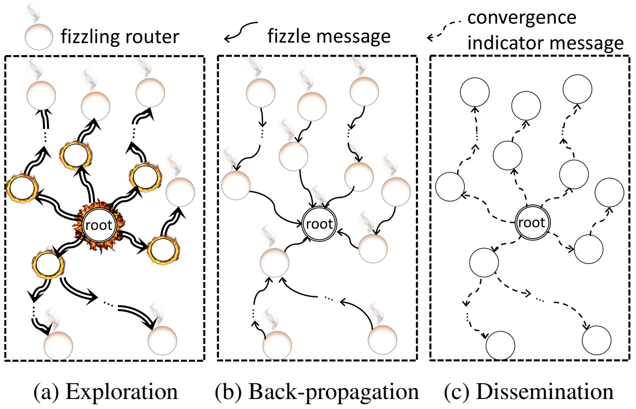


Figure 2: 3-phase distributed convergence detection.

a fizzle indicator to its peer that previously sent it m thereby initiating the second back-propagation phase. Each router locally keeps track of each message pertaining to e that it sends to each neighbor and waits for the corresponding fizzle acknowledgment to be back-propagated. When the router that initiated the root cause event has received fizzle acknowledgements for all messages it originated, it determines e to have converged, which initiates the third dissemination phase wherein, starting with the root router, each router forwards the convergence indicator along each link previously traversed in the exploration phase, at which point it drops all state related to e for convergence detection.

3.3.1 Formal event-action protocol

In order to formally reason about the safety and liveness properties of the distributed convergence detector, we codify it in event-action format in Algorithm 1. The key notation is as shown in Table 1. Where there is little room for confusion, we drop the argument R implicitly fixing it to *self* at a router.

Algorithm 1 shows how a router R handles three distinct events: (1) receipt of a root cause message $\langle \text{GRC}, E \ldots \rangle$ from its ground incarnate $v(R)$ that initiates path exploration; (2) receipt of a CBGP message from a peer cloud router; and (3) receipt of a FIZZLE message from a peer cloud router.

The first event handler processes the received root cause message by "simulating" the corresponding ground event, which produces a set of resulting update messages announcing or withdrawing a set of paths to affected prefixes, a set denoted as *paths(E)*. If the root event E does not change R's FIB, then routing has trivially converged (line 7). Else, for each changed entry in R's FIB causing a new update subject to its export policy, it creates a unique timestamp as a two-tuple consisting of a strictly increasing logical clock returned by *now()* and the router's identity. (This logical clock does not need to reflect the happens-before relationship between events like Lamport clocks for reasons that should be clear from the formal proofs in §A.) The router stores each resulting update to its peers in a map $sent[E]$ and remembers the cause of each sent update

Algorithm 1 Distributed convergence detection (DCD) and route computation at cloud router $v(R)$

CBGP	Message type of BGP messages exchanged by cloud routers
GRC	Message type of root cause messages sent by a ground router
v(R)	Cloud incarnate of ground router R
paths(E)	Paths affected by E, a unique root cause label, to one or more prefixes
FIB(R)	Forwarding table of router R
send(m, N)/*recv*(m,N))	send/receive message m to/from peer N
BGPImport(F,m,R)	New FIB resulting from processing message m at router R with FIB F
BGPExport(F_1,F_2,R)	Announce/withdraw messages by R, filtered by its export policy, upon a FIB change from F_1 to F_2

Table 1: Notation used by Algorithm 1.

as the original GRC message in a *cause* map indexed by the timestamp *ts* of the sent update. By definition of *now()*, each sent update has a unique timestamp.

The second event handler, the common-case action invoked at a cloud router beyond the root router, is similar to the first but with two important differences. First, if a received update $\langle \text{CBGP}, E, p, asPath, ts \rangle$ from a peer does not change its FIB, it responds with the corresponding $\langle \text{FIZZLE}, E, ts \rangle$. Second, if it does change its FIB, it remembers the cause of each resulting export-policy-filtered update as the incoming update.

The third event handler purges entries from the *sent*[E] map upon receipt of the corresponding fizzle messages (removing the message with timestamp *ts* from the set $sent[E][ts_0]$ in line 31). If the *sent* set caused by an update is emptied at a non-root router, it back-propagates a fizzle to the peer that sent the incoming causal update (line 35). When an incoming fizzle message empties the *sent*[E] map at the root router (line 33), it declares the distributed processing of event E as converged, and initiates the third dissemination phase (deferred to §A).

We need to formally prove the correctness property that when a root router thinks routing has converged, that is indeed the case; and the liveness property that the above protocol will eventually terminate under realistic conditions.

3.3.2 Safety, liveness, and efficiency

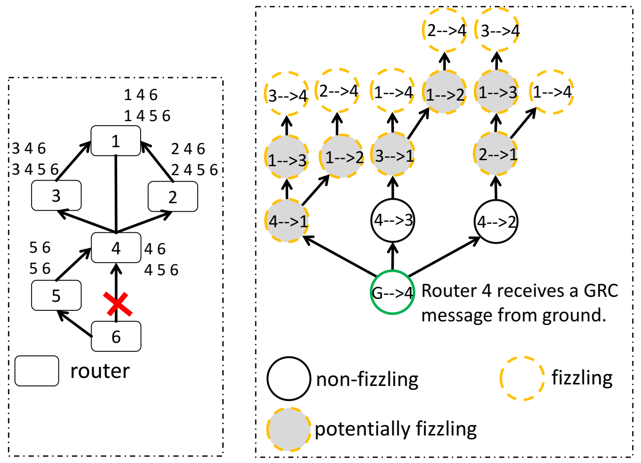
The formal proofs of all claims herein are deferred to §A.

Theorem 3.1. SAFETY*: If converged(E) is true at the root cloud router that received the* GRC*, then no further* CBGP *message for E will be received by any cloud router.*

Theorem 3.2. LIVENESS*: Algorithm 1 eventually terminates, i.e., converged(E) is set at the root router, if BGP is safe*[1] *and all cloud routers are available for sufficiently long.*

The safety and liveness proofs rely on a construction called the *directed message graph* produced by any execution instance of Algorithm 1, as illustrated in Figure 3, wherein each vertex corresponds to a message—either the original GRC or a CBGP message—and there is a directed edge from a message m_1 to another message m_2 if m_1 *caused* m_2, i.e., m_2 was sent in lines 14 or 26 in response to the receipt of m_1 in lines 1 or 16 respectively. We say that $m_1 \rightarrow m_2$ (read as m_1 *happened before* m_2) if there exists a directed path from m_1 to m_2 in the graph. It is straightforward to show (Lemma A.1) that the directed message graph is a directed tree, i.e., it is acyclic and each vertex has exactly one incoming edge. The proof of safety relies on showing that if $m_1 \rightarrow m_2$, then m_1 fizzles only after m_2 has previously fizzled (Lemma A.3) and when *converged*(E) is true at the root router, no CBGP messages for E are under propagation anywhere (Lemma A.4). The proof of liveness relies on showing that, with safe BGP policies, every CBGP message eventually receives a matching FIZZLE (Lemma A.5) as well as on Lemma A.3 and on the assumption

[1]"BGP is safe" means that it is guaranteed to converge to a stable route configuration [13] and is unrelated to *safety* in the theorem just above.



(a) Routing topology (b) Message DAG

Figure 3: (a) Routing topology: root cause is the failure of link 4-6, arrows are from customer to provider, and no arrows means a peer relationship. (b) Potential message DAG evolution: an execution instance of Algorithm 1 produces a prefix of the shown directed tree where dashed-greyed (yellow) circles may or may not be a fizzling message, dashed (yellow) ones are fizzling, and solid ones are non-fizzling messages.

that a router records all state changes in a local persistent log before sending messages based on the changes.

For concision, we defer a codification of Algorithm 1's *dissemination* phase to §A.3. This phase does not impact safety or liveness as defined above but is needed to show the stronger liveness property that the algorithm terminates for all impacted cloud routers (not just the root).

Theorem 3.3. EFFICIENCY*: The root router (Any router) in Algorithm 1 detects convergence within at most* 2Δ (3Δ) *time and* $2M$ $(3M)$ *messages where* Δ *and* M *are respectively the actual convergence delay and number of messages incurred by the distributed route computation in the cloud.*

Although a $3\times$ delay overhead may seem high and it may cursorily appear possible to reduce that overhead with simple optimizations, our attempts at doing so while preserving provable safety and liveness have been elusive. Fortunately, our experiments (§4.1) show that (1) convergence delays in the cloud are significantly smaller than those in the ground, so a $3\times$ overhead in the cloud is still a big net win; and (2) the overhead is much smaller than $3\times$ because messages in the first exploration phase can contain a large number (even thousands) of prefixes, but messages in the other two phases are like small acknowledgments.

3.3.3 Concurrent event processing

The discussion above implicitly focused on sequentially processing one root event at a time. However, we can not afford the luxury of a centralized monitor or other mechanisms to ensure sequential processing of root events for the same reason that convergence detection had to be distributed in the first place. With multiple concurrent root events being processed by different cloud routers, Algorithm 1 in conjunction with the high-level end-to-end protocol in §3.1.1 has a problem: the FIBs dispatched by a cloud router in step II.2.b may be inconsistent as they may reflect the incomplete processing of one or more root events being concurrently processed in the system, which in turn could result in transient loops or blackholes in the data plane at ground routers (as can happen in ground-BGP today even with just a single root event). However, the safety and liveness properties above as well as Route Computation Equivalence as formalized in the next subsection still hold, so our CIRCA implementation simply processes concurrent root cause events in parallel. A more detailed discussion of the pros and cons of concurrent event processing while preserving route consistency in the ground data plane is deferred to a technical report [38].

3.4 Route Computation Equivalence despite link or router failures

Informally, this section shows that any decentralized policy routing (or "ground") protocol, including but not necessarily limited to BGP, satisfying a naturally desirable consistency property (ECC, as formalized below) can offload its route computation to CIRCA with the guarantee that the CIRCA-equipped system will eventually achieve the same routing outcomes as the unmodified ground protocol despite failures, a property referred to as Route Computation Equivalence. Unlike the safety and liveness properties shown for CIRCA's cloud *control plane*, the results in this section subsume the *data plane* or end-to-end forwarding behavior on the ground.

Network state model. We model the ground network as a state machine with root cause events effecting state transitions. The *state* of the network encompasses the (up/down) state of all links and routers as well as any configuration information (link costs, operator-specified policies at a router, etc.) that potentially impacts routing outcomes. Let S_0 denote the initial state of a network and $[e_1,\ldots,e_k]$ denote a sequence of root cause events such that each event e_i transitions the network from state S_{i-1} to state S_i. The state of the network after an event or a sequence of events is denoted using the operator '$|$' as in $S_1 = S_0|e_1$ or $S_k = S_0|[e_1,\ldots,e_k]$.

Definition 1. EVENTUALLY CONSISTENT CONVERGENCE (ECC)*: If no root cause events occur for a sufficiently long period, forwarding behavior should converge to reflect the state of the network just after the most recent root cause event.*

We posit *eventually consistent convergence* as defined above as an intrinsically desirable property for any practical routing protocol. ECC as defined is rather weak because "eventual" allows routes to be inconsistent with global network state for arbitrarily long, but BGP today does satisfy this property provided routing policies are safe (or convergent) and every event is eventually detected and acted upon by incident routers immediately impacted by it.

3.4.1 Unreplicated CIRCA ensures RCE

We next formally define Route Computation Equivalence.

Let $\mathbf{D}(S)$ represent any distributed route computation function that, given network state S, returns a set of possible *routing outcomes*, i.e., a set $\{\mathbf{GFIB}_1, \mathbf{GFIB}_2, \ldots\}$ wherein each element represents global forwarding behavior as captured by the union of the FIBs of all routers in the network. The reason $\mathbf{D}(S)$ is a set of size greater than one is to incorporate non-determinism as BGP even with safe policies in general can have multiple stable routing configurations, e.g., the DISAGREE gadget [13] converges to one of two possible stable routing outcomes depending on node reaction times. Let $\mathbf{GFIB}(t)$ denote the forwarding routes adopted by ground routers at time t. We would like to show that if a distributed route computation process satisfies ECC, CIRCA preserves those ECC routing outcomes. Formally,

Definition 2. ROUTE COMPUTATION EQUIVALENCE (RCE)*:* Given an initial network state S_0 and a finite sequence of root case events $[e_1, \ldots, e_n]$, a cloud-assisted routing protocol is said to preserve equivalence with respect to a distributed route computation function $\mathbf{D}(S)$ if it ensures that $\lim_{t\to\infty} \mathbf{GFIB}(t) \in \mathbf{D}(S_n)$ where $S_n = S_0|[e_1, \ldots, e_n]$.

Next, we show that a single-datacenter (or unreplicated) pure CIRCA deployment ensures RCE despite intermittent failures (proof deferred to Appendix B), where *pure* means all ground routers have been upgraded to rely only on CIRCA.

Theorem 3.4. *If for a sufficiently long period—(i) all ground routers can reach a* CIRCA *cloud replica and vice versa; and (ii) all cloud routers are available and can communicate in a timely manner—a pure* CIRCA *system ensures Route Computation Equivalence with any distributed route computation function that satisfies Eventually Consistent Convergence.*

3.4.2 Replicated CIRCA ensures RCE

To see why Theorem 3.4 holds even in a replicated CIRCA deployment without any replica coordination protocol, we simply observe that each CIRCA replica independently ensures RCE, i.e., the FIBs it computes reflect the most recent state of the network provided it eventually receives all root cause event reports (in any order). If each ground router is responsible for relaying each root event to all of its cloud avatars, no replica coordination protocol between CIRCA replica sites is necessary. CIRCA cloud routers may optionally relay root events to its siblings on other replica sites as an optimization, but this is not necessary for ensuring Route Computation Equivalence. An analogous observation, namely that no sophisticated replica coordination protocol is needed for safety, has been long known for a single-domain route computation service (e.g., RCP [4]), but not for interdomain routing. Furthermore, the technical reasons why they hold in the CIRCA architecture based on processing root cause events consistently are very different from RCP that relied on an assumption of consistent views of the ground network despite partitions across replicated route servers.

Overhead of faults. CIRCA's simple design maintains RCE despite arbitrary failure patterns but failures, specifically of cloud routers or link failures inducing ground-cloud unreachability, have two costs: (1) growing log of unprocessed root events at ground routers, and (2) transient forwarding loops or blackholes. As detailed in the techreport [38], the former is bounded by the size of the total configuration state at a router and the latter can be alleviated (but not eliminated) by replicating CIRCA datacenters in a *pure* CIRCA deployment or by relying on BGP co-existence mechanisms below.

Conveniently, ground router failures are a non-issue because of the fate sharing property that it is the only router stalled by its failure; neighboring ground routers will detect and process its failure as a normal root cause event.

3.5 Co-existence & incremental deployability

Co-existence refers to the ability of ground routers to leverage the CIRCA cloud while continuing to rely on ground-BGP as a fallback or an optimization under the (possibly impractical) assumption that all ground routers have been upgraded to be CIRCA-capable. *Incremental deployability* refers to the ability to gainfully deploy CIRCA despite upgrading only a subset of ground routers to be CIRCA-capable. (As defined, a deployment can not be both co-existent and incremental.)

3.5.1 Co-existence with ground-BGP

CIRCA's support for co-existence enables ground routers to get the best of both worlds, i.e., adopt forwarding outcomes from whichever plane—ground or cloud—converges earlier, thereby also implicitly relying on ground-BGP alone as a fallback when the cloud is unreachable. To this end, ground-BGP needs to be extended so as to tag each message with the corresponding root cause event label, and ground-BGP routers need to relay the tag in any incoming message by inserting it into any outgoing messages caused by it.

A ground router R uses the root event label $E = [seqn, R]$ in a ground-BGP message as follows. If R has already received $\Delta FIBEntries(E)$ for E from the cloud, it rejects any further ground-BGP messages tagged with E from impacting its FIB, otherwise it continues processing ground-BGP messages as usual through its decision engine with one difference: it marks any changes to its FIB as a result of E as such and keeps a copy of the original entry for the corresponding prefix, which essentially allows R to undo the effect of any ground-BGP messages tagged with E. When R eventually receives $\Delta FIBEntries(E)$ from the cloud, irrespective of whether or not ground-BGP has already converged at R (necessarily unbeknownst to it), it installs $\Delta FIBEntries(E)$ anyway undoing the effect of any ground-BGP messages pertaining to E.

Co-existence further requires ground routers to maintain a route information base (RIB), or the set of available routes, unlike universal CIRCA (wherein every router is CIRCA-capable) that only required ground routers to maintain a FIB (or the set of *adopted* routes). Maintaining a RIB plus a FIB is no different from ground-BGP today, and requires ground routers to continue processing messages tagged with E so as to update its RIB (but not its FIB) even after it has received the corresponding $\Delta FIBEntries(E)$ from its cloud incarnate. Maintaining a RIB in co-existent CIRCA also enables ground routers to employ fast reroute or backup routing options during the ground or cloud convergence period.

3.5.2 Incremental deployability

Incremental deployment means that some ground routers may be completely CIRCA-unaware, so such legacy routers can not even parse BGP messages with root cause labels. In such scenarios, the benefits of CIRCA would be limited to root cause events that originate within and whose exploration fizzles entirely within a contiguous island of routers all of which have been upgraded to be CIRCA-capable. For events that entirely fizzle within the contiguous upgraded island, the protocol is identical to the co-existent scenario (§3.5.1). If an event spills out of this island, it is recognized as such by any CIRCA cloud router at the island's boundary. When a cloud router detects a spill-over, it immediately aborts the exploration by back-propagating an ABORT message (instead of a FIZZLE), enabling the root router to conclude that the CIRCA cloud can not compute the outcome of that event after all.

CIRCA needs an additional mechanism in order to preserve RCE in incremental deployment scenarios, in particular, to ensure that cloud routers do not diverge from their ground counterparts. To this end, each *boundary router* in the CIRCA cloud, i.e., any router whose ground incarnate has at least one neighbor that has not been upgraded to be CIRCA-capable, establishes receive-only ground-BGP sessions with those (ground) routers, wherein a *receive-only* session is one that only receives, but never sends, any announcements. Note that, notwithstanding this additional peering requirement, because of the non-deterministic nature of ground-BGP, it is possible for some events to (not) fizzle within the upgraded island in the cloud even though they might have not fizzled (fizzled) within the corresponding island on the ground. §B formally shows why RCE is nevertheless preserved under incremental CIRCA deployment scenarios.

3.6 CIRCA implementation

We implemented a Quagga-based prototype of CIRCA including the complete north-south protocol and the distributed convergence detection algorithm as described in roughly 2,430 lines of code. We have not implemented co-existence or incremental deployability mechanisms (§3.5) but evaluate their benefits via simulations based on real AS topologies.

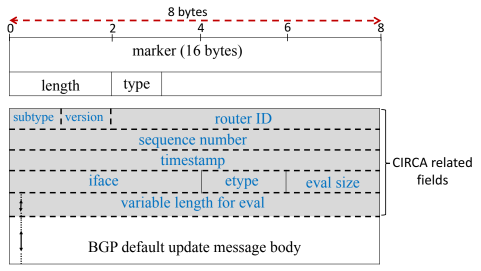


Figure 4: Header and body of a CIRCA BGP packet

Figure 4 shows the format of header and body of a CIRCA packet. The header is just the BGP header as also implemented in Quagga. The new fields are shown in gray background and are as follows. The subtype identifies the internal type of a CIRCA packet and include message types such as GRC, FIZZLE, and CONVERGED used in the convergence detection protocol. The `router ID` and `sequence number` two-tuple uniquely identify a root cause event E in Alg.1; `timestamp` is a unique ID for each message in Alg.1; and `iface`, `etype`, and `eval` are as described in §3.1.1. The rest of the packet is just the body of a BGP update packet with path attributes and network layer reachability information.

4 Evaluation

In this section, we conduct a prototype- and measurement-driven evaluation of these questions: (1) Does CIRCA help significantly drive down convergence delays by being "care-free" about message complexity? (2) Does CIRCA help improve end-to-end convergence delays including (a) the overhead of distributed convergence detection and (b) north-south communication delays? (3) Does CIRCA yield incremental benefit in incremental deployment scenarios?

All prototype-driven experiments are conducted on an Emulab LAN testbed of 150 physical machines each with 8 cores. All interfaces on used physical machines are connected to gigabit ports on HP ProCurve switches 5412zl series. We use three experimental-net switches (procurve3-procurve5), each with approximately 240 ports. A fourth switch (procurve1) acts as the center of a "hub and spoke" topology for the experimental network. The link speed between each pair of machines is 1Gbps and that of each virtual interface is 10Mbps.

4.1 Impact of MRAI timers

4.1.1 Single-router AS setup

In order to evaluate the convergence delay vs. message complexity tradeoff in the CIRCA cloud, we conduct a prototype-driven evaluation on the Emulab testbed using different realistic Internet topologies extracted from 2018 CAIDA AS-level topology gathered from RouteViews BGP tables [42] and varying MRAI timer values. Our topology includes 60,006 ASes and 261,340 links with inferred relationships between linked ASes [11]. Because of our limited physical resources

Number of routers in topology	20	60	180	540	1200
Average degree of routers	4	8	13	19	29
Average number of prefixes	225	296	180	155	106
All unique prefixes	4.5k	17.8k	32k	82.7k	125.3k

Table 2: Properties of used topologies.

(150 physical machines with 1200 cores), we extract contiguous subgraphs of the AS topology of varying sizes from 20 to a maximum of 1200 ASes. For extracting a subgraph of n ASes from the CAIDA data set, we first randomly pick an AS and perform a breadth-first search until the number of selected nodes reaches n. We increase the network size by only adding new nodes to the smaller subgraphs. The average degree of nodes and the number of prefixes belonging to each AS in our extracted topologies are shown in Table 2.

Our experiments retain Quagga's so-called "burst" MRAI timer implementation where all updates to a given peer are held until the timer expires, at which time all queued updates are announced. Quagga applies the MRAI timer only on updates, not on withdrawals, a behavior we retain. The published official BGP4 protocol specification RFC 4271 [39] suggests that route withdrawal messages are also to be limited by the MRAI timer; a change from earlier version (RFC 4098) where withdrawals could be sent immediately [40].

We emulate four different root cause events in our experiment; node up, node down, link up and link down. For each network size and MRAI value, we first assign the routers in the network to physical machines randomly and set the same MRAI timer on all routers and then wait for a long enough duration until routes to all prefixes at all routers stabilize. At this point, we randomly pick a router in the topology and trigger a random root cause event, and repeat this process 30 times for each topology size and MRAI value. We log each BGP message and post-process log files from all routers at the end of each run to compute the convergence delay.

Figure 5 shows the average convergence delay of 30 simulated root cause events using different MRAI values. In computing the convergence delay of each root event, we do not count the time it takes for the root router to detect the event because this delay ($\approx$ one to few seconds) will be incurred by ground routers but not CIRCA cloud routers. We consider the time when the last immediately impacted incident router detects the event as the beginning of the convergence period.

A couple observations are noteworthy. First, the absolute values of the convergence delay with zero MRAI timers are small. Convergence delay increases as expected with the topology size and number of affected prefixes of root router and the highest (average) value observed is 2.3 seconds with 1200 ASes. We conduct a smaller-scale experiment with multiple routers per AS using realistic intradomain topologies (deferred to a techreport [38]). Unsurprisingly, the qualitative trend of increasing convergence delays with increasing iBGP

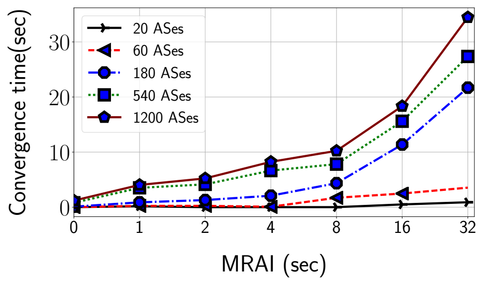

Figure 5: Average convergence delay of BGP across all root events with different MRAI timers on Emulab.

MRAI values persists. Second, convergence delay monotonically increases with the MRAI timer value and a zero timer yields the lowest convergence delay. This observation is in contrast to an established body of prior research [9, 12, 28, 43] suggesting a non-monotonic relationship between MRAI timer values and convergence delays and the existence of a minima for convergence delay at an MRAI value greater than zero, and that lower or zero MRAI values can significantly exacerbate convergence delays.

There is no contradiction however with prior findings. Previous work has been largely based on simulations and toy topologies (e.g., [12, 43]) and assumed unrealistically high values of message processing delays, e.g., random delay from zero to 1 second for each message in [12] and a uniformly distributed delay between 1 and 30 milliseconds for message processing [43]. There is no fundamental reason for message processing delays to be that high on modern processors and we find that they are at best tens of microseconds in Quagga (after we systematically disabled unnecessary timers).

4.1.2 Reconciling prior findings

As a sanity check, to verify that with artificially inflated message processing delays, we can reproduce the nonmonotonicity observed in prior work, we reduce the number of physical machines in our Emulab setup from 150 to 50 machines and rerun the experiment with the largest topology size (1200). With this setup, each 8-core machine now has almost 24 Quagga instances running on it compared to roughly eighth Quagga instances per machine (or one Quagga instance per core) in the earlier setup. Quagga is single-threaded software, so a Quagga instance can not leverage other cores on a physical machine even if they are idle.

Figure 6 shows that the nonmonotonic behavior is reproducible with more compute stress. However, it is important to clarify that this behavior is not solely because of the modest 3× decrease in resource provisioning. Because Quagga is a single-threaded software, an MRAI timer of 0 causes it to spin in a busy wait consuming 100% CPU utilization on each core even with one core per Quagga instance, a problem that exacerbates with 3-4 Quagga instances per core. Without this implementation artifact of wasteful busy waiting, we were unable to reproduce the nonmonotonic behavior observed in

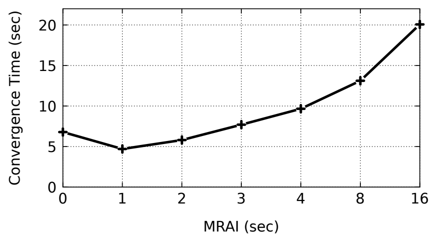

Figure 6: Non-monotonic trend of convergence delay vs. MRAI timer value with the 1200-AS topology.

prior work. Our observations therefore suggest that, with modern processing fabrics in routers, it may be worth revisiting whether conservatively set high MRAI values are appropriate even in ground-BGP today.

4.1.3 Extrapolating our findings to 60K ASes

Can even larger topologies going all the way up to 60K ASes result in prohibitively high message complexity exacerbating convergence delays? We think it unlikely for several reasons.

First, most root events are unlikely to impact a very large number of ASes unless a prefix is rendered altogether unreachable [36]. Second, even if an event impacts all ASes, with realistic Gao-Rexford policies, although pathological cases of exponential message complexity are theoretically possible, they require contrived topologies and unrealistic assumptions about relative speeds of routers to manifest in practice [22]. Even so, it may be possible to manage resource more effectively, e.g., we show in an experiment (deferred to a techreport [38]) that there is room to improve the core utilization by 30× in our testbed with multi-threading and careful mapping of virtual routers to cores. Third, even if many routers get affected by some root cause events, it is unlikely that the FIB entries (as opposed to just RIB entries) on most of the routers will change. Fourth, if message complexity does become prohibitive, with ultra-low LAN propagation delays in the CIRCA cloud, queued messages can be batch-processed (with no intervening exports) so as to provide a self-clocking mechanism to slow down announcements similar in spirit to MRAI timers but without relying on conservative, static values. This idea is similar to the proposed adaptive or dynamic MRAI values wherein the MRAI value is increased if there is more "unfinished work" in the queue and decreased if not [32, 43].

4.2 End-to-end convergence delay

In this section, we evaluate end-to-end convergence delay including the overhead of distributed convergence detection and north-south communication delays for a root cause event.

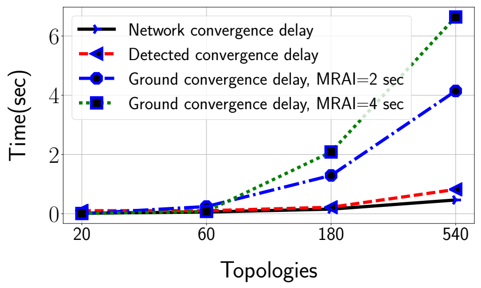

Figure 7: Difference between actual convergence delay in cloud, convergence detection delay using our algorithm, and ground convergence delay.

4.2.1 Convergence detection overhead

First, we evaluate the overhead introduced by the distributed convergence detection algorithm (Algorithm 1) to detect convergence after the protocol actually converges in cloud. As before, we estimate the ground-truth convergence delay by processing router logs and compare it to the time reported by our algorithm and repeat each root event injection 20 times.

We conduct this experiment with 20, 60, 180, and 540 ASes respectively in the ground and cloud setups with 20 randomly simulated root cause events in the ground setup in isolation. On ground, we set MRAI 2 and 4 seconds. Each ground router has a connection with its avatar in the cloud and both advertise the same list of prefixes in the network. We consider three different root cause event types in the ground network; node down, link up and link down. We have a single router AS setup for this experiment. The average degree of nodes in our topology and the number of prefixes belonging to each AS are shown in Table 2.

Figure 7 shows the average of the detected convergence time and the ground-truth convergence delay in cloud and also on ground for all root cause events for different topology sizes. Per design, we might expect the root router to take roughly 2× the time to detect and for the last router to take up to 3× time, but the observed overhead is much smaller. The reason for this fortuitous discrepancy is that messages in the first exploration phase usually contain a large number (even thousands) of prefixes, which increases processing and transmission times in that phase, but not in the other two phases.

4.2.2 End-to-end delay in getting new FIB entries

In this experiment, we evaluate the end-to-end delay for obtaining new FIB entries from the cloud.

We assume the ground routers in an island with different sizes have been upgraded to CIRCA. We run the ground instance of the routers and their avatars in a LAN (our Emulab CIRCA testbed). While we can find the convergence detection time of each router using our implemented CIRCA system, for measuring ground and cloud communication delay, we can not use the delay between ground routers and their avatars in the LAN as real Internet delay. We can estimate the

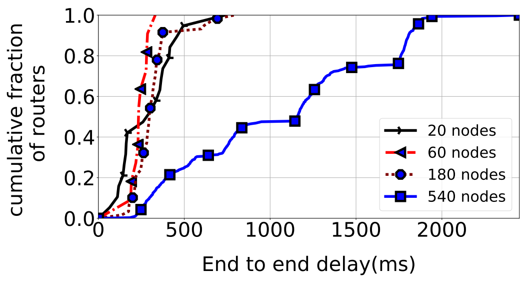

Figure 8: CDF on the end-to-end convergence delay for routers in different topology sizes

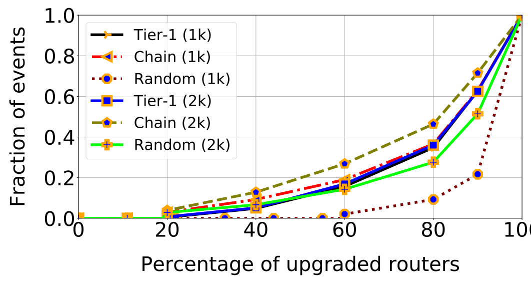

Figure 9: CDF on fraction of root cause events fizzled inside the island of upgraded routers using different approach in an island of 1,000 (1k) and 2,000 (2k) ASes

delay from Internet routers to their avatars by pinging routers in target ASes at the ground from their avatars at the cloud. The prefixes of each AS on the Internet are identifiable from the Routeviews data set [42]. For five original prefixes of our target ASes, we generate an IP address for each prefix by adding 100 to the end of the prefix, e.g., 10.10.8.100 for the prefix 10.10.8.0/24. We ping target IP addresses three times and get the average ping delay from that AS to our data center. For the roughly 20% of IP addresses for which we do not get any result, we assume 100 ms as the one-way delay.

We conduct this experiment for varying topology sizes with 20 randomly simulated root cause events on the ground in isolation. We consider 20, 60,180, and 540 ASes on the ground and in the cloud.

Figure 8 shows the end-to-end delay of getting the first entry in the FIB table to ground routers in an island with different sizes after simulating the root cause event on the ground. The end-to-end delay is the sum of the delay in sending event data to the cloud (approximated crudely as the ping delay), detecting the stable state of the network by each router, and receiving the new FIB entries from the cloud (ping delay) across all root cause events and routers affected by our root cause events. In small topologies, most of the routers (80%) get the FIB entry across all root cause events in less than 400 ms. However, for our biggest topology size, 540 nodes, we have 1.5 seconds for around 80% of routers. As explained in section 4.1.3, most of the delay is because of the delay in the first phase of our convergence detection algorithm and could be further optimized.

4.3 Incremental deployment of CIRCA

We evaluate the fraction of root cause events that fizzle entirely within an island of upgraded single-router ASes chosen as a subset of the Internet's AS topology. We sequentially simulate 20 randomly chosen root cause events originating within each upgraded island. We consider different approaches for selecting the upgraded routers: (1) *tier-1* that first "upgrades" the contiguous ASes that do not have any provider and then their customers, and so on; (2) *random* that picks ASes in the network randomly (possibly in a non-contiguous manner); and (3) *chain* that picks a random contiguous chain of customer-provider ASes. We do not consider stub ASes in our experiment as candidate ASes for upgrading.

Figure 9 shows the fraction of root cause events that fizzle entirely within upgraded islands of different sizes with different approaches. For example, for covering 40% of all root cause events, we need to upgrade roughly 80% of routers with the *chain* or *tier-1* approaches.

5 Discussion: Security, privacy, open issues

Our first stab at a practical interdomain-routing-as-a-service system leaves open questions that merit further discussion.

Any new system inevitably introduces new vulnerabilities. Our high-level goal in this work was to limit misbehavior to what is already possible in BGP's control plane, and to limit information disclosure explicitly by design, however CIRCA itself introduces new security vulnerabilities as well as side-channel information leakage as discussed below.

Side channel leakage. First, CIRCA allows a rogue AS to exploit rapid convergence as a probing mechanism to infer policies of other ASes by willfully tampering its announcements and observing how others react, an attack also possible in "slow motion" in ground-BGP, and mechanisms similar to route flap damping may be necessary in the CIRCA cloud if such "fast-forwarded" probing attacks were to become a credible threat. FIZZLE messages expose a new side channel allowing an attacker to use the time between a CBGP message and its corresponding FIZZLE to infer more information than is explicitly revealed by ground-BGP. Note that, given that every CBGP is guaranteed to eventually elicit a corresponding FIZZLE, the information leaked by this side channel is limited to the convergence delay. Third, if a single provider owns the entire network infrastructure in the CIRCA cloud, it can monitor control traffic patterns (despite encryption) to derive more information than is realistically possible in ground-BGP today. We defer further analyses of and defenses against these and other information leakage attacks to future work.

Security vulnerabilities. CIRCA's design allows BGP in the distributed cloud protocol to be drop-in replaced by S-BGP [23] (or other related security extensions like soBGP, BGPSec, etc.) while qualitatively preserving its convergence delay benefits as well as safety, liveness, and route computation equivalence guarantees provided the secured variant of BGP is guaranteed to produce routing outcomes *equivalent* to its unsecured version. CIRCA largely continues to be vulnerable to protocol *manipulation attacks* [47] against which cryptographic mechanisms as in S-BGP alone cannot protect, however known manipulation attacks based on abusing MRAI timers allowing an off-path adversary to potentially permanently disconnect good ASes despite the existence of good policy-compliant paths between them are ineffective in CIRCA because of its avoidance of MRAI timers.

CIRCA's liveness guarantee (§3.3.2) relies on the safety of BGP policies, which potentially allows a rogue AS to change its policies (in a possibly self-defeating manner) simply to stall the CIRCA control plane. Although the rogue AS could mount this attack even in ground-BGP today, an ameliorating factor on the ground is that routers will continue to update their FIBs and forward traffic throughout the never-ending convergence period, potentially over loops or blackholes. In the CIRCA cloud in contrast, any root cause event—necessarily a policy change event (as opposed to a link/node down/up event)—that results in a safety violation will never converge, so ground routers will never receive the updated FIBs corresponding to that particular event. However, there are two alleviating factors in CIRCA. First, ground routers can fall back on ground BGP with CIRCA's support for BGP co-existence for that root event. Second, other root events can proceed unaffected with CIRCA's default "careless" concurrent event processing approach. These factors suggest that CIRCA-enabled BGP will be no worse than BGP in the presence of safety-violating policy attacks.

Non-convergent path exploration can be cleanly limited by augmenting the CIRCA cloud protocol with a TTL (time-to-live) mechanism that aborts (or force-fizzles) path exploration along any path in the directed message tree after a predefined maximum number of hops. A second design choice is to augment the cloud protocol with a TTL that upon expiration causes a cloud router to dispatch its current FIB to its ground avatar, reset the TTL to its maximum value, and resume the (never-ending) path exploration phase for that root event, a design that in effect induces ground routers to jump from one set of potentially inconsistent FIBs to another in a never-ending manner (similar to BGP). Such adaptations will not preserve RCE as defined because RCE is not well defined in the absence of ECC that will not hold under unsafe or non-convergent BGP policies, however the second design choice in practice comes close to emulating BGP behavior in non-convergent scenarios. We defer a more detailed design and analysis of CIRCA with unsafe BGP policies to future work.

Honest-but-curious threat model. CIRCA as described herein trusts each (replicated) cloud provider to provide and maintain the physical infrastructure in a non-curious manner, but its design can be extended to support a honest-but-curious cloud provider. One option is to employ emerging secure computing platforms [34] to prevent the entity controlling the physical machine from snooping on protected customer data within the machine, an approach that does however implicitly involve the manufacturer of the secure computing processor (e.g, Intel with SGX). To prevent a cloud provider controlling the OS on the machine from using the pattern of memory accesses from leaking information, further techniques such as Oblivious RAM [48] will be required. A quirkier alternative is to organize each replicated CIRCA location similar in spirit to a global exchange point with a "bring-your-own-hardware" model in conjunction with physical security mechanisms, a design wherein the CIRCA cloud itself is federated obviating a trusted infrastructure provider.

Security and robustness benefits. Our hypothesis is that the long-term potential benefits of CIRCA are likely to outweigh the impact of new vulnerabilities it introduces. First, CIRCA provides a clean slate enabling early adopters to employ from the get go secure BGP mechanisms that have seen two decades of research and standardization work but little deployment in practice. Second, with willing AS participants, it is intrinsically easier to monitor select portions of control traffic in the CIRCA cloud compared to ground-BGP today in order to detect misbehavior such as protocol manipulation attacks. Third, CIRCA enables new opportunities such as augmenting the CIRCA cloud with mechanisms for "what-if" analysis allowing operators to ascertain whether an action will have the intended effect before performing that action.

6 Conclusions

In this paper, we presented the design, formal analysis, implementation, and prototype-driven evaluation of CIRCA, a logically centralized architecture for interdomain routing control. Although logical centralization of network control is a widely embraced direction in recent years in intradomain networks, attempts to extend that vision to Internet-wide interdomain routing have been limited to on-paper designs or small-scale evaluations. To our knowledge, this is the first work to present a full-fledged design and implementation of an interdomain routing control platform. Our underlying technical contributions include a novel distributed convergence detection algorithm; demonstrating the potential for significantly reducing BGP's tail latencies; formally ensuring route computation equivalence with a broad class of BGP-like protocols, and designing mechanisms for enabling incremental deployment and coexistence with BGP.

A Algorithm 1: Safety and liveness proofs

In this section, we formally prove the safety and liveness properties satisfied by Algorithm 1. The proofs rely on a construction called the *directed message graph* produced by any execution instance of Algorithm 1 and defined as follows.

Definition 3. DIRECTED MESSAGE GRAPH: *The directed message graph of an instance of Algorithm 1 is a directed graph $G = (\mathcal{V}, \mathcal{E})$ such that each vertex in $\mathcal{V}$ denotes a sent message (either the original* GRC *or a* CBGP *message) and $\mathcal{E}$ has a directed edge from a message m_1 to another message m_2 if m_1 caused m_2, i.e., m_2 was sent in lines 14 or 26 respectively in response to the receipt of m_1 in lines 16 or 1.*

We say that $m_1 \to m_2$ (or m_1 *happened before* m_2) if there is a directed path from message m_1 to m_2 in the graph.

Lemma A.1. *The directed message graph produced by any execution of Algorithm 1 is a directed tree.*

Proof. Acyclicity follows from the observation that each message sent by Algorithm 1 is unique, as identified by the unique two-tuple timestamp assigned in lines 11 or 23, thus the directed message graph is a directed acyclic graph (DAG). That DAG is also a tree because each message is caused by at most one other message: a CBGP message is caused by either a unique CBGP message (line 13) or the original GRC (line 25) and the original GRC being the root of the DAG is not caused by any other message. □

In the proofs below, we will use *tree*(m) denote the subtree rooted at m in the directed message tree produced by an instance of Algorithm 1 (which is well-defined because of Lemma A.1 just above).

A.1 Proof of safety

We introduce the following lemmas in order to prove safety (Theorem 3.1).

Lemma A.2. *If a router receives a* FIZZLE *for a* CBGP *message m_1 that it sent, then tree(m_1) is finite.*

Proof. Suppose the execution of Algorithm 1 started at time 0 and the router in the lemma's premise received the FIZZLE for m_1 at some (finite) time t_1. Further assume that the time since a router sends a FIZZLE until the corresponding neighboring router receives it is lower bounded by a constant time $c > 0$ (as would be the case in any real implementation of Algorithm 1). To show that *tree*(m_1) is finite, we show that every path rooted at m_1 is finite as follows.

Consider the set *caused*(m_1) of the immediate children of m_1, which is the set of messages sent by the recipient of m_1 in either the `for` loop on either line 10 (if m_1 were a GRC message) or line 22 (if m_1 were a CBGP message). By inspection of Algorithm 1, a FIZZLE is sent only at two places, line 20 and line 35. In the former case (line 20), the causal message m_1 did not spawn any further child messages at the recipient of m_1, so *caused*(m_1) is empty implying that *tree*(m_1) is of unit size.

In the latter case (line 35), the recipient of m_1 must have previously remembered the set of caused messages *caused*(m_1) in its local map (the *sent*$[E][ts(m_1)]$ map in lines 12 or 24) and subsequently sent a FIZZLE for m_1 back to its sender when the *sent* map got emptied at the recipient (line 34), i.e., the recipient of m_1 received a FIZZLE for every message in *caused*(m_1). By assumption, the recipient of m_1 must have received a FIZZLE for every message in *caused*(m_1) by time no later than $t - c$.

Let *caused*$^k(m_1)$ recursively denote the set of messages caused by *caused*$^{k-1}(m_1)$ for $k > 1$. By repeating the above argument, all messages in *caused*$^k(m_1)$ must have received a corresponding FIZZLE from their respective recipients by time $t - kc$. By assumption, the algorithm began execution at time 0, so the depth of *tree*(m_1) is at most t/c.

□

Lemma A.3. *A router receives a* FIZZLE *for a* CBGP *message m_1 it sent only if for every message m_2 (sent by any router) such that $m_1 \to m_2$, the sender of m_2 had previously received a matching* FIZZLE *from the recipient of m_2.*

Proof. The proof is by induction on the depth of the subtree *tree*(m_1) rooted at m_1, which by Lemma A.2 is finite.

Consider a topological sort of *tree*(m_1) with the root m_1 at level 0 and all the messages in *caused*$^k(m_1)$ at level $k > 0$. Let the depth or maximum level be d (that is well defined because of Lemma A.2). The lemma's claim is trivially true for a level d message as it did not cause any further messages. Suppose that the claim is true for messages at all levels in $[i, d]$ (both inclusive) for some $1 < i < d$. Consider a non-leaf message m at level $i - 1$ sent by a router for some root event E. By line 35, the recipient router can issue a FIZZLE for m only if its *sent*$[E]$ is empty, i.e., only if it has received a matching FIZZLE for every message in *caused*(m), which completes the inductive step for level i, proving the lemma. □

Lemma A.4. *When converged(E) is set to true at the root router, sent$[E]$ is empty at every router.*

Proof. There are two cases to consider.

Case 1: *converged(E) is set upon receipt of a* GRC *message*

In this case, the root router will terminate before sending any CBGP message. No router will send any further CBGP messages because a CBGP message can only be sent in response to the receipt of a CBGP or GRC message.

Case 2: *converged(E) is set upon receipt of a* FIZZLE.

By inspection of code, this case can happen only if the router receiving the FIZZLE is the router that received the root cause GRC message. *converged*(E) is set at the root router only when its *sent*$[E]$ map is empty (line 7). By inspection (line 31), an entry in *sent*$[E]$ is removed *only if* the matching FIZZLE is received. Thus, the root router must have received a matching FIZZLE for each message it sent including all the level 1 messages immediately caused by the root GRC message. By Lemma A.3, every sent message for E (at any router) must have received a matching FIZZLE. By line 31, an entry in *sent*$[E]$ is removed *if* the matching FIZZLE is received. So, if every sent message for E has received a matching FIZZLE, *sent*$[E]$ must be empty at all routers, proving the claim. □

We complete the proof of safety as follows.

Theorem 3.1. SAFETY: If *converged(E)* is true at the root cloud router that received the GRC, then no further CBGP message for E will be received by any cloud router.

Proof. By Lemma A.4 above, *sent*$[E]$ is empty at every router at this point, so there is no in-propagation CBGP message for E as every sent message at any router has already received the corresponding FIZZLE. The root router that received the GRC message terminates immediately after setting *converged*(E), so it will not send any further CBGP messages for E. A CBGP message can be sent by a non-root router (line 26) only upon receiving an in-propagation CBGP message, so no non-root router will send any further CBGP messages either. □

Technical note. If we assume safe BGP policies, the onerousness in Lemma A.2 would be unnecessary as the directed message tree would be bounded by definition. However, the proof of CIRCA's safety (unlike the proof of its liveness immediately below) does not require the safety of the underlying BGP policies, so we chose the more onerous formal route to make that independence clear.

A.2 Proof of liveness

The liveness proofs below implicitly assume that routers in the CIRCA cloud either do not fail or employ a persistent write-ahead log to record all local state changes before sending messages based on those changes. (Unlike liveness, neither failures nor the availability of a persistent log impacts safety.)

Lemma A.5. *If BGP policies are safe, every sent* CBGP *message eventually receives a matching* FIZZLE *if all cloud routers are available for a sufficiently long duration.*

Proof. The proof of this claim is by induction and is similar in spirit to Lemma A.3. The assumed safety of BGP policies by definition bounds the size of the directed message tree. Consider a topological sort as before partitioning the tree into levels where level k nodes are the messages in $caused^k(\text{GRC})$ where we have used GRC as a shorthand for the original GRC message that initiated Algorithm 1 at the root router. Let d denote the depth of the tree.

The claim is true for level d messages because of lines 19–26: a router receiving a CBGP message must either cause a new CBGP (the else block starting line 21) or issue a FIZZLE for the received CBGP (line 20). Level d messages do not cause any further CBGP messages, so routers receiving them will issue a corresponding FIZZLE.

The inductive step is as follows. Suppose the claim holds for levels i to d for $1 < i < d$. Consider a level $i-1$ message m with timestamp ts received by a router that causes it to send the set $caused(m)$ of level i messages. By the inductive assumption, each level i message m_1 eventually receives a matching FIZZLE, and each such FIZZLE removes the corresponding entry from $sent[E][ts_1]$ at the router that received m_1 where ts_1 is the timestamp of m_1. Thus, when the recipient of m has received matching FIZZLEs for all level i messages caused by the incoming level $i-1$ message m, its $sent[E][ts]$ map becomes empty triggering the matching FIZZLE for m, which completes the inductive step, proving the lemma. □

Theorem 3.2. LIVENESS: Algorithm 1 eventually terminates if the underlying BGP policies are safe[2] and all cloud routers are available for a sufficiently long duration.

Proof. To prove that Algorithm 1 terminates, i.e., *converged*(E) is set at the root router, we consider two cases, the first of which as in the safety proof is trivial.

Case 1: *No* CBGP *messages are sent.*

In this case, the algorithm trivially terminates in line 7.

Case 1: CBGP *messages are sent.*

The proof of the theorem follows by observing that, by Lemma A.5, the root router must eventually receive a matching FIZZLE for all (level 1) CBGP messages caused by the root GRC (in line 26). At this point, its *sent*$[E]$ map must be empty for the following reason: Lemma A.3 implies that any level 2 or higher CBGP message sent by any router must have already fizzled, so any level 2 or higher CBGP sent by the root router must have also already fizzled and consequently already removed from its *sent*$[E]$ map. By line 32, an empty *sent*$[E]$ map causes Algorithm 1 to terminate. □

Note that although the proofs above did not explicitly invoke the "*all cloud routers are available for a sufficiently long duration*" assumption, they implicitly relied on that in conjunction with a persistent write-ahead log in all claims with the word "*eventually*" in the proofs above.

[2]A reminder that "safe" here means that a stable route configuration exists [13] and is unrelated to *safety* in Theorem 3.1

A.3 Proof of efficiency

Algorithm 1 omitted a formal description of the third *dissemination* phase for a concise exposition of the key safety and liveness properties. For completeness, we codify the dissemination phase in event-action format as well. The root router that received the GRC message for event E, instead of exiting when $converged(E)$ becomes true (on line 33), initiates the dissemination phase by sending to itself the COMMIT message $\langle$COMMIT$, E, ts\rangle$ where ts is the timestamp of the original GRC message as assigned on line 9 in Algorithm 1. The event handler for a received commit message is below.

Dissemination phase of Algorithm 1

```
1: event RECV(⟨COMMIT, $E, ts$⟩, $N$)   ▷ upon receipt of a commit
   message from cloud router N at cloud router $v(R)$
2:     $p \leftarrow$ all affected prefixes in $fizzled[E][ts]$
3:     send(⟨FBGP, $E, p, FIB(p)$⟩, R)   ▷ southbound FIB dispatch
4:     for each $[N_1, p_1, ts_1]$ : $fizzled[E][ts]$ do
5:         send(⟨COMMIT, $E, ts_1$⟩, $N_1$)
6:     $fizzled[E][ts] \leftarrow \emptyset$
7:     if $fizzled[E] = \emptyset$ then exit
```

THEOREM 3.3. EFFICIENCY: *The root router (Any router) in Algorithm 1 detects convergence within at most 2Δ (3Δ) time and $2M$ ($3M$) messages where Δ and M are respectively the actual convergence delay and number of messages incurred by the underlying distributed route computation protocol.*

Proof. The convergence indicating COMMIT messages disseminated in Algorithm 1's third phase by design follow the exact same paths as the CBGP messages in the directed message tree in the first (exploration) phase. This claim follows from the observation that when $converged(E)$ is set at the root router, Lemma A.4 implies that every entry ever previously added to the *sent*[E] map (in lines 12 or 24) has already been removed, and by inspection of lines 31 and 30, every entry removed from the $sent[E]$ map is added to the $fizzled[E]$ map.

Assuming safety of the underlying BGP policies, every CBGP message eventually begets a matching FIZZLE in the reverse direction in the second (back-propagation) phase and a matching COMMIT in the same direction in the third (dissemination) phase, thus the number of messages in each phase is identical. The "*actual convergence delay and number of messages incurred by the underlying distributed route computation protocol*" are defined as those of the first phase alone. The root router detects convergence at the end of the second phase when $converged(E)$ becomes true. Each router detects convergence when its $fizzled[E]$ map gets emptied, which necessarily happens for every router in the third phase by an inductive argument similar to that used in Lemma A.5. □

Technical notes. The efficiency proof conservatively assumes that the second and third phases incur at most as much delay as the first phase. In a practical implementation, this assumption is more than true in that the first phase is likely to incur much more delay than the other two phases. The reason is that the first phase CBGP messages may carry a large number (hundreds or thousands) of prefixes resulting in large transfer sizes at each hop but the second and third phase messages are small control messages as they just need to convey the root cause event identifier and timestamp.

The dissemination phase as strictly codified above may result in any given router dispatching southward portions of the modified FIB entries for a single root cause event in multiple bursts (via line 3) in the third phase. It is straightforward to modify the protocol so as to either dispatch the entire set of modified FIB entries as a single message just before exit (on line 7) instead or send a termination marker southward just before exiting so that the ground incarnate can apply all modified FIB entries atomically. This modification may reduce transient inconsistencies in the ground forwarding plane, especially if cloud routers intermittently fail and pre-computed backup routing options are available to ground routers.

B Route computation equivalence

THEOREM 3.4. ROUTE COMPUTATION EQUIVALENCE: *If for a sufficiently long period—(i) all ground routers can reach a* CIRCA *cloud datacenter and vice versa; and (ii) all cloud routers are available and can communicate in a timely manner—a pure* CIRCA *system ensures Route Computation Equivalence with any distributed route computation function that satisfies Eventually Consistent Convergence.*

Proof. Let $\mathbf{D}(S)$ denote any distributed route computation function. Suppose the initial network state is S_0 and a sequence of root cause events $[e_1, \ldots, e_n]$ (but no further events) occurs. Consider the following mutually exclusive and exhaustive set of event sequences: $\{[e_{11}, e_{12}, \ldots], [e_{21}, e_{22}, \ldots], \ldots, [e_{m1}, e_{m2}, \ldots]\}$ where e_{ij} denotes an event at router i with (local) sequence number j and m denotes the total number of routers, i.e., each sequence in this set is an ordered subset of events in the original event sequence all of which were detected by the same router in that local order.

The theorem follows from the following claims: (1) CIRCA eventually processes all root events; (2) CIRCA processes root events in an order consistent with the local order at ground routers; (3) processing the root events in any global order consistent with local orders results in the same final routing outcomes. The first two claims are straightforward: the first follows from the assumption of sufficiently long periods of cloud-ground reachability and cloud router availability; the second follows from line II.1 in the north-south protocol.

The last of the above claims is the non-intuitive one and needs a proof. The proof surprisingly follows from the assumption that the ground routing protocol ensures Eventually Consistent Convergence. Consider any reordering of the $\mathcal{F} = [f_1, \ldots, f_n]$ of the original event sequence $\mathcal{E} = [e_1, \ldots, e_n]$ that preserves local order. We claim that $S_0|\mathcal{F} = S_0|\mathcal{E}$, i.e., the network arrives at the same final state given any local-order-preserving reordering[3] of an event sequence.

To see why, suppose events only consisted of link up and link down events for a given link. A link event will be detected and reported by one or both of the incident ground routers, say A and B. No matter how many times the link goes up or down in a given sequence of events, in any local-order-preserving reordering of that sequence, both A and B will agree on the final state of the link. Note that the claim is not true in general for a non-local-order-preserving reordering, for example, if link $A-B$ went down and then came back up, but the last event was reported by A and reported as a link down event, the final state of the network (and by consequence routing outcomes) will be different.

The complete proof follows from showing the third claim, namely that any *sequentially consistent* reordering of events produces the same final outcome, in a manner similar to above for other root cause events including node up/down events, link cost changes, as well as combinations of such events. □

We conjecture that RCE given ECC as above holds for more general policy or other configuration changes at routers. It is straightforward to see that any set of configuration changes across distributed routers will preserve RCE if the final state is the same given any sequentially consistent reordering of those changes. However, it is unclear to us if this property always holds or to what extent it holds in practice. For example, if the value of a router configuration parameter is determined based on the value of another parameter at a different router, the final network configuration state may depend on the precise total order of all events, i.e., it is sensitive to different reorderings even if they are sequentially consistent.

B.1 Practical considerations for RCE

The high-level CIRCA design may require or benefit from some adaptations in practice as summarized below in order to preserve route computation equivalence. A more detailed investigation of these is deferred to future work.

IGP-awareness: A root event such as a link cost change or, more generally, any intradomain root event that potentially affects interdomain routes at any router needs to be conveyed somehow to that router. In an intradomain routing protocol such as OSPF, link-state advertisements (LSA) accomplish that purpose. There are two natural design alternatives in CIRCA to accomplish the same: (1) piggypack the root cause event label in LSAs similar to CIRCA's CBGP messages; (2) use iBGP to disseminate the root event network-wide within the domain. The latter approach has the benefit of being largely decoupled from the intradomain routing protocol and works well for intradomain routing protocols that are *global* by design like link-state routing, but not so well for *decentralized* protocols like distance-vector routing wherein a router by design does not know the final outcome of the route computation until the decentralized computation completes. In practice, "full-mesh-iBGP-as-LSA" suffices to maintain route computation equivalence for any shortest path routing protocol or, more generally, any intradomain routing protocol that lends itself to a global implementation, i.e., one where an individual router can immediately compute its final intradomain routing outcome for any given change to global (intradomain) network state.

Root cause event grammar: Although the variable-length description $\langle etype, eval \rangle$ (refer §3.1.1 and Figure 4) is in principle sufficiently general to allow CIRCA to represent arbitrary changes to router configuration state, and parsing it is a purely intradomain concern, there may be value in minimally standardizing this representation across different router vendors for the sake of a reusable implementation. For example, the unix utility `diff` is a naive way to represent changes to router configuration files in a platform-agnostic manner. A more systematic vendor-specific or -neutral grammar for representing root cause events is conceivable.

Domain consolidation: Consolidating route computation for routers in the same domain by employing a single well-provisioned router server (similar in spirit to RCP [4]) instead of one-one mapping ground routers to virtual routers is likely to improve resource efficiency and thereby reduce the provisioning cost of route servers. The consolidated approach blurs the distinction between the abstract "single-router-AS" model and ASes in practice, arguably making it easier for operators to monitor and understand routing dynamics within their networks. Maintaining route computation equivalence requires that the consolidated server is guaranteed to computes a routing outcome that could have been computed by the correspondning ground protocol.

[3]Or a *sequentially consistent* ordering in distributed computing parlance.

XRD: Scalable Messaging System with Cryptographic Privacy

Albert Kwon — *MIT*
David Lu — *MIT PRIMES*
Srinivas Devadas — *MIT*

Abstract

Even as end-to-end encrypted communication becomes more popular, private messaging remains a challenging problem due to metadata leakages, such as who is communicating with whom. Most existing systems that hide communication metadata either (1) do not scale easily, (2) incur significant overheads, or (3) provide weaker guarantees than cryptographic privacy, such as differential privacy or heuristic privacy. This paper presents XRD (short for Crossroads), a metadata private messaging system that provides cryptographic privacy, while scaling easily to support more users by adding more servers. At a high level, XRD uses multiple mix networks in parallel with several techniques, including a novel technique we call aggregate hybrid shuffle. As a result, XRD can support 2 million users with 228 seconds of latency with 100 servers. This is 13.3× and 4× faster than Atom and Pung, respectively, which are prior scalable messaging systems with cryptographic privacy.

1 Introduction

Many Internet users today have turned to end-to-end encrypted communication like TLS [18] and Signal [40], to protect the *content* of their communication in the face of widespread surveillance. While these techniques are starting to see wide adoption, they unfortunately do not protect the *metadata* of communication, such as the timing, the size, and the identities of the end-points. In scenarios where the metadata are sensitive (e.g., a government officer talking with a journalist for whistleblowing), encryption alone is not sufficient to protect users' privacy.

Given its importance, there is a rich history of works that aim to hide the communication metadata, starting with mix networks (mix-nets) [10] and dining-cryptographers networks (DC-Nets) [11] in the 80s. Both works provide formal privacy guarantees against global adversaries, which has inspired many systems with strong security guarantees [14, 55, 35, 53]. However, mix-nets and DC-nets require the users' messages to be processed by either centralized servers or every user in the system, making them difficult to scale to millions of users. Systems that build on them typically inherit the scalability limitation as well, with overheads increasing (often superlinearly) with the number of users or servers [14, 55, 35, 53]. For private communication systems, however, supporting a large user base is imperative to providing strong security; as aptly stated by prior works, "anonymity loves company" [20, 49]. Intuitively, the adversary's goal of learning information about a user naturally becomes harder as the number of users increases.

As such, many recent messaging systems have been targeting scalability as well as formal security guarantees. Systems like Stadium [52] and Karaoke [37], for instance, use differential privacy [22] to bound the information leakage on the metadata. Though this has allowed the systems to scale to more users with better performance, both systems leak a small bounded amount of metadata for each message, and thus have a notion of "privacy budget". A user in these systems then spends a small amount of privacy budget every time she sends a sensitive message, and eventually is not guaranteed strong privacy. Users with high volumes of communication could quickly exhaust this budget, and there is no clear mechanism to increase the privacy budget once it runs out. Scalable systems that provide stronger cryptographic privacy like Atom [34] or Pung [5], on the other hand, do not have such a privacy budget. However, they rely heavily on expensive cryptographic primitives such as public key encryption and private information retrieval [3]. As a result, they suffer from high latency, in the order of ten minutes or longer for a few million users, which impedes their adoption.

This paper presents a point-to-point metadata private messaging system called XRD that aims to marry the best aspects of prior systems. Similar to several recent works [5, 34, 52], XRD scales with the number of servers. At the same time, the system cryptographically hides all communication metadata from an adversary who controls the entire network, a constant fraction of the servers, and any number of users. Consequently, it can support virtually unlimited amount of communication without leaking privacy against such an adversary. Moreover, XRD only uses cryptographic primitives that are significantly faster than the ones used by prior works, and can thus provide lower latency and higher throughput than prior systems with cryptographic security.

A XRD deployment consists of many servers. These servers are organized into many small chains, each of which acts as a local mix-net. Before any communication, each user creates a *mailbox* that is uniquely associated with her, akin to an e-mail address. In order for two users Alice and Bob to have a conversation in the system, they first pick a number of chains using a specific algorithm that XRD provides. The algorithm guarantees that *every* pair of users intersects at one of the chains. Then, Alice and Bob send messages addressed to their own mailboxes to all chosen chains, except to the chain where their choices of chains align, where they send their messages for each other. Once all users submit their messages, each chain shuffles and decrypts the messages, and forwards the shuffled messages to the appropriate mailboxes. Intuitively, XRD protects the communication metadata because (1) every pair of users is guaranteed to meet at a chain which makes it equally likely for any pair of users to be communicating, and (2) the mix-net chains hide whether a user sent a message to another user or herself.

One of the main challenges of XRD is addressing active attacks by malicious servers, where they tamper with some of the users' messages. This challenge is not new to our system, and several prior works have employed expensive cryptographic primitives like verifiable shuffle [14, 55, 35, 52, 34] or incurred significant bandwidth overheads [34] to prevent such attacks. In XRD, we instead propose a new technique called *aggregate hybrid shuffle* that can verify the correctness of shuffling more efficiently than traditional techniques.

XRD has two significant drawbacks compared to prior systems. First, with N servers, each user must send $O(\sqrt{N})$ messages in order to ensure that every pair of users intersects. Second, because each user sends $O(\sqrt{N})$ messages, the workload of each XRD server is $O(M/\sqrt{N})$ for M users, rather than $O(M/N)$ like many prior scalable messaging systems [34, 52, 37]. Thus, prior systems could outperform XRD in deployment scenarios with large numbers of servers and users, since the cost of adding a single user is higher and adding servers is not as beneficial in XRD.

Nevertheless, our evaluation suggests that XRD outperforms prior systems with cryptographic guarantees if there are less than a few thousand servers in the network. XRD can handle 2 million users (comparable to the number of daily Tor users [1]) in 228 seconds with 100 servers. For Atom [34] and Pung [5, 4], two prior scalable messaging systems with cryptographic privacy, it would take over 50 minutes and 15 minutes, respectively. (These systems, however, can defend against stronger adversaries, as we detail in §2 and §7.) Moreover, the performance gap grows with more users, and we estimate that Atom and Pung require at least 1,000 servers in the network to achieve comparable latency with 2 million or more users. While promising, we find that XRD is not as fast as systems with weaker security guarantees: Stadium [52] and Karaoke [37], for example, would be 3× and 23× faster than XRD, respectively, in the same deployment scenario. In terms of user costs, we estimate that 40 Kbps of bandwidth is sufficient for users in a XRD network with 2,000 servers, and the bandwidth requirement scales down to 1 Kbps with 100 servers.

In summary, we make the following contributions:

- Design and analyze XRD, a metadata private messaging system that can scale by distributing the workload across many servers while providing cryptographic privacy.
- Design a technique called aggregate hybrid shuffle that can efficiently protect users' privacy under active attacks.
- Implement and evaluate a prototype of XRD on a network of commodity servers, and show that XRD outperforms existing cryptographically secure designs.

2 Related work

In this section, we discuss related work by categorizing the prior systems primarily by their privacy properties, and also discuss the scalability and performance of each system.

Systems with cryptographic privacy. Mix-nets [10] and DC-Nets [11] are the earliest examples of works that provide cryptographic (or even information theoretic) privacy guarantees against global adversaries. Unfortunately, they have two major issues. First, they are weak against active attackers: adversaries can deanonymize users in mix-nets by tampering with messages, and can anonymously deny service in DC-Nets. Second, they do not scale to large numbers of users because all messages must be processed by either a small number of servers or every user in the system. Many systems that improved on the security of these systems against active attacks [14, 55, 35, 53] suffer from similar scalability bottlenecks. Riposte [13], a system that uses "private information storage" to provide anonymous broadcast, also requires all servers to handle a number of messages proportional to the number of users, and thus faces similar scalability issues.

A recent system Atom [34] targets both scalability and strong anonymity. Specifically, Atom can scale *horizontally*, allowing it to scale to larger numbers of users simply by adding more servers to the network. At the same time, it provides sender anonymity [46] (i.e., no one, including the recipients, learns who sent which message) against an adversary that can compromise any fraction of the servers and users. However, Atom employs expensive cryptography, and requires the message to be routed through hundreds of servers in series. Thus, Atom incurs high latency, in the order of tens of minutes for a few million users.

Pung [5, 4] is a system that aims to provide metadata private messaging between honest users with cryptographic privacy. This is a weaker notion of privacy than that of Atom, as the recipients (who are assumed to be honest) learn the senders of the messages. However, unlike most prior works, Pung can provide private communication even if *all servers* are malicious by using a cryptographic primitive called computational private information retrieval (CPIR) [12, 3]. Its powerful threat model comes unfortunately at the cost of performance: Though Pung scales horizontally, the amount of work required per user is proportional to the total number of users, resulting in the total work growing superlinearly with the number of users. Moreover, PIR is computationally expensive, resulting in throughput of only a few hundred or thousand messages per minute per server.

Systems with differential privacy. Vuvuzela [53] and its horizontally scalable siblings Stadium [52] and Karaoke [37] aim to provide differentially private (rather than cryptographically private) messaging. At a high level, they hide the communication patterns of honest users by inserting dummy messages that are indistinguishable from real messages, and reason carefully about how much information is leaked at each round. They then set the system parameters such that they could support a number of sensitive messages; for instance, Stadium and Karaoke target 10^4 and 10^6 messages, respectively. Up to that number of messages, the systems allow users to provide a plausible cover story to "deny" their actual actions. Specifically, the system ensures that the probability of Alice conversing with Bob from the adversary's perspective is within e^ε (typically, $e^\varepsilon \in [3,10]$) of the probability of Alice conversing with any other user with only a small failure probability δ (typically, $\delta = 0.0001$). This paradigm shift has allowed the systems to support larger numbers of users with lower latency than prior works.

Unfortunately, systems with differential privacy suffer from two drawbacks. First, the probability gap between two events may be sufficient for strong adversaries to act on. For instance, if Alice is ten times as likely to talk to Bob than Charlie, the adversary may act assuming that Alice is talking to Bob, despite the plausible deniability. Second, there is a "privacy budget" (e.g., 10^4 to 10^6 messages), meaning that a user can deny a limited number of messages with strong guarantees. Moreover, for best possible security, users must constantly send messages, and deny every message. For instance, Alice may admit that she is not in any conversation (thinking this information is not sensitive), but this could have unintended consequences on the privacy of another user who uses the cover story that she is talking with Alice. The budget could then run out quickly if users want the strongest privacy possible: If a user sends a message every minute, she would run out of her budget in a few days or years with 10^4 to 10^6 messages. Although the privacy guarantee weakens gradually after the privacy budget is exhausted, it is unclear how to raise the privacy levels once they have been lowered.

These shortcomings can particularly affect journalists and their sources. Many journalists mention the importance of long-term relationships with their sources for their journalistic process [41, 43], and the difficulty of maintaining private relationships with them. In a differentially private system, if the journalist and the source are ten times as likely to be talking as two other users, then the adversary might simply assume the journalist and the source's relationship. Furthermore, these relationships often last many years [43], which could cause the privacy budget to run out. This may put the journalist and the source in jeopardy.

Scalable systems with other privacy guarantees. The only private communication system in wide-deployment today is Tor [21]. Tor currently supports over 2 million daily users using over 6,000 servers [1], and can scale to more users easily by adding more servers. However, Tor does not provide privacy against an adversary that monitors significant portions of the network, and is susceptible to traffic analysis attacks [19, 30]. Its privacy guarantee weakens further if the adversary can control some servers, and if the adversary launches active attacks [29]. Similar to Tor, most free-route mix-nets [44, 24, 49, 15, 39] (distributed mix-nets where each messages is routed through a small subset of servers) cannot provide strong privacy against powerful adversaries due to traffic analysis and active attacks.

Loopix [47] is a recent iteration on free-route mix-nets, and can provide fast asynchronous messaging. To do so, each user interacts with a semi-trusted server (called "provider" in the paper), and routes her messages through a small number of servers (e.g., 3 servers). Each server inserts small amounts of random delays before routing the messages. Loopix then reasons about privacy using entropy. Unfortunately, the privacy guarantee of Loopix weakens quickly as the adversary compromises more servers. Moreover, Loopix requires the recipients to trust the provider to protect themselves.

3 System model and goals

XRD aims to achieve the best of all worlds by providing cryptographic metadata privacy while scaling horizontally without relying on expensive cryptographic primitives. In this section, we present our threat model and system goals.

3.1 Threat model and assumptions

A deployment of XRD would consist of hundreds to thousands of servers and a large number of users, in the order of millions. Similar to several prior works on distributed private communication systems [34, 52], XRD assumes an adversary that can monitor the entire network, control a fraction f of the servers, and control up to all but two honest users. We assume, however, that there exists a public key infrastructure that can be used to securely share public keys of online servers and users with all participants at any given time. These keys, for example, could be maintained by key transparency schemes [36, 42, 51].

XRD does not hide the fact that users are using XRD. Thus, for best possible security, users should stay online to avoid intersection attacks [31, 16]. XRD also does not protect against large scale denial-of-service (DoS) attacks. It can, however, recover from a small number of benign server failures or disruptions from malicious users. In addition, XRD provides privacy even under DoS, server churn, and user churn (e.g., Alice goes offline unexpectedly without her conversation partner knowing). We discuss the availability properties further in §5 and §7.3.

Finally, XRD assumes that the users can agree to start talking at a certain time out-of-band. This could be done, for example, via two users exchanging this information offline, or by using systems like Alpenhorn [38] that can initiate conversations privately.

Cryptographic primitives. XRD assumes existence of a group of prime order p with a generator g in which discrete log is hard and the decisional Diffie-Hellman assumption holds. We will write $\mathsf{DH}(g^a, b) = g^{ab}$ to denote Diffie-Hellman key exchange. In addition, XRD makes use of authenticated encryption.

Authenticated encryption [6]: XRD relies on an authenticated encryption scheme for confidentiality and integrity, which consists of the following algorithms:

- $c \leftarrow \mathsf{AEnc}(\mathsf{s}, \mathsf{nonce}, m)$. Encrypt message m and authenticate the ciphertext c using a symmetric key s and a nonce nonce. Typically, s is used to derive two other keys for encryption and authentication.
- $(b, m) \leftarrow \mathsf{ADec}(\mathsf{s}, \mathsf{nonce}, c)$. Check the integrity of and decrypt ciphertext c using the key s and a nonce nonce. If the check fails, then $b = 0$ and $m = \perp$. Otherwise, $b = 1$ and m is the underlying plaintext.

In general, the adversary cannot generate a correctly authenticated ciphertext without knowing the secret key used for ADec. We use Encrypt-then-HMAC for authenticated encryption, which has the additional property that the ciphertext serves as a commitment to the underlying plaintext with the secret key being the opening to the commitment [28].

3.2 Goals

XRD has three main goals.

Correctness. Informally, the system is correct if every honest user successfully communicates with her conversation partner after a successful execution of the system protocol.

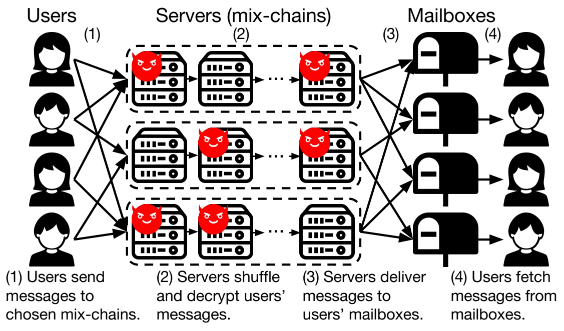
Privacy. Similar to prior messaging systems [53, 5, 52, 37], XRD aims to provide relationship unobservability [46], meaning that the adversary cannot learn anything about the communication between two honest users. Informally, consider any honest users Alice, Bob, and Charlie. The system provides privacy if the adversary cannot distinguish whether Alice is communicating with Bob, Charlie, or neither. XRD only guarantees this property among the honest users, as malicious conversation partners can trivially learn the metadata of their communication. We provide a more formal definition in Appendix B. (This is a weaker privacy goal than that of Atom [34], which aims for sender anonymity.)

Scalability. Similar to prior work [34], we require that the system can handle more users with more servers. If the number of messages processed by a server is $C(M,N)$ for M users and N servers, we require that $C(M,N) \to 0$ as $N \to \infty$. $C(M,N)$ should approach zero polynomially in N so that adding a server introduces significant performance benefits.

4 XRD overview

Figure 1 presents the overview of a XRD network. At a high level, XRD consists of three different entities: users, mix servers, and mailbox servers. Every user in XRD has a unique *mailbox* associated with her, similar to an e-mail address. The mailbox servers maintain the mailboxes, and are only trusted for availability and not privacy.

To set up the network, XRD organizes the mix servers into many chains of servers such that there exists at least one honest server in each chain with overwhelming probability (i.e., an anytrust group [55]). Communication in XRD is carried out in discrete rounds. In each round, each user selects a fixed set of ℓ chains, where the set is determined by the user's public key. She then sends a fixed size message to each of the selected chains. (If the message is too small or large, then the user pads the message or breaks it into multiple pieces.) Each message contains a destination mailbox, and is onion-encrypted for all servers in the chain.



Users
Servers (mix-chains)
Mailboxes
(1)
(2)
(3)
(4)
(1) Users send messages to chosen mix-chains.
(2) Servers shuffle and decrypt users' messages.
(3) Servers deliver messages to users' mailboxes.
(4) Users fetch messages from mailboxes.

Figure 1: Overview of XRD operation.

Once all users submit their messages, each chain acts as a local mix-net [10], decrypting and shuffling messages. During shuffling, each server also generates a short proof that allows other servers to check that it behaved correctly. If the proof does not verify, then the servers can identify who misbehaved. If all verification succeeds, then the last server in each chain forwards the messages to the appropriate mailbox servers. (The protocol for proving and verifying the shuffle is described in §6.) Finally, the mailbox servers put the messages into the appropriate mailboxes, and each user downloads all messages in her mailbox at the end of a round.

The correctness and security of XRD is in large part due to how each user selects the chains. As we will see in §5, the users are required to follow a specific algorithm to select the chains. The algorithm guarantees that *every* pair of users have at least one chain in common and the choices of the chains are publicly computable. For example, every user selecting the same chain will achieve this property, and thus correctness and security. In XRD, we achieve this property while distributing the load evenly.

Let us now consider two scenarios: (1) a user Alice is not in a conversation with anyone, or (2) Alice is in a conversation with another user Bob. In the first case, she sends a dummy message encrypted for herself to each chain that will come back to her own mailbox. We call these messages *loopback messages*. In the second case, Alice and Bob compute each other's choices of chains, and discover at which chain they will intersect. If there are multiple such chains, they break ties in a deterministic fashion. Then, Alice and Bob send the messages encrypted for the other person, which we call *conversation messages*, to their intersecting chain. They also send loopback messages on all other chains.

Security properties. We now argue the security informally. We present a more formal definition and arguments of privacy in Appendix B. Since both types of messages are encrypted for owners of mailboxes and the mix-net hides the origin of a message, the adversary cannot tell if a message going to Alice's mailbox is a loopback message or a conversation message sent by a different user. This means that the network pattern of all users is the same from the adversary's perspective: each user sends and receives exactly ℓ messages, each of which could be a loopback or a conversation message. As a result, the adversary cannot tell if a user is in a conversation or not. Moreover, we choose the chains such that every pair of users intersects at some chain (§5), meaning the probability that Alice is talking to a particular honest user is the same for all honest users. This hides the conversation metadata.

The analysis above, however, only holds if the adversary does not tamper with the messages. For instance, if the adversary drops Alice's message in a chain, then there are two possible observable outcomes in this chain: Alice receives (1) no message, meaning Alice is not in a conversation in this chain, or (2) one message, meaning someone intersecting with Alice at this chain is chatting with Alice. This information leakage breaks the security of XRD. We propose a new protocol called aggregate hybrid shuffle (§6) that efficiently defends against such an attack.

Scalability properties. Let n and N be the number of chains and servers in the network, respectively. Each user must send at least $\sqrt{n}$ messages to guarantee every pair of users intersect. To see why, fix ℓ, the number of chains a user selects. Those chains must connect a user Alice to all M users. Since the total number of messages sent by users is $M \cdot \ell$, each chain should handle $\frac{M \cdot \ell}{n}$ messages if we distribute the load evenly. We then need $\frac{M \cdot \ell}{n} \cdot \ell \geq M$ because the left hand side is the maximum number of users connected to the chains that Alice chose. Thus, $\ell \geq \sqrt{n}$. In §5, we present an approximation algorithm that uses $\ell \approx \sqrt{2n}$ to ensure all users intersect with each other while evenly distributing the work. This means that each chain handles $\approx \frac{\sqrt{2}M}{\sqrt{n}}$ messages, and thus XRD scales with the number of chains. If we set $n = N$ and each server appears in k chains for $k << \sqrt{N}$, which means $C(M,N) = \frac{k\sqrt{2}M}{\sqrt{N}} \to 0$ polynomially as $N \to \infty$ (§3.2). We show that k is logarithmic in N in §5.2.1.

5 XRD design

We now present the details of a XRD design that protects against an adversary that does *not* launch active attacks. We then describe modifications to this design that allows XRD to protect against active attacks in §6.

5.1 Mailboxes and mailbox servers

Every user in XRD has a mailbox that is publicly associated with her. In our design, we use the public key of a user as the identifier for the mailbox, though different public identifiers like e-mail addresses can work as well. The mailboxes are maintained by the mailbox servers, with simple put and get functionalities to add and fetch messages to a mailbox.

Algorithm 1 Mix server routing protocol

Server i is in chain x which contains k servers with its mixing key pair $(\mathsf{mpk}_i = g^{\mathsf{msk}_i}, \mathsf{msk}_i)$. In each round r, it receives a set of ciphertexts $\{c_i^j = (g^{x_j}, \mathsf{AEnc}(\mathsf{DH}(\mathsf{mpk}_i, x_j), r||\mathsf{x}, c_{i+1}^j))\}_{j \in [M]}$, either from an upstream server if $i \neq 1$, or from the users if $i = 1$.

1. **Decrypt and shuffle:** Compute $c_{i+1}^j = \mathsf{ADec}(\mathsf{DH}(g^{x_j}, \mathsf{msk}_i), r||\mathsf{x}, c_i^j)$ for each j, and randomly shuffle $\{c_{i+1}^j\}$.

2a. **Relay messages:** If $i < k$, then send the shuffled $\{c_{i+1}^j\}$ to server $i+1$.

2b. **Forward messages to mailbox:** If $i = k$, then each decrypted message is of the form $(\mathsf{pk}_u, \mathsf{AEnc}(\mathsf{s}, r||\mathsf{x}, m_u))$, where pk_u is the public key of a user u, s is a secret key, and m_u is a message for the user. Send the message to the mailbox server that manages mailbox pk_u.

5.2 Mix chains

XRD uses many parallel mix-nets to process the messages. We now describe their formation and operations.

5.2.1 Forming mix chains

We require the existence of an honest server in every chain to guarantee privacy. To ensure this property, we use public randomness sources [7, 50] that are unbiased and publicly available to randomly sample k servers to form a chain, similar to prior works [34, 52]. We set k large enough such that the probability that all servers are malicious is negligible. Concretely, the probability that a chain of length k consists only of malicious servers is f^k. Then, if we have n chains in total, the probability there exists a group of only malicious servers is less than $n \cdot f^k$ via a union bound. Finally, we can upper bound this to be negligible. For example, if we want this probability to be less than 2^{-64} for $f = 20\%$, then we need $k = 32$ for $n < 2000$. This makes k depend logarithmically on N. In XRD, we set $n = N$ for N servers, meaning each server appears in k chains on average.

We "stagger" the position of a server in the chains to ensure maximal server utilization. For instance, if a server is part of two chains, then it could be the first server in one chain and the second server in the other chain. This optimization has no impact on the security, as we only require the existence of an honest server in each group. This helps minimize the idle time of each server.

5.2.2 Processing user messages

After the chains form, each mix server i generates a *mixing key pair* $(\mathsf{mpk}_i = g^{\mathsf{msk}_i}, \mathsf{msk}_i)$, where msk_i is a random value in $\mathbb{Z}_p$. The public mixing keys $\{\mathsf{mpk}_i\}$ are made available to all participants in the network, along with the ordering of the keys in each chain. Now, each chain behaves as a mix-net [10]: users submit some messages onion-encrypted using the mixing keys (§5.3), and the servers decrypt and shuffle the messages in order. Algorithm 1 describes this protocol.

5.2.3 Server churn

Some servers may go offline in the middle of a round. Though XRD does not provide additional fault tolerance mechanisms, only the chains that contain failing servers are affected. Furthermore, the failing chains do not affect the security since they do not disturb the operations of other chains and the destination of the messages at the failing chain remains hidden to the adversary. Thus, conversations that use chains with no failing servers are unaffected. We analyze the empirical effects of server failures in §7.3.

5.3 Users

We now describe how users operate in XRD.

5.3.1 Selecting chains

XRD needs to ensure that all users' choices of chains intersect at least once, and that the choices are publicly computable. We present a scheme that achieves this property. Upon joining the network, every user is placed into one of $\ell+1$ groups such that each group contains roughly the same number of users, and such that the group of any user is publicly computable. This could be done, for example, by assigning each user to a pseudo-random group based on the hash of the user's public key. Every user in a group is connected to the same ℓ servers specified as follows. Let C_i be the ordered set of chains that users in group i are connected to. We start with $C_1 = \{1,\ldots,\ell\}$, and build the other sets inductively: For $i = 1,\ldots,\ell$, group $i+1$ is connected to $C_{i+1} = \{C_1[i], C_2[i], \ldots, C_i[i], C_i[\ell]+1, \ldots, C_i[\ell]+(\ell-i)\}$, where $C_x[y]$ is the y^{th} entry in C_x.

By construction, every group is connected to every other group: Group i is connected to group j via $C_i[j]$ for all $i < j$. As a result, every user in group i is connected to all others in the same group (they meet at all chains in C_i), and is connected to users in group j via chain $C_i[j]$.

To find the concrete value of ℓ, let us consider C_ℓ. The last chain of C_ℓ, which is the chain with the largest index, is $C_\ell[\ell] = \ell^2 - \sum_{i=1}^{\ell-1} i = \frac{\ell^2+\ell}{2}$. This value should be as close as possible to n, the number of chains, to maximize utilization. Thus, $\ell = \lceil\sqrt{2n+0.25}-0.5\rceil \approx \lceil\sqrt{2n}\rceil$. Given that $\ell \geq \sqrt{n}$ (§4), this is a $\sqrt{2}$-approximation.

5.3.2 Sending messages

After choosing the ℓ mix chains, the users send one message to each of the chosen chains as described in Algorithm 2. At a high level, if Alice is not talking with anyone, Alice generates ℓ loopback messages by encrypting dummy messages (e.g., messages with all zeroes) using a secret key known only to her, and submits them to the chosen chains. If she is talking with another user Bob, then she first finds where they intersect by computing the intersection of Bob's group and her group (§5.3.1). If there is more than one such chain, then she breaks the tie by selecting the chain with the smallest index. Alice then generates $\ell-1$ loopback messages and one encrypted message using a secret key that Alice and Bob shares. Finally, Alice sends the message for Bob to the intersecting chain, and sends the loopback messages to the other chains. Bob mirrors Alice's actions.

Algorithm 2 User conversation protocol

Consider two users Alice and Bob with key pairs $(\mathsf{pk}_A = g^{\mathsf{sk}_A}, \mathsf{sk}_A)$ and $(\mathsf{pk}_B = g^{\mathsf{sk}_B}, \mathsf{sk}_B)$ who are connected to sets of ℓ chains C_A and C_B (§5.3.1). The network consists of chains $1,\ldots,n$, each with k servers. Alice and Bob possess the set of mixing keys for each chain. Alice performs the following in round r.

1a. **Generate loopback messages:** If Alice is not in a conversation, then Alice generates ℓ loopback messages: $m_{\mathsf{x}} = (\mathsf{pk}_A, \mathsf{AEnc}(\mathsf{s}_A^{\mathsf{x}}, r||\mathsf{x}, 0))$ for $\mathsf{x} \in C_A$, where $\mathsf{s}_A^{\mathsf{x}}$ is a chain-specific symmetric key known only to Alice.

1b. **Generate conversation message:** If Alice is in a conversation with Bob, then she first computes the shared key $\mathsf{s}_{AB} = \mathsf{DH}(\mathsf{pk}_B, \mathsf{sk}_A)$, and the symmetric encryption key for Bob $\mathsf{s}_B = \mathsf{KDF}(\mathsf{s}_{AB}, \mathsf{pk}_B, r)$ where KDF is a secure key derivation function (e.g., HKDF [33]). Alice then generates the conversation message: $m_{\mathsf{x}_{AB}} = (\mathsf{pk}_B, \mathsf{AEnc}(\mathsf{s}_B, r||\mathsf{x}, \mathsf{msg}))$, where msg is the plaintext message for Bob and $\mathsf{x}_{AB} \in C_A \cap C_B$ is the first chain in the intersection. She also generates $\ell-1$ loopback messages m_{x} for $\mathsf{x} \in C_A, \mathsf{x} \neq \mathsf{x}_{AB}$.

2. **Onion-encrypt messages:** For each message m_{x}, let $c_{k+1} = m_{\mathsf{x}}$, and let $\{\mathsf{mpk}_i\}$ be the mixing keys for chain $\mathsf{x} \in C_A$. For $i = k$ to 1, generate a random value $x_i \in \mathbb{Z}_p$, and compute $c_i = (g^{x_i}, \mathsf{AEnc}(\mathsf{DH}(\mathsf{mpk}_i, x_i), r||\mathsf{x}, c_{i+1}))$. Send c_1 to chain x.

3. **Fetch messages:** At the end of the round, fetch and decrypt the messages in her mailbox, using ADec with matching $\mathsf{s}_A^{\mathsf{x}}$ or $\mathsf{s}_A = \mathsf{KDF}(\mathsf{s}_{AB}, \mathsf{pk}_A, r)$.

5.3.3 User churn

Like servers, users might go offline in the middle of a round, and XRD aims to provide privacy in such situations. However, the protocol presented thus far does not achieve this goal. If Alice and Bob are conversing and Alice goes offline without Bob knowing, then Alice's mailbox will receive Bob's message while Bob's mailbox will get one fewer message. Thus, by observing mailbox access counts and Alice's availability, the adversary can infer their communication.

To solve this issue, we require Alice to submit two sets of messages in round r: the messages for the current round r, and *cover messages* for round $r+1$. If Alice is not communicating with anyone, then the cover messages will be loopback messages. If Alice is communicating with another user, then one of the cover messages will be a conversation message indicating that Alice has gone offline.

If Alice goes offline in round τ, then the servers use the cover messages submitted in $\tau-1$ to carry out round τ. Now, there are two possibilities. If Alice is not in a conversation, then Alice's cover loopback messages are routed in round τ, and nothing needs to happen afterwards. If Alice is conversing with Bob, then at the end of round τ, Bob will get the message that Alice is offline via one of the cover messages. Starting from round $\tau+1$, Bob now sends loopback messages instead of conversation messages to hide the fact that Bob was talking with Alice in previous rounds. This could be used to end conversations as well. Malicious servers cannot fool Bob into thinking Alice has gone offline by replacing Alice's messages with her cover messages because the honest servers will ensure Alice's real messages are accounted for using our defenses described in §6.

6 Aggregate hybrid shuffle

Adversarial servers can tamper with the messages to leak privacy in XRD. For example, consider a mix-net chain where the first server is malicious. This malicious server can replace Alice's message with a message directed at Alice. Then, at the end of the mixing, the adversary will make one of two observations. If Alice was talking to another user Bob, Bob will receive one fewer message while Alice would receive two messages. The adversary would then learn that Alice was talking to Bob. If Alice is not talking to anyone on the tampered chain, then Alice would receive one message, revealing the lack of conversation on that chain.

Prior works [14, 55, 35, 52, 34] have used traditional verifiable shuffles [45, 25, 8, 27] to prevent these attacks. At a high level, verifiable shuffles allow the servers in the chain (one of which is honest) to verify the correctness of a shuffle of another server; namely, that the plaintexts underlying the outputs of a server is a valid permutation of the plaintexts underlying the inputs. Unfortunately, these techniques are computationally expensive, requiring many exponentiations.

In XRD, we make an observation that help us avoid traditional verifiable shuffles. For a meaningful tampering, the adversary necessarily has to tamper with the messages *before* they are shuffled by the honest server. Otherwise, the adversary does not learn the origins of messages. For example, after dropping a message in a server downstream from the honest server, the adversary might observe that Alice did not receive a message. The adversary cannot tell, however, whether the dropped message was sent by Alice or another user, and does not learn anything about Alice's communication pattern. (Intuitively, the adversarial downstream servers do not add any privacy in any case.) In this section, we describe a new form of verifiable shuffle we call *aggregate hybrid shuffle* (AHS) that allows us to take advantage of this fact. In particular, the protocol guarantees that the honest server will receive and shuffle all honest users' messages, or the honest server will detect that someone upstream (malicious servers or users) misbehaved. We will then describe how the honest server can efficiently identify all malicious participants who deviated from the protocol, without affecting the privacy of honest users. Table A in Appendix A summarizes the notations used in AHS.

6.1 Key generation with AHS

When the chain is created, the servers generate three key pairs: *blinding*, *mixing*, and *inner* key pairs. The inner keys are per-round keys, and each server i generates its own inner key pair $(\mathsf{ipk}_i = g^{\mathsf{isk}_i}, \mathsf{isk}_i)$. The other two keys are long-term keys, and are generated in order starting with the first server in the chain. Let $\mathsf{bpk}_0 = g$. Starting with server 1, server $i = 1,\ldots,k$ generates $(\mathsf{bpk}_i = \mathsf{bpk}_{i-1}^{\mathsf{bsk}_i}, \mathsf{bsk}_i)$ and $(\mathsf{mpk}_i = \mathsf{bpk}_{i-1}^{\mathsf{msk}_i}, \mathsf{msk}_i)$ in order. In other words, the base of the public keys of the server i is $\mathsf{bpk}_{i-1} = g^{\prod_{a<i}\mathsf{bsk}_a}$. The public mixing key of the last server, for example, would be $\mathsf{mpk}_k = \mathsf{bpk}_{k-1}^{\mathsf{msk}_k} = g^{\mathsf{msk}_k \cdot \prod_{a<k}\mathsf{bsk}_a}$. Each server also has to prove to all other servers that it knows the private keys that match the public keys in zero-knowledge [9]. All public keys are made available to all servers and users.

6.2 Sending messages with AHS

Once the servers generate the keys, user Alice can submit a message to a chain. To do so, Alice now employs a double-enveloping technique to encrypt her message [26]: she first onion-encrypts her message for all servers using the inner keys, and then onion-encrypts the result with the mixing keys. Let *inner ciphertext* be the result of the first onion-encryption, and *outer ciphertext* be the final ciphertext. The inner ciphertexts are encrypted using $\prod_i \mathsf{ipk}_i$ as the public key, which allows users to onion-encrypt in "one-shot": i.e., $e = (g^y, \mathsf{AEnc}(\mathsf{DH}(\prod_i \mathsf{ipk}_i, y), r, m))$ in round r with message m and a random y. Without y, one must know all $\{\mathsf{isk}_i\}$ to compute $\mathsf{DH}(\prod_i \mathsf{ipk}_i, y)$, which makes this a "one-shot" onion-encryption. To generate the outer ciphertext for chain x, Alice performs the following.

1. Generate her outer Diffie-Hellman key: a random $x \in \mathbb{Z}_p$ and (g^x, x).
2. Generate a NIZK that proves she knows x that matches g^x (using knowledge of discrete log proof [9]).
3. Let $c_{k+1} = e$, and let $\{\mathsf{mpk}_i\}$ for $i \in [k]$ be the mixing keys of the servers in the chain. For $i = k$ to 1, compute $c_i = \mathsf{AEnc}(\mathsf{DH}(\mathsf{mpk}_i, x), r||\mathsf{x}, c_{i+1})$.

$c = (g^x, c_1)$ is the final outer ciphertext. This is nearly identical to Algorithm 2, except that the user does not generate a fresh pair of Diffie-Hellman keys for each layer of encryption. To submit the message, Alice sends c and the NIZK to all servers in the chain.

6.3 Mixing with AHS

Before mixing begins in round r, the servers in chain x have $c^j = (X_1^j = g^{x_j}, c_1 = \mathsf{AEnc}(\mathsf{DH}(\mathsf{mpk}_1, x_j), r||\mathsf{x}, c_2^j))$ for user j. The servers first verify all NIZKs the users submit, and agree on the inputs for this round. This can be done, for example, by sorting the users' ciphertexts, hashing them using a cryptographic hash function, and then comparing the hashes. Then, starting with server 1, server $i = 1,\ldots,k$ perform the following:

1. **Decrypt and shuffle:** Similar to Algorithm 1, decrypt each message. Each message is of the form $(X_i^j, c_i^j = \mathsf{AEnc}(\mathsf{DH}(\mathsf{mpk}_i, x_j), r||\mathsf{x}, c_{i+1}^j)$. Thus, $(b^j, c_{i+1}^j) = \mathsf{ADec}(\mathsf{DH}(X_i^j, \mathsf{msk}_i), r||\mathsf{x}, c_i^j)$. If any decryption fails (i.e., $b^j = 0$ for some j), then mixing halts and the server can start the blame protocol described in §6.4. Randomly shuffle $\{c_{i+1}^j\}$.
2. **Blind and shuffle:** Blind the users' Diffie-Hellman keys $\{X_i^j\}$ using the blinding key: $X_{i+1}^j = (X_i^j)^{\mathsf{bsk}_i}$ for each j. Then, shuffle the keys using the same permutation as the one used to shuffle the ciphertexts.
3. **Generate zero-knowledge proof:** Generate a proof that $(\prod_j X_i^j)^{\mathsf{bsk}_i} = \prod_j X_{i+1}^j$ by generating a NIZK that shows $\log_{\prod_j (X_i^j)}(\prod_j X_{i+1}^j) = \log_{\mathsf{bpk}_{i-1}} \mathsf{bpk}_i (= \mathsf{bsk}_i)$. Send the NIZK with the shuffled $\{X_{i+1}^j\}$ to all other servers in the chain. All other servers verify this proof using $\{X_i^j\}$ they received previously, $\{X_{i+1}^j\}$, bpk_{i-1}, and bpk_i.
4. **Forward messages:** If $i < k$, then send the shuffled $\{(X_{i+1}^j, c_{i+1}^j)\}$ to server $i+1$.

When the last server finishes shuffling and no server reports any errors during mixing, our protocol guarantees that the honest server mixed all the honest users' messages successfully. At this point, the servers reveal their private per-round inner keys $\{\mathsf{isk}_i\}$. With this, the last server can decrypt the inner ciphertexts to recover the users' messages.

Analysis. We first argue correctness of AHS (i.e., every message is successfully delivered if every participant followed the protocol) by showing that the encryption and decryption keys match at all layers. Consider the key user j used to encrypt the message for server i and the Diffie-Hellman key server i receives. User j encrypts the message using the key $\mathsf{DH}(\mathsf{mpk}_i, x_j) = g^{x_j \cdot \mathsf{msk}_i \prod_{a<i} \mathsf{bsk}_a}$. The Diffie-Hellman key server i receives is $X_i^j = g^{x_j \cdot \prod_{a<i} \mathsf{bsk}_a}$. The key exchange then results in $\mathsf{DH}(X_i^j, \mathsf{msk}_i) = g^{\mathsf{msk}_i \cdot x_j \prod_{a<i} \mathsf{bsk}_a}$, which is the same as the one the user used.

The scheme protects against honest-but-curious adversaries (i.e., does not reveal anything about the permutation used to shuffle the messages), as the inputs and outputs of a server look random: If decisional Diffie-Hellman is hard, then $g^{x \cdot \mathsf{bsk}_i}$ is indistinguishable from a random value given g^x and g^{bsk_i} for random x and bsk_i. Thus, by observing $\{g^{x_j}\}$ (input) and $\{g^{x_{\pi(j)} \cdot \mathsf{bsk}_i}\}$ (output) of an honest server where π is a random permutation, the adversary cannot learn anything about the relationships between the inputs and outputs.

We now provide a high level analysis that the honest server will always detect upstream servers tampering with honest users' messages. The detailed proof is in Appendix A. Let server h be the honest server. First, since we only need to consider upstream adversaries, we will simplify the problem, and view all upstream malicious servers as one collective server with private blinding key $\mathsf{bsk}_A = \sum_{i<h} \mathsf{bsk}_i$. For the adversary to successfully tamper, it must generate $\{X_h^j\}$ such that $(\prod X_1^j)^{\mathsf{bsk}_A} = \prod X_h^j$; otherwise it would fail the NIZK verification in step 3 of §6.3. Let $X_T \neq \emptyset$ be the set of honest users whose messages were tampered. The adversary needs to know the keys used for authenticated decryption to generate valid ciphertexts that differ from the users' ciphertexts. However, the adversary cannot compute $((g^{x_j})^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$ for $j \in X_T$ (the keys used for authenticated encryption), since x_j and msk_h are unknown random values and Diffie-Hellman is hard. Thus, to tamper with messages undetected, the adversary needs to change the users' Diffie-Hellman keys (i.e., $X_h^j \neq (X_1^j)^{\mathsf{bsk}_A}$ for $j \in X_T$), such that it can compute the keys used for authenticated decryption (i.e., $(X_h^j)^{\mathsf{msk}_h}$ for $j \in X_T$).

In the beginning of a round, the adversary controlled users have to prove their knowledge of discrete logs of their Diffie-Hellman keys after seeing the honest users' keys. The adversarial user are thus forced to generate keys independently of the honest users' input. Then, the adversary's goal is essentially to find $\{X_h^j\}_{j \in X_T}$ such that $(\prod_{j \in X_T} X_1^j)^{\mathsf{bsk}_A} = \prod_{j \in X_T} X_h^j$, with $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$. Assume the adversary is successful. Then, it could compute $((\prod_{j \in X_T} X_1^j)^{\mathsf{bsk}_A})^{\mathsf{msk}_h} = \prod_{j \in X_T} (X_h^j)^{\mathsf{msk}_h}$, since it knows $(X_h^j)^{\mathsf{msk}_h}$ for $j \in X_T$ (recall that these are the keys used for authenticated decryption, which the adversary must know). This means that the adversary computed $((\prod_{j \in X_T} X_1^j)^{\mathsf{bsk}_A})^{\mathsf{msk}_h} = g^{\mathsf{msk}_h \cdot \mathsf{bsk}_A \cdot \sum_{j \in X_T} x_j}$ only given $\{g^{x_j}\}_{j \in X_T}$, bsk_A, and $(g^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$, where $\{x_j\}_{j \in X_T}$ and msk_h are random values independent of bsk_A. This breaks the Diffie-Hellman assumption, and thus the adversary must not be able to tamper with messages undetected.

6.4 Blame protocol

There are two ways an honest server can detect misbehavior: a NIZK fails to verify or an authenticated decryption fails. If a malicious user cannot generate a correct NIZK in step 2 in §6.2 or if a malicious server misbehaves and cannot generate a correct NIZK in step 3 in §6.3, then the misbehavior is detected and the adversary is immediately identified. In the case where a server finds some misauthenticated ciphertexts, the server can start a blame protocol that allows the server to identify who misbehaved. The protocol guarantees that users are identified if and only if they purposefully sent misauthenticated ciphertexts. In addition, the protocol ensures that honest users remain private in all cases, even if malicious servers try to falsely accuse honest users.

Once server h identifies an misauthenticated ciphertext, it starts the blame protocol by revealing the problem ciphertext (X_h^j, c_h^j). Then, the servers execute the following:

1. For $i = h-1, \ldots, 1$, the servers reveal X_i^j that matches X_{i+1}^j (i.e., $(X_i^j)^{\mathsf{bsk}_i} = X_{i+1}^j$). Each server proves to all other servers it calculated X_{i+1}^j correctly by showing that $\log_{X_i^j}(X_{i+1}^j) = \log_{\mathsf{bpk}_{i-1}}(\mathsf{bpk}_i)(= \mathsf{bsk}_i)$ with a NIZK [9].

2. For $i = h-1, \ldots, 1$, the servers reveal c_i^j that matches c_{i+1}^j (i.e., $c_i^j = \mathsf{AEnc}(\mathsf{DH}(X_i^j, \mathsf{msk}_i), r||\mathsf{x}, c_{i+1}^j)$. Each server proves it correctly decrypted the ciphertext by revealing the key used for decryption $k_i^j = (X_i^j)^{\mathsf{msk}_i}$, and showing that $\log_{X_i^j}(k_i^j) = \log_{\mathsf{bpk}_{i-1}}(\mathsf{mpk}_i)$ with a NIZK. The other servers can verify the correctness of the decryption operation by checking the NIZKs and decrypting the ciphertext themselves.

3. All servers check that c_1^j revealed by the first server matches the user submitted ciphertext (§6.2).

4. Similar to step 2, server h (the accusing server) reveals its Diffie-Hellman exchanged key $k_h = (X_h^j)^{\mathsf{msk}_h}$, and shows that $\log_{X_h^j}(k_h) = \log_{\mathsf{bpk}_{h-1}}(\mathsf{mpk}_h)$. All servers verify that $\mathsf{ADec}(k_h, r||\mathsf{x}, c_h^j)$ fails.

If there are multiple problem ciphertexts, the blame protocol can be carried out in parallel for each ciphertext. Steps 1 and 2 can be done simultaneously as well. If the servers successfully carry out the blame protocol, then they have identified actively malicious users. At this point, those ciphertexts are removed from the set, and the upstream servers are required to repeat the AHS protocol; since the accusing servers have already removed all bad ciphertexts, the servers just have to repeat step 3 of §6.3 to show the keys were correctly computed. If any of the above steps fail, then the servers delete their private inner keys.

Analysis. The accusing server and the upstream servers are required to reveal the exchanged key used to decrypt the ciphertexts, and the correctness of the key exchange is proven through the two NIZKs in step 1 and step 2. All servers can use the revealed keys to ensure that the submitted original ciphertext decrypts to the problem ciphertext. Since the outer ciphertext behaves as a commitment to all layers of encryption (§3), the servers get a verifiable chain of decryption starting with the outer ciphertext to the problem ciphertext if a user submits misauthenticated ciphertext. Moreover, if an honest user submits a correctly authenticated ciphertext, she will never be accused successfully, since an honest user's ciphertext will authenticate at all layers. Thus, a user is identified if and only if she is malicious.

Importantly, the users' privacy is protected even after a false accusation. After a malicious server accuses an honest user, the malicious server learns either the outer ciphertext (if the server is upstream of server h) or the inner ciphertext (if the server is downstream of server h) the user sent. In either case, the message remains encrypted for the honest server, by the mixing key in the former case or by the inner key in the latter case. The blame protocol will fail when the malicious server fails to prove that the honest user's ciphertext is misauthenticated, and the ciphertext will never be decrypted. As such, the adversary never learns the final destination of the user's message, and XRD protects the honest users' privacy.

7 Implementation and evaluation

To evaluate XRD, we wrote a prototype in approximately 4,000 lines of Go. We used the NIST P-256 elliptic curve [2] for our cryptographic group, and used AES with SHA-256-based key derivation function [33] and HMAC [32] for our authenticated encryption scheme. The servers communicated using streaming gRPC over TLS. Our prototype assumes that the servers' and users' public keys, and the public randomness for creating the chains are provided by a higher level functionality. Finally, we set the number of chains n equal to the number of servers N (§5.2.1).

In this section, we investigate the cost of users and the performance of XRD for different network configurations. For majority of our experiments, we assumed $f = 0.2$ (i.e., 80% of the servers are honest) unless indicated otherwise. We used 256 byte messages, similar to evaluations of prior systems [53, 52, 5]; this is about the size of a standard SMS message or a Tweet. We used c4.8xlarge instances on Amazon EC2 for our experiments, which has 36 Intel Xeon E5-2666 CPUs with 60 GB of memory and 10 Gbps links.

We compare the results against four prior systems: Stadium [52], Karaoke [37], Atom [34], and Pung [5, 4]. For Stadium and Karaoke, we report the performance for $e^{\varepsilon} = 10$ and $e^{\varepsilon} = 4$, respectively, (meaning the probability of Alice talking with Bob is within $10\times$ and $4\times$ the probability of Alice talking with any other user) and allow up to 10^8 rounds of communication with strong security guarantees ($\delta < 10^{-4}$), which are the parameters the used for evaluation in their papers. We show results for Pung with XPIR (used in the original paper [5]) and with SealPIR (used in the follow-up work [4]) when measuring user overheads, and only with XPIR when measuring end-to-end latency. We do this because SealPIR significantly improves the client performance and enables more efficient batch messaging, but introduces extra server overheads in the case of one-to-one messaging.

As mentioned in §2, the four systems scale horizontally, but offer different security properties. To summarize, Stadium and Karaoke provide differential privacy guarantees against the same adversary assumed by XRD. Thus, their users can send a limited number of sensitive messages with strong privacy, while XRD users can do so for unlimited messages. Atom provides cryptographic sender anonymity [46] under the same threat model. Finally, Pung provides messaging with cryptographic privacy against an adversary who can compromise all servers rather than a fraction of servers. To the best of our knowledge, we are not aware of any scalable private messaging systems that offer the same security guarantee under a similar threat model to XRD.

7.1 User costs

We first characterize computation and bandwidth overheads of XRD users using a single core of a c4.8xlarge instance. In order to ensure that every pair of users intersects, each user sends $\sqrt{2N}$ messages (§5.3.1). This means that

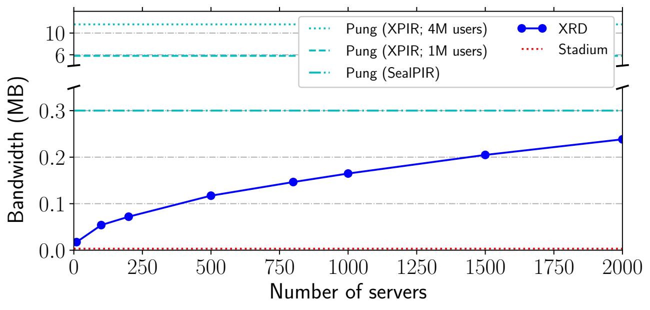


Figure 2: Required user bandwidth per round as a function of number of servers in the network.

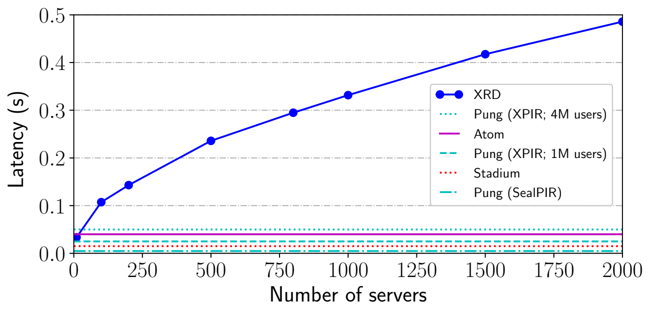

Figure 3: Required user computation as a function of number of servers with a single core. The computation could easily be parallelized with more cores for XRD.

the overheads for users increase as we add more servers to the network, as shown in Figure 2 and 3. This is a primary weakness of XRD, since our horizontal scalability comes at a higher cost for users. Still, the cost remains reasonable even for large numbers of servers. With 2,000 servers, each user must submit about 238 KB of data. For 1 minute rounds, this translates to about 40 Kbps of bandwidth requirement. A similar trend exists for computation overhead as well, though it remains relatively small: it takes less than 0.5s with fewer than 2,000 servers in the network. Computation could also be easily parallelized with more cores, since users can generate the messages for different chains independently. The cover messages make up half of the client overhead (§5.3.3).

User costs in prior works do not increase with the number of servers. Still, Pung with XPIR incurs heavy user bandwidth overheads due to the cost of PIR. With 1 million users, Pung users transmit about 5.8 MB, which is about 25× worse than XRD when there are fewer than 2,000 servers. Moreover, per user cost of XPIR is proportional to the total number of users: the bandwidth cost increases to 11 MB of bandwidth for 4 million users. The SealPIR variant, however, is comparable to that of XRD, as the users can compress the communication using cryptographic techniques. Stadium, Karaoke, and Atom incur minimal user bandwidth cost, with less than a kilobyte of bandwidth overhead (only Stadium is shown Figure 2). Thus, for users with heavily limited resources, prior works can be more desirable than XRD.

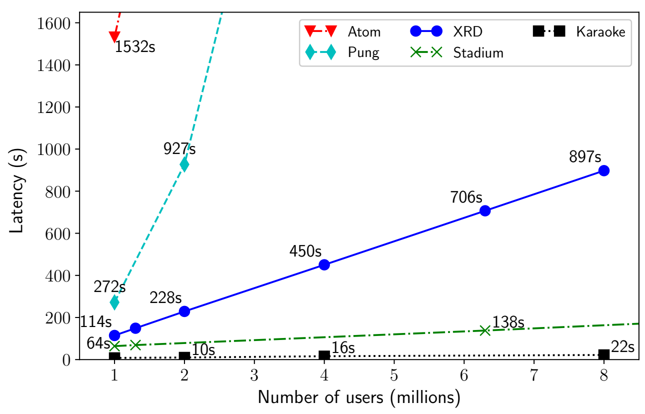

Figure 4: End-to-end latency of XRD and prior systems with varying numbers of users with 100 servers.

7.2 End-to-end latency

Experiment setup. To evaluate the end-to-end performance, we created a testbed consisting of up to 200 c4.8xlarge instances. We ran the instances within the same data center to avoid bandwidth costs, but added 40-100ms of round trip latency between servers using the Linux `tc` command to simulate a more realistic distributed network. Our evaluations consider all parts of the AHS protocol (§6), but assume all users are following the protocol. We then evaluate the blame protocol (§6.4) separately.

We used many c4.8xlarge instances to simulate millions of users, and also used ten more c4.8xlarge instances to simulate the mailboxes. We generate all users' messages before the round starts, and measure the critical path of our system by measuring the time between the last user submitting her message and the last user downloading her message.

We estimate the latency of Pung with M users and N servers by evaluating it on a single c4.8xlarge instance with M/N users. This is the best possible latency Pung can achieve because (1) Pung is embarrassingly parallel, so evenly dividing users across all the servers should be ideal [5, §7.3], and (2) we are ignoring the extra work needed for coordination between the servers (e.g., for message replication). For Stadium, we report the latency when the length of each mix chain is nine servers. For Karaoke, we report the numbers reported in their paper.

We focus on the following questions in this section, and compare against prior work:

- What is the end-to-end latency of XRD, and how does it change with the number of users?
- How does XRD scale with more servers?
- What is the effect of f, the fraction of malicious servers, on latency?
- How fast is the blame protocol?

Number of users. Figure 4 shows the end-to-end latency of XRD and prior works with 100 servers. XRD was able to handle 2 million users in 228s, and the latency scales linearly

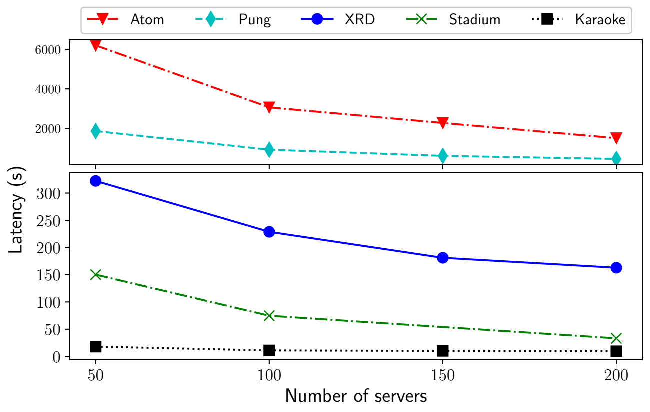

Figure 5: End-to-end latency of XRD for varying numbers of servers with 2 million users. We show Pung and Atom on a different time scale.

with the number of users. This is 13.3× and 4× faster than Atom and Pung, and 3× and 22.8× worse than Stadium and Karaoke for the same deployment scenario. Though processing a single message in XRD is faster than doing so in Stadium (since Stadium relies on verifiable shuffle, while XRD uses AHS), the overall system is still slower. This is because each XRD user submits many messages. For example, each user submits 15 messages with 100 servers, which is almost equivalent to adding 15 users who each submit one message. Unfortunately, the performance gap would grow with more servers due to each user submitting more messages (the rate at which the gap grows would be proportional to $\sqrt{2N}$). While XRD cannot provide the same performance as Stadium or Karaoke with large numbers of users and servers, XRD can provide stronger cryptographic privacy.

When compared to Pung, the speed-up increases further with the number of users since the latency of Pung grows superlinearly. This is because the server computation per user increases with the number of users. With 4 million users, for example, XRD is 8× faster. For Atom, the latency increases linearly, but with higher slope. This is due to its heavy reliance on expensive public key cryptography and long routes for the messages (over 300 servers).

Scalability. Figure 5 shows how the latency decreases with the number of servers with 2 million users.We experimented with up to 200 servers, and observed the expected scaling pattern: the latency of XRD reduces as $\sqrt{2/N}$ with N servers (§4). In contrast, prior works scale as $1/N$, and thus will outperform XRD with enough servers. Still, because XRD employs more efficient cryptography, XRD outperforms Atom and Pung with less than 200 servers.

To estimate the performance of larger deployments, we extrapolated our results to more servers. We estimate that XRD can support 2 million users with 1,000 servers in about 84s, while Stadium and Karaoke can do so in about 8s and 2s, respectively. (At this point, the latency between servers would be the dominating factor for Stadium and Karaoke.) This

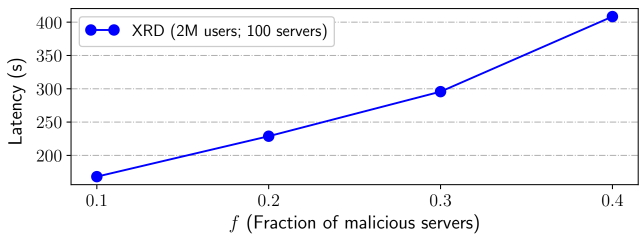

Figure 6: Latency of XRD for different values of f.

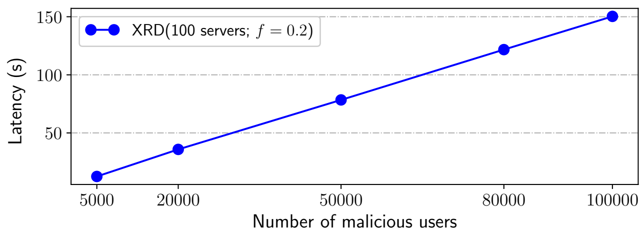

Figure 7: Latency of blame protocol.

gap increases with more users, as described previously. For Atom and Pung, we estimate that the latency would be comparable to XRD with about 3,000 servers and 1,000 servers in the network, respectively, for 2 million users. Pung would need more servers with more users to catch up to XRD due to the superlinear increase in latency with the number of users.

Impact of f. During setup, the system administrator should make a conservative estimate of f to form the chains. Larger f affects latency because it increases in the length of the chains k (§5.2.1). Concretely, with $n = 100$, k must satisfy $100 \cdot f^k < 2^{-64}$. Thus, $k > \frac{\log(2^{-64}/100)}{\log(f)}$, which means that the length of a chain (and the latency) grows as a function of $\frac{-1}{\log(f)}$. Figure 6 demonstrates this effect. The latency grows slowly for $f < 0.5$. This function, however, grows rapidly when $f >> 0.5$, and thus the latency would be significantly worse when considering larger values of f.

Atom would experience the same effect since its mix chains are created using the same strategy as XRD. Karaoke also experiences similar increase in latency with f, as every message must be routed through a number of servers proportional to $|\frac{1}{\log f}|$ as well. Stadium would face more significant increase in latency with f as its mix chains similarly get longer with f, and the length of the chains has a superlinear effect on the latency due to zero-knowledge proof verification [52, §10.3]. The latency of Pung does not increase with f since it already assumes $f = 1$.

Blame protocol. Malicious users could send misauthenticated ciphertexts to trigger the blame protocol, and slow down the system. Since malicious users' messages are removed as soon as servers find them, the users cause the most slowdown when the misauthenticated ciphertexts are discovered at the last server. The performance of the blame protocol also depends on the number of malicious users. In Figure 7, we therefore show the latency of the blame protocol

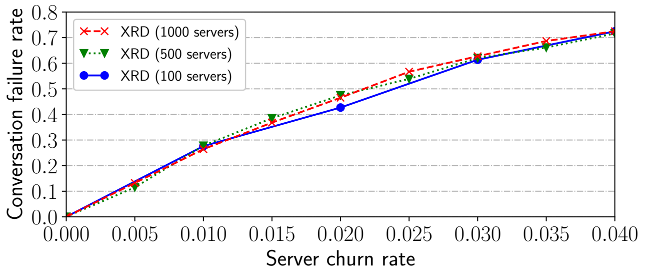

Figure 8: Fraction of conversations that fail in a given round due to server failures for different server churn rates.

as a function of the number of malicious users in a chain of 32 servers when the last server detects misbehavior. The blame protocol requires two discrete log equivalence proofs and decryption per user for each layer of encryption (§6.4).

Concretely, if 5,000 users misbehave in a chain, the blame protocol takes about 13s. This cost increases linearly with the number of users: if 100,000 users misbehave in a chain (which corresponds to approximately a third of all users being malicious with 100 servers and 2 million users in the network), the protocol takes about 150s. As a result, the overall round would take 378s, instead of 228s, for 2 million users. Still, this is 8× and 2.4× faster than Atom and Pung. In practice, the blame protocol could be faster since the honest server is likely to be not the last server. For example, if the honest server is the 16th server, then the blame protocol would take half the time. The overall round would then take around 303s.

While this is a significant increase in latency, malicious users are removed from the network once servers identify them. To cause serious slowdowns across many rounds, the adversary needs to constantly create new malicious users. Then, by employing defenses against Sybil attacks (e.g., imposing a small cost for user registration such as proof-of-work [23] or CAPTCHA [54]), we could limit the effectiveness of an adversary.

Malicious users can have varying degree of impact in prior systems. Pung and Karaoke are not affected by malicious users, and Stadium has a blame protocol similar to XRD to handle malicious users. Atom, however, is the significantly affected: a single malicious user can launch a DoS attack in the faster variant used for comparison in this paper [34, §4.4]. The slower variant of Atom that can handle adversarial users is at least 4× slower [34, §6], meaning it would be at least 30× slower than XRD overall.

7.3 Availability

To estimate the effect of server churn on a XRD network, we simulated deployment scenarios with 2 million users and different numbers of servers. We assumed that all users were in a conversation, and show the fraction of the users whose conversation messages did not reach their partner in Figure 8. For example, if 1% of the servers fail in a given round (comparable to server churn rate in Tor [1]), then we expect about 27% of the conversations to experience failure, and the end-points would have to resend their conversation messages. Unfortunately, the failure rate quickly increases with the server churn rates, reaching 70% with 4% server failures, as more chains contain at least one failing server. Thus, it would be easy for the adversary who controls a non-trivial fraction of the servers to launch a denial-of-service attack. Addressing this concern remains important future work.

When compared to Pung, the availability guarantees can be significantly worse, assuming Pung replicates all users' messages across all servers. In this case, the conversation failure rate would be equal to the server churn rate with users evenly distributed across all Pung servers, and the users connected to the failing servers could be rerouted to other servers to continue communication. Atom can tolerate any fraction γ of the servers failing using threshold cryptography [17], but the latency grows with γ. For example, to tolerate $\gamma = 1\%$ servers failing, we estimate that Atom would be about 10% slower [34, Appendix B]. Stadium and Karaoke, however, are more affected by server churn. Stadium uses two layers of parallel mix-nets, and fully connects the chains across the two layers. As a result, even one server failure would cause the whole system to come to a halt. (Stadium does not provide a fault recovery mechanism, and the security implications of continuing the protocol without the failing chains are not analyzed [52].) Similarly, Karaoke uses layers of interconnected mixing servers, and a single server failure results in the failure of the whole network.

8 Conclusion

XRD provides a unique design point in the space of metadata private communication systems by achieving cryptographic privacy and horizontal scalability using efficient cryptographic primitives. XRD organizes the servers into multiple small chains that process messages in parallel, and can scale easily with the number of servers by adding more chains. We hide users' communication patterns by ensuring every user is equally likely to be talking to any other user, and hiding the origins of users' messages through mix-nets. We then efficiently protect against active attacks using a novel technique called aggregate hybrid shuffle. Our evaluation on a network of 100 servers demonstrates that XRD can support 2 million users in 228 seconds, which is 13× and 4× faster than Atom and Pung, two prior systems with cryptographic privacy guarantees.

A Security of aggregate hybrid shuffle

The adversary's goal is to have an upstream server successfully tamper with some messages without getting detected by the honest server. To model this, we consider the following security game between three parties: the client, the adversary, and the verifier. All parties are given the total number of users M. The client controls users in set $X_H \subset [M]$ (this models the honest users), and the adversary controls users in set $X_A = [M] \setminus X_H$. In addition, the adversary controls servers $1, \ldots, h-1$, and the verifier controls server h (i.e., the honest server). To simplify the presentation, we assume the adversary uses the identity permutation for all servers, but it is easy to adapt this proof to any arbitrary permutation. Table A lists the notation used in aggregate hybrid shuffle, and summarizes their purposes.

1. The adversary sends the client and the verifier the public keys bpk_i and mpk_i and ipk_i for $i = 1, \ldots, h-1$. It also generates NIZKs to prove that it knows the values $\mathsf{bsk}_i = \log_{\mathsf{bpk}_{i-1}}(\mathsf{bpk}_i)$ and $\mathsf{msk}_i = \log_{\mathsf{bpk}_{i-1}}(\mathsf{mpk}_i)$ for $i = 1, \ldots, h-1$, where $\mathsf{bpk}_0 = g$. It sends the public keys and NIZKs to the verifier.
2. The verifier verifies the NIZKs. The verifier then generates the key pairs $(\mathsf{bpk}_h = \mathsf{bpk}_{i-1}^{\mathsf{bsk}_h}, \mathsf{bsk}_h)$, $(\mathsf{mpk}_h = \mathsf{bpk}_{i-1}^{\mathsf{msk}_h}, \mathsf{msk}_h)$, and $(\mathsf{ipk}_h, \mathsf{isk}_h)$, and sends the public keys to the client and the adversary.
3. The client generates random $\{x_j\}_{j \in X_H}$, and $\{c^j = (X_1^j = g^{x_j}, c_1^j)\}_{j \in X_H}$ using the protocol described in §6.2. It also generates a NIZK that it knows x_j that corresponds to X_1^j for each j, and sends both $\{c^j\}$ and the NIZKs to the adversary and the verifier.
4. The adversary generates its input messages $\{c^j = (X_1^j, c_1^j)\}_{j \in X_A}$ (not necessarily by following the protocol in §6.2). It generates a NIZK that shows it knows the discrete log of X_1^j and sends $\{c^j\}_{j \in X_A}$ and the NIZKs to the client and the verifier.
5. The verifier verifies all NIZKs.
6. For $i = 1, \ldots, h-1$, the adversary sends the verifier $\{X_{i+1}^j\}_{j \in [M]}$, and a NIZK that shows

$$\left(\prod_{j=1}^{M} X_i^j\right)^{\mathsf{bsk}_i} = \prod_{j=1}^{M} X_{i+1}^j$$

   by proving that

$$\log_{\prod_{j=1}^{M} X_i^j}\left(\prod_{j=1}^{M} X_{i+1}^j\right) = \log_{\mathsf{bpk}_{i-1}}(\mathsf{bpk}_i)\ .$$

   It also sends the ciphertexts $\{c_h^{j\prime}\}$ to the verifier.
7. The verifier verifies all NIZKs, and checks that $\mathsf{ADec}((X_h^j)^{\mathsf{msk}_h}, c_h^{j\prime}) = (1, \cdot)$ for all $j \in [M]$.

The game halts if the verifier fails to verify any NIZKs or authenticated decryption ever fails (i.e., returns $(0,\cdot)$). The adversary wins the game if the game does not halt and it has successfully tampered with some messages. In other words, the adversary wins if

1. $\left(\prod_{j=1}^{M} X_i^j\right)^{\mathsf{bsk}_i} = \prod_{j=1}^{M} X_{i+1}^j$ for all $i = 1, \ldots, h-1$,
2. there exists $X_T \subset X_H$ such that $|X_T| > 0$ and for all $j \in X_T$ one of the two properties is true: (1) $(X_1^j)^{\prod_{i<h} \mathsf{bsk}_i} \neq X_h^j$, or (2) $(X_1^j)^{\prod_{i<h} \mathsf{bsk}_i} = X_h^j$ and $c_h^j \neq c_h^{j\prime}$ (i.e., the adversary tampered with some messages),
3. and $\mathsf{ADec}((X_h^j)^{\mathsf{msk}_h}, c_h^{j\prime}) = (1, \cdot)$ for all $j \in [M]$.

We will now show that if the adversary can win this game, then it can also break Diffie-Hellman. Assume the adversary won the game. Let $\mathsf{bsk}_A = \prod_{i<h} \mathsf{bsk}_i$ be the product of the private blinding key of the adversary. If the adversary won, then the first condition implies that $(\prod_{j=1}^{M} X_1^j)^{\mathsf{bsk}_A} = \prod_{j=1}^{M} X_h^j$. Now, consider three boolean predicates for j: $c_h^j \overset{?}{=} c_h^{j\prime}$, $(X_1^j)^{\mathsf{bsk}_A} \overset{?}{=} X_h^j$, and $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h})$, where $\mathsf{KNOW}(x) = 1$ if the adversary knows (or can compute) x, and 0 otherwise. There are eight possible combinations of the predicates, and we consider

Table 1: Summary of notation used in aggregate hybrid shuffle.

Notation	Description
M	The total number of users.
N	The total number of servers.
n	The total number of chains.
$(\mathsf{isk}_i, \mathsf{ipk}_i = g^{\mathsf{isk}_i})$	Per-server private-public key pair used to encrypt and decrypt the inner most layer of ciphertexts. Used to protect the messages under active attacks by malicious servers or users.
$(\mathsf{bsk}_i, \mathsf{bpk}_i)$	Per-server private-public key pair used to blind the users' Diffie-Hellman keys. After shuffling and decrypting the messages, each server blinds the Diffie-Hellman keys by raising them to the private key bsk_i. This hides which output message is associated with which input while preserving some structures of the Diffie-Hellman keys, which allows us to generate efficient zero-knowledge proofs to prove the correctness of the shuffle. The public component is used to derive the public keys used to encrypt messages for the mix chain (i.e., $\{\mathsf{mpk}_i\}$). bpk_i is $g^{\prod_{k\leq i}\mathsf{bsk}_k}$ for server i in a mix chain.
$(\mathsf{msk}_i, \mathsf{mpk}_i)$	Per-server private-public key pair used to encrypt and decrypt messages for shuffling. mpk_i is $(g^{\prod_{k<i}\mathsf{bsk}_k})^{\mathsf{msk}_i}$ for server i in a mix chain.
x^j	The private Diffie-Hellman key of user j used to encrypt the messages for a mix chain. The user uses the same x^j for all layers of encryption, but the effective private Diffie-Hellman key of a layer changes after a server processes the messages due to blinding.
X_i^j	The public Diffie-Hellman key of user j used to encrypt her message for server i. If everyone is behaving correctly, then this should be $(g^{\prod_{k<i}\mathsf{bsk}_k})^{x^j}$.
c_i^j	The actual ciphertext component that encrypts the message. User j will derive the encryption key using its private key x^j and the public mixing key mpk_i. Server i will derive the decryption key using its private mixing key msk_i and X_i^j.

each combination for $j \in X_H$. We indicate which combinations are possible for the adversary to satisfy, given that all authenticated decryptions were successful.

1. $c_h^j \neq c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 0$: **IMPOSSIBLE.** Since the adversary does not know the key used to decrypt (i.e., $(X_h^j)^{\mathsf{msk}_h}$), it cannot generate a valid ciphertext.

2. $c_h^j \neq c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$: **POSSIBLE.** Since the adversary knows the key used to decrypt it could generate a valid ciphertext.

3. $c_h^j \neq c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 0$: **IMPOSSIBLE.** Same argument as case 1.

4. $c_h^j \neq c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$: **IMPOSSIBLE.** If possible, then the adversary can break the Diffie-Hellman assumption. Namely, given only $X_1^j = g^{x_j}$, bsk_A, and $(g^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$ for random x_j and msk_h and an independently generated bsk_A, it can compute $(X_h^j)^{\mathsf{msk}_h} = g^{x_j \cdot \mathsf{bsk}_A \cdot \mathsf{msk}_h}$. If this were possible, then given g^a and g^b for random a and b, the adversary could generate an bsk_A, compute $(g^b)^{\mathsf{bsk}_A}$, and compute $g^{a \cdot b \cdot \mathsf{bsk}_A}$. It could then break the Diffie-Hellman assumption and compute g^{ab} by raising $g^{a \cdot b \cdot \mathsf{bsk}_A}$ to bsk_A^{-1}.

5. $c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 0$: **IMPOSSIBLE.** If possible, then c_h^j authenticates under two different keys $(X_1^j)^{\mathsf{bsk}_A \cdot \mathsf{msk}_h}$ and $(X_h^j)^{\mathsf{msk}_h}$. However, if we model the underlying hash function of HMAC as a random oracle, then the HMAC instantiated with a random key is a random function. This implies that the probability that the same ciphertext authenticates under two different keys (i.e., collision of two random functions) is negligible when using Encrypt-then-HMAC.

6. $c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$: **POSSIBLE.** Since the adversary knows and controls the key used for decryption (in particular, the HMAC), it may be able to find a key that is different from the key used to encrypt that results in valid decryption.

7. $c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 0$: **POSSIBLE.** This corresponds to an untampered message.

8. $c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$: **IMPOSSIBLE.** Same argument as case 4.

Thus, there are three possible combinations of predicates: ($c_h^j \neq c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$), ($c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} \neq X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 1$), and ($c_h^j = c_h^{j'}$, $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$, $\mathsf{KNOW}((X_h^j)^{\mathsf{msk}_h}) = 0$). The first two cases correspond to X_T (tampered messages), and the second corresponds exactly to $X_H \setminus X_T$ (untampered messages).

Similarly, consider $j \in X_A$. The adversary generates the ciphertexts $\{c_h^{j'}\}$ for the verifier. Thus, the adversary must know $(X_h^j)^{\mathsf{msk}_h}$, the key used to authenticate the ciphertext, for $j \in X_A$.

Now, we consider the product of the users' Diffie-Hellman keys. Because all NIZKs have to be verified, we have that

$$\left(\prod_{j=1}^{M} X_1^j\right)^{\mathsf{bsk}_A} = \left(\prod_{j=1}^{M} X_h^j\right).$$

Consider $X_U = X_H \setminus X_T$, i.e., the set of messages that did not change. Then, we can divide both sides by the values associated with X_U since $(X_1^j)^{\mathsf{bsk}_A} = X_h^j$ for $j \in X_U$:

$$\left(\prod_{j \in X_T \cup X_A} X_1^j\right)^{\mathsf{bsk}_A} = \left(\prod_{j \in X_T \cup X_A} X_h^j\right),$$

since $X_T \cup X_A = [M] \setminus X_U$. We can rewrite this as

$$\left(\prod_{j \in X_T} X_1^j\right)^{\mathsf{bsk}_A} = \left(\prod_{j \in X_T \cup X_A} X_h^j\right) / \left(\prod_{j \in X_A} X_1^j\right)^{\mathsf{bsk}_A}. \quad (1)$$

Based on our analysis of the possible predicates for X_T and X_A, the adversary must know $(X_h^j)^{\mathsf{msk}_h}$ for $j \in X_T \cup X_A$. Moreover, the adversary knows $\log_g(X_1^j)$ for $j \in X_A$ (it was required to prove the knowledge in step 4 of the game). Thus, the adversary can compute $((X_1^j)^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$ by computing $((g^{\mathsf{bsk}_A})^{\mathsf{msk}_h})^{\log_g(X_1^j)}$ for $j \in X_A$ (it knows $\mathsf{mpk}_h = (g^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$). As a result, it can compute

$$\left(\prod_{j \in X_T \cup X_A} \left(X_h^j\right)^{\mathsf{msk}_h}\right) / \prod_{j \in X_A} \left(\left(X_1^j\right)^{\mathsf{bsk}_A}\right)^{\mathsf{msk}_h}.$$

This, however, is

$$\begin{aligned}
&\left(\prod_{j \in X_T \cup X_A} \left(X_h^j\right)^{\mathsf{msk}_h}\right) / \prod_{j \in X_A} \left(\left(X_1^j\right)^{\mathsf{bsk}_A}\right)^{\mathsf{msk}_h} \\
&= \left(\left(\prod_{j \in X_T \cup X_A} X_h^j\right) / \left(\prod_{j \in X_A} X_1^j\right)^{\mathsf{bsk}_A}\right)^{\mathsf{msk}_h} \\
&= \left(\left(\prod_{j \in X_T} X_1^j\right)^{\mathsf{bsk}_A}\right)^{\mathsf{msk}_h},
\end{aligned}$$

where the last step uses the equality from equation 1. This means that given $\{X_1^j = g^{x_j}\}$, bsk_A, and $(g^{\mathsf{bsk}_A})^{\mathsf{msk}_h}$ for unknown random $\{x_j\}$ and msk_h, and bsk_A that was generated independently of $\{x_j\}$ and msk_h, the adversary was able to compute $g^{\mathsf{bsk}_A \cdot \mathsf{msk}_h \cdot \sum_{j \in X_T} x_j}$. This essentially breaks Diffie-Hellman.

In more detail, consider the following adversary A_{DH} that tries to break Diffie-Hellman. A_{DH} is given g^a and g^b for random a and b, and is asked to compute g^{ab}. To compute this, A_{DH} simulates the above game by simulating the clients and the honest server. To do so, A_{DH} chooses the blinding keys $\{\mathsf{bsk}_i\}$, and sets $\mathsf{mpk}_h = (\prod_i g^{\mathsf{bsk}_i})^b = (g^b)^{\mathsf{bsk}_A}$; i.e., the private mixing key of the honest server is b. Then, it generates the inputs from the client by generating a random r_j for $j \in X_H$ and setting $g^{x_j} = g^{a+r_j}$. It also generates the inputs associated with each message. The adversary (a simulator) can generate valid NIZKs of knowledge of discrete logs in the random oracle model [48]. For the first layer of encryption (which is for the "honest server" whose secret key is the unknown b), generate random values for c_h^j, since ciphertexts are indistinguishable from random values. For the other layers of encryption, it can generate correctly authenticated ciphertexts by using g^{x_j}, $\{\mathsf{bsk}_i\}_{i<h}$, and $\{\mathsf{msk}_i\}_{i<h}$ without knowing the value of a.

At the end of the game, the adversary can compute $g^{\mathsf{bsk}_A \cdot b \cdot (\sum_{j \in X_T} x_j)}$, as described previously. From this, the adversary can compute the following:

$$\begin{aligned}
g^{\mathsf{bsk}_A \cdot b \cdot (\sum_{j \in X_T} x_j)} &= g^{\mathsf{bsk}_A \cdot b \cdot (\sum_{j \in X_T} (a+r_j))} \\
&= g^{\mathsf{bsk}_A \cdot b \cdot (|X_T| a + \sum_{j \in X_T} r_j)}.
\end{aligned}$$

Since the adversary knows bsk_A and r_j for $j \in X_T$, it can compute

$$g^{|X_T|ab} = (g^{\mathsf{bsk}_A \cdot b \cdot (|X_T| a + \sum_{j \in X_T} r_j)} / (g^b)^{\mathsf{bsk}_A \sum_{j \in X_T} r_j})^{\mathsf{bsk}_A^{-1}}.$$

From this, it can recover g^{ab}, and break Diffie-Hellman. Therefore, the adversary cannot win the above game if Diffie-Hellman is hard, meaning that it could satisfy at most two out of the three conditions to win the game. In turn, this implies that the honest server will always catch an upstream malicious server misbehaving.

B Security game and proof sketches

We define the security of our system using the following security game played between a challenger and an adversary. Both the challenger and the adversary are given the set of users $[M] = \{1, 2, \ldots, M\}$, the set of servers $[N]$, the fraction f of servers the adversary can compromise, and the number of chains n.

1. The adversary selects the set of malicious servers $A_s \subset [N]$ such that $|A_s| \le f \cdot N$, and the set of malicious users $A_c \subset [M]$ such that $|A_c| \le M - 2$. The adversary sends A_s and A_c to the challenger. Let $H_s = [M] \setminus A_s$ and $H_c = [N] \setminus A_c$ denote the set of honest servers and users.

2. The challenger computes the size of each chain k as a function of f and n, as described in §5.2. Then, it creates n mix chains by repeatedly sampling k servers per group at random. The challenger sends the chain configurations to the adversary.

3. The adversary and the challenger generate blinding keys, mixing keys, and inner keys as described in §6.1 and Appendix A.

4. The adversary picks some honest users $H_t \subset H_c$ such that $|H_t| \geq 2$. It generates sets of chains $\{C_x\}$ for $x \in H_t$ such that $C_x \cap C_y \neq \emptyset$ for all $x, y \in H_t$. For $\mathsf{c} \in [n]$, let $U_\mathsf{c} = \{x \in H_t : \mathsf{c} \in C_x\}$. For each chain c, it also generates the potential messages $\{m^\mathsf{c}_{xy}\}$ for $x, y \in U_\mathsf{c}$ where m^c_{xy} is the message that may be sent from user x to user y in chain c. The adversary sends H_t, $\{\{m^\mathsf{c}_{xy}\}\}$, and $\{C_x\}$ to the challenger.
5. The challenger first verifies that every pair of C_x and C_y intersects at least once. If this is not the case, the game halts. The challenger then performs the following for each chain $\mathsf{c} \in [n]$. First, it creates conversation pairs for each chain c $\{(X_i, Y_i)_\mathsf{c}\} \subset U_\mathsf{c} \times U_\mathsf{c}$ at random such that every $x \in U_\mathsf{c}$ appears in exactly one of the pairs. In other words, every user has a unique conversation partner per chain. (If $X_i = Y_i$, then that user is talking with herself.) For each $(x, y) \in \{(X_i, Y_i)_\mathsf{c}\}$, the challenger onion-encrypts the messages m^c_{xy} from x to y and m^c_{yx} from y to x with the keys of servers in chain c. Then, it uses the protocol described in §6.2 to submit the ciphertexts and the necessary NIZKs.
6. The adversary generates inputs to the chains for the users in A_c, and sends them to the chains.
7. The challenger and the adversary take turns processing the messages in each chain. Within a chain, they perform the following for $i = 1, \ldots, k$:
   (a) If server $i \in H_s$, the challenger performs protocol described in §6.3 to shuffle and decrypt the messages, and also generate an AHS proof. The challenger then sends the proof to the adversary, and the resulting messages to the owner of server $i+1$.
   (b) If server $i \in A_s$, the adversary generates some messages along with an AHS proof. Then, sends the AHS proof to the challenger, and sends the messages to the owner of server $i+1$.

   The challenger verifies all AHS proofs.
8. The challenger and the adversary decrypt the final result of the shuffle (i.e., the inner ciphertexts).
9. The challenger samples a random bit $b \leftarrow 0, 1$. If $b = 0$, then send the adversary $\{(X_i, Y_i)_\mathsf{c}\}$ for $\mathsf{c} \in [n]$. If $b = 1$, then sample random conversation pairs $\{(X'_i, Y'_i)_\mathsf{c}\} \subset U_\mathsf{c} \times U_\mathsf{c}$ for each chain with the same constraint as in step 5, and send the adversary the newly sampled pairs.
10. The adversary makes a guess b' for b.

The adversary wins the game if the game does not come to a halt before the last step and $b' = b$. The adversary need not follow the protocol described in this paper. The advantage of the adversary in this game is $|\Pr[b' = b] - \frac{1}{2}|$. We say that the system provides metadata private communication if the advantage is negligible in the implicit security parameter.

Note that this game models a stronger version of XRD, which allows users to communicate with multiple users on different chains rather than only one user. We could change the game slightly to force the challenger to send loopback messages in step 5 to model having just one conversation.

Proof sketches. First, we argue that the adversary needs to tamper with messages prior to the last honest server shuffling, as stated in §6. To see why, consider an adversary that only tampers with the messages after the last honest server. The adversary can learn the recipients of all messages, but not the senders. As a result, the adversary does not learn anything about whether two users $x, y \in U_\mathsf{c}$ received messages because there exists a conversation pair $(x, y)_\mathsf{c}$, or because there were two conversation pairs $(x, x)_\mathsf{c}$ and $(y, y)_\mathsf{c}$. This means that any set of conversation pairs is equally likely to be sampled by the challenger from the adversary's view, meaning that the adversary does not gain any advantage. Thus, we consider an adversary who tampers with messages prior to the honest server processing the messages.

In this scenario, the adversary in step 7 must follow the protocol (e.g., no tampering with the messages), as analyzed in Appendix A. Given this restriction, we now argue that the adversary does not learn anything after playing the security game by describing how a simulator of an adversary could simulate the whole game with only the public inputs and the private values of the adversary.

The simulator can simulate step 3 by generating random public keys. It can simulate step 5 by generating random values in place of the ciphertexts that encrypt the users' messages $\{\{m^\mathsf{c}_{xy}\}\}$, since the ciphertexts are indistinguishable from random. It then randomly matches a user in U_c to one of the generated random values for each chain c, and sets the destination of each message as the matched user. It onion-encrypts the final message using the randomly generated public keys and the adversary's public keys. In step 7, the adversary simulates the challenger by randomly permuting the messages, and removing a layer of the encryption from the messages. (It can remove a layer of encryption since it knows all layers of onion-encryption.) Finally, it could simulate the challenger's last challenge by picking sets of randomly generated conversation pairs, subject to the constraints in step 5. The distribution of the messages generated and exchanged in the security game and in the simulator are indistinguishable for a computationally limited adversary.

High Throughput Cryptocurrency Routing in Payment Channel Networks

Abstract

Despite growing adoption of cryptocurrencies, making fast payments at scale remains a challenge. Payment channel networks (PCNs) such as the Lightning Network have emerged as a viable scaling solution. However, completing payments on PCNs is challenging: payments must be routed on paths with sufficient funds. As payments flow over a single channel (link) in the same direction, the channel eventually becomes depleted and cannot support further payments in that direction; hence, naive routing schemes like shortest-path routing can deplete key payment channels and paralyze the system. Today's PCNs also route payments atomically, worsening the problem. In this paper, we present Spider, a routing solution that "packetizes" transactions and uses a multi-path transport protocol to achieve high-throughput routing in PCNs. Packetization allows Spider to complete even large transactions on low-capacity payment channels over time, while the multi-path congestion control protocol ensures balanced utilization of channels and fairness across flows. Extensive simulations comparing Spider with state-of-the-art approaches shows that Spider requires less than 25% of the funds to successfully route over 95% of transactions on balanced traffic demands, and offloads 4x more transactions onto the PCN on imbalanced demands.

1 Introduction

Despite their growing adoption, cryptocurrencies suffer from poor scalability. For example, the Bitcoin [5] network processes 7 transactions per second, and Ethereum [14] 15 transactions/second, which pales in comparison to the 1,700 transactions per second achieved by the VISA network [56]. Scalability thus remains a major hurdle to the adoption of cryptocurrencies for retail and other large-scale applications. The root of the scalability challenge is the inefficiency of the underlying consensus protocol: every transaction must go through full consensus to be confirmed, which can take anywhere from several minutes to hours [43].

A leading proposal among many solutions to improve cryptocurrency scalability [23, 32, 40] relies on so-called *payment channels*. A payment channel is a cryptocurrency transaction that escrows or dedicates money on the blockchain for exchange with a prespecified user for a predetermined duration. For example, Alice can set up a payment channel with Bob in which she escrows 10 tokens for a month. Now Alice can send Bob (and only Bob) signed transactions from the escrow account, and Bob can validate them privately in a secure manner without mediation on the blockchain (§2). If Bob or Alice want to close the payment channel at any point, they can broadcast the most recent signed transaction message to the blockchain to finalize the transfer of funds.

The versatility of payment channels stems from **payment channel networks** (PCNs), in which users who do not share direct payment channels can route transactions through intermediaries for a nominal fee. PCNs enable fast, secure transactions without requiring consensus on the blockchain for every transaction. PCNs have received a great deal of attention in recent years, and many blockchains are looking to PCNs to scale throughput without overhauling the underlying consensus protocol. For example, Bitcoin has deployed the Lightning network [10, 15], and Ethereum uses Raiden [18].

For PCNs to be economically viable, the network must be able to support high *transaction throughput*. This is necessary for intermediary nodes (routers) to profitably offset the opportunity cost of escrowing funds in payment channels, and for encouraging end-user adoption by providing an appealing quality of payment service. But, a transaction is successful only if all channels along its route have sufficient funds. This makes payment channel *routing*, the protocol by which a path is chosen for a transaction, of paramount importance.

Existing payment channel routing protocols achieve poor throughput, for two main reasons. First, they attempt to route each incoming transaction atomically and instantaneously, in full. This approach is harmful, particularly for larger transactions, because a transaction fails completely if there is no path to the destination with enough funds. Second, existing routing protocols fail to keep payment channels *balanced*. A payment channel becomes imbalanced when the transaction rate across it is higher in one direction than the other; the party making more transactions eventually runs out of funds and cannot send further payments without "refilling" the channel via either an on-chain transaction (i.e., committing a new transaction to the blockchain) or coordinated cyclic payments between a series of PCN nodes [39]. Most PCNs today route transactions naively on shortest paths with no consideration for channel balance; this can leave many channels depleted, reducing throughput for everyone in the network. We describe a third problem, the creation of *deadlocks* in certain scenarios, in §3.

In this paper we present *Spider*, a multi-path transport protocol that achieves balanced, high-throughput routing in PCNs, building on concepts in an earlier position paper [51]. Spider's design centers on two ideas that distinguish it from existing approaches. First, Spider senders "packetize" transactions, splitting them into transaction-units that can be sent across different paths at different rates. By enabling congestion-control-like mechanisms for PCNs, this packet-switched approach makes it possible to send large payments on low-capacity payment channels over a period of time. Second, Spider develops a simple multi-path congestion control algorithm that promotes balanced channels while maximizing throughput. Spider's senders use a simple one-bit congestion signal from the routers to adjust window sizes, or the number of outstanding transaction-units, on each of their paths.

Spider's congestion control algorithm is similar to multi-path congestion control protocols like MPTCP [59] developed for Internet congestion control. But the routing problem it solves in PCNs differs from standard networks in crucial ways. Payment channels can only route transactions by moving a finite amount of funds from one end of the channel to the other. Because of this, the capacity of a payment channel — the transaction rate that it can support — varies depending on how it is used; a channel with balanced demand for routing transactions in both directions can support a higher rate than an imbalanced one. Surprisingly, we find that a simple congestion control protocol can achieve such balanced routing, despite not being designed for that purpose explicitly.

We make the following contributions:

1. We articulate challenges for high-throughput routing in payment channel networks (§3), and we formalize the balanced routing problem (§5). We show that the maximum throughput achievable in a PCN depends on the nature of the transaction pattern: circulation demands (participants send on average as much as they receive) can be routed entirely with sufficient network capacity, while demands that form Directed Acyclic Graphs (DAGs) where some participants send more than they receive cannot be routed entirely in a balanced manner. We also show that introducing DAG demands can create deadlocks that stall all payments.
2. We propose a packet-switched architecture for PCNs (§4) that splits transactions into transaction-units and multiplexes them across paths and time.
3. We design Spider (§6), a multi-path transport protocol that (i) maintains balanced channels in the PCN, (ii) uses the funds escrowed in a PCN efficiently to achieve high throughput, and (iii) is fair to different payments.
4. We build a packet-level simulator for PCNs and validate it with a small-scale implementation of Spider on the LND Lightning Network codebase [15]. Our evaluations (§7) show that (i) on circulation demands where 100% throughput is achievable, compared to the state-of-the-art, Spider requires 25% of the funds to route over 95% of the transactions and completes 1.3-1.8x more of the largest 25% of transactions based on a credit card transactions dataset [34]; (ii) on DAG demands where 100% throughput is not achievable, Spider offloads 7-8x as many transactions onto the PCN for every transaction on the blockchain, a 4x improvement over current approaches.

2 Background

Bidirectional payment channels are the building blocks of a payment channel network. A bidirectional payment channel allows a sender (Alice) to send funds to a receiver (Bob) and vice versa. To open a payment channel, Alice and Bob jointly create a transaction that escrows money for a fixed amount of time [46]. Suppose Alice puts 3 units in the channel, and Bob puts 4 (Fig. 1). Now, if Bob wants to transfer one token to Alice, he sends her a cryptographically-signed message asserting that he approves the new balance. This message is not committed to the blockchain; Alice simply holds on to it. Later, if Alice wants to send two tokens to Bob, she sends a signed message to Bob approving the new balance (bottom left, Fig. 1). This continues until one party decides to close the channel, at which point they publish the latest message to the blockchain asserting the channel balance. If one party tries to cheat by publishing an earlier balance, the cheating party loses all the money they escrowed to the other party [46].

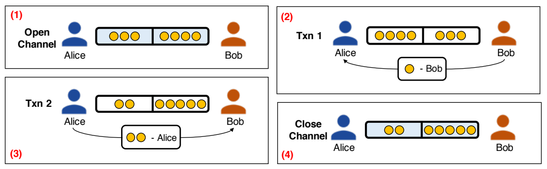

Figure 1: Bidirectional payment channel between Alice and Bob. A blue shaded block indicates a transaction that is committed to the blockchain.

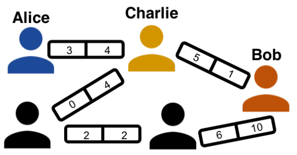

Figure 2: In a payment channel network, Alice can transfer money to Bob by using intermediate nodes' channels as relays. There are two paths from Alice to Bob, but only the path (Alice, Charlie, Bob) can support 3 tokens.

A payment channel network is a collection of bidirectional payment channels (Fig. 2). If Alice wants to send three tokens to Bob, she first finds a path to Bob that can support three tokens of payment. Intermediate nodes on the path (Charlie) will relay payments to their destination. Hence in Fig. 2, two transactions occur: Alice to Charlie, and Charlie to Bob. To incentivize Charlie to participate, he receives a routing fee. To prevent him from stealing funds, a cryptographic hash lock ensures that all intermediate transactions are only valid after a transaction recipient knows a private key generated by Alice [18]. [1] Once Alice is ready to pay, she gives that key to

[1]The protocol called Hashed Timelock Contracts (HTLCs) can be implemented in two ways: the sender generates the key, as in Raiden [18] or the receiver generates the key, as in Lightning [46]. Spider assumes that the sender generates the key.

Bob out-of-band; he can either broadcast it (if he decides to close the channel) or pass it to Charlie. Charlie is incentivized to relay the key upstream to Alice so that he can also get paid. Note that Charlie's payment channels with Alice and Bob are independent: Charlie cannot move funds between them without going through the blockchain.

3 Challenges in Payment Channel Networks

A major cost of running PCNs is the collateral needed to set up payment channels. As long as a channel is open, that collateral is locked up, incurring an opportunity cost for the owner. For PCNs to be financially viable, this opportunity cost should be offset by routing fees, which are charged on each transaction that passes through a router. To collect more routing fees, routers try to process as many transactions as possible for a given amount of collateral. A key performance metric is therefore the *transaction throughput per unit collateral* where throughput itself is measured either in number of transactions per second or transaction value per second.

Current PCN designs exhibit poor throughput due to naive design choices in three main areas: (1) *how* to route transactions,(2) *when* to send them and, (3) *deadlocks*.

Challenge #1: How to route transactions? A central question in PCNs is what route(s) to use for sending a transaction from sender to destination. PCNs like the Lightning and Raiden networks are source-routed. [2] Most clients by default pick the shortest path from the source to the destination.

However, shortest-path routing degrades throughput in two key ways. The first is to cause underutilization of the network. To see this, consider the PCN shown in Fig. 3a. Suppose we have two clusters of nodes that seek to transact with each other at roughly the same rate on average, and the clusters are connected by two paths, one consisting of channels $a-b$, and the other channel c. If the nodes in cluster A try to reach cluster B via the shortest path, they would all take channel c, as would the traffic in the opposite direction. This leads to congestion on channel c, while channels a and b are under-utilized.

A second problem is more unique to PCNs. Consider a similar topology in Figure 3b, and suppose we fully utilize the network by sending all traffic from cluster A→B on edge a and all traffic from cluster B→A on edge b. While the rate on both edges is the same, as funds flow in one direction over a channel, the channel becomes *imbalanced*: all of the funds end up on one side of the channel. Cluster A can no longer send payments until it receives funds from cluster B on the edge a or it deposits new funds into the channel a via an on-chain transaction. The same applies to cluster B on edge b. Since on-chain transactions are expensive and slow, it is desirable to avoid them. Routing schemes like shortest-path routing do not account for this problem, thereby leading to reduced throughput (§7). In contrast, it is important to choose routes that actively prevent channel imbalance. For example, in Figure 3b, we could send half of the A→B traffic on edge a, and half on edge b, and the same for the B→A traffic. The challenge is making these decisions in a fully decentralized way.

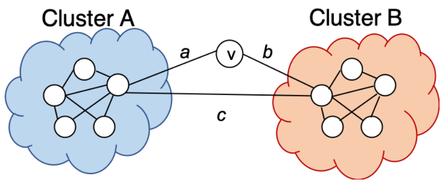
Challenge #2: When to send transactions? Another problem is *when* to send transactions. Most existing PCNs are circuit-switched: transactions are processed instantaneously and atomically upon arrival [18, 46]. This causes a number of problems. If a transaction's value exceeds the available balance on each path from the source to the destination, the transaction fails. Since transaction values in the wild tend to be heavy-tailed [29, 34], either a substantial fraction of real transactions will fail as PCN usage grows, or payment channel operators will need to provision higher collateral to satisfy demand.

Even when transactions do not fail outright, sending transactions instantaneously and atomically exacerbates the imbalance problem by transferring the full transaction value to one side of the channel. A natural idea to alleviate these problems is to "packetize" transactions: transactions can be split into smaller transaction-units that can be multiplexed over space (by traversing different paths) and in time (by being sent at different rates). Versions of this idea have been proposed before; atomic multi-path payments (AMP) enable transactions to traverse different paths in the Lightning network [3], and the Interledger protocol uses a similar packetization to conduct cross-ledger payments [54]. However, a key observation is that it is not enough to subdivide transactions into smaller units: to achieve good throughput, it is also important to multiplex in *time* as well, by performing congestion control. If there is a large transaction in one direction on a channel, simply sending it out in smaller units that must all complete together doesn't improve the likelihood of success. Instead, in our design, we allow each transaction-unit to complete independently, and a congestion control algorithm at the sender throttles the rate of these units to match the rate of units in the opposite direction at the bottlenecked payment channel. This effectively allows the tokens at that bottleneck to be replenished and reused multiple times as part of the same transaction, achieving a multiplicative increase in throughput for the same collateral.

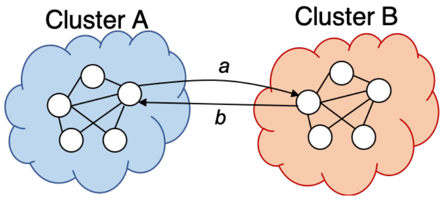
Challenge #3: Deadlocks. The third challenge in PCNs is the idea that the introduction of certain flows can actively harm the throughput achieved by other flows in the network. To see this, consider the topology and demand rates in Figure 3c. Suppose nodes 1 and 2 want to transmit 1-unit transactions to node 3 at rates of 1 and 2 units/second, respectively, and node 3 wants to transact 2 units/sec with node 1.[3] Notice that the specified transaction rates are imbalanced: there is a net flow of funds out of node 2 and into nodes 1 and 3. Suppose the payment channels are initially balanced, with 10 units on each side and we only start out with flows between nodes 1 and 3. For this demand and topology, the system can sustain 2 units/sec by only having nodes 1 and 3 to send to each other at a rate of 1 unit/second.

[2] This was done in part for privacy reasons: transactions in the Lightning network use onion-routing, which is easy to implement with source routing [33].

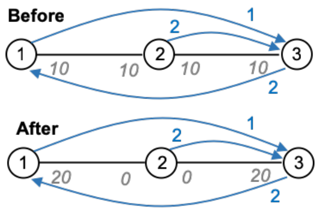
[3] For simplicity, we show three nodes, but a node in this example could represent a cluster of many users who wish to transact at the rates shown in aggregate.



(a) Underutilized channels



(b) Imbalanced channels



(c) Deadlock

Figure 3: Example illustrating the problems with state-of-the-art PCN routing schemes.

However, once transactions from node 2 are introduced, this example achieves zero throughput at steady-state. The reason is that node 2 sends transactions to node 3 faster than its funds are being replenished, which reduces its funds to 0. Slowing down 2's transactions would only delay this outcome. Since node 2 needs a positive balance to route transactions between nodes 1 and 3, the transactions between 1 and 3 cannot be processed, despite the endpoints having sufficient balance. The network finds itself in a *deadlock* that can only be resolved by node 2 replenishing its balance with an on-chain transaction.

Why these problems are difficult to solve. The above problems are challenging because their effects are closely intertwined. For example, because poor routing and rate-control algorithms can cause channel imbalance, which in turn degrades throughput, it is difficult to isolate the effects of each. Similarly, simply replacing circuit switching with packet-switching gives limited benefits without a corresponding rate control and routing mechanism.

From a networking standpoint, PCNs are very different from traditional communication networks: payment channels do not behave like a standard communication link with a certain capacity, say in transactions per second. Instead, the capacity of a channel in a certain direction depends on two factors normally not seen in communication networks: (a) the rate that transactions are received in the reverse direction on that channel, because tokens cannot be sent faster on average in one direction than they arrive in the other, (b) the delay it takes for the destination of a transaction to receive it and send back the secret key unlocking the funds at routers (§2). Tokens that are "in flight", i.e. for which a router is waiting for the key, cannot be used to service new transactions. Therefore the network's capacity depends on its delay, and queued up transactions at a depleted link can hold up funds from channels in other parts of the network. This leads to cascading effects that make congestion control particularly critical.

4 Packet-Switched PCN

Spider uses a packet-switched architecture that splits transactions into a series of independently routed *transaction-units*. Each transaction-unit transfers a small amount of money bounded by a *maximum-transaction-unit (MTU)* value. Packetizing transactions is inspired by packet switching for the Internet, which is more effective than circuit switching [41]. Note that splitting transactions does not compromise the security of payments; each transaction-unit can be created with an independent secret key. As receivers receive and acknowledge transaction-units, senders can selectively reveal secret keys only for acknowledged transaction-units (§2). Senders can also use proposals like Atomic Multi-Path Payments (AMP) [3] if they desire atomicity of transactions.

In Spider, payments transmitted by source *end-hosts* are forwarded to their destination end-hosts by *routers* within the PCN. Spider routers queue up transaction-units at a payment channel whenever the channel lacks the funds to forward them immediately. As a router receives funds from the other side of its payment channel, it uses these funds to forward transaction-units waiting in its queue. Current PCN implementations [15] do not queue transactions at routers—a transaction fails immediately if it encounters a channel with insufficient balance on its route. Thus, currently, even a temporary lack of channel balance can cause many transactions to fail, which Spider avoids.

5 Modeling Routing

A good routing protocol must satisfy the following objectives:

1. **Efficiency.** For a PCN with a fixed amount of escrowed capital, the aggregate transaction throughput achieved must be as high as possible.
2. **Fairness.** The throughput allocations to different users must be fair. Specifically, the system should not starve transactions of some users if there is capacity.

Low latency, a common goal in communication networks, is desirable but not a first order concern, as long as transaction latency on the PCN is significantly less than an on-chain transaction (which can take minutes to hours today). However, as mentioned previously (§3), very high latency could hurt the throughput of a PCN, and must therefore be avoided. We assume that the underlying communication network is not a bottleneck and PCN users can communicate payment attempts, success and failures with one another easily since these messages do not require much bandwidth.

To formalize the routing problem, we consider a fluid model of the system in which payments are modeled as continuous "fluid flows" between users. This allows us to cast routing as an optimization problem and derive decentralized algorithms from it, analogous to the classical Network Utility Maximization (NUM) framework for data networks [45]. More specifically, for the fluid model we consider a PCN modeled as a graph $G(V,E)$ in which V denotes the set of nodes (i.e., end-hosts or routers), and E denotes the set of payment channels between them. For a path p, let x_p denote the (fluid) rate at which payments are sent along p from a source to a destination. The fluid rate captures the long-term average rate at which payments are made on the path.

For maximizing throughput efficiency, routing has to be done such that the total payment flow through each channel is as high as possible. However, routers have limited capital on their payment channels, which restricts the maximum rate at which funds can be routed (Fig. 3a). In particular, when transaction units are sent at a rate $x_{u,v}$ across a payment channel between u and v with $c_{u,v}$ funds in total and it takes Δ time units on average to receive the secret key from a destination once a payment is forwarded, then $x_{u,v}\Delta$ credits are locked (i.e., unavailable for use) at any point in time in the channel. This implies that the average rate of transactions (across both directions) on a payment channel cannot exceed $c_{u,v}/\Delta$. This leads to *capacity constraints* on channels.

Sustaining a flow in one direction through a payment channel requires funds to be regularly replenished from the other direction. This requirement is a key difference between PCNs and traditional data networks. In PCNs if the long-term rates $x_{u,v}$ and $x_{v,u}$ are mismatched on a channel (u,v), say $x_{u,v} > x_{v,u}$, then over time all the funds $c_{u,v}$ will accumulate at v deeming the channel unusable in the direction u to v (Fig. 3b). This leads to *balance constraints* which stipulate that the total rate at which transaction units are sent in one direction along a payment channel matches the total rate in the reverse direction.

Lastly, for enforcing fairness across flows we assume sources have an intrinsic *utility* for making payments, which they seek to maximize. A common model for utility at a source is the logarithm of the total rate at which payments are sent from the source [31, 37, 38]. A logarithmic utility ensures that the rate allocations are proportionally fair [38]—no individual sender's payments can be completely throttled. Maximizing the overall utility across all source-destination pairs subject to the capacity and balance constraints discussed above, can then be computed as

$$\text{maximize} \quad \sum_{i,j\in V} \log\Big(\sum_{p\in\mathcal{P}_{i,j}} x_p\Big) \tag{1}$$

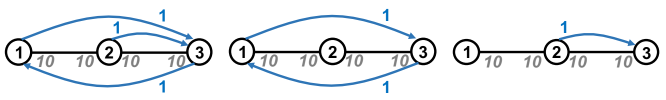
$$\text{s.t.} \quad \sum_{p\in\mathcal{P}_{i,j}} x_p \le d_{i,j} \quad \forall i,j\in V \tag{2}$$

$$x_{u,v}+x_{v,u} \le \frac{c_{u,v}}{\Delta} \quad \forall(u,v)\in E \tag{3}$$

$$x_{u,v} = x_{v,u} \quad \forall(u,v)\in E \tag{4}$$

$$x_p \ge 0 \quad \forall p\in\mathcal{P}, \tag{5}$$

where for a source i and destination j, $\mathcal{P}_{i,j}$ is the set of all paths from i to j, $d_{i,j}$ is the demand from i to j, $x_{u,v}$ is the total flow going from u to v for a channel (u,v), $c_{u,v}$ is the total amount of funds escrowed into (u,v), Δ is the average round-trip time of the network taken for a payment to be completed, and $\mathcal{P}$ is the set of all paths. Equation (2) specifies *demand constraints* which ensures that the total flow for each sender-receiver pair across all of their paths, is no more than their demand.



(a) Payment graph (b) Circulation (c) DAG

Figure 4: Payment graph (denoted by blue lines) for a 3 node network (left). It decomposes into a maximum circulation and DAG components as shown in (b) and (c).

5.1 Implications for Throughput

A consequence of the balance constraints is that certain traffic demands are more efficient to route than certain others. In particular, demands that have a *circulation* structure (total outgoing demand matches total incoming demand at a router) can be routed efficiently. The cyclic structure of such demands enables routing along paths such that the rates are naturally balanced in channels. However, for demands without a circulation structure, *i.e.,* if the demand graph is a directed acyclic graph (DAG), balanced routing is impossible to achieve in the absence of periodic replenishment of channel credits, regardless of how large the channel capacities are.

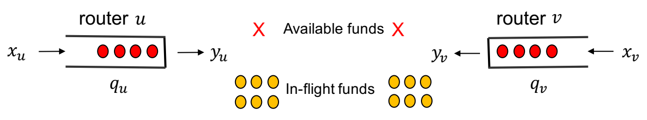
For instance, Fig. 4a shows the traffic demand graph for a PCN with nodes $\{1,2,3\}$ and payment channels between nodes $1-2$ and $2-3$. The weight on each blue edge denotes the demand in transaction-units per second between a pair of users. The underlying black lines denote the topology and channel sizes. Fig. 4b shows the circulation component of the demand in Fig. 4a. The entire demand contained in this circulation can be routed successfully as long as the network has sufficient capacity. In this case, if the confirmation latency for transaction-units between 1 and 3 is less than 10s, then the circulation demand can be satisfied indefinitely. The remaining component of the demand graph, which represents the DAG, is shown in Fig. 4c. This portion cannot be routed indefinitely since it shifts all tokens onto node 3 after which the $2-3$ channel becomes unusable.

App. A formalizes the notion of circulation and shows that the maximum throughput achievable by any balanced routing scheme is at most the total demand contained within the circulation.

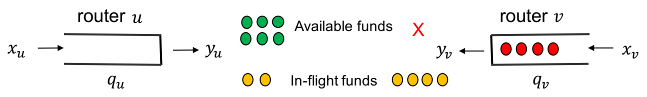
6 Design

6.1 Intuition

Spider routers queue up transactions at a payment channel whenever the channel lacks funds to forward them immediately (§5). Thus, queue buildup is a sign that either transaction-units



(a) A capacity limited payment channel.



(b) An imbalance limited payment channel.

Figure 5: Example of queue growth in a payment channel between routers u and v, under different scenarios of transaction arrival rates at u and v. (a) If the rate of arrival at v, x_v, and the rate of arrival at u, x_u, are such that their sum exceeds the channel capacity, neither router has available funds and queues build up at both u and v. (b) If the arrival rates are imbalanced, *e.g.*, if $x_v > x_u$, then u has excess funds while v has none, causing queue build-up at v.

are arriving faster (in both directions) than the channel can process (Fig. 5a) or that one end of the payment channel lacks sufficient funds(Fig. 5b). It indicates that the capacity constraint (Equation 3) or the balance constraint (Equation 4) is being violated and the sender should adjust its sending rate.

Therefore, if senders use a congestion control protocol that controls queues, they could detect both capacity and imbalance violations and react to them. For example, in Fig. 5a, the protocol would throttle both x_u and x_v. In Fig. 5b, it would decrease x_v to match the rate at which queue q_v drains, which is precisely x_u, the rate at which new funds become available at router v.

This illustrates that a congestion controller that satisfies two basic properties can achieve both efficiency and balanced rates:

1. *Keeping queues non-empty,* which ensures that any available capacity is being utilized, *i.e.,* there are no unused tokens at any router.
2. *Keeping queues stable (bounded),* which ensures that (a) the flow rates do not exceed a channel's capacity, (b) the flow rates are balanced. If either condition is violated, then at least one of the channel's queues would grow.

Congestion control algorithms that satisfy these properties abound (*e.g.,* Reno [19], Cubic [35], DCTCP [22], Vegas [27], etc.) and could be adapted for PCNs.

In PCNs, it is desirable to transmit transaction-units along multiple paths to better utilize available capacity. Consequently, Spider's design is inspired by multi-path transport protocols like MPTCP [59]. These protocols couple rate control decisions for multiple paths to achieve both high throughput and fairness among competing flows [58]. We describe an MPTCP-like protocol for PCNs in §6.2–6.3. In §6.4 we show that the rates found by Spider's protocol for parallel network topologies, match the solution to the optimization problem in §5.

6.2 Spider Router Design

Fig. 6 shows a schematic diagram of the various components in the Spider PCN. Spider routers monitor the time that each

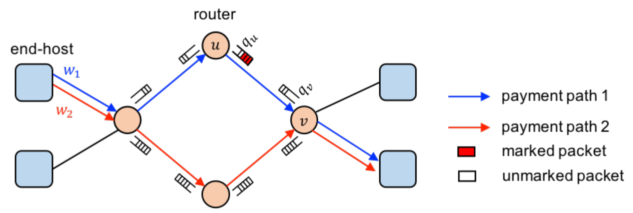


Figure 6: Routers queue up transaction-units and schedule them based on priorities when funds become available. and transaction priorities. If the delay through the queue for a packet exceeds a threshold, they mark the packet. End-hosts maintain and adjust windows for each path to a receiver based on the marks they observe.

packet spends in their queue and mark the packet if the time spent exceeds a pre-determined threshold T. If the transaction-unit is already marked, routers leave the field unchanged and merely forward the transaction-unit. Routers forward acknowledgments from the receiving end-host back to the sender which interprets the marked bit in the ack accordingly. Spider routers schedule transaction-units from their queues according to a scheduling policy, like Smallest-Payment-First or Last-In-First-Out (LIFO). Our evaluations (§7.5) shows that LIFO provides the highest transaction success rate. The idea behind LIFO is to prioritize transaction units from new payments, which are likely to complete within their deadline.

6.3 Spider Transport Layer at End-Hosts

Spider senders send and receive payments on a PCN by interfacing with their transport layer. This layer is configured to support both atomic and non-atomic payments depending on user preferences. Non-atomic payments utilize Spider's packet-switching which breaks up large payments into transaction-units that are delivered to the receiver independently. In this case, senders are notified of how much of the payment was completed allowing them to cancel the rest or retry it on the blockchain. While this approach crucially allows token reuse at bottleneck payment channels for the same transaction (§3), senders also have the option of requesting atomic payments (likely for a higher fee). Our results (§7) show that even with packetization, more than 95% payments complete in full

The transport layer also involves a multi-path protocol which controls the rates at which payments are transferred, based on congestion in the network. For each destination host, a sender chooses a set of k paths to route transaction-units along. The route for a transaction-unit is decided at the sender before transmitting the unit. It is written into the transaction-unit using onion encryption, to hide the full route from intermediate routers [17, 33]. In §7.5, we evaluate the impact of different path choices on Spider's performance and propose using edge-disjoint widest paths [21] between each sender and receiver in Spider.

To control the rate at which payments are sent on a path, end-hosts maintain a window size w_p for every candidate path to a destination. This window size denotes the maximum number of transaction-units that can be outstanding on path p at any point in time. End-hosts track the transaction-units that have been sent out on each path but have not yet been acked or canceled. A new transaction-unit is transmitted on a path p only if the total amount pending does not exceed w_p.

End-hosts adjust w_p based on router feedback on congestion and imbalance. In particular, on a path p between source i and receiver j the window changes as

$$w_p \leftarrow w_p - \beta, \qquad \text{on every marked packet and,} \tag{6}$$

$$w_p \leftarrow w_p + \frac{\alpha}{\sum_{p':p' \in \mathcal{P}_{i,j}} w_{p'}}, \qquad \text{on every unmarked packet.} \tag{7}$$

Here, α and β are both positive constants that denote the aggressiveness with which the window size is increased and decreased respectively. Eq. (6)–(7) are similar to MPTCP, but with a multiplicative decrease factor that depends on the fraction of packets marked on a path (similar to DCTCP [22]).

We expect the application to specify a deadline for every transaction. If the transport layer fails to complete the payment within the deadline, the sender cancels the payment, clearing all of its state from the PCN. In particular, it sends a cancellation message to remove any transaction-units queued at routers on each path to the receiver. Notice that transaction-units that arrive at the receiver in the meantime cannot be unlocked because we assume the sender holds the secret key (§2). Senders can then choose to retry the failed portion of the transaction again on the PCN or on the blockchain; such retries would be treated as new transactions. Canceled packets are considered marked and Spider decreases its window in response to them.

6.4 Optimality of Spider

Under a fluid approximation model for Spider's dynamics, we can show that the rates computed by Spider are an optimal solution to the routing problem in Equations (1)–(5) for parallel networks (such as Fig. 20 in App. B). In the fluid model, we let $x_p(t)$ denote the rate of flow on a path p at time t; for a channel (u,v), $f_{u,v}(t)$ denotes the fraction of packets that are marked at router u as a result of excessive queuing. The dynamics of the flow rates $x_p(t)$ and marking fractions $f_{u,v}(t)$ can be specified using differential equations to approximate the window update dynamics in Equations (6) and (7). We elaborate more on this fluid model, including specifying how the queue sizes and marking fractions evolve, in App. B.

Now, consider the routing optimization problem (Equations (1)–(5)) written in the context of a parallel network. If Spider is used on this network, we can show that there is a mapping from the rates $\{x_p\}$ and marking fractions $\{f_{u,v}\}$ values after convergence, to the primal and dual variables of the optimization problem, such that the Karush-Kuhn-Tucker (KKT) conditions for the optimization problem are satisfied. This proves that the set of rates found by Spider is an optimal solution to the optimization problem [26]. The complete and formal mathematical proof showing the above is presented in App. B.

7 Evaluation

We develop an event-based simulator for PCNs, and use it to extensively evaluate Spider across a wide range of scenarios. We describe our simulation setup (§7.1), validate it via a prototype implementation (§7.2), and present detailed results for circulation demands (§7.3). We then show the effect of adding DAG components to circulations (§7.4), and study Spider's design choices (§7.5).

7.1 Experimental Setup

Simulator. We extend the OMNET++ simulator (v5.4.1) [1] to model a PCN. Our simulator accurately models the network-wide effects of transaction processing, by explicitly passing messages between PCN nodes (endhosts and routers).[4] Each endhost (i) generates transactions destined for other endhosts as per the specified workload, and (ii) determines when to send a transaction and along which path, as per the specified routing scheme. All endhosts maintain a view of the entire PCN topology, to compute suitable source-routes. The endhosts can't view channel balances, but they do know each channel's size or total number of tokens (€). Endhosts also split generated transactions into MTU-sized segments (or transaction-units) before routing, if required by the routing scheme (e.g. by Spider). Each generated transaction has a *timeout* value and is marked as a failure if it fails to reach its destination by then. Upon receiving a transaction, an endhost generates an acknowledgment that is source-routed along its reverse path.

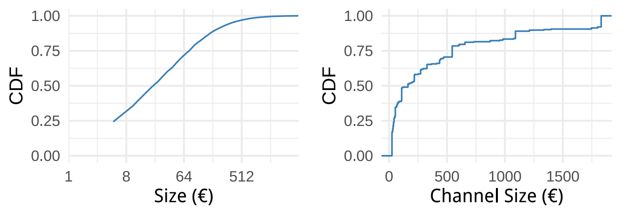
A router forwards incoming transactions and acknowledgments along the payment channels specified in their route, while correspondingly decrementing or incrementing the channel balances. Funds consumed by a transaction in a channel are *inflight* and unavailable until its acknowledgment is received. A transaction is forwarded on a payment channel only if the channel has sufficient balance; otherwise the transaction is stored in a *per-channel queue* that is serviced in a last in first out (LIFO) order §7.5. If the queue is full, an incoming transaction is dropped, and a failure message is sent to the sender.
Routing Schemes. We implement and evaluate five different routing schemes in our simulator.
(1) Spider: Every Spider sender maintains a set of up to k edge-disjoint widest paths to each destination and a window size per path. The sender splits transactions into transaction-units and sends a transaction-unit on a path if the path's window is larger than amount inflight on the path. If a transaction-unit cannot be sent, it is placed in a per-destination queue at the sender that is served in LIFO order. Spider routers mark transaction-units experiencing queuing delays higher than a pre-determined threshold. Spider receivers echo the mark back to senders who adjust the window size according to the equations in §6.3.

[4]https://github.com/spider-pcn/spider-omnet

(2) Waterfilling: Waterfilling uses balance information explicitly in contrast to Spider's 1-bit feedback. As with Spider, a sender splits transactions into transaction-units and picks up to k edge-disjoint widest paths per destination. It maintains one outstanding probe per path that computes the bottleneck (minimum) channel balance along it. When a path's probe is received, the sender computes the available balance based on its bottleneck and the in-flight transaction-units. A transaction-unit is sent along the path with the highest available balance. If the available balance for all of the k paths is zero (or less), the transaction-unit is queued and retried after the next probe.
(3) Shortest Path: This baseline sends transactions along the shortest path to the destination without transaction splitting.
(4) Landmark Routing: Landmark routing, as used in prior PCN routing schemes [42, 47, 50], chooses k well-connected *landmark* nodes in the topology. For every transaction, the sender computes its shortest path to each landmark and concatenates it with the shortest path from that landmark to the destination to obtain k distinct paths. Then, the sender probes each path to obtain its bottleneck balance, and partitions the transaction such that each path can support its share of the total transaction. If such a partition does not exist or if any of the partitions fail, the transaction fails.
(5) LND: The PCN scheme currently deployed in the Lightning Network Daemon (LND) [15] attempts first send a transaction along the shortest path to its destination. If the transaction fails due to insufficient balance at a channel, the sender removes that channel from its local view, recomputes the shortest path, and retries the transaction on the new path until the destination becomes unreachable or the transaction times out. A channel is added back to the local view 5 seconds after its removal.
(6) Celer: App. C.1 compares Spider to Celer's cRoute as proposed in a white-paper [11]. Celer is a back-pressure routing algorithm that routes transactions based on queue and imbalance gradients. Due to computation overheads associated with Celer's large queues, we evaluate it on a smaller topology.
Workload. We generate two forms of payment graphs to specify the rate at which a sender transacts with every other receiver: (i) pure circulations, with a fixed total sending rate x per sender generated by adding x random permutation matrices; (ii) circulations with a DAG component, having a total rate y generated by sampling y different sender-receiver pairs where senders and receivers are chosen from two separate exponential distributions. The distribution's skew is set proportional to the desired DAG component in the total traffic matrix.

We translate the rates from the payment graph to discrete transactions with a Poisson arrival process The transaction size distribution (Fig. 7a) is drawn from credit card transaction data [34], and has a mean of 88€ and median 25€ with the largest transaction being 3930€. Each sender sends 30 tx/sec on average shared across 10 destinations. Note that a sender represents a router in our setup, sending transactions to other routers on behalf of many users.
Topology. We set up an LND node [15] to retrieve the Lightning Network topology on July 15, 2019. We snowball sample [36] the full topology (which has over 5000 nodes and 34000 edges), resulting in a PCN with 106 nodes and 265 payment channels. For compatibility with our transaction dataset, we convert LND payment channel sizes from Satoshis to €, and set the minimum channel size to the median transaction size of 25€. The distribution of channel sizes for this topology has a mean and median size of 421€ and 163€ respectively (Fig. 7b). This distribution is highly skewed, resulting in a mean that is much larger than the median or the smallest payment channels. We refer to this distribution as the Lightning Channel Size Distribution (LCSD). We draw channel propagation delays based on ping times from our LND node to all reachable nodes in the Lightning Network, resulting in RTTs of about a second.

We additionally simulate two synthetic topologies: a Watts-Strogatz small world topology [20] with 50 nodes and 200 edges, and a scale-free Barabasi-Albert graph [4] with 50 nodes and 336 edges. We set the per-hop delay to 30ms in both cases, resulting in RTTs of 200-300ms. For payment channel sizes, we use real capacities in the Lightning topology and sample capacities from LCSD for synthetic topologies. We vary the mean channel size across experiments by proportionally scaling up the size of each payment channel. All payment channels are initialized with perfect balance.
Parameters. We set the MTU as 1€. Every transaction has a timeout of 5 seconds. Schemes with router queues enabled have a per-channel queue size of 12000€. The number of path choices is set to $k = 4$ for schemes that use multiple paths. We vary both the number of paths and the nature of paths in §7.5. For Spider, we set α (window increase factor) to 10, β (multiplicative decrease factor) to 0.1, and the marking threshold for the queue delay to 300ms. For the experiments in §7.4, we set this threshold to 75ms to for faster response to congestion.
Metrics. We use the following evaluation metrics: (i) *transaction success ratio:* the number of completed transactions over the number of generated transactions. A packetized transaction is complete when all of its transaction-units are successful, (ii) *normalized throughput:* the total amount of payments (in €) completed over the total amount of payments generated, (iii) *transaction latency*: time between arrival and completion for successful transactions, and (iv) *offload factor*: number of transactions offloaded to the PCN for every on-chain transaction. All of these metrics are computed over a measurement



(a) Transaction Size Distribution (b) LN Channel Size Distribution

Figure 7: Transaction dataset and channel size distribution used for real-world evaluations.

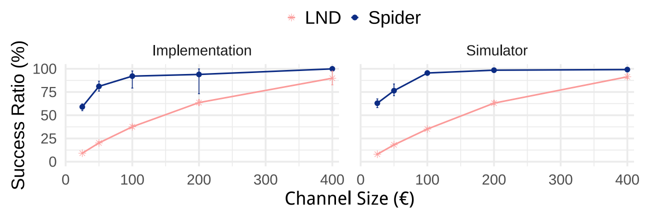


Figure 8: Comparison of performance on simulator and implementation for LND and Spider on a 10 node scale-free topology with 1€ transactions. Spider outperforms LND in both settings. Further, the average success ratio on the simulator and implementation for both schemes are within 5% of each other.

interval when all schemes are in steady-state. Unless specified otherwise, we use a measurement interval of 800-1000s, run experiments for 1010s, and denote the maximum and minimum statistic across five runs using error-bars.

7.2 Prototype Implementation

To support Spider, we modify the Lightning Network Daemon (LND) [15] which is currently deployed on the live Bitcoin Network. We repurpose the router queues to queue up transactions (or HTLCs) that cannot be immediately serviced. When a transaction spends more than 75ms in the queue, Spider marks it. The marking is echoed back via an additional field in the transaction acknowledgement (`FulfillHTLC`) to the sender. We maintain a per-receiver state at the sender to capture the window and number inflight on each path, as well as the queue of unattempted transactions. Each sender finds 4 edge-disjoint shortest paths to every destination. We do not implement transaction-splitting.

We deploy our modified LND implementation [15] on Amazon EC2's `c5d.4xlarge` instances with 16 CPU cores, 16 GB of RAM, 400 GB of NVMe SSD, and a 10 Gbps network interface. Each instance hosts one end-host and one router. Every LND node is run within a docker container with a dedicated bitcoin daemon [6]. We create our own regtest [8] blockchain for the nodes. Channels are created corresponding to a scale-free graph with 10 nodes and 25 edges. We vary the mean channel size from 25€ to 400€. Five circulation payment graphs are generated with each sender sending 100 tx/s (each 1€). Receiving nodes communicate invoices via etcd [13] to sending nodes who then complete them using the appropriate scheme. We run LND and Spider on the implementation and measure the transaction RTTs to inform propagation delays on the simulator. We then run the same experiments on the simulator.

Fig. 8 shows the average success ratio that Spider and LND achieve on the implementation and the simulator. There are two takeaways: (i) Spider outperforms LND in both settings and, (ii) the average success ratio on the simulator is within 5% of the implementation for both schemes. Our attempts at running experiments at larger scale showed that the LND codebase is not optimized for high throughput. For example, persisting HTLC state on disk causes IO bottlenecks and variations of tens of seconds in transaction latencies even on small topologies. Given the fidelity and flexibility of the simulator, we chose to use it for the remaining evaluations.

7.3 Circulation Payment Graph Performance

Recall that on circulation payment graphs, *all* the demand can theoretically be routed if there is sufficient capacity (§5.1 and App. A). However, the capacity at which a routing scheme attains 100% throughput depends on the scheme's ability to balance channels: the more balanced a scheme is, the less capacity it needs for high throughput.

Efficiency of Routing Schemes. We run five circulation traffic matrices on our three topologies (§7.1). Notice that the channel sizes are much larger on the Lightning Topology compared to the other two due to the highly skewed nature of capacities (Fig. 7b). We measure success ratio for the transactions across different channel sizes. Fig. 9 shows that on all topologies, Spider outperforms the state-of-the-art schemes. Spider successfully routes more than 95% of the transactions with less than 25% of the capacity required by LND. At lower capacities, Spider completes 2-3$\times$ more transactions than LND. This is because Spider maintains balance in the network by responding quickly to queue buildup at payment channels, thus making better use of network capacity. The explicit balance-aware scheme, Waterfilling, also routes more transactions than LND. However, when operating in low capacity regimes, where many paths are congested and have near-zero available balance, senders are unable to use just balance information to differentiate paths. As a result, Waterfilling's performance degrades at low capacity compared to Spider which takes into account queuing delays.

Size of Successful Payments. Spider's benefits are most pronounced at larger transaction sizes, where packetization and congestion control helps more transactions complete. Fig. 10 shows success ratio as a function of transaction size. We use mean channel sizes of 4000€ and 16880 € for the synthetic and real topologies, respectively. Each shaded region denotes a different range of transaction sizes, each corresponding to about 12.5% of the transactions in the workload. A point within a range represents the average success ratio for transactions in that interval across 5 runs. Spider outperforms LND across all sizes, and is able to route 5-30% more of the largest transactions compared to LND.

Impact on Latency. We anticipate Spider's rate control mechanism to increase latency. Fig. 11 shows the average and 99th percentile latency for successful transactions on the Lightning topology as a function of transaction size. Spider's average and tail latency increase with transaction size because larger transactions are multiplexed over longer periods of time. However, the tail latency increases much more than the average because of the skew in channel sizes in the Lightning topology: most transactions use large channels while a few unfortunate large transactions need more time to reuse tokens from smaller channels. Yet, the largest Spider transactions experience at most 2 seconds of additional delay when

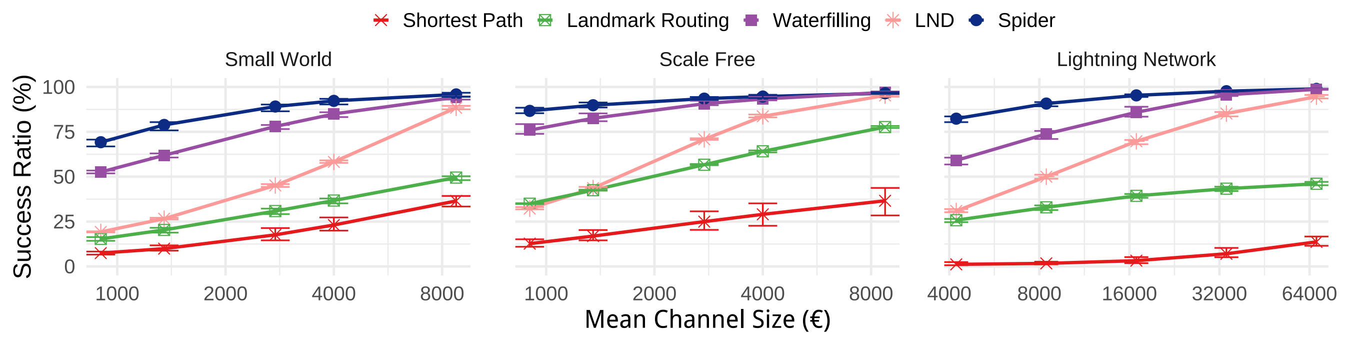

Figure 9: Performance of different algorithms on small-world, scale-free and Lightning Network topologies, for different per sender transaction arrival rates. Spider consistently outperforms all other schemes achieving near 100% average success ratio. Note the log scale of the x-axes.

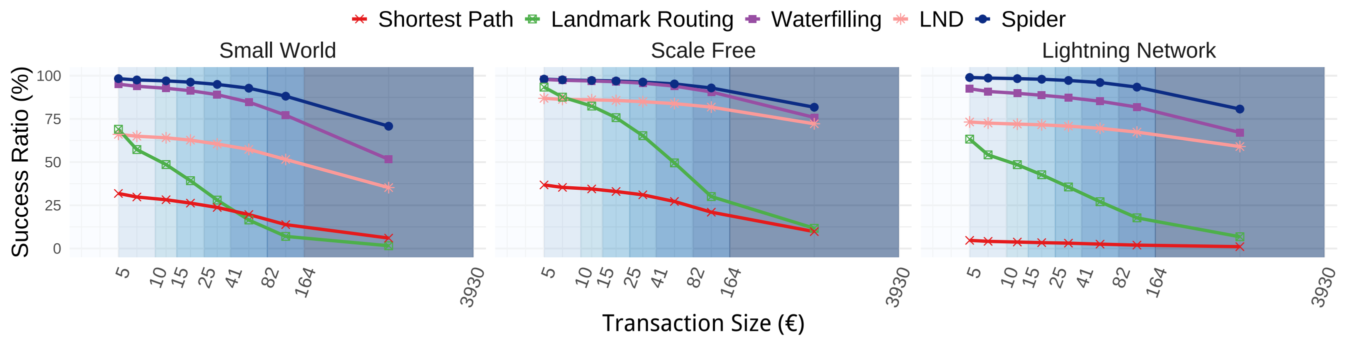

Figure 10: Breakdown of performance of different schemes by size of transactions completed. Each point reports the success ratio for transactions whose size belongs to the interval denoted by the shaded region. Each interval corresponds roughly to a 12.5% weight in the transaction size CDF shown in Fig. 7a. The graphs correspond to the midpoints of the corresponding Lightning sampled channel sizes in Fig. 9.

compared to LND, a small hit relative to the 20% increase in overall success ratio at a mean channel size of 16880€. LND's latency also increases with size since it retries transactions, often upto 10 times until it finds a single path with enough capacity. In contrast, Landmark Routing and Shortest path are size-agnostic in their path-choice for transactions.

Waterfilling pauses transactions when there is no available balance and resumes sending when balance becomes available. Small transactions are unlikely to be paused in their lifetime while mid-size transactions are paused a few times before they complete. In contrast, large transactions are likely to be paused many times, eventually getting canceled if paused too much. This has two implications: (i) the few large transactions that are successful with Waterfilling are not paused much and contribute smaller latencies than mid-size transactions, and (ii) Waterfilling's conservative pause and send mechanism implies there is less contention for the large transactions that are actually sent into the network, leading to smaller latencies than what they experience with Spider.

7.4 Effect of DAGs

Real transaction demands are often not pure circulations: consumer nodes spend more, and merchant nodes receive

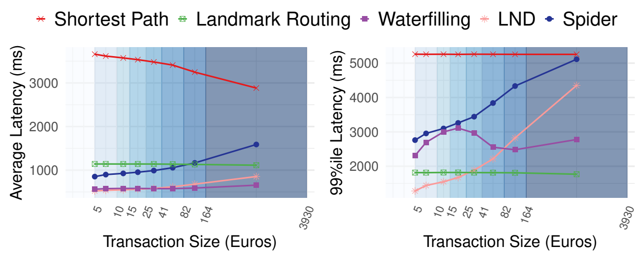

Figure 11: Average and 99%ile transaction latency for different routing schemes on the Lightning topology. Transactions experience 1-2s of additional latency with Spider relative to LND for a 20% improvement in throughput.

more. To simulate this, we add 5 DAG payment graphs (§7.1) to circulation payment graphs, varying the relative weight to generate effectively 5%, 20% and 40% DAG in the total demand matrix. We run all schemes on the Lightning topology with a mean channel size of 16880€; results on the synthetic topologies are in App. C.4.

Fig. 12 shows the success ratio and normalized throughput. We immediately notice that no scheme achieves the theoretical upper bound on throughput (i.e., the % circulation demand). However, throughput is closer to the bound when there is a smaller DAG component in the demand matrix. This suggests

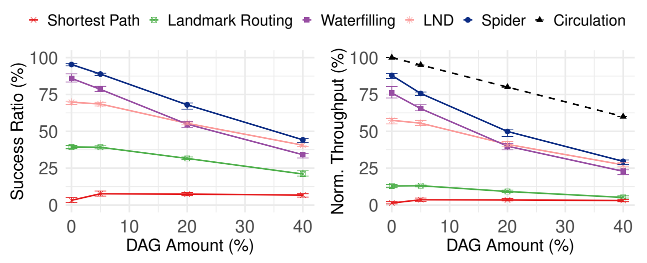

Figure 12: Performance of different algorithms on the Lightning topology as the DAG component in the transaction demand matrix is varied. As the DAG amount is increased, the normalized throughput achieved is further away from the expected optimal circulation throughput.

that not only is the DAG itself unroutable, it also alters the PCN balances in a way that prevents the circulation from being fully routed. Further, the more DAG there is, the more affected the circulation is. This is because the DAG causes a deadlock (§3).

To illustrate this, we run two scenarios: (i) a pure circulation demand X for 3000s, and (ii) a traffic demand $(X+Y)$ containing 20% DAG for 2000s followed by the circulation X for 1000s after that. Here, each sender sends 200€/s of unit-sized transactions in X. We observe a time series of the normalized throughput over the 3000s. The mean channel size is 4000€ and 16990€ for the synthetic and real topologies respectively.

Fig. 13 shows that Spider achieves 100% throughput (normalized by the circulation demand) at steady state for the pure circulation demand on all topologies. However, when the DAG component is introduced to the demand, it affects the topologies differently. Firstly, we do not observe the expected 80% throughput for the circulation in the presence of the DAG workload suggesting that the DAG affects the circulation. Further, even once the circulation demand is restored for the last 1000s, in the scale free and Lightning Network topology, the throughput achieved is no longer 100%. In other words, in these two topologies, the DAG causes a deadlock that affects the circulation even after the DAG is removed.

As described in §3, the solution to this problem involves replenishing funds via on-chain rebalancing, since DAG demands continuously move money from sources to sinks. We therefore implement a simple rebalancing scheme where every router periodically reallocates funds between its payment channels to equalize their *available balance*. The frequency of rebalancing for a router, is defined by the number of successful transaction-units (in €) between consecutive rebalancing events. In this model, the frequency captures the on-chain rebalancing cost vs. routing fee trade-off for the router.

Fig. 14 shows the success ratio and normalized throughput achieved by different schemes when rebalancing is enabled for the traffic demand with 20% DAG from Fig. 12, or Fig. 13. Spider is able to achieve 90% success ratio even when its routers rebalance only every 10,000€ routed while LND is never able to sustain more than 85% success ratio even when rebalancing for every 10€ routed. This is because LND deems

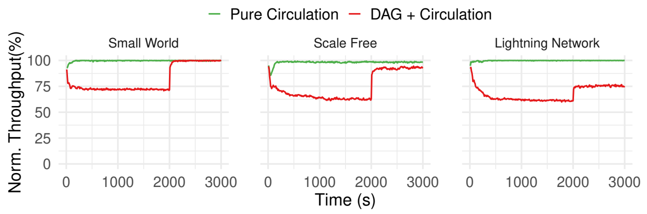

Figure 13: Comparing throughput when a pure circulation demand is run for 3000s to a scenario where a circulation demand is restored for 1000s after 2000s of a demand with 20% DAG. The throughput achieved on the last 1000s of circulation is not always the expected 100% even after the DAG is removed.

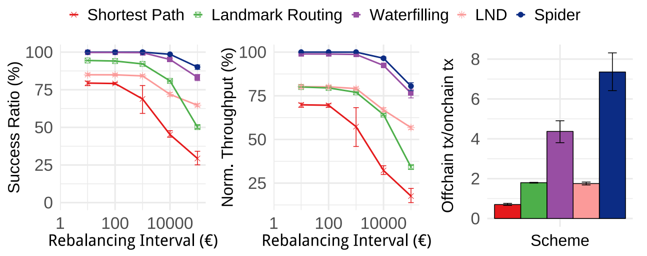

Figure 14: Performance of different algorithms on the Lightning topology when augmented with on-chain rebalancing. Spider needs less frequent rebalancing to sustain high throughput. Spider offloads 3-4x more transactions onto a PCN per blockchain transaction than LND.

a channel unusable for 5 seconds every time a transaction fails on it due to lack of funds and this is further worsened by its lack of transaction splitting. This implies that when using Spider, routers need to pay for only one on-chain transaction typically costing under 1€ [7] for every 10,000€ routed. Thus, for a router to break even, it would have to charge 1€ for every 10000€ routed. This translates into significantly lower routing fees for end-users than today's payment systems [12]. Fig. 14 also captures the same result in the form of the best offloading or number of off-chain PCN transactions per blockchain transaction achieved by each algorithm. Transactions that fail on the PCN as well as rebalancing transactions are counted towards the transactions on the blockchain. Spider is able to route 7-8 times as many transactions off-chain for every blockchain transaction, a 4x improvement from the state-of-the-art LND.

7.5 Spider's Design Choices

In this section, we investigate Spider's design choices with respect to the number of paths, type of paths, and the scheduling algorithm that services transaction-units at Spider's queues. We evaluate these on both the real and synthetic topologies with channel sizes sampled from the LCSD, and scaled to have mean of 16880€ and 4000 € respectively .

Choice of Paths. We vary the type of paths that Spider uses by replacing edge-disjoint widest paths with edge-disjoint shortest paths, Yen's shortest paths [60], oblivious paths [48] and

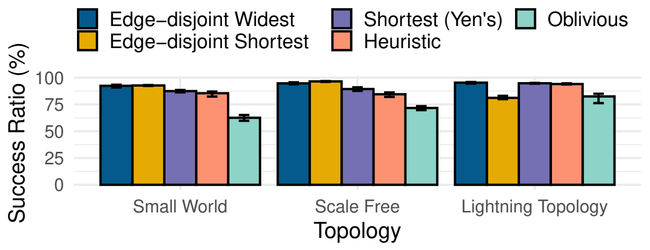

Figure 15: Performance of Spider as the type of paths considered per sender-receiver pair is varied. Edge-disjoint widest outperforms others by 1-10% on the Lightning Topology without being much worse on the synthetic topologies.

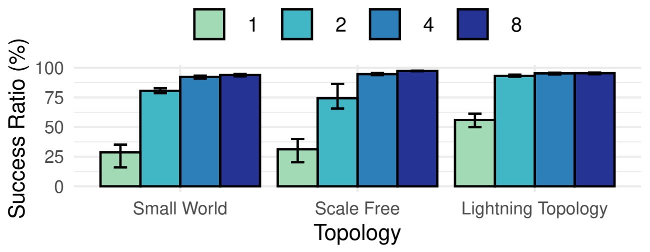

Figure 16: Performance of Spider as the number of edge-disjoint widest paths considered per sender-receiver pair is varied on different topologies. Increasing the number of paths increases success ratio, but the gains are low in going from 4 to 8 paths.

a heuristic approach. For the widest and oblivious path computations, the channel size acts as the edge weight. The heuristic picks 4 paths for each flow with the highest bottleneck balance/RTT value. Fig. 15 shows that edge-disjoint widest paths outperforms other approaches by 1-10% on the Lightning Topology while being only 1-2% worse that edge-disjoint shortest paths on the synthetic topologies. This is because widest paths are able to utilize the capacity of the network better when there is a large skew (Fig. 7b) in payment channel sizes.

Number of Paths. We vary the maximum number of edge-disjoint widest paths Spider allows from 1 to 8. Fig. 16 shows that, as expected, the success ratio increases with an increase in number of paths, as more paths allow Spider to better utilize the capacity of the PCN. While moving from 1 to 2 paths results in 30-50% improvement in success ratio, moving from 4 to 8 paths has negligible benefits (<5%). This is because the sparseness of the three PCN topologies causes most flows to have at most 5-6 edge-disjoint widest paths. Further, Spider prefers paths with smaller RTTs since they receive feedback faster resulting in the shortest paths contributing most to the overall rate for the flow. As a result, we use 4 paths for Spider.

Scheduling Algorithms. We modify the scheduling algorithm at the per-destination queues at the sender as well as the router queues in Spider to process transactions as per First-In-First-Out (FIFO), Earliest-Deadline-First (EDF) and Smallest-Payment-First (SPF) in addition to the LIFO baseline. Fig. 17 shows that LIFO achieves a success ratio that is 10-28% higher than its counterparts. This is because

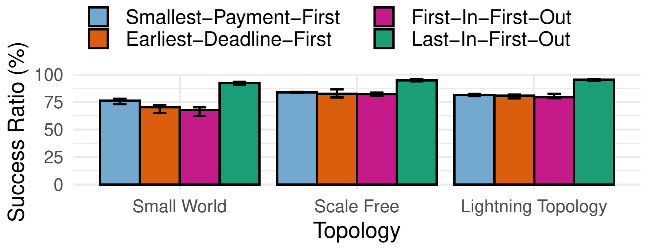

Figure 17: Performance of Spider as the scheduling algorithm at the sender and router queues is varied. Last in first out outperforms all other approaches by over 10% on all topologies.

LIFO prioritizes transactions that are newest or furthest from their deadlines and thus, most likely complete especially when the PCNs is overloaded. Spider's rate control results in long wait times in the sender queues themselves. This causes FIFO and EDF that send out transactions closest to their deadlines to time out immediately in the network resulting in poor throughput. When SPF deprioritizes large payments at router queues, they consume funds from other payment channels for longer, reducing the effective capacity of the network.

7.6 Additional Results

In addition to the results described so far, we run additional experiments that are described in the Appendices.

1. We compare Spider to Celer, as proposed in a white-paper [11], and show that Spider outperforms Celer's success ratio by 2x on a scale free topology with 10 nodes and 25 edges (App. C.1).
2. We evaluate the schemes on the synthetic and real topologies with a simpler channel size distribution where all channels have equal numbers of tokens. Even in this scenario, Spider is able to successfully route more than 95% of the transactions with less than 25% of the capacity required by LND (App. C.2).
3. We evaluate the schemes for their fairness across multiple payments and show that Spider does not hurt small payments to gain on throughput (App. C.3).
4. We show the effect of DAG workloads on synthetic topologies. In particular, we identify deadlocks with those topologies too and show that Spider requires rebalancing only every 10,000€ successfully routed to sustain high success ratio and normalized throughput (App. C.4).

8 Related Work

PCN Improvements. Nodes in current Lightning Network implementations, maintain a local view of the network topology and source-route transactions along the shortest path [2, 15]. Classical max-flow-based alternatives are impractical for the Lightning Network that has over 5000 nodes and 30,000 channels [9, 16] due to their computational complexity. Recent proposals have used a modified version of max-flow that differentiates based on the size of transactions [57]. However, inferring the size of payments is hard in an onion-routed network like Lightning.

Two main alternatives to max-flow routing have been proposed: landmark routing and embedding-based routing. In *landmark routing*, select routers (landmarks) store routing tables for the rest of the network, and nodes only route transactions to a landmark [55]. This approach is used in Flare [47] and SilentWhispers [42, 44]. *Embedding-based* or *distance-based* routing learns a vector embedding for each node, such that nodes that are close in network hop distance are also close in embedded space. Each node relays each transaction to the neighbor whose embedding is closest to the destination's embedding. VOUTE [49] and SpeedyMurmurs [50] use embedding-based routing. Computing and updating the embedding dynamically as the topology and link balances change is a primary challenge of these approaches. Our experiments and prior work [51] show that Spider outperforms both approaches.

PCN improvements outside of the routing layer focus on rebalancing existing payment channels more easily [28, 39]. Revive [39] leverages cycles within channels wanting to rebalance and initiates balancing off-chain payments between them. These techniques are complementary to Spider and can be used to enhance overall performance. However, §7.4 shows that a more general rebalancing scheme that moves funds at each router independently fails to achieve high throughput without a balanced routing scheme.

Utility Maximization and Congestion Control. Network Utility Maximization (NUM) is a popular framework for developing decentralized transport protocols in data networks to optimize a fairness objective [37]. NUM uses link "prices" derived from the solution to the utility maximization problem, and senders compute rates based on these router prices. Congestion control algorithms that use buffer sizes or queuing delays as router signals [22,30,53] are closely related. While the Internet congestion control literature has focused on links with fairly stable capacities, this paper shows that they can be effective even in networks with capacities dependent on the input rates themselves. Such problems have also been explored in the context of ride-sharing, for instance [24, 25], and require new innovation in both formulating and solving routing problems.

9 Conclusion

We motivate the need for efficient routing on PCNs and propose Spider, a protocol for balanced, high-throughput routing in PCNs. Spider uses a packet-switched architecture, multi-path congestion control, and and in-network scheduling. Spider achieves nearly 100% throughput on circulation payment demands across both synthetic and real topologies. We show how the presence of DAG payments causes deadlocks that degrades circulation throughput, necessitating on-chain intervention. In such scenarios, Spider is able to support 4x more transactions than the state-of-the-art on the PCN itself.

This work shows that Spider needs less on-chain rebalancing to relieve deadlocked PCNs. However, it remains to be seen if deadlocks can be prevented altogether. Spider relies on routers signaling queue buildup correctly to the senders, but this work does not analyze incentive compatibility for rogue routers aiming to maximize fees. A more rigorous treatment of the privacy implications of Spider routers relaying queuing delay is left to future work.

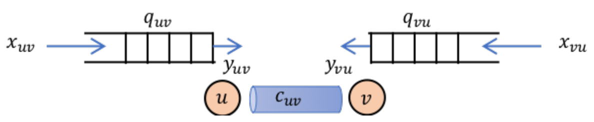

Figure 19: Model of queues at a payment channel between nodes u and v. x_{uv} and y_{uv} denote the rates at which transaction-units for v arrive into and get serviced at the queue at u respectively. c_{uv} is the capacity of the payment channel and q_{uv} denotes the total number of transaction-units waiting in u's queue to be serviced.

Appendices

A Circulations and Throughput Bounds

For a network $G(V,E)$ with set of routers V, we define a *payment graph* $H(V,E_H)$ as a graph that specifies the payment demands between different users. The weight of any edge (i,j) in the payment graph is the average rate at which user i seeks to transfer funds to user j. A *circulation graph* $C(V,E_C)$ of a payment graph is any subgraph of the payment graph in which the weight of an edge (i,j) is at most the weight of (i,j) in the payment graph, and moreover the total weight of incoming edges is equal to the total weight of outgoing edges for each node. Of particular interest are *maximum circulation graphs* which are circulation graphs that have the highest total demand (i.e., sum of edge weights), among all possible circulation graphs. A maximum circulation graph is not necessarily unique for a given payment graph.

Proposition 1. *Consider a payment graph H with a maximum circulation graph C^*. Let $\nu(C^*)$ denote the total demand in C^*. Then, on a network in which each payment channel has at least $\nu(C^*)$ units of escrowed funds, there exists a balanced routing scheme that can achieve a total throughput of $\nu(C^*)$. However, no balanced routing scheme can achieve a throughput greater than $\nu(C^*)$ on any network.*

Proof. Let $w_{C^*}(i,j)$ denote the payment demand from any user i to user j in the maximum circulation graph C^*. To see that a throughput of $\nu(C^*)$ is achievable, consider routing the circulation demand along the shortest paths of any spanning tree T of the payment network G. In this routing, for any pair of nodes $i,j \in V$ there exists a unique path from i to j in T through which $w_{C^*}(i,j)$ amount of flow is routed. We claim that such a routing scheme is perfectly balanced on all the links. This is because for any partition $S,V\backslash S$ of C^*, the net flow going from S to $V\backslash S$ is equal to the net flow going from $V\backslash S$ to S in C^*. Since the flows along an edge e of T correspond precisely to the net flows across the partitions obtained by removing e in T , it follows that the flows on e are balanced as well. Also, for any flow (i,j) in the demand graph C^*, the shortest path route from i to j in T can cross an edge e at most once. Therefore the total amount of flow going through an edge is at most the total amount of flow in C^*, which is $\nu(C^*)$.

Next, to see that no balanced routing scheme can achieve a throughput greater than $\nu(C^*)$, assume the contrary and suppose there exists a balanced routing scheme SCH with a throughput greater than $\nu(C^*)$. Let $H_{\texttt{SCH}} \subseteq H$ be a payment graph where the edges represent the portion of demand that is actually routed in SCH. Since $\nu(H_{\texttt{SCH}}) > \nu(C^*)$, $H_{\texttt{SCH}}$ is not a circulation and there exists a partition $S,V\backslash S$ such that the net flow from S to $V\backslash S$ is strictly greater than the net flow from $V\backslash S$ to S in $H_{\texttt{SCH}}$. However, the net flows routed by SCH across the same partition $S,V\backslash S$ in G are balanced (by assumption) resulting in a contradiction. Thus we conclude there does not exist any balanced routing scheme that can achieve a throughput greater than $\nu(C^*)$. □

B Optimality of Spider

B.1 Fluid Model

In this section we describe a fluid model approximation of the system dynamics under Spider's protocol. Following a similar notation as in §5, for a path p we let $x_p(t)$ denote the rate of flow on it at time t. For a channel (u,v) and time t, let $q_{u,v}(t)$ be the size of the queue at router u, $f_{u,v}(t)$ be the fraction of incoming packets that are marked at u, $x_{u,v}(t)$ be the total rate of incoming flow at u, and $y_{u,v}(t)$ be the rate at which transactions are serviced (*i.e.,* forwarded to router v) at u. All variables are real-valued. We approximate Spider's dynamics via the following system of equations

$$\dot{x}_p(t) = \left[\frac{x_p(t)}{\sum_{p' \in \mathcal{P}_{i_p,j_p}} x_{p'}(t)} - \sum_{(u,v)\in p} f_{u,v}(t) x_p(t) \right]^+_{x_p(t)} \quad \forall p \in \mathcal{P} \tag{8}$$

$$\dot{q}_{u,v}(t) = [x_{u,v}(t) - y_{u,v}(t)]^+_{q_{u,v}(t)} \quad \forall (u,v) \in E \tag{9}$$

$$\dot{f}_{u,v}(t) = [q_{u,v}(t) - q_{\text{thresh}}]^+_{f_{u,v}(t)} \quad \forall (u,v) \in E, \tag{10}$$

where $y_{u,v}(t) = y_{v,u}(t) =$

$$\begin{cases} \frac{c_{u,v}}{2\Delta} & \text{if } q_{u,v}(t) > 0 \;\&\; q_{v,u}(t) > 0 \\ \min\{\frac{c_{u,v}}{2\Delta}, x_{v,u}(t)\} & \text{if } q_{u,v}(t) > 0 \;\&\; q_{v,u}(t) = 0 \\ \min\{\frac{c_{u,v}}{2\Delta}, x_{u,v}(t)\} & \text{if } q_{u,v}(t) = 0 \;\&\; q_{v,u}(t) > 0 \\ \min\{\frac{c_{u,v}}{2\Delta}, x_{u,v}(t), x_{v,u}(t)\} & \text{if } q_{u,v}(t) = 0 \;\&\; q_{v,u}(t) = 0 \end{cases} \tag{11}$$

for each $(u,v) \in E$. Let i_p and j_p denote the source and destination nodes for path p respectively. Then, $\mathcal{P}_{i_p,j_p}$ denotes the set of all paths i_p uses to route to j_p. Equation (8) models how the rate on a path p increases upon receiving successful acknowledgements or decreases if the packets are marked, per Equations (6) and (7) in §6.3. If the fraction of packets marked at each router is small, then the aggregate fraction of packets that return marked on a path p can be approximated by the sum $\sum_{(u,v)\in p} f_{u,v}$ [52]. Hence the rate which marked packets arrive for a path p is $\sum_{(u,v)\in p} f_{u,v} x_p$. Similarly, the rate which successful acknowledgements are received on a path p is $x_p(1 - \sum_{(u,v)\in p} f_{u,v})$, which can be approximated as simply x_p if the marking fractions are small. Since Spider increases the window by $1/(\sum_{p'\in\mathcal{P}_{i_p,j_p}} w_{p'})$ for each successful acknowledgement received, the average rate at which x_p increases is $x_p/(\sum_{p'\in\mathcal{P}_{i_p,j_p}} x_{p'})$. Lastly, the rate x_p cannot become negative; so if $x_p = 0$ we disallow $\dot{x}_p$ from being negative. The notation $(x)_y^+$ means x if $y > 0$ and 0 if $y = 0$.

Equations (9) and (10) model how the queue sizes and fraction of packets marked, respectively, evolve at the routers. For a router u in payment channel (u,v), by definition $y_{u,v}$ is the rate at which transactions are serviced from the queue $q_{u,v}$, while transactions arrive at the queue at a rate of $x_{u,v}$ (Figure 19). Hence the net rate at which $q_{u,v}$ grows is given by the difference $x_{u,v} - y_{u,v}$. The fraction of packets marked at a queue grows if the queue size is larger than a threshold q_{thresh}, and drops otherwise, as in Equation (10). This approximates the marking model of Spider (§6.2) in which packets are marked at a router if their queuing delay exceeds a threshold.

To understand how the service rate $y_{u,v}$ evolves (Equation (11)), we first make the approximation that the rate at which transactions are serviced from the queue at a router u is equal to the rate at which tokens are replenished at the router, *i.e.*, $y_{u,v} = y_{v,u}$ for all $(u,v) \in E$. The precise value for $y_{u,v}$ at any time, depends on both the arrival rates and current occupancy of the queues at routers u and v. If both $q_{u,v}$ and $q_{v,u}$ are non-empty, then there are no surplus of tokens available within the channel. A token when forwarded by a router is unavailable for Δ time units, until its acknowledgement is received. Therefore the maximum rate at which tokens on the channel can be forwarded is $c_{u,v}/\Delta$, implying $y_{u,v} + y_{v,u} = c_{u,v}$ or $y_{u,v} = y_{v,u} = c_{u,v}/(2\Delta)$ in this case. If $q_{u,v}$ is non-empty and $q_{v,u}$ is empty, then there are no surplus tokens available at u's end. Router v however may have tokens available, and service transactions at the same rate at which they are arriving, *i.e.*, $y_{v,u} = x_{v,u}$. This implies tokens become available at router u at a rate of $x_{v,u}$ and hence $y_{u,v} = x_{v,u}$. However, if the transaction arrival rate $x_{v,u}$ is too large at v, it cannot service them at a rate more than $c_{u,v}/(2\Delta)$ and a queue would start building up at $q_{v,u}$. The case where $q_{u,v}$ is empty and $q_{v,u}$ is non-empty follows by interchanging the variables u and v in the description above. Lastly, if both $q_{u,v}$ and $q_{v,u}$ are empty, then the service rate $y_{u,v}$ can at most be equal to the arrival rate $x_{v,u}$. Similarly $y_{v,u}$ can be at most $x_{u,v}$. Since $y_{u,v} = y_{v,u}$ by our approximation, we get the expression in Equation (11).

We have not explicitly modeled delays, and have made simplifying approximations in the fluid model above. Nevertheless this model is useful for gaining intuition about the first-order behavior of the Spider protocol. In the following section, we use this model to show that Spider finds optimal rate allocations for a parallel network topology.

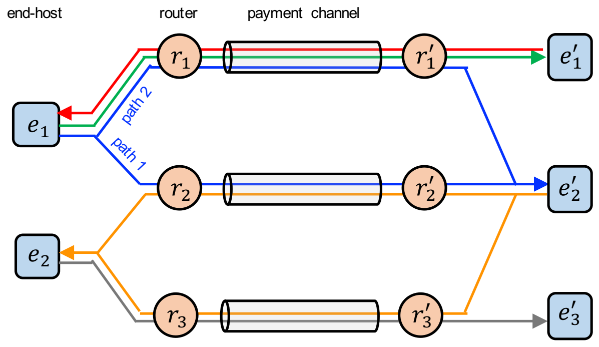

Figure 20: Example of a parallel network topology with bidirectional flows on each payment channel.

B.2 Proof of Optimality

Consider a PCN comprising of two sets of end-hosts $\{e_1,\ldots,e_m\}$ and $\{e'_1,\ldots,e'_n\}$ that are connected via k parallel payment channels $(r_1,r'_1),\ldots,(r_k,r'_k)$ as shown in Figure 20. The end-hosts from each set have demands to end-hosts on the other set. The end-hosts within a set, however, do not have any demands between them. Let the paths for different source-destination pairs be such that for each path p, if p contains a directed edge (r_i, r'_i) for some i then there exists another path (for a different source-destination pair) that contains the edge (r'_i, r_i). We will show that running Spider on this network results in rate allocations that are an optimal solution to the optimization problem in Equations (1)–(5). Under a fluid model for Spider as discussed in §B.1, assuming convergence, we observe that in the steady-state the time derivatives of the rate of flow of each path (Equation (8)) must be non-positive, *i.e.*,

$$\frac{1}{\sum_{p'\in\mathcal{P}_{i_p,j_p}} x^*_{p'}} - \sum_{(u,v)\in p} f^*_{u,v} \begin{cases} = 0 & \text{if } x^*_p > 0 \\ \le 0 & \text{if } x^*_p = 0 \end{cases} \quad \forall p \in \mathcal{P}, \quad (12)$$

where the superscript * denotes values at convergence (*e.g.*, x^*_p is the rate of flow on path p at convergence). Similarly, the rate of growth of the queues must be non-positive, or

$$x^*_{u,v} \begin{cases} = y^*_{u,v} & \text{if } q^*_{u,v} > 0 \\ \le y^*_{u,v} & \text{if } q^*_{u,v} = 0 \end{cases} \quad \forall (u,v) \in E. \quad (13)$$

Now, consider the optimization problem in Equations (1)–(5) for this parallel network. For simplicity we will assume the sender-receiver demands are not constrained. From Equation (13) above, the transaction arrival rates $x^*_{u,v}$ and $x^*_{v,u}$ for a channel (u,v) satisfy the capacity constraints in Equation (3). This is because $x^*_{u,v} \le y^*_{u,v}$ from Equation (13) and $y_{u,v}(t)$ is at most $\frac{c_{u,v}}{2\Delta}$ from Equation (11). Similarly the transaction arrival rates also satisfy the balance constraints in Equation (4). To see this, we first note the that the queues on all payment channels through which a path (corresponding to a sender-receiver pair) passes must be non-empty. For otherwise, if a queue $q^*_{u,v}$ is empty then the fraction of marked packets on a path p through (u,v) goes to 0, and the rate of flow x^*_p would increase as per Equation (8). Therefore we have $x^*_{u,v} = y^*_{u,v}$ (from Equation (13)) for every channel. Combining this with $y_{u,v}(t) = y_{v,u}(t)$ (Equation (11)), we conclude that the arrival rates are balanced on all channels. Thus the equilibrium rates $\{x^*_p : p \in \mathcal{P}\}$ resulting from Spider are in the feasible set for the routing optimization problem.

Next, let $\lambda_{u,v} \geq 0$ and $\mu_{u,v} \in \mathbb{R}$ be the dual variables corresponding to the capacity and balance constraints, respectively, for a channel (u, v). Consider the following mapping from $f^*_{u,v}$ to $\lambda_{u,v}$ and $\mu_{u,v}$

$$\lambda^*_{u,v} \leftarrow (f^*_{u,v} + f^*_{v,u})/2 \quad \forall (u,v) \in E \tag{14}$$

$$\mu^*_{u,v} \leftarrow f^*_{u,v}/2 \quad \forall (u,v) \in E, \tag{15}$$

where the superscript * on the dual variables indicate that they have been derived from the equilibrium states of the Spider protocol. Since $f_{u,v}(t)$ is always non-negative (Equation (10)), we see that $\lambda^*_{u,v} \geq 0$ for all (u,v). Therefore $\{\lambda^*_{u,v} : (u,v) \in E\}$ and $\{\mu^*_{u,v} : (u,v) \in E\}$ are in the feasible set of the dual of the routing optimization problem.

Next, we have argued previously that the queues on all payment channels through which a path (corresponding to a sender-received pair) passes must be non-empty. While we used this observation to show that the channel rates $x^*_{u,v}$ are balanced, it also implies that the rates are at capacity, *i.e.*, $x^*_{u,v} = c_{u,v}/(2\Delta)$, or $x^*_{u,v} + x^*_{v,u} = c_{u,v}/\Delta$ for all (u,v). This directly follows from Equation (13) and the first sub-case in Equation (11). It follows that the primal variables $\{x^*_p : p \in \mathcal{P}\}$ and the dual variables $\{\lambda^*_{u,v} : (u,v) \in E\}, \{\mu^*_{u,v} : (u,v) \in E\}$ satisfy the complementary slackness conditions of the optimization problem.

Last, the optimality condition for the primal variables on the Lagrangian defined with dual variables $\{\lambda^*_{u,v} : (u,v) \in E\}$ and $\{\mu^*_{u,v} : (u,v) \in E\}$ stipulates that

$$\frac{1}{\sum_{p' \in \mathcal{P}_{i_p,j_p}} x_{p'}} - \sum_{(u,v) \in p} (\lambda^*_{u,v} + \mu^*_{u,v} - \mu^*_{v,u}) \begin{cases} = 0 & \text{if } x_p > 0 \\ \leq 0 & \text{if } x_p = 0 \end{cases}, \tag{16}$$

for all $p \in \mathcal{P}$. However, note that for any path p

$$\begin{aligned}\sum_{(u,v) \in p} (\lambda^*_{u,v} + \mu^*_{u,v} - \mu^*_{v,u}) &= \sum_{(u,v) \in p} \frac{f^*_{u,v} + f^*_{v,u}}{2} + \frac{f^*_{u,v}}{2} - \frac{f^*_{v,u}}{2} \\ &= \sum_{(u,v) \in p} f^*_{u,v},\end{aligned} \tag{17}$$

where the first equation above follows from our mapping for $\lambda^*_{u,v}$ and $\mu^*_{u,v}$ in Equations (14), (15). Combining this with Equation (12), we see that $x_p \leftarrow x^*_p$ for all $p \in \mathcal{P}$ is

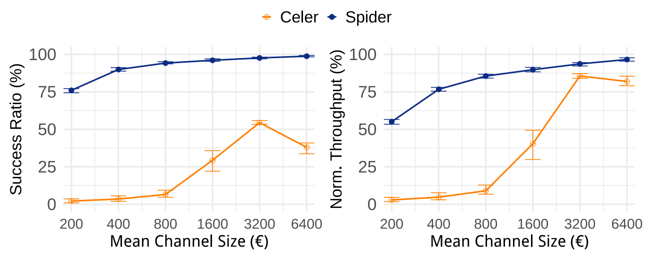

Figure 21: Spider's performance relative to Celer on a 10 node scale free topology. Spider achieves a 2x improvement in success ratio even at Celer's peak performance. Celer's performance dips after a peak since it maintains larger queues at higher capacities, eventually causing timeouts.

a valid solution to the Equation (16). Hence we conclude that $\{x^*_p : p \in \mathcal{P}\}$ and $\{\lambda^*_{u,v} : (u,v) \in E\}$, $\{\mu^*_{u,v} : (u,v) \in E\}$ are optimal primal and dual variables, respectively, for the optimization problem. The equilibrium rates found by Spider for the parallel network topology are optimal.

C Additional Results

C.1 Comparison with Celer

We run five circulation traffic matrices for 610s on a scale free topology with 10 nodes and 25 edges to compare Spider to Celer [11], a back-pressure based routing scheme. Each node sends 30 txns/s and we vary the mean channel size from 200€ to 6400 €. We measure the average success ratio and success volume for transactions in the 400-600s interval and observe that Spider outperforms Celer at all channel sizes. Celer splits transactions into transaction-units at the source but does not source-route individual transaction-units. Instead, transaction-units for a destination are queued at individual routers and forwarded on the link with the maximum queue and imbalance gradient for that destination. This approach tries to maximize transaction-units in queues to improve network utilization. However, queued-up and in-flight units in PCNs hold up tokens in other parts of the network while they are in-flight waiting for acknowledgements, reducing its capacity. Celer transactions also use long paths, sometimes upto 18 edges in this network with 25 edges. Consequently, tokens in Celer spend few seconds in-flight in contrast to the hundreds of milliseconds with Spider. The time tokens spent in-flight also increases with channel size since Celer tries to maintain larger queues. Celer's performance dips once the in-flight time has increased to the point where transactions start timing out before they can be completed. Due to computational constraints associated with large queues, we do not run Celer on larger topologies.

C.2 Circulations on Synthetic Topologies

We run five circulation traffic matrices for 1010s on our three topologies with all channels having exactly the tokens denoted by the channel size. Fig. 22 shows that across all topologies,

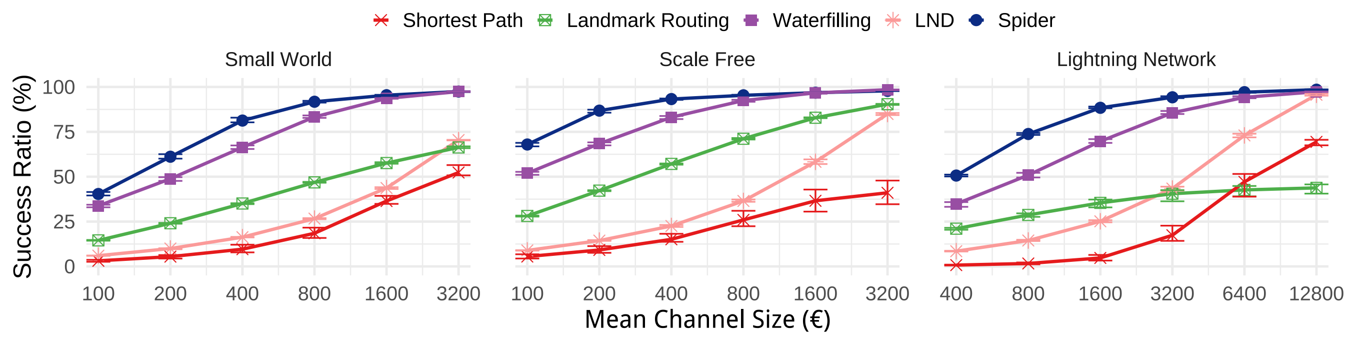

Figure 22: Performance of different algorithms on different topologies with equal channel sizes with different per sender transaction arrival rates. Spider consistently outperforms all other schems achieving near 100% average success ratio. Error-bars denote the maximum and minimum success ratio across five runs. Note the log scale of the x-axes.

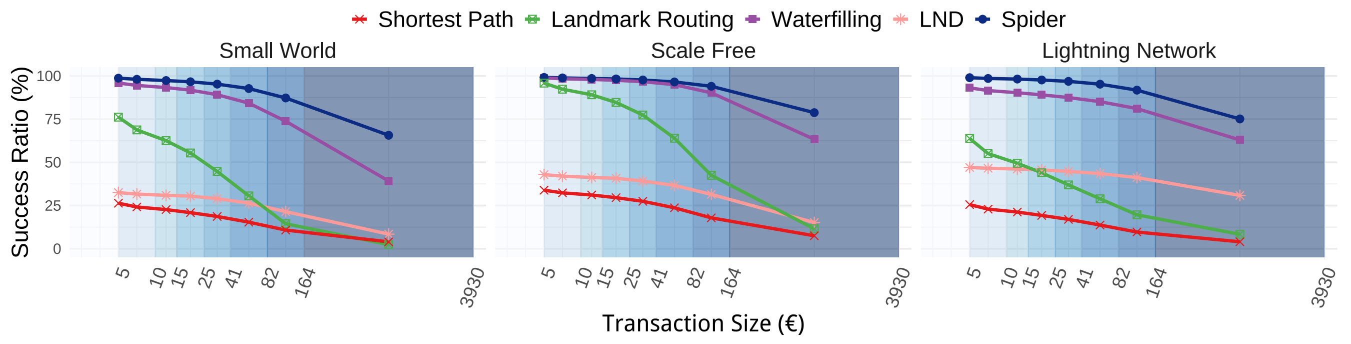

Figure 23: Breakdown of performance of different schemes by size of transactions completed. Each point reports the success ratio for transactions whose size belongs to the interval denoted by the shaded region. Each interval corresponds roughly to 12.5% of the CDF denoted in Fig. 7a. The graphs correspond to the (right) midpoints of the corresponding Lightning sampled channel sizes in Fig. 9.

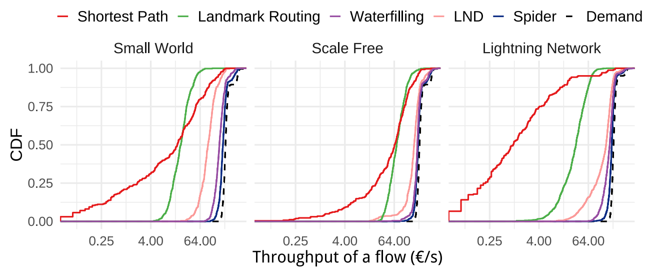

Figure 24: CDF of normalized throughput achieved by different flows under different schemes across topologies. Spider achieves close to 100% throughput given its proximity to the black demand line. Spider is more vertical line than LND because it is fairer: it doesn't hurt the throughput of smaller flows to attain good overall throughput.

Spider outperforms the state-of-the-art schemes on success ratio. Spider is able to successfully route more than 95% of the transactions with less than 25% of the capacity required by LND. Further Fig. 23 shows that Spider completes nearly 50% more of the largest 12.5% of the transactions attempted in the PCN across all three topologies. Even the waterfilling heuristic outperforms LND by 15-20% depending on the topology.

C.3 Fairness of Schemes

In §7.3, we show that Spider outperforms state-of-the art schemes on the success ratio achieved for a given channel capacity. Here, we break down the success volume by flows (sender-receiver pairs) to understand the fairness of the scheme to different pairs of nodes transacting on the PCN. Fig. 24 shows a CDF of the absolute throughput in €/s achieved by different protocols on a single circulation demand matrix when each sender sends an average of 30 tx/s. The mean channel sizes for the synthetic topologies and the real topologies with LCSD channel sizes are 4000€ and 16880€ respectively. We run each protocol for 1010s and measure the success volume for transactions arriving between 800-1000s. We make two observations: (a) Spider achieves close to 100% throughput in all three scenarios, (b)Spider is fairer to small flows (most vertical line) and doesn't hurt the smallest flows just to benefit on throughput. This is not as true for LND.

C.4 DAG Workload on Synthetic Topologies

Fig. 25 shows the effect of adding a DAG component to the transaction demand matrix on the synthetic small world and scale free topologies. We observe the success ratio and

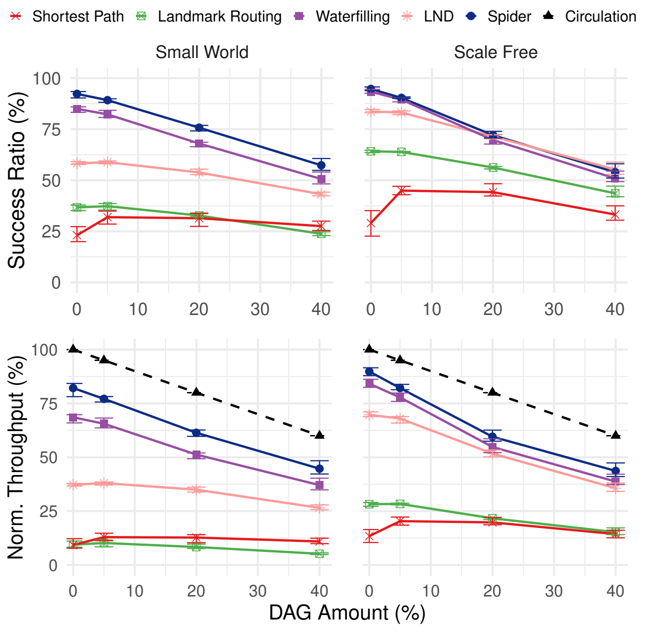

Figure 25: Performance of different algorithms across all topologies as the DAG component in the transaction demand matrix is varied. As the DAG amount is increased, the normalized throughput achieved is further away from the expected optimal circulation throughput. The gap is more pronounced on the real topology.

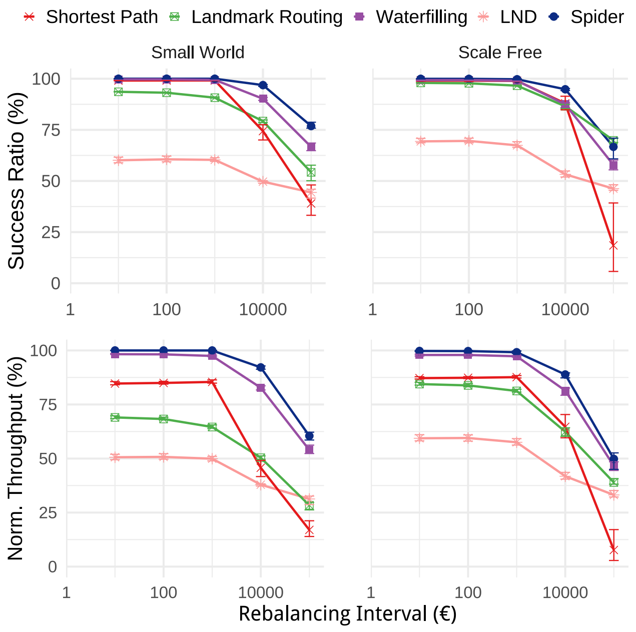

Figure 26: Performance of different algorithms across all topologies as the DAG component in the transaction demand matrix is varied. As the DAG amount is increased, the normalized throughput achieved is further away from the expected optimal circulation throughput. The gap is more pronounced on the real topology.

normalized throughput of different schemes with five different traffic matrices with 30 transactions per second per sender under 5%, 20%, 40% DAG components respectively. No scheme is able to achieve the maximum throughput. However, the achieved throughput is closer to the maximum when there is a smaller component of DAG in the demand matrix. This suggests again that the DAG affect PCN balances in a way that also prevents the circulation from going through. We investigate what could have caused this and how pro-active on-chain rebalancing could alleviate this in §7.4.

Fig. 26 shows the success ratio and normalized throughput achieved by different schemes when rebalancing is enabled for the 20% DAG traffic demand from Fig. 25. Spider is able to achieve over 95% success ratio and 90% normalized throughput even when its routers balance only every 10,000 € while LND is never able to sustain more than 75% success ratio even when rebalancing for every 10€ routed. This implies that Spider makes PCNs more economically viable for both routers locking up funds in payment channels and end-users routing via them since they need far fewer on-chain rebalancing events to sustain high throughput and earn routing fees.

PrivateEye: Scalable and Privacy-Preserving Compromise Detection in the Cloud

Behnaz Arzani[1], Selim Ciraci[2], Stefan Saroiu[1], Alec Wolman[1], Jack W. Stokes[1], Geoff Outhred[2], Lechao Diwu[2]

[1]*Microsoft Research,*[2]*Microsoft*

Abstract – Today, it is difficult for operators to detect compromised VMs in their data centers (DCs). Despite their benefits, the compromise detection systems operators offer are mostly unused. Operators are faced with a dilemma: allow VMs to remain unprotected, or mandate all customers use the compromise detection systems they provide. Neither is appealing: unprotected VMs can be used to attack other VMs. Many customers would view a mandate to use these detection systems as unacceptable due to privacy and performance concerns. Data from a production cloud show their compromise detection systems protect less than 5% of VMs.

PrivateEye is a scalable and privacy-preserving solution. It uses summaries of network traffic patterns obtained from the vSwitch, rather than installing binaries in customer VMs, introspection at the hypervisor, or packet captures. It addresses the challenge of protecting all VMs at DC-scale while preserving customer privacy and using low-signal data. We developed PrivateEye to meet the needs of production DCs. Evaluation on VMs of both internal and customer VM's shows it has an *area under the ROC curve* – the graph showing the model's true positive rate vs its false positive rate – of 0.96.

1 Introduction

Data center (DC) VMs today are largely unprotected – customers often don't use the compromise detection systems operators offer [1–3]. These systems monitor processes, network traffic, and CPU and disk usage from inside the VM or through introspection at the hypervisor to detect if the VM is compromised. We refer to them as OBDs (operator-provided and introspection-based detectors). Customers are reluctant to use OBDs due to privacy and performance concerns. Operators can mandate all 1^{st}-party VMs (those running the provider's workloads) use OBDs but can't require the same of their customers: our measurements of Azure reveal over 95% of VMs don't use OBDs! Operators are thus limited to using non-intrusive methods that prevent VMs from being compromised (e.g., firewalls, ACLs, [4, 5]). But these techniques do not always detect attacks before they succeed (see §2) and without additional protections, VMs in the DC can become and remain compromised for a long time.

It is important to close this gap and protect all VMs. Compromised VMs can be used to attack the DC infrastructure, or another customer's co-located VMs [6]. Operators need to be able to detect compromised VMs and protect all customers without needing their explicit permission or cooperation to do so. Our goal is to provide protection at *DC scale* while *preserving customer privacy*, *without visibility into customer VMs* and *without extensive and expensive monitoring*.

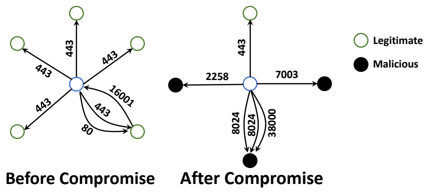

Figure 1: A VM's flows before and after compromise. The numbers on the edges are port numbers.

Here lies an interesting challenge: OBDs monitor process execution, check binaries and VM logins [1–3, 7–12], but without such detailed information, what hope do we have? Two observations help tackle this problem. First, we can learn the behavior of common attackers using information collected from VMs where OBDs *are* deployed. Second, a VM's flow patterns often change once it is compromised [13] e.g., the VM starts communicating with a command and control server (C&C), attempts to find and compromise other vulnerable VMs, or tries to attack the DC infrastructure. For example, Figure 1 shows a compromised VM discovered in Azure and its flow pattern before and after compromise. Our analysis of compromised VMs in Azure shows it is common to observe changes in network flow patterns when VMs are compromised. We expect our observations to be applicable to other providers' DCs as well.

Others have tried using network data to detect compromised machines but their work doesn't satisfy our scalability and privacy needs. Many studies [14–23] route traffic through middleboxes, rely on packet captures, or deep packet inspection (DPI) to extract features which are difficult, if not impossible, to gather through other means (e.g., packet payload). Continuous packet captures at scale come with prohibitive performance overheads and violate privacy by capturing application payloads. Packet captures contain personally identifiable information (PII), e.g. users' IP addresses, with stringent usage requirements [24]. Routing through middleboxes limits scalability, results in single points of failure, adds latency, and reduces throughput [25].

We present PrivateEye, a compromise detection system that runs at DC scale. PrivateEye is tailored to detect common attackers targeting the cloud, runs continuously, and complies with GDPR mandates [24]. It avoids expensive data collection by using flow pattern summaries to detect compromised VMs. It uses OBDs' detections on the VMs the operator can protect to learn the *change* in flow patterns of compromised VMs. Most OBD detections, which we use to train the model, are customer VMs (see §9), and so the learned model is expected to generalize to non-1^{st}-party VMs: PrivateEye applies this model to *all* VMs in the DC. PrivateEye uses random forests (RFs), an interpretable, supervised, machine learning (ML) model. These models generalize well and can infer, potentially complex, relationships in the input and are interpretable [26]. They often have higher accuracy compared to deployed heuristics (§4) while having similar performance overhead. PrivateEye leverages these properties to offer a practical solution for compromise detection at scale.

PrivateEye's role is to monitor all VMs in the DC and narrow the search space of VMs that need to be investigated. It is designed to have accuracy comparable to OBDs. Once PrivateEye identifies a suspicious VM, operators can use other, more invasive, methods which require customer permission to confirm its detections before shutting down the VM or moving them into a sandbox (see §5).

PrivateEye uses detections from OBDs inside VMs running real workloads to learn the change in the network behavior of compromised VMs. Deployed OBDs (only 5% of VMs) provide PrivateEye with a continuous feed of detections: PrivateEye can identify changes in the attacker's behavior as well as new attacks as it can be continuously retrained in the background. PrivateEye is one of the few systems that can leverage a continuous stream of detections. Attackers may attempt to avoid detection. Retraining may not be sufficient to detect all such attempts, but PrivateEye is still beneficial as it makes it harder for attackers to damage other VMs and the DC infrastructure: they would need to constantly modify their malware to avoid detection. Our contributions are:

1) Creating a scalable, privacy-preserving, compromise detection system that runs without needing customer permission. It operates without packet captures, without DPI, without fine-grained per-packet data, without using IP addresses, and without visibility into the VM.

2) Reporting on a deployment of PrivateEye's collection agent (CA) that has been running on *every* host across all DCs of our cloud for two years. It collects network-level data by querying the vSwitch [27] co-located on the same host.

3) Addressing the practical challenges of extracting features from coarse-grained flow summaries [28]. We use a novel feature construction approach that allows the ML model to detect changes in a VM's flow pattern while protecting customer privacy and keeping the feature vector small.

4) Evaluating PrivateEye using data from our public cloud as well as analyzing the model's false and true positives, feature importance, and design tradeoffs using the same dataset.

Our evaluations on a mix of both our internal and customer VMs, running real workloads, and set aside for testing, shows PrivateEye detects $\sim 96\%$ of the compromised VMs detected by OBDs with only a modest 1% false positive rate. This true/false positive rate is acceptable for our needs.

2 We need DC-scale compromise detection

We first show the need for DC-scale compromise detection:

Cloud VMs are constantly under attack. Brute-force attacks continue to pose a threat to DCs. We show the distribution of the arrival rate of SSH login attempts by unauthorized users to VMs located in 3 major cloud providers and 4 different regions across the globe (Figure 2). We deployed 120 VMs in each provider's DCs. We see VMs are subject to repeated login attempts and at least 3 VMs in each region experience at least one SSH login attempt per second (VMs in these experiments were monitored to ensure none of them are compromised). The time to discovery of a VM – the time from when it is deployed to the first SSH login attempt – is also short: many VMs are discovered in less than 15 minutes (Figure 3). VMs are under constant threat. This is not surprising but it serves to show we need constant monitoring of VMs in case any of these attempts succeed.

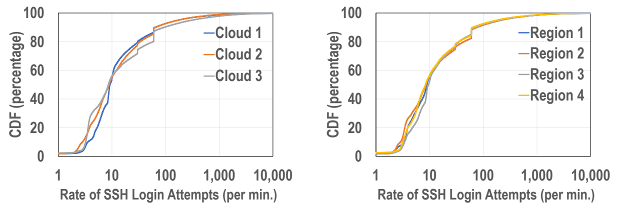

Figure 2: CDF of Rate of SSH login attempts for each provider (left) and for each region (right).

VMs *do* get compromised when customers are careless. Customers may fail to use strong passwords – providers enforce them, but many users change these passwords afterwards. Such VMs are susceptible to brute-forcers. We created 100 of them in our DCs – we ensured they were not co-located with other VMs and monitored them to ensure they did not harm other VMs. We chose passwords from the top 30 of the 1000 most used passwords [29]. The minimum time to compromise – the time from when it was instantiated to when the first successful login occurred – was 5 minutes (password 12345678) with a maximum of 47 hours (password: baseball). These VMs did not have OBDs, and none of them were flagged by any other intrusion detection service.

Compromised VMs are used to attack other VMs. Many exploits require code to be co-located with the victim. Access to a VM in the cloud allows attackers to bypass ACLs and firewalls that only protect VMs from external attackers. Compromised VMs may attempt to compromise other VMs: in one day, our OBDs found 1637 VMs attempting SQL-injection attacks and 74 attempting brute-force login. While small compared to the massive scale of the DC, these numbers only describe those VMs with OBDs. The magnitude of the problem is much greater when scaled up to all VMs.

OBDs (during Jan-June 2018) showed 14% of alerts were VMs brute-forcing other VMs and 13.87% were VMs scan-

ning for vulnerable ports. Furthermore, 7.7% of compromised VMs were compromised through brute-force attacks.

3 PrivateEye's threat model

Our threat model is similar to other infrastructure services. We do not trust any VM (they can run arbitrary code). We assume we can trust the hypervisors, network, and hardware.

PrivateEye relies on detections from OBDs deployed on a subset of VMs. We use this data as labels during training for the ML model. We assume this data cannot be faked, manipulated, or altered. We also assume OBDs can accurately detect when a VM is compromised. Specifically, we assume false positive/negatives rate of OBDs is sufficiently small – after all, they are accurate enough to be used to protect the provider's 1^{st}-party VMs which are critical to its business.

Malware can adapt its behavior in order to conceal malicious behavior. We assume OBDs adapt to such changes and re-training PrivateEye with their more recent detections can help it adapt to them as well (see §9). We assume many attackers do not discriminate between VMs that are protected by OBDs and those that are not: the same attackers that successfully compromise protected VMs can also (one can argue more easily) compromise others and by learning their behavior, through OBD detections, PrivateEye can protect other (unprotected) VMs in the DC from these attackers.

4 Simple heuristics are ineffective

Our operators have used insights from past OBD detections to build a rule-based solution. To motivate using ML, we compare PrivateEye to this strawman which was used to protect VMs without OBDs in our DCs. It encodes learnings from honeypots and past OBD detections to a per-VM score which measures the similarity of a VM's flows to those attacking honeypots or past OBD detections. Metrics such as having more than 500 flows/sec to a port/IP, changing DNS servers, or too many DNS flows increase the score. The increase is weighted by the operators' confidence in the signature.

This (strawman) heuristic identifies VMs engaged in brute-force or port-sweeping attacks accurately but rarely detects other compromises. We use the area under the receiver operating characteristic curve (ROC) – the graph that plots the true positive rate vs false positive rate of an algorithm – or AUC to measure accuracy. Higher AUCs indicate better accuracy. The heuristic has an AUC of 0.5 (PrivateEye's is 0.96). Indeed, by only testing on port-sweeping VMs, the heuristic's AUC increases to 0.69. Looking at its false positives, 10 legitimate VMs, spanning 3 Virtual Networks (VNets), had scores above 10 (A VNet is a virtual network set up by a user to connect its VMs). Three of the VMs were in our canary VNet. Canaries continuously ping on port 10000 to check network connectivity: all of the VNet's VMs had many flows to port 10000 which is why they all had high scores

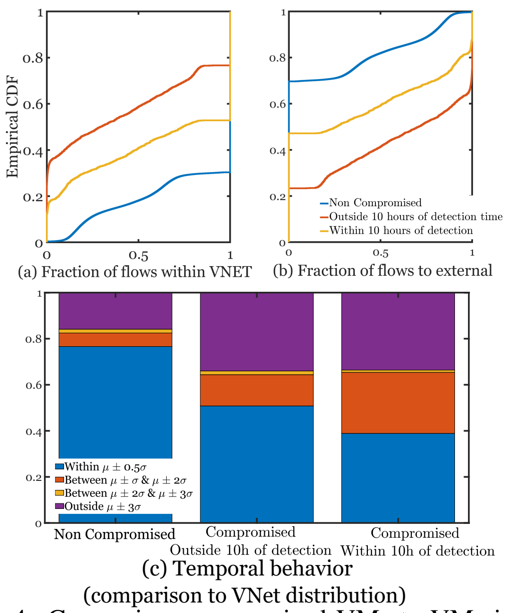

Figure 4: Comparing compromised VMs to VMs in their VNET. μ: average Bps of a VNet to each destination; σ: standard deviation. (a) Distribution of flows to VMs in the VNET. (b) Distribution of flows to IPs outside of the DC. (c) Temporal behavior.

(≥ 2). PrivateEye's high AUC shows using ML with the right features helps avoid such false positives.

5 PrivateEye's design requirements

Our design requirements for PrivateEye are:

GDPR compliance. The European law on data privacy (GDPR [24]) mandates any personally identifiable information (PII) should be tracked in case the customer wishes to inspect (or delete) it. Operators are required to answer customer requests within 48 hours and have two choices: join and tag data with meta-data to be able to identify which customer it relates to or avoid storing any and all PII data. For example, a VM's public IP (and the IPs it communicates with) has to be mapped to the customer's account and stored with *all* network telemetry from their VM. Public IPs are dynamically allocated and would need to be tracked in time which can result in significant and unnecessary overhead.

Even without such customer requests, this data has to be deleted from all company data-stores after 30 days to avoid violations. GDPR makes it expensive to sustain solutions relying on PII data. PrivateEye relies on 10-minute flow pattern summaries and ignores specific IP addresses.

Low runtime overhead. PrivateEye should have low performance overhead, should be able to run at DC-scale, and shouldn't interfere with ongoing traffic. Many, state-of-the-art, compromise detection systems have high performance overhead and cannot be used extensively in the cloud. For example, DPI (e.g., [15]) adds additional per-packet delays which prohibits serving traffic at line-rate ($40 - 100$ Gbps). Packets may be mirrored to dedicated middleboxes that can run DPI off the critical path but our experience with simi-

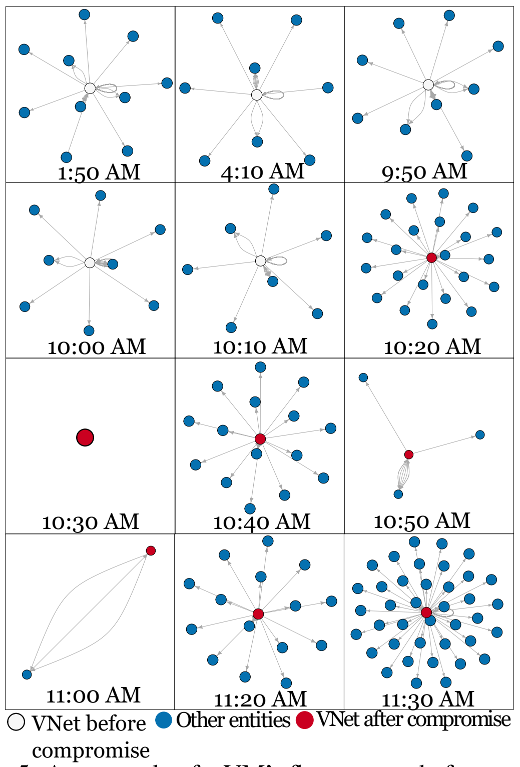

Figure 5: An example of a VM's flow pattern before and after it was compromised.

lar systems (e.g., EverFlow [30]) show they put significant load on the network and that they are hard to scale. We can re-implement DPI based solutions using new programmable switches [31] to improve performance, however, these solutions are not yet ready for production as packets need to be re-circulated [32] which prevents serving packets at line-rate.

Detect malware in the wild. Many past approaches observed malware in a sandbox to build behavioral signatures (e.g., [7]). Malware may change its behavior if it detects it is in a sandbox (e.g, [33]). OBD detections from production VMs provide a rich dataset about malware behavior in the wild which PrivateEye can learn from. PrivateEye uses this learned behavior to detect other instances of compromise.

Ability to generalize. Customers constantly bring up new VMs and shut-down old ones. We should not rely on learning from specific VMs or even customers. PrivateEye can generalize to VMs (and even customers) not in its training set: our evelauation test sets (see 8) comprises of customer and internal VMs and VNets that are never in the training set.

Operate as a first line of defense. OBDs use extensive monitoring. PrivateEye has a more restricted view of the VMs. It is used as a preliminary detector to avoid unnecessary penalty (OBD mandate) on a large number of customers. Its goal is to reduce monitoring overhead and operational complexity and to protect *all* VMs without needing customer permission until further investigation is necessary. Once it flags a VM as suspect, it can raise an alert to the customer to ask for permission to investigate the VMs further through other more invasive and expensive techniques at the operator's disposal.

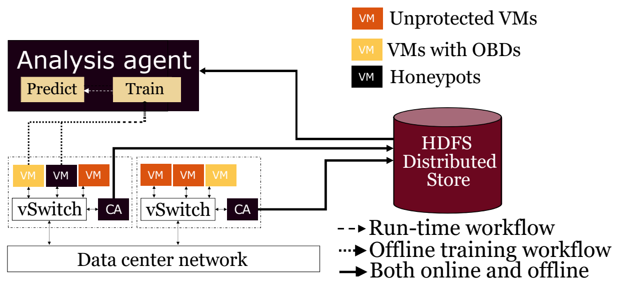

Figure 6: **System overview of PrivateEye.**

For example, our operators have access to VHD-scanners and can also use DPI-based systems on *one-time* packet captures of the VM's traffic[1]. PrivateEye provides "just-cause" for operators to use these tools when it flags a VM as suspect. These approaches are automated and can be run without operator intervention. PrivateEye assigns scores to each detection allowing operators to pick the right tradeoff between the true and false positive rates for their needs. PrivateEye is not meant to fully replace OBDs, we encourage customers who require stronger protections to opt-in to OBDs providers offer.

6 System Design

PrivateEye runs continuously and scales to large clouds with low overhead. The privacy sensitive fields it collects are anonymized using a keyed hash message authentication code (HMAC) during data collection and *deleted* once we construct the features. Figure 6 shows PrivateEye's design. We use two arrow types to differentiate training and run-time workflows. PrivateEye has two parts: the collection agent (CA) and the analysis agent (AA). The CA is responsible for data collection and the AA for analysis and detection. We next describe the key ideas behind its design:

A VM's flow pattern changes when it is compromised. We have observed a VM's flow patterns change once compromised. Almost all malware we studied (using our honeypots) changed the machine's DNS, few connected to the same set of external IPs, some connected on the reserved port for NTP to non-NTP servers, and those mining for digital currency had flows on port 30303. We ask whether these changes are visible on VMs running real workloads (as opposed to idle honeypots)? We leverage 1-month of our OBD detections to answer this question and compare the flow pattern of compromised VMs to others in their VNet. Within each VNet, we see similar behavior for all VMs. But when the VM is compromised, it starts to deviate from the typical behavior of other VMs in its VNet (Figure 4).

Figure 4 a-b compares the *spatial* distribution – the fraction of flows going to other VMs belonging to the same customer vs. to other VMs in the DC vs. machines outside of the DC – of flows originating from VMs sharing a VNet. We observe only 30% of the non-compromised VMs have flows destined to IPs outside of their VNet whereas this number is as high as 50% as we get closer to when the compromise was detected and roughly 80% around the time of detection. It

[1]These are only collected *if* the VM is suspected.

seems, at least in these instances, after the VMs were compromised they tended to communicate more with destinations outside their VNet. The VM's *temporal* behavior also shows changes in behavior around the time of compromise (Figure 4-c). The volume of traffic each VM sends to *individual IPs* is often close to the VNet average but when compromised, VMs exhibit increased deviations from this mean. Our manual analysis of their flow patterns showed noticable changes in behavior after compromise. We omit most of this analysis due to space restrictions but show one example. We show (Figure 5) the flow pattern of a 1^{st}-party VM before it was detected as being compromised (11:30 AM). We see the VM's flow pattern change drastically from its, previously stable, normal behavior when we get closer to the time of detection. We use these insights when constructing features.

We can get accurate flow-summaries from the vSwitch with low overhead. The vSwitch [27] processes all packets of all flows to/from the VM and keeps simple, per-flow state (Table 2) for all active flows. PrivateEye leverages this feature to obtain accurate per-VM flow summaries (see §7.1).

Using OBDs to create labeled data for training. PrivateEye is trained on data from VMs running OBDs. Our DCs run two types of OBDs: (a) Those running on our 1^{st}-party VMs: these VMs often have in-kernel instrumentation for detecting compromise. (b) Those running on customer VMs: customers can opt-in and use OBDs and if they do so, they can deploy and run them inside their VMs. All of the OBDs we use are built on top of Defender [34] (Windows) and ClamAV [35] (Linux) but also monitor irregular login behavior, system calls, and many other parameters. Although OBDs are intrusive the system as a whole meets our privacy requrements: Azure owns all 1^{st}-party VMs, and the only 3^{rd}-party VMs where we use OBDs are those where the customer has explicitly given permission. Note, customer OBDs are less common but, interestingly, despite their lower popularity most compromise detections are from these OBDs (see §9).

We hypothesize many compromised VMs exhibit similar flow-pattern changes to those compromised VMs that were detected by OBDs; because often attackers run attacks against IPs in the cloud irrespective of the services deployed behind those IPs or who owns them (non-targetted attacks §2). Our evaluations confirm this hypothesis as PrivateEye is tested on internal and customer VMs and workloads that are not in the training set and achieves an AUC of 0.96.

Using supervised-learning to learn flow-pattern changes. Anomaly detection and clustering approaches seem natural approaches for solving our problem. We have tried anomaly detection [36], cross entropy [37], ECP [38], TSNE [39], and k-means [40], and also AutoEncoders [41] but anomalies were routinely observed in many VM's lifetimes and it was hard for operators to distinguish between anomalies that were caused by malware and those which were intended VM behavior. Even a tainting + clustering approach i.e., marking points in the clusters with compromised examples as compromised, resulted in higher false positives compared to PrivateEye.

Metric	Description
Time	Timestamp of data collected
Direction	Incoming to/Outgoing from VM
Anonymized Source IP	Source IP in first SYN packet*
Anonymized Source VNetId	VNetId of source IP if any*
Anonymized Dest IP	Destination IP in first SYN packet*
Anonymized Dest VNetId	VNetId of destination IP if any*
Protocol	Protocol if known
Dest Port	Destination port in first SYN packet
BPS In	# of bytes/sec incoming to VM
BPS Out	# of bytes/sec outgoing from VM
PPS In	# of packets/sec incoming to VM
PPS Out	# of packets/sec outgoing to VM
Unique Flows	# of unique 5-tuples collected
Total Flows	# of unique 5-tuples (both collected and missed flows)

Table 2: Data collected by the CA (*not* the features). *These fields are removed entirely after feature creation.

We need to detect *specific changes* that point to the VM becoming compromised (as opposed to finding all anomalies). We chose supervised learning and specifically random forests as they have low overhead. They are debug-able, explainable, highly accurate, and resilient to overfitting [42]. They construct multiple decision trees over a random subset of features during training. Each decision tree uses a greedy algorithm to (1) iteratively pick features with the most information gain [43], (2) makes a decision using values of each feature, and (3) iterates until it reaches a "leaf". Leaves either consist of samples with a single label, or have samples where one label is the majority. At run-time, the algorithm traverses the tree for each test case and returns the majority label (from training) at the leaf. Random forests output the mean prediction across trees and the fraction of trees that predicted each label. We use this fraction as a score to measure confidence and to control PrivateEye's false positives. Operators use it to decide what to do. We set the model's hyperparameters (e.g., max-depth) using Bayesian optimization [44].

Using informative features. In section §7.1 we will describe PrivateEye's CA and how it collects the raw data in Table 2. Privacy-sensitive fields, such as the IPs and VNet ID, are anonymized. Here, we describe the raw data itself, the challenges in extracting privacy-preserving features from this raw data, and how we create these features.

PrivateEye uses three sets of features: graph-based, protocol-based, and aggregate features:

(1) Graph-based features. We want to detect the changes in a VM's flow pattern that indicate it is compromised. The IPs the VM connects to are a crucial part of these flow patterns but using them as features is not possible for two reasons:

Privacy – IPs are anonymized and removed once the features are created. We cannot map IPs geographically nor can we classify them according to the AS that owns them.

Data-sparsity – using IPs as features results in a large feature vector (2^{32}) and by extension an extremely sparse training set. The curse of dimensionality dictates: to maintain accuracy, as the number of features increase, the number of training samples must also increase [45]. This is especially problematic for training supervised models as compromised

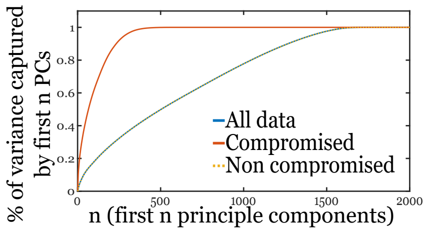

Figure 7: Variance captured by the first n PCs.

VMs are rare – our datasets are imbalanced and have more non-compromised examples and far fewer compromised examples. Using IP-prefixes is not possible: the smallest usable prefix size (to avoid spanning multiple ASes) is \24 but this results in a 2^{24} feature vector which is, again, too large.

Proior work [20, 28, 46, 47] have acknowledged this problem and attempted to solve it by operating at the granularity of flows instead of VMs – classifying individual flows as malicious to avoid using IPs as features. While finding malicous flows is useful when implementing ACLs or firewalls it is hard to identify compromised VMs without viewing their flow patterns as a whole and, in some cases, comparing the VM's flow patterns to that of others. Other works in networking (e.g., [42, 48, 49]) have also used ML. But IPs are not relevant to the problems they tackle and are not used as features. But in the context of compromise detection, IPs play an important part. We present a novel feature construction approach which allows us to summarize graph evolutions, including IP-related changes, using temporal and spatial features. We do not need access to the specific IPs for constructing these features (avoiding privacy problems) nor do we need to use 2^{32} feature-vectors (avoiding data-sparsity problems). Our intuition, based on the observations we presented earlier, is that to detect changes in a VM's flow pattern, features should describe its change both in time and space and compare it not just to its own past behavior but also to others.

Temporal graph-features: capture how a VM's flow patterns change over time compared to itself and other VMs. We will first describe the intuition behind our solution in the context of an example:

Suppose a compromised VM connects to a C&C server with IP a.b.c.d. We can, for all VMs in the DC, build the CDF of bytes sent to IP a.b.c.d over time. If only a few of the other VMs in its DC have been compromised, flows to IP a.b.c.d from the compromised VM would fall in the top portion of this CDF, e.g. the top 10%. The flow to IP a.b.c.d falls into this top 10% interval because such flows were unique to compromised VMs – by mapping the flow to this interval we capture the relevant information for detecting whether the VM is compromised. Other, similar changes are also possible. This is why we use a combination of four such CDFs:

- For each VM, the distribution of each flow according to its "Bps out" over the course of one hour.
- For each VM, the distribution of all flow according to their "Bps out" over the course of 10 minutes.
- For each remote IP, the distribution of all flows to that IP address across all VMs in the DC according to their "Bps out" over 10 minutes.
- For each remote IP, the distribution of all flows connecting to that IP address across all VMs in the DC according to their "Bps out" in 1 hour.

We divide each CDF into five buckets: top 1%, top 1-10%, middle, bottom 1-10%, and bottom 1%. Flows are then projected to a lower dimension based on the bucket they fall into on each of these CDFs . The results are then combined with other features for each VM in each 10 minute period.

These CDFs describe a VM's flows through time as compared to itself and other VMs in the same region. There are other possible CDFs we could use. Finding the optimal selection is the subject of future work.

Spatial graph-features: We classify each flow in one of three categories based on its endpoints: (a) both are in the same VNet (b) both belong to the cloud provider (different VNets) (c) one is an external IP. We aggregate each metric in Table 2 for each group. We can build these groups using the anonymized VNetIds (which we remove after feature construction). Specifically, the same anonymized VNetIds point to VMs in the same VNet, different ones point to VMs in different VNets, and absent Ids point to external IPs.

(2) Protocol Features. A flow's destination port can help identify the application protocol being used. Often attackers/malware use specific protocols for communication. There are numerous examples we found when deploying PrivateEye where the set of protocols used by the VM changed once it was compromised. We created a list of 32 ports of interest including 22 (SSH), 53 (DNS), 80 (HTTP), 123 (NTP), 443 (TLS), 30303 (mining digital currency), and 3389 (RDP). For each of these ports, we aggregated five of the metrics shown in Table 2 to construct six features: "Direction" (incoming vs. outgoing), "PPS In", "PPS Out", "BPS In", "Unique Flows".

(3) Aggregate Features. Finally, we also use the total number of bytes sent/received and the total number of incoming/outgoing connections as additional features.

There is no good linear summary of the feature-set. We have constructed $k = 2116$ features. We next check whether there is a more compact representation of the data using Principle Component Analysis (PCA) [50]. Each principal component (PC) corresponds to an Eigenvalue of the data, and the sum of these Eigenvalues equals its variance. We find we need to keep 75% of the PCs to keep 99% of the variance (Figure 7). Therefore, PCA is not a good candidate for dimensionality reduction in this problem.

Interestingly, if we only focus on compromised VMs, we see 99% of the variance in the dataset can be captured with only 16% of the PCs: the space of compromised VMs (as described by these features) is more compact. But, there is little overall linear dependence across features. This is yet another motivation for using information theoretic and/or ML-based techniques as the number of features is large and it is hard to build human-tuned heuristics using these features.

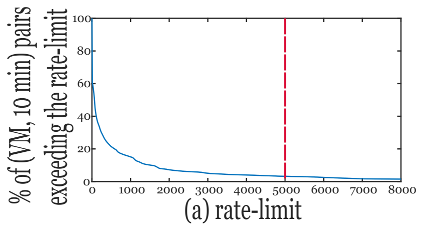

Figure 8: Percentage of (VM, 10 minute) pairs (y-axis) with more than n (x-axis) flows.

7 System Implementation

We next discuss each of PrivateEye's building blocks in more detail and describe how they are implemented in practice.

7.1 The collection agent

A highly performant CA is crucial in achieving our performance and scalability requirements. We have deployed our CA on all hosts across all our DCs. It runs continuously and polls the vSwitch for the data in Table 2 every 10 seconds. The vSwitch records this data for each flow and for each VM within this period: the choice of polling period does not result in data loss but only impacts CPU usage.

The interface to the vSwitch uses read locks[2]. Although the vSwitch has higher priority to obtain the lock, the CA limits its query to 5000, randomly selected, flows per 10s and per VM to reduce the impact of contention. If the total flows within the polling period exceed this limit for a VM, the vSwitch reports the total. To reduce the overhead of saving data, the CA aggregates some of the fields in Table 2 over 10-minute epochs. This aggregation is on the fields that store bytes, packets, and flows, and we also aggregate flows based on their destination port. As a result, a 10-minute dataset from a region, with over $300,000$ servers, is 109 MB.

To choose the 5,000 limit we looked at the 10s epochs with more flows than any given limit, for one hour, in one DC (Figure 8). Only 4% of samples have more than 5,000 flows. Thus, using this limit results in data-loss for only 4% of the samples. Our data shows on average VMs have 1843.9 ± 9.5 flows in each epoch. The distribution has a long tail; when the number of flows exceeds 5,000 the number of flows is 18890.6 ± 104.0. We accept this loss and show in §8 that we can detect compromised VMs despite this limit. The vSwitch team confirmed the vSwitch continued to process packets at line-rate when using this limit.

We designed the CA from scratch despite systems such as NetFlow [51] and IPFix [52], which are already deployed in our DCs. These systems are used for traffic engineering, DDOS protection, and other tasks. They run on our core routers and sample 1 out of 4096 packets traversing the network core. Because of this sampling, they are biased towards monitoring "chatty" VMs and "elephant" flows. Also, they do not capture flows that do not traverse the network core. Therefore, IpFix/NetFlow are not adequate for PrivateEye which requires more complete knowledge of per-VM flow patterns. Work such as [53] show the shortcomings of such monitoring systems even when used in heavy-hitter detection systems. Other in-network monitoring systems such as [4, 54] are also inadequate as they require a specific type of sampling unsuitable for PrivateEye [4] or require hardware upgrades currently not possible [54]. PrivateEye limits the number of records it extracts in each 10s. This limit also results in occasional data-loss but does not suffer from the same problems. The limit is applied to each VM separately and doesn't bias the dataset towards chatty VMs. We capture data from the host's vSwitch which has all records for the VM's flows irrespective of where they are routed. The CA is a software component on the host and requires no hardware changes. IPFix captures fewer flows per VM than our CA and also misses capturing traffic from a large number of VMs (Figure 9).

[2]The table is also used by other systems that need a consistent view.

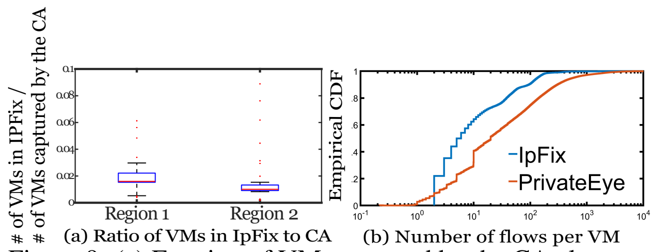

Figure 9: (a) Fraction of VMs captured by the CA also captured by IpFix. (b) CDF of number of flows captured per (VM,10 min) for IpFix vs. the CA (x-axis log scale).

The CA has low overhead – typical usage of only 0.1% of the host CPU and a maximum of 15 MB of RAM.

Finally, we note the CA can also be implemented using programmable switches. We use vSwitches as they are more widely deployed in our networks (and those of others).

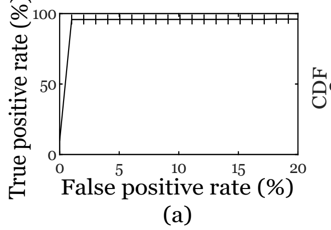
7.2 The Analysis Agent

The AA has two roles: (1) train a classifier using past detections of OBDs (offline), (2) to run the classifier and predict which VMs are compromised (online). It is alerted when there is a new detection from any of the OBDs on any of the VMs and tags the data from those VMs with a "compromised" label. This data is then added to the training set. This training set is persisted in a distributed data store. The AA is periodically retrained using this data to keep up with any changes in the set of malware or the OBDs themselves.

Data collected by the CA for all other VMs (those without OBDs) is sent through a stream processing pipeline where we create the features. These features are then passed through the RF model which determines whether the VM is compromised. We are in the process of deploying the AA in our DCs. We describe this deployment in more detail in §9.

8 Evaluation

We evaluate PrivateEye using data from Microsoft's cloud. We have shown parts of the evaluation – which helped justify our design choices – in earlier sections (e.g.,§7.1). In this section, our goal is to answer questions about PrivateEye's accuracy (§8.2), the features that help it achieve this accuracy (§8.2), the causes behind its mis-classifications (§8.2), and its performance overhead (§8.3). We also looked into how it can



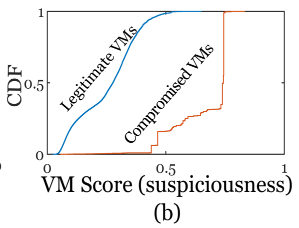


Figure 10: (a) PrivateEye's ROC. (b) PrivateEye's scores (CDF).

be used in the context of an example use-case (Appendix §A).

8.1 Methodology

Data. Each point, (x_i, y_i), in our data corresponds to a VM in a 10 minute period, where x_i is the 2116×1 feature vector described in §6 and y_i is a label: compromised or legitimate.

Labeling. We use OBDs from over 1,000,000 internal and customer VMs to create labeled data for evaluation. These VMs run diverse workloads and use both Windows and Linux OSes. A direct implication of this labeling is that PrivateEye's accuracy can only be as high as OBDs. OBDs can have false positives (negatives), but because operators use them to protect their own 1^{st}-party VMs, we assume these are negligible. OBDs with higher accuracy only improve PrivateEye.

We train and test PrivateEye on *all* detections from these OBDs – we do not restrict PrivateEye to detecting a particular type of compromise: its goal is to detect any compromise OBDs can detect. Most OBD detections were from (different) *customer* VMs (0.87 of the total compromises) – see §9 for further discussion on this. For most OBD detections we also saw external, network-level, signs of malicious behavior. When available, we also report on results from the operator's manual investigations to confirm their detections.

Train-test split. We need to split the data into a train and test set. It is important to do so correctly: if there is *information leakage* between the train and test set we may artificially boost accuracy. For example, we cannot split the data by time because some VMs will have lifetimes spanning both the train and test set. In training, the model may learn the behavior of the VM itself as opposed to whether it is compromised, and when used in practice, it would have much lower accuracy than what we see in testing. The test set should be representative of how the system is used in practice – it is tested on VMs it has never seen before (VMs that are not in the training set). These constraints imply the VMs in the training set cannot be in the test set. We take an even more conservative approach: *We split the data by VNet*. This ensures each VM, and those in its VNet that have similar workloads (§2), only appear in either the training or the test set but not in both.

Addressing class-imbalance. RFs need a similar number of training samples for each label to achieve high accuracy. Unfortunately, our data suffers from *class-imbalance*: a small fraction of our data is labeled compromised (only 0.1%). This can lead to an RF that classifies everything as legitimate while achieving (artificial) high accuracy. We use a standard technique to solve this issue: down-sampling [55]. Down-

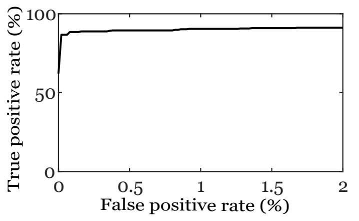

Figure 11: ROC for per VM classification.

sampling randomly chooses a subset of the more popular label for training. But too much down-sampling can reduce the volume of data available for training which can also hurt accuracy. We use Bayesian Optimization to find the right trade-off. To improve accuracy, we use the 'balanced' option in SKLearn's RF function which weights the samples for each label to make up for the lower number of samples.

Performance metrics. PrivateEye's output for each sample x_i at time t_i is a *score* and a decision on whether the VM was compromised in the 10 minute epoch prior to t_i. The score measures the level of suspicion towards that VM. Operators can use it to decide whether to investigate the VM further.

We use an ROC to measure accuracy – we vary the threshold applied to the scores to decide whether the VM is compromised: ROC shows the true positive rate (TPR) vs the false positive rate (FPR). The area under the ROC (AUC) summarizes the significance of the ROC: an AUC of 1 indicates a perfect test, and an AUC of 0.5 indicates a random test [56].

8.2 Classifier Evaluation

Our goal in this section is to answer questions such as:

- What is PrivateEye's accuracy?
- What causes PrivateEye's false positives/negatives?
- How does PrivateEye's RF compare to other models?
- Are the features we created effective?
- How does PrivateEye's sampling limit affect accuracy?

We next describe the answer to these questions in detail.

Accuracy: PrivateEye has a high AUC (0.96). We use 20-fold cross validation and show the mean of the 20 outputs and the 95^{th} percentile confidence interval (Figure 10-a). PrivateEye can detect 95.77% of compromised samples with 1% FPR. The scores are correlated with the labels (Figure 10-b): the gap between the distribution of scores for compromised and legitimate VMs confirms the accuracy of the model.

PrivateEye's long-term accuracy is also high. PrivateEye checks each VM every 10 minutes to see if any are compromised. But what if operators want to do so less-often e.g., before the VM is shut-down (once over the VM's life-time)? They can aggregate the scores across consecutive samples to do so. Many aggregators are possible: we use the sum of all scores over the lifetime of the VM (other aggregators achieved similar results). The ROC is produced using this new score (Figure 11). PrivateEye's accuracy remains high (90.75% TPR for 1% FPR) albeit slightly lower than before – possibly due to the longer lifespan of legitimate VMs: compromised VMs are typically shut-down more quickly resulting in a lower aggregated score. This result also confirms the ROC in

Figure 10-a is not dominated by samples from a single VM.

We further experimented with different choices of n, where n is the number of 10-minute intervals that need to pass before we make a prediction. The ROC curves were bounded by those of Figure 10-a and b but do not show an explicit trend.

PrivateEye's FNs were *mostly* OBD false positives. PrivateEye's FNR (average) is 5%. This implies (on average) 5% of samples were reported incorrectly as legitimate. But most (70%) of these samples were actually false positives (FPs) of the OBDs (remember OBDs tend to be conservative as they protect internal VMs) – operators investigating the alerts identified them as FPs e.g, in one case the investigation report mentioned: "This was a FP detection as the vulnerability scanner contains data to scan for CVE-2006-3439".

Our investigations of PrivateEye's FNs revealed other interesting information. For example, we grouped FN samples based on which VM they describe and found 86% were cases where all samples for the VM were labeled legitimate. These VMs are part of the training set for other folds during cross validation: it appears PrivateEye is resilient to errors in the labels it uses for training (given the 95% TPR). We need to investigate this point further to confirm this hypothesis.

Some VMs had a mix of compromised and legitimate detections (14% of FN samples). These VMs were involved in port-sweeping attacks but we found no correlation with the number of active flows or the volume of traffic. OBDs assign a "severity" to their detections to report their confidence in the detection. All of PrivateEye's FNs were low severity.

PrivateEye's FPs have similar flow-patterns to compromised VMs. We manually inspect the flow patterns of VMs PrivateEye mistakenly reported as compromised. Most such VMs had a small number of flows to non-reserved ports. In a few cases, the VM had *only* a small number of flows on the DNS port (53) to another VM in its VNet (VMs in the same VNet belong to the same customer). In another instance, the VM had *no* outgoing flows, but multiple VMs from the DC were attempting RDP connections to it. None of the VMs in these VMs' VNets had similar flow patterns. These behaviors are similar to compromised VMs which explains why these VMs were mistakenly flagged by PrivateEye.

PrivateEye detected attacks OBDs missed. We observed two separate instances where SQL servers were conducting port-sweeping attacks on another VM. In both cases the attack lasted for one 10 minute epoch but PrivateEye detected it. OBDs did not. These VMs were only active for a short duration (less than a few hours). The short period of the attack and the short life-span of the VM may explain why the

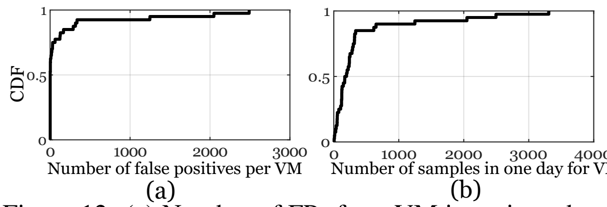

Figure 12: (a) Number of FPs for a VM in a given day. (b) Number of samples in a day for VMs with an FP.

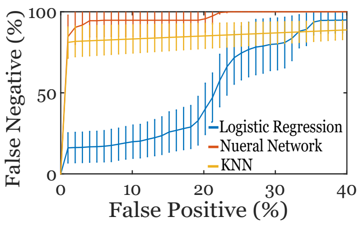

Figure 13: Performance of other ML algorithms.

OBDs did not detect these attacks.

Consecutive detections can help reduce FPs. We ran samples for legitimate VMs in the test set through PrivateEye and grouped the results by VM. For over 60% of these VMs PrivateEye had only a single FP (Figure 12-a): we could use consecutive detections as a potential means of reducing FPs. For example, we can change the detection granularity to every 20 minutes instead of 10 where we require two consecutive detections to declare a VM compromised. This approach can result in reduced true positives – as seen earlier in the more extreme example where we make one decision in the entire lifetime of the VM. Further understanding of PrivateEye's FPs requires manual inspection from within the VM but, sadly, we are unable to report on the results of such analysis.

Random forests (RFs) are a good first choice [14, 48, 57]. We compared RFs with many other ML algorithms and show RoCs for a subset (Figure 13). RFs outperformed all other models we tried. The closest algorithm to the RF were neural networks[3] (NN) which have an 81% TPR for a 1% FPR.

All features contribute to the detection. We have seen there is no compact, linear, representation of the features that would capture all the information in the data §6. We dig deeper to see which class of features are most helpful. To do so: (1) we use each class individually (Figure 14-a), and (2) we remove each class altogether (Figure 14-b). Removing graph features individually (spatial, temporal) has little impact on TPR (0.2%) but removing both can drastically reduce it (18%). Most classes (except spatial features) can find compromised VMs with a TPR $\geq 70\%$ and an FPR $\leq 5\%$. We conclude all features significantly contribute to detection (though they are not equally important). To validate these observations, we experimented with various feature selection techniques (Figure 15). We refer the reader to [58] for the description of these techniques due to space restrictions.

Aggregate features have good predictive power: a TPR of 77.7% for 5% FPR when used as the only features and resulting in 7% drop in TPR when removed: were most compromised VMs engaging in volumetric attacks? We found this *not to be the case* – the maximum traffic sent by compromised VMs across all samples was 2.6 MBps (median 0.0 Bps) vs. 10.3 GBps (meidan 189.62 Bps) for legitimate VMs.

Comparison to other VMs helps detection. Graph features compare the VM to others by mapping flows onto intervals on various CDFs (see §7.2). What happens if we use CDFs that

[3]We used a single hidden layer with 1000 neurons. Experiments with additional hidden layers in the NN and different numbers of hidden dimensions produced similar results.

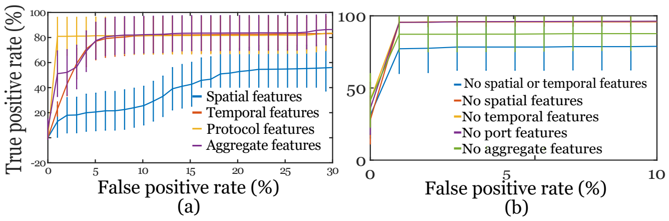

Figure 14: (a) Contribution of each feature class to the overall accuracy. (b) ROC without each feature class.

compare a VM with its own history instead of that of all VMs in the DC? The TPR drops to 80% for 1% FPR (Figure 16) indicating the comparison to other VMs is indeed useful.

The choice of sampling limit is important. The CA rate-limits the number of flow entries it queries from the vSwitch to $5,000$ every 10 seconds. This rate-limit allows us to capture over 97% of each VM's flows (§7.1). We next measure the impact of this rate-limit on the TPR by lowering it. We cannot simulate this behavior accurately by "down-sampling" our data as we have aggregated the flows to remove the source port and IP addresses. Instead, we change the rate-limit threshold across all US regions for two months and collect a new dataset. We cannot do a complete sensitivity analysis with multiple rate-limits as this would be costly – we need to capture at least a month's worth of data for training. Therefore, we limit our experiment to just one threshold: 900 flows per 10 second interval. Such a rate limit will result in data loss for over 30% of our training samples (Figure 8). The results show a *significant* decrease in accuracy (Figure 17-a): 80% TPR for 40% FPR. We conclude PrivateEye needs to capture as many flows as possible to maintain high accuracy.

More training data helps compensate for lower rate-limits (Figure 17-b). We start with 92% TPR for 59.6% FPR, and by just adding 8 more days worth of data to the training set it can reach the same TPR for 23.23% FPR.

PrivateEye is unable to detect the type of compromise. PrivateEye cannot specify the type of malware installed on the VM. Our dataset contains additional information about a *fraction* of the compromised VMs e.g., compromised through SSH or RDP brute-force, malware found, port-scanner, port-sweeper, SQL-injection, RDP/SSH brute-forcer, spammer, or others. However, PrivateEye has low accuracy when identifying the type of compromise (70% TPR for 1% FPR) – it is known that multi-class classifiers tend to have lower accuracy [42]. Besides, not all detections have this additional information.

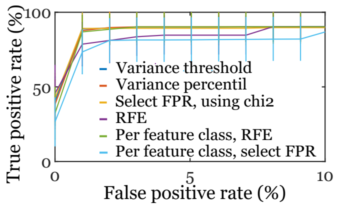

Figure 15: ROC for different feature selection methods.

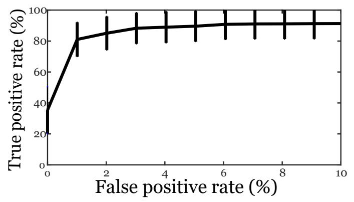

Figure 16: ROC: Impact of the choice of CDFs.

8.3 Performance overhead

One motivation for designing PrivateEye was the need to scale intrusion detection systems to the entire DC. Here we evaluate whether PrivateEye meets this scalability requirement:

- What is the memory and CPU usage of the CA?
- What is the impact of the CA on ongoing traffic?
- What is the expected load on the AA?
- What is the overhead of training the AA?

The CA has low CPU and memory overhead. The CA is deployed across *all* production hosts of a large cloud provider for over 2 years and includes data for over 15,000,000 VMs and 300,000 VNets in the US alone. We chose 100 hosts randomly from DCs across the globe and recorded the CA's CPU and disk usage both in the morning and afternoon. Figure 18 shows its memory usage. Its CPU usage remained bellow 0.1% across all hosts at all times.

The CA does not impact ongoing traffic. Our experience with the CA is that it causes no impact on ongoing traffic. This is in part because the CA has lower priority when obtaining the lock on the vSwitch table. We instrumented the CA on one host to record the time spent, from *user space*, in each query to the vSwitch. The time captures the time spent in contention on the vSwitch table's read-lock and the time it takes to read x entries (where x is the CA rate-limit). There are 8 VMs on the host. We run a SYN flood attack against one of them to simulate different levels of load. We show the time for attacked and non-attacked VMs (Table 3). The results show both the rate-limit and the load (volume of traffic) on a given VM affect the time spent querying the vSwitch for data about that VM but not for data about other VMs. The CPU usage of the CA remained below 0.1% throughout this experiment.

The load on the AA is acceptable. PrivateEye's AA is trained offline using data from the 5% of VMs monitored by the OBDs. The trained model is distributed across each DC region to serve detections every 10 minutes. To quantify the load the AA will have to handle, we looked at the number of flow records per second the CA captured in three regions

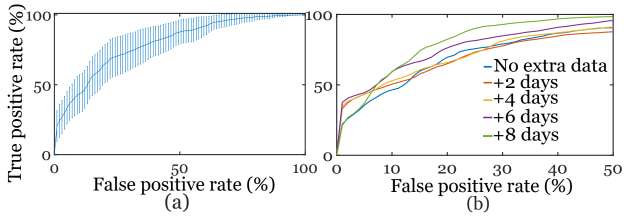

Figure 17: (a) ROC with a rate-limit of 900 flows per 10 seconds. (b) ROC when more data is added.

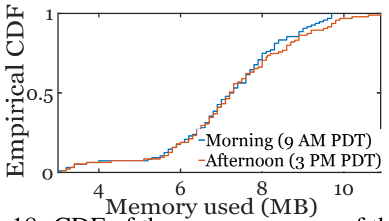

Figure 18: CDF of the memory usage of the CA.

both in the morning and afternoon (Figure 19). The highest rate is around 900,000 flows per second. We expect this volume of data can be easily processed in 10 minute periods.

Training overhead is low. We use Bayesian Optimization to configure our RFs which resulted in an ensemble of 158 trees with a maximum depth of 4. The average training time for such an RF is 5 minutes and $56s \pm 3.76s$ with our two month training set and using 172.87 GB of RAM (peak). The high memory usage is because of the SKlearn implementation which holds the entire dataset in memory.

9 Discussion

This section presents a discussion of the challenges and limitations of a detection system like PrivateEye.

PrivateEye's accuracy. PrivateEye is only as accurate as the OBDs it uses. Thus, our evaluation focuses on comparing PrivateEye to OBDs. OBDs tend to be highly accurate as they are the only systems protecting 1^{st}-party VMs. But, it is challenging to *guarantee* a VM is legitimate. In reality, a legitimate VM is one that passes all detectors deployed in the DC. Should some of these VMs, in fact, be compromised it may cause PrivateEye to have mispredictions (§8). Similarly, we do not know precisely when a VM was compromised but only when it was detected and some of our compromised data may be from when the VM was not yet compromised. Our results in §8 show PrivateEye to be resilient to mislabels.

Generalizing PrivateEye to the entire DC. In our evaluations we partitioned the set of labeled VNets to create a train/test set to emulate how PrivateEye will be used in practice. The VMs we tested PrivateEye on were those which were absent from the training set. These VMs run both Windows and Linux and span a variety of workloads including those of customers who have subscribed to OBDs. We are reasonably confident PrivateEye can detect most compromised VMs. We would have liked to show a small-scale evaluation of PrivateEye where we manually investigated VMs that are not protected by OBDs. However, we were not able to obtain permission to do so.

rate-limit	SYN flood flows per second	Query time (μs) for non attacked VMs	Query time (μs) for attacked VM
900	0	585.3 ± 34.1	-
5000	0	2707.27 ± 105.4	-
10000	0	5097.56 ± 261.0	-
900	10000	780.9 ± 110.4	75276.6 ± 6387.5
5000	10000	2933.3 ± 251.7	71961.0 ± 15607.0
10000	10000	5690.1 ± 430.2	75115.5 ± 18360.8
900	50000	504.6 ± 29.2	70760.4 ± 4611.2
5000	50000	2713.4 ± 272.4	75180.8 ± 1639.3
10000	50000	5699.0 ± 289.4	46922.6 ± 9214.63

Need for retraining. We can retrain PrivateEye to adapt to changes in malware behavior. Retraining may not be enough to allow PrivateEye to detect all such changes, but the change in malware should increase the time to compromise of VMs due to the attackers needing to avoid conspicuous network flows.

The use of ML. Our work on PrivateEye is the first privacy preserving compromise detection system that can run at scale. Other, for example graph theoretic approaches, could be used as well. It is unclear how such algorithms can adapt to changes in malware behavior. This is clearer for ML models where the re-training of the model can update the system. Graph-based NNs are also applicable [59, 60]. It may be possible to improve the accuracy of PrivateEye even further by using these models. This is a subject of future work.

Deploying the AA. We are currently in the process of deploying the AA using Resource Central [61]. Resource Central allows us to store our model in Azure and serves predictions using that model at run-time. It is highly scalable, and we have already used it to deploy several other ML models in production. However, there are still other questions that we still need to answer, for example, who should build the CDFs and what CDFs are best?

Attacks against PrivateEye. PrivateEye itself may be targeted by attackers to reduce the operator's detection capabilities. Adversarial learning [62] is a sub-field of machine learning that studies such attacks. A study of how to guard against such attacks is beyond the scope of this work.

Higher number of 3^{rd}-party compromises. 87% of our compromised data were 3^{rd}-party VMs, however, the majority of monitored VMs in our data are 1^{st}-party VMs. The higher number of 3^{rd}-party compromises is likely due to the tighter protections on 1^{st}-party VMs. We looked at how this could influence our results and conducted preliminary experiments where we eliminated all 1^{st}-party VMs from the data. On average we achieved 86.71% TPR for 3% FPR (83% FPR for 2.5% TPR). We expect accuracy to improve by increasing the number of samples (the dataset has far fewer datapoints than the original) and by re-tuning the model.

Prior work. We have extensively evaluated the performance of PrivateEye and have also compared it to systems currently deployed across the provider's production DCs. Most prior work are not comparable to PrivateEye as they require packet captures (or introspection) we cannot collect because we need customer permission. PrivateEye is not a replacement for these systems but is designed for DC operators (as opposed to customers). Customers can continue using alternative solutions to protect their VMs. In §7.1 we compared the CA to NetFlow and showed it captures more information. The aggregations and anonymizations applied by the CA prohibit direct comparisons of our AA to NetFlow-based approaches.

Ethical considerations. We annonymized all privacy sensitive information during data collection and *removed them* after feature construction. We conducted all experiments using data from a large cloud provider. The data was either collected from 1^{st}-party VMs under the operator's control or from 3^{rd}-party VMs where the operator had customer permission to monitor the VM. We had explicitly asked permission for deploying the honeypots described in §2 and monitored them closely to ensure they did not cause harm to other VMs. These VMs were not co-located with other VMs.

10 Related Work

We discussed a number of prior works in §1,§7.1, and §7.2. Most do not provide the scalability and privacy characteristics we need [14–20].

Two lines of previous work relate to PrivateEye. One shows the multitude of today's security problems and challenges providers face [6, 63–65]. The other identify malware, compromises, and other types of bad behavior [66–75]. These works can further be divided into two categories:

Network traffic-based Compromise Detection. PrivateEye does not focus on a specific type of attack – it detects any compromise the OBDs can detect. Many prior works identify specific types of bad behavior [5, 5, 9, 12, 19, 21, 22, 47, 57, 76–98]. Some focus on anomaly detection ([99] is a survey of such approaches). Nemean [100] builds intrusion signatures from honeypot packet traces. SNARE finds spammers using packet headers [21]. The work in [18] uses event ordering to identify malware families. VMWall constructs application-aware firewalls aimed at stopping attacks [11]. [90] uses domain knowledge about worms to construct informative features, thus avoiding using IPs (our features capture most of the same information). These works focus on a specific attack which prevents them from comprehensive protection of VMs. Works such as [14–16] rely on packet captures or DPI [101] to identify malicious flows. Packet captures and DPI at DC-scale across all hosts are not possible due to the prohibitive performance overhead. The work of [102] relies on malware propagation to detect the source of attack through analyzing network traffic at key vantage points. However, it does not target identifying the infected nodes. The work of [83] encodes IP addresses through per-source entropies to detect worm attacks; such an approach removes most of the informative properties of individual destination IPs. Such an approach is typically useful when detecting worms and volumetric attacks. The work of [103, 104] discuss other limitations of this approach. Perhaps the closest work to ours is [105] which uses IPFix data from core routers to detect machines that are compromised through SSH brute force attacks. Aside from targeting a specific form of compromise, [105] is based on a fixed set of rules derived through observing a limited set of malware. It is difficult for the approach to adapt to changes in malware behavior. Finally, [47] uses external IP reputation sources to reduce its false positives. This violates our privacy requirements. In addition, we have observed the intersection of malicious IPs reported by commercial IP reputation services and IPs attacking our VMs to be relatively small ($< 10\%$).

Many such works [9, 19, 21, 22, 57] are trained using labels from commercial anti-virus software. Our approach enables us to build a detector that is customized to the cloud because our OBDs detect malicious behavior that occurs in real cloud VMs that are running real workloads. Using OBDs deployed on production VMs running real workloads for labeling allows PrivateEye to avoid problems faced by works such as [106–108] which run malware in emulation mode or in a sandbox to obtain signatures for detection. Many malware can detect when in emulation mode and therefore change their behavior in such situations [18].

Binary-based Compromise Detection. One approach collects malware binaries from honeypots, constructs features from them and then uses Support Vector Machines [7]. Another, clusters binaries found on compromised machines based on their structure, runtime behavior, and the context of the host [8]. Netbait [9] crowd-sources probes gathered from (distributed) infected machines to detect worms. Another approach analyzes memory dumps to construct signatures of the in-memory behavior of malware [10]. Unlike these approaches, PrivateEye performs its classification using networking data alone. Today's privacy requirements, performance constraints, and the new mandates from GDPR make the use of binary and memory inspection techniques in DCs difficult.

Other works also exist [90, 109–113]. Many of these inspired PrivateEye, however, in contrast to these works, PrivateEye's design is aimed at running at scale, having strong privacy requirements, and compliance with GDPR mandates.

11 Conclusion

PrivateEye is a privacy preserving compromise detection system that runs at DC-scale without requiring customer permission. It achieves a true positive rate of 95.77% for a 1% false positive rate.

A Using PrivateEye

PrivateEye is designed as a preliminary detector and its detections should be followed up with more expensive techniques (e.g., [15]). These techniques are computationally expensive and require customer permission. PrivateEye's role is to reduce the number of VMs that need to be investigated and to protect all VMs at all times with low overhead.

Sometimes, obtaining customer permissions takes too long e.g., if a new vulnerability is discovered that could be exploited by compromised machines (e.g., Heartbleed [114]) the provider may not have time to obtain permission. The operator may choose to move suspect VMs to a sandbox[4] until the appropriate patch is applied to all VMs and devices. If obtaining customer permission in time is not possible, PrivateEye can be used to decide whether a VM should be moved or not. But what are the implications of using PrivateEye as the only compromise detection system in the DC?

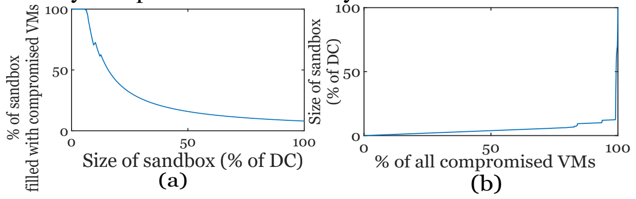

Figure 20: **(a) Fraction of the sandbox occupied by compromised VMs. (b) Sandbox size needed to isolate $x\%$ of compromised VMs.**

For a sandbox size k the operator needs to decide which VMs to put in the sandbox. Using PrivateEye's scores, one choice is to move the top k most suspicious VMs. Figure 20-a illustrates what fraction of the sandbox would be occupied by compromised VMs for different values of k. As the sandbox size increases the utility of the sandbox diminishes–an increasing number of legitimate VMs end up in the sandbox. The choice of k is a tradeoff between the number of VMs that need to be migrated and the number of compromised VMs captured. Figure 20-b examines this tradeoff in our dataset. The operator needs to consider the combination of these graphs when choosing an appropriate k. The larger the sandbox, the more effective it is in reducing the number of compromised VMs outside the sandbox. However, larger k means that it is more likely to place legitimate VMs in the sandbox impacting their performance. To avoid penalizing legitimate VMs, the operator can choose not to migrate a VM if its score is below a threshold. Finding the optimal threshold depends on the operator's needs.

[4]A sandbox could be a host that only runs suspect VMs (limit damage of side-channels) or where more stringent ACLs are imposed.

Telekine: Secure Computing with Cloud GPUs

Abstract

GPUs have become ubiquitous in the cloud due to the dramatic performance gains they enable in domains such as machine learning and computer vision. However, offloading GPU computation to the cloud requires placing enormous trust in providers and administrators. Recent proposals for GPU trusted execution environments (TEEs) are promising but fail to address very real side-channel concerns. To illustrate the severity of the problem, we demonstrate a novel attack that enables an attacker to correctly classify images from ImageNet [17] by observing only the timing of GPU kernel execution, rather than the images themselves.

Telekine enables applications to use GPU acceleration in the cloud securely, based on a novel GPU stream abstraction that ensures execution and interaction through untrusted components are independent of any secret data. Given a GPU with support for a TEE, Telekine employs a novel variant of API remoting to partition application-level software into components to ensure secret-dependent behaviors occur only on trusted components. Telekine can securely train modern image recognition models on MXNet [10] with 10%–22% performance penalty relative to an insecure baseline with a locally attached GPU. It runs graph algorithms using Galois [75] on one and two GPUs with 18%–41% overhead.

1 Introduction

GPUs have become popular computational accelerators in public clouds. Accuracy improvements enabled by GPU-accelerated computation are driving the success of machine learning and computer vision in application domains such as medicine [38, 88] transportation [67], finance [32], insurance [69], gaming [89], and communication [70].

Unfortunately, it is currently impossible to run GPU workloads in the cloud without trusting the provider, eliminating cloud GPUs as an option for security-conscious users. Users must trust the provider because the provider controls the layer of privileged software responsible for management and provisioning. Even dedicated cloud instances (e.g., Amazon's EC2 dedicated hosts [1]) run the provider's virtualization software, making GPUs vulnerable to malicious or curious

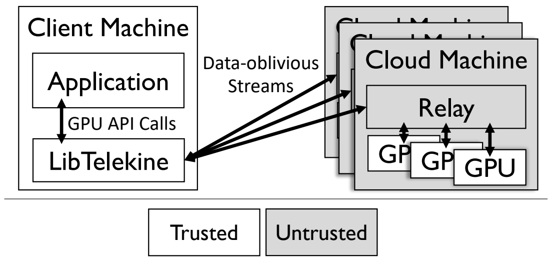

Figure 1. Telekine components and their organization.

cloud administrators. Virtualization software runs at a host machine's highest privilege level, exposing a wide attack surface that includes GPU memory, execution context, and firmware. Finally, unfettered visibility into host/device communication exposes both data and timing channels.

Trusted execution environments (TEEs) should, in principle, make the cloud an option for users who refuse to trust the provider. TEEs provide a hardware root of trust, allowing users to access cloud compute resources without trusting provider software–including the privileged software of the hypervisor and operating system. TEE hardware protects the privacy and integrity of user code and data from administrators and from attackers who control privileged software. TEEs exist currently on Intel CPUs via software guard extensions (SGX) [44], ARM CPUs via TrustZone [59], and RISC-V CPUs via Keystone [55]. Researchers have proposed GPU-based TEEs [100] and TEE extensions for GPUs [45], though none have been built or deployed. However, as we argue below, a design that simply composes components that run in hardware-supported CPU and GPU TEEs will fail to provide strong security due to side channels.

GPU-accelerated applications have three main software components: (1) an API and a user library (e.g., CUDA [66] or HIP [39]) that provides high-level programming functionality and executes on a CPU; (2) CPU-side control code at the user and the system level that manages communication with the GPU, and (3) GPU kernels (programs) that execute on the GPU device itself. It is the data and code that moves between the CPU and GPU that potentially creates side channels visible to CPU-side code.

An attacker can extract meaningful information from the execution time of code on the GPU, which privileged software can compute on the CPU by observing communication with the GPU. For example, we demonstrate a novel attack on image recognition machine learning models that allows malicious system software to correctly classify images from ImageNet [17] used as input to the model. By observing only the timing of a model trained to classify images (the image model), we build a new model (the timing model) that can classify images based on the execution timing of layers in the image model. Even if a security-conscious user encrypts their input data (and decrypts it on the GPU), a cloud provider's system administrator can use the timing information of GPU kernels (measured on the CPU) in the image model to classify its input images. We train the timing model to distinguish images of two classes with 78% accuracy. For more classes, accuracy decreases but stays above random guessing.

We propose Telekine, a system that enables the secure use of cloud GPUs without trusting the platform provider. GPU TEEs provide a secure execution environment but leave the user open to side channels when communication depends on secret data. Telekine makes communication with the GPU TEE data oblivious, that is, completely independent of secrets contained in the input data. Data obliviousness is a strong property that excludes the existence of side-channel attacks against CPU-side code and host/device communication whose observable behavior (e.g., timing, memory accesses, DMA sizes, etc.) depends on secret input data.

Telekine has three components (shown in Figure 1): libTelekine that runs on a trusted user machine (a *client*), GPUs physically attached to a cloud machine (a *server*) that supports GPU TEEs with specific security requirements (§3.1), and the relay which facilitates communication between libTelekine and the GPU. Telekine uses a GPU TEE because it needs a mechanism to protect GPU computation from the cloud provider; a GPU TEE is tailored to that task.
