Telekine protects the application and GPU runtime by moving it from the cloud to the client. The advantage of this approach is that the user must already trust their client machine, and the application and user libraries are large and complex and therefore prone to side-channel attacks, making them difficult to secure if they execute in the cloud. The disadvantage is that GPU libraries assume a local GPU with a fast, high-bandwidth connection to the CPU. Telekine decouples the user library from low-level GPU control by interposing on the GPU API and efficiently forwarding these calls to the server (a technique known as API remoting) which has been used to virtualize GPUs [6, 8, 22, 23, 30, 33, 50, 57, 58, 85, 101, 107], but to our knowledge has never been used for security. A client using Telekine does not need to have a GPU installed.

Telekine treats the CPU-side control code on the cloud server ("Relay" in Figure 1) as completely untrusted, almost as if it were part of the network. The client machine establishes a cryptographically secure channel directly with the code executing on the cloud GPU. The network and the CPU-based code on the server can delay the computation, but cannot compromise its privacy or integrity.

Telekine secures the communication between the client machine and the cloud GPU by transforming the user's GPU API calls into *data-oblivious streams*. Data-oblivious streams are similar to constant time defenses [3] in that they aim to remove timing channels by ensuring that observable events are deterministic regardless of secrets. Telekine constructs data-oblivious streams by reducing all API calls to a sequence of code execution (`launchKernel`) and data movement (`memcpy`) commands. It then schedules these commands at a fixed rate, possibly creating new commands, or splitting `memcpy` commands into fixed-size pieces. Fixed-sized, fixed-rate communication is data oblivious; it ensures that any observable patterns are independent of the input data and therefore devoid of side-channel information. Fixed-rate communication is not a novel way to eliminate side channels, but Telekine's design shows how to apply it efficiently to modern GPU-based computing.

Given that Telekine requires a GPU TEE, it is logical to wonder why it does not use a CPU TEE. After all, putting the application and programming libraries into a CPU TEE would reduce the latency and increases the bandwidth for communication between libTelekine and the GPU. Unfortunately, Intel and ARM TEEs do not prevent side channels as part of their threat model [48, 78]. Keystone [55] and Komodo [25] intend to address side channels for RISC-V and ARM respectively, but work is ongoing. Also, making existing applications data oblivious is difficult for programmers, requires access to source code (not needed by Telekine), and often slows down a program greatly (e.g., Opaque [109] slows down data analytics by 1.6–46×). Should future CPU TEEs evolve to address side channels, Telekine can use them. Much of Telekine focuses on securing the communication between trusted components, which can be an improved CPU TEE and a GPU TEE or they can be the client machine and server GPU TEE, as they are in our prototype.

Telekine is the first system to offer efficient, secure execution of GPU-accelerated applications on cloud machines under a strong and realistic threat model. We use Telekine to secure several GPU-accelerated applications via two frameworks: the MXNet [10] machine learning framework and the Galois graph processing system [75]. On a realistic testbed Telekine provides strong secrecy and integrity guarantees, including side-channel protection. MXNet [10] training for three different, modern image recognition models incur a 10–22% performance penalty relative to a baseline with a locally attached GPU. MXNet inference for the same models over a connection from Austin, TX to the Vultur's Dallas, TX datacenter [102] incurs a penalties of 0-8% for batch sizes of 64 images. Telekine runs graph algorithms using Galois [75] on one and two GPUs with 18%–41% overhead.

This paper makes the following contributions.

- We demonstrate a CPU-side timing attack on deep neural networks that allows a compromised OS to correctly classify images in encrypted input (§4).
- We provide a design and prototype for Telekine, a system that eliminates CPU-based side-channel attacks against a GPU TEE with a novel variant of API remoting to execute secret-dependent code on the GPU TEE and a trusted client (§5).
- We thoroughly evaluate the performance, robustness, and security of Telekine protecting a variety of important workloads on one and two GPUs: machine learning and graph processing (§7).

2 Threat model

In all current cloud GPU platforms, the cloud provider's privileged software, and hence administrators, can gain easy access to GPU state, creating a significant attack surface including explicit channels such as GPU memory, firmware, and execution context. Work in this area agrees on the vulnerability of GPU state to privileged software [45, 100].

Telekine assumes a powerful adversary who controls all software on the platform, including privileged software such as device drivers, the host operating system and hypervisor. This captures typical cloud platforms, where the platform provider has full control over all software, and attackers can run malicious code on the same physical device as a target cloud application [81]. A malicious provider, a malicious administrator, or an OS-level attacker can use their control of privileged software to steal the secrets of tenants. We assume that the adversary cannot, however, compromise hardware–the physical GPU package.

Telekine assumes a GPU TEE, with capabilities similar to current research proposals like Graviton [100]. The details can vary, but a GPU TEE establishes secure memory on the GPU device and provides a protocol to initiate a computation that can be remotely attested to start from the correct state (code and initial data) and execute privately and without interference from the CPU side. We provide additional detail on Telekine's TEE requirements in Section 3.1.

GPU TEEs do not, by themselves, secure communication with the CPU and our attack (§4) shows how much information there is in the precise timing of CPU/GPU communication. Telekine protects communication with the GPU, guaranteeing that the adversary cannot learn about input data directly or through side channels, including timing channels.

While secure control of a GPU has been proposed [45, 100], there has been little work securing side channels. These side channels undercut the security of the TEE. In addition to the timing attack we developed (§4), AES key extraction using shared GPU hardware [31, 46, 47] has been demonstrated. And recent side-channel attacks [64] have shown practical methods to fingerprint websites using performance counters observed during GPU rendering in the browser.

2.1 Guarantees

Telekine provides the following secrecy properties which prevent any explicit or implicit data flow from input data to an external observer.

S1 (content): Messages are encrypted to ensure their content cannot be directly read by an observer.

S2 (timing): The transmit schedule for messages is fixed. Any transmission delays are independent of input data.

S3 (size): The size of each message is fixed. Telekine pads and/or splits messages to achieve fixed-sized messages.

Telekine also provides the following integrity properties to ensure that any result the user receives is either a result that could have been generated by a GPU hosted by a completely benign cloud provider, or an error.

I1 (content): The content of all communication is protected by an end-to-end integrity check; a message authentication code (MAC) allows Telekine to detect modifications, returning an error if any are detected.

I2 (order): Each message carries a sequence number which allows Telekine to detect out of order messages. The sequence numbers also prevent replay attacks.

I3 (API-preserving): Commands issued by the application should affect GPU state in the same way they would on a local GPU, regardless of any transformations that Telekine applies.

GPU commands have semantics that Telekine must maintain for correctness. For example, GPU runtimes expose a *stream* [71] abstraction to application code. API calls issued by the application on the same stream are executed serially in the order they were issued. A kernel launched from a particular stream will block the completion of subsequent API calls on that stream until that kernel terminates. Applications can have many streams which map to different command queues exposed by hardware. API calls made on separate streams can be executed in parallel. Telekine must respect the data dependence semantics of streams.

2.2 Limitations.

Physical side channels and denial of service attacks are out of scope. In situations where an adversary monitoring physical side channels like temperature [62], power [54], or acoustical emanations [11] is a concern, Telekine would need to be augmented with other techniques to maintain security. In our threat model, a cloud provider wishing to deny service can always do so, e.g., by interrupting the network or refusing to run user processes.

Telekine provides clients a mechanism to disguise their end-to-end runtime but does not impose policy. Applications can choose the most efficient policy for their security needs. We believe end-to-end runtime is a poor predictor of input data (and our experiments in Section 4 bear this out), further justifying the clients setting policy.

3 GPU background

Applications use GPUs through high-level, vendor-provided APIs such as CUDA [66] and HIP [39]; they include a user-level runtime and OS-level driver that communicate through a combination of `ioctl` system calls and memory-mapped command queues. The driver is responsible for creating mappings from virtual memory to physical MMIO regions. After these privileged operations are complete, any software that has a mapping (user or OS) may communicate directly with the device using registers or command queues exposed through the MMIO regions.

While memory management, synchronization, and other features (e.g., IPC, power management, etc.) require interaction with the driver state (e.g., creating and managing memory mappings), a workload that pre-allocates all of its required GPU memory and uses only data transfer and kernel launch primitives can function completely by writing commands into the GPU's command queue. It is possible to construct and submit these commands without referring to any state maintained by either the runtime or the driver. As we show in Section 5, this property enables Telekine's relay to be effectively stateless.

3.1 GPU TEE

Telekine requires a TEE on the GPU and Graviton [100] is a detailed proposal from the literature that provides the basic functionality that any GPU TEE (or indeed any TEE) should provide: secrecy for GPU code and input data, integrity for the GPU computation, and remote attestation for the computation's initial state. Graviton achieves most of its functionality by changing the GPU firmware, so it does not require extensive changes to the GPU hardware itself (neither does Telekine). This is achievable because the modern GPU firmware runs on a fully programmable control processor [68]. We explain GPU TEE functionality by saying what the GPU does, but the implementation could be firmware, hardware, or both.

The integrity, secrecy, and ordering of the commands sent to the GPU are ensured by a secure channel. Before computation begins, the client machine and the GPU agree on a shared symmetric key via a key exchange protocol (e.g., Diffie-Hellman). The client uses this key to send commands using a protocol like transport layer security (TLS) which provides a secure channel ([100] §5.2).

The integrity of the computation is assured by the GPU, which checks the initial execution conditions and attests these conditions to the remote user, who can verify that the expected code has been loaded into the expected address range with the expected permissions, and that the hardware generating the attestation is genuine. There are many variations on remote attestation, but it is a common feature for modern enclaves like SGX [14] and Keystone [55]. Telekine expects the GPU to have been initialized with all of the GPU kernels the application intends to launch and any initial data when attestation has completed.

Telekine and Graviton split GPU memory into untrusted and trusted regions so the untrusted host OS/Hypervisor can DMA into untrusted GPU memory, enabling efficient data transfers; the GPU can then copy data between untrusted GPU memory and trusted memory. This mechanism provides GPU memory protection even though the IOMMU is under control of the untrusted kernel. Telekine and Graviton disable unified memory, which allows privileged CPU code to demand page GPU memory and exposes side-channel memory access information.

The GPU TEE should turn off or refuse to report the state of any performance counters. Recent GPU side-channel attacks [28, 64] have successfully used timing data from GPU performance counters.

Due to Telekine's focus on side channels, it has requirements beyond the previously proposed GPU TEEs. These requirements are more straightforward to provide than the core TEE functionality.

Eliminate GPU side channels. Some TEE designs allow different tenants/principals to execute concurrently (e.g., SGX, Keystone), sharing the underlying hardware. Concurrent execution is attractive from a utilization perspective but it provides a rich side-channel attack surface which has plagued the security of CPU TEE designs. Telekine assumes side channels from concurrent principals (e.g., memory access timing and bandwidth) do not exist on the GPU TEE. A conservative design which prevents hardware side channels is to disallow concurrent execution. Graviton TEEs scrub their state (e.g., registers, memory, caches) after resources are freed so there is no danger of tenants observing transient state from previous computation.

Conceal kernel completions. GPUs signal the CPU via an interrupt when a kernel has completed its execution. Interrupt timing leaks information about the kernel's runtime. Rather than rely on interrupts, Telekine uses data-oblivious streams (§5.1) that include tagged buffers that allow the GPU to communicate computational results back to the client. The platform only sees DMA from the GPU to untrusted CPU memory at a fixed rate.

Support no-op kernel launches. Dependences between GPU kernels often cause the launch of one kernel to wait for another's completion, which provides indirect timing information. The GPU TEE must support a no-op kernel launch command so that Telekine can generate cover traffic ensure the adversary sees kernel launches at a fixed rate.

Timely command consumption. The GPU TEE should consume its command queue independently of how long kernels take to execute on the GPU. If the GPU waits until each kernel completes before dequeueing the next launch command, it can fall behind the input queue fill rate, allowing the input queue to fill. The adversary can detect this situation by observing how often the encrypted queue content changes, creating a proxy for kernel execution time. The GPU should consume command queue entries at a fixed rate, discard the no-ops, and store the real commands internally until they can be executed. Telekine can hold back real kernel launches and send no-op launches in their places to ensure these internal GPU queues do not fill up.

3.2 Communicating with GPUs

GPUs can be connected to the CPU memory interconnect (integrated) or to the PCIe bus (discrete). We focus on PCIe-attached GPUs because they are preferred in performance-focused settings like the cloud due to their higher memory bandwidth and better performance.

The PCIe interfaces provide two forms of communication: memory-mapped I/O (MMIO) and direct memory access (DMA). MMIO re-purposes regions of the physical memory address space for device communication. Contiguous physical ranges, or *BARs* (base-address-regions) are reserved by the hardware, and the hardware redirects loads/stores targeting those regions to the device. Modern GPUs use MMIO BARs to expose registers for configuring the device, and frequently accessed device memory (e.g., command queues).

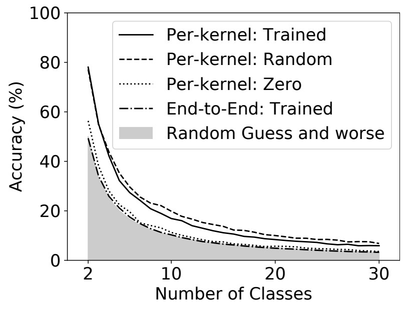
Any software that can obtain a mapping to MMIO can potentially communicate with the GPU to control it (through a register or command queue interface) or read/write its memory (through an MMIO memory BAR or by configuring DMA transfers to/from it). Telekine assumes GPU TEE support similar to Graviton [100] to prevent MMIO access to GPU status and configuration registers during secure execution.

The hypervisor and/or host operating system controls the PCIe bus, which routes packets to multiple devices connected to the PCIe root complex in a tree topology. Packets in transit to/from the GPU may be visible to other devices. Privileged host software may change the routing topology dynamically and can install pseudo-devices that allow it to sniff traffic. Securing communication with the GPU must defend against these passive and active PCIe attacks.

4 Example side-channel attack

Telekine addresses software attacks launched by an adverary resident on a cloud host, such as those launched by a malicious system administrator or a network-based attacker who has compromised the platform's privileged software. These attacks use privileged software to compromise the privacy or integrity of user code and data. Telekine is particularly focused on protecting against timing channels because effective, general-purpose attacks using timing channels have recently been demonstrated at the architecture level [53, 60, 84, 96], the OS level [97, 105], and the GPU programming level [46, 47]. Modern CPU TEEs exclude side channels from their threat model [31, 48, 78], leaving current hardware-supported security primitives vulnerable to side-channel attack. Telekine offers a unique and efficient security solution for cloud resident, GPU-based computation.

We demonstrate a proof-of-concept attack on machine learning inference in which the adversary uses the execution timing of individual GPU kernels to learn information about encrypted input data. Our attack allows privileged software on the cloud



(a) Batches of size 1

Purity	Accuracy
0.25	29.3%
0.40	33.0%
0.60	41.0%
0.80	50.0%
0.90	56.1%
1.00	65.4%

(b) Batches of size 32

Figure 2. Accuracy of multiclass classification for side-channel attacks. (a) shows the accuracy for a baches of size 1 with an increasing number of classes. (b) shows the accuracy for batches of size 32, 4 classes, and varies how much of the batch contains the target image (purity)

host to correctly classify images using only the timing of GPU kernel execution obtained on the CPU. The attacker can train their timing model on their own input, they do not need the victim's training data. The image data remains encrypted while on the CPU and the attack does not require any access to GPU architectural or microarchitectural state (including GPU timers).

Attack basics. Convolutional neural networks (CNNs) are a popular neural network architecture for analyzing images [37, 40, 91]. Each network consists of multiple layers, including convolutions, which are good at detecting features of the input image that the remainder of the network can use to classify the image. When CNNs are executed on a GPU, the computation for each layer roughly corresponds to the execution of a single GPU kernel. While the actual mapping between layers and kernels is often more complex, the intuition behind our attack is that the timing of the execution of certain CNN layers (and hence their GPU kernels) indicates the presence or absence of certain features within the input image. This makes the per-layer execution time itself a rich feature.

Telekine defeats the attack by removing the adversary's ability to infer the timing of individual kernels. The adversary retains only the ability to measure the end-to-end runtime of the inference task. However, our data shows that end-to-end runtime provides very little predictive value, making the attack not much more accurate than randomly guessing (Figure 2a). Telekine gives users the mechanism to disguise their end-to-end execution time, should they decide to do so (§2.2).

Attack details. We demonstrate this attack on ResNet50 [37], a CNN widely used for image recognition, using the timing of GPU kernel completion events as detected by the operating system on the CPU (though we monitor a function in the GPU's user-level runtime for ease of implementation). We evaluate the accuracy of our attack using 5-fold cross validation.

We start with a pre-trained model for the standard ImageNet [17] dataset which contains 1,000 different image classes. Figure 2a shows the accuracy of distinguishing image classes based on the timing of the pre-trained model's layers (Per-kernel: Trained), versus the same attack using only end-to-end timing information (End-to-end: Trained). The accuracy of the per-kernel classifier is startlingly good for small numbers of classes: 78% for two classes, 55% for three and 42% for four. As the number of classes of input images increases, the accuracy of our classification declines, but it remains much better than random guessing, outperforming guessing by over 1.9× even among 30 input image classes.

We believe the root cause of the attack is timing dependent GPU operations, probably multiplication by zero. We compare a pre-trained model (Per-kernel: Trained with no zero-valued weights), a randomly initialized model (Per-kernel: Random with 0.2% zero-valued weights), and a model whose weights are all zero (Per-kernel: Zero with 100% zero-valued weights). The zero model has bad accuracy that is close to random guessing. A randomly initialized model is best, followed by the pre-trained model.

These results were generated using MXNet [10] ported to HIP on the ROCm version 1.8 stack for AMD GPUs which is used in the prototype; we saw similar results on the 2.9 version. Preliminary tests showed that this specific attack is much less powerful on NVIDIA GPUs.

Batched classification. Because inference is often done in batches, we examine the accuracy of a batched attack. We construct batches by splitting each ImageNet class into disjoint training and test sets. Images are then randomly sampled from each of these sets to form the batches.

We present the accuracy of our attack when distinguishing four ImageNet classes in batches of size 32 (Figure 2b.) Each batch is made up of the given fraction of images from a primary class (Purity), and randomly selected images from the remaining three classes. Our objective is to correctly identify the primary class.

Batches help, with the accuracy of our attack improving with larger batch sizes. Larger batches execute more operations, effectively amplifying the timing signal our attack relies on. Moreover, larger batches smooth out execution timings for outlier images which would otherwise be less recognizable to our attack model. When distinguishing four classes (Figure 2b), the batched attack is better than random guessing even when only 25% of the input images come from the target class. The accuracy increases with higher batch purity, outperforming single images by up to 64%.

5 Design

Telekine secures GPU-based computation from active attackers, including side-channel threats. Side channels include the execution timing of individual GPU kernels as well as data movement to and from the GPU. Telekine achieves its security by transforming an application's computation so that all communication—including data movement—among trusted components is data oblivious. Telekine only trusts the client machine and the in-cloud GPU TEE and must, therefore,

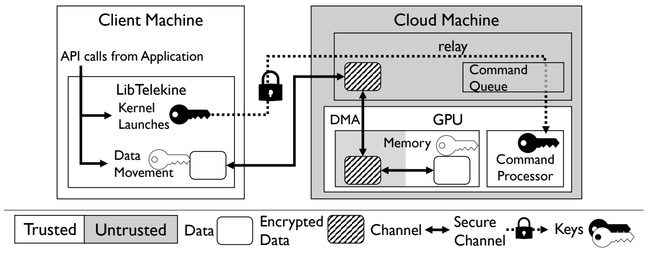


Figure 3. Detailed Telekine overview.

efficiently coordinate the computation between these entities, even though communication occurs over a wide area network, rather than over higher-bandwidth, lower-latency fabric like a data center network or a PCIe bus.

Telekine consists of three components (depicted in Figure 1 with detail in Figure 3).

- LibTelekine: a library that intercepts GPU API calls from the application and transparently transforms the calls into a data-oblivious command stream.
- Relay: an untrusted process that runs in the cloud and directs the client's command stream to the GPU.
- GPU: a GPU (or multiple GPUs) with TEE support that meets Telekine's requirements (see §3.1 for details).

LibTelekine is linked into the application running on the client. During its execution, the application issues a stream of GPU commands through the normal GPU API. Similar to normal API remoting [8, 21, 101], libTelekine redirects API calls made by the client to a server process with a GPU runtime–the relay on the cloud machine. Telekine treats the relay almost as if it were part of the network, relying on it to communicate with the GPU but protecting that communication with end-to-end techniques. The relay is not part of Telekine's trusted computing base.

All communication between libTelekine and the GPU is protected with authenticated encryption (AES-GCM [24] in our prototype) and sequence numbers. This creates a secure channel satisfying the secrecy property *S1 (content)* and the integrity properties *I1 (content)* and *I2 (order)* (described in §2.1), ensuring that the GPU commands issued by libTelekine can only be read by the GPU, and any tampering or reordering is detectable. However, by observing when messages are exchanged with the GPU (regardless of whether they are encrypted), the adversary can get timing information about the computation on the GPU.

Telekine's goal is to remove all timing information from the encrypted stream of GPU commands. It removes timing information by sending commands (GPU runtime API calls like `launchKernel` and `memcpy`) at a fixed rate, independent of input data. Fixed rating is a simple idea, but Telekine must overcome two major challenges to fix-rate GPU communication.

1. Different GPU command types are distinguishable because they have different sizes and they result in different communication patterns with the GPU. (e.g.,

launchKernel commands interact with MMIO ring buffers and memcpy commands are handled using DMA). Telekine must ensure that the attacker's ability to distinguish between these commands conveys no information about the input data.

2. Conventional GPU command streams (§2.1) exhibit a variety of data-dependent behavior whose timing is externally visible (e.g., a kernel launch after a data transfer will wait for the data transfer to finish). Telekine must maintain the ordering semantics induced by such data dependencies.

Telekine introduces a new primitive to overcome these challenges: *data-oblivious streams*. Data-oblivious streams transparently replace conventional GPU streams (and applications may have more than one), maintaining their semantics while making their communication with the GPU data oblivious. First, they separate commands by type, and schedule each type independently. Second, they split, pad, and batch commands of each type so that the encrypted payload is always the same size for messages of that type, satisfying *S3 (size)*. Third, they inject management commands as needed to maintain data-dependencies across message types, satisfying *I3 (API-preserving)*. Finally, data-oblivious streams send the transformed commands according to a fixed schedule, satisfying *S2 (timing)*.

The relay, privileged software on the cloud machine, and the network stack can delay commands since they are under complete control of the (possibly adversarial) cloud provider. However, they cannot delay commands in a way that leaks input data because all observable behavior of the trusted computing base (including its timing) is independent of input data.

5.1 Data-oblivious stream construction

Constructing data-oblivious streams only requires reasoning about memcpy and launchKernel commands. The TEE takes care of initialization (§3.1). The only other runtime commands deal with stream synchronization, and Telekine transforms those commands into memcpy and launchKernel commands as well (discussed fully in §5.4). memcpy commands are visible to the untrusted host's privileged software because GPU drivers use DMA for efficient data transfers. In Telekine, the data itself is protected and copied to/from a fixed staging area in untrusted GPU memory so the destination/-source of the memcpy does not leak information.

Conventional GPU streams can create timing channels from memcpy and launchKernel commands because a memcpy command waits for all previous launchKernel commands on the same stream. To eliminate this channel, Telekine uses two GPU streams to construct a single data-oblivious stream. Telekine uses one GPU stream to launch the application's kernels; this stream is called the ExecStream. Telekine uses the other stream—called the XferStream—to move data to and from the GPU. Telekine ensures that commands on the XferStream never leak information about the kernel execution time by waiting for commands on the ExecStream.

The ExecStream. Application kernels are all launched on the ExecStream. LibTelekine maintains a queue of the launchKernel commands requested by the application and releases the commands in order according to the fixed-rate schedule. The GPU consumes these commands independently of any ongoing kernel execution and buffers them internally since their execution must be serialized according to GPU stream semantics. Telekine honors data dependences between memcpy and launchKernel commands by inserting data management kernels that block the progress of the ExecStream by spinning until the data is in place.

The XferStream. Data transfers requested by the application are launched on the XferStream. Unlike launchKernel commands, memcpy commands are directional (i.e., client-to-GPU and GPU-to-client), and directions are detectable. For example, because the adversary can observe interaction with the network, it can differentiate between messages that came over the network in transit to the GPU, and messages copied from the GPU that are being sent over the network. LibTelekine maintains separate queues for each direction and schedules them independently to avoid leaking information. Data for client-to-GPU transfers starts on the client, flows through the relay and into untrusted memory on the GPU. LibTelekine then enqueues a kernel, which moves the data from the untrusted staging memory into trusted GPU memory. Similarly, in the GPU-to-client direction, Telekine first enqueues a launchKernel on the XferStream to move the data into untrusted GPU memory, then issues a memcpy to copy it to the relay where it can be transferred over the network back to the client.

Fixed-size commands. Telekine ensures that all memcpy commands are the same size by splitting and padding the memcpy commands issued by the application to a standard size. When there are no pending memcpy commands, Telekine maintains the same rate of data flow by scheduling dummy, standard-sized memcpys to/from a staging buffer. Similarly, all launchKernel commands are padded to the same size (320 bytes in our prototype). When no launchKernel command is available, Telekine schedules no-op launchKernel commands.

Schedules. Any schedule Telekine uses for GPU communication is secure so long as it does not depend on the data being protected. Our prototype uses simple schedules which send a fixed number of fixed-sized commands after each fixed-time interval. For instance, Telekine might launch 16 kernels on the ExecStream every 3 milliseconds, and send then receive 4MB of data every 6 milliseconds on the XferStream.

Schedules can leak the category. While scheduling work at a fixed rate is a well-known technique to avoid side-channel leakage, the exact schedule is relevant to performance. We

Algorithm 1 Telekine's replacement functions for `memcpy` and `launchKernel`. Splitting and padding steps are omitted for brevity.

```
 1: function LaunchKernel($kern$,$args$...)
 2:     Enqueue($kernelQueue$,$\{kern,args\}$)
 3: end function
 4:
 5: function MemcpyH2D($src$,$dst$)
 6:     $buf$ ←ChooseTaggedBuffer()
 7:     LaunchKernel(copy_in, $buf$, $dst$)
 8:     Enqueue($dataQueueH2D$, $\{src, buf\}$)
 9: end function
10:
11: function MemcpyD2H($src$, $dst$)
12:     $buf$ ←ChooseTaggedBuffer()
13:     LaunchKernel(copy_out, $src$, $buf$)
14:     Enqueue($dataQueueD2H$, $\{buf, dst\}$)
15: end function
```

Algorithm 2 Periodic tasks performed by Telekine according to the schedule. Encryption and decryption steps are omitted for brevity.

```
 1: loop                                   ▷ ExecStream Thread
 2:     if Empty($kernelQueue$) then
 3:         $op$ ←no_op
 4:     else
 5:         $op$ ←Dequeue($kernelQueue$)
 6:     end if
 7:     WaitForScheduledTime()
 8:     RemoteLaunchKernel($op$)
 9: end loop
10:
11: loop              ▷ XferStream Client-to-GPU (H2D) Thread
12:     if Empty($DataQueueH2D$) then
13:         $src$ ←dummy_CPU
14:         $dst$ ←ChooseTaggedBuffer()
15:     else
16:         $\{src, dst\}$ ←Dequeue($dataQueueH2D$)
17:     end if
18:     WaitForScheduledTime()
19:     RemoteMemcpy($src$, $dst$)
20: end loop
21:
22: loop              ▷ XferStream GPU-to-Client (D2H) Thread
23:     if Empty($DataQueueD2H$) then
24:         $src$ ←ChooseTaggedBuffer()
25:         $dst$ ←dummy_CPU
26:     else
27:         $\{src, dst\}$←Peek($dataQueueD2H$)
28:     end if
29:     WaitForScheduledTime()
30:     RemoteMemcpy($src$, $dst$)
31:     if $dst \neq$ dummy_CPU then
32:         if TagMatches($dst$) then
33:             Dequeue($dataQueueD2H$)
34:         end if
35:     end if
36: end loop
```

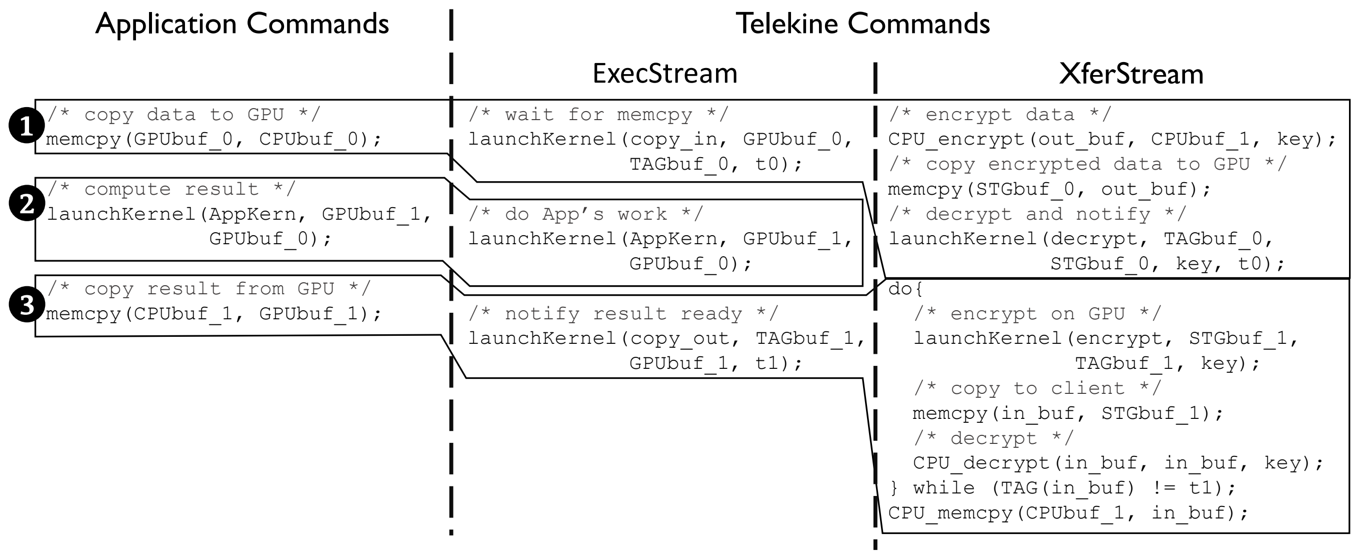
report our schedules in Table 1, and they are the same for all tasks of a given category, e.g., training different machine learning models with MXNet. However, they can differ across categories, e.g., Galois has a different ExecStream schedule from MXNet (§7). Under our threat model, the adversary would be able to differentiate these workloads from their network traffic. A user can always choose a more generic, but lower performing schedule if this is a concern.

5.2 Telekine operation

Algorithm 1 and Algorithm 2 provide a high-level description of Telekine's data-oblivious streams. In Algorithm 1, Telekine intercepts the application's calls to `launchKernel` and `memcpy` and transforms them into interactions with queues: kernelQueue, dataQueueH2D, and dataQueueD2H (splitting, padding, and encryption steps are omitted for brevity). The Telekine threads shown in Algorithm 2 dequeue the commands and release them to the GPU according to the schedule. Telekine waits at lines 7, 18, and 29 for the next available time slot ensuring that interactions with the queues do not influence the timing of messages.

Most `memcpy` commands have strict ordering requirements with respect to kernels that operate on their data. The `memcpy` then `launchKernel` idiom ensures that the launched kernel has fresh data to process. While Telekine decouples `memcpy` commands by scheduling them on their own stream for security, it needs to preserve the original ordering semantics expected by the application. Telekine maintains these semantics by injecting its own data management kernels into the ExecStream (shown on lines 7 and 13 of Algorithm 1) to enforce the ordering expected by the application. These data management kernels operate on *tagged buffers* which Telekine uses to synchronize data access.

Tagged buffers. Tagged buffers are pre-allocated staging buffers on the GPU, each with an associated tag slot. Telekine assigns every `memcpy` operation a tagged buffer and a unique tag, represented by "ChooseTaggedBuffer" in Algorithm 1 and Algorithm 2. Data management kernels producing data (e.g., copying out the result of a kernel computation) write the tag into the tag slot of the chosen tagged buffer after the operation has completed and a memory barrier completes. Data management kernels that consume data (e.g., waiting for data a kernel expects to use as input) wait until the tag slot of the assigned buffer contains the expected value since they cannot be sure the buffer data is valid until the tag value matches its expectation.



```
/* copy data to GPU */
memcpy(GPUbuf_0, CPUbuf_0);
```

```
/* wait for memcpy */
launchKernel(copy_in, GPUbuf_0,
             TAGbuf_0, t0);
```

```
/* encrypt data */
CPU_encrypt(out_buf, CPUbuf_1, key);
/* copy encrypted data to GPU */
memcpy(STGbuf_0, out_buf);
/* decrypt and notify */
launchKernel(decrypt, TAGbuf_0,
             STGbuf_0, key, t0);
```

```
/* compute result */
launchKernel(AppKern, GPUbuf_1,
             GPUbuf_0);
```

```
/* do App's work */
launchKernel(AppKern, GPUbuf_1,
             GPUbuf_0);
```

```
/* copy result from GPU */
memcpy(CPUbuf_1, GPUbuf_1);
```

```
/* notify result ready */
launchKernel(copy_out, TAGbuf_1,
             GPUbuf_1, t1);
```

```
do{
  /* encrypt on GPU */
  launchKernel(encrypt, STGbuf_1,
               TAGbuf_1, key);
  /* copy to client */
  memcpy(in_buf, STGbuf_1);
  /* decrypt */
  CPU_decrypt(in_buf, in_buf, key);
} while (TAG(in_buf) != t1);
CPU_memcpy(CPUbuf_1, in_buf);
```

Figure 4. API calls made by the application and their mapping to underlying commands performed by Telekine.

Data management kernels. Telekine inserts its own data management kernels into the ExecStream which either produce or consume tagged buffers depending on the direction of the transfer. There are two kernels: `copy_in` and `copy_out`. Both kernels take an application-defined memory location, a tagged buffer, and a tag as arguments. For CPU-to-GPU `memcpys`, libTelekine inserts a `copy_in` launch into the ExecStream. The `copy_in` will repeatedly check the tag slot of the buffer, completing the copy to the application's buffer only after verifying the tag slot matches the tag it was given as an argument. To service GPU-to-CPU `memcpys`, Telekine inserts a `copy_out` into the ExecStream after the application kernel which generates the data. The `copy_out` writes the data to the assigned tagged buffer, followed by the tag to signal to Telekine that the data is ready. Since libTelekine runs on the client it has no way of knowing when the copy out has completed until the tagged buffer has been copied back, so it will retry the same GPU-to-CPU copy until the tag is correct corresponding to a complete copy. This is represented by the PEEK operation on line 27 of Algorithm 2, the operation is only dequeued after libTelekine verifies that the `copy_out` kernel did its work on line 32.

GPU-to-GPU data copies. Emerging hardware supports dedicated, high-bandwidth, cross-GPU communication links such as NVLink [26]. NVLink improves cross-GPU data copy efficiency but does not change the fundamental communication mechanisms used in a GPU stack. Telekine currently implements GPU-to-GPU copies as two copies: one from the first GPU back to the client and the second from the client to the second GPU. Direct GPU-to-GPU copies using NVLink would be far more efficient, but to be data oblivious they would have to occur at a fixed rate. We leave this task for future work.

Discussion. The XferStream is carefully constructed so that it never synchronizes with the ExecStream. The XferStream contains DMA operations which the OS can detect; if application kernels on the ExecStream occupy the GPU causing the encryption kernels on the XferStream—and transitively the DMAs—to wait, then the platform can learn some information about kernel execution times. There may still be leakage between the XferStream and the ExecStream because we cannot guarantee that kernels of the former will not interfere with the latter. However, we believe this leakage to be hard to exploit in practice, we have not seen it in any of our benchmarks, and we expect that future GPU features like strict priority [72] or preemption [92] will allow Telekine to seal the leak.

5.3 Data movement example.

Figure 4 shows an example of how Telekine transforms application commands into equivalent, data-oblivious commands on the ExecStream and XferStream. The application issues 3 commands: ❶ copy data to the GPU, ❷ launch a kernel to process that data, and ❸ copy the results of the computation out of the GPU back to the CPU.

❶ : The application requests a `memcpy` from `CPUbuf_0` to `GPUbuf_0`. In response, Telekine chooses a tag, `t0`, and tagged buffer, `TAGbuf_0`, for this operation, then enqueues a kernel, `copy_in`, on the ExecStream. The `copy_in` kernel will spin on the GPU, using atomic operations to check the end of `TAGbuf_0` until it sees `t0`, then copy the contents of `TAGbuf_0` into `GPUbuf_0`. On the XferStream, Telekine encrypts the data, then copies the encrypted data to a staging buffer in untrusted GPU memory `STGbuf_0`. Finally, Telekine launches a kernel, `decrypt`, on the XferStream which reads the encrypted data out of untrusted memory and decrypts it into `TAGbuf_0`. After the data is written, the tag `t0` is appended

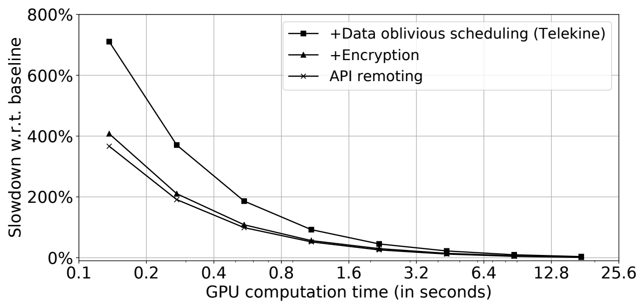


Figure 5. A microbenchmark which shows how Telekine overheads decrease as the running time of the GPU computation increases.

after a memory barrier, signaling to `copy_in` that the data is ready.

❷ : The application launches its kernel, `AppKern`, which processes the data in `GPUbuf_0` and writes its result into `GPUbuf_1`. Since `AppKern` is launched on the ExecStream after `copy_in` it will wait for `copy_in` to complete, ensuring that the data will be in `GPUbuf_0` before `AppKern` starts. The platform cannot detect that `AppKern` has started.

❸ : The application issues a request to copy the results of `AppKern` from `GPUbuf_1` to `CPU_buf1`. In response, Telekine again chooses a tag and tagged buffer, `t1` and `TAGbuf_1` respectively, and immediately enqueues a `copy_out` kernel on the ExecStream. After the application's kernel, `AppKern`, has completed, `copy_out` moves the result of its computation in `GPUbuf_1` into `TAGbuf_1` then atomically appends `t1`. While waiting for `copy_out` to finish, Telekine periodically encrypts `TAGbuf_1` into a staging buffer in untrusted memory, `STGbuf_1`, then issues a `memcpy` operation to copy the contents of `STGbuf_1` to a client-side buffer, `in_buf`. Telekine decrypts `in_buf` and checks the tag. If the tag matches `t1`, `copy_out` and `AppKern` must have completed and the data can be copied into `CPUbuf_1`. If not, this process will be repeated during the next scheduled GPU to client transfer.

5.4 Synchronizing data-oblivious streams

Applications sometimes wish to synchronize with their GPU streams (i.e., wait for all outstanding commands to complete), or synchronize one GPU stream with another (i.e., ensure another stream has completed some operation, n, before this stream starts operation, m). Telekine handles both of these cases by injecting kernels that increment a counter in GPU memory between kernels in the ExecStream. Because of stream semantics, the increment kernel only runs after all previous kernels in the stream, providing an accurate count of how many application kernels have executed. Telekine copies that counter back to the client periodically and can block the application thread until all submitted work has completed.

	ExecStream		XferStream		
Benchmark	Quantum	Size	Quantum	Size	Bandwidth
Microbench	15ms	32kerns	30ms	1MB	533 Mb/s
MXNet	15ms	512kerns	30ms	1MB	533 Mb/s
Galois1	15ms	32kerns	30ms	1MB	533 Mb/s
Galois2	15ms	32kerns	30ms	1MB	533 Mb/s

Table 1. Data-oblivious schedule parameters and the network bandwidth required. MicroBench from §7.1; MXNet from §7.2; Galois1 executes on one GPU, Galois2 on two from §7.3. ExecStream sizes are number of kernel launches, each of which is 320 bytes. XferStream streams contribute twice their size to bandwidth consumption because Telekine copies data in both directions at every quantum.

6 Implementation

The Telekine prototype is based on AMD's ROCm 1.8 [2], an open-source software stack for AMD GPUs. Telekine requires an open-source stack because we split its functionality between user and cloud machines. NVIDIA is generally thought to have higher hardware and software performance as well as better third-party software support. But NVIDIA only officially supports closed-source drivers and runtimes.

LibTelekine and the relay. All applications were ported to use HIP [39], the ROCm CUDA replacement. LibTelekine marshals the arguments of HIP API calls to be sent over a TLS protected TCP connection to the relay to support initialization. The libTelekine and relay prototype are based on code generated by AvA [107]; they total 8,843 and 5,650 lines of C/C++/HIP code respectively (measured by cloc [12]).

GPU TEE. GPU TEE requirements are made explicit in Section 3.1, and most of those requirements are safety properties that do not impact performance. A notable exception is the cryptography required to secure the secrecy and integrity of kernel launch commands. We model the timing of these features by decrypting kernel launch commands in the relay.

7 Evaluation

We quantify the overheads of the security Telekine provides by comparing it to an insecure baseline: applications run on cloud provider machines that offload computation to GPUs directly through the GPU runtime.

We measure Telekine across two testbeds. The first is the *simulated testbed* which simulates wide-area network (WAN) latency and bandwidth, providing a controlled environment for measurement. The second is the *geodist testbed* in which the server and client are geodistributed and connected by the Internet. Both testbeds use the same "cloud machine" (the *server*), which has an Intel i9-9900K CPU with 8 cores @3.60GHz, 32GB of RAM and two Radeon RX VEGA 64 GPUs each with 8GB of RAM. All machines are running Ubuntu 16.04.6 LTS with Linux kernel version 4.13.0, and AMD's ROCm-1.8 runtime and HIP-1.5 compiler.

In the simulated testbed, the client has an Intel Xeon E3-1270 v6 processor with 4 cores @3.8GHz and 32GB of RAM.

	ResNet	InceptionV3	DenseNet
Model size	97.5 MB	90.9 MB	30.4 MB
Input size			
Input image	224x224x3	299x299x3	224x224x3
Batch size	64	64	48
Data size per batch	9.2 MB	16.4 MB	6.9 MB
Single-GPU training baseline			
T-put	20.27 MB/s	11.05 MB/s	13.57 MB/s
T-put (less sync)	22.69 MB/s	11.66 MB/s	17.46 MB/s

Table 2. Overview of machine learning training on MXNet. Input size is given in pixel dimensions, batch size in images per GPU. T-put is throughput.

Both this client and the server are equipped with a Gtek X540 10Gb NIC, which we connect directly. We simulate a client-to-cloud network connection in a controlled environment using `netem` [65], which allows us to add network delays and limit bandwidth. We always limit the bandwidth of the connection to 1Gbps and unless otherwise mentioned we add delays in both directions so that the total round trip time (RTT) is 10ms. These parameters are conservative for a network connection to an edge cloud server [16, 106].

In the geodist testbed, the client is a VM hosted by vultr [102] in their Dallas, TX datacenter (the server is in Austin, TX). The VM has 8 vCPUs and 32GB of RAM. We measured the RTT between the server and this client at 12ms, and the average bandwidth at 877Mbps.

Different applications use different schedules to get good performance, though Table 1 shows strong similarity among the data-oblivious schedules we use for evaluation.

7.1 Telekine performance tradeoff

Figure 5 shows the performance tradeoff for a microbenchmark with 16MB of input and output and a GPU kernel with a configurable running time on the simulated testbed. The different lines show the costs of specific sources of overhead. The "API remoting" line uses the XferStream and the ExecStream over the network. The "+Encryption" line adds encryption to API remoting. Finally, the "Data-oblivious scheduling" line adds the data-oblivious schedule described in Table 1 to encryption. When the GPU kernel executes for only 0.14 seconds, the overhead of Telekine is nearly 8×. Once the computation takes 4.4s the overhead is only 22%. Telekine is a remote execution system; it makes communication more expensive because of its oblivious scheduling as well as network delay and limited bandwidth. It is most efficient when computation dominates communication, which is the case for our benchmarks.

7.2 Machine learning algorithms

We port MXNet [10], a state-of-the-art machine learning library, to run on the HIP runtime. Our port is based on MXNet v1.1.0 (git commit `07a83a03`). We also use AMD's MIOpen library for efficient neural network operators. Some parts of MXNet adaptively choose from different GPU kernel implementations by measuring execution times on the available hardware and choosing the most performant option. To ensure the baseline and Telekine are running the same kernels for measurement purposes, we record the kernels chosen by the baseline, and hard-code those kernel choices for all runs.

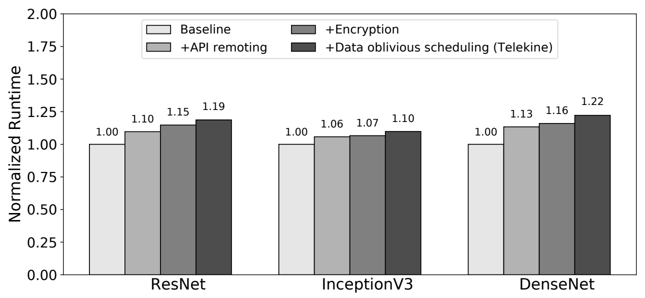

Figure 6. Performance of machine learning training algorithms using a single GPU with Telekine on the simulated testbed.

ResNet	InceptionV3	DenseNet
1.23×	1.08×	1.20×

Table 3. Performance of machine learning training algorithms on Telekine, measured on the geodist testbed.

Optimizing MXNet. We applied several optimizations to MXNet which help to mitigate the fact that Telekine is communicating with the GPU over a WAN:

- The models we evaluate represent the pixel channels of the input bitmaps using 4-byte floating point quantities, even though they range in integer values from 0 to 255. To save network bandwidth, we send bytes instead of floats, reducing bandwidth by 4×. Bytes are changed back floats on the GPU.
- We determined that MXNet was overly conservative in its GPU synchronization strategy and were able to reduce the number of synchronizations it performs by removing unnecessary calls to `hipStreamSyncronize` ("less sync" in Table 2). Telekine also optimizes synchronization calls by using tagged buffers (§5.1) to coordinate data transfers.

Machine learning training. We evaluate the training performance of deep neural networks on Telekine using three state-of-the-art convolutional neural network architectures: ResNet [37], InceptionV3 [91], and DenseNet [40]. All models are trained using the ImageNet dataset (a substantial data set consisting of 1.4 million training images). For ResNet, we use the 50-layer variant. For DenseNet, we use the 121-layer variant. We evaluated all networks using batches size of 64. Table 2 summarizes the input sizes that were used to evaluate the three network architectures.

Figure 6 shows the performance of training three neural nets on Telekine using the simulated tesdbed, normalized to the insecure baseline. The bars break down Telekine's overheads and match the descriptions from Section 7.1. Both Telekine and the baseline use a single GPU. Table 3 shows the same

Batch size	ResNet Base	ResNet Telekine	InceptionV3 Base	InceptionV3 Telekine	DenseNet Base	DenseNet Telekine
Simulated testbed						
1	20	273 (13.7x)	29	259 (8.93x)	26	248 (9.54x)
8	42	270 (6.43x)	65	264 (4.06x)	47	241 (5.13x)
64	233	389 (1.67x)	368	559 (1.52x)	246	405 (1.65x)
256	988	1195 (1.21x)	1520	1806 (1.19x)	946	1163 (1.23x)
Geodist testbed						
1	20	200 (10.0x)	31	205 (6.61x)	26	201 (7.73x)
8	69	241 (3.49x)	111	247 (2.23x)	84	209 (2.49x)
64	462	481 (1.04x)	637	685 (1.08x)	484	483 (1.00x)

Table 4. Latencies (in ms) of machine learning inference workloads with the baseline system (Base in the table) and Telekine.

experiment on the geodist testbed; the results are similar to the simulated testbed.

Machine learning inference. We evaluate neural network inference workloads for ResNet, InceptionV3, and DenseNet with Telekine. For inference, latency is the priority for users, but throughput is still a priority for providers. Batching inference can substantially improve throughput by fully utilizing hardware capabilities and amortizing the overheads from other system components [15]. We evaluate the latency of inference with different batch sizes, ranging from 1 to 256. Our baseline is an insecure server with one local GPU, communicating with the over the network. Table 4 shows the inference latency of three neural networks with different batch sizes. The overheads with on the simulated testbed for batches of size of 256 are 21%, 19%, and 23% for ResNet, InceptionV3, and DenseNet, respectively which are slightly improved compared to the overheads we report for training (§7.2), although the training batch size was 64. With a batch size of 64, the overheads on the simulated testbed inflate to 67%, 52%, and 65%. When we move to the geodist testbed, the performance of the baseline suffers more that Telekine; at batches of size 64, the standard deviation of our measurements exceed the differences between the mean Telekine and baseline runs. Clipper [15] uses an adaptive batch size to meet the latency requirement of the application, which Telekine could adopt.

7.3 Graph algorithms

Galois is a framework designed to accelerate parallel applications with irregular data access patterns, such as graph algorithms [75]. We port Galois's GPU computation to use the HIP runtime instead of CUDA and evaluate it on three graph algorithms: breadth-first search (BFS), PageRank, and single source shortest paths (SSSP). All measurements use the USA roads graph dataset [18]. Figure 5 shows the performance of these applications on Telekine with one and two GPUs. The baseline is an unmodified system with local GPU(s). Baseline performance for single GPU applications is: BFS 54.1s, SSSP 74.6s, Pagerank 60.9s; for two GPUs: BFS 36.4s, SSSP 42.8s. For the input distributed with Galois, two GPU Pagerank slows down, so we do not evaluate it.

Application		Normalized runtime
BFS	(1 GPU)	1.18x
SSSP	(1 GPU)	1.21x
Pagerank	(1 GPU)	1.29x
BFS	(2 GPUs)	1.38x
SSSP	(2 GPUs)	1.41x

Table 5. Performance of Galois applications with Telekine.

RTT (ms)	ResNet	InceptionV3	DenseNet
10	1.19x	1.10x	1.22x
20	1.29x	1.13x	1.37x
30	1.44x	1.16x	1.49x
40	1.53x	1.18x	1.66x
50	1.62x	1.30x	2.09x

Table 6. Normalized runtime of machine learning workloads with respect to network round trip time (RTT).

Telekine imposes moderate overheads on single-GPU Galois applications, adding latency to data transfer times. Galois implements each graph algorithm as a single GPU kernel that is iteratively called until the algorithm reaches termination. Multi-GPU applications exchange data between GPUs through the host after each iteration. Telekine imposes higher overheads for multi-GPU workloads because of increased data movement over the network.

7.4 WAN latency sensitivity

Telekine assumes that the client communicates with the server over a WAN. The greater distances crossed by WANs result in longer round trip times (RTTs). The batching of commands that Telekine does for security also makes it resilient to these increased RTTs, especially when the ratio of GPU computation to communication is high. To demonstrate this we increased the RTT between our machines using `netem` [65] and ran the machine learning training benchmarks for different RTTs (Table 6). Overheads increase with RTT. At 30ms which we measured to be the RTT between the client and an Amazon EC2 instance, the overhead for InceptionV3 is still only 16%.

8 Related Work

Enclave-based security. Several recently proposed systems aim to protect applications from an untrusted platform. Haven [7], SCONE [4], and Graphene-SGX [95] provide an environment to support unmodified legacy applications. Ryoan [43] protects user data from untrusted code and an untrusted platform. VC3 [83] and Opaque [109] provide SGX-protected data processing platforms. None of these systems allow for GPU computation and none of them focus on the communication issues that then arise.

Trusted execution environments on GPUs. HIX [45] extends an SGX-like design with duplicate versions of the enclave memory protection hardware to enable MMIO access from code running in an SGX enclave. This enables HIX to guarantee that a single enclave has exclusive access to the MMIO regions exported by a GPU, in principle, defeating a malicious

OS that wants to interpose or create its own mappings to them. While this design provides stronger GPU isolation than current enclaves, it remains vulnerable to side-channel attacks because communication is not data oblivious.

Graviton [100] supports GPU TEEs based on *secure contexts* that use the GPU command processor to protect memory from other concurrently executing contexts. Similar to Telekine, Graviton secures communication using cryptographic techniques. Telekine can adopt many of Graviton's clever mechanisms for its TEE functionality (§3.1), such as restricting access to GPU page tables without trusting the kernel driver. But Graviton does not protect against side channels, which is Telekine's primary mission.

The opportunity to provide stronger security for GPU-accelerated applications using TEEs and oblivious communication has been observed by others [41].

Securing accelerators. SUD emulates a kernel environment in user space to isolate malicious device drivers [9]. Previous work has explored techniques to support trusted I/O paths, leveraging hypervisor support [103, 110] or system management mode [52]. Our work focuses on the secure use of GPUs with untrusted system software and does not rely on support from the software at lower privilege layers. Border Control [74] addresses security challenges for accelerator-based systems but focuses on protecting the system from a malicious accelerator, rather than Telekine which protects CPU and GPU code from an untrusted platform.

GPU security and protection. Studies have analyzed GPU security properties and vulnerabilities [112]. Frigo et al. [28] demonstrate techniques that leverage integrated GPUs to accelerate side-channel attacks from browser codes using JavaScript and WebGL. PixelVault [98] exploits physical isolation between CPUs and GPUs to implement secure storage for keys, though it was shown to be insecure [112]. CUDA Leaks [77] shows techniques to exfiltrate data from the GPU to a malicious user. Attacks that take advantage of GPU memory reuse without re-initialization are a common theme [36, 56, 111]. Several systems have proposed mechanisms that bring the GPU under tighter control of system software, exploring OS support [34, 49, 63, 82], access to OS-managed resources [51, 86, 87], hypervisor support [20, 30, 33, 85, 90, 93, 101] and GPU architectural support for cross-domain protection [5, 13, 76, 79, 99].

Secure machine learning. Ohrimenko et al. describe an SGX-based system for multi-party machine learning on an untrusted platform [73]. Their data-oblivious algorithm for convolutional neural networks explicitly does not support state-of-the-art operations that are data dependent (e.g., max pooling). Telekine can support any data-dependent operations but requires a GPU TEE. Chiron [42] provides a framework for untrusted code to design and train machine learning models in SGX. Telekine does not support untrusted code, but does allow the use of GPUs which Chiron excludes. CQSTR [108] lets a *trusted* platform operator confine untrusted machine learning code so that it can be securely applied to user data. By contrast, Telekine protects user data from an untrusted platform operator. MLcapsule [35] protects service provider secrets (machine learning model) and client data by running machine learning algorithms in an SGX enclave but does not suggest extensions to allow secure GPU acceleration.

Slalom [94] secures training of DNNs using a combination of TEEs and local GPUs. Slalom's guarantees are achieved by partitioning DNN training into linear layers using matrix multiplication, which are offloaded to a GPU, the remaining operators, which execute on the CPU in a TEE such as SGX. Matrix multiplication is verified and turned private using algorithmic techniques [27], which enables secure GPU offload without requiring GPU TEE support.

Recent work [19, 61] demonstrates how to efficiently *apply* neural networks to encrypted data. As far as we know, today there are no practical techniques for *training* deep neural networks on encrypted data.

API remoting. API remoting [6, 22, 23, 50, 57, 58, 80, 104] is an I/O virtualization technique that interposes a high-level user-mode API. API calls are forwarded to a user-level computing framework [85] on a dedicated appliance VM [101], or on a remote server [23, 50]. To our knowledge, Telekine is the first system to use API remoting as a security technique.

OS-level time protection. Recent extensions to seL4 [29] suggest general OS-level techniques that prevent timing-based covert channels by eliminating sharing of hardware resources that can form the basis of covert channels. The techniques do not yet generalize to I/O-attached accelerators.

9 Conclusion

Telekine enables secure GPU acceleration in the cloud. Telekine protects in-cloud computation with a GPU TEE and application/library computation by placing it on a client machine. It secures their communication with a novel GPU stream abstraction that ensures the execution is independent of input data. Telekine allows GPU-accelerated workloads such as training machine learning models to leverage cloud GPUs while providing strong secrecy and integrity guarantees that protect the user from the platform's privileged software and its administrators.

TimeCrypt: Encrypted Data Stream Processing at Scale with Cryptographic Access Control

Lukas Burkhalter[1], Anwar Hithnawi[1,2], Alexander Viand[1], Hossein Shafagh[1], Sylvia Ratnasamy[2]

[1]*ETH Zürich* [2]*UC Berkeley*

Abstract

A growing number of devices and services collect detailed *time series* data that is stored in the cloud. Protecting the confidentiality of this vast and continuously generated data is an acute need for many applications in this space. At the same time, we must preserve the *utility* of this data by enabling authorized services to *securely* and *selectively* access and run analytics. This paper presents TimeCrypt, a system that provides *scalable* and *real-time* analytics over large volumes of encrypted time series data. TimeCrypt allows users to define expressive data access and privacy policies and enforces it cryptographically via encryption. In TimeCrypt, data is encrypted end-to-end, and authorized parties can only decrypt and verify *queries* within their authorized access scope. Our evaluation of TimeCrypt shows that its memory overhead and performance are competitive and close to operating on data in the clear.

1 Introduction

Recent years have seen explosive growth in systems and devices that collect time series data and relay it to cloud-based services for analysis. This growth is only expected to accelerate with the proliferation of IoT devices, telemetry services, and improvements in data analytics. However, with this growth has come mounting concerns over data protection and data privacy [66]. Today, the public concern over data privacy and confidentiality is reaching new heights in light of the growing scale and scope of data breaches [17, 29, 56]. To grasp the extent of this issue, one can look at the number of data breaches reported under the new GDPR *obligation to notify*, which has already exceeded 65,000 in the first year [73].

Over the last decade, encrypted databases [60, 61, 63, 75, 81] have emerged as a promising solution to tackle the problem of data breaches. The approach of keeping data encrypted while in-use allows users to query encrypted data while preserving both confidentiality and functionality. Research in this domain has led to various encrypted database designs, including designs for key-value stores [25], batch analytics [60], graph databases [53], and relational databases [63, 81]. This motivates the following natural question: *can we enable encrypted data processing for time series workloads?*

Time series workloads come with unique performance and security requirements that existing encrypted data processing systems fail to meet:

(i) Scalability and Interactivity. Query processing over time series data must simultaneously scale to large volumes of data, support low-latency interactive queries, *and* sustain high write throughput. To meet these challenges several dedicated databases have been designed for time series workloads [12, 33, 42, 45, 50, 62, 78]. A key aspect of these systems is their use of in-memory indices that store aggregate statistics, enabling faster query response times and data summarization. As we discuss in §6/§7, prior work on encrypted data processing does not easily lend itself to maintaining these in-memory indices. The overhead of the crypto primitives in encrypted data processing needs to be negligible to meet the scaling, latency, and performance requirements associated with time series workloads.

(ii) Secure Sharing. A key challenge in modern systems is that privacy must co-exist with the desire to extract value from the data, which typically implies *sharing* data to be analyzed by third-party services [54]. Hence, a truly comprehensive approach to data protection must also comprise mechanisms for secure sharing of encrypted data. Sharing should also be *fine-grained* since it is undesirable and often unnecessary to give parties unfettered access to the data. Instead, users may want to *(1)* share only aggregated statistics about the data (e.g., avg/min/max), *(2)* limit the resolution at which such statistics are reported (e.g., hourly vs. per-minute), *(3)* limit the time interval over which queries are issued (e.g., only June 2019), *(4)* or a combination of the above. Moreover, the desired granularity and scope of sharing can vary greatly across users and applications. Hence, support for encrypted query processing must go hand-in-hand with access control that limits the scope of data that users might query. The sharing paradigm in data-stream systems is distinctly different than in conventional databases. Data-stream settings feature a multitude of data sources continuously pushing data to the cloud, where various services that are often not known in advance can subscribe to consume and analyze data streams. Therefore, such systems require flexible access policies. Frequently, there is a need to fuse and analyze data from different sources collectively; this implies that we need to devise an end-to-end encryption scheme that is compatible with this sharing paradigm.

TimeCrypt. In this paper, we present TimeCrypt, a system that augments time series databases with efficient encrypted data processing. TimeCrypt provides cryptographic means to restrict the query scope based on data owners' defined policies. With TimeCrypt, data owners can cryptographically restrict user A to query encrypted data at a defined temporal range and granularity, while simultaneously allowing user B to execute queries on the same data at a different granularity without *(i)* introducing ciphertext expansion or data redundancy, *(ii)* introducing any noticeable delays, or *(iii)* requiring a trusted entity to facilitate this.

In this work, we introduce a partially homomorphic-encryption-based access control construction (HEAC) that supports both fine-grained *access control* and *computations* over encrypted data within a *unified scheme*. These two aspects have traditionally been addressed independently: the former through cryptographically enforced access control schemes [35, 39, 49, 59, 83] and the latter through encrypted data processing [60, 63, 75, 81]. HEAC simultaneously supports both while meeting the performance and access control requirements of time series workloads. A key insight behind the design of HEAC is based on the observation that time series data streams are continuous and time is the natural attribute for accessing and processing this data. Hence, we discretize data streams into fixed-length time segments, and encrypt each segment with a different key using symmetric-key homomorphic encryption. This allows us to express fine-grained access policies at the stream segment granularity. This, however, raises two challenges; we need to manage a large number of keys in an efficient and scalable manner and translate stream access policies to the corresponding keys succinctly. To overcome these challenges in HEAC, we associate keys with temporal segments. With this, we avoid the need to maintain a mapping between keys and ciphertexts. We derive these keys from a hierarchical key-derivation tree construction that allows us to express fine-grained access policies over stream data and share keys efficiently (i.e., with logarithmic complexity).

We provide an implementation and evaluation of a prototype of TimeCrypt on top of Cassandra. We evaluate TimeCrypt in a range of scenarios combining IoT devices, AWS (for data storage and processing), and time series traces from real-world applications. We show that TimeCrypt can support a wide range of applications by developing four applications which vary in complexity and scalability requirements. Finally, we show that TimeCrypt's performance is competitive with the baseline (plaintext) and it outperforms prior work by a factor of 2 to 52 (§6). Considering an ingest workload with 5.77 million data points per second *on a single machine*, TimeCrypt's throughput is reduced only by 2.9% for both data ingest and statistical queries over encrypted data.

Contributions. In summary, our contributions are:

- We introduce HEAC, an encryption-based access control construction for stream data that is additively homomorphic. HEAC additionally provides verifiable computations over ciphertexts to ensure the integrity of the outsourced encrypted computation.
- We design, implement, and evaluate TimeCrypt, the first scalable privacy-preserving time series database that meets the scalability and low-latency requirements associated with time series workloads. We introduce a design that protects the data confidentiality, yet maintains its utility by efficiently supporting a rich set of functionalities and analytics that are key to time series data. TimeCrypt supports data lifecycle operations such as ongoing data summarization and deletion that are common in time series databases. TimeCrypt supports expressive data access and privacy policies, enforceable by encryption.
- We make TimeCrypt's code publicly available[1], both as a standalone system and as a library to be integrated with other time series databases.

2 Overview

TimeCrypt achieves its competitive performance through a careful design of cryptographic primitives tailored for time series data workloads. To understand the rationale behind our techniques, we start this section by presenting relevant background on time series data, then we give an overview of TimeCrypt, and describe our security model.

2.1 Background on Time Series Data

Time series Applications. Time series data is increasingly prevalent across a wide range of systems (e.g., monitoring, telemetry, IoT) in diverse domains such as health, agriculture [82], transportation [69], operational insight [2], and smart cities. The growth of time series data is largely attributed to the rising demand for instrumentation. Individuals and organizations are continuously logging various metrics which report the state of systems or organisms for better diagnoses, forecasting, decision making, and resource allocation. The ability to capture and analyze this data in a timely manner is key for automation and is enabling a whole new spectrum of applications [2, 33, 40, 69, 82]. The proliferation of time series data has been coupled with increasing demand for high-performance analytics over large volumes of time series, and has led to numerous designs for databases that are optimized for time series workloads [12, 33, 42, 45, 50, 62, 78].

Time series Workloads. *(i) Write and Read:* Data is append-only and typically generated at an extremely high rate (high velocity) and is initially stored at a high resolution (large volume) [12, 62]. It is not unusual for applications in this space to report hundreds of millions of data points per day [7, 12].

[1] Available at: https://timecrypt.io/

Hence, sustaining high read and write throughputs and scalability are key requirements when storing and processing time series data. Time is the primary dimension for accessing and processing data. Queries primarily consider temporal ranges (e.g., values from the last 3h) rather than targeting individual points. *(ii) Analytics:* Queries are primarily of aggregate and statistical nature, and specialized indices for accelerating statistical queries are common in time series databases [12, 42, 65]. Additionally, analytics of diagnostic (e.g., anomaly or trend detection) and predictive nature (e.g., forecasting) are common in this space. *(iii) Data decay:* Time series data is often machine generated, continuous, and massive. Simultaneously, the value and relevance of data decays rapidly with time. Analytics largely favor recent data over older, and roll up aggregation is commonly applied to older data to reduce storage requirements. Hence, data retention and summarization [7, 62] are crucial for these systems.

The goal of our work is to retain the performance, functionality, and scalability of existing time series databases while augmenting them with strong security and privacy guarantees.

2.2 Architecture

TimeCrypt's architecture is analogous to that of conventional times-series databases [10, 11, 12, 42, 50], where a standard distributed key-value store is extended with additional logic for time series workloads. TimeCrypt includes a trusted *client library* to realize end-to-end encryption paired with access control and integrity verification. TimeCrypt consists of two components (i.e., the client and server libraries) and involves four parties (i.e., data owner, data producer, data consumer, and database server), as illustrated in Fig. 1. A *data producer* is an entity (e.g., IoT device) that generates and uploads time series data, and runs TimeCrypt's client library which handles stream preprocessing and encryption. The *data owner* can express access permissions to its generated data. Meanwhile, *data consumers* are entities (e.g., services) that are authorized to access a user's data to provide added value, such as visualizations, monitoring, and diagnoses. TimeCrypt's server executes statistical and analytical queries directly on encrypted data. TimeCrypt supports a rich set of foundational queries that are widely used in time series workloads (§4), i.e., statistical queries (e.g., min/max/mean), analytics (e.g., prediction, trend detection), and lifecycle operations (e.g., ongoing data summarization, deletion). The server builds *in-memory encrypted indices* to support fast queries and analytics (§4).

2.3 Goals for Stream Data Access Control

Encryption is an effective tool for protecting data from external threats, breaches, or malicious providers. However, a truly comprehensive approach to data protection must also include mechanisms for enforcing access control policies, to support the privacy and security principles of least privilege and data minimization, where data is protected by limiting unnecessary

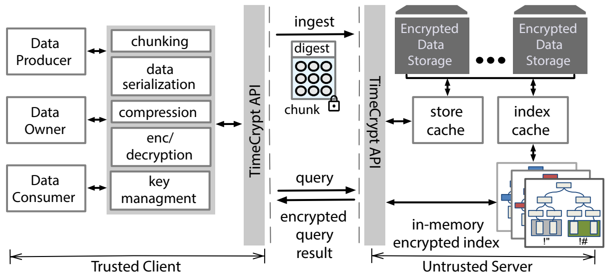

Figure 1: TimeCrypt's architecture.

exposure. State-of-the-art relational databases have security mechanisms designed for this purpose. The most adopted approach to support access control is based on views[2] and row-level access policies. However, specifying effective access control policies necessitates taking into consideration the semantics of data. Therefore, we investigated the major state-of-the-art time series databases [1, 4, 12, 42, 58, 65, 78] to understand the state of affairs in stream data access policies. We found that the only access policy restriction provided at the database interface, if any, is at the stream unit (i.e., grant or decline access to the entire stream). This binary protection level is however too coarse. This prompted the following question: What type of policies can offer the fine-grained protection that is required for selective and secure sharing of data streams? Stream data access control literature [24, 71] and time series applications designed for multi-user settings[5, 40] both recognize that policies which are expressed in time, resolution, and attributes are ideal for fine-grained access restrictions on streams. Examples of such policies can be a user choosing to simultaneously share hourly averages of their measured heart rate with their doctor and per-minute averages with their trainer but only for the duration of their workout session. Similarly, a datacenter operator might share resource utilization levels with a tenant but only for the duration of her job. Our goal is to translate these stream-specific sharing semantics into a cryptographically enforceable access control mechanism.

2.4 Threat Model

Our goal is to maintain the confidentiality and integrity of computations running on a cloud infrastructure that is potentially subject to an adversary that can read and tamper with data and manipulate query execution. In order to support sharing, we require a public-key infrastructure, such that entities can be identified and that a private/public key-pair can be associated with them. TimeCrypt provides the following guarantees in this setting:

Confidentiality. Data is encrypted using semantically secure encryption before it leaves the client device. Since decryption keys are never disclosed to the cloud provider, data confidentiality is guaranteed even in the case of a system compromise

[2] A view; also referred to as virtual table, is a dynamic window of a subset of the rows and columns in a database.

or malicious provider. Note that we do not employ property-revealing encryption, avoiding their inherent information leakage issues [55]. Our cryptographic access control mechanism ensures that data consumers can only query and access data according to the access policies defined by the data owner.

Integrity. TimeCrypt's integrity protection guarantees that, if a query completes, its output is equivalent to a correct execution on a trusted platform. Therefore, a malicious server cannot affect the computation, except by denying service. Note that even in case an integrity key for a stream is leaked, confidentiality remains intact.

Access Patterns. Similar to previous work [60, 63, 74, 81], TimeCrypt is non-oblivious, i.e., it does not protect against access pattern-based inferences in a trade-off for performance and scalability. Therefore, an adversary can learn which data the consumers are authorized to access by observing access patterns. TimeCrypt could be complemented with Oblivious RAM approaches [67] to hide these access patterns.

Access Control Collusion. Resolution based sharing in combination with interval sharing is not collusion resistant, even when considering a plaintext system. For example, any entity with access to aggregation over the intervals $[t_0, t_2)$ and $[t_1, t_2)$, can trivially derive the aggregation $[t_0, t_1)$ over the overlapped range by computing the difference. Hence, clients must be careful when sharing different resolutions over overlapping intervals. Furthermore, TimeCrypt comes with a trade-off between performance and collusion resistance when sharing non-continuous intervals. In the default mode, an adversary with access to two non-continuous intervals can compute the aggregation between the two intervals. For cases where this poses a privacy risk to applications, TimeCrypt provides a mechanism to prevent such collusion (§3.1) at the cost of increased decryption time.

A full security analysis with formal definitions and proofs can be found in the appendix of the extended version of the paper [23].

2.5 TimeCrypt Approach

TimeCrypt is a new encrypted time series database design that meets the scalability and low-latency requirements associated with time series workloads. We propose a new approach for data stream encryption that supports processing over encrypted data streams, computation integrity, and powerful access control within a unified scheme.

Data Abstraction. TimeCrypt stores data points in a stream as time-ordered chunks of predefined time intervals, i.e., $[t_i, t_{i+1})$ with a fixed interval size $\Delta = t_{i+1} - t_i$. Each data chunk also includes an encrypted digest that consists of statistical summaries about the underlying data. The digest enables TimeCrypt to compute statistical queries over time ranges efficiently, as we discuss next. At the client, the chunks are encrypted with standard symmetric encryption while the digests are encrypted with HEAC.

Aggregatable Digests. As HEAC is additively homomorphic[3], it supports secure aggregation of ciphertexts. However, to support queries beyond sum, we leverage *aggregatable encoding techniques* that exist in literature to support sophisticated statistical and analytical queries over encrypted data. At a high level, we introduce a per-chunk digest, which holds a vector of encoded values $\{x_0, ..., x_n\}$ that are encrypted with HEAC. To process queries, the server computes the aggregate function on the encrypted encodings across different digests. With this, we can support statistical queries that are inherently aggregation-based (e.g., sum, mean) or can be transformed to be aggregation-based (e.g., min/max, regression) (§4).

Encryption and Access Control. A key aspect of our scheme is tied to the observation that time series data streams are continuous. Consequently, to enable encrypted data processing that natively supports access control, we model data streams as a series of time segments, where each segment is encrypted with a different encryption key. We introduce a time-encoded keystream that maps keys to segments of the data stream, such that when a user restricts access to the data stream, only the corresponding range in the keystream is shared with the data consumer (§3.1). Based on the access policy, a data consumer is provided with the necessary decryption keys via an access tokens. Access tokens are encrypted with the data consumer's public key (hybrid encryption) and stored at the server. To enable sharing without enumerating all the keys and to support a *succinct key state*, we derive keys from a hierarchical tree key-derivation construction (§3.3). We also introduce a technique to support restricting access to a particular resolution level (§3.3.2), e.g., aggregated values at 10-minute resolution.

3 Encryption in TimeCrypt

In this section, we introduce the cryptographic components of TimeCrypt and present HEAC in more detail. HEAC, in essence is based on a symmetric homomorphic encryption [27]. However, we improve its performance by a factor of 2x for time series workloads by mapping keys to time and optimizing it for in-range ciphertext aggregations. Furthermore, we extend it to support fine-grained cryptographic access control capabilities tailored to time series data. Finally, we ensure computation integrity on encrypted data via Homomorphic Message Authentication Codes.

3.1 Symmetric Homomorphic Encryption.

We encrypt an integer m_i from the message space $[0, M-1]$ as $c_i = Enc_{k_i}(m_i) = m_i + k_i \ mod \ M$, with key $k_i \in [0, M-1]$. Given k_i, one can decrypt c_i as $Dec_{k_i}(c_i) = c_i - k_i \ mod \ M = m_i$. This scheme is semantically secure when the keys are pseudorandom and no key is reused [27].

[3] An additive homomorphic encryption scheme supports additions on ciphertexts, such that $decrypt(C_1 \oplus C_2) = decrypt(C_1) + decrypt(C_2)$.

Given the aggregated secret keys, one can decrypt the aggregated ciphertexts:

$$\sum_{i=0}^{n} m_i = Dec_{\sum_{i=0}^{n} k_i}(\sum_{i=0}^{n} c_i) = \sum_{i=0}^{n} c_i - \sum_{i=0}^{n} k_i \ mod\ M \quad (1)$$

We set M to 2^{64}, to support all integer sizes, without leaking any information about their original size.

Key Canceling. In the above scheme, the local computation to aggregate keys is linear in the number of aggregated ciphertexts, forcing the client to perform the same amount of computations as the server. We reduce this linear overhead to a constant, by leveraging the fact that time series data is generally aggregated in-range (i.e., over a contiguous range in time) as discussed in §2.1. We can therefore employ *key canceling* [6, 19, 31, 60]. This technique will also be relevant later, when we discuss integrity and access control (§3.2, §3.3). To enable this optimization, we choose the individual encryption keys such that the inner keys cancel each other out during aggregation. We do this by replacing the individual key k_i with a composite key that links subsequent messages:

$$Enc_{k'_i}(m_i) = m_i + k'_i \ mod\ M, \text{ with } k'_i = k_i - k_{i+1} \quad (2)$$

For decryption of an in-range aggregated ciphertext (Eq. 1), we now require only the two boundary keys:

$$\sum_{i=0}^{n} k'_i = (k_0 - \cancel{k_1}) + (\cancel{k_1} - \cancel{k_2}) \dots (\cancel{k_n} - k_{n+1}) \quad (3)$$

With key canceling, the decryption time in TimeCrypt is independent of the number of in-range aggregated ciphertexts. This scheme remains semantically secure [23, 27, 31]; an attacker without access to the keys cannot exploit the canceling property. However, when given access to keys for two non-continuous intervals, an adversary could learn aggregates about the skipped time between the two intervals. For example, when given access to $k_0, \dots, k_5$ and $k_{10}, \dots, k_{15}$, they could compute $\sum_{i=5}^{10} m_i \mod M$, given k_5 and k_{10}. The ramifications of this issue arise when users share adjacent intervals in the same stream with small gaps. TimeCrypt provides a hybrid key-canceling mechanism that limits this leakage in a trade-off for longer decryption times. We split the keys into epochs by replacing some k_i with non-canceling skip-keys k'_i, k''_i in $k_{i-1} - k_i$ and $k_i - k_{i+1}$, respectively. With this, we can share one interval per epoch without leakage. This increases the cost of aggregations over the epoch borders by two key derivations and one addition.

Time-Encoded Keystream. In TimeCrypt, access permissions are expressed with temporal ranges, e.g., Sep-14-15:00 till Sep-17-06:00 2019. Internally, TimeCrypt *chunks* data into fixed time segments of size Δ, which can be set per stream (e.g., 10 s intervals). In addition to the raw data points, each chunk is augmented with digests that are used for statistical query processing. Each chunk is encrypted with a fresh key from the keystream, indexed by the time window of the chunk. Assuming the data stream starts at timestamp t_0, the chunk digest m_i for the interval from t_i to t_{i+1} is encrypted as $c_i = Enc_{k_i - k_{i+1}}(m_i)$. By mapping keys to temporal ranges, a time range implicitly determines the position of the used key in the keystream. As a result, we sidestep the need to store identifiers of the keys along with the ciphertexts and avoid ciphertext expansion.

3.2 Integrity

Homomorphic encryption schemes are by design malleable, and therefore susceptible to ciphertext manipulation. In our setting, a dishonest server could try to drop, duplicate, or manipulate ciphertexts, resulting in incorrect query outputs. Incentives for deviations from the protocol could be as simple as trying to preserve resources by reducing the complexity of queries [72]. Beyond malicious behavior, integrity checks help to prevent faulty executions (e.g., data corruption, hardware faults, or misconfigurations). Ensuring computation integrity is essential, but is rarely considered in existing encrypted databases. Computation integrity can be achieved by requiring the server to provide a proof that the encrypted result was computed using the targeted data and function. Along this line, we introduce a verification protocol that allows the server to validate the output of in-range aggregations over ciphertexts with a succinct tag that can be verified in constant time at the client. To generate the proof, we use homomorphic Message Authentication Codes (HoMAC) [28]. While HoMACs have been introduced as cryptographic building blocks in the literature, existing solutions do not achieve integrity while maintaining scalability.

HoMAC. Conventional Message Authentication Codes (MACs) are small tags generated for each ciphertext which later ensure the authenticity and integrity of the ciphertext. *HoMACs* [9, 28] are conceptually similar to MACs, but additionally allow the server to perform computations like aggregations over the ciphertexts, and to produce new tags that authenticate the outputs of the computation. More precisely, the client generates a HoMAC tag σ for each ciphertext c and uploads (c, σ), where σ is defined as follows:

$$\sigma = HoMAC_s(c) = (s - c)/Z \mod p \quad (4)$$

where s is a per-ciphertext key, Z the HoMAC key, and p a prime number. The server computes aggregations on both the ciphertext and *HoMAC* tags $\sum_{i=0}^{n-1}(c_i, \sigma_i) = (c_{res}, \sigma_{res})$. The resulting tag σ_{res} authenticates and verifies that the output c_{res} corresponds to that specific aggregation. A client in possession of the *HoMAC* key material can verify the result by checking that the received σ_{res} tag matches the ciphertext c_{res}:

$$\sum_{i=0}^{n-1} s_i \overset{?}{=} c_{res} + \sigma_{res} Z \mod p \quad (5)$$

HoMACs are interesting for our use-case, since their symmetric nature makes them appealing to integrate with HEAC.

In contrast to authenticated data structures [46, 84], which can be used for outsourced computation verification, HoMAC tags do not need to be updated when new data is inserted. However, without further optimization, their verification overhead prevents their use in our setting.

Integrity Protocol. While HoMACs provide the desired integrity guarantees, they suffer from a verification overhead that is linear in the number of records in the aggregation query. Therefore, we apply a similar key canceling technique as already discussed above in the context of encryption: We define a *HoMAC* keystream $\{s_0, s_1, s_2, ...\}$ and, for each ciphertext c_i, the client computes the *HoMAC* tag σ_i as follows:

$$HoMAC_{s'_i}(c_i) = (s'_i - c_i)/Z = (s_i - s_{i+1} - c_i)/Z \bmod p \quad (6)$$

Setting $s'_i = s_i - s_{i+1}$ enables a constant time verification at the client side regardless of the input size, since only the two outer keys are required:

$$\sum_{i=0}^{n-1} s'_i = s_0 - s_n \overset{?}{=} c_{res} + \sigma_{res} Z \mod p \quad (7)$$

Using the key canceling concept in both encryption and integrity is a key enabler for our efficient cryptographic access control (§3.3). Since verification of aggregation results does not require access to the individual messages that were aggregated, our integrity protocol also integrates well with the resolution-based access control (§3.3.2).

HoMAC Security. For an attacker, it is computationally infeasible to generate a forged ciphertext and a tag which pass the verification. Note that we use different HoMAC key streams not just per-stream, but also per type of digest, i.e., target function. Therefore, the server cannot substitute a digest aggregation with another. In the case of key leakage, a party with access to the HoMAC key Z would be able to forge tags, but data confidentiality always remains intact. For a complete security treatment of HoMAC we refer to [28, 31] and the extended paper [23].

3.3 Cryptographic Access Control

The symmetric homomorphic encryption and HoMAC both require a pseudorandom keystream with one key for each message. The conventional approach to efficiently generating such keystreams would be to leverage a pseudorandom function with an initially exchanged secret key. This allows handling a large number of keys with one secret. However, with this approach, one could only share the entire data stream (i.e., all-or-none or in other words no fine-grained access control). Instead, we want to allow efficient sharing of arbitrary intervals, and want to allow users to restrict access to lower-resolution data, e.g., hourly or daily summaries. To realize this granular access control and to allow data owners to cryptographically enforce the scope of access to their data, we design a novel key derivation construction.

k0 k1 k2 k3 k4 k5 k6 k7 ...

Figure 2: TimeCrypt's key derivation tree (leafs form a keystream).

3.3.1 Key Derivation Trees

Our key derivation is based on *key derivation trees*, i.e. balanced binary trees where each node contains a unique pseudorandom string. The leaf nodes represent the inputs to a key derivation function (KDF) to compute the keystream $\{k_0, k_1, k_2, ..., k_{2^h-1}\}$ as depicted in Fig. 2. The key derivation tree is built top-down from a secret random seed as the root. The child nodes are generated with a pseudorandom generator (PRG) that takes the parent string as the input. Our PRG consists of $G_0(x)$ for the left-hand child and $G_1(x)$ for the right-hand child, where x is the parent node. This procedure is applied recursively until the desired depth h in the tree is reached. We select a large h such that the keystream is virtually infinite, especially when considering that high-frequency streams will be chunked into e.g., one chunk per second. The pseudorandom generator can be realized from hash functions $G_0(x) = H(0||x), G_1(x) = H(1||x)$ with x as the key.

Access Token. The key derivation tree allows us to share segments of the keystream efficiently. Instead of sharing the segment key-by-key, the client shares a few inner tree nodes, combined into an *access token*. For instance in Fig. 2's toy example, a data owner grants access to the stream from t_0 to t_7, and the corresponding key segment $\{k_0, \dots, k_7\}$ is shared using a single node. In practice, a single node in the tree can be used to share thousands of keys. Note that given a node it is computationally not feasible (i.e., due to one-way property of PRGs) to compute the parent, sibling, or any of the ancestor nodes. Hence, a data consumer cannot compute any keys outside the segment they are granted access to.

Token Distribution. Once the data owner specifies an access policy for a data consumer, the TimeCrypt client generates an access token which encapsulates the inner nodes of the tree needed to derive the corresponding shared keystream segment specified in the access policy. We use the same key derivation tree for the encryption and HoMAC keystreams, but with a different KDF[4]. The token also contains encoded information about the subtree height and key identifier offset. TimeCrypt then encrypts the tokens with the data consumer's public key (i.e., hybrid encryption) and stores it at the server, such that the data consumer can fetch it to gain access to the keying

[4]Each leaf node of the primary key derivation tree is used to produce cryptographic keys needed for its corresponding chunk. Namely, keys for each element in the digest (i.e., query type), chunk, and HoMAC. Hence, we use different KDFs with the same node.

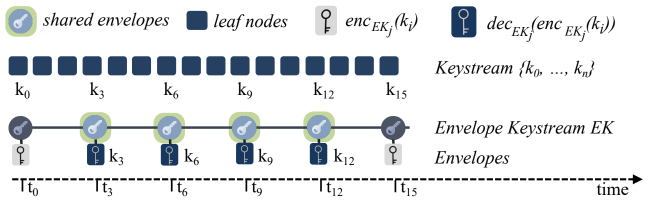

Figure 3: Envelope encryption for resolution-based access, showing envelopes required to share $[t_3, t_{12}]$ at a resolution of 3Δ.

material required to decrypt the data or query results. Note that TimeCrypt's key distribution is pluggable and we can employ alternative solutions. For instance, we can encrypt the token with attribute based encryption [83] to share tokens based on attributes (e.g., month as a key attribute).

3.3.2 Resolution-based Access Restriction

We now discuss how TimeCrypt provides crypto-enforced access control over the *resolution* at which data can be queried; i.e., the data owner not only restricts access to a time range per data consumer but also defines the temporal granularity (e.g., per minute) at which they can retrieve or query data.

Resolution Levels. In TimeCrypt, the highest resolution for queries and access control is defined by the chunk size Δ. Whenever we aggregate over an interval, we reduce the data resolution. For example, with one second chunks, an aggregation over 60 chunks results in a per-minute resolution. We can exploit the fact that keys cancel out during in-range aggregations, as described in §3.1, to cryptographically restrict access to lower resolution levels. In general, a ciphertext generated through an in-range aggregation over the time period $[t_i, t_j)$ has the form:

$$\sum_{x=i}^{j-1} c_x = \sum_{x=i}^{j-1} m_x + k_i - k_j \tag{8}$$

where the inner keys are canceled out. Hence, given access to just the boundary keys k_i and k_j, one can decrypt the aggregation, but none of the individual ciphertexts. Resolution levels must be multiples of the chunk size Δ and the segments at a given level must not overlap. Otherwise, data consumers could compute the difference of two aggregates overlapping by e.g., one chunk, allowing them to learn the data for that chunk which would violate the resolution-based access policy. For example, if the data owner wants to restrict access to a 3-fold resolution of the chunk size, the data owner would share only $\{k_0, k_3, k_6, \ldots\}$ with the data consumer. The data consumer can then decrypt the aggregated ciphertexts at the 3-fold (i.e., $3 \cdot \Delta$) or lower resolutions, but cannot access higher resolutions since the inner keys are missing.

Envelopes. While a data owner could share the boundary keys required for resolution-based access directly, this is not efficient since the number of keys necessary is linear in the length of the shared interval. Instead, the data producer stores the required boundary keys for a stream on the server, protected by another layer of encryption, the *envelope*. The keys used for the envelope encryption are derived from a new tree-based keystream $\{\bar{k}_0, \bar{k}_1, \bar{k}_2, \ldots\}$. For each resolution level, we use a different keystream for the envelope encryption. For example, if a data owner wants to make a per-minute resolution available for a stream with 20 s data chunks, the data owner encrypts the boundary keys $\{k_0, k_3, k_6, \ldots\}$ with the envelope keystream, and stores $\{enc_{\bar{k}_1}(k_0), enc_{\bar{k}_2}(k_3), enc_{\bar{k}_3}(k_9), \ldots\}$ on the server, as shown in Fig. 3.

Sharing a stream at a lower resolution is then again a matter of sharing a single access token, with the difference that the token now contains nodes of the key derivation tree for the envelope keystream, rather than for the original encryption keystream. A lower-resolution query returns, in addition to the encrypted result, two envelopes containing the two boundary keys required to decrypt the aggregated ciphertext. The overhead of resolution-based access control is similar to access control without resolution restrictions (§3.3), i.e., an access token consist of at most $O(log(n))$ nodes from the key derivation tree.

Dynamic Resolution Levels. In TimeCrypt, a user does not need to decide a priori on a fixed resolution for data consumers and can dynamically at any point in time define a new resolution. E.g., Alice can share her health data with a physician at minute-level (high-resolution) during physiotherapy from Jan-to-Feb, and from March reduce the resolution to hourly (low-resolution). The physician only sees high-resolution data for Jan-Feb and only hourly-data from March onwards.

3.4 Access Control Extensibility

Beyond temporal and resolution-based access policies, our construction also lends itself to enabling privacy policies on encrypted data, as combining ciphertexts from multiple users creates valid ciphertexts under a new *virtual aggregate key*. In the context of private operations, privacy policies permit a data consumer (e.g., analyst) to only run cross-stream aggregate queries, without having access to individual data streams. Similar to data access policies, privacy policies in our system are enforceable via encryption. As a concrete example, a user might want to allow a research lab to query her data but only if aggregated with a fixed set of n users, to preserve her individual privacy. Ensuring that a data consumer can only decrypt aggregates across a set of users can be realized by ensuring that she only has access to the *virtual aggregate key* (i.e., the data consumer never sees the keys for a particular user's stream in isolation). For instance, if a service is authorized to access an aggregate query over n encrypted messages from different users, then sharing only the *virtual aggregate key* $\sum_{i=1}^{i=n} k_i$ will ensure that the analyst can only decrypt the aggregated result. Therefore, we need a way to compute the *virtual aggregate key* without exposing the individual keys k_i of each user to any of the involved parties; the storage provider, authorized data consumer, or other users.

Function	Description
(1) `CreateStream(uuid, [config])`	Create a new stream, config defines parameters, e.g., chunk interval, operators.
(2) `DeleteStream(uuid)`	Delete specified stream with all associated data.
(3) `RollupStream(uuid, res,` [T_s, T_e]`)`	Rollup an existing stream or a segment of it to the specified resolution.
(4) `InsertRecord(uuid, [t, val])`	Serialize data points in a chunk and append to the end of the stream.
(5) `GetRange(uuid,` T_s, T_e`)`	Retrieve all data records within the specified time interval.
(6) `GetStatRange([uuid],` T_s, T_e`, resolution, [operators])`	Retrieve statistics for the given time interval and resolution, default [sum, count, mean, var, freq].
(7) `DeleteRange(uuid, start, end)`	Delete specified segment of the stream, while maintaining per-chunk digest.
(8) `GrantViewAccess(viewid, [princ-id])`	Grant access to an existing View.
(9) `CreateView(viewid, [policy])`	Create a View with the given policy in JSON format.
(10) `CheckView(viewid, princ-id)`	Retrieve a View token.

Table 1: TimeCrypt's basic API.

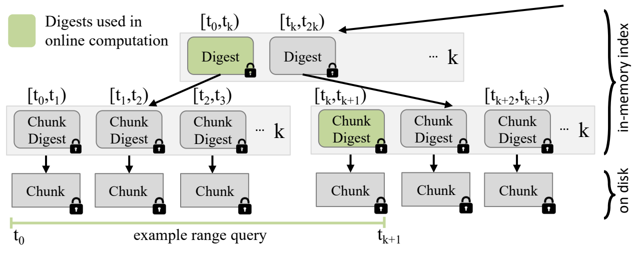

Figure 4: A statistical index for time series data with a *k*-ary time-partitioned aggregation tree. The pre-computed encrypted index allows for fast response times for statistical queries.

This can be accomplished by a secure aggregation protocol [6, 19] between the involved users and the analyst. The inputs to the protocol are the users' individual keys k_i and the output is the blinded contributions towards the *virtual aggregate key*. Queries across streams can be performed efficiently on the server, and the analyst can only decrypt the final result via a *virtual aggregate key*. In §6, we discuss a private crowdsourcing application atop of TimeCrypt that uses this technique.

4 Fast Analytics and Processing

To meet the requirements of time series databases, TimeCrypt must handle massive amounts of data, yet at the same time be able to serve queries with low latency. We address this challenge by introducing efficient client-side serialization/encryption and efficient encrypted indices on the server.

Client-side Data Serialization. The client serializes and encrypts data chunks containing the raw data, and digests. The content of a digest is set per stream based on the supported queries. The *default* query configuration of TimeCrypt supports *sum*, *count*, and *mean*. Other query types such as *variance*, *standard deviation*, *histogram*, bucket *min*/*max*, approximated *quantiles*, *trend detection*, and limited *filter* queries, can be enabled.

Server-side In-memory Encrypted Index. TimeCrypt's server maintains an in-memory encrypted index based on a time-partitioned aggregation tree over encrypted data. This is a key building-block that enables us to serve low-latency analytics on large encrypted data streams and enables efficient data retention. The index structure is a k-ary tree, where each internal node (digest) holds k statistical summaries of the subtree below it. The tree leaves store the chunk digests encrypted with HEAC at the client and represent the highest resolution data summaries (Fig. 4). On the arrival of a new chunk digest, the server inserts it as a leaf node, and updates statistical summaries of the parent nodes's by performing an encrypted aggregation. Any operation that can be expressed as an aggregation of the intermediate results from the child subtrees can be included in the summaries (see §4). Time series workloads are in-order and append-only, therefore updating the tree is straightforward. The encrypted index enables TimeCrypt to significantly decrease the response time for statistical queries, as the server avoids expensive serial scans. When executing a statistical range query over a time interval, the server traverses the tree and selects only the digests required to cover this interval, as illustrated in Fig. 4.

Statistical Queries. So far, we have developed the means to evaluate aggregates over ciphertexts, now we briefly[5] discuss how we combine aggregation with known encoding techniques [32, 47, 68] to allow TimeCrypt to compute more sophisticated statistics over ciphertexts. At a high level, each per-chunk digest holds a vector of encoded values that are encrypted with HEAC. For example, this vector might include the encrypted *sum* and *count* of the data points in the chunk. From this, we can then also calculate the *mean*. To compute quadratic functions, e.g., *var* and *stdev*, the vector includes the *sum of squares* of the points in the chunk. We can also include the *frequency count* of data points in the chunk, which yields valuable information to compute several statistical functions, such as *min, max, top N, bottom N, histograms, and quantiles.* For frequency counts, we use a vector $[c_{v_1},..,c_{v_n}]$, where each element in the vector c_{v_i} tracks the count of data points with value v_i. This works well for small n, which is often the case for (discrete) time series data. For larger ranges of values, we approximate the frequency count, i.e., each c_{v_i} tracks the count of a small range (*bin*) around v_i [32].

Advanced Analytics. In principle, any operations with aggregatable transformations can be supported in TimeCrypt, including a variety of sketch algorithms [52]. In addition, we can support many forms of machine learning, e.g., via aggregation-based encodings that allow private training of linear models [32, 47, 68]. These types of analytics are often employed in time series data to understand and detect runtime

[5]Due to space constraints, we keep the description here brief and refer to [32, 47, 68] for detailed description.

anomalies, trends, and patterns. We show how such analytics can be realized in TimeCrypt, using the example of *private trend detection*, i.e., identifying a general tendency over a defined time interval. It allows users to estimate the magnitude of a trend and is a highly related task to event detection (e.g., runtime anomalies). Linear regression using least-squares is a simple yet powerful method for trend detection [15]. To compute a linear regression model over a stream, the per chunk digest is defined as ($\sum_i x_i$, $\sum_i t_i x_i$) for $i \in [0, n)$. This way the expensive aggregations are done at the server. Such learning on summarized data also delivers privacy gains, as the raw data is not exposed in the training phase. In §6, we discuss the performance aspects of implementing such applications atop TimeCrypt.

Filter Queries. TimeCrypt supports filter queries with predefined predicates. One can define digest encodings that contain statistics over the values of the underlying chunk filtered with a predicate P (e.g., the sum of all values larger than 10). In the query phase, the filtered digests are used to compute statistics over the values matching the predicate P.

Time-Decayed Data Processing. As time series data ages, it is often aggregated into lower resolutions for long-term retention of historical data, while high-resolution data is aged-out. Typical strategies are based on compact summaries through aggregates [7, 43, 80]. TimeCrypt natively supports these approaches: as our index maintains aggregated summaries of the raw data, we can selectively delete aged-out raw data and prune lower nodes in the index. For example, we implement a retention policy based on the time-decayed merge algorithm [7] which keeps the data store compact (logarithmic in the input size) by dynamically re-compacting older data as new data arrives.

5 Prototype

API. TimeCrypt is realized as a service which exposes an interface similar to conventional time series stores [7, 12, 50]; applications can insert encrypted data, retrieve encrypted data by specifying an arbitrary time range, and process statistical queries over arbitrary ranges of encrypted data, as summarized in Table 1. In TimeCrypt, each stream is identified by a unique UUID and associated *stream metadata*, e.g., hostname, data type, sensor ID, location. Each stream has one writer (i.e., data producer) and one or multiple readers (i.e., consumers). A data owner can grant and specify access polices to consumers.

Granting Access to Stream Views. Data owners can manage access to their stream resources with the View API. *Views* define what a data consumer can access within the scope of the *View*. *Views* are set in JSON format, containing a unique identifier and a list of per stream access policies. In the current version, an owner can define the time range and the granularity that is accessible per stream, as for example: *"viewid": 2999, "streams": [{"uuid": [9,10], "from": "1546315200", "to": "1546315800", "granularity": "60s" }]*. This *View* defines an access scoped to stream 9 and 10 in the specified time window with a minute granularity. After the user defines a policy, the API assembles the access token with the necessary inner nodes of the key construction for the specified *View* (§3.3). The client library then derives a *View* key, encrypts the token along with the JSON description using AES-GCM and uploads it to the server. To give data consumers access to the *View*, the client invokes the *GrantViewAccess* command, which encrypts the *View* key with the respective consumer's public keys. The authorized consumers can download the tokens for the given *View* and can query the streams in the defined scope by the access policy. Though access policies are enforced by encryption, the intricacies of the key management are insulated from users in our design.

Reference Implementation. TimeCrypt's prototype is implemented in Java and consists of 6k SLOC with additional 4k SLOC for the applications and benchmark code. We used *Netty* [44] for network communication. TimeCrypt's server and client communicate over Google's *protobuffers* [37] protocol. The current prototype uses Cassandra [26] as the storage backend. The encrypted index is augmented with the in-memory cache *caffeine* [51] to speed up index node access. For the implementation of the cryptographic schemes, we used the Java security provider and a native C implementation of AES-NI. We compare the encrypted index performance with HEAC against alternative private aggregation schemes. We implemented three variants of the encrypted index based on Paillier [77] (Java *BigIntegers*), EC-ElGamal (OpenSSL [57]), and ASHE (we implemented it as described in [60]). Our code is available online.

6 Evaluation

In this section, we evaluate TimeCrypt's practicality. Our evaluation answers three core questions: *(1)* Can TimeCrypt meet the performance requirements of time series applications? *(2)* What are the performance gains of HEAC compared to alternatives? — HEAC supports access control and secure computation simultaneously; both aspects have traditionally been addressed with different schemes, consequently we examine alternatives independently in our evaluation. *(3)* Can TimeCrypt run compelling real-world applications?

Setup. Our experiments are conducted in Amazon AWS, on M5 instances equipped with a 2.5 GHz CPU running Ubuntu (16.04 LTS). TimeCrypt's server runs on an m5.2xlarge instance with 8 virtual processor cores (vcores) and 32 GB of RAM and a Cassandra node runs on an m5.xlarge instance with 4 vcores and 16 GB of RAM. The clients are simulated on several m5.xlarge instances. The client and server are located in the same data center network, with up to 10 Gbps bandwidth. In the microbenchmark, we quantify the overheads of encryption and decryption on end devices. We consider resource-constrained IoT devices; this class of devices is a major source of sensitive time series data. We use IoT OpenMotes (32-bit ARM M3 SoC 32 MHz) and a MacBook Pro 2.8 GHz Intel Core i7, with 16 GB RAM.

System	Micro	Index - Size	Average Ingest Time			Average Query Time (worst-case)		
	ADD	$1M$	$1k$	$1M$	$100M$	$1k$	$1M$	$100M$
TimeCrypt	1ns	8.1MB (1x)	10μs (1.7x)	16μs (1.3x)	22μs (1.3x)	21μs (1.6x)	46μs (1.3x)	50μs (1.1x)
TimeCrypt+	3ns	24.3MB (3x)	16μs (2.6x)	35μs (2.9x)	39μs (2.3x)	38μs (2.9x)	87μs (2.4x)	109μs (2.4x)
Plaintext	1ns	8.1MB (1x)	6μs (1x)	12μs (1x)	17μs (1x)	13μs (1x)	36μs (1x)	45μs (1x)

Table 2: Overview of evaluation results on the cloud, with 128-bit security, except for plaintext. The largest index size with 100M chunks, represents 50 billion data points in our health app.

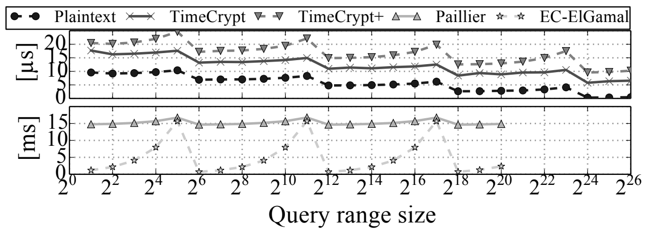

Figure 5: Aggregate queries over varying time ranges (i.e., query range size). Aggregating the entire index corresponds to retrieving the encrypted root.

We quantify the overhead of **TimeCrypt** (confidentiality) and **TimeCrypt+** (confidentiality plus query verification), and compare it to *(i)* operating on **plaintext** as the baseline, and *(ii)* **prior work** where we consider alternative encryption schemes for encrypting the digest, i.e., *Paillier* (used in CryptDB [63]), *EC-ElGamal* (used in Pilatus [74]) and *ASHE* (used in Seabed [60]). For access control, we compare to a strawman solution and a construction of KP-ABE (used in Sieve [83]), that we use to realize temporal access control similar to that supported by HEAC. Unless noted otherwise, we use 128-bit security [13], i.e., 3072-bit keys for Paillier and 256-bit elliptic curves for EC-ElGamal (i.e., prime256v1). For the microbenchmarks, we use synthetic large data that resembles the mhealth application (§6.4) dataset.

6.1 Encrypted Data Processing Performance

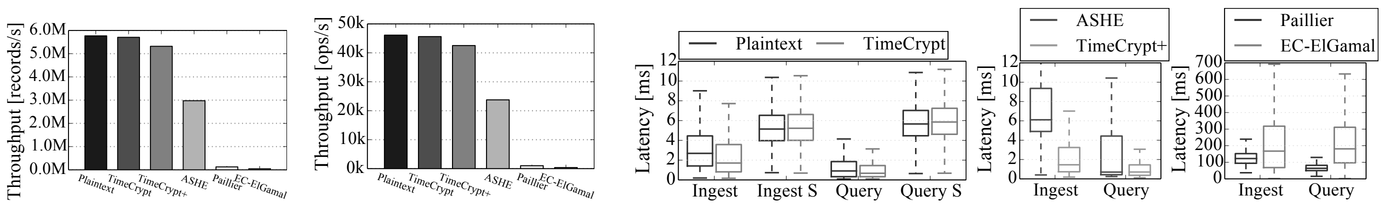
We now discuss the evaluation results of different aspects of the encrypted index, as summarized in Table 2. In the microbenchmark, the index supports one statistical operation (i.e., sum) for isolated overhead quantification, whereas in the E2E benchmark the index supports all our default queries. In all experiments, we instantiate 64-ary index trees and a keystream with one billion keys via the key derivation tree.

Index Size Expansion. To improve query efficiency, in-memory time series databases aggressively seek to reduce storage footprint, to support a model where almost all recent data can be stored in memory. When considering encryption for time series data, the degree of ciphertext expansion has a direct impact on the encrypted index storage footprint, hence impacting query efficiency. TimeCrypt has no ciphertext expansion for 64-bit values, TimeCrypt+ introduces a 128-bit expansion due to the HoMAC tag. The encryption schemes in prior work [63, 75, 81] exhibit large ciphertext expansion, e.g., for one million chunks we experience 96x index size expansion with Paillier. Hence, limiting the performance gains of in-memory processing and impacting query latency. ASHE [60] uses an encoding where the expansion depends on the order of aggregation. With in-range aggregation this amounts to 12.5% higher expansion compared to TimeCrypt.

Ingest Time. On each ingest, i.e., insertion of a leaf node, statistical aggregates of ancestor nodes are updated. In TimeCrypt, additions are as efficient as in *plaintext*. Hence, the average ingest time increases slightly due to the encryption cost; 1.3x for the large index. With verification the average ingest time increases by 3.2x due to the HoMAC overhead.

Query Performance. Fig. 5 shows the performance of the index for statistical range queries of different lengths, i.e., $[0, 2^x]$ with $x \in [0..26]$. As the length of queries increases fewer tree levels are traversed, which results in fewer cache fetches and lower computation time, e.g., the index depth of five is observable in Fig. 5. For plaintext and TimeCrypt the resulting pattern is similar due to the low cost of additions, while for TimeCrypt the decryption overhead is visible. Queries with non-power-of-k ranges require an index *drill down* on either end of the range. This increases the computation time logarithmic, $O(2(k\text{-}1)log_k(n))$ for a worst-case alignment, and not linear to the n stored chunks.

Comparison to Alternatives. In Fig. 6, we show HEAC's performance gains relative to the encryption schemes used in the other encrypted systems. For this experiment we launch an ingest/query workload, with one machine and 100 threads, where each thread constantly performs four statistical queries after each chunk ingest. The plaintext setting reaches a throughput of 5.77M records/s for ingest and 46.1k ops/s for statistical queries, as shown in Fig. 6a-b. TimeCrypt demonstrates an outstanding throughput for both ingest and statistical queries with only 2.9% slowdown compared to plaintext. With verification (TimeCrypt+), the slowdown increases to 7.8% due to the larger index size and HoMAC computations. TimeCrypt is by a factor of 2x, 20x, and 52x faster than ASHE, EC-ElGamal, and Paillier, respectively. Despite ASHE's lower encryption and decryption cost, the system throughput is by 2x lower due to the higher aggregation costs on the server. This is due to ASHE's key-encoding updates, which TimeCrypt eliminates with the time-to-key mapping. Fig. 6c-d shows the respective observed query latency. The impact of a small index cache (1 MB) is distinct, but similar for both plaintext and TimeCrypt, due to higher cache misses.



(a) Ingests (b) Statistical Queries (c) TimeCrypt vs. Plaintext (d) TimeCrypt+ & Alternatives

Figure 6: Latency and throughput for ingest and statistical queries for TimeCrypt with HEAC vs. EC-ElGamal, Paillier, & ASHE, and operating on plaintext indices. Heavy load experiment with a read-write ratio of 4 to 1, and also with extremely small (S) index cache (1 MB). The AWS load generator creates 1200 streams with 100 clients, corresponding to 48579 streams in our health app (Δ:10s, 50Hz data rate).

	HEAC		ASHE	Paillier
	[Enc/Dec]	[HoMAC]	[Enc/Dec]	[Enc/Dec]
IoT	1.08ms	20μs	0.3ms	1.59s / 1.62s
Laptop	5.1μs	0.2μs	1.5μs / 1.3μs	30ms / 15ms

Table 3: Performance of crypto operations with at least 80-bit security and 32-bit integers on IoT devices (OpenMote) vs. laptop (MacBook). TimeCrypt uses a key derivation tree with 2^{30} keys.

To compare how other encrypted systems perform while processing encrypted time series workloads, we run one aggregate query over one billion data records on CryptDB, Pilatus, Seabed, and TimeCrypt. Seabed requires seconds to process this query while CryptDB and Pilatus require minutes, whereas TimeCrypt can process such a query within a few milliseconds on a single machine.

6.2 Client Performance

Table 3 summarizes the enc/decryption and HoMAC costs of HEAC in TimeCrypt. TimeCrypt's cryptographic costs are dominated by the key derivation tree. Enc/decryption amount to 5.1 μs, which accounts for the time to compute the key. With HoMAC the clients incur 4% higher costs. To put this in prospective, this is three orders of magnitude faster than Paillier, EC-ElGamal, and ABE schemes with only few attributes. ASHE is faster in enc/decryption; the slight overhead in HEAC is due to the cost of deriving keys from our key derivation construction to support access control. Though overall, TimeCrypt is more performant in ingest and query performance due to its faster aggregations. The overhead of resolution-based access is defined by the access granularity. For instance, with 10 s chunk intervals and minute and hourly resolutions, the encryption cost increases by only 1% per day.

Low Power Devices. TimeCrypt is particularly compelling for battery-powered constrained devices used in the IoT and environmental sensing, where the power consumption of encryption is a serious challenge. Assuming one minute chunk intervals with TimeCrypt default queries, encryption consumes only 1.4% (400mJ) more battery per day on an OpenMote device compared to sending data in the clear.

6.3 Access Control

In the following, we look at the performance and scalability of our encryption-based access control mechanism. The overhead can be quantified as the cost of key distribution, deriving HoMAC and encryption keys, and computing the resolution envelopes. To characterize the overhead, we consider an example scenario where a data owner has 1000 streams and shares a subset of each stream with a data consumer.

Naïve Key Management. TimeCrypt realizes access control by encrypting units of stream data with unique keys. Consequently, efficient key distribution is important for the scalability of this approach. In a naïve approach, data owner can compile all the keys associated with the specified access policy and distribute the keys encrypted individually to each principle. However, this leads to access tokens of size $O(n)$ where n is the number of keys (i.e., units of stream data included in the access policy). With our key derivation construction, we have a logarithmic worst-case complexity in the number of shared stream units $O(log(n))$.

Communication. An access token in TimeCrypt contains in the worst-case $2(\log(n)-1)$ inner nodes of the tree key-derivation construction where n is the number of keys in the tree. This reduces the communication cost from a naïve approach from 50 GB to 1.28 MB, considering one year of data shared in our example scenario. With resolution-based access policies, the data consumer has to additionally download two envelopes per aggregation query (72 additional bytes).

Computation. Deriving the access token for all streams requires 145 ms. The decryption keys can be computed at a rate of 400k per second. With resolution-based access, the principal has to perform an additional decryption (for the envelope), which reduces the rate to 380k keys per second.

Storage. The storage cost can be broken down into two parts; key storage at the data consumer (1.28 MB), and resolution-related keying material at the server, which grows linearly with time (i.e., the envelopes). With a stream that consists of 10 s chunk intervals over one year with hour/day/month resolution support, the server stores 1.6 MB keying material (45.7k envelopes) per stream.

Comparison to an ABE-based Approach. Although, key-policy attribute-based encryption (KP-ABE) (used in Sieve [83]) is a powerful tool for access control, it comes

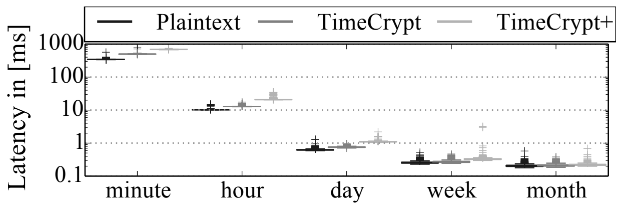


Figure 7: Latency in log-scale for statistical queries of one month data in our health app (121M records). The x-axis shows the granularity of the requested data from one minute to one month.

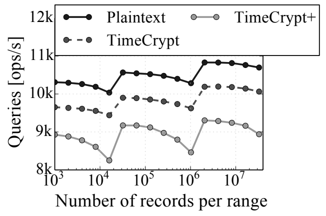
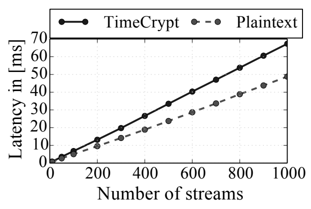


(a) DevOps Application



(b) SmartEnergy Application

Figure 8: Applications: (a) DevOps trend detection queries on CPU utilization over different number of records. (b) Energy consumption queries for a day over multiple streams in a smart meter application.

with a relatively high computational cost, especially for low-power devices and when used to enable fine-grained polices as needed in time series data. Compared to KP-ABE (implementation from [3]), HEAC is three orders of magnitude more efficient for encryption/decryption. For an IoT device encrypting one chunk per minute, an ABE-based solution drains one order of magnitude more battery life compared to HEAC. Additionally, ABE does not support computation on encrypted data.

Interrupt Key Canceling. TimeCrypt can add epoch borders to reduce the risk of leakage from aggregating the skipped interval between two shared non-continuous intervals (§3.1). Each additional epoch border within the query range incurs an additional computational cost to decryption (i.e., one key derivation and two additions). For example, considering a weekly epoch and a daily epoch in a data stream, the decryption cost for a monthly aggregate result increases by a factor of 2.5x and 14.5x, respectively. However, even for fine-grained epochs (e.g., over 300 per range), the decryption latency remains well below 1 ms and would not impact user perception.

6.4 Applications

In this section, we evaluate the end-to-end overhead of TimeCrypt and its effectiveness in running complex, real-world applications. We developed four apps atop of TimeCrypt that represent different challenging requirements and workloads.

mHealth Views - Interactivity. We implemented an mHealth dashboard for the Biovotion health tracker [18]. The dashboard shows summary plots of the underlying data (i.e, windowed AVG). The data consists of 12 different metrics at 50 Hz from the Biovotion sensor over two weeks, which we stretch to one year worth of data. Fig. 7 shows the response time for aggregation plots of last month's data (121M records). We also consider the extreme case of plotting one-month data at minute granularity (403 MB plot), which induces an overhead of 1.45x (2.0x for TimeCrypt+) in latency compared to plaintext. With lower granularity, the overhead sharply decreases and reaches 1.06x (1.29x for TimeCrypt+).

DevOps Trend Detection - Complex Analytics. We developed a trend detection app for CPU utilization. We use a CPU monitoring dataset generated by the time series benchmark suite [79] with 10 metrics, 10s data rate, and per minute chunk size Δ over one year. The results of a two-dimensional linear regression model on different ranges of an encrypted CPU monitoring stream are shown in Fig. 8a. TimeCrypt matches the plaintext performance (0.75% slowdown).

Smart Energy Service - Access Control Scalability. We extended a smart meter application, where a service computes the aggregated energy consumption per day over households. Each smart meter uploads a chunk every 5s, but the service can only compute per day aggregates for each stream. We use the ECO dataset [48], which contains smart meter data sampled at 1 HZ rate and collected over 8 months. Fig. 8b shows the query latency for the aggregated energy consumption over up to 1000 streams. TimeCrypt's overhead is attributed to multi-stream processing and resolution-based access. The overhead stems from the linearly increasing decryption costs in the number of streams that are aggregated.

Crowdsourced mHealth - Privacy Policy Transformation. We enhance the mHealth app with a crowdsourcing feature which enables users to opt-in their data to be part of crowdsourcing for a targeted research project, as described in §3.4. For *n* users, the secure aggregation protocol [19] adds a communication overhead of *n* Diffie-Hellman key exchanges per user to create the envelopes. The envelope enc/decryption increases linearly (e.g., below 1 ms for 100 users).

7 Related Work

There is a large body of research on privacy-preserving systems, encrypted search, and secure outsourced computation. For brevity, we focus our discussion here on works that are closest to TimeCrypt.

Encrypted Databases. Fuller et al. [34] provide a comprehensive overview of the encrypted database landscape. We now discuss several works in this space that are analogues to TimeCrypt. CryptDB [63] and Monomi [81] augment relational databases with encrypted data processing capabilities, however, encryption schemes used in these systems are not efficient enough to support interactive queries on large data. Seabed [60] focuses on Spark-like batch processing workloads and resorts to symmetric partial-homomorphic encryption to enable interactive queries on big data but without the tight latency requirements of time series data. CryptDB, Monomi, and Seabed do not support cryptographic access control or verifiable computation, as the case with TimeCrypt.

ENKI [41] and Pilatus [74] support sharing and encrypted computations but they scale poorly with the number of principals and the size of data. Also, they do not support fine-grained policies. Bolt [40] is an encrypted data storage system for time series data that supports retrieval of encrypted chunks but does not support server-side computation on encrypted data or fine-grained sharing. BlindSeer [61] enables private boolean search queries over an encrypted database by building an index with Yao's garbled circuits and primarily targets private search over large data with no support for statistical queries. It integrates access control for search queries but requires two non-colluding parties. Another line of research considers building data processing systems in trusted execution environments [14, 64, 72], which can provide confidentiality and integrity of queries. In TimeCrypt, we do not require dedicated hardware and rely on cryptographic primitives to ensure confidentiality and integrity of computation.

Cryptography-based Access. Cryptographically enforced access control is explored by crypto-systems [35] such as identity-based encryption, attribute-based encryption (ABE), predicate encryption, and functional encryption. They enable complex access control to encrypted data. ABE [8, 16, 38, 39, 59, 70] is the most expressive among them, though it comes with limitations with respect to fine-grained access and and dynamic updates [35]. Current ABE-based systems lack homomorphic capabilities (i.e., no computation on ciphertexts) and scalability required for time series data workloads. In general, adding homomorphic capabilities to ABE remains an open challenge [22]. Recently, important progress has been made on constructions of homomorphic attribute based encryption [20, 22, 30, 36]. However, they remain limited in functionality and are computationally expensive. A related line of work is searching over encrypted data with predicate evaluation [21, 76]. While predicate encryption schemes [21, 76] support range queries over encrypted data, they lack the required efficiency in our setting, as they require a linear scan through the database and also due to their underlying computationally expensive pairing-crypto.

8 Conclusion

In this paper, we presented TimeCrypt, a new scalable system that enables fast analytics over large encrypted data streams. TimeCrypt introduces HEAC, a novel encryption construction that enables execution of real-time analytics over encrypted stream data and empowers data owners to enforce access restrictions on encrypted data based on their privacy and access control preferences. Our evaluation on various large-scale workloads shows TimeCrypt's performance is close to operating on plaintext data, demonstrating the feasibility of providing high-performance and strong confidentiality guarantees when operating on large-scale sensitive time series data.

Ghostor: Toward a Secure Data-Sharing System from Decentralized Trust

*Yuncong Hu, *Sam Kumar, and Raluca Ada Popa
University of California, Berkeley

Abstract

Data-sharing systems are often used to store sensitive data. Both academia and industry have proposed numerous solutions to protect the user privacy and data integrity from a compromised server. Practical state-of-the-art solutions, however, use weak threat models based on *centralized trust*—they assume that part of the server will remain uncompromised, or that the adversary will not perform active attacks. We propose Ghostor, a data-sharing system that, using only *decentralized trust*, (1) hides user identities from the server, and (2) allows users to detect server-side integrity violations. To achieve (1), Ghostor avoids keeping any per-user state at the server, requiring us to redesign the system to avoid common paradigms like per-user authentication and user-specific mailboxes. To achieve (2), Ghostor develops a technique called *verifiable anonymous history*. Ghostor leverages a blockchain *rarely*, publishing only a single hash to the blockchain *for the entire system* once every epoch. We measured that Ghostor incurs a 4–5x throughput overhead compared to an insecure baseline. Although significant, Ghostor's overhead may be worth it for security- and privacy-sensitive applications.

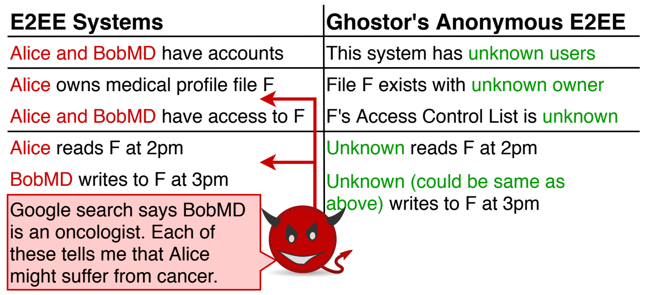
1 Introduction

Systems for remote data storage and sharing have seen widespread adoption over the past decade. Every major cloud provider offers it as a service (e.g., Amazon S3, Azure Blobs), and it is estimated that 39% of corporate data uploaded to the cloud is related to file sharing [51]. Given the relentless attacks on servers storing data [45], a long-standing problem in academia [14, 31, 35, 41, 49, 55, 60, 64, 75, 87] and industry [27, 46, 52, 77, 98] has been to provide useful security guarantees even when the storage server, and some users, are compromised by an adversary.

To address this, early systems [35, 48] have users encrypt and sign files. However, a sophisticated adversary can still:

- observe metadata about *users' identities* [24, 38, 47, 102]. Even if the files are encrypted, the adversary sees which users are sharing a file, which user is accessing a file at a given time, and the list of users in the system. Fig. 1 shows an example where the attacker can conclude that Alice has cancer from such metadata. Further, this allows the attacker to learn the graph of user social relations [81, 89].
- perform active attacks. Despite the signatures, an adversary can revert a file to an earlier state as in a *rollback attack*, or hide users' updates from each other as in a *fork attack*, without being detected. These are dangerous if, for example, the shared file is Alice's medical profile, and she does not learn that her doctor changed her treatment.

*Sam Kumar and Yuncong Hu contributed equally to this work. They are listed in alphabetical order by last name.



E2EE Systems
Ghostor's Anonymous E2EE
Alice and BobMD have accounts
This system has unknown users
Alice owns medical profile file F
File F exists with unknown owner
Alice and BobMD have access to F
F's Access Control List is unknown
Alice reads F at 2pm
Unknown reads F at 2pm
BobMD writes to F at 3pm
Unknown (could be same as above) writes to F at 3pm
Google search says BobMD is an oncologist. Each of these tells me that Alice might suffer from cancer.

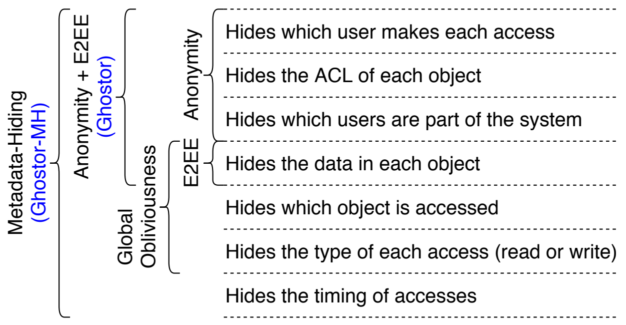
Figure 1: An example of what a server attacker sees in a typical E2EE system versus Ghostor's Anonymous E2EE

Research over the past 15 years has striven to mitigate these attacks by providing *anonymity*—hiding users' identities from the storage server—or *verifiable consistency*—enabling users to detect rollback and fork attacks. In achieving these stronger security guarantees, however, state-of-the-art systems employ weaker threat models that rely on centralized trust: a trust assumption on a *few specific machines*. For example, they rely on a trusted party [66, 90], split the server into two components assuming one is honest [49, 54, 74], or assume the adversary is honest-but-curious (not malicious) [7, 16, 65, 104] meaning the attacker does not change the server's data or execution.

Attackers have notoriously performed highly targeted attacks, spreading malware with the ability to modify software, files, or source code [62, 106, 107]. In such attacks, a determined attacker can compromise any few *central servers*. Ideally, we would avoid *any trust* in the server or other clients, but unfortunately, that is impossible: Mazières and Shasha [69] proved that, if one cannot assume that clients are reliably online [55], clients cannot detect fork attacks without placing some trust in the server. Hence, this paper asks the question: Can we achieve strong privacy and integrity guarantees in a data-sharing system without relying on *centralized trust*?

To answer this question, we design and build Ghostor, an object store based on *decentralized trust* that achieves *anonymity* and *verifiable linearizability* (abbreviated VerLinear). At a high level, anonymity[1] means that the protocol does not reveal directly to the server any user identity with any request, as previously defined in the secure storage literature [54, 65, 74, 104]. As shown in Fig. 1, the server does not see which user owns which objects, which users have read or

[1]Outside of secure storage, *anonymity* is sometimes defined differently. In secure messaging, for example, an anonymous system is expected to hide the timing of accesses [97] and which files/mailboxes are accessed, but not necessarily the system's membership [26].



Metadata-Hiding
(Ghostor-MH)
Anonymity + E2EE
(Ghostor)
Anonymity
Global
Obliviousness
E2EE
Hides which user makes each access
Hides the ACL of each object
Hides which users are part of the system
Hides the data in each object
Hides which object is accessed
Hides the type of each access (read or write)
Hides the timing of accesses

Figure 2: Information leakage in a data-sharing system and associated privacy properties

write permissions to a given object, or even who are the users of the system. The server essentially sees **ghost**s accessing the **stor**age, hence the name "**Ghostor**." VerLinear means clients can verify that each write is reflected in later reads, except for benign reordering of concurrent operations as formalized by linearizability [42]. To achieve these properties, we build Ghostor's integrity on top of a consistent storage primitive based on decentralized trust, like a blockchain [17, 73, 105] or verifiable ledger [30, 44], while using it only *rarely*.

1.1 Hiding User Identities

Achieving anonymity in practical data-sharing systems like Ghostor is difficult because common system design paradigms, like user login, per-user mailboxes on the server, and client-side caching, let the server track users. We re-architect the system to avoid these paradigms (§4), using data-centric key distribution and encrypted key lists instead of server-side ACLs. Like prior systems [4, 33, 57], Ghostor uses cryptographic keys as capabilities, allowing the server and other users to verify each access is performed by an authorized user. Ghostor also leverages this technique to achieve anonymity by having all users authorized in a particular way *share* the same capability, and by distributing these capabilities to users without revealing ACLs to the server. We find this technique, *anonymously distributed shared capabilities*, interesting because anonymity is not typically a goal of public-key access control [4, 33] or capability-based systems [63, 72, 84].

An additional challenge is to guard against resource abuse while preserving anonymity. This is typically done by enforcing per-user resource quotas (e.g., Google Drive requires users to pay for additional space), but this is incompatible with Ghostor's anonymity. One solution is for users to pay for each operation via an anonymous cryptocurrency (e.g., Zcash [105]), but this puts an expensive blockchain operation in the critical path. To avoid this, Ghostor leverages blind signatures [18, 22, 23] to allow a user to pay the Ghostor server for service in bulk and in advance, while removing the linkage between payments and operations.

Relationship to obliviousness. Fig. 2 positions Ghostor's anonymity with respect to other privacy properties. Global obliviousness [7, 66], which hides which *object* is accessed across all uncompromised objects and users in the system, is orthogonal to Ghostor's anonymity, which hides which *user* performs each access. Obliviousness and anonymity are also complementary: (1) In some cases, without obliviousness, users may be identified based on access patterns. (2) Without anonymity, knowing which user issued a request may reveal information about what data that request may access. We view Ghostor's techniques for anonymity as a *transformation*:

- If applied to an E2EE system, we obtain **Ghostor, an anonymous E2EE system**.
- If applied to a globally oblivious scheme, we obtain **Ghostor-MH, a data-sharing scheme that hides all metadata** (except when initializing a group of objects or redeeming payments, as explained in Appendix D).

Hiding metadata from a malicious adversary, as in Ghostor-MH, is a very strong guarantee—existing globally oblivious schemes inherently reveal user identities [66] or assume the adversary is honest-but-curious [7, 65]. However, globally oblivious data-sharing schemes, like Ghostor-MH, are theoretical schemes that are far from practical. Thus, Ghostor-MH is only a proof of concept demonstrating the power of Ghostor's techniques to lift a globally oblivious scheme all the way to virtually zero leakage for a malicious adversary.

1.2 Verifiable Consistency

To provide VerLinear, prior work has clients sign hashes [55] so the clients can verify that they see the same hash, or store hashes on a separate hash server [49], trusted not to collude with the storage server. Neither technique can be used in Ghostor: client signatures are at odds with anonymity, and the hash server is a trusted party, which Ghostor aims to avoid.

One way to adapt the prior designs to Ghostor's decentralized trust is to store hashes on a blockchain, which can be accomplished by running the hash server in a smart contract. Unfortunately, this design is **too slow to be practical**. The client posts a hash on the blockchain for every object write, which is expensive: blockchains incur high latency per transaction, have low transaction throughput, and require cryptocurrency payment for each transaction [17, 73, 105].

To sidestep the limitations of a blockchain, we design Ghostor to only interact with the blockchain rarely and outside of the critical path. Ghostor divides time into intervals called *epochs*. At the end of each epoch, the Ghostor server publishes to the blockchain a small *checkpoint*, which summarizes the operations performed during that epoch for all objects and users in the system. Each user can then verify that the results of their accesses during the epoch are consistent with the checkpoint. The consistency properties of a blockchain ensure all clients see the same checkpoint, so the server is committed to a single history of operations and cannot perform a fork attack. Commit chains [53] and monitoring schemes [15, 93] are based on similar checkpoints, but Ghostor applies them to object storage while maintaining users' anonymity.

A significant obstacle is that a hash-chain-based history is not amenable to concurrent appends. Each entry in the history contains the hash of the previous entry, causing one

Goal	Technique
Anonymous user access control	Anonymously distributed shared capabilities (§4)
Anonymous server integrity verification	Verifiable anonymous history (§5)
Concurrent operations on a single object	Optimized `GET`s, two-phase protocol for `PUT`s (§5.4)
Anonymous resource abuse prevention	Blind signatures and proof of work (§6)
Hiding user IP addresses	Anon. network, e.g., Tor (§8)

Table 1: Our goals and how Ghostor achieves each one

operation to fail if a concurrent operation appends a new entry. Existing techniques for concurrent operations, such as SUNDR's VSLs [64], reveal *per-user* version numbers that would undermine Ghostor's anonymity. Our insight in Ghostor is to have the *server*, not the client, populate the hash of the previous entry when appending a new entry. To make this safe despite a malicious adversary, we carefully design a conflict resolution strategy, involving multiple *linked* entries in the history for each write, that prevents attackers from manipulating data via replay or time-stretch attacks.

We call the resulting design a *verifiable anonymous history*.

1.3 Summary of Contributions

Our goals and techniques are summarized in Table 1. Overall, this paper's contributions are:

- We design an object store providing anonymity and verifiable linearizability based only on *decentralized trust*.
- We develop techniques to (1) share capabilities for anonymity and distribute them anonymously, (2) create and checkpoint a verifiable anonymous history, and (3) support concurrent operations on a single object with a hash-chain-based history.
- We combine these with existing building blocks to instantiate Ghostor, an object store with anonymity and VerLinear.
- We also apply these to a globally oblivious scheme to instantiate Ghostor-MH, which hides nearly all metadata.

We also implemented Ghostor and evaluated it on Amazon EC2. Overall, Ghostor brings a 4-5x throughput overhead on top of a simplistic and completely insecure baseline. There are two types of latency overhead. Completing an individual operation takes several seconds. Afterward, it may take several minutes for a checkpoint to be incorporated into the blockchain, to confirm that no active attack has occurred for a batch of operations. We explain how these latencies play out in the context of a particular application, EHR Sharing (§7.1).

2 System Overview

Ghostor is an object store, which stores unstructured data items ("objects") and allows shared access to them by multiple users. We instantiate Ghostor as an object store (as in Amazon S3 or Azure Blobs) because it is a basic primitive on top of which more complex systems can be built. Fig. 3 illustrates Ghostor's architecture. Multiple users, with separate clients,

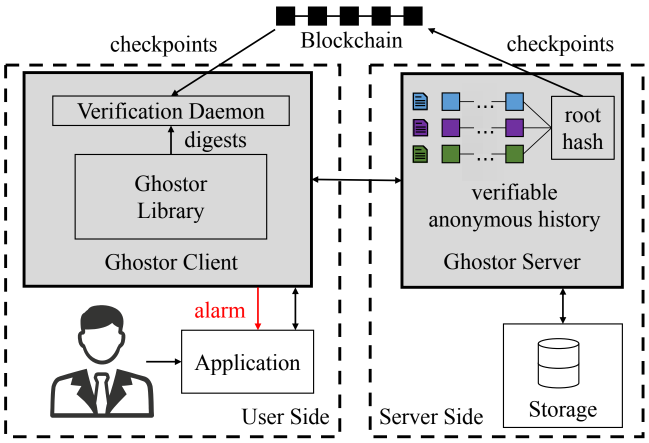


Figure 3: System overview of Ghostor. Shaded areas indicate components introduced by Ghostor.

have shared access to objects on the Ghostor server.

Server. The Ghostor storage server processes requests from clients. At the end of each epoch, the server generates a single small checkpoint and publishes it to the blockchain.

Client. The client software consists of a Ghostor library, linked into applications, and a verification daemon, which runs as a separate process. The Ghostor library receives requests from the application and interacts with the server to satisfy each request. Upon accessing an object, the library forwards a digest summarizing the operation to the verification daemon. At the end of each epoch, the daemon (1) fetches object histories from the server, (2) verifies that they are consistent with the server's checkpoint on the blockchain, and (3) checks that the digests collected during the epoch are consistent with the object histories, as explained in §5.

The daemon stores the user's keypair. If a user loses her secret key, she loses access to all objects that she created or was granted access to. Similarly, an attacker who steals a user's secret key can impersonate that user. To securely back up her key on multiple devices, a user can use standard techniques like secret sharing [82, 83, 99]. A user who accesses Ghostor from multiple devices uses the same key on all devices.

Application developers interact with Ghostor using the API below. Developers can work with usernames, ACLs, and object IDs, but Ghostor clients will not expose them to the Ghostor server. Below is a high-level description of each API call; a step-by-step technical description is in Appendix A.

◊ **create_user**(): Creates a Ghostor user by generating keys for a new user. This operation runs entirely in the Ghostor client—the server does not know this operation was invoked.

◊ user.**pay**(*sum*): Users pay the server through an anonymous cryptocurrency such as Zcash [105], and obtain *tokens* from the server proportional to the amount paid. These tokens can later be *anonymously redeemed* and used as proof of payment when invoking the below API functions.

◊ user.**create_object**(*id*): Creates an object with ID *id*, owned by user who invokes this. The client expends one token obtained from a previous call to **pay**. The *id* can be a meaningful name (e.g., a file path). It lives only within the client—the server receives some cryptographic identifier—so different clients can assign different *id*s to the same object.

◊ user.**set_acl**(*id*, *acl*): The user who invokes this must be the owner of the object with ID *id*. This function sets a new ACL for that object. For simplicity, only the owner of an object can set its ACL, but Ghostor can be extended to permit other users as well. The client encodes *acl* into an object header that hides user identities, as in §4. If new users are given access, they are notified via an out-of-band channel. Existing data-sharing systems also have this requirement; for example, Dropbox and Box send an email with an access URL to the user. In Ghostor, all keys are transferred in-band; the out-of-band channel is used only to *inform* the user that she has been given access. Ghostor does not require a specific out-of-band channel; for example, one could use Tor [29] or secure messaging [95,97].

◊ user.**get_object**(*id*), user.**put_object**(*id*, *content*): The user can GET or PUT an object if permitted by its ACL.

3 Threat Model and Security Guarantees

Against a malicious attacker who has compromised the server, Ghostor provides:

- verifiable linearizability, as described in §3.2, and
- a notion of user anonymity, described in §3.3: briefly, it does not reveal user identities, but reveals object access patterns. Ghostor-MH additionally hides access patterns.

Ghostor does not protect against attacks to availability. Nevertheless, its anonymity makes it more difficult for the server to selectively deny service to (or fork views of) certain users. Users, and the Ghostor client instances running on their behalf, can be malicious and can collude with the server.

Formal definitions and proofs for these properties require a large amount of space, so we relegate them to Appendix E and Appendix F. Below, we include only <u>*informal*</u> definitions.

3.1 Assumptions

Ghostor is designed to derive its security from decentralized trust. Thus, our threat model assumes an adversary who can compromise any few machines, as described below.

Blockchain. Ghostor makes the standard assumption that the blockchain is immutable and consistent (all users see the same transaction history). This is based on the assumption that, in order to attack a blockchain, the adversary cannot simply compromise a few machines, but rather a significant fraction of the world's computing power. Ghostor's design is not tied to a specific blockchain. Our implementation uses Zcash [105] because it supports both public and private transactions; we use Zcash's private transactions for Ghostor's anonymous payments. The privacy guarantees of Zcash can be implemented on top of other blockchains as well [11].

Network. We assume clients communicate with the server in a way that does not reveal their network information. This can be done using mixnets [21] or secure messaging [95,97] based on decentralized trust. Our implementation uses Tor [29].

3.2 Verifiable Linearizability

If an attack is immediately detectable to a user—for example, if the server fails to honor payment or provides a malformed response (e.g., bad signature)—we consider it an attack on *availability*, which Ghostor does not prevent.

Clients should be able to detect active attacks, including fork and rollback attacks. Some reordering of concurrent operations, however, is benign. We use *linearizability* [42] to define when reordering at the server is considered benign or malicious. *Informally*, linearizability requires that after a PUT completes, all later GETs return the value of either (1) that PUT, (2) a PUT that was concurrent with it, or (3) a PUT that comes after it. We provide a more formal definition in Appendix F. Ghostor provides *verifiable linearizability* (abbreviated *VerLinear*). This means that if the server deviates from linearizability, clients can detect it at the end of the epoch. We discuss how to choose the epoch length in §9. Ghostor does not provide consistency guarantees for malicious user, or for objects for which a malicious user has write access.

Guarantee 1 (Verifiable linearizability)**.** *For any object F and any list E of consecutive epochs, suppose that, for each epoch in E, the set of honest users who ran the verification procedure includes all writers of F in that epoch (or is nonempty if F was not written).* ***If*** *the server did not linearizably execute the operations that verifying clients performed in the epochs that they verified,* ***then*** *at least one of the verifying clients will encounter an error in the verification procedure and can generate a proof that the server misbehaved.*

3.3 Anonymity

As explained in §1.1, Ghostor's anonymity means that the server sees no user identities associated with any action. In particular, an adversary controlling the server cannot tell which user accesses each object, which users are authorized to access each object, or which users are part of the system.

Ghostor. We informally define Ghostor's privacy via a *leakage function*: what the server learns when a user makes each API call (§2). For **create_object** – **put_object**, the server learns the object identifier and the type of the operation. The server also sees the time of the operation, and the size of the encrypted ACL and encrypted object, which can be hidden via padding at an extra cost. **create_user** leaks no information to the server, and **pay** reveals only the sum paid and when. The server learns no user identities, no object contents, and no ACLs. If the attacker has compromised some users, he learns the contents of objects those users can access, including prior versions encrypted under the same key. Collectively, the verification daemons leak the number of clients performing verification for each object. If all clients in an object's ACL are honest and running, this equals the ACL size. If the ACL is padded to a maximum size, the owner should run verification more times to hide the ACL size. Ghostor does *not* hide access patterns or timing (Fig. 2). An adversary who uses

Keypair or Key	Description
(PVK, PSK)	Signing keypair used to set ACL
(RVK, RSK)	Signing keypair used to get object
(WVK, WSK)	Signing keypair used to put object
(OSK)	Symmetric key for object contents

Table 2: Per-object keys in Ghostor. The server uses the global signing keypair (SVK, SSK) to sign digests for objects.

this information cannot see the contents of files and ACLs because they are encrypted. But such an adversary could try to deduce correlations between which users issue different operations based on access patterns and timing, and in some cases, identify the user based on that information. This can be partially mitigated by carefully designing the application using Ghostor (§4.5). In contrast, Ghostor-MH does hide access patterns. In Appendix E, we formally define Ghostor's privacy guarantee in the simulation paradigm of Secure MPC.

Ghostor-MH. We informally define Ghostor-MH's privacy via a leakage function, as above. **create_object** reveals that a group of objects was created. **set_acl**, **get_object**, and **put_object** reveal nothing if the object's ACL contains only honest users; otherwise, they reveal which object was accessed. **create_user** and **pay** have the same leakage as described for Ghostor above. The leakage function also includes the total number of honest users in the system.

4 Hiding User Identities

System design paradigms used in typical data-sharing systems are incompatible with anonymity. We identify the incompatible system design patterns and show how Ghostor replaces them. Ultimately, we arrive at *anonymously distributed shared capabilities*, which allow Ghostor to enforce access control for anonymous users without server-visible ACLs.

4.1 No User Login or User-Specific Mailboxes

Data-sharing systems typically have some storage space on the server, called an *account file*, dedicated to a user's account. For example, Keybase [52] has a user account and Mylar [75] has a user mailbox where the user receives a key to a new file. Accesses to the account file, however, can be used to *link user operations*. As an example, suppose that when a user accesses an object, her client first retrieves the decryption key from a user-specific mailbox. This violates anonymity because the server can tell whether or not two accesses were made by the same user, based on whether the same mailbox was accessed first. Instead, Ghostor's anonymity requires that *any sequence of API calls (§2) with the same inputs, when performed by any honest user, results in the same server-side accesses*.

Ghostor does not have any user-specific storage as in existing systems. To allow in-band key exchange, Ghostor associates a *header* with each object. The object header functions like an object-specific mailbox, in that it is used to distribute the object's keys among users who have access to the object. Unlike a user-specific mailbox, it preserves anonymity because, for a given object, each user reads the *same* header

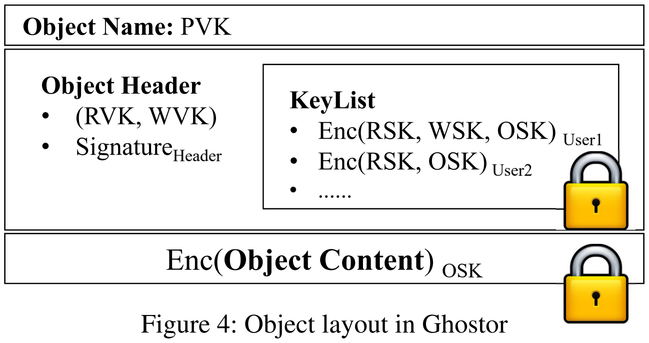

Figure 4: Object layout in Ghostor

before accessing it.

4.2 No Server-Visible ACLs

An honest server must be able to prevent unauthorized users from modifying objects, and users must be able to verify that objects returned by the server were produced by authorized writers. This is typically accomplished by having writers sign objects, and having the server check that the user who signed the object is on the object's ACL. However, this requires the ACL to be visible to the server, which violates anonymity.

We observe that by switching to a design based on *shared capabilities*, we can allow the server and other users to verify that writes are indeed made by authorized users, without requiring the server or other users to know the ACL of the object, or which users are authorized. Every Ghostor object has three associated signing keypairs (Table 2). All users of the object (and the server) know the verifying keys PVK, RVK, and WVK because PVK is the name of the object, and RVK and WVK are in the object header; the associated signing keys PSK, RSK, and WSK are *capabilities* that grant access to set the ACL, get the object, and put the object, respectively. To distribute these capabilities to users in the object's ACL, the owner places a *key list* in the object header. The key list contains, for each user, a list of capabilities encrypted under that user's public key. If a user has read/write access to an object, her entry in the key list contains WSK, RSK, and OSK; a user with only read access is given a dummy key instead of WSK. Crucially, different users with the same permission *share the same capability*, so the server cannot distinguish between users on the basis of which capability they use. When accessing an object, a user downloads the header and decrypts her entry in the key list to obtain OSK (used to decrypt the object contents) and her capabilities for the object.

Users sign updates to the object with WSK, allowing the server and other users to verify that each update is made by a user with write access. PSK is stored locally by the owner and is used to sign the header. The owner can set the object's ACL by (1) freshly sampling (RVK, RSK), (WVK, WSK), and OSK, (2) re-encrypting the object with OSK and signing it with WSK, (3) creating a new object header with an updated key list, (4) signing the new header with PSK, and (5) uploading it to the server. (RVK, RSK) will be relevant in §5.

Ghostor's object layout is summarized in Fig. 4.

4.3 No Server-Visible User Public Keys

Prior systems [64] reveal the user's public key to the server when the client interacts with it. For example, SUNDR requires users to provide a signature along with each operation. First, the signature itself could leak the user's public key. Second, to check the legitimacy of writes, the server needs to know the user's public key to verify the signature. The server can use the public key as a *pseudonym* to track users.

The key list in §4.2, however, potentially leaks users' public keys: each entry in the key list is a set of capabilities encrypted under a user's public key, but public-key encryption is only guaranteed to hide the message being encrypted, not the public key used to encrypt it. For example, an RSA ciphertext leaks which public key was used for encryption. Therefore, Ghostor uses *key-private* encryption [10], which is guaranteed to hide both the message and the public key.

In summary, Ghostor has users *share* capabilities for anonymity, and then distributes the capabilities anonymously, without revealing ACLs to the server. We call the resulting technique *anonymously distributed shared capabilities*.

4.4 No Client-Side Caching

Assuming that an object's ACL changes rarely, it may seem natural for clients to locally cache an object's keypairs $(\mathsf{RVK}, \mathsf{RSK})$ and $(\mathsf{WVK}, \mathsf{WSK})$, to avoid downloading the header on future accesses to that object. Unfortunately, the mere fact that a client did not download the header before performing an operation tells the server that the *same user* recently accessed that object. As a result, Ghostor's anonymity prohibits user-specific caching. That said, *server-side* caching of commonly accessed objects is allowed.

4.5 Careful Application Design

Ghostor does not hide access patterns or timing information from the server. A sophisticated adversary could, for example, deny or delay accesses to a particular object and see how access patterns shift, to try and deduce which user made which accesses. Therefore, one should carefully design the application using Ghostor to avoid leaking user identities in its access patterns. For example, just as Ghostor has no client-side caching or user-specific mailboxes, an application using Ghostor should avoid caching data locally to avoid requests to the server or using an object as a user-specific mailbox. Note that Ghostor-MH hides these access patterns.

5 Achieving Verifiable Consistency

Ghostor's *verifiable anonymous history* achieves the "verifiable equivalent" of a blockchain for critical-path operations, while using the underlying blockchain rarely. It consists of: (1) a hash chain of digests, (2) periodic checkpoints on a real blockchain, and (3) a verification procedure that does not require knowledge of user identities.

5.1 Hash Chain of Digests in Ghostor

We now achieve fork consistency for a single object in Ghostor using techniques inspired from SUNDR [64], but modified because SUNDR is not anonymous. Each access to an object, whether a `GET` or a `PUT`, is summarized by a *digest* shown in Table 3. The object's history is stored as a chain of digests.

Field	Description
Epoch	epoch when operation was committed
PVK, WVK, RVK	permission/writer/reader verifying key
$\mathsf{Hash}_{\mathsf{prev}}$	hash of previous digest in chain
$\mathsf{Hash}_{\mathsf{keylist}}$	hash of key list
$\mathsf{Hash}_{\mathsf{data}}$	hash of object contents
$\mathsf{Sig}_{\mathsf{client}}$	client signature with RSK, WSK, or PSK
$\mathsf{Sig}_{\mathsf{server}}$	server signature using SSK
nonce	random nonce chosen by client

Table 3: A digest for an operation in Ghostor

To access the object, a client first produces a digest summarizing that operation as in Table 3. This requires fetching the object header from the server, so that the client can obtain the secret key (RSK, WSK, or PSK) for the desired operation. Then the client fetches the latest digest for the object and computes $\mathsf{Hash}_{\mathsf{prev}}$ in the new digest. To `GET` the object, the client copies $\mathsf{Hash}_{\mathsf{data}}$ from the latest digest; to `PUT` it, the client hashes the new contents to obtain $\mathsf{Hash}_{\mathsf{data}}$. If the client is changing permissions, then $\mathsf{Hash}_{\mathsf{keylist}}$ is calculated from the new header; otherwise, it is copied from the latest digest.

Then the client signs the digest with the appropriate key and provides the signed digest to the server. The server signs the digest using SSK, appends it to a log, and returns the signed digest and the result of the operation. At the end of the epoch, the client downloads the digest chain for that object and epoch, and verifies that (1) it is a valid history for the object, and that (2) it contains the operations performed by that client. We specify protocol details in Appendix A.

Ghostor's digests differ from SUNDR in two main ways. First, for anonymity, a client does not sign digests using the user's secret key, but instead uses RSK, WSK, or PSK, which can be verified without knowing the user's public key. When inspecting the digest, the server no longer learns which user performed the operation, only that the user has the required permission. Second, each digest is signed by the server. Thus, if the server violates linearizability, the client can assemble the offending digests into a *proof of misbehavior*.

5.2 Checkpoint and Verification

The construction so far is susceptible to fork attacks [64], in which the server presents two users with different views over the same object. To detect fork attacks, Ghostor requires the server to produce a *checkpoint* at the end of each epoch, consisting of the hash of the object's latest digest and the epoch number, and publish the checkpoint to the blockchain. The *verification procedure* run by a client consists of fetching the checkpoint from the blockchain, checking it corresponds to the hash for the last digest in the list of digests obtained from the server, and running the verification in §5.1. The blockchain guarantees that all users see the same checkpoint. This prevents the server from forking two users' views, as the latest digests for two different views cannot both match the published checkpoint. In this way, we bootstrap the blockchain's consistency guarantees to achieve verifiable consistency over an entire epoch of operations.

5.3 Multiple Objects per Checkpoint

So far, the server puts one checkpoint in the blockchain *per object*, which is undesirable when there are many objects. We address this as follows. The server computes the hash of the final digest of each object, builds a Merkle tree over those hashes, and publishes the root hash in the blockchain as a single checkpoint for all objects. To verify integrity at the end of an epoch, a Ghostor client fetches the digest chain from the server for objects that are either (1) accessed by the client during the epoch or (2) owned by the client's user. It verifies that all operations that it performed on those objects are included in the objects' digest chains. Then, it requests Merkle proofs from the server to check that the hash of the latest digest is included in the Merkle tree at the correct position based on the object's PVK. Finally, it verifies that the Merkle root hash matches the published checkpoint.

Although we maintain a separate digest chain for each object, the collective history of operations, across all objects, is also linearizable. This follows from the classical result that linearizability is a local property [42]. Thus, Ghostor provides *verifiable linearizability across all objects, while supporting full concurrency for operations on different objects*.

5.4 Concurrent Operations on a Single Object

As explained in §5.1, the client must fetch the latest digest from the server to construct a digest for a new GET or PUT. If two clients attempt to GET or PUT an object concurrently, they may retrieve the same latest digest for that object, and therefore construct new digests that both have the same $\mathsf{Hash}_{\mathsf{prev}}$. An honest server can only accept one of them; the other operation must be aborted. A naïve fix is for clients to acquire locks (or leases) on objects during network round trips, but this limits single-object throughput according to client round-trip times. How can we allow concurrent operations on a single object without holding server-side locks during round trips? We explain our techniques at a high level below; Appendix A contains a full description of our protocol.

GETs. We optimize GETs so that clients need not fetch the latest digest, obviating the need to lock for a round trip. When a client submits a GET request to the server, the client need not include $\mathsf{Hash}_{\mathsf{prev}}$, $\mathsf{Hash}_{\mathsf{data}}$, or $\mathsf{Hash}_{\mathsf{keylist}}$ in the digest presented to the server. The client includes the remaining fields and a signature over only those fields. Then, the server chooses the hashes for the client and returns the resulting digest, signed by the server. Although the server can replay operations, this is harmless because GETs do not affect data. When the verification daemon verifies a GET, it checks the client signature without including $\mathsf{Hash}_{\mathsf{prev}}$, $\mathsf{Hash}_{\mathsf{data}}$, or $\mathsf{Hash}_{\mathsf{keylist}}$.

PUTs. The above technique does not apply to PUTs, because the server can roll back objects by replaying PUTs. Simply using a client-provided nonce to detect replayed PUTs is not sufficient, because the server can delay incorporating a PUT (which we call a *time-stretch* attack) to manipulate the final object contents. For PUTs, Ghostor uses a two-phase protocol. In the PREPARE phase, the client operates in the same way as GET, but signs the digest with WSK; the server fills in the hashes, signs the resulting digest, appends it to the object's digest chain, and returns it to the client. In the COMMIT phase, the client creates the final digest for the operation—omitting $\mathsf{Hash}_{\mathsf{prev}}$ and appending an additional field $\mathsf{Hash}_{\mathsf{prep}}$, which is the hash of the server-signed digest obtained in the PREPARE phase—and uploads it to the server with the new object contents. The server fills in $\mathsf{Hash}_{\mathsf{prev}}$ based on the object's digest chain (which could have changed since the PREPARE phase), signs the resulting digest, appends it to the object's digest chain, and returns it to the client. The server can replay PREPARE requests, but it does not affect object contents. The server cannot generate a COMMIT digest for a replayed PREPARE request, because the client signed the COMMIT digest including the hash of the server-signed PREPARE digest, which includes $\mathsf{Hash}_{\mathsf{prev}}$. The server can replay a COMMIT request for a particular PREPARE request, but this is harmless because of our conflict resolution strategy described below.

Resolving Conflicts. If two accesses are concurrent (i.e., neither commits before the other prepares), then linearizability does not require any particular ordering of those operations, only that all clients perceive the same ordering. If a GET is concurrent with a PUT (GET digest between the PREPARE and COMMIT digests for a PUT), Ghostor linearizes the GET as happening before the PUT. This allows the result of the GET to be served immediately, without waiting for the PUT to finish. For concurrent PUTs, it is unsafe for the linearization order to depend on the COMMIT digest, because the server could perform a time-stretch or replay attack on a COMMIT digest, to manipulate which PUT wins. Therefore, Ghostor chooses as the winning PUT the one whose PREPARE digest is latest. The server can still delay PREPARE digests, but the client can choose not to COMMIT if the delay is unacceptably large. To simplify the implementation of this conflict resolution procedure, we require that the PREPARE and COMMIT phases happen over the same session with the client, during which the server can keep in-memory state for the relevant object. This allows the server to match PREPARE and COMMIT digests without additional accesses to secondary storage.

Verification Complexity. To verify PUTs, the verification daemon must check that $\mathsf{Hash}_{\mathsf{data}}$ only changes on COMMIT digests for winning writes. Thus, it must keep track of all PREPARE digests since the latest PREPARE digest whose corresponding COMMIT has been seen. We can bound this state by requiring that PUT requests do not cross an epoch boundary.

ACL Updates. We envision that updates to the ACL will be rare, so our implementation does not allow **set_acl** operations to proceed concurrently with GETs or PUTs. It may be possible to apply a two-phase technique, similar to our concurrent PUT protocol, to allow **set_acl** operations to proceed concurrently with other operations. We leave exploring this to future work.

6 Mitigating Resource Abuse

To prevent resource abuse, commercial data-sharing systems, like Google Drive and Dropbox, enforce per-user resource quotas. Ghostor cannot do this, because Ghostor's anonymity prevents it from tracking users. Instead, Ghostor uses two techniques to prevent resource abuse without tracking users: anonymous payments and proof of work.

6.1 Anonymous Payments

A strawman approach is for users to use an anonymous cryptocurrency (e.g., Zcash [105]) to pay for each expensive operation (e.g., operations that consume storage). Unfortunately, this requires a separate blockchain transaction for each operation, limiting the system's overall throughput.

Instead, Ghostor lets users pay for expensive operations *in bulk* via the **pay** API call (§2). The server responds with a set of *tokens* proportional to the amount paid via Zcash, which can later be redeemed *without using the blockchain* to perform operations. Done naïvely, this violates Ghostor's anonymity; the server can track users by their tokens (tokens issued for a single **pay** call belong to the same user).

To circumvent this issue, Ghostor uses *blind signatures* [18, 22, 23]. A Ghostor client generates a random token and *blinds* it. After verifying that the client has made a cryptocurrency payment, the server signs the blinded token. The blind signature protocol allows the client to *unblind* it while preserving the signature. To redeem the token, the client gives the unblinded signed token to the server, who can verify the server's signature to be sure it is valid. The server cannot link tokens at the time of use to tokens at the time of issue because the tokens were blinded when the server originally signed them.

6.2 Proof of Work (PoW)

Another way to mitigate resource abuse is **proof of work (PoW)** [6]. Before each request from the client, the server sends a random $\mathsf{challenge}$ to the client, and the client must find a proof such that $\mathsf{Hash}(\mathsf{challenge}, \mathsf{proof}, \mathsf{request}) < \mathsf{diff}$. diff controls the difficulty, which is chosen to offset the amplification factor in the server's work. Because of the guarantees of the hash function, the client must iterate through different proofs until it finds one that works. In contrast, the server efficiently checks the proof by computing one hash.

6.3 Anonymous Payments & PoW in Ghostor

Ghostor uses anonymous payments and PoW together to mitigate resource abuse. Our implementation requires anonymous payment only for **create_object**, which requires the server to commit additional storage space for the new object. This is analogous to systems like Google Drive or Dropbox, which require payment to increase a user's storage limit but do not charge based on the count or frequency of object accesses. Implicit in this model are hard limits on object size and per-object access frequency, which Ghostor can enforce. Although our implementation requires payment only for **create_object**, an alternate implementation may choose to require payment for every operation except **pay**. Ghostor requires PoW for all API calls. This includes **pay** and **create_object**, to offset the cost of Zcash payments and verifying blind signatures.

7 Applying Ghostor to Applications

In this section, we discuss two applications of Ghostor that we implemented: EHR Sharing and Ghostor-MH.

7.1 Case Study: EHR Sharing

Our goal in this section is to show how a real application may interface with Ghostor's semantics (e.g., ownership, key management, error handling) and how Ghostor's security guarantees might benefit a real application. To make the discussion concrete, we explore a particular use case: multi-institutional sharing of electronic health records (EHRs). It has been of increasing interest to put patients in control of their data as they move between different healthcare providers [37, 43, 85]. As it is paramount to protect medical data in the face of attackers [28], various proposals for multi-institutional EHR sharing use a blockchain for access control and integrity [5, 70]. Below, we explore how to design such a system using Ghostor to store EHRs in a central object store, using only decentralized trust. We also implemented the system for Open mHealth [3].

Each patient owns one or more objects in the central Ghostor system representing their EHRs. Each patient's Ghostor client (on her laptop or phone) is reponsible for storing the PSKs for these objects. The PSKs could be stored in a wristband, as in [70], in case of emergency situations for at-risk patients. When the patient seeks treatment from a healthcare provider, she can grant the healthcare provider access to the objects containing the relevant information in Ghostor. Each healthcare provider's Ghostor client maintains a local *metadata database*, mapping patient identities (object IDs, §2) to PVKs. This mapping could be created when a patient checks in to the office for the first time (e.g., by sharing a QR code).

Benefits. Existing proposals leverage a blockchain to achieve integrity guarantees [5, 70] but use the blockchain more heavily than Ghostor: for example, they require a blockchain transaction to grant access to a healthcare provider, which results in poor performance and scalability. Additionally, Ghostor provides anonymity for sharing records.

Epoch Time. An important aspect of Ghostor's semantics is that one has to wait until the next epoch before one can verify that no fork has occurred. It is reasonable to fetch a patient's record at the time that they check in to a healthcare facility, but before they are called in for treatment. This allows the time to wait until the end of an epoch to overlap with the patient's waiting time. In the case of scheduled appointments, the record can be fetched in advance so that integrity can be verified by the time of the appointment. An epoch time of 15–30 minutes would probably be sufficient.

Error Handling. If a healthcare provider detects a fork when verifying an epoch, it informs other healthcare providers of the integrity violation out-of-band of the Ghostor system. Ghostor does not constrain what happens next. One approach, used in Certificate Transparency (CT), is to abandon the Ghostor server for which the integrity violation was detected. We envision that there would be a few Ghostor servers in the system, similar to logs in CT, so this would require affected users to migrate their data to a new server. Another approach is to handle the error in the same way that blockchain-based systems [5, 70] handle cases where the hash on the blockchain does not match the hash of the data—treat it as an availability error. While neither solution is ideal, it is better than the status quo, in which a malicious adversary is free to perform fork or rollback attacks undetected, causing patients to receive incorrect treatments based on old or incorrect data, potentially resulting in serious physical injury.

7.2 A Metadata-Hiding Data-Sharing Scheme

Ghostor's anonymity techniques can be combined with a globally oblivious scheme, AnonRAM [7], to obtain a *metadata-hiding* object-sharing scheme, *Ghostor-MH*. Ghostor-MH is *not* a practical system, but only a theoretical scheme; our goal is to show that Ghostor's techniques are complementary to and compatible with those in globally oblivious schemes. Below we summarize how we apply Ghostor's techniques in Ghostor-MH; we discuss Ghostor-MH in more detail in Appendix D. First, we apply Ghostor's principle of switching from a user-centric to a data-centric design. Whereas each ORAM instance in AnonRAM corresponds to a user, each ORAM instance in Ghostor-MH corresponds to an *object group*, a fixed-sized set of objects with a shared ACL. Second, we apply the design of Ghostor's object header in Ghostor-MH. This is accomplished by storing the ORAM secret state, encrypted, on the server. Finally, we use similar techniques to mitigate resource abuse in Ghostor-MH as we do in Ghostor.

8 Implementation

We implemented a prototype of Ghostor in Go. It consists of three parts, as in Fig. 3, server (≈ 2100 LOC), client library (≈ 1000 LOC), and verification daemon (≈ 1000 LOC), which all depend on a set of core Ghostor libraries (≈ 1400 LOC).

Our implementation uses Ceph RADOS [101] for consistent, distributed object storage. We use SHA-256 for the cryptographic hash and the NaCl secretbox library (which uses XSalsa20 and Poly1305) for authenticated symmetric-key encryption. For *key-private* asymmetric encryption (to encrypt signing keys in the object header), we implemented the El Gamal cryptosystem, which is *key-private* [10], on top of the Curve25519 elliptic curve. We use an existing blind signature implementation [1] based on RSA with 2048-bit keys and 1536-bit hashes. We use Ed25519 for digital signatures.

As discussed in §3, Ghostor uses external systems for anonymous communication and payment. In our implementation, clients use Tor [29] to communicate with the server and Zcash 1.0.15 for anonymous payments. We build a Zcash test network, separate from the Zcash main network. Ghostor,

Figure 7: Operations for verification

however, could also be deployed on the Zcash main chain. Zcash is also used as the blockchain to post checkpoints. Our implementation runs as a *single* Ghostor server that stores its data in a scalable, fault-tolerant, distributed storage cluster. We discuss how to scale to *multiple* servers in Appendix B.

We implemented a proof of concept of our theoretical scheme Ghostor-MH (§7.2), in ≈ 2100 additional LOC. As it is a theoretical scheme, our focus in evaluating Ghostor-MH is simply to understand the latency of operations. Ghostor-MH includes AnonRAM's functionality, which, to our knowledge, has not been previously implemented. We omit zero-knowledge proofs in our implementation, as they are similar to AnonRAM and are not Ghostor-MH's innovation.

9 Evaluation

We run our experiments on Amazon EC2. Ghostor's storage cluster consists of three `i3en.xlarge` servers. We configure Ceph to replicate each object (key-value pair) on two SSDs on different machines, for fault-tolerance.

9.1 Microbenchmarks

Basic Crypto Primitives. We measured the latency of crypto operations used in Ghostor's critical path. En/decryption of object contents varies linearly with the object size, and takes ≈ 2 ms for 1 MiB. Key-private en/decryption for object headers and signing/verification of digests takes less than 150 us.

Blind Signatures. We also measure the blind signature scheme used for object creation, which consists of four steps. (1) The client *generates* a blinded hash of a random number. (2) The server *signs* the blinded hash. (3) The client *unblinds* the signature, obtaining the server's signature over the original number. (4) The server *verifies* the signature and the number during object creation. Results are shown in Fig. 5.

Verification Procedure. In Fig. 7, we measure the overhead of verification for digests in a single epoch. For client verification time, we perform an end-to-end test, measuring the total time to fetch digests and to verify them. The client has 1,000 signed digests for operations the client performed during the epoch that the client needs to check were included in the history of digests. We vary the total number of digests in the object's history for that epoch. The reported values in Fig. 7a are the total time to verify the object, divided by the total number of operations on the object, indicating the verification time *per digest*. The trend indicates a constant overhead when the total number of operations on the object is small, that is amortized when the number of operations is large.

Fig. 7b shows the server's overhead to compute the Merkle root. We inserted objects using YCSB (§9.2.2) during an epoch, and measured the time to compute the Merkle root at the end of that epoch. For 10,000 objects, this takes about 2.5 seconds; for 1,000,000 objects, it takes about 280 seconds. Reading the latest digest for each object (leaves of the Merkle tree) dominates the time to compute the Merkle root (2 seconds for 10,000 objects, 272 seconds for 1,000,000 objects). The reason is that our on-disk data structures are optimized for single-object operations, which are in the critical path. In particular, each object's digest chain is stored as a separate batched linked list, so reading the latest digests requires a separate read for each object.

9.2 Server-Side Overhead

This section measures to what extent anonymity and VerLinear affect Ghostor's performance. To ensure that the bottleneck was on the server, we set proof of work to minimum difficulty and do not use anonymous communication (§3), but we return to evaluating these in §9.3.

We measure the end-to-end performance of operations in Ghostor, both as a whole and for instantiations of Ghostor having only anonymity or VerLinear. We compare these to an insecure baseline as well as to competitive solutions for privacy and verifiable consistency, as we now describe.

1. Insecure system ("Insec"). This system uses the traditional ACL-based approach for serving objects. Each object access is preceded by a read to the object's ACL to verify that the user has permission to access the object. Similarly, creating an object requires a read to a per-user account file. It provides no security against a compromised server.

2. End-to-End Encrypted system ("E2EE"). This system encrypts objects placed on the server using end-to-end encryption similarly to SiRiUS [35]. Such systems have an encrypted KeyList similar to Ghostor's, but clients can cache their keys locally on most accesses unlike Ghostor.

3. Ghostor's anonymity system ("Anon"). This is Ghostor with VerLinear disabled. This fits a scenario where one wants to hide information from a *passive* server attacker. Unlike the E2EE system above, this system cannot cache keys locally—every operation incurs an additional round trip to fetch the KeyList from the server. In addition, every operation incurs yet another round trip at the beginning for the client to perform a proof of work. On the positive side, the server does not maintain any per-user ACL.

4. Fork Consistent system ("ForkC"). This system maintains Ghostor's digest chain (§5.1), but does not post checkpoints. Each operation appends to a per-object log of digests, using the techniques in §5.4. This system also performs an ACL check when creating an object.

5. Ghostor's VerLinear system ("VLinear"). This system corresponds to the VerLinear mechanism in §5 (including §5.2). This matches a use case where one wants integrity, but does not care about privacy. We do not include the verification procedure, already evaluated in §9.1.

6. Ghostor. This system achieves both anonymity and VerLinear, and therefore incurs the costs of both guarantees.

9.2.1 Object Accesses

In each setup, we measured the latency for create, `GET`, and `PUT` operations (Fig. 8a), throughput for `GET`s/`PUT`s to a single object (Fig. 9a), and the throughput for creating objects and for `GET`s/`PUT`s to multiple objects (Fig. 9b).

Fork consistency adds substantial overhead, because additional accesses to persistent storage are required for each operation, to maintain each object's log of digests. Ghostor, which both maintains a per-object log of digests and provides anonymity, incurs additional overhead because clients do not cache keys, requiring the server to fetch the header for each operation. In contrast, for Anon, the additional cost of reading the header is offset by the lack of ACL check. For 1 MiB objects, en/decryption adds a visible overhead to latency.

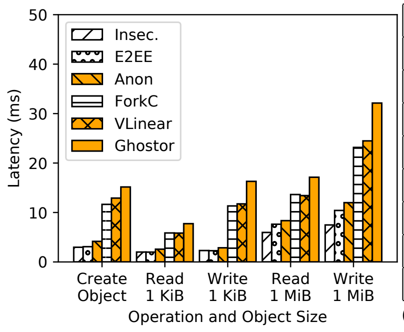
End-to-end encryption adds little overhead to throughput; this is because we are measuring throughput at the *server*, whereas encryption and decryption are performed by *clients*. The only factor affecting server performance is that the ciphertexts are 40 bytes larger than plaintexts.

Single-object throughput is lower for ForkC, VLinear, and Ghostor, because maintaining a digest chain requires requests to be serialized across multiple accesses to persistent storage. In contrast, Insec, E2EE, and Anon serve requests in parallel, relying on Ceph's internal concurrency control.

In the multi-object experiments, in which no two concurrent requests operate on the same object, this bottleneck disappears. For small objects, throughput drops in approximately an inverse pattern to the latency, as expected. For large objects, however, all systems perform commensurately. This is likely because reading/writing the object itself dominated the throughput usage for these experiments, without any concurrency overhead at the object level to differentiate the setups.

9.2.2 Yahoo! Cloud Serving Benchmark

In this section, we evaluate our system using the Yahoo! Cloud Serving Benchmark (YCSB). YCSB provides different workloads representative of various use cases, summarized in Table 6. We do not use Workload E because it involves range queries, which Ghostor does not support. As shown in Fig. 9c, anonymity incurs up to a 25% overhead for benchmarks containing insertions, owing to the additional accesses to storage required to store used object creation tokens. However, it shows essentially no overhead for `GET`s and `PUT`s. Fork



(a) Latency benchmarks

Operation	ms
Proof of Work	0.57
Read Header	1.1
Cl. Processing	0.68
Check Cl. Digest	0.14
Read/Fill Digest	3.2
Append Digest	1.5
Read Data	2.1
Cl. Processing	9.1

(b) Latency Breakdown for Ghostor, Read 1 MiB

Figure 8: Latency measurements

consistency adds a 3–4x overhead compared to the Insec baseline. VerLinear adds essentially no overhead on top of fork consistency; this is to be expected, because the overhead of VerLinear is outside of the critical path (except for insertions, where the overhead is easily amortized). Ghostor, which provides both anonymity and VerLinear, must forgo client-side caching, and therefore incurs additional overhead, with a 4–5x throughput reduction overall compared to the Insec baseline.

9.3 End-to-End Latency

We now analyze the performance of Ghostor from the client's perspective, including the cost of proof of work and anonymous communication (§3).

9.3.1 Microbenchmarks

The latency experienced by a Ghostor client is the latency measured in Fig. 8, plus the additional overhead due to the proof of work mechanism and anonymous communication. The difficulty of the proof of work problem is adjustable. For the purpose of evaluation, we set it to a realistic value to prevent denial of service. Fig. 8b indicates that it takes ≈ 32 ms for a Ghostor operation; therefore, we set the proof of work difficulty such that it takes the client, on average, 100 times longer to solve (≈ 3.2 s). Fig. 10 shows the distribution of latency for the client to solve the proof of work problem. As expected, the distribution appears to be memoryless.

In our implementation, a client connects to a Ghostor server by establishing a circuit through the Tor [29] network. The performance of the connection, in terms of both latency and throughput, varies according to the circuit used. Fig. 10 shows the distribution of (1) circuit establishment time, (2) round-trip time, and (3) network bandwidth. We used a fresh Tor circuit for each measurement. Based on our measurements, a Tor circuit usually provides a round-trip time less than 1 second and bandwidth of at least 2 Mb/s.

9.3.2 Macrobenchmarks

We now measure the end-to-end latency of each operation in Ghostor's client API (§2), including all overheads experienced by the client. As explained in §9.3.1, the overhead due to proof of work and Tor is quite variable; therefore, we repeat each experiment 1000 times, using a separate Tor circuit each time, and report the distribution of latencies for each operation in Fig. 12. Comparing Fig. 12 to Fig. 8, the client-side latency is dominated by the cost of PoW and Tor; Ghostor's core techniques in Fig. 8 have relatively small latency overhead. For the `pay` operation, we measure only the time to redeem a Zcash payment for a single token, not the time for proof of work or making the Zcash payment (see §9.4 for a discussion of this overhead). `GET` and `PUT` for large objects are the slowest, because Tor network bandwidth becomes a bottleneck. The `create_user` operation (not shown in Fig. 12) is only 132 microseconds, because it generates an El Gamal keypair locally without any interaction with the server.

9.4 Zcash

In our implementation, we build our own Zcash test network to avoid the expense from Zcash's main network. Since our system leverages Zcash in a minimal way, the overhead of Zcash is not on the critical path of our protocol. According to the Zcash website [105] and block explorer [2], the block size limit is about 2 MiB, and block interval is about 2.5 minutes. In the past six months, the maximum block size has been less than 150 KiB and the average transaction fee has been much less than 0.001 ZEC (0.05 USD at the time of writing). Hence, even with shorter epochs (less time for misbehavior detection), the price of Ghostor's checkpoints is modest since there is a single checkpoint per epoch for the whole system.

9.5 Ghostor-MH

For completeness, we evaluate the *theoretical* Ghostor-MH scheme presented in §7.2, focusing only on the latency of accessing an object. We do not use Tor and we set the PoW difficulty to minimum. Latency is dominated by en/decryption on the client, because object contents and ORAM state are encrypted with El Gamal encryption, which is much slower than symmetric-key encryption. Fig. 11a shows the object access latency for an object group, as we vary its size. It scales logarithmically, as expected from Path ORAM. An additional overhead of ≈ 2 s comes from re-encrypting ORAM client state (32 KiB, after padding and encryption) on each access. Fig. 11b shows the object access latency as we vary the number of object groups (each object group is 31 KiB). It scales linearly, because the client makes fake accesses to *all* other object groups to hide which one it truly accessed. Latency could be improved by using multiple client CPU cores.

10 Related Work

Systems Providing Consistency. We have already compared extensively with SUNDR [64]. Venus [87] achieves eventual consistency; however, Venus requires some clients to be frequently online and is vulnerable to malicious clients. Caelus [55] has a similar requirement and does not resist collusion of malicious clients and the server. Verena [49] trusts one of two servers. SPORC [31], which combines fork consistency with operational transformation, allows clients to recover from a fork attack, but does not resist faulty clients. Depot [67] can tolerate faulty clients, but achieves a weaker

notion of consistency than VerLinear. Furthermore, its consistency techniques are at odds with anonymity. Ghostor and these systems use hash chains [39, 68] as a key building block.

Systems Providing E2EE. Many systems provide end-to-end encryption (E2EE), but leak significant user information as discussed in §3.3: academic systems such as Persona [8], DEPSKY [13], CFS [14], SiRiUS [35], Plutus [48], ShadowCrypt [41], M-Aegis [60], Mylar [75] and Sieve [99] or industrial systems such as Crypho [27], Tresorit [46], Keybase [52], PreVeil [76], Privly [77] and Virtru [98].

Systems Using Trusted Hardware. Some systems, such as Haven [9] and A-SKY [25], protect against a malicious server by using trusted hardware. Existing trusted hardware, like Intel SGX, however, suffer from side-channel attacks [96].

Oblivious Systems. A complementary line of work to Ghostor aims to hide access patterns: *which* object was accessed. Standard Oblivious RAM (ORAM) [36, 86, 100] works in the single-client setting. Multi-client ORAM [7, 40, 50, 65, 66, 80, 90] extends ORAM to support multiple clients. These works either rely on central trust [80, 90] (either a fully trusted proxy or fully trusted clients) or provide limited functionality (not providing global object *sharing* [7], or revealing user identities [66]). GORAM [65] assumes the adversary controlling the server does not collude with clients. Furthermore, it only provides obliviousness within a single data owner's objects, not *global obliviousness* across all data owners.

AnonRAM [7] and PANDA [40] provide global obliviousness and hide user identity, but are slow. They do not provide for sharing objects or mitigate resource abuse. One can realize these features by applying Ghostor's techniques to these schemes, as we did in §7.2 to build Ghostor-MH. Unlike these schemes, Ghostor-MH is a *metadata-hiding object-sharing scheme* providing both global obliviousness and anonymity without trusted parties or non-collusion assumptions.

Decentralized Storage. Peer-to-peer storage systems, like OceanStore [56], Pastry [79], CAN [78], and IPFS [12], allow users to store objects on globally distributed, untrusted storage without any coordinating central trusted party. These systems are vulnerable to rollback/fork attacks on mutable data by malicious storage nodes (unlike Ghostor's VerLinear). While some of them encrypt objects for privacy, they do not provide a mechanism to distribute secret keys while preserving anonymity, as Ghostor does. Recent blockchain-based decentralized storage systems, like Storj [92], Swarm [94], Filecoin [32], and Sia [88], have similar shortcomings.

Decentralized Trust. As discussed in §1, blockchain systems [17, 20, 73, 103] and verifiable ledgers [61, 71] can serve as the source of decentralized trust in Ghostor.

Another line of work aims to provide efficient auditing mechanisms. EthIKS [15] leverages smart contracts [17] to monitor key transparency systems [71]. Catena [93] builds log systems based on Bitcoin transactions, which enables efficient auditing by low-power clients. It may be possible to apply techniques from those works to optimize our verification procedure in §5.2. However, none of them aim to build secure data-sharing systems like Ghostor.

Secure Messaging. Secure messaging systems [26, 95, 97] hide network traffic patterns, but they do not support object storage/sharing as in our setting. Ghostor can complementarily use them for its anonymous communication network.

11 Conclusion

Ghostor is a data-sharing system that provides *anonymity* and *verifiable linearizability* in a strong threat model that assumes only *decentralized trust*.

A Full Protocol Description for Ghostor

Below, we describe the client-server protocol used by Ghostor.

A.1 `GET` Protocol

1. Server sends a PoW challenge to the client (§6).
2. Client sends the server the PoW solution, PVK of the object that the user wishes to access, and the server returns the object header and current epoch.
3. The client assembles a digest for the `GET` operation, including the epoch number, PVK, RVK, WVK, and a random nonce, and signs it with RSK (obtained from the header). It sends the signed digest to the server.
4. Server reads the latest digest and checks that the client's candidate digest is consistent with it. If not (for example, if the header was changed in-between round trips), the server gives the client the object header, and the protocol returns to Step 3.
5. Server adds $\text{Hash}_{\text{prev}}$, $\text{Hash}_{\text{header}}$, and $\text{Hash}_{\text{data}}$ to the digest (according to the order in which it commits operations on the object). Then it signs it and adds it to the log of digests for that object.
6. Server returns the object contents and the digest, including the server's signature, to the client.
7. Client checks that the signed digest matches the object contents and digest that the client provided. If so, it returns the object contents to the user and sends the signed digest to the verification daemon.

A.2 `PUT` Protocol

1. Server sends a PoW challenge to the client (§6).
2. Client sends the server the PoW solution and PVK of the object to `PUT`, and the server returns the object header, current epoch, and latest server-signed digest for that object.
3. The client assembles a PREPARE digest for the write operation, including the epoch number, PVK, RVK, WVK, and signs it with WSK (obtained from the header). It sends the signed digest to the server.
4. Server reads the latest digest and checks that the client's candidate digest is consistent with it. If not, then the server gives the client the object header, and the protocol returns to Step 3.
5. Server adds $\text{Hash}_{\text{prev}}$, $\text{Hash}_{\text{header}}$, and $\text{Hash}_{\text{data}}$ to the digest (according to the order in which it commits operations on the object). Then it signs it and adds it to the log of digests for that object.
6. Server returns the signed digest to the client.
7. Client assembles a COMMIT digest for the write operation, including the same fields as the PREPARE digest, and also $\text{Hash}_{\text{prep}}$ and $\text{Hash}_{\text{data}}$ according to the new data. Then it signs it and uploads it to the server, including the new object contents.
8. Server decides if this `PUT` "wins." It wins as long as no other `PUT` whose PREPARE digest is after this `PUT`'s PREPARE digest has already committed. If this `PUT` wins, then the server performs the write, signs the digest, and adds it

to the log of digests for that object. If not, it still signs the digest and adds it to the log, but it replaces $\mathsf{Hash}_{\mathsf{data}}$ with the current hash of the data, including the value provided by the client as an "addendum" so that the verification daemon can still verify the client's signature. The server may also reject the COMMIT digest if the key list changed meanwhile due to a **set_acl** operation.

9. Server returns the digest, including the server's signature, to the client.
10. Client checks that the signed digest matches the object contents and digest that the client provided. If so, it sends the signed digest to the verification daemon.

A.3 Access Control

1. Server sends a PoW challenge to the client (§6).
2. Client sends the server the PoW solution and PVK of the object to write, and the server returns the object header, current epoch, and latest server-signed digest for that object.
3. The client assembles a digest for the write operation, including all fields, and signs it with PSK. It sends the signed digest to the server. Client also signs PVK with PSK and includes that signature in the request. Client also includes the new header.
4. Server acquires a lock (lease) on the object for this client (unless it is already held for this client), reads the latest digest, and checks that the client's candidate digest is consistent with it. If not, then the server gives the client the object header, and the protocol returns to Step 3. When returning to Step 3, the server checks if the client's signature over PVK is correct. If so, the server holds the lock on the object during the round trip. If not, the server releases it.
5. Server updates the header, signs the digest, adds it to the log of digests for that object, and releases the lock.
6. Server returns the digest, including the server's signature, to the client.
7. Client checks that the signed digest matches the object contents and digest that the client provided. If so, it returns the object contents to the user and sends the signed digest to the verification daemon.

The owner of the object generates new keys and encrypts the object under the new key. If a user is being granted access, the owner may still generate new keys to prevent the server from learning whether or not a user was revoked. The owner shuffles the key list upon any change to it. The owner may also add padding to hide the number of users in the key list.

A.4 Object Creation

1. Server sends a PoW challenge to the client (§6)
2. Client sends the server the PoW, PVK of the object that the user wishes to create, a token signed by the server for proof of payment (§2), the header for the new object, and the object's first digest (for which $\mathsf{Hash}_{\mathsf{prev}}$ is empty). This involves generating all the keys in Fig. 4) for the new object.
3. Server verifies the signature on the token, and checks that it has not been used before.
4. Server "remembers" the hash of the token by storing it in permanent storage.
5. Server writes the object header. It signs the digest and creates a log for this object containing only that digest.
6. Server returns the digest, including the server's signature, to the client.
7. Client checks that the signed digest matches the object contents and digest that the client provided. If so, it returns the object contents to the user and sends the signed digest to the verification daemon.

A.5 Verification Procedure

At the end of each epoch, the verification daemon downloads the digest chain and checkpoints to verify operations performed in the epoch.

1. Server sends a PoW challenge to the daemon (§6). (The server will request additional PoWs for long lists of digests as it streams them to the daemon in Step 3.)
2. Daemon responds with PoW and requests the object's digest chain from the server for that epoch. It sends the server a signed digest for that object, so the server knows this is a legitimate request.
3. Server returns the digest chain for that object, along with a Merkle proof.
4. Daemon retrieves the Merkle root from the checkpoint in Zcash, and verifies the server's Merkle proof to check that the last digest in the digest chain is included in the Merkle tree at the correct position based on the object's PVK.
5. Daemon verifies that all digests corresponding to the user's operations are in the digest chain, and that the diges chain is valid.

To check that the digest chain is valid, the daemon checks:

1. $\mathsf{Hash}_{\mathsf{prev}}$ for each digest matches the previous digest. If this digest is the first digest in this epoch, the previous digest is the last digest in the previous epoch. The daemon knows this previous digest already since the daemon must have checked the previous epoch. If this is the first epoch, then $\mathsf{Hash}_{\mathsf{prev}}$ should be empty.
2. $\mathsf{Hash}_{\mathsf{prep}}$ in each COMMIT digests matches an earlier PREPARE digest in the same epoch, and each PREPARE digest matches with at most one COMMIT digest.
3. $\mathsf{Hash}_{\mathsf{data}}$ only changes in winning COMMIT digests, which are signed with WSK.
4. WVK, RVK, and $\mathsf{Hash}_{\mathsf{keylist}}$ only change in digests signed with PSK, and PVK never changes.
5. The epoch number in digests matches the epoch that the client requested, and never decreases from one digest to the next.
6. $\mathsf{Sig}_{\mathsf{client}}$ is valid and signed using the correct signing key. For example, if this operation is read, $\mathsf{Sig}_{\mathsf{client}}$ must be signed using RSK.

A.6 Payment

First, the user pays the server using an anonymous cryptocurrency such as Zcash [105], and obtains a proof of payment from Zcash. Then, the client obtains tokens from the server, as follows:

1. Server sends a PoW challenge to the client (§6).
2. Client sends the server the PoW, proof of payment, and *t* blinded tokens, where *t* corresponds to the amount paid.
3. Server checks that the proof of payment is valid and has not been used before.
4. Server "remembers" the proof of payment by storing it in persistent storage.
5. Server signs the blinded tokens, ensuring that *t* indeed corresponds to the amount paid, and sends the signed blinded tokens to the client.
6. Client unblinds the signed tokens and saves them for later use.

B Extension: Scalability

Our implementation of Ghostor that we evaluated in §9 consists of a single Ghostor server, which stores data in a storage cluster that is internally replicated and fault-tolerant (Ceph RADOS). In this appendix, we discuss techniques to scale this setup by replicating the Ghostor server as well.

Given that we consider a malicious adversary, it may seem natural to use PBFT [20]. PBFT, however, is neither necessary nor sufficient in Ghostor's setting. It is not necessary because we already post checkpoints to a ledger based on decentralized trust (§5.2) to achieve verifiable integrity. It is not sufficient because we assume an adversary who can compromise any few machines across which we replicate Ghostor, which is incompatible with Byzantine Fault Tolerance.

The primary challenge to replicating the Ghostor server is *synchronization*: if multiple operations on the same object may be handled by different servers, the servers may concurrently mutate the on-disk data structure for that object. A simple solution is to use object-level locks provided by Ceph RADOS. This is probably sufficient for most uses. But, if server-side caching of objects in memory is implemented, caches in the Ghostor servers would have to be kept coherent.

Alternatively, one could partition the object space among the servers, so each object has a single server responsible for processing operations on it. A set of *load balancer* servers run Paxos [58, 59] to arrive at a consensus on which servers are up and running, so that requests meant for one server can be re-routed to another if it goes down. Note that Paxos is outside of the critical path; it only reacts to failures, not to individual operations. Based on the consensus, the load balancers determine which server is responsible for each object. Because all objects are stored in the same storage pool, the objects themselves do not need to be moved when Ghostor servers are added or removed, only when storage servers are added or removed (which is handled by Ceph). Object-level locks in Ceph RADOS would still be useful to enforce that at most one server is operating on a Ghostor object at a time.

C Extension: Files and Directories

Our design of Ghostor can be extended to support a hierarchy of directories and files. Each directory or file corresponds to a PVK and associated Ghostor object; the PVK has a similar role to an inode number in a traditional file system. The Ghostor object corresponding to a directory contains a mapping from name to PVK as a list of *directory entries*. Given the PVK of a root directory and a filepath, a client iteratively finds the PVK of each directory from left to right; in the end, it will have the PVK of the file, allowing it to access the Ghostor object corresponding to a file. The procedure is analogous to resolving a filepath to an inode number in a traditional file system. The Ghostor object corresponding to a file may either contain the file contents directly, or it may contain the PVKs of other objects containing the file data, like an inode in a traditional file system.

The "no user-side caching" principle §4 applies here, in the sense that clients may not cache the PVK of a file after resolving it once. A client must re-resolve a file's PVK on each access; caching the PVK and accessing the file without first accessing all parent directories would reveal that the same user has accessed the file before.

D Additional Description of Ghostor-MH

§7.2 explains Ghostor-MH at a high level. §8 and §9 describe our implementation and evaluation of Ghostor-MH.

Appendix D.2 below provides a more in-depth explanation of Ghostor-MH. We first provide more details about AnonRAM in Appendix D.1. This is necessary because, as explained in §7.2, we construct Ghostor-MH by applying Ghostor's techniques to AnonRAM [7].

D.1 Overview of AnonRAM

ORAM [36] is a technique to access objects on a remote server without revealing which objects are accessed. Many ORAM schemes, such as Path ORAM [91], allow a *single user* to access data. Path ORAM [91] works by having the client shuffle a small amount of server-side data with each access, such that the server cannot link requests to the same object. Clients store mutable *secret state*, including a stash and position map, used to find objects after shuffling.

AnonRAM extends single-user ORAM to support *multiple users*. Each AnonRAM user essentially has her own ORAM on the server. When a user accesses an object, she (1) performs the access as normal in her own ORAM, and (2) performs a *fake access* to all of the other users' ORAMs. To the server, the fake accesses are indistinguishable from genuine accesses, so the server does not learn to which ORAM the user's object belongs. This, together with each individual ORAM hiding which of its objects was accessed, results in global obliviousness across all objects in all ORAMs.

To support fake accesses, *re-randomizable* public-key encryption (e.g., El Gamal) is used to encrypt objects in each

ORAM. To guard against malicious clients, the server requires a zero-knowledge proof with each real or fake access, to prove that *either* (1) the client knows the secret key for the ORAM, *or* (2) the new ciphertexts encrypt the same data as existing ciphertexts (i.e., they were re-randomized correctly).

A limitation of AnonRAM is that there is *no object sharing among users*; each user can access only the objects she owns. Furthermore, AnonRAM and similar schemes (§10) are *theoretical*—they consider oblivious storage from a cryptographic standpoint, but do not consider challenges like payment, user accounts, and resource abuse.

D.2 Ghostor-MH

Recall from §7.2 that we apply to AnonRAM Ghostor's principle of switching from a user-centric to a data-centric design. Each ORAM now corresponds to an *object group*, which is a fixed-size set of objects with a shared ACL. Each object group has one object header and one digest chain.

Ghostor-MH uses Path ORAM, which organizes server-side storage as a binary tree. To guard against a malicious adversary controlling the server, we build a Merkle tree over the binary tree, and compute $\mathsf{Hash}_{\mathsf{data}}$ in each digest as the hash of the Merkle root and ORAM secret state. This allows each client to efficiently compute the new $\mathsf{Hash}_{\mathsf{data}}$ after each ORAM access, without downloading the entire ORAM tree. The ORAM secret state is stored on the server, encrypted with OSK, so multiple clients can access an object group. This is analogous to Ghostor's object header, which stores an object's keys encrypted on the server.

To access an object, a client (1) identifies the object group containing it, (2) downloads the object header and encrypted ORAM secret state, (3) obtains OSK from the object header, (4) decrypts the ORAM secret state, (5) uses it to perform the ORAM access, (6) encrypts and uploads the new ORAM secret state, (7) computes a new digest for the operation, (8) has the server sign it, and (9) sends it to the verification daemon. For all other object groups, the client performs a *fake access* that fetches data from the server and generates a digest, but only re-randomizes ciphertexts instead of performing a real access. This hides which object group contains the object. When writing an object, the client pads it to a maximum size (the ORAM block size) to hide the length of the object.

Below, we explain some more details about Ghostor-MH:

Fake accesses. OSK is replaced with an El Gamal keypair. This allows ciphertexts in the ORAM tree and the ORAM secret state to be re-randomized. We no longer attach a client signature to each digest, but instead modify the zero-knowledge proof in AnonRAM to prove that *either* the client can produce a signature over the digest with WSK, *or* the ciphertexts were properly re-randomized.

Hiding timing. Similar to secure messaging systems [97], Ghostor-MH operates in rounds (shorter than epochs) to hide timing. In each round, each client either accesses an object as described above, or performs a fake access on all ORAMs if there is no pending object access. Each client chooses a random time during the round to make its request to the server.

Using tokens. In a globally oblivious system like Ghostor-MH, it is impossible to enforce the per-object quotas discussed in §6.3. Thus, it is advisable to require users to expend tokens for *all* operations (except **pay**), not just **create_object**. Our PoW mechanism applies to Ghostor-MH unchanged.

Object group creation. The server can distinguish payment (to obtain tokens) and object group creation from `GET`/`PUT` operations. The most secure solution is to have a setup phase to create all object groups and perform all payment in advance. Barring this, we propose adding a special round at the start of each epoch, used only for creation and payment; all object accesses during an epoch happen after this special round.

List of object groups. To make fake accesses, each client must know the full list of object groups. To ensure this, we can add an additional digest chain to keep track of all created object groups, checkpointed every epoch with the rest of the system.

Changing permissions. In our solution so far, the server can distinguish a **set_acl** operation from object accesses. To fix this, we require the owner of each object group to perform exactly one **set_acl** for that object group during each epoch; if he does not wish to change it, he sets it to the same value.

Concurrency. When a client iterates over all ORAMs to make accesses (fake or real), the client locks each ORAM individually and releases it after the access. No "global lock" is held while a client makes fake accesses to all ORAMs.

E Ghostor's Privacy Guarantee

In this appendix, we use the simulation paradigm of Secure Multi-Party Computation (SMPC) [19] to define Ghostor's privacy guarantee. We begin in Appendix E.1 by providing an overview of our definition and proof sketch, along with an explanation of how our simulation-based definition matches the one in §3.3.

E.1 Overview

We formally define Ghostor's anonymity by specifying an *ideal world*. We provided a definition in §3.3, but we consider it to be informal because it does not clearly state what the adversary learns if some users are compromised/malicious. The ideal world is specified such that it is easy to reason about what information the adversary learns; what the adversary learns in the ideal world is our definition of what an anonymous object sharing system leaks to an adversary (i.e., what *anonymity* does not hide). In the ideal world, clients interact with an uncorruptible trusted party $\mathcal{F}$ called an *ideal functionality*. On each API call issued by a client, $\mathcal{F}$ services the request and provides to the adversary (denoted $\mathcal{S}$ in the ideal world) a well-defined subset of information in the API call. The subset of information that $\mathcal{F}$ gives to $\mathcal{S}$ defines what information Ghostor leaks to the adversary, and provides a clear definition of what anonymity means in our setting. To allow for a malicious adversary, $\mathcal{S}$ chooses what response is returned to the client. $\mathcal{S}$ may violate integrity in a way that the client will only detect at the end of the epoch (e.g., fork attack), but cannot deny service by returning a message that the client would immediately detect as fake (e.g., a message with a bad or missing signature).

To prove that Ghostor achieves that definition of anonymity, we additionally define a *real world*. The purpose of the real world is to model the Ghostor system in the abstract environment we used for the ideal world. In the real world, clients interact directly with the adversary (denoted $\mathcal{A}$ in the real world), which services the requests and learns some information. The protocol that clients use to interact with $\mathcal{A}$ is the same as that used in the actual Ghostor system.

In both worlds, there is another party $\mathcal{Z}$ called the environment. The environment can communicate freely with the adversary and decides what operations the clients issue.

E.1.1 Summary of Proof Sketch

To prove that Ghostor achieves our definition of anonymity as specified in the ideal world, we demonstrate that for every real-world adversary $\mathcal{A}$ in the real world, there exists an ideal-world adversary $\mathcal{S}$ in the ideal world such that the environment $\mathcal{Z}$ cannot distinguish whether it is interacting with the real world or the ideal world. Intuitively, this means that any "attack" that the real-world adversary $\mathcal{A}$ can perform in the real world, can also be performed by the ideal-world $\mathcal{S}$ in the ideal world. Because the ideal-world setup is, by definition, anonymous, this shows that any attacks that $\mathcal{A}$ can perform are those allowed by anonymity, which implies that the real-world setup achieves anonymity.

Given a real-world adversary $\mathcal{A}$, we construct the corresponding ideal-world adversary $\mathcal{S}$ via a simulation. This means that $\mathcal{S}$ uses $\mathcal{A}$ as a black box by carefully simulating a "real world" that runs in tandem with the ideal world.

E.1.2 Map to Definition of Anonymity in §3.3

In §3.3, we explained Ghostor's privacy guarantee in terms of a leakage function. Anonymity, as defined by our ideal world below, maps to the leakage function given in §3.3 as follows. The leakage function in §3.3 is largely the same as the information that $\mathcal{F}$ gives to $\mathcal{S}$ on each API call (Appendix E.2.2). There are a few minor differences, which we now explain. Timing information is not included in Appendix E.2.2 because the model we use in our cryptographic formalization does not have a notion of time. That said, the order in which the requests are processed is given to $\mathcal{S}$; it is implicit in the order in which $\mathcal{F}$ sends messages to it. Finally, although not explicit in Appendix E.2.2, $\mathcal{S}$ can infer how many round trips are performed between the client and server in processing each operation: as long as there is no client-side caching of data (§4.4), the adversary can infer how many round trips are required from the client-server protocol (Appendix A), because we do not model concurrently executing operations. We consider the protocol to be public, so this does not reveal any meaningful information.

Our definition of anonymity matches the everyday use of the word "anonymity" because $\mathcal{S}$ does not receive any user-specific information for operations issued by honest users on objects that no compromised user is authorized to access. Furthermore, $\mathcal{S}$ does not see the membership of the system (public keys of users) or even know how many users exist in the system, apart from corrupt/maliicous users.

E.1.3 Limitations of our Formalization

Although our cryptographic formalization is useful to prove Ghostor's anonymity, there are some aspects of Ghostor that it does not model. First, we do not directly model the anonymous payment (e.g., Zcash) aspect of Ghostor. Instead, we assume the existence of an ideal functionality for Zcash, $\mathcal{F}_{\text{Zcash}}$, that can be queried to validate payment (i.e., learn how much was paid and when). Second, we do not directly model network information (e.g., IP addresses) leaked to the server when clients connect, because this is hidden by the use of an anonymity network like Tor (§8). Third, whereas the Ghostor system allows operations to be processed concurrently (i.e., round trips of different operations may be interleaved), our formalization assumes that the Ghostor server processes each operation one at a time. Fourth, we do not fully model Ghostor's integrity mechanisms, such as the return value of `obtain_digests`.

Users may also be malicious (i.e., controlled by the adversary). In our formalization, the adversary may compromise users, but we restrict the adversary to doing so *statically*. This means that the adversary compromises users at the time of their creation. The environment $\mathcal{Z}$ may choose to give the adversary control over certain users and clients to try and distinguish the ideal world from the real world.

E.2 Ideal World

We define an ideal functionality for an anonymous object sharing system in the simulation paradigm, which captures Ghostor's privacy guarantee. Our notation and setup are as follows. The environment $\mathcal{Z}$ interacts with the party P representing a Ghostor client, which simply relay messages to the ideal functionality $\mathcal{F}$. The ideal-world adversary $\mathcal{S}$ interacts with $\mathcal{F}$.

E.2.1 Execution in the Ideal World

Control begins with the environment $\mathcal{Z}$. The environment may request P to initiate an operation provided by Ghostor's Client API: `GET`, `PUT`, `set_acl`, `create_user`, `obtain_token`, or `obtain_digests`. This is done via Initiate and New_User messages. In the ideal world, the P is a *dummy party*, which forwards these Initiate and New_User messages to $\mathcal{F}$.

We model `create_object` as a special case of `set_acl`. We find this convenient because both `create_object` and `set_acl` set the object's header. Furthermore, our implementation (§8) uses the same RPC call to handle both.

To perform certain operations (e.g., `GET`, `PUT`, `set_acl`, etc.), a user keypair is necessary. This user keypair can be used for asymmetric encryption/decryption with a key-private encryption scheme, and is used in order to obtain the object's signing key from the object header. To formalize this, we draw a distinction between *users* and *clients*. Users have keypairs and are represented in the ideal world with IDs; in contrast, the client is P. Each Initiate message contains the user_ID of the user on whose behalf the operation will be performed. That there is only client that will actually perform the operation informally captures the guarantee given by the anonymity network, that the server cannot tell apart different Ghostor clients on the basis of network information.

In summary, each Initiate message contains:

- user_ID specifying which user's keypair to use for this request
- opcode, which can be one of `GET`, `PUT`, `set_acl`, `create_user`, `obtain_token`, or `obtain_digests`
- new_contents if opcode = `PUT` or opcode = `set_acl`
- new_header if opcode = `set_acl`
- payment_ID (forwarded to $\mathcal{F}_{\text{Zcash}}$) if opcode = `obtain_token`
- object_ID specifying the object on which this request operates
- Payment token to fund the operation (if applicable)

No information related to proof of work is included because $\mathcal{S}$ will be able to simulate it without any external information. Upon receiving an Initiate message, $\mathcal{F}$ reveals some information to $\mathcal{S}$, described in Appendix E.2.2.

As mentioned earlier, we allow users to be corrupted, but require corruption to be static: users are corrupted at the time they are created. This is handled by the New_User message, which contains:

- inform, a bit indicating if the adversary is aware of this user
- compromise, a bit indicating if this user is corrupted or not

Upon receiving a New_User message, $\mathcal{F}$ generates a random user_ID, and keeps track of whether the user is compromised. If the inform bit is set, then the user_ID is given to the adversary $\mathcal{S}$ so that malicious users may add this user to ACLs. If the user is compromised, then $\mathcal{F}$ uses this information to give more information to $\mathcal{S}$ when processing requests (see Appendix E.2.2). In each `PUT` operation, $\mathcal{F}$ generates a fresh ID, denoted content_ID, to represent the contents being written to that object. We refer to this mapping from `PUT` operation to content_ID as the *content table*.

E.2.2 Information that $\mathcal{F}$ gives to $\mathcal{S}$

Each Initiate message that the dummy party P sends to $\mathcal{F}$ represents an API call (§2) to the server. Given each API call, $\mathcal{F}$ processes the request and reveals some information to $\mathcal{S}$. First, $\mathcal{F}$ checks if the user issuing the request is malicious or not. If the user is malicious, then $\mathcal{F}$ reveals to $\mathcal{S}$ all information about the request, including which user makes the request and all arguments to the request. If the user issuing the request is honest, then $\mathcal{F}$ reveals to $\mathcal{S}$ the opcode and the following information:

- For `create_user`, the user_ID is given to $\mathcal{S}$ if either the inform or compromise bits are set. Otherwise, nothing is given to $\mathcal{S}$.
- For `GET`, $\mathcal{F}$ gives $\mathcal{S}$ only the object_ID of the object being accessed. $\mathcal{S}$ gives back to $\mathcal{F}$ the content_ID of the content to be returned, or $\perp$ if the operation fails or is aborted by $\mathcal{S}$.
- For `PUT`, $\mathcal{F}$ gives $\mathcal{S}$ only the object_ID of the object being accessed, and the content_ID and *length* of the object contents being written. However, if a malicious user has ever been on the ACL of the object, the object contents are given to $\mathcal{S}$ in cleartext.
- For `set_acl`, $\mathcal{F}$ scans the ACL being set, identifying which users are malicious. For each honest user in the ACL, $\mathcal{F}$ replaces the corresponding rows of the ACL with NULL. As object is being re-encrypted, $\mathcal{F}$ either gives $\mathcal{S}$ a content_ID and length, or the cleartext contents, depending on whether a malicious user has ever been on the ACL of the object.
- For `obtain_token`, $\mathcal{F}$ reveals to $\mathcal{S}$ the payment_ID. $\mathcal{S}$ responds with tokens that can be redeemed with future operations. $\mathcal{F}$ returns integers back to the party, which can be used as payment tokens in future Initiate messages to pay for operations. $\mathcal{F}$ keeps track of which of these tokens are spent, based on feedback from $\mathcal{S}$ indicating for which operations the payment was accepted.
- For `obtain_digests`, $\mathcal{F}$ reveals to $\mathcal{S}$ the epoch number and object_ID for which digests are to be obtained.

Additionally, $\mathcal{F}$ checks that the payment token provided in the Initiate message is valid, and reveals to $\mathcal{S}$ a single bit indicating whether a valid token was provided.

We have not yet specified what $\mathcal{F}$ returns to P. In order to allow the adversary to make arbitrary integrity violations during an epoch, the return value must originate from $\mathcal{S}$. For `GET`, $\mathcal{S}$ returns the content_ID for the returned content; $\mathcal{F}$ translates it back into actual content and gives it to the party P who requested it. For `obtain_token`, $\mathcal{F}$ forwards the response from $\mathcal{S}$ back to P. For operations involving token payment, $\mathcal{S}$ gives $\mathcal{F}$ a bit indicating whether the payment was accepted, which is forwarded to the original party P. For operations performed by a malicious user, P gives $\mathcal{Z}$ the result of the operation.

At any time, $\mathcal{S}$ can send $\mathcal{F}_{\text{Zcash}}$ a payment_ID. If it does so, it will receive from $\mathcal{F}_{\text{Zcash}}$ a response message indicating if the payment to the server is valid, and if so, and how much was paid and when.

E.3 Real World

The real world models Ghostor's execution. We will prove that our model of Ghostor in the real world reveals essentially the same information to the adversary as is revealed to the adversary in the ideal world.

The real world has the following key differences from the ideal world, in order to properly model Ghostor's execution:

- The party P handles Initiate messages from $\mathcal{Z}$, instead of simply forwarding them to $\mathcal{F}$.
- The party P sends Request messages to $\mathcal{A}$ and receive Response messages from $\mathcal{A}$ (instead of $\mathcal{F}$).

- The party P encrypts object headers and object contents, and $\mathcal{A}$ receives the ciphertexts, according to the Ghostor protocol.

Upon receiving an $\mathsf{Initiate}$ message from $\mathcal{Z}$, the P performs the operation specified in the $\mathsf{Initiate}$ message by interacting with $\mathcal{A}$ according to the Ghostor protocol (Appendix A). We do not specify the protocol in additional detail here because it is already specified in Appendix A. Upon receiving a $\mathsf{New\_User}$ message, P creates a keypair $(\mathsf{pk}, \mathsf{sk})$ and generates a $\mathsf{user\_ID}$ for the new user and stores them locally. If the $\mathsf{compromise}$ bit is set, it shares the secret key with $\mathcal{A}$, and if either the inform or $\mathsf{compromise}$ bits are set, then it informs $\mathcal{A}$ of the $\mathsf{user\_ID}$ and public key. As in the ideal world, malicious users' results are given to $\mathcal{Z}$.

For `obtain_token`, recall that we model Zcash as an ideal functionality $\mathcal{F}_{\text{Zcash}}$, which allows the adversary to validate a payment transaction via Zcash and learn how much was paid and when. Although $\mathcal{A}$ *may* follow the protocol in Appendix A at times, it is not obligated to; it may violate the protocol in ways that are not immediately detectable to the clients. $\mathcal{Z}$ can also create users via $\mathsf{New\_User}$ messages, which are handled locally by P. They generate the corresponding keypair and locally store which $\mathsf{user\_ID}$ maps to that keypair. If the $\mathsf{New\_User}$ message has the inform bit set, then the $\mathsf{user\_ID}$ and pk for that user are given to $\mathcal{A}$; if the $\mathsf{compromise}$ bit is set, then $\mathcal{A}$ is also given sk for that user.

E.4 Simulator

We now describe a simulator $\mathcal{S}$ that, given any real-world adversary $\mathcal{A}$, performs the same attack in the ideal world as $\mathcal{A}$ does in the real world, by invoking $\mathcal{A}$ as a black box. Note that $\mathcal{S}$, by the design of $\mathcal{F}$, is not given any user identities, yet needs to interact with $\mathcal{A}$ as *some* user. The key idea is that $\mathcal{S}$ simply creates a single "dummy" user keypair, and performs all interaction with $\mathcal{A}$ on behalf of honest users as that one user. The design of Ghostor is such that the server cannot distinguish this from a separate keypair being consistently used for each honest user.

$\mathcal{S}$ works by simulating a real world in which $\mathcal{A}$ exists as a black box. Recall that the real world consists of the parties P, $\mathcal{Z}$, and $\mathcal{A}$; for clarity, we use Q to refer to P in this simulated real world, to distinguish it from P in the ideal world.

E.4.1 State Maintained by $\mathcal{S}$

$\mathcal{S}$ maintains a pool of tokens to use. Successful calls to `obtain_token` contribute to this token pool, $\mathcal{S}$ stores tokens in this pool. For operations that require payment, $\mathcal{F}$ does not tell $\mathcal{S}$ which particular tokens to use, so $\mathcal{S}$ chooses tokens randomly from the pool.

$\mathcal{S}$ also maintains a *ciphertext table*. In the messages received, certain *encryptable* pieces of data (e.g., $\mathsf{content\_IDs}$) correspond to encrypted data in the actual Ghostor. To account for this, the ciphertext table maps each encryptable datum received by $\mathcal{S}$ to a fake ciphertext.

- The fake ciphertext corresponding to object contents is an encryption of a "zero string" of the same length as the object contents. The key used to encrypt the zero string is the same as the key normally used to encrypt object contents.[2]
- The fake ciphertext corresponding to a NULL entry in the object header is an encryption of a "zero string" of the same length as the plaintext object header entry, using the dummy user keypair.

E.4.2 Overview

Now, we explain how $\mathcal{S}$ interacts with $\mathcal{A}$ upon receiving information from $\mathcal{F}$. When $\mathcal{F}$ asks $\mathcal{S}$ to start an operation, it interacts with $\mathcal{A}$ over multiple round trips according to the Ghostor protocol via the simulated party, making sure to *blind* the request messages appropriately by replacing ciphertexts with fake ciphertexts. All object header entries corresponding to non-corrupt users are blinded; entries are created for them in the ciphertext table. The decision of whether to blind the object contents depends on whether a corrupt user has permission to read the object. Note that $\mathcal{F}$ has already determined this by the time it has sent the message to $\mathcal{S}$, and has NULLed object header entries for non-corrupt users and replaced data for each object not shared with corrupt users with an ID from its contents table. Therefore, $\mathcal{S}$ simply needs to create fake ciphertexts for object data that correspond to IDs in $\mathcal{F}$'s content table and for NULLed object header entries. Any object contents or object header entries that are not blinded are encrypted exactly as in the normal Ghostor system; $\mathcal{S}$ then forwards the ciphertexts to $\mathcal{A}$.

E.4.3 Simulator Functionality

Now, we describe the simulator more precisely. For operations that require payment, $\mathcal{S}$ verifies that the message it received from $\mathcal{F}$ indicates that a valid token were paid. Then it chooses a token randomly from its store, unblinds it, and uses it when interacting with $\mathcal{A}$. If the operation is successful, it marks the token as "used" so it is not chosen for a later operation.

`create_user`. Suppose $\mathcal{S}$ receives a message from $\mathcal{F}$ with a `create_user` opcode. If the $\mathsf{compromise}$ bit is set, then $\mathcal{S}$ generates a keypair $(\mathsf{pk}, \mathsf{sk})$ for this user and stores the mapping from the provided $\mathsf{user\_ID}$ to this keypair. If the inform bit or $\mathsf{compromise}$ bit is set, then $\mathcal{A}$ is informed of this $\mathsf{user\_ID}$, as if Q received a $\mathsf{New\_User}$ message.

`set_acl`. Suppose $\mathcal{S}$ receives a message from $\mathcal{F}$ with a `set_acl` opcode. $\mathcal{S}$ has the party Q perform a `set_acl` operation.

- If this operation creates the object, then $\mathcal{S}$ generates the keypairs for the object, and creates the encrypted key list for the object. $\mathcal{S}$ constructs each entry of the key list correctly in plaintext, and then encrypts each one as follows. If the entry corresponds to a malicious user, then it encrypts the entry using that user's public key. If the entry corresponds to an honest user, then it creates a fake ciphertext (encryption of zero string of the same length) using the honest

[2] $\mathcal{S}$ has access to this key because it executed `set_acl` for this object in the past.

keypair shared by all honest users and adds the mapping in the ciphertext table. Then it completes the operation using the resulting encrypted keylist.

- If this operation operates on an existing object, then $\mathcal{S}$ performs the operation using PSK (with a check if the owner is malicious). If the message from $\mathcal{F}$ includes a content_ID and length, then $\mathcal{S}$ has the same operation include a fake ciphertext for the re-encrypted object contents; otherwise if $\mathcal{F}$ includes the contents, then $\mathcal{S}$ encrypts it to produce the new data ciphertext. In both cases, the key to encrypt the object data is updated with a fresh one.

`PUT`. Suppose $\mathcal{S}$ receives a message from $\mathcal{F}$ with a `PUT` opcode. There are three cases:

- Suppose the `PUT` was performed by an honest user, and no malicious users have ever been on the ACL. $\mathcal{S}$ receives the ID of the object and the length of the contents being written. In the simulation, $\mathcal{S}$ has Q perform a `PUT` operation, using WSK. $\mathcal{S}$ uses a fake ciphertext (encrypted string of zeros of the correct length) and adds a mapping from the provided content_ID to the fake ciphertext in the ciphertext table.
- Suppose the `PUT` was performed by an honest user, but malicious users have been on the ACL of the object. $\mathcal{S}$ receives the ID of the object and the object contents. Then $\mathcal{S}$ encrypts the object contents and uses the resulting ciphertext instead of using a fake ciphertext, and has Q interact with $\mathcal{A}$ to write the fake ciphertext to the specified object.
- Suppose the `PUT` was performed by a malicious user. Then $\mathcal{S}$ has Q perform the operation using the information in the Initiate message, without using any fake ciphertexts.

`GET`. Suppose that $\mathcal{S}$ receives a message from $\mathcal{F}$ with a `GET` opcode. There are two cases:

- Suppose the `GET` was performed by an honest user. In this case, $\mathcal{S}$ gets the object_ID of the object being accessed. Then $\mathcal{S}$ has Q perform the `GET` operation using RSK. The ciphertext returned by $\mathcal{A}$ is translated back to a content_ID based on the ciphertext table (or decrypted if it is not a fake ciphertext), and given back to $\mathcal{F}$.
- Suppose the `GET` was performed by a malicious user. In this case, $\mathcal{S}$ gets the entire Initiate message used to initiate this operation. Then $\mathcal{S}$ has Q perform the `GET` operation using the keypair for that malicious user. The ciphertext returned by $\mathcal{A}$ is translated back to a content_ID based on the ciphertext table (or decrypted if it is not a fake ciphertext), and given back to $\mathcal{F}$.

`obtain_token`. Suppose that $\mathcal{S}$ receives a message from $\mathcal{F}$ with an `obtain_token` opcode. The message contains the payment_ID, which is forwarded to $\mathcal{A}$. The tokens produced by $\mathcal{A}$ are then collected by $\mathcal{S}$. $\mathcal{S}$ keeps the tokens from $\mathcal{A}$ in its global pool of tokens. Then $\mathcal{S}$ forwards identifiers for the tokens back to $\mathcal{F}$ as the return value. If $\mathcal{A}$ attempts to send a message to $\mathcal{F}_{\text{Zcash}}$ (as part of `obtain_token` or at any other time), then $\mathcal{S}$ sends the message to $\mathcal{F}_{\text{Zcash}}$ in the ideal world, and gives the response to $\mathcal{A}$ in simulation.

`obtain_digests`. Suppose that $\mathcal{S}$ receives a message from $\mathcal{F}$ with an `obtain_digests` opcode. The message is forwarded to $\mathcal{A}$.

Notably, this model does not include the *payment* phase in which the client initiates a Zcash transaction to transfer funds. Instead, we model Zcash as a trusted party, which the adversary cannot control. This ensures that the server learns nothing during the payment phase in the actual protocol. Formally, we define an ideal Zcash functionality $\mathcal{F}_{\text{Zcash}}$, which the adversary can use to check if a Zcash transaction ID is valid. $\mathcal{F}_{\text{Zcash}}$ reveals only the time of the transaction and the amount paid. Modeling Zcash (i.e., providing a real-world setup that realizes $\mathcal{F}_{\text{Zcash}}$) is out of scope for this work.

E.5 Proof Sketch

We are now ready to define Ghostor's anonymity. We denote the security parameter as κ throughout this paper.

Theorem 1 (Privacy in Ghostor)**.** *Suppose that in Ghostor, the data encryption scheme is CCA2-secure, the ACL encryption scheme is CPA-secure, the ACL encryption scheme is key-private, payment tokens are blind, and $\mathcal{F}_{Zcash}$ is an ideal functionality for Zcash. For every non-uniform probabilistic polynomial-time real-world adversary $\mathcal{A}$, there exists a non-uniform probabilistic polynomial-time ideal-world adversary $\mathcal{S}$ such that for every non-uniform probabilistic polynomial-time environment $\mathcal{Z}$, $\mathcal{Z}$ cannot distinguish the real world with adversary $\mathcal{A}$ from the ideal world with adversary $\mathcal{S}$.*

Proof. We shall demonstrate that for every real-world adversary $\mathcal{A}$, there exists an ideal-world adversary (simulator) $\mathcal{S}$ such that there exists no environment $\mathcal{Z}$ probabilistic polynomial-time in κ that can distinguish between interacting with the real world and interacting with the ideal world. Specifically, for an arbitrary real-world adversary $\mathcal{A}$, we construct an ideal-world adversary $\mathcal{S}$ that uses $\mathcal{A}$ as a black box to perform the same attack in the ideal world as $\mathcal{A}$ performs in the real world. $\mathcal{S}$ simulates an environment that is computationally indistinguishable from the real world, meaning that $\mathcal{A}$ will behave the same way in simulation with at most a negligible difference in probability. We take $\mathcal{S}$ as the simulator described in Appendix E.4.

There are two things to prove:

1. From $\mathcal{A}$'s perspective, the simulated world provided by $\mathcal{S}$ is computationally indistinguishable from the real world.
2. From $\mathcal{Z}$'s perspective, the real world with adversary $\mathcal{A}$ is computationally indistinguishable from the ideal world with adversary $\mathcal{S}$.

To show that these statements are true, we consider a sequence of seven hybrid setups. Although the two statements above are in principle separate, we use the same sequence of hybrids to prove both of them. Note that $\mathcal{H}_0$ is equivalent to the real-world setup, and $\mathcal{H}_6$ is equivalent to the simulated setup. In a true hybrid argument, only one operation can be modified at a time; our hybrids in the proof sketch below should be interpreted as key stages.

Hybrid $\mathcal{H}_0$. This is exactly the real-world setup in Appendix E.3.

Hybrid $\mathcal{H}_1$. This is the same as $\mathcal{H}_0$, except that we replace $\mathcal{A}$ with $\mathcal{S}$. $\mathcal{S}$, in this hybrid, maintains a simulated party Q corresponding to P, and internal to $\mathcal{S}$, these simulated parties interact with $\mathcal{A}$. P interacts with $\mathcal{S}$; when $\mathcal{S}$ receives a message from P, it forwards it to $\mathcal{A}$ via Q, and when $\mathcal{A}$ sends a message to one of $\mathcal{S}$'s simulated parties Q, it forwards it to P. Similarly, when $\mathcal{A}$ sends a message to $\mathcal{F}_{\text{Zcash}}$, $\mathcal{S}$ forwards the message to $\mathcal{F}_{\text{Zcash}}$, obtains the response, and forwards it to $\mathcal{A}$, as if $\mathcal{A}$ communicated with $\mathcal{F}_{\text{Zcash}}$ directly.

$\mathcal{S}$ acts simply as a relay, shuttling data back and forth between P and Q and between $\mathcal{A}$ and $\mathcal{F}_{\text{Zcash}}$. In particular, the messages observed by $\mathcal{A}$ and $\mathcal{Z}$ are exactly the same as before. Therefore, neither $\mathcal{A}$ nor $\mathcal{Z}$ can distinguish $\mathcal{H}_0$ from $\mathcal{H}_1$.

Hybrid $\mathcal{H}_2$. This is the same as $\mathcal{H}_1$, except that we now introduce the ideal functionality $\mathcal{F}$. $\mathcal{F}$, in this hybrid, just relays messages back and forth between the real-world party P and the simulator $\mathcal{S}$.

Here, the newly introduced $\mathcal{F}$ acts as another intermediate relay. Again, the messages observed by $\mathcal{A}$ and $\mathcal{Z}$ are distributed exactly the same as before. Therefore, neither $\mathcal{A}$ nor $\mathcal{Z}$ can distinguish $\mathcal{H}_1$ from $\mathcal{H}_2$.

Hybrid $\mathcal{H}_3$. We change P to a dummy party as in the ideal world. Instead, $\mathcal{S}$ handles participating in the protocol as the honest clients, including PoW. The requests for operations are forwarded by the party P to $\mathcal{F}$.

Although $\mathcal{S}$ now uses its dummy user keypair to interact with the server, the encryption is *key-private*; the server cannot distinguish an ACL entry encrypted under a user's key from the same ACL entry encrypted with $\mathcal{S}$'s dummy user key. Therefore, neither $\mathcal{Z}$ nor $\mathcal{A}$ can distinguish $\mathcal{H}_2$ from $\mathcal{H}_3$.

Hybrid $\mathcal{H}_4$. This is the same as $\mathcal{H}_3$, except that $\mathcal{F}$ replaces ACL entries of honest users with NULL; $\mathcal{S}$ replaces NULL entries with encryptions of zero under the dummy key, for the ACLs of the real-world protocol.

The *semantic security* of the encryption scheme used for ACLs guarantees that, to the adversary, an encryption of zero is indistinguishable from the actual encrypted ACL entry. Therefore, neither $\mathcal{Z}$ nor $\mathcal{A}$ can distinguish $\mathcal{H}_3$ from $\mathcal{H}_4$.

Hybrid $\mathcal{H}_5$. This is the same as $\mathcal{H}_4$, except that $\mathcal{F}$ also replaces object contents with IDs in its content table, and $\mathcal{S}$ in turn replaces these IDs with fake ciphertexts in its ciphertext table. In particular, if all users in an object's ACL are honest, then $\mathcal{F}$ and $\mathcal{S}$, together, replace the contents of the object with an encryption of the zero message of the same length, using the same key normally used to encrypt the object contents.

The *semantic security* of the encryption scheme used to encrypt object contents guarantees that $\mathcal{A}$ cannot distinguish between the fake ciphertext and the actual ciphertext. Furthermore, because the plaintext is returned as the result of the operation, we need to be sure that $\mathcal{A}$ cannot create a new valid ciphertext with a different plaintext distribution. Fortunately, the fact that we use CCA2-secure *authenticated encryption* guarantees this; the adversary cannot create a new ciphertext based on the fake one. Therefore, neither $\mathcal{A}$ nor $\mathcal{Z}$ can distinguish $\mathcal{H}_4$ from $\mathcal{H}_5$.

Hybrid $\mathcal{H}_6$. This is the same as $\mathcal{H}_5$, except that $\mathcal{S}$ keeps track of a pool of tokens, $\mathcal{S}$ gives $\mathcal{F}$ identifiers for the tokens, and $\mathcal{F}$ gives $\mathcal{S}$ a bit indicating if a valid token was used instead of specifying which token was used.

The *blindness* property of the blind signature scheme means that, to the server, different payment tokens, after being unblinded, are indistinguishable from each other. To the environment $\mathcal{Z}$, the interface is exactly the same and tokens are expended exactly as before. Therefore, neither $\mathcal{A}$ nor $\mathcal{Z}$ can distinguish $\mathcal{H}_5$ from $\mathcal{H}_6$. $\square$

F Ghostor's Integrity Guarantee

In this appendix, we state the integrity guarantee provided by Ghostor.

F.1 Linearizability

Before we formalize Ghostor's VerLinear guarantee, we define linearizability as a consistency property. Linearizability is well-studied in the systems literature [34,42], and providing a comprehensive survey of this literature and a fully general definition is out of scope for this paper. Here, we aim to define linearizability in the context of Ghostor, to help frame our contributions.

Definition 1 (Linearizability). *Let F be a set of objects stored on a Ghostor server, and let U be a set of users who issue read and write operations on those objects. The server's execution of those operations is* linearizable *if there exists a linear ordering L of those operations on F, such that the following two conditions hold.*

1. *The result of each operation must be the same as if all operations were executed one after the other according to the linear ordering L.*
2. *For every two operations A and B where B was dispatched after A returned, it must hold that B comes after A in the linear ordering L.*

In Ghostor, **an object's digest chain implies a linear ordering** L of `GET` and `PUT` operations, as follows.

Linear ordering L implied by a digest chain. The linear ordering L to which the server commits is based on the digest chain as follows. First, we assign a sequence number to write operations according to the order of their PREPARE digests in the digest chain. Next, we bind each operation to a digest in the digest chain as follows:

- Each read is bound to the digest representing that read.
- A write with sequence number i is bound to the first COMMIT digest whose sequence number is at least i. **This is either the COMMIT digest for this write, or the COMMIT digest for a concurrent write that wins over this one based on the conflict resolution policy in §5.4.**

Assuming the digest chain is well-formed (all cases except Case 1 below), each write will be bound to a COMMIT digest that is after its PREPARE digest and before or at its COMMIT digest. Finally, we generate the linear ordering as follows:

- If two operations are bound to different digests, then they appear in L in the same order as the digests appear in the digest chain.
- If two writes are bound to the same digest, then they are ordered in L according to their sequence numbers.

For example, suppose the digest chain contains $(R_1, P_1, R_2, P_2, R_3, C_2, R_4, P_3, R_5, C_1, R_6, C_3, R_7, P_4, R_8, C_4, R_9)$, where R denotes a read digest, P denotes a PREPARE digest, and C denotes a COMMIT digest. The corresponding linear ordering of operations is $L = (R_1, R_2, R_3, W_1, W_2, R_4, R_5, R_6, W_3, R_7, R_8, W_4, R_9)$, where R denotes a read operation and W denotes a write operation.

F.2 Verifiable Linearizability

We begin by stating and proving Theorem 2 below, which specifies the achieved guarantees when some users perform the verification procedure for an epoch. Then, we present the VerLinear property of Ghostor as Corollary 1, a special case of Theorem 2. We use this approach because Theorem 2, despite being a more general statement, has fewer edge cases than Corollary 1, and we feel its proof is easier to understand in isolation. The statement of Corollary 1 maps directly to our informal definition of verifiable linearizability in §3; the key differences are only that Corollary 1 is explicit that security depends on collision resistance of Ghostor's hash function and existential unforgeability of Ghostor's signature scheme, introduces variables that are useful in the proof, and states the security guarantee as the contrapositive of Guarantee 1.

Theorem 2 (Epoch Verification Theorem)**.** *Suppose the hash function H used by Ghostor is a collision-resistant hash function with security parameter κ. Let $\mathcal{B}$ be a non-uniform adversary that is probabilistic polynomial-time in κ performing an active attack on the server. Let E be a list of consecutive epochs. For each epoch $e \in E$, let U_e be a set of users for whom the verification procedure for a particular object F detected no problems during epoch e, and let O_e be the set of operations performed by those users on F.* ***If*** *$U_e \neq \varnothing$ (i.e., U_e is nonempty) for all $e \in E$,* ***then*** *there exists, with probability at least $1 - \mu(\kappa)$, where μ denotes a negligible function, a linear ordering L of operations in $O = \bigcup_{e \in E} O_e$ and possibly some other operations, such that for the users in U and their operations O, the following two statements hold.*

1. *The result of each successful operation is the same as if all operations were executed one after the other according to L.*
2. *For every two operations A and B where B was dispatched after A returned, B comes after A in L.*

Proof. We will perform a reduction to show that if there exists an adversary $\mathcal{B}$ that can cause one of the two conditions to be violated, then there exists an adversary $\mathcal{A}$ that can violate the collision-resistance of H with non-negligible probability. For concreteness, suppose that $\mathcal{B}$ performs such an attack with non-negligible probability $\delta(\kappa)$ (so that the condition in the theorem holds with probability $1 - \delta(\kappa)$). We will explain how $\mathcal{A}$ can succeed in finding a hash collision with non-negligible probability.

By the nature of the attack, $\mathcal{B}$ is able to violate the property in the theorem statement, while remaining undetected by users in U. Observe that $\mathcal{B}$'s attack must fall into at one of four cases.

1. There exists at least one object such that $\mathcal{B}$ does not commit to a valid digest chain for an epoch, for some honest user.
2. There exists at least one object such that $\mathcal{B}$ commits to a different digest chain for different honest users.
3. There exists an operation on an object $f \in F$ whose result is different from the result that would be obtained by applying the operations one after the other in the linear ordering implied by f's digest chain.
4. There exist operations a and b on the same object, where a was issued after b completed, but a precedes b in the linear ordering implied by the digest chain.

In particular, if $\mathcal{B}$'s attack does not fall into one of these cases, then the locality property proved in §3 of [42] guarantees that $\mathcal{B}$'s behavior is consistent with the theorem statement (linearizability of operations in L). We will show that no matter which of the above four cases describes $\mathcal{B}$'s attack, $\mathcal{A}$ can find a hash collision.

Case 1. In this case, $\mathcal{B}$ returns an invalid linear ordering to a user when the user performs an `obtain_digests` operation. The ordering could be invalid because the digest is not signed properly, or the digests do not form a well-formed chain. This also includes the case where a user's operation is missing from the digest chain. Because we require that $U_e \neq \varnothing$ for all $e \in E$, this will be detected with probability 1. Therefore, we do not consider this case.[3] An important note is that if each L_e is valid, then L is valid.

Case 2. In this case, the adversary returns different histories to different users. Because the histories differ, they cannot be the same in all epochs; we consider an epoch e in which they differ. This allows us to confine our argument to a single epoch. In particular, there exist two `obtain_digests` operations on the same object during epoch e, for which $\mathcal{B}$ returns different histories in a way that is not detectable.[4] We define two subcases.

In the first subcase, the leaf of the Merkle tree, containing the hash of the final digest for the object in the epoch, is differ-

[3]For the purpose of this proof, it does not matter which party signs the digest, only that it was signed with the correct signing key (which is a per-object key rather than a per-user key). In the actual Ghostor system, only an authorized user can produce the signature due to the existential unforgeability of the signature scheme.

[4]If for all $e \in E$ where the histories differ, only a single call is made to `obtain_digests`, then the server cannot commit to multiple histories, and therefore cannot attack the protocol in this way; therefore, we do not consider this case.

ent for each call. However, given our consistency assumption for the blockchain, each user will see the same Merkle root. Furthermore, because the leaves of the Merkle tree are sorted and each intermediate node indicates the range of objects in each of its children, each node in the root-to-leaf path unambiguously specifies the hash of the next node in the path. Because the first element (root) is the same for the paths returned in each call to `obtain_digests`, but the last element is different, there must be a hash collision somewhere along the path. $\mathcal{A}$ finds this collision.

In the second subcase, both calls to `obtain_digests` see the same Merkle leaf and therefore the same hash of the final digest, but see different digest chains regardless. Observe that the last digest and first digest, for this epoch's digest chain, are fixed based on the checkpoint for this epoch and the checkpoint for the previous epoch, which the client can obtain from the server (to make the argument simpler, we consider the final digest of the previous epoch to also be the first digest of the current epoch). Furthermore, the user knows the hashes of these digests, from the checkpoints on the blockchain. Therefore, if first or last digests of the digest chains returned to both calls to `obtain_digests` differ, then $\mathcal{A}$ can use them to find a hash collision (since their hashes must match the Merkle leaves). If these digests match, then the intermediate digests must differ. To find a collision in this case, $\mathcal{A}$ simply walks backwards along the digest chains, until they differ. $\mathcal{A}$ can use the digests on each chain, at the point that they differ, to obtain a hash collision.

Case 3. Observe that the result of any committed write is "Success." Therefore, we can restrict this case to *reads that return the wrong value*.

Suppose that a read operation in O_e (for some $e \in E$) returned a value that is not consistent with the linear ordering for the object. In order for the operation to be considered successful, the $\mathsf{Hash}_{\mathsf{data}}$ value in the signed digest received by the client must match the hash of the returned object contents. Furthermore, the verification procedure guarantees that the $\mathsf{Hash}_{\mathsf{data}}$ value in each digest corresponding to a read matches the $\mathsf{Hash}_{\mathsf{data}}$ value in the latest write at that time—it does this by checking that $\mathsf{Hash}_{\mathsf{data}}$ never changes as the result of a read, and that it only changes in the COMMIT digests of winning writes. It follows that the incorrect value returned by the read operation, and the correct value that should have been returned (which was written by the latest write), have the same hash. $\mathcal{A}$ can present these two values as a hash collision.

Case 4. If an operation is missing from the digest chain entirely, this will be detected by the client that issued the operation. We now consider the case where the digests appear in the wrong order. Concretely, let op_1 and op_2 be two operations, where op_2 is issued after op_1 completed. If op_1 is a `PUT`, then d_1 is its COMMIT digest; otherwise, if op_1 is a `GET`, d_1 is the single digest for that `GET`. If op_2 is a `PUT`, then d_2 is its PREPARE digest; otherwise, if op_2 is a `GET`, d_2 is the single digest for that `GET`. Because op_2 is issued after op_1 completed, their digests should unambiguously appear in order in the digest chain: d_1 appears before d_2. Now, suppose d_1 appears sometime after d_2, so that the linear ordering is inconsistent with execution order. In this case, $\mathcal{A}$ waits until the users have run the verification procedure, and then rewinds $\mathcal{B}$'s state to a point after $\mathcal{B}$ has committed op_1, but before op_2 has been issued. The client places a fresh nonce in d_2 this time around, but otherwise execution is resumed as before. $\mathcal{A}$ waits until the user runs the verification procedure again, and it compares the digest chains produced by $\mathcal{B}$'s execution both times. Because all that changed is the client's nonce in d_2, and it is taken from the same uniform random distribution, $\mathcal{B}$'s probability of performing a successful attack is still non-negligible. So the probability that $\mathcal{B}$ performed a successful attack in both distributions is non-negligible ($\delta(\kappa)^2$). In this case, $\mathcal{A}$ walks the digest chains backward starting at d_1; the digest chains must differ at some point, because d_2 precedes d_1 in the first history, d_2 has a different random nonce in the second history, and the digest for d_1 is the same in both histories. This way, $\mathcal{A}$ can obtain a hash collision. □

Although the two conditions in Theorem 2 are the same as those in Definition 1, Theorem 2 does *not* guarantee linearizability of operations in O (operations performed by users in U). This is because the linear ordering L in Theorem 2 includes *additional* operations in the system beyond those in O, which could be digests that the server replayed or operations performed by users who did not run the verification procedure. This motivates us to state Corollary 1, which specifies under what conditions a set of users can be sure that their operations were processed in a linearizable way. Because our definition is now in line with linearizability (Definition 1), we can leverage the locality property of linearizability [42] to state the corollary in terms of a single object.

Corollary 1 (Verifiable Linearizability)**.** *Suppose the hash function H used by Ghostor is a collision-resistant hash function and the signature scheme is existentially unforgeable. For any adversary probabilistic polynomial-time in κ, any object F, and any list E of consecutive epochs: suppose that for each epoch $e \in E$, the set U_e of users who ran the verification procedure on F during epoch e (1) is nonempty (i.e., $U_e \neq \varnothing$) and (2) contains all users who wrote the object F during epoch e (and possibly other users too). With probability at least $1-\mu(\kappa)$, where μ denotes a negligible function,* ***if*** *no user detects a problem when running the verification procedure,* ***then*** *the server's execution of operations in $O = \bigcup_{e \in E} O_e$ is linearizable, where O_e is the set of operations performed by users in U_e during epoch e.*

Proof. By Theorem 2, we know that there exists a linear ordering L containing all operations in O plus some other authorized operations on F such that Properties #1 and #2 in the statement of Theorem 2 hold for operations in O, with respect to L. Because each U_e contains all users who wrote

f during epoch e, and the signature scheme is existentially unforgeable, we know that all operations in L that are not in O must be reads. Let ℓ denote the subset of L consisting only of operations in O. Now, observe that Properties #1 and #2 in the statement of Theorem 2 also hold for the operations in O *with respect to* ℓ. This is because (1) L is the same as ℓ with some additional read operations, so the result of each operation, when operations are executed one after the other, is the same for both orderings, and (2) the relative ordering of operations in O is the same in both L and ℓ. Because ℓ contains only the operations in O and it satisfies Properties #1 and #2, it fulfills Definition 1. Therefore, the execution of operations in O is linearizable. $\square$

Fawkes: Faster Mobile Page Loads via App-Inspired Static Templating

Shaghayegh Mardani*, Mayank Singh†, Ravi Netravali*
*UCLA, †IIT Delhi

Abstract

Despite the rapid increase in mobile web traffic, page loads still fall short of user performance expectations. State-of-the-art web accelerators optimize computation or network fetches that occur *after* a page's HTML has been fetched. However, clients still suffer multiple round trips and server processing delays to fetch that HTML; during that time, a browser cannot display any visual content, frustrating users. This problem persists in warm cache settings since HTML is most often marked as uncacheable because it usually embeds a mixture of static and dynamic content.

Inspired by mobile apps, where static content (e.g., layout templates) is cached and immediately rendered while dynamic content (e.g., news headlines) is fetched, we built Fawkes. Fawkes leverages our measurement study finding that 75% of HTML content remains unchanged across page loads spread 1 week apart. With Fawkes, web servers extract static, cacheable HTML templates for their pages offline, and online they generate dynamic patches which express the updates required to transform those templates into the latest page versions. Fawkes works on unmodified browsers, using a JavaScript library inside each template to asynchronously apply updates while ensuring that JavaScript code only sees the state that it would have in a default page load despite downstream content having already been loaded. Across a wide range of pages, phones, and live wireless networks, Fawkes improves interactivity metrics such as Speed Index and Time-to-first-paint by 46% and 64% at the median in warm cache settings; results are 24% and 62% in cold cache settings. Further, Fawkes outperforms recent server push and proxy systems on these metrics by 10%-24% and 69%-73%.

1 Introduction

Mobile web browsing has rapidly grown in popularity, generating more traffic than its desktop counterpart [18, 20, 57]. Given the importance of mobile web speeds for both user satisfaction [11, 12, 23] and content provider revenue [21], many systems have been developed by both industry and academia to accelerate page loads. Prior approaches have focused on pushing content to clients ahead of time [61, 70, 76, 19], compressing data between clients and servers [4, 67, 63], intelligent dependency-aware request scheduling [14, 42], offloading tasks to proxy servers [47, 65, 10, 6], and rewriting pages for the mobile setting (either by automatically serving post-processed objects to clients [71, 43, 51], or by manually modifying pages to follow mobile-focused guidelines [24, 34]). Yet despite these efforts, mobile page loads continue to fall short of user expectations in practice. Even on a state-of-the-art phone and LTE cellular network, the median page still takes over 10 seconds to load [7, 61].

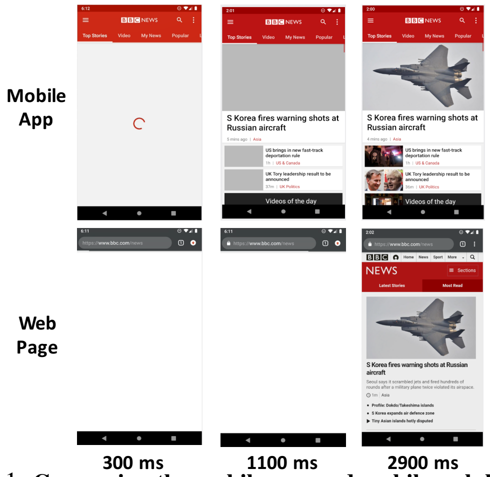

Figure 1: **Comparing the mobile app and mobile web browser loading processes for BBC News over an LTE cellular network.**

Our key observation is that, while existing optimizations are effective at reducing network fetch delays and client-side computation costs during page loads, *they all ignore a large and fundamental bottleneck in the page load process: the download of a page's top-level HTML file*. To fetch a page's top-level HTML, a browser often incurs multiple network round trips for connection setup (e.g., DNS lookups, TCP and TLS handshakes), server processing delays to generate and serve content, and transmission time. These tasks can sum to delays of hundreds of milliseconds, particularly on high-latency mobile links.[1] Only after receiving and parsing a page's HTML object can the browser discover subsequent objects to fetch and evaluate, make use of previously cached objects, or render any content to the blank screen. Thus, from a client's perspective, the entire page load process is blocked on downloading the page's top-level HTML object. This is true even in warm cache scenarios, since HTML objects are most often marked as uncacheable [44] (§2).

Eliminating these early-stage inefficiencies would be fruitful for two reasons. First, overall load times would reduce since client-side computation and rendering tasks for cached content could begin earlier and be overlapped with network and server-side processing delays for new content; the CPU is essentially idle as top-level HTML files are fetched in traditional page loads. Second, and more importantly, browsers could immediately display static content, rather than showing only a blank screen as the HTML is fetched (Figure 1). This is critical as numerous web user studies and recent performance metrics highlight user emphasis on content becoming visible quickly and progressively [46, 25, 35, 49, 66].

[1] These delays persist even for HTML objects served from CDNs since last-mile mobile link latencies still must be incurred.

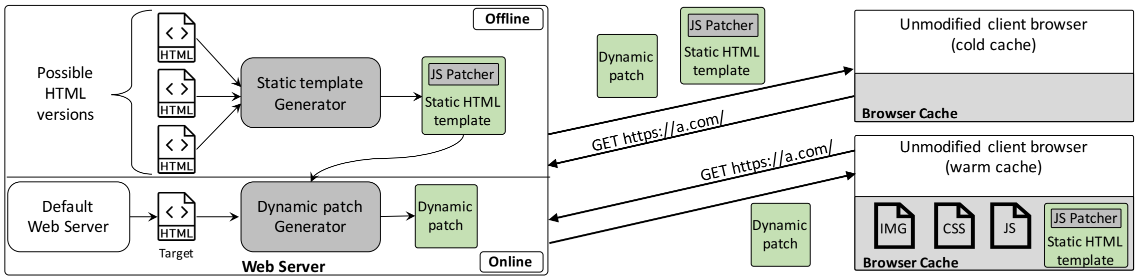

Figure 2: **Overview of cold and warm cache page loads with Fawkes. Servers return static, cacheable HTML templates, as well as uncacheable dynamic patch files that list the updates required to convert those templates into the latest page. Updates are performed dynamically using the Fawkes JavaScript patcher library that is embedded in the templates.**

To enable these benefits, we draw inspiration from mobile apps which, despite sharing many components with the mobile web (e.g., client devices, networks, content), are able to deliver lower startup delays (Figure 1). Apps reduce startup times by aggressively separating static content from dynamic content. At the start of executing a task (akin to loading a page), an app will issue a request for dynamic content *in parallel* with rendering locally cached content like structural templates, images, and banners. Once downloaded, dynamic content is used to patch the already-displayed static content.

Like apps, web pages already cache significant amounts of content across loads: 63% and 93% of the objects and bytes are cacheable on the median page. Yet startup times in warm cache page loads remain high due to download delays of top-level HTML files (§2). But why are HTML objects marked as uncacheable? The reason is that they typically bundle static content defining basic page structure with dynamic content (e.g., news headlines or search results). HTML which embeds dynamic content must be uncacheable so clients see the most recent page. Thus, at first glance, it appears that addressing this challenge with app-like templating would require a rethink of how web pages are written. However, our measurement study (§2) reveals that web pages are already highly amenable to such an approach given the large structural and content similarities for HTML objects across loads of a page. For instance, 75% of HTML tags on the median top 500 page have fixed attributes and positions across 1 week, and could thus be separated into static templates.

We present **Fawkes**, a new web acceleration system that modifies the early steps in the page load process to mirror that of mobile apps (Figure 2). Fawkes optimizes page loads in a two-step process. In the first phase, which is performed offline, web servers *automatically* produce static, cacheable HTML templates, which capture all content that remains unchanged across versions of a page's top-level HTML. The second phase occurs during a client page load; servers generate dynamic patches, which express the updates (i.e., DOM transformations) required to convert template page state into the latest version of a page. During cold cache page loads, browsers download precomputed templates while dynamic patches are being produced, and can quickly begin rendering template content and fetching referenced external objects as patches are pushed. In warm cache settings, browsers can immediately render/evaluate templates and referenced cached objects while asynchronously downloading the dynamic patch needed to generate the final page.

Realizing this approach with legacy pages and unmodified browsers requires Fawkes to solve multiple challenges:

- On the server-side, generating templates is difficult: traditional tree comparison algorithms [75, 36, 16, 54, 55] do not consider invariants involving a page's JavaScript and DOM state, but templates execute to completion prior to patches being applied and thus must be *internally consistent*. For example, removing an attribute on an HTML tag can trigger runtime errors if downstream JavaScript code accesses that attribute; an acceptable template must keep or omit both of these components. In addition, graph algorithms are far too slow to be used for online patch generation. Instead, Fawkes uses an empirically-motivated heuristic which trades off patch generation time for patch optimality (i.e., number of operations; note that the final page is unchanged). Our insight is that tags largely remain on the same depth level of the tree as HTML files evolve over time. This enables Fawkes to use a breadth-first-search variant which generates patches 2 orders of magnitude faster (in 20 ms) with comparable content.
- On the client-side, each static template embeds a special JavaScript library which Fawkes uses to asynchronously download dynamic patches and apply the listed updates. The primary challenge is in ensuring *view invariance* for JavaScript code that is inserted via an update: that code must see the same JavaScript heap and DOM state as it would have seen during a normal page load. For example, consider an update which adds a `<script>` tag to the top of the HTML template. If that script executes a DOM method that reads DOM state, the return value may include DOM nodes pertaining to downstream tags in the template—this state is already loaded in a Fawkes page load, but not in a default one, and may trigger execution errors. To provide view invariance, Fawkes uses novel shims around DOM methods which prune the DOM state returned by native methods based on knowledge of page structure and the position of the script calling the method.

We evaluated Fawkes using more than 500 real pages, live wireless networks (cellular and WiFi), and two smartphone models. Our experiments reveal that Fawkes significantly accelerates warm cache mobile page loads compared to default browsers: median benefits are 64% for Time-to-first-paint (TTFP), 46% for Speed Index (SI), 26% for Time-to-interactive (TTI), and 22% for page load time (PLT). Despite targeting warm cache settings, Fawkes speeds up cold cache loads by 62%, 24%, 20%, and 17% on the same metrics. Fawkes also outperforms Vroom [61] and WatchTower [47], two recent mobile web accelerators, by 69%-73% and 10%-24% on warm cache TTFP and SI. Importantly, Fawkes is complementary to these approaches; Fawkes with Vroom achieves Fawkes's TTFP and SI benefits, while exceeding Vroom's PLT improvements by 22%. Source code and experimental data for Fawkes are available at https://github.com/fawkes-nsdi20.

2 Motivation

We begin with a range of measurements that illustrate the startup discrepancies between mobile apps and web pages (§2.1), and the amenability of web pages to app-like templating (§2.2). Results used the LTE setup described in §5.1.

2.1 Mobile Apps vs. Mobile Web

We compare the load process of mobile apps and web pages by analyzing equivalent tasks across 10 web services; services were selected by randomly choosing web pages from the Alexa US top 100 list [5], and discarding those without a corresponding mobile app. Our corpus includes news, recommendation platforms, search engines, and social media applications. For each service, we equate loading a homepage with a mobile browser to loading the home screen with the mobile app. When applicable, we also compare equivalent searches on both platforms. We load each task in the mobile app and website back to back, and for each task, we log the time until the first paint to the screen and collect screenshots for three events: the first time either platform displays content to the user (Time-to-first paint, or TTFP), an intermediate checkpoint with additional displayed content, and the time when both platforms reach their final visual state. Mobile app screenshots and paint events are captured via the Apowersoft Recorder [8] and Android Systrace [31] tools, respectively. Since apps have content cached during installation, for fair comparison, we consider warm cache page loads (back to back). Certain mobile apps operate by displaying a logo for several seconds during startup, prior to displaying the home screen. We do not consider such apps here.

Startup delays are far lower with apps than web pages. Across the corpus, our experiments reveal that TTFP values are between 3.5×–5.2× lower with mobile apps than mobile web pages. Figure 1 provides a representative example of loading the home page for BBC News. As shown, despite the high network latencies and potential server processing delays, the mobile app is able to quickly display static content that establishes the overall app layout and logos in under 300 ms. We verified that the reason for this is that the app quickly pulls this content from its local cache while asynchronously fetching dynamic news headlines. In contrast, the BBC web page remains blank as the browser establishes a connection to the backend and downloads the top-level HTML for the page. Only upon receiving the HTML object can the browser begin rendering any static or dynamic content to the screen–this does not begin until 1200 ms, 4× longer than the app.

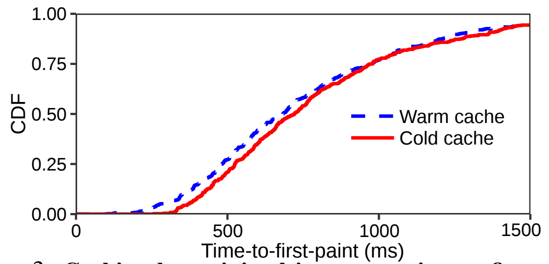

Figure 3: **Caching has minimal impact on time-to-first-paint since browsers cannot render cached content until they download the top-level HTML (typically uncacheable).**

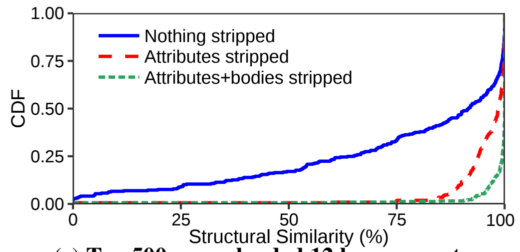
Problem: uncacheable HTML limits caching benefits for the web. The above discrepancies between mobile apps and web pages are indicative of a fundamental difference in the startup tasks on the two platforms. Web HTML objects are used to set the context for the remainder of a page load, establishing render and JavaScript engine processes, creating a DOM tree (i.e., the browser's programmatic representation of the page's HTML) and JavaScript heap, and so on. However, most HTML objects are marked as uncacheable. For example, 72% are uncacheable across back to back loads of the top 500 pages; this number jumps to 85% for loads separated by 5 minutes. As a result, browsers are unable to make use of other objects marked as cacheable (e.g., images, CSS) until they download an HTML object; for reference, 53% and 93% of objects and bytes are cacheable on the median page. Figure 3 illustrates this point: median TTFP values are only 5.3% lower in warm cache scenarios than during cold cache page loads despite so many objects being cached.

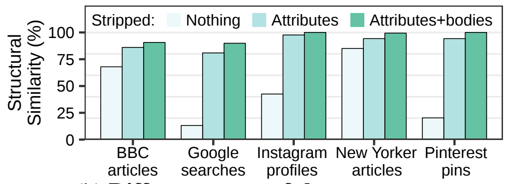
2.2 Templating Opportunities for the Web

Motivated by the startup discrepancies between mobile app and web page loads described above, we investigated how amenable web pages are to app optimizations. Our analysis focuses on the feasibility of extracting static templates from HTML objects that can be cached across page loads. We consider two different sets of sites: the Alexa top 500 landing pages [5], and a smaller set which includes 10 pairs of different pages of the same type (e.g., different news articles or search results). More dataset details are provided in §5.

We loaded each page (or pair of pages in the smaller corpus) multiple times to mimic different warm cache scenarios: back to back, 12 hours apart, 24 hours apart, and 1 week apart. In each setting, we compared the resulting top-



(a) **Top 500 pages loaded 12 hours apart.**



(b) **Different pages of the same type.**

Figure 4: **Structural similarity for HTML files over time. Similarity is defined as the percentage of shared tag sequences (including tag attributes, bodies, and types).**

level HTML objects to determine structural similarities. We identify each tag as a tuple consisting of its tag type (e.g., `<div>`), HTML attributes (e.g., `class`), and body (e.g., inline script code). Since static templates can be patched during page loads, we also consider tuple versions with all tag attributes stripped, and with both tag attributes and bodies stripped. Additionally, since HTML can be modeled as a tree where ordering matters, for each tag T, we generate a sequence of tags by following parent tags up from T to the root node. We then define structural similarity as the fraction of sequences that remain identical across the HTML versions.

Opportunity: HTML structure and content is largely unchanged over time. Figure 4 shows that HTML objects exhibit high structural similarity. For example, for the median top 500 page, 92% of HTML tags remain identical across loads separated by 12 hours; these numbers jump to 98% and 100% when attributes are stripped alone or with bodies. These trends persist for different pages of the same type. For instance, two different Instagram profile pages exhibit structural similarity of 98% when only attributes are stripped. The trends also persist for other time windows. For example, median similarities in the 1-week setting are 75% and 95% with nothing and attributes stripped, respectively.

Key Takeaways:

- Mobile apps exhibit a desirable startup process compared to mobile web pages because apps explicitly separate static and dynamic content, and immediately render cached static content while dynamic content is fetched. Web pages, on the other hand, remain blocked (blank screen) on downloading uncacheable HTML objects, despite most other objects being cacheable.
- Mobile web pages are amenable to app-like templating of static content since HTML objects (typically uncacheable) have large structural similarities over long time periods.

3 Design

Figure 2 shows the high-level design of Fawkes. Clients use unmodified browsers to load pages as normal. On the server side, websites must run Fawkes to handle incoming client HTTP(S) requests. The server-side Fawkes code performs two primary tasks. For a given page, Fawkes statically analyzes possible variants of the unmodified top-level HTML objects for the page and extracts a single **static HTML template** which maximally captures shared HTML content across versions. The generation of the static HTML template is performed offline, i.e., not during a client page load. Then, when a user loads the page, Fawkes compares the static HTML template to the target HTML, or the one that the default web server would have served without Fawkes, and generates a **dynamic patch**, which is a JSON file with an ordered list of DOM updates required to convert the template page into the target one.

The static HTML template includes an inline **JavaScript "patcher" library** that asynchronously downloads the dynamic patch file, and upon receiving it, dynamically applies the listed updates. During cold cache loads, Fawkes's server first returns the cacheable, static HTML template, and then streams the dynamic patch with HTTP/2 server push soon after; the template is sent earlier since it is precomputed, and this allows the browser to quickly start rendering template content and fetching referenced external resources. During warm cache page loads, the browser immediately begins to evaluate and render the cached template and other cached objects that it references as the patch downloads.

3.1 Server-Side Operation

In order to generate static HTML templates, Fawkes's server-side component leverages state-of-the-art tree matching algorithms [54, 55]. The goal of these algorithms is to determine the minimum distance between two (or more) tree structures; recall that HTML files are structured as trees (§2). In particular, these algorithms take as input a set of trees whose nodes are assigned labels. The algorithms then compute a set of operations that, if applied, would efficiently transform the first input tree into the second. Operations typically comprise three primary types: *delete* operations remove a node and connect its children to its parent, *insert* operations add a node to a specific position in the tree, and *rename* operations do not change node positions but instead only alter a node's label. Algorithm execution works much like string edit distance techniques, using dynamic programming and assigning each operation a cost of 1.

Altering tree matching algorithms: Fawkes must alter existing tree matching algorithms in several ways to ensure that they are compatible with HTML and web semantics. First, existing algorithms require each tree node to be labeled with an individual string. However, HTML tags can include state beyond simple tag type (e.g., `<div>` or `<link>`), each of which could be shared across versions of a page. Properties include attributes (e.g., `class`) that control the tag's behavior with respect to CSS styling rules and interactions with JavaScript code, and bodies such as inline JavaScript code or text to print. Failing to consider attributes during HTML comparison can result in either broken pages if attributes are incorrectly treated as equivalent, or suboptimal templates if shared attributes are not maximally preserved, i.e., any attribute discrepancy would require omitting a tag. Thus, Fawkes's tree comparison algorithm labels each HTML tag with a (type, [attributes], body) three-tuple.

Second, Fawkes opts to not support *rename* operations, and instead only supports new *merge* operations. Unlike rename operations that can entirely change a node's label to deem it equivalent to a node in the other tree, merge operations can only alter a tag's attributes or body to claim such equivalence. Importantly, merge operations do not allow tag types to be modified. The reasoning behind this decision is that different tags impose different semantic restrictions on HTML structure. For instance, an `<img>` tag is self-closing, and cannot contain children tags, while `<div>` tags can have arbitrary children structures. Rewriting a `<div>` tag to an `<img>` tag would thus trigger cascading effects on existing children tags, leading to smaller templates.

Generating static HTML templates: Fawkes uses the above tree matching framework to generate static HTML templates from a set of HTML files. We describe how to get this input set in §3.3, and for simplicity, describe the approach assuming two input HTML files. To start, Fawkes runs its tree matching algorithm to generate a set of operations which, if applied, would convert *HTML1* to *HTML2*. Fawkes then iterates through HTML1 and selectively applies certain updates to only keep content that is shared across the inputs. Delete operations are directly applied to HTML1 as they represent content which is not shared across versions and thus should not be part of the static HTML template. Similarly, insert operations are ignored as they represent content that must be added to reach HTML2 and is thus not shared. Finally, Fawkes strips all content (tag attributes and bodies) referenced by merge operations as these highlight discrepancies between HTML versions.

While applying these operations and generating static HTML templates, Fawkes must be careful to preserve page semantics and not violate inherent dependencies between page state. In particular, Fawkes must ensure that static HTML templates are *internally consistent* and do not trigger JavaScript execution errors when parsed; this is important as templates are parsed to completion prior to any patch updates being applied. The key challenge is that altering an HTML tag's attributes or body can have downstream effects due to the shared state between JavaScript code and the DOM tree [42]. For example, a downstream `<script>` tag may access an upstream `<p>` tag's attribute. Deleting that `<p>` tag's attribute can thus trigger execution errors when the browser reaches the `<script>` tag. Similarly, different `<script>` tags can share state on the JavaScript heap. As a simple example, an upstream tag may define a variable which the downstream tag accesses. Thus, cutting the upstream tag's body can trigger downstream execution errors.

Existing tree matching algorithms are unaware of such dependencies and are agnostic to the HTML execution environment. Thus, Fawkes applies a post-processing step to ensure that such dependencies are not violated in the static HTML template. Fawkes essentially iterates through the static HTML template, and upon detecting an altered tag, cuts downstream `<script>` tags. Fawkes could leverage techniques like Scout [42] to more precisely characterize the dependencies between tags and JavaScript code in an effort to preserve more state in static HTML templates. However, accurately capturing such fine-grained dependencies would require web servers to also execute HTML content and load pages. Our empirical results motivate that templates derived from static tree analysis sufficiently keep the browser occupied with render and fetch tasks as dynamic patches are fetched, obviating the need for dynamic processing.

Generating dynamic patches: Fawkes servers must generate dynamic patches that list updates which, if applied, would convert the page state produced by a template into its desired final form. The inputs for patch generation are the static HTML template and the target HTML which is the file that a default web server would serve during the current page load.

The tree comparison algorithm described above can produce the desired set of transformation updates that a patch must contain. However, such algorithms are far too slow for patch generation which, unlike template generation, must be performed online, during client page loads. Thus, Fawkes uses a tree comparison heuristic which trades off patch generation time for optimality in terms of number of operations in the patch. The key insight is empirically motivated: we observe that tags most often remain on the same depth level of a tree as HTML files evolve over time. Our analysis of HTML files for 600 pages over a week revealed that, at the median and 95th percentile, 0% and 1% of tags in target HTML files were at a different depth than they were a week earlier. This property favors a breadth-first-search approach over a depth-first-search one, and implies that we need not consider new positions for a tag outside of its current level (as traditional algorithms would). So, for each level in the target HTML file, Fawkes's algorithm works as follows:

1. Create hash maps for both the target and template HTML files that list all of the nodes for a given tag type in the order they appear on that level (from left to right).
2. Iterate through the template's level from left to right and handle each node in one of two ways. If the node's tag type exists in the same level of the target, match this node to the closest node of the same type with the same parent, and remove that node's entry from the target's hash map; if no node has a matching parent, match to the closest node of the same type. Record a *merge* op-

eration by comparing the attributes and bodies for the matched nodes. Else, if the tag type does not exist in the same level of the target, delete this node in the template and record a *delete* operation.

3. Once we reach the end of the template's level, apply *move* operations to order all matched nodes in the template in the same way as they appear in the target; objects which remain in the same position do not require any operation. Note that *move* operations (which simply change the position of a node) are not supported by traditional tree diffing algorithms, and are only enabled by our heuristic's "look ahead" hash maps. Also, note that moves made at this level are immediately reflected in lower levels of the tree as children are reordered.
4. Finally, from left to right, insert any remaining nodes listed in the target's hash map to the appropriate position. Record *insert* operations for these additions.

The key limitation of this heuristic is with respect to nodes moving across levels in the tree. Traditional algorithms can identify such cases, while Fawkes's approach would automatically require a delete at the original level and an insert at the new level. However, as noted above, such transformations are rare. In addition, matching nodes to their closest counterparts with the same parent could be suboptimal: an inserted node in the target can create cascading suboptimal rename and move operations for nodes of that type. Despite such potential inefficiencies, correctness of the final page load is unaffected. We compare this heuristic to standard tree comparison algorithms and other heuristics in §5.5.

Each update in a dynamic patch must identify a node to which the update should be applied. Fawkes identifies DOM nodes by their child paths from the root of the HTML tree. For example, a child path of [1,3,2] represents an HTML tag that can be reached by traversing the first child of the root HTML tag, the third child of that tag, and then the second child of that tag. Child path ids are easy to compare and can be computed purely based on HTML tree structure.

3.2 Client-Side Operation

To load a page, a mobile browser first loads the static HTML template, whose initial tag is the Fawkes patcher JavaScript library. The patcher begins by issuing an asynchronous XMLHttpRequest (XHR) request for the page's latest dynamic patch. The patcher defines a callback function on the XHR request which will be executed upon receiving the dynamic patch JSON file to apply updates. The patcher then defines the DOM shims required by the callback to apply the dynamic patch updates (described below). Finally, the patcher removes its HTML `<script>` tag from the page to prevent violating downstream state dependencies and to ensure that the final page's DOM tree is unmodified. We note that the state defined by the patcher persists on the JavaScript heap despite its tag being removed from the page.

Applying updates: Upon downloading the dynamic patch, the patcher's callback function iterates over the listed updates and applies them in order until completion. To apply a given update, the patcher first obtains a reference to the affected DOM node (i.e., the one listed in the update) by walking the DOM tree based on the listed child path. The patcher then uses native DOM methods to apply the update.

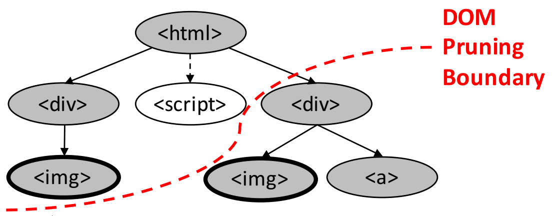


Figure 5: **Update challenge 1: provide view invariance to JavaScript code by hiding downstream DOM state. Shaded nodes are part of the static HTML template. The `<script>` tag is inserted via Fawkes's patcher and calls a DOM method to find `<img>` tags. The native DOM method would return the two nodes outlined in bold, even though the rightmost one would not be returned in the default page load; Fawkes's DOM shims prune the rightmost node from the return value.**

For insert operations, the patcher first creates a new DOM node using document.createElement(), sets the appropriate attributes with Element.setAttribute(), and then adds it to the appropriate position in the DOM tree by calling document.insertBefore(). Adding nodes to the DOM tree can have cascading effects with respect to rendering and layout tasks (both of which are expensive). To mitigate these overheads, Fawkes intelligently looks ahead in the update list to determine if subsequent updates reference the node being added by the current insert update [43, 22]. In these cases, Fawkes constructs a DOM subtree on the JavaScript heap prior to applying the entire subtree to the actual DOM. Fawkes uses similar techniques to handle merge and delete operations.

Handling DOM discrepancies: There are two main challenges with applying updates, both of which relate to JavaScript execution and its interaction with the DOM tree. Fawkes handles both using a novel set of shims (or wrappers) around DOM methods, which are the vehicles with which JavaScript can access or modify the DOM tree.

- The first issue is with providing *view invariance* for JavaScript code inserted via an update: that code must see the same JavaScript heap and DOM state as it would have seen during a normal page load. This is challenging since updates are not applied until after a page's static HTML template is entirely parsed. For example, consider Figure 5 where an inserted `<script>` tag invokes a DOM method to read `<img>` tags in the page. The return value for this method would include an `<img>` tag that is downstream in the page's HTML; this divergence from the default page load could trigger JavaScript execution errors or alter page semantics. To handle this, Fawkes shims all DOM methods which return a DOM node or a list of DOM nodes; examples include document.getElementById() and document.getElementsbyTagName(). Each shim calls the native method and prunes the result prior to returning it to the client. Pruning is done by identifying the position in the DOM tree of the script invoking the DOM method, and then removing DOM nodes in the result which are below that position in the DOM tree. Fawkes's shims skip pruning for callback functions (e.g., timers) and provide *view plausibility* since the page makes no guarantee on what DOM state those asynchronous events can encounter. We note that it is not possible for inserted scripts to see less DOM state than it would in a default page load because updates are ordered with respect to HTML positions.

- The second issue is that JavaScript code can alter the DOM tree in ways that affect the child path ids for subsequent updates. The reason is that the child path ids listed in the dynamic patch are based on the static HTML, which does not consider JavaScript execution, but are applied to the dynamic DOM tree which JavaScript code can manipulate (Figure 6). To handle this, Fawkes shims DOM methods that affect DOM structure, either by adding, removing, or relocating nodes; example methods include document.appendChild() and document.insertBefore(). Each shim calls the native method, logs its effect on DOM structure (e.g., the child path of an added node), and then returns the value. When the patcher attempts to apply an update, it first checks this log, and modifies the child paths in the remaining updates based on the listed DOM changes. We note that JavaScript can also invalidate a listed update, e,g,. by replacing a `<div>` tag with an `<img>` tag in the same position. Fawkes's shims detect these alterations, and the patcher discards such updates since JavaScript takes priority over HTML for final page structure.

3.3 Identifying HTML Objects to Consider

Fawkes's server-side static template generation inherently relies on having a set of representative HTML files from which to extract a template. Here we discuss several approaches for websites to generate this input set for each of their pages; Fawkes is agnostic to the specific approach that a site uses for this. We note that the input set need not be comprehensive and cover all possible HTML versions for a page since patches will include all necessary updates to reach the target page. However, considering a comprehensive set of HTML objects can reduce the number of updates required at runtime, leading to improved performance.

Option 1: empirical analysis: One approach is for web servers to log the HTML objects that they would serve to clients over time without Fawkes. Fawkes can then periodically recompute a static HTML template based on the latest served HTML files to account for structural modifications that developers make to the page. An advantage of this approach is that the static HTML templates will inherently be based off of the popular pages that are actually served to clients. For instance, if a very rare state configuration would

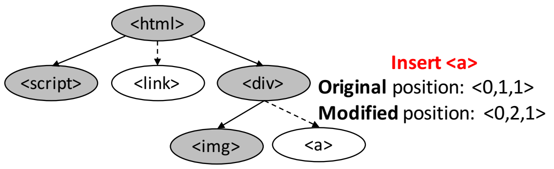

Figure 6: **Update challenge 2: revise update positional information to reflect JavaScript execution. Shaded nodes are part of the static HTML template. Upon execution, the `<script>` tag inserts an adjacent `<link>` tag into the page. Later, when the patcher tries to apply an update to insert an `<a>`, the listed child path id has gone out of date and must be updated.**

alter the structure of a page, most page loads would benefit from *not* considering this version in template generation.

Option 2: leveraging web frameworks: An alternative approach is to leverage the model-view-controller architecture that many popular web frameworks (e.g., Django, Ruby on Rails, and Express) use. In these systems, incoming requests are mapped to a controller function which generates a response by executing application logic code that combines application data and premade HTML blocks. Note that these blocks are small, spanning only a few tags each, and are significantly augmented with HTML tags generated by application logic–this precludes us from using these blocks as our templates. To leverage this structure, we can perform standard static program analysis [62, 37] on application code (particularly the controller for the URL under consideration) to determine the possible HTML block combinations and dynamically produced HTML code that could result for a page.

Option 3: hybrid approach: A final approach is to perform static program analysis on the application backend source code to determine what inputs affect HTML structure, e.g., Cookie values, database state, time of day, etc. Fawkes can then simply probe the backend with different input values to generate a range of potential HTML objects that could be returned to clients; static HTML template generation would then work in the same way as Option 1.

Case studies: Our evaluation (§5) primarily focuses on Option 1. However, to validate the feasibility of the remaining options, we analyzed the source code of two real open source web applications: Reddit [2] and ShareLatex [1]. Both applications follow the MVC model described above, with Reddit using the Python Pylons framework [58] and ShareLatex using NodeJS's Express [50]. For both applications, we wrote custom static analyzers which profile the controller for the sites' landing pages. The output of the profiler is an intermediate template that intertwines HTML code with Python (or JavaScript) logic that, when executed, reads in application variables and outputs a fully formed HTML file. Following branch conditions and unrolling loop bodies in the intermediate template revealed that a ShareLatex project page has 16 possible HTML structures, while Reddit can have over 150. We note that, for this analysis, any tag insertion/deletion or change in tag composition (e.g., an attribute value) is treated as a new page structure. Consequently, despite the large number of potential HTML structures, both pages are highly amenable to large static templates.

3.4 Subtleties

Handling different template versions: Since Fawkes clients cache static HTML templates, and Fawkes servers can decide to generate new templates based on page modifications or popularity changes, it is possible that different clients have different template versions cached. One option is to have clients check for updates prior to evaluating cached templates using the If-Modified-Since HTTP header, but this would eliminate most of Fawkes's warm cache benefits as a browser would have to incur multiple round trips before rendering any content for the user. Instead, to handle these differences, static templates include a hash of the template contents as a variable in the inline patcher code. The patcher includes this information in its XHR request for a dynamic patch file; no browser modifications are required.

In order to make use of hash information in client requests, Fawkes servers must maintain a mapping of hashes to past static HTML template files which covers the max duration over which the templates are cacheable, i.e., if the templates for a URL are set to be cacheable for 1 day, the Fawkes server must store an entry for each template version served over the past day. Importantly, we expect these storage overheads to be low as our results highlight that templates remain largely unchanged on the order of weeks, and across personalized versions of pages for different users (§2 and §5).

Updating cached templates: Fawkes can use the hash-based approach described above to ensure benefits despite variations in cached templates. However, over time, Fawkes servers may wish to update cached templates to reflect significant changes in page structure that may deem past versions poor in terms of performance. For this, Fawkes servers simply send updated templates along with dynamic patches served with HTTP/2 server push. Because the pushed templates will remain cacheable for longer durations than the currently cached versions, default browsers will automatically replace the cached template for subsequent loads.

Static templates across URLs: In scenarios where static templates are generated for individual URLs by considering their possible HTML variants, templates can be cached directly under the page's URL. However, as we discuss in §2 and §5, Fawkes's template caching approach can provide significant benefits across different URLs of the same page type, e.g., different search result pages or news articles. To support such scenarios efficiently, browsers must slightly alter their caching approach to allow objects to be cacheable across multiple URLs. Websites can specify a regular expression that precisely covers the URLs for which the template applies, and browsers would use the same cached template for any load which matches that regular expression.

4 Implementation

On the server-side, Fawkes's template and dynamic patch generation code are written in 1912 and 462 lines of Python and C++ code, respectively. Both components are implemented as standalone modules for seamless integration with existing web servers and content management platforms [17, 73]. Module inputs are a set of HTML files, and outputs are full formed HTML and JSON files that can be directly shipped to client browsers. For template generation, Fawkes extended the APTED tree comparison tool [55, 56]. HTML parsing and modification are done using Beautiful Soup [60].

On the client-side, Fawkes's JavaScript patcher library consumes 3 KB when compressed with Brotli [27]. The patcher is written entirely using native DOM and JavaScript methods, and is thus compatible with unmodified web browsers. We note that the DOM shims are shared across pages, and thus could be cached as a separate object from each page's static template to reduce bandwidth costs.

5 Evaluation

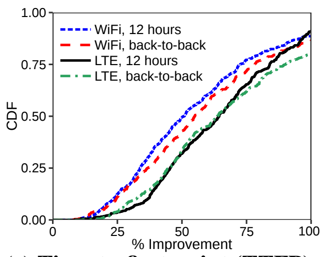
5.1 Methodology

We evaluated Fawkes using two phones, a Nexus 6 (Android Nougat; 2.7 GHz quad core processor; 3 GB RAM) and a Galaxy Note 8 (Android Oreo, 2.4 Ghz octa core; 6 GB RAM). Fawkes performed similarly across the two devices, so we only report results for the Nexus 6. Unless otherwise noted, page loads were run with Google Chrome (v75).

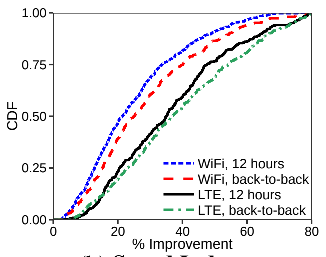
Our experiments consider two different sets of pages:

- Alexa top 500 US landing pages [5]. We augment this list with 100 interior pages that were randomly chosen from a pool of 1000 pages generated by a monkey crawler [3] that clicked links on each site's landing page.
- a smaller set of 20 pages that includes pairs of different pages of the same type. Starting from the Alexa top 50 list, we identified page types that have many versions, and manually generated pairs for each one, e.g., two Google search results and two public Twitter profile pages.

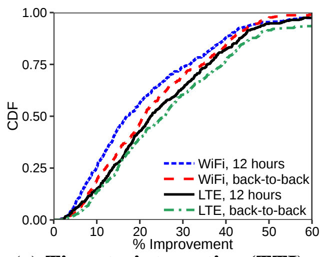
In order to create a reproducible test environment and because Fawkes involves page modifications, our evaluation uses the Mahimahi web record-and-replay tool [48]. We recorded versions of each page in our corpus at multiple times to mimic different warm cache scenarios: back to back page loads, and page loads separated by 12 and 24 hours. Mobile-optimized (including AMP [24]) pages were used when available. To replay pages, we hosted the Mahimahi replay environment on a desktop machine. Mobile phones were connected to the desktop machine via both USB tethering and live wireless networks (Verizon LTE and WiFi) with strong signal strength. The desktop initiated page loads on the mobile device using Lighthouse [28], and all control traffic for this was sent over the USB connection. All web and DNS traffic were sent over the live wireless networks into Mahimahi's replay environment. We modified



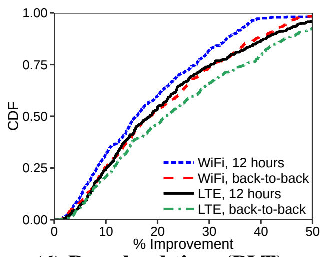
(a) **Time-to-first-paint (TTFP)**



(b) **Speed Index**



(c) **Time-to-interactive (TTI)**



(d) **Page load time (PLT)**

Figure 7: **Distributions of warm cache (back to back and 12 hour) per-page improvements with Fawkes vs. a default browser (i.e., using each page's default HTML) for 600 pages.**

Mahimahi to faithfully replay the use of HTTP/2 (including server push decisions) and server processing delays observed during recording; details of these modifications are listed in §A.1.

In accordance with §3, in all experiments, Fawkes's templates are generated a priori (i.e., offline). We apply server processing delays for a given template as the median delay observed for objects marked as cacheable in the default load of the page; these objects likely represent premade content. Note that this strategy ensures that templates experience the observed server-side delays that do not relate to content generation, e.g., delays due to high server load. Unless otherwise noted, templates are generated using the first and current versions of a page (i.e., a version at time 0, and the version in the back to back load, 12 hours later, etc.); we present results for other template generation strategies in §5.5. Dynamic patches are generated online by Mahimahi's web servers. Server processing times for patches include both the observed server processing time for the page's original HTML file, as well as the time taken to generate a patch.

We evaluate Fawkes on multiple web performance metrics. Page load time was measured as the time between the `navigationStart` and `onload` JavaScript events. We also consider three state-of-the-art metrics which better relate to user-perceived performance: 1) Speed Index (SI), which represents the time needed to fully render the pixels in the intial view of the page, 2) Time-to-first-contentful-paint (TTFP), which measures the time until the first DOM content is rendered to the screen, and 3) Time-to-interactive (TTI), which measures how quickly a page becomes interactive with rendered content, an idle network, and the ability to immediately support user inputs. All three metrics were measured using pwmetrics [32]. In all experiments, we load each page three times with each system under test, rotating amongst them in round robin fashion; we report numbers per system based on the load with the median page load time.

Correctness and limitations: To ensure a faithful evaluation, we analyzed the pages in our 600-page corpus to identify and exclude those that experience replay errors due to either Mahimahi's (22 pages) or Fawkes's limitations (17 pages). Details about our correctness checks are in §A.2.

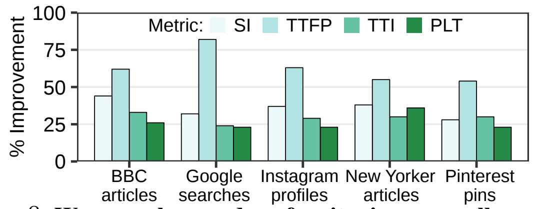


Figure 8: **Warm cache speedups for sites in our smaller corpus.**

5.2 Improving User-Perceived Web Performance

Warm Cache: Figure 7 illustrates Fawkes's ability to improve performance for our 600-page corpus, compared to a default browser, across a variety of web performance metrics and warm cache settings; we omit results for the 24 hour setting due to space constraints, but note that the trends were the same. Benefits with Fawkes are most pronounced on the metrics that evaluate visual loading progress, SI and TTFP. For example, in the 12 hour warm cache setting, median SI improvements are 38% and 22% on the LTE and WiFi networks, respectively. Improvements jump to 67% and 51% for TTFP; these benefits directly characterize Fawkes's immediate rendering of static HTML templates, compared to the lengthy blank screen in a default page load. Table 3 lists the raw time savings pertaining to these improvements.

Despite targeting quick visual feedback, Fawkes's results are also significant for more general web performance metrics like TTI and PLT: median improvements in the 24 hour scenario are 20% and 17% in the LTE setting. The reason is that in warm cache settings, Fawkes enables browsers to utilize network and CPU resources that go idle in standard page loads as HTML objects are being loaded. Browsers can immediately perform required rendering and processing tasks (which are non-negligible on mobile devices [43, 41, 69, 61]) of both template content and referenced cached objects; at the same time, browsers can issue requests for any referenced uncacheable objects to make use of the idle network.

Across all metrics, Fawkes's benefits are higher in LTE settings than on WiFi networks. The reason is that network latencies are higher on LTE networks: in our setup, last mile (access link) RTT values were consistently around 82 ms for LTE and 17 ms for WiFi. Higher round trip times increase the time that default page loads are blocked on fetching top-level HTML objects while Fawkes parses its templates.

As expected, benefits were consistently higher in the back-

Property	back to back	12 hours	24 hours
Static template size (KB)	102 (601)	77 (343)	73 (358)
Dynamic patch size (KB)	6 (249)	44 (491)	52 (460)

Table 1: **Analysis of Fawkes's templates and dynamic patches across warm cache scenarios with different time windows. Results list median (95th percentile) values for each property.**

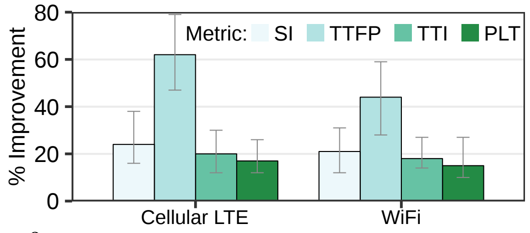

Figure 9: **Cold cache speedups with Fawkes versus a default browser on our 600-page corpus. Bars represent medians, and error bars span from the 25th to 75th percentile.**

to-back warm cache setting than when page loads were separated by 12 or 24 hours. This is because HTML objects undergo fewer changes across back-to-back loads, leading to larger templates and fewer updates (Table 1). Larger templates result in immediate feedback that more closely resembles the final page, as well as increased opportunities to utilize idle CPU and network resources. Note that patch sizes include page content (e.g., inline scripts) to be inserted.

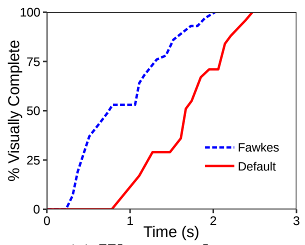
Figure 8 illustrates similar warm cache benefits (over the LTE network) for representative sites in our smaller corpus. Templates are made by consideringdifferent versions of the same page type. We note that TTFP benefits were highest for Google search pages because those pages incur the highest server processing times (for result generation).

Cold Cache: Although Fawkes's template-based approach primarily targets warm cache settings, benefits are significant in cold cache scenarios (Figure 9). For example, median SI and TTFP improvements were 24% and 62% for the LTE network. These results consider templates generated using HTML files generated 24 hours apart. The reason for these benefits mirror those in warm cache settings, but with smaller savings. Since static HTML templates are served faster than dynamic patches, browsers still have a window to perform template rendering and compute tasks with Fawkes while the default page load is blocked. Browsers largely use this time to quickly fetch referenced uncached objects, making better use of the idle network. Like in warm cache settings, SI and TTFP benefits drop to 21% and 44% on the WiFi network due to the decreased network round trip times.

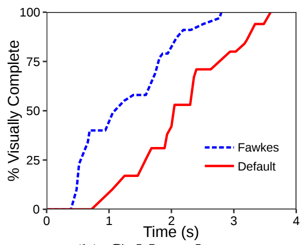
5.3 Understanding Fawkes's Benefits

Case study: To better understand Fawkes's performance, we analyzed the visual progress of page loads both with and without Fawkes. Visual progress tracks the fraction of the browser viewport (i.e., the part of the page that is visible without scrolling) that has been rendered to its final form.

Figure 10 shows warm and cold cache results for a representative site in our corpus, the Yahoo homepage. In the



(a) **Warm cache.**



(b) **Cold cache.**

Figure 10: **Visual progress with and without Fawkes for the Yahoo homepage. Warm cache loads were 12 hours apart.**

warm cache scenario, Fawkes is able to make an immediate jump (53% in 790 ms) in visual progress by parsing and rendering a large part of the static HTML template, as well as referenced static objects which are also in the browser cache. In contrast, the default browser is blocked on the multiple network round trips and server processing delays required to fetch the page's top-level HTML object; visual progress does not increase until 1110 ms into the load. The initial render (29% in 1270 ms) is also much smaller than with Fawkes because the default HTML parse gets quickly blocked on fetching an uncacheable JavaScript file—rendering is blocked until this file is fetched and evaluated. Fawkes also has to fetch this file, but this occurs via an applied update, at which point Fawkes has already reached 53% visual completeness. We note that evaluation of this script (and thus blocked rendering) is 27 ms worse with Fawkes due to overheads from DOM shims. However, these overheads are overshadowed by the large early lead in visual progress that Fawkes achieves.

In the cold cache setting, both Fawkes and the default browser incur network delays to fetch an HTML object for the page. However, this delay is lower for Fawkes as the static template is pre-generated. From this point, the page loads are largely similar to the warm cache setting: Fawkes makes a larger immediate jump in visual progress (40% in 690 ms vs. 17% in 1250 ms) as the default browser gets quickly blocked on fetching an external script, while Fawkes does so only after the template is parsed. From there, both page loads progressively render content, but Fawkes never relinquishes its lead. We note that, though it is not visible in the graphs, Fawkes issues requests for non-blocking external objects (e.g., images) that are listed in the template earlier.

Template content: Fawkes's early template parsing enables browsers to 1) process referenced cached objects sooner in warm cache loads, and 2) quickly issue requests for referenced external objects in cold cache loads. To understand how often these optimizations are applied, we analyzed the static URLs listed in Fawkes's templates; we considered templates generated using loads 12 hours apart. We found that, on the median page, templates referenced 46% of the page's objects, of which 72% were cacheable.

Patch generation: As described in §3, Fawkes opts to run a tree comparison heuristic rather than a state-of-the-art tree diffing algorithm. Fawkes's heuristic is designed to trade off

Algorithm	# of operations	Execution time (ms)
Fawkes's heuristic	2 (667)	20 (59)
Insert-first heuristic	2 (3013)	30 (70)
Delete-first heuristic	2 (3065)	30 (70)
State-of-the-art tree diffing algorithm (§3)	17 (136)	2717 (19702)

Table 2: **Fawkes's dynamic patch generation heuristic yields a desirable tradeoff between patch generation time and patch optimality, compared to other heuristics and a state-of-the-art tree diffing algorithm (which Fawkes uses for template generation). Results list median (95th percentile) values.**

System	SI	TTFP	TTI	PLT
Default	2.9 (3.9)	0.5 (0.5)	3.6 (4.4)	4.0 (5.2)
Fawkes	1.8 (2.9)	0.2 (0.3)	2.8 (3.5)	3.3 (4.2)
Vroom	2.4 (3.4)	0.6 (0.5)	2.9 (3.3)	3.2 (3.8)
WatchTower	2.0 (2.5)	0.6 (0.6)	2.6 (3.0)	2.8 (3.6)
Fawkes + Vroom	1.8 (2.9)	0.2 (0.3)	2.6 (3.14)	2.5 (3.4)

Table 3: **Median warm (cold) cache raw times for our 600-page corpus on an LTE cellular network. All results are in seconds, and warm cache loads are spread by 12 hours.**

patch generation time for optimality (in terms of number of operations). To evaluate Fawkes's heuristic on this tradeoff, we compare it to the tree diffing algorithm Fawkes uses for template generation, and two additional heuristics: 'insert-first' and 'delete-first' breadth-first-search approaches where discrepancies discovered when comparing a level in the template and target are handled by first inserting the missing node or deleting the mismatched node, respectively, and then accounting for any remaining deltas (Table 2). As shown, Fawkes's heuristic runs 2 orders of magnitude faster than existing tree diffing algorithms. Median operations are lower with Fawkes's heuristic due to its *move* operation. 95th percentile operations are 5× worse with Fawkes's heuristic due to the inefficiences described in §3.1, but we note that this large gap is only present in 8% of pages.

Importantly, across all warm cache page loads, Fawkes completes heuristic execution and shipping patches to clients *before* client-side template processing completes; shipping patches before this does not improve performance a template parsing must conclude prior to patch application.

5.4 Comparison with Vroom and WatchTower

We compared Fawkes with two recent mobile web optimization systems, Vroom [61] and WatchTower [47]. With Vroom, web servers user HTTP/2 server push to proactively send static resources that they own to clients ahead of future requests. In addition, Vroom servers send HTTP preload headers [68] to let clients quickly download resources that they will soon need from other domains. In contrast, WatchTower accelerates page loads by selectively using proxy servers based on page structural properties and network conditions. When enabled, a proxy loads a page locally using a headless browser and fast network links, and streams individual resources back to the client for processing. Our evaluation considers WatchTower's HTTPS-sharding mode, where each HTTPS origin runs their own proxy to preserve HTTPS security. Proxies were run on EC2 in California where the WatchTower paper reported the highest speedups.

Table 3 compares Fawkes with Vroom and WatchTower for both cold and warm cache loads of our 600 page corpus over an LTE network; trends were similar on the WiFi network. As shown, Fawkes is able to significantly improve performance on the interactivity-focused metrics compared to these systems. For example, median warm cache Speed Index values were 24% and 10% lower with Fawkes than with Vroom and WatchTower, respectively. Fawkes's TTFP benefits over these systems were 69%-73% since acceleration techniques with WatchTower and Vroom only take affect *after* incurring multiple network round trips and server processing delays to download HTML objects.

Our results also show that Vroom and WatchTower are more effective than Fawkes at reducing PLT; median benefits are 3.3% and 16.6%, respectively. The reason is that both Vroom and WatchTower can mask network round trips required to fetch external objects throughout the page load, including those triggered by non-HTML objects. Fawkes, on the other hand, focuses on early parts of a page load–indeed, targeting startup bottlenecks is what differentiates Fawkes from prior acceleration techniques. Importantly, we note that Fawkes's early-stage optimizations are largely complementary to prior techniques.To validate this, we reran the experiment above using a combination of Fawkes and Vroom. Vroom's server hints on the top-level HTML were sent along with Fawkes's dynamic patches. As shown in Table 3, this combination outperforms any tested system in isolation.

5.5 Additional Results

Stale HTML templates: Our warm cache evaluation considered static templates that were generated using the HTML object at time 0 and the one for the current time (e.g., 12 hours). Although this is possible using the techniques presented in §3.3 to generate representative HTML files for a page, it is not the sole practical deployment scenario. An alternative approach would be to generate static HTML templates with only back-to-back loads at a time 0, and use this for future warm cache loads. To evaluate the impact of such stale templates, we loaded the pages in our corpus using both stale (i.e., generated at time 0) and up-to-date (generated using HTML files at time 0 and the current time) templates. We considered staleness of 12 and 24 hours, and observed minimal performance degradations. For example, on the LTE network, median SI values dropped by only 4.2% and 6.8% for the 12 and 24 hour scenarios; TTFP values were unchanged.

Personalized pages: We selected 20 sites from our 600 page corpus that supported user accounts. For each site, we made two user accounts, selecting different preferences when possible, e.g., order results based on time or popularity. We then generated static templates from the HTML objects that each user account fetched. Finally, we loaded one of the user's pages 12 hours later with a warm cache, and compared performance to that of a default browser. Fawkes was able to reduce SI by 27% and 18% on the LTE and WiFi networks, respectively. It is important to note that these trends may not hold for all personalization strategies. For example, pages like Facebook can display structurally diverse content over time and across users. However, our results illustrate that many pages do remain structurally similar across users.

Energy savings and other browsers: Fawkes reduces (per-page) energy usage by 7-18%, and its speedups persist across other browsers (e.g., Firefox). Details provided in §A.3.

6 Related Work

Server push systems: Numerous systems, including Vroom (§5.4), aim to accelerate mobile page loads by leveraging HTTP/2's server push feature [9], where servers proactively push resources to clients in anticipation of future requests [61, 19, 70]. Fawkes is largely complementary to server push systems as these approaches reduce fetch times for resources loaded after the top-level HTML. In contrast, Fawkes speeds up page startup times.

Proxy and backend accelerators: Compression proxies [4, 63, 67, 52] compress objects in-flight between clients and servers, while remote dependency resolution proxies [65, 47, 48, 64] perform object fetches on behalf of clients. Fawkes is orthogonal to these approaches, and can mask the network indirection and computation overheads associated with proxying. In addition, Fawkes preserves the end-to-end nature of the web, avoiding the security challenges of proxying.

More recently, Prophecy [43], Shandian [71], and Opera Mini [51] return post-processed versions of objects to reduce client-side computation and bandwidth costs. All three systems must incur the same network round trips and (more) server processing delays that default page loads to download top-level HTML objects–only then do their acceleration techniques help. These delays are exactly what Fawkes aims to alleviate. We also note that Fawkes's patcher and shims tackle a fundamentally different challenge than those in Prophecy and Shandian: Fawkes must execute JavaScript code in an environment with fast-forwarded DOM state.

Dependency-aware scheduling: Certain systems have improved the scheduling of network requests based on inherent dependencies in page content. Klotski [14] analyzes pages offline to identify high-priority objects in terms of user utility, and uses knowledge of network bandwidth to stream them to clients before they are needed. Polaris [42] uses a client-side request scheduler that reorders requests to minimize the number of effective round trips in a page load without violating state dependencies. However, both systems are unable to process or render content prior to an HTML download. Thus, these systems can work side by side with Fawkes.

JavaScript UI frameworks: Libraries like Vue.js [74], AngularJS [26], and React [22] efficiently update client-side page state during page loads. A key feature across these frameworks is the use of a virtual DOM, where JavaScript-based DOM updates are first performed on a lightweight DOM representation, and aggregate results (rather than intermediate layout and render events) are applied to the actual DOM. Using such efficient update strategies, these frameworks support client-side page rendering, whereby a page's top-level HTML embeds only a single JavaScript library that is responsible for downloading and rendering downstream page content. While these frameworks focus on efficiently updating content during a page load and require developers to rewrite pages, Fawkes operates on unmodified pages and aims to quickly display content shared across page loads. Further, unlike the client-side page rendering approach, Fawkes's static templates embed both the JavaScript patcher library *and* all of a page's static HTML content. This, in turn, ensures that Fawkes can render static content while fetching downstream (dynamic) content.

Accelerating HTML loading: Google's SDCH [15] allows web servers to specify cacheable components of HTML files; on subsequent loads, servers need only send new components or deltas to cached ones, thereby saving bandwidth. Unlike Fawkes, SDCH does not allow browsers to render cached HTML components *until the entire HTML is constructed*. Thus, SDCH does not face the view invariance challenges that Fawkes's patcher does, and SDCH is unable to reduce web startup times by rendering cached HTML content quickly for users. Other industry efforts have focused on dividing pages into modular components called "pagelets", which can be generated and processed independently and in parallel [13, 33]. Pagelets share Fawkes's goal of improving resource utilization to more quickly display content to users. However, unlike Fawkes, individual pagelets do not include a mechanism for automatically separating static and dynamic HTML, and instead use a single response that is shipped only after the pagelet's dynamic content is generated.

7 Conclusion

Inspired by the mobile app startup process, this paper presents Fawkes, a mobile web acceleration system that generates cacheable, static HTML templates that can be immediately rendered to quickly display content to users as page updates are fetched. Fawkes represents a shift in the web acceleration space, by focusing on leveraging underutilized resources at the *beginning* of page loads. We find that Fawkes brings median warm cache reductions of 46%, 64%, 26%, and 22% for SI, TTFP, TTI, and PLT, and outperforms state-of-the-art server push and proxy-based acceleration systems by 10%-24% and 69%-73% on SI and TTFP.

A Appendix

A.1 Mahimahi Modifications

To compute per-object server processing delays, we first recorded the RTT to each origin in a page as the median time between the TCP SYN and SYN/ACK packets across all connections with that origin. We then defined the server processing delay for an object as its TTFB minus 1 RTT (for the transmission of the HTTP request and initial response bytes); when applicable, we also subtracted out connection setup delays (1 or 2 RTTs depending on whether the resource was downloaded via HTTP or HTTPS). Lastly, we modified Mahimahi's `replayserver` to wait for the corresponding server processing delay before shipping back any object.

A.2 Correctness and Limitations

To ensure a faithful evaluation of Fawkes, we analyzed the pages in our corpora to identify and exclude pages that experience replay errors due to either Mahimahi or Fawkes. We excluded 22 pages due to Mahimahi replay errors, most of which were the result of SSL errors for pages that leverage the Server Name Indication (SNI) feature in SSL/TLS certificates (which Mahimahi does not support), and missing resources that Mahimahi's URL matching heuristic was unable to remedy.

On the remaining pages, correctness with Fawkes was evaluated by forcing determinism upon JavaScript execution (e.g., using fixed return values for calls to `Math.Random()`) [39, 45], and comparing loads with and without Fawkes in three ways: 1) a pixel-by-pixel analysis of the final page (using pwmetrics' screenshots and visual analysis tools [32]), 2) the number of registered JavaScript event handlers (logged using shims on the `addEventListener` mechanism and by iterating over the DOM tree after the `onload` event fired [46]), and 3) the browser console errors printed during the page load. We excluded the 17 pages that differed on any of these three properties from our evaluation. Further investigation revealed two key reasons for such discrepancies, which are limitations with Fawkes:

- Although Fawkes cuts downstream JavaScript in templates after the first tag removal or alteration, it does not remove CSS. The reason is that CSS rules can significantly affect the styling of template content, bringing it closer to the final page version. However, CSS and JavaScript code can share state in the form of DOM node attributes. As a result, downstream CSS files in a page's template can modify DOM attribute state that patched (upstream) JavaScript code can subsequently access—this can alter page execution and lead to errors.
- JavaScript code can dynamically rewrite downstream HTML using the `document.write()` interface. However, Fawkes's patches are based on a page's static HTML, which does not reflect JavaScript execution. Thus, because our current implementation of Fawkes does not use shims for `document.write()`, it is possible for JavaScript code in the template to (correctly) rewrite downstream HTML content, that is (incorrectly) resurrected by the Fawkes patcher.

A.3 Additional Results

Energy consumption: To examine the impact that Fawkes has on energy usage, we connected a Nexus 6 phone to a Monsoon power monitor [40] and loaded our 600 page corpus. During cold cache loads, Fawkes's speedups reduce median per-page energy usage by 11% and 7% compared to a default browser on the LTE and WiFi networks, respectively. Benefits jump to 18% and 11% in warm cache settings (12 hours apart). In both cases, benefits are higher on LTE due to the higher network latencies and the fact that LTE radios consume more energy than WiFi hardware when active [65].

Additional browsers: Since Fawkes does not require any browser modifications, we also evaluated Fawkes with Firefox (v68) using our 600 page corpus and the same experimental setup from §5.1. Benefits in the 12 hour warm cache setting were quite comparable, despite Firefox using a different rendering engine than Chrome. Fawkes reduced median SI by 21% and 34% on the WiFi and LTE networks.

A.4 Additional Related Work

Mobile-optimized pages: Certain sites cater to mobile settings by serving pages that involve less client-side computation, fewer bytes, and fewer network fetches. For example, Google AMP [24, 34] is a recent mobile web standard that requires developers to rewrite pages using restricted forms of HTML, JavaScript, and CSS. Unlike AMP, Fawkes accelerates legacy pages without needing developer effort. Further, Fawkes provides complementary benefits and can lower AMP startup delays: Fawkes's TTFP and SI reductions were 58% and 27% for the 23 AMP pages in our corpus.

Prefetching: Prefetching systems predict user browsing behavior and optimistically download objects prior to user page loads [53, 38, 72]. Unfortunately, such systems have witnessed minimal adoption due to challenges in predicting what pages a user will load and when; inaccurate page and timing predictions can waste device resources or result in stale page content [59]. By rendering static templates as soon as a user navigates to a page, Fawkes is able to achieve comparable TTFP reductions without the issues of prefetching.

Progressive Web Apps (PWAs): Google recently proposed PWAs [29], applications that are written using standard web languages (e.g., HTML, JavaScript), can be loaded by a standard web browser, but are installed as an application on a user device. PWAs use service workers [30] which employ aggressive caching and custom update logic to run offline and support push notifications from servers. Fawkes shares the idea of improving use of web caching and app-like update logic. However, in contrast to PWAs which require developer effort for creation (and potentially maintenance), Fawkes transparently applies app-like templating to legacy pages.

VMscatter: A Versatile MIMO Backscatter

Xin Liu[*], Zicheng Chi[*], Wei Wang, Yao Yao, and Ting Zhu
University of Maryland, Baltimore County

Abstract

In this paper, we design and implement a versatile MIMO backscatter (VMscatter) system, which leverages the diversity features of MIMO to dramatically decrease bit error rate (BER) and increase throughput with negligible overhead. Our approach is different from existing WiFi MIMO backscatter approaches which simply reflect the signals from the WiFi MIMO sender and do not take advantage of MIMO technologies' advanced features (i.e., low bit error rate and high throughput). In our approach, the backscatter can achieve the same full diversity gain as traditional MIMO system by implementing the space-time coding on the backscatter tag under the constraint that backscatter tags cannot control the reflected signals to be orthogonal. Moreover, the backscatter can reflect excitation signals from the senders that have either a single antenna or multiple antennas. To implement the VMscatter system, we addressed the special design challenges such as complicated channel estimations among the sender, tag, and receiver by using a novel pre-scatter channels elimination method and a post-scatter channels equalization method. Our VMscatter design introduces negligible overheads (in terms of hardware cost, energy consumption, and computation) on the backscatter tag. We further extended our design to support any number of antennas that the sender, tag, and receiver have. Our MIMO backscatter design is generic and has the potential to be extended to achieve massive MIMO. We extensively evaluated our system in different real-world scenarios. Results show that the BER is reduced by a factor of 862 compared to the most related work MOXcatter [68].

1 Introduction

In the last few years, backscatter systems have been proposed to piggyback data on ambient signals such as WiFi [33, 59], Bluetooth [30], LoRa [28, 47], FM [53], etc. By doing this, the backscatter device consumes very little energy to wirelessly transmit data, which can enable lots of Internet-of-Things applications, such as device tracking [31], smart homes and smart health [5, 30]. On the other hand, the Multiple-Input Multiple-Output (MIMO) technique has become an essential element of wireless communication. To explore the benefits of the MIMO technique, researchers have proposed various important approaches, such as full duplex MIMO [10, 11, 15], multi-user MIMO [9, 19, 35, 48–50, 56], massive MIMO [12, 29, 32, 65, 66], distributed MIMO [26, 27], and MIMO networks [21, 25, 43, 44, 57, 67].

Although MIMO has been widely used and explored in wireless systems, little work has been conducted to effectively integrate MIMO techniques into a backscatter system for more reliable and faster backscatter communications. The only related work (MOXcatter [68]) tries to backscatter MIMO signals from the WiFi MIMO sender. However, the multiple antennas on MOXcatter do not take advantage of advanced features of MIMO technology. Specifically, although MOXcatter uses multiple antennas, the phase changes among these antennas are always the same when reflecting the WiFi signals. Therefore, MOXcatter does not fully leverage the spatial diversity, which leads to even higher bit error rate and lower throughput than the corresponding non-MIMO WiFi backscatter system FreeRider [62]. Moreover, the MOXcatter tag needs explicit control signals from the sender to identify whether the sender is sending a single stream or multiple streams signals. These explicit control signals prevent MOXcatter to be widely deployed in an environment where the sender is uncontrollable.

Different from existing WiFi backscatters that reflecting non-MIMO [14, 33, 61, 62] and MIMO [68] signals, our high-level goal in this paper is to design a versatile MIMO backscatter (VMscatter) system, which leverages the diversity features of MIMO to dramatically decrease bit error rate (BER) with negligible overhead because the backscatter communication has a very low signal-to-noise ratio (SNR) which leads to a high BER. With a lower BER, the backscatter communication can have a longer effective communication range, better robustness, and better reliability. We note that the sender of VMscatter is not required to be a MIMO device. In our design, we encountered the following challenges:

C1. How to realize MIMO transmissions on a low-power

[*]Both authors contributed equally to the paper

backscatter tag for reliable communication? A traditional MIMO system improves the reliability by utilizing a space-time coding scheme to generate orthogonal symbols (which increase the diversity gain) among antennas. However, the low-power backscatter tag cannot demodulate the incoming ambient signals (which are used to piggyback backscatter data) due to limited resources on the tag. Therefore, the backscatter tag is not able to generate orthogonal symbols. We discovered that by implementing space-time coding on the backscatter tag, we can achieve the same full diversity gain as traditional MIMO systems, even though the reflected backscattered symbols are non-orthogonal. We note that the non-orthogonality is not a hard constraint. Our proposed algorithm is applicable for the reflected symbols being either orthogonal or non-orthogonal. However, it is very challenging to implement space-time coding on the tag by only turning on/off the switches, because we do not want to increase the tag's computation and energy overheads.

C2. How to demodulate the backscattered data? The MIMO backscatter system is more complicated than traditional MIMO system because we need to deal with the pre-scatter channels (i.e., the channels between the sender and the backscatter tag) and post-scatter channels (i.e., the channels between the backscatter tag and the receiver) for proper demodulation. For example, a 2×2 MIMO system has four different physical channels among the two sender antennas and two receiver antennas. The receiver needs to estimate these four channels in order to correctly demodulate the data. With a two-antenna backscatter tag in the middle (i.e., $2 \times 2 \times 2$ setup), the situation becomes even more complicated. To obtain the backscattered data, eight physical channels need to be estimated (i.e., four pre-scatter channels and four post-scatter channels). Furthermore, we also considered frequency mismatch (including cumulative clock drift and oscillator instability) between the VMscatter tag and receiver as well.

C3. How to achieve a generic $M \times K \times N$ setup? As a versatile MIMO backscatter system, it needs to support an arbitrary number of antennas at the sender, tag, and receiver sides (shown in Fig. 1). It is important to support any number (i.e., M) of antennas that the senders may have, because we want to leverage various types of existing infrastructures. However, it is very challenging to achieve this because the lower-power backscatter tag cannot decode the packet from the sender to obtain the knowledge of the number of antennas. Existing work such as MOXcatter [68]) needs to modify the sender to explicitly send out control messages (i.e., four consecutive special packets) to the tag so that the tag can identify the types of the sender's excitation signals (i.e., MIMO v.s. non-MIMO), which is impractical. We mathematically demonstrate how to eliminate the impact of the pre-scatter channels such that the impact of the number (i.e., M) of senders' antennas can be eliminated (see Sec. 4.3). Therefore, we do not need to modify the sender. We further describe how to support an arbitrary number of antennas at both the tag (i.e., K) and receiver (i.e., N) sides (see Sec. 4.4). We also validate our design using both experiments and simulations.

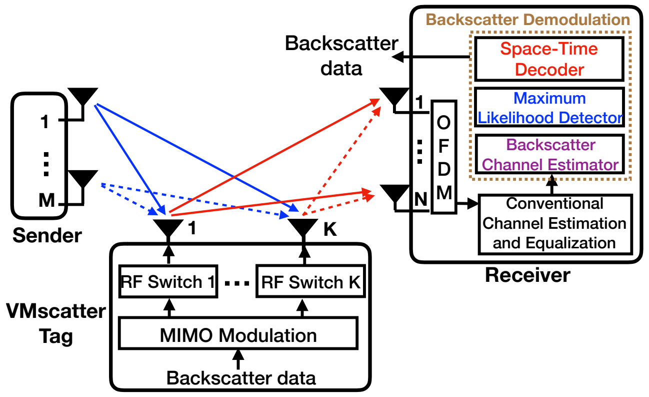

Figure 1: System Architecture

Our key contributions are as follows:

• To the best of our knowledge, this is the first work that designed and implemented a versatile MIMO system, which leverages the diversity features of MIMO to dramatically decrease bit error rate (BER) and increase throughput with negligible hardware cost, energy consumption, and computation overheads on the low-power backscatter tag.

• To implement the versatile MIMO backscatter system, we addressed the special design challenges on the backscatter tag (e.g., how to implement space-time coding by only turning on/off the switches) and on the receiver side (e.g., frequency mismatch and complicated channel estimations among the sender, tag, and receiver).

• Our design is generic. It can support an arbitrary number of antennas at the sender, tag, and receiver. The design principles have the potential to be extended to achieve massive MIMO.

• We build a hardware prototype of the proposed VMscatter system and design an IC circuit. We also extensively evaluated our system under different real-world settings. Evaluation results demonstrate that VMscatter can provide faster and orders of magnitude more reliable communication than state-of-the-art backscatter systems. For example, VMscatter's bit error rate is smaller than that of MOXcatter by a factor of more than 800.

2 Motivation and Design Overview

Our work is motivated by the recent advances in MIMO technology, such as Surface MIMO [16] which enables MIMO communication between devices using surfaces coated with conductive paint or cloth. For example, a single-antenna sender-receiver pair can achieve 3×3 MIMO communication by using two points of contact on the conductive surface. By doing this, the number of antennas on the sender and receiver sides can be as low as 1.

We also note that with the advances in printed antennas [3, 23] and RF Micro-Electro-Mechanical Systems (MEMS) [4, 6, 36] technologies, multiple antennas can be integrated into a device. Therefore, it is essential to explore how to achieve MIMO on backscatter tags and what the benefits are.

Applications. Since MIMO technology can enable reliable and fast communication, by leveraging the advantages of MIMO technology, our VMscatter has the potential to be applied to applications in noisy and multipath-rich environments, such as smart buildings and smart cities for low-power and reliable sensing data collection.

As shown in Fig. 1, our system contains three parts:

Sender: The sender does not need to be controlled for transmitting explicit control messages. The sender can be equipped with either a single antenna or multiple antennas.

VMscatter Tag: The backscatter tag piggybacks backscatter data on the ambient signals emitted by the sender. To support a variety of existing infrastructures, our VMscatter tag can naturally support any number of sender antennas without the need of explicit control messages. The MIMO modulation module not only modulates the binary data into in-phase and quadrature values but also encodes the data depending on the number of available antennas. Two coding methods can be used for reducing bit error rate or increasing throughput (details in Sec. 4.2). The RF switches for different antenna ports reflect the incoming RF signals based on the output of the MIMO modulation module. By doing this, the backscatter data piggybacks on the ambient RF signal and the MIMO signals are transmitted out.

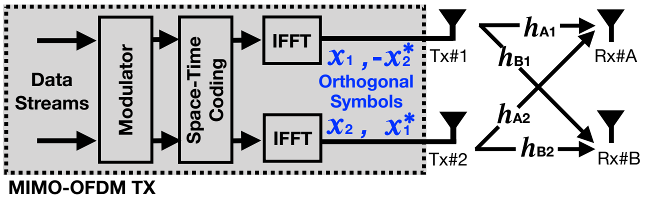
Receiver: The receiver takes the incoming signal and decomposes the signal by using an FFT module. A backscatter packet structure is proposed to cooperate with the conventional channel estimation and equalization module for eliminating the impact of the pre-scatter channel (the channel between the sender and the VMscatter tag). A backscatter demodulation module (including the backscatter channel estimator, maximum likelihood detector, and space-time decoder) is designed on top of the conventional channel estimation and equalization module. The backscatter channel estimator and maximum likelihood detector are used to combat the impact of the post-scatter channel, cumulative clock drift, and oscillator instability. The space-time decoder decodes the data obtained from all the antennas according to the coding method (detailed in Sec. 4.3).

3 Space-Time Coding for MIMO Backscatter

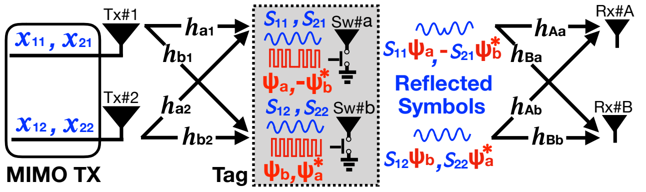
In this section, we first provide the background of a traditional MIMO system. then, we describe why we cannot use existing backscatter systems to achieve MIMO. In the end, we discuss why VMscatter is different.

3.1 Background of Space-Time Coding for MIMO System

We first review the background of space-time coding for the $M \times N$ MIMO-OFDM system which serves as the base of the advanced WiFi protocol (e.g., IEEE 802.11n). For the sake of simplicity, we show the structure of a typical 2×2 MIMO-OFDM system with Alamouti space-time coding [7] in Fig. 2(a). Traditional MIMO systems use complex modules



(a) The structure of a typical 2×2 Alamouti MIMO system



(b) The structure of MIMO backscatter for a $2 \times 2 \times 2$ setup. The pre-scatter and post-scatter channels are $\mathbf{H_R}$ and $\mathbf{H_T}$.

Figure 2: 2×2 Alamouti MIMO system and $2 \times 2 \times 2$ MIMO Backscatter. Conventional MIMO systems need to create the orthogonal symbols to construct the space-time coding. MIMO backscatter can realize the diversity gain of the space-time coding by using the non-orthogonal symbols.

to create orthogonal symbols which provide the full diversity gain [55] for reliable wireless communications. Fig. 2(a) shows the creation process of the orthogonal symbols. First, the data streams (i.e., bit streams) are modulated to complex values (i.e., in-phase and quadrature values). Next, the space-time coding module encodes the complex values based on Alamouti code scheme and feeds the coded data into the Inverse Fast Fourier Transform (IFFT) module for each antenna. Then, each IFFT module efficiently allocates the coded data on multiple subcarriers to form two OFDM symbols (e.g., $\{x_1, -x_2^*\}$ or $\{x_2, x_1^*\}$). Finally, two antennas are used to transmit the four OFDM symbols in two time slots. Because of the orthogonal design in the code scheme, the code matrix formed by the four transmitted symbols fulfills the orthogonal property [54]:

$$\begin{bmatrix} x_1 & x_2 \\ -x_2^* & x_1^* \end{bmatrix}^{\mathrm{H}} \cdot \begin{bmatrix} x_1 & x_2 \\ -x_2^* & x_1^* \end{bmatrix} = (|x_1|^2 + |x_2|^2) \cdot \begin{bmatrix} 1 & \\ & 1 \end{bmatrix} \quad (1)$$

where $(\cdot)^{\mathrm{H}}$ denotes the complex conjugate transpose operator, $(\cdot)^*$ denotes the conjugate operator. Hence, Alamouti code has a full diversity gain [55].

During wireless transmission, the transmitted symbols suffer from channel fading and at the receiver, their sum will be received. Therefore, the 2×2 MIMO system with Alamouti Code can be represented by the following:

$$\begin{aligned} \begin{bmatrix} y_{1A} \\ y_{1B} \end{bmatrix} &= \begin{bmatrix} h_{A1} & h_{A2} \\ h_{B1} & h_{B2} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} n_{1A} \\ n_{1B} \end{bmatrix} \\ \begin{bmatrix} y_{2A} \\ y_{2B} \end{bmatrix} &= \begin{bmatrix} h_{A1} & h_{A2} \\ h_{B1} & h_{B2} \end{bmatrix} \cdot \begin{bmatrix} -x_2^* \\ x_1^* \end{bmatrix} + \begin{bmatrix} n_{2A} \\ n_{2B} \end{bmatrix} \end{aligned} \quad (2)$$

where $[y_{1A}, y_{1B}]^{\mathsf{T}}$ denotes the received vector in the first time slot by receive antennas 1 and 2 respectively, $[y_{2A}, y_{2B}]^{\mathsf{T}}$ denotes the received vector in the second time slot by receive antennas 1 and 2 respectively, h_{nm} denotes the channel impulse response from the m^{th} transmit antenna to the n^{th} receive antenna, and n_{nm} denotes the corresponding noise.

3.2 Why can't we use existing backscatter systems to achieve MIMO?

Since the existing backscatter tag (such as the system in [33, 62, 68]) cannot afford the demodulation (which requires power hungry modules) of incoming signals, the orthogonal property is not guaranteed for backscattered signals. As shown in Fig. 2(b), let us assume the pre-scatter channel (i.e., the channel between the sender and VMscatter tag) is $\mathbf{H_R}$ and the post-scatter channel (i.e., the channel between VMscatter tag and the receiver) is $\mathbf{H_T}$:

$$\mathbf{H_R} = \begin{bmatrix} h_{a1} & h_{a2} \\ h_{b1} & h_{b2} \end{bmatrix}, \quad \mathbf{H_T} = \begin{bmatrix} h_{Aa} & h_{Ab} \\ h_{Ba} & h_{Bb} \end{bmatrix}$$

In the t^{th} time slot, let x_{tk} be the transmitted symbol on the k^{th} transmit antenna, s_{tk} be the incoming symbol on the k^{th} backscatter switch and n^{R}_{tk} be the corresponding noise. Then, the incoming symbol vectors in two time slots can be represented by the following:

$$\begin{bmatrix} s_{1a} \\ s_{1b} \end{bmatrix} = \mathbf{H_R} \cdot \begin{bmatrix} x_{11} \\ x_{12} \end{bmatrix} + \begin{bmatrix} n^{\mathrm{R}}_{1a} \\ n^{\mathrm{R}}_{1b} \end{bmatrix}, \quad \begin{bmatrix} s_{2a} \\ s_{2b} \end{bmatrix} = \mathbf{H_R} \cdot \begin{bmatrix} x_{21} \\ x_{22} \end{bmatrix} + \begin{bmatrix} n^{\mathrm{R}}_{2a} \\ n^{\mathrm{R}}_{2b} \end{bmatrix} \quad (3)$$

From Eqn. 3, we can see that the information of the incoming symbol s_{tk} includes the channel interference $\mathbf{H_R}$ and the baseband value of the transmitted symbol x_{tk}. The backscatter cannot estimate the channel or demodulate the baseband signals without high power components. Therefore, the backscatter does not have knowledge about the incoming signals and cannot guarantee the backscattered signals to be orthogonal.

As a result, even though the backscatter leverages the space-time coding scheme to code its data, the reflected symbols are not orthogonal. For example, as shown in Fig. 2(b), if the backscatter wants to transmit the data $\{\psi_a, \psi_b\}$, the coded data being modulated into the incoming symbols $[s_{1a}, s_{1b}, s_{2a}, s_{2b}]$ are $[\psi_a, \psi_b, -\psi_b^*, \psi_a^*]$. Therefore, the reflected symbols are $[s_{1a}\psi_a, s_{1b}\psi_b, -s_{2a}\psi_b^*, s_{2b}\psi_a^*]$. The representation of the received vectors in two time slots are:

$$\begin{aligned} \begin{bmatrix} y_{1A} \\ y_{1B} \end{bmatrix} &= \mathbf{H_T} \cdot \begin{bmatrix} s_{1a}\psi_a \\ s_{1b}\psi_b \end{bmatrix} + \begin{bmatrix} n^{\mathrm{T}}_{1A} \\ n^{\mathrm{T}}_{1B} \end{bmatrix} \\ \begin{bmatrix} y_{2A} \\ y_{2B} \end{bmatrix} &= \mathbf{H_T} \cdot \begin{bmatrix} -s_{2a}\psi_b^* \\ s_{2b}\psi_a^* \end{bmatrix} + \begin{bmatrix} n^{\mathrm{T}}_{2A} \\ n^{\mathrm{T}}_{2B} \end{bmatrix} \end{aligned} \quad (4)$$

where n^{T}_{tm} is the noise of the received symbol y_{tm}. By plugging the reflected symbols into Eqn. 1, we obtain

$$\begin{bmatrix} s_{1a}\psi_a & s_{1b}\psi_b \\ -s_{2a}\psi_b^* & s_{2b}\psi_a^* \end{bmatrix}^{\mathrm{H}} \cdot \begin{bmatrix} s_{1a}\psi_a & s_{1b}\psi_b \\ -s_{2a}\psi_b^* & s_{2b}\psi_a^* \end{bmatrix} \neq \mathbb{R} \cdot \begin{bmatrix} 1 & \\ & 1 \end{bmatrix}$$

where $\mathbb{R}$ is a real number. It is clear that the four reflected symbols cannot fulfill the orthogonal property.

3.3 Why is VMscatter different?

In this section we describe our VMscatter's two unique features: i) it achieves the same full diversity gain as traditional MIMO system without transmitting orthogonal signals; and ii) our demodulation scheme estimates the complicated channels among sender, backscatter tag, and receiver while solving the demodulation errors caused by practical facts (e.g., cumulative clock drift and oscillator instability).

Feature 1: Although there is no orthogonal symbols for the MIMO backscatter to construct the space-time coding, we discover that MIMO backscatter can achieve the same full diversity gain as the space-time coding by using the non-orthogonal symbols.

Firstly, we define $\mathrm{M}(s_{ij}, s_{pq}) = \mathbf{H_T} \cdot \mathbf{diag}(s_{ij}^{-1}, s_{pq}^{-1}) \cdot \mathbf{H_T}^{-1}$. By multiplying $\mathrm{M}(s_{ij}, s_{pq})$ to both sides of Eqn. 4, we get:

$$\begin{aligned} \mathrm{M}(s_{1a}, s_{1b}) \begin{bmatrix} y_{1A} \\ y_{1B} \end{bmatrix} &= \mathbf{H_T} \cdot \begin{bmatrix} \psi_a \\ \psi_b \end{bmatrix} + \mathrm{M}(s_{1a}, s_{1b}) \begin{bmatrix} n_{1A} \\ n_{1B} \end{bmatrix} \\ \mathrm{M}(s_{2a}, s_{2b}) \begin{bmatrix} y_{2A} \\ y_{2B} \end{bmatrix} &= \mathbf{H_T} \cdot \begin{bmatrix} -\psi_b^* \\ \psi_a^* \end{bmatrix} + \mathrm{M}(s_{2a}, s_{2b}) \begin{bmatrix} n_{2A} \\ n_{2B} \end{bmatrix} \end{aligned} \quad (5)$$

We note that Eqn. 5 has the same standard representation as that of conventional 2×2 Alamouti MIMO systems (showed in Eqn. 2). In other words, if the value of $\mathrm{M}(s_{ij}, s_{pq})$ in Eqn. 5 is known, the MIMO backscatter system can also achieve full diversity gain, as proven in the following:

$$\begin{bmatrix} \psi_a & \psi_b \\ -\psi_b^* & \psi_a^* \end{bmatrix}^{\mathrm{H}} \cdot \begin{bmatrix} \psi_a & \psi_b \\ -\psi_b^* & \psi_a^* \end{bmatrix} = (|\psi_a|^2 + |\psi_b|^2) \cdot \begin{bmatrix} 1 & \\ & 1 \end{bmatrix} \quad (6)$$

To realize the space-time coding, the conjugate operations are required. Traditional RFID works by selecting different antenna impedance loading. To reduce the design complexity, VMscatter only leverages the two states of switch (on and off) to realize the conjugate operation (detailed in Sec. 4.2).

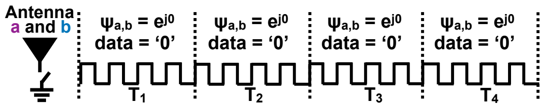
Feature 2: To solve Eqn. 5, we must know $\mathrm{M}(s_{ij}, s_{pq})$. However, to detect $\mathrm{M}(s_{ij}, s_{pq})$, we face two challenges. The first challenge is that the backscatter tag does not exactly shift the ambient signal as the desired phase in reality because of some practical facts (such as cumulative clock drift and oscillator instability). The difference of the desired shifting phase and the real shifting phase interfere the detection result of $\mathrm{M}(s_{ij}, s_{pq})$. The second challenge is that the existing channel estimation module cannot resolve both of the pre-scatter and post-scatter channels to extract the backscatter data. We will discuss how to overcome these two challenges in Sec. 4.3.

4 Design

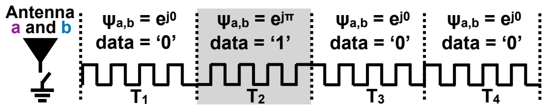
This section presents the detailed design of the VMscatter system. We first propose the channel model of the VMscatter system. Secondly, we introduce the modulation scheme at the VMscatter tag. Thirdly, we describe the demodulation scheme at the receiver. Finally, we explain how to extend from $2 \times 2 \times 2$ to $M \times K \times N$.

4.1 VMscatter Channel Model

In order to explain the signal propagations of our MIMO backscatter, we build a mathematical channel model for our system. Though a backscatter tag does not "receive" the signal (the tag "reflects" the signal out immediately when the signal comes in), we decompose the receiving and transmitting



(a) Example of transmitting data '0000'



(b) Example of transmitting data '0100'

Figure 3: Basic Modulation. The signal in the shaded time slot is shifted by π.

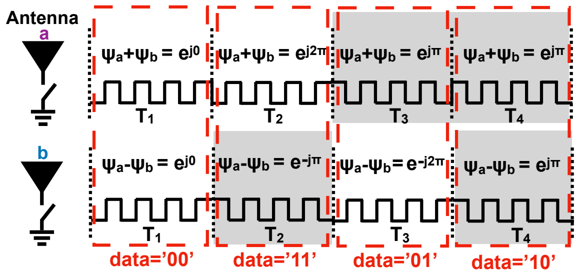


Figure 4: An example of improving throughput. Eight bits "00110110" are transmitted during four time slots. The signals in the shaded time slots are shifted by π.

processes in the channel model. Fig. 2(b) shows the channel model of a $2\times2\times2$ setup. Without loss of generality, let us take the receive vector in the first time slot (i.e., $[y_{1A}, y_{1B}]$) as an example to describe the channel model. From Eqn. 4 and 3, we can rewrite the representation of the receive vector in the first time slot as:

$$\begin{bmatrix} y_{1A} \\ y_{1B} \end{bmatrix} = \mathbf{H_T}\cdot\begin{bmatrix} s_{1a}\psi_a \\ s_{1b}\psi_b \end{bmatrix} + \begin{bmatrix} n_{1A}^{\mathrm{T}} \\ n_{1B}^{\mathrm{T}} \end{bmatrix} = \mathbf{H_T}\cdot\begin{bmatrix} \psi_a & \\ & \psi_b \end{bmatrix}\cdot\begin{bmatrix} s_{1a} \\ s_{1b} \end{bmatrix} + \begin{bmatrix} n_{1A}^{\mathrm{T}} \\ n_{1B}^{\mathrm{T}} \end{bmatrix} \quad (7)$$

Let us assume X, Y, Ψ, and N are the transmitted signal at the sender, the received signal at the receiver, the backscatter data, and the noise respectively. We rewrite Eqn. 7 here:

$$\mathrm{Y} = \mathbf{H_T}\Psi\mathbf{H_R}\mathrm{X} + \mathrm{N} \quad (8)$$

Eqn. 8 gives the channel model of a $2\times2\times2$ MIMO backscatter system. It proves that the backscatter modulation not only splits the whole channel (from sender to receiver) into two parts: $\mathbf{H_R}$ and $\mathbf{H_T}$, but also inserts the backscatter information into the whole channel. Therefore, to demodulate the backscatter data, it is important to estimate the channel $\mathbf{H_R}$ and $\mathbf{H_T}$. However, since existing channel estimators estimate the whole channel without considering the backscatter modulation, the estimation result is interfered by the backscatter data. To address this challenge, we first need to understand the backscatter modulation scheme.

4.2 MIMO Modulation @ VMscatter Tag

In this section, we introduce how a VMscatter tag creates MIMO signals which can increase the communication performance. Our goal is to realize MIMO transmission while maintaining low power consumption at a power constrainted VMscatter tag. The MIMO transmission can significantly reduce the bit error rate (BER) or increase the throughput by increasing the number of antennas. It is challenging to transmit spatial coded information at a lower power VMscatter tag to improve the communication performance at the receiver side. To understand it, we first introduce the basic modulation scheme with a $2\times2\times2$ setup, then describe two coding methods for improving the throughput and reducing the BER.

Basic modulation scheme: In a basic modulation scheme, the backscatter tag shifts the phase of an ambient OFDM signal on one antenna port or multiple antenna ports (transmitting same data on all ports) to transmit backscatter data. For example, the phase can be shifted by $e^{j\theta_k}$, where k is the index of antennas. $\theta_k = 0$ or π indicates data bit "0" or "1".

Fig. 3 shows a simple example that, in a $2\times2\times2$ setup, two antennas (a and b) transmit the same data by using RF switches (i.e., ADG902 [8]) to shift the ambient signal's phase. In Fig. 3(a), continuous square waves ($\theta_{a,b} = 0$) from T_1 to T_4 are driving the RF switches. Thus, no phase shift is caused to the ambient OFDM signal and the data of "0000" is transmitted. In Fig. 3(b), the square waves are shifted by $\theta_{a,b} = \pi$ during T_2 which yields the data of "0100" being transmitted.

Improving throughput: The VMscatter tag takes advantage of the MIMO system to increase throughput. For example, with two antennas, the throughput can be doubled. To increase throughput, the data is encoded across two antennas as follows: at time slot T_n, the aggregate value of two data streams (i.e., $\psi_a+\psi_b$) is transmitted from antenna a while the difference (i.e., $\psi_a-\psi_b$) is transmitted from antenna b simultaneously. Thus, the received signals at the receiver are:

$$\mathrm{Y} = \mathbf{H_T}\begin{bmatrix} \psi_a+\psi_b & \\ & \psi_a-\psi_b \end{bmatrix}\mathbf{H_R}\mathrm{X} + \mathrm{N} \quad (9)$$

Fig. 4 shows that 8 bits (i.e., "00110110") are encoded and transmitted on antenna a and b during time slots T_1 to T_4. The phase changes of $\psi_a+\psi_b$ and $\psi_a-\psi_b$ can be defined as $e^{j(a+b)}$ and $e^{j(a-2b)}$. For example, during T_2, data "11" is transmitted. Therefore, antenna a is transmitting $\psi_a+\psi_b = e^{j2\pi} = 1$ (i.e., zero phase change) while antenna b is transmitting $\psi_a-\psi_b = e^{-j\pi} = -1$ (i.e., a phase inversion).

Reducing BER: It is more challenging to reduce the BER on power constrained backscatter tag. In the VMscatter system, in order to have a more reliable transmission, we utilize the space-time coding on top of the basic modulation across all the antennas (i.e., the antennas at the VMscatter tag) and adjacent time slots. However, it is very challenging to implement space-time coding on the tag by only turning on/off the switches, because we do not want to increase the tag's computation and energy overheads. We note that since the backscatter data is real number, the conjugate of the backscatter data is itself. For example, $\psi_a = \psi_a^*$ and $-\psi_b^* = -\psi_b$. Therefore, VMscatter can construct the space-time coding by using the two states of switch (on and off). Fig. 5 shows the coding sequence. At a given time slot T_n, two streams of data are simultaneously transmitted from antennas a and b. The data transmitted from antennas a and b are denoted by ψ_a and ψ_b, respectively, where $\psi_a = e^{j\theta_a}$ and $\psi_b = e^{j\theta_b}$. During the

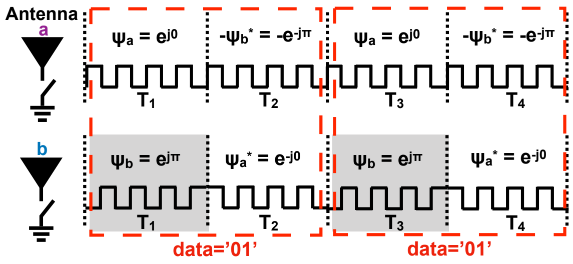

Figure 5: An Example of reducing BER. Four bits "0101" are transmitted during four time slots. The signals in the shaded time slots are shifted by π.

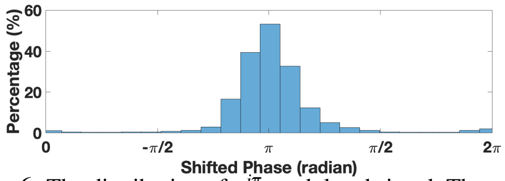

Figure 6: The distribution of $e^{j\pi}$ modulated signal. The sender-to-tag distance is 3 ft and the tag-to-receiver distance is 6 ft. We observe that the shifted phases are distributed between 0 and 2π.

next time slot T_{n+1}, data $-\psi_b^* = -e^{-j\theta_b}$ is transmitted from antenna a while data $\psi_a^* = e^{-j\theta_a}$ is transmitted from antenna b. By plugging the coding sequence into the channel model (Eqn. 8), the received signals in two time slots are:

$$\begin{aligned} Y_1 &= \mathbf{H_T}\begin{bmatrix}\psi_a & \\ & \psi_b\end{bmatrix}\mathbf{H_R}X_1 + N_1 \\ Y_2 &= \mathbf{H_T}\begin{bmatrix}-\psi_b^* & \\ & \psi_a^*\end{bmatrix}\mathbf{H_R}X_2 + N_2 \end{aligned} \tag{10}$$

Fig. 5 illustrates how four bits of data (i.e., "0101") are transmitted on antenna a and b during time slots T_1 to T_4. We take time slots T_1 and T_2 as an example. During T_1, the first data bit "0" (represented by $\psi_a = e^{j0}$) is transmitted from antenna a while the second data bit "1" (represented by $\psi_b = e^{j\pi}$) is transmitted from antenna b. During T_2, the encoded data (according to Eqn. 10) $-\psi_b^* = -e^{-j\pi}$ and $\psi_a^* = e^{-j0}$ are transmitted from antenna a and b, respectively.

4.3 MIMO Demodulation @ Receiver

In Sec. 4.2, we described the modulation scheme on a low power VMscatter tag. In this section, we will introduce how to demodulate the signal from a VMscatter tag. The most challenging part is to estimate the pre-scatter channel $\mathbf{H_R}$ (the channel between sender and backscatter) and post-scatter channel $\mathbf{H_T}$ (the channel between backscatter and receiver) in a MIMO setup, which is crucial for achieving reliable backscatter communication.

To demodulate the backscatter data, the **first challenge** is that in reality, the backscatter tag does not exactly shift the ambient OFDM signal by $e^{j\theta_k}$, which may yield demodulation error at the receiver. As we introduced in Sec. 4.2, the backscatter tag shifts the ambient signal by $e^{j\theta_k}$, where k is the index of the antennas, to modulate backscatter data. i.e. $\theta_k = 0$ indicates data bit "0", $\theta_k = \pi$ indicates data bit "1". However, due to some practical facts (i.e., cumulative clock

drift and oscillator instability), the backscattered signal is not exactly shifted by $e^{j\theta_k}$. Fig. 6 shows the distribution of a backscattered signal sample set. The desired phase shift is $e^{j\theta_k}$, where $\theta_k = \pi$. The total symbols of the sample set are more than 800,000. We can observe that around 50% of the symbols are shifted by π while another 50% are shifted either less or more than π.

The **second challenge** is that the existing channel estimation method (i.e., simply solving the channel matrix) cannot resolve both of the pre-scatter channel matrix $\mathbf{H_T}$ and post-scatter channel matrix $\mathbf{H_R}$, which is important to demodulate the backscatter data (as we modeled in Eqn. 8). As shown in Fig. 7, the conventional channel estimation module relies on the Long Training Fields (LTFs) in the preamble to estimate the channel between the sender and receiver. Then the equalizer uses the estimated channel matrix to compensate for the upcoming data symbol. However, with a backscatter tag in the middle (of the sender and the receiver), we need to resolve both channel matrices $\mathbf{H_T}$ and $\mathbf{H_R}$ (as shown in Eqn. 11) for reliable demodulation.

To overcome the **first challenge**, we have the following analysis. Though the two practical facts (cumulative clock drift and oscillator instability) cause the frequency mismatch between the VMscatter tag and OFDM receiver, these two facts behave as a phase offset in the demodulation procedure. Fig. 6 shows the distribution of a sample set of the backscatter signal. The expected phase is π because the VMscatter tag transmits a $e^{j\pi}$. However, due to the cumulative clock drift and oscillator instability, a portion of the symbols are not as expected. To show the impact of these two practical facts, we elaborate Eqn. 8 to be:

$$Y = \mathbf{H_R}\Psi P\mathbf{H_T}X + N = \mathbf{H_R}\Psi\mathbf{H'_T}X + N \tag{11}$$

where P is the unwanted phase offset caused by cumulative clock drift and oscillator instability. Since the essences of P and $\mathbf{H_T}$ are all phase offsets, we can combine them as $\mathbf{H'_T} = P\mathbf{H_T}$. So far, we have solved the **first challenge** and the **second challenge** becomes resolving $\mathbf{H_R}$ and $\mathbf{H'_T}$.

To overcome this challenge, we propose a special backscatter packet structure (shown in Fig. 8) as well as a backscatter

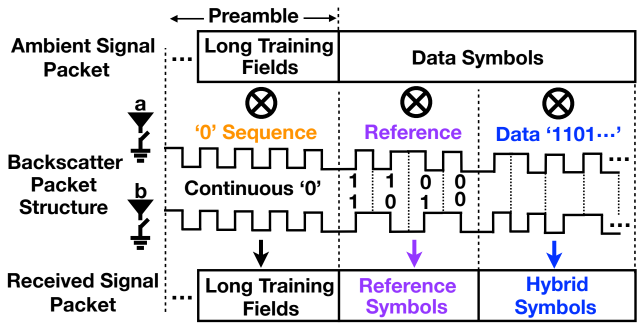

Figure 8: VMscatter packet structure. It includes three fields: i) 0s sequence, in which the VMscatter transmits continuous "0" on both antennas to pass through the LTFs from the ambient signal; ii) reference signal, in which the VMscatter transmitted agreed symbols on two antennas; and iii) backscatter data.

demodulation module on top of the conventional channel estimation and equalization modules (shown in Fig. 7). The packet includes three fields: **i) "0" sequence**; **ii) reference signal**; and **iii) backscatter data**.

i) "0" sequence: The VMscatter tag transmits a "0" sequence during the ambient signal's Long Training Fields (LTFs). The "0" sequence can shift the LTFs to the adjacent channel for minimizing the strong self-interference from the original channel and getting a high SNR [63]. However, it does not embed any useful backscatter data in the LTFs. Thus, the backscatter data Ψ in this filed equals to an identity matrix I_2 and Eqn. 11 becomes:

$$Y_{LTFs} = \mathbf{H_R} I_2 \mathbf{H'_T} X_{LTFs} + N = \mathbf{H_E} X_{LTFs} + N \tag{12}$$

where $\mathbf{H_E} = \mathbf{H_R} I_2 \mathbf{H'_T} = \mathbf{H_R H'_T}$ is the channel response for the transmitted LTFs (i.e., X_{LTFs}). Since X_{LTFs} are known to the receiver, $\mathbf{H_E}$ is resolved by the existing channel estimator (shown in Fig. 7). Then it is used to equalize the data symbol in existing equalizers by using the following equation:

$$\widetilde{X} = \mathbf{H_E^{-1}}\, Y = \mathbf{H_T'^{-1}}\, \mathbf{H_R^{-1}}\, Y \tag{13}$$

where $\widetilde{X}$ is the estimated symbol value. By plugging Eqn. 11 into Eqn. 13, we will get:

$$\widetilde{X} = \mathbf{H_T'^{-1}} \cancel{\mathbf{H_R^{-1}}} \cancel{\mathbf{H_R}} \Psi \mathbf{H'_T} X + \mathbf{H_E^{-1}} N = \mathbf{H_T'^{-1}} \Psi \mathbf{H'_T}\, \mathbf{X} + \mathbf{H_E^{-1} N} \tag{14}$$

We note that the impact of the pre-scatter channel $\mathbf{H_R}$ is eliminated so far by using the "0" sequence and the existing channel estimation and equalization process. To obtain Ψ, we need to resolve $\mathbf{H'_T}$. $\mathbf{H_E^{-1}}$N is random noise which can be resolved by a Maximum Likelihood estimation.

ii) Reference signal: To resolve $\mathbf{H'_T}$, we designed the second field **Reference signal** in the VMscatter packet structure (Fig. 8). A group of agreed on (between VMscatter tag and OFDM receiver) symbols are transmitted to estimate $\mathbf{H'_T}$. The backscatter channel estimation module (in Fig. 7) calculates the estimated $\widetilde{\mathbf{H'}}_\mathbf{T}$ by using:

$$\widetilde{\mathbf{H'}}_\mathbf{T} = \underset{\mathbf{H'_T}}{\arg\min} \sum_{\Psi_{ref}} ||\widetilde{X} - \mathbf{H_T'^{-1}}\, \Psi_{ref}\, \mathbf{H'_T}\, X||^2 \tag{15}$$

where Ψ_{ref} is the backscatter reference symbols as shown in Fig. 8. X can be obtained from the original TX-RX channel

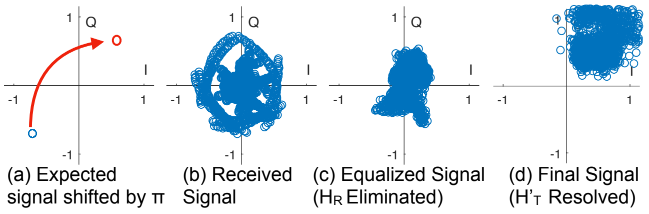

Figure 9: The Example Signals at Each Demodulation Stage.

without backscatter's interference (similar techniques are proposed in [61, 62]). Eqn. 15 is a minimum mean squared error (MMSE) channel estimator. A reduced complexity MMSE estimator can be achieved by employing the optimal rank reduction [60], which has a computational complexity of $O(LSC^2)$. Where L is the number of reference symbols, S is the number of subcarriers and $C = min(K,N)$. For a low power edge computing platform Jetson Nano [45] (only cost $99) implemented on an ARM A57 processor with 472 Giga -Floating Point Operations per Second, it can solve a 4×4 MIMO channel estimation (with 4 reference symbols and 64 subcarriers) in $\frac{4*64*4^2}{472*10^9} = 8ns$, which is shorter than a symbol duration $4\mu s$.

iii) Data: After resolving $\mathbf{H'_T}$, a maximum likelihood estimation module (shown in Fig. 7) is used to calculate the upcoming data field. The maximum likelihood estimation module minimizes the Euclidean distance between the equalized values $\widetilde{X} = \begin{bmatrix} \tilde{x}_A & \tilde{x}_B \end{bmatrix}^\intercal$ and all possible estimated values $\widetilde{X}_{MLE} = \begin{bmatrix} \tilde{x}_{A\_MLE} & \tilde{x}_{B\_MLE} \end{bmatrix}^\intercal = \widetilde{\mathbf{H'}}_\mathbf{T}^{-1}\, \Psi\, \widetilde{\mathbf{H'}}_\mathbf{T}\, X$, where $\tilde{x}_A$ and $\tilde{x}_B$ are the values on RX antenna A and B, respectively. $\widetilde{X}$ is obtained from Eqn. 14. $\widetilde{\mathbf{H'}}_\mathbf{T}$ is obtained from Eqn. 15. $\Psi = \text{Diag}(e^{j\theta_a}, e^{j\theta_b})$ is the possible backscattered data, X is obtained from the original TX-RX channel as we mentioned before. Thus, the backscatter data can be obtained by the following equation:

$$\begin{bmatrix} \tilde{\theta}_a \\ \tilde{\theta}_b \end{bmatrix} = \underset{\theta_a,\theta_b \in \{0,\pi\}}{\arg\min} \sum_{s=A,B} \sum_{t=0}^{T} ||\tilde{x}_s(n+t),\, \tilde{x}_{s\_MLE}(n+t)||^2 \tag{16}$$

where $T = 1$ for VMscatter low bit error rate mode and $T = 0$ for VMscatter high throughput mode.

After demodulating $[\tilde{\theta}_a, \tilde{\theta}_b]^\intercal$, the space-time decoding module calculates the data bit value based on the coding method as proposed in Sec. 4.2.

Fig. 9 shows example signals at different demodulation stages. In Fig. 9(a), the blue circle indicates the I/Q values of the ambient signal while the red circle indicates that the signal is shifted by π after backscattering. Fig. 9(b) shows the received signal without any equalization. We can observe the rotating pattern which may be caused by channel and frequency mismatch. Fig. 9(c) shows the signal passed through the conventional channel estimation and equalization module, in which the pre-scatter channel $\mathbf{H_R}$ is eliminated. Finally, the signal in Fig. 9(d) is processed by our backscatter demodulation module where $\mathbf{H'_T}$ (which includes the post-scatter channel $\mathbf{H_T}$ and cumulative clock drift and oscillator instability P) is resolved. We can observe that most dots are in the first quadrant, which can be correctly demodulated.

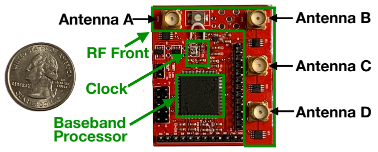

Figure 10: The hardware tag of VMscatter.

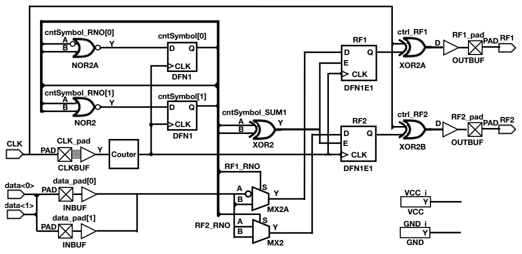

Figure 11: VMscatter tag hardware diagram.

4.4 From $2 \times 2 \times 2$ to $M \times K \times N$

In this section, we extend the backscatter MIMO system from $2 \times 2 \times 2$ to $M \times K \times N$.

Modulation. To reduce BER, in Sec. 4.2, we already show the 2×2 coding matrix (i.e., Matrix 17 shown below).

$$\Gamma(\theta_a, \theta_b) = \begin{bmatrix} e^{j\theta_a} & e^{j\theta_b} \\ -e^{-j\theta_b} & e^{-j\theta_a} \end{bmatrix} \quad (17)$$

When there are 4 antennas on the backscatter ($K = 4$), the transmitted backscatter data becomes $\{\theta_a, \theta_b, \theta_c, \theta_d\}$. Then, from Matrix 17, the coding matrix will be extended as follows:

$$\Gamma(\theta_a, \theta_b, \theta_c, \theta_d) = \begin{bmatrix} \Gamma(\theta_a, \theta_b) & \Gamma(\theta_c, \theta_d) \\ -\Gamma^*(\theta_c, \theta_d) & \Gamma^*(\theta_a, \theta_b) \end{bmatrix} \quad (18)$$

Each element in the coding Matrix 18 can be calculated from Matrix 17. In other words, for the backscatter with 4 antennas, each element in the coding matrix can be represented by the coding matrix of the backscatter with 2 antennas. Therefore, for the backscatter with K antennas, the coding matrix can be represented as follow:

$$\Gamma(\theta_1, \ldots, \theta_K) = \begin{bmatrix} \Gamma(\theta_1, \ldots, \theta_{\frac{K}{2}}) & \Gamma(\theta_{1+\frac{K}{2}}, \ldots, \theta_K) \\ -\Gamma^*(\theta_{1+\frac{K}{2}}, \ldots, \theta_K) & \Gamma^*(\theta_1, \ldots, \theta_{\frac{K}{2}}) \end{bmatrix} \quad (19)$$

In this coding matrix, each element can be calculated from the coding matrix of backscatter with $K/2$ antennas.

Demodulation. In Sec. 4.3 Eqn. 15, we have built the backscatter channel estimation model to estimate the prescatter channel $\mathbf{H}'_\mathbf{T}$. In this model, $\mathbf{H}'_\mathbf{T}$ is a 2×2 matrix and has the invertible matrix $\mathbf{H}'^{-1}_\mathbf{T}$. For a $M \times K \times N$ setup, $\mathbf{H}'_\mathbf{T}$ can be represented as a $M \times K$ matrix. When $M = K$, $\mathbf{H}'_\mathbf{T}$ is invertible and $\mathbf{H}'^{-1}_\mathbf{T}$ exists. When $M \neq K$, the invertible matrix can be replaced by the pseudoinverse matrix $(\mathbf{H}'^{\mathrm{T}}_\mathbf{T}\mathbf{H}'_\mathbf{T})^{-1}\mathbf{H}'^{\mathrm{T}}_\mathbf{T}$ [20]. Therefore, we can still leverage the backscatter channel estimation model and the maximum likelihood estimation model to estimate $\mathbf{H}'_\mathbf{T}$ and further demodulate the backscatter data.

5 Evaluation

5.1 Implementation

Hardware Tag. We implement VMscatter on a customized four-layer printed circuit board (PCB). As shown in Fig. 10, the hardware tag has three components: a $20MHz$ clock oscillator, a baseband processor and an RF front. In the evaluation, we show the impact of different oscillator accuracies.

We use a low-power FPGA (Microsemi Igloo Nano AGLN250 [40]) as the baseband processor. The processor controls the RF front, which consists of 4 RF switches (ADG902) and connects up to 4 antennas. All the design introduced in Sec. 4.2 is implemented in the processor. Fig. 11 shows a basic VMscatter that can support 2 antennas.

Comparing with conventional backscatter systems [62, 68], VMscatter only needs to add several low-power RF switches and antennas to build the MIMO system. These switches and antennas can be easily implemented on conventional backscatter systems. The space-time coding can be achieved by shifting the phase of the backscatter data to its orthogonal alternative, which also can be easily employed on the conventional backscatter system. To be more specific, as mentioned in Passive WiFi [34], the phase shift can be realized by shifting the initial phase of the square wave on the switch. As a result, the modulation complexity of VMscatter is low.

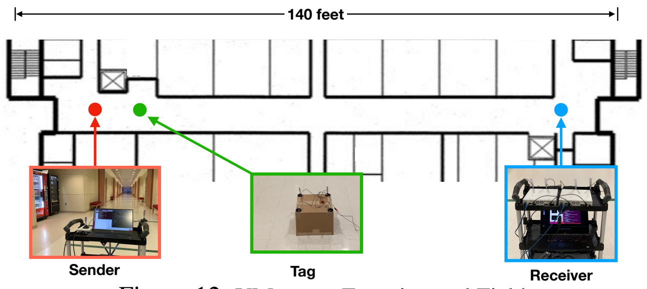

Figure 12: VMscatter Experimental Field

Sender and Receiver Implementation. As shown in Fig. 12, we implement the MIMO-OFDM sender on a B210 USRP, which connects two antennas and is placed 3 feet away from the tag. The sender's output power is set as 0 dBm. The receiver is implemented on two X310 USRPs with four $9dbi$ omnidirectional antennas. Therefore, there is a 2×4 MIMO across the sender and receiver. Each receiving antenna is connected to a UBX-160 daughterboard, which down-converts the backscattered signal to the baseband signal and samples it. To synchronize and align the sample clocks, the two USRPs are connected in a daisy chain configuration [1], where one device in the chain is configured as a master and exports its 10MHz clock and PPS time references to the other device.

5.2 Experiment Setup

To extensively evaluate the performance of VMscatter, we conducted the experiments in the following configurations:

Single Input Multiple Output (SIMO): The sender has a single data stream (therefore a single transmitting antenna). We evaluate the performance of VMscatter in SIMO with different number of backscatter antennas (2 and 4), which constructs a $1 \times 2 \times 2$ and a $1 \times 4 \times 4$ setup, respectively.

Multiple Input Multiple Output (MIMO): The sender has two independent data streams (therefore two transmitting antennas). We evaluate the performance of VMscatter in MIMO

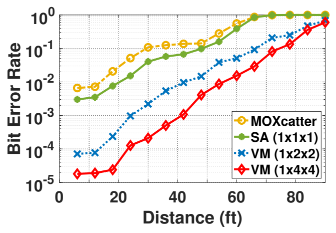

Figure 13: BER

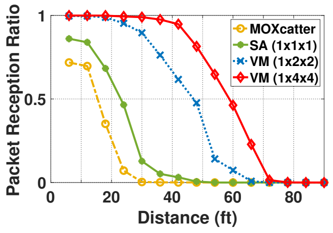

Figure 14: PRR vs. Distance

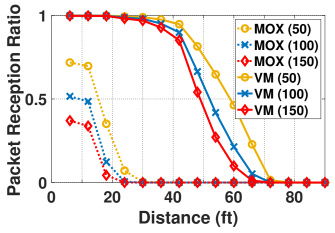

Figure 15: PRR vs. Packet Length

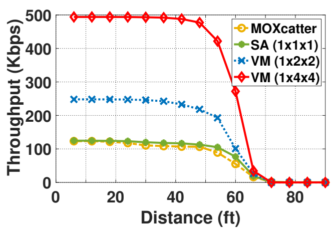

Figure 16: Throughput

with different number of antennas (2 and 4), which constructs a $2 \times 2 \times 2$ and a $2 \times 4 \times 4$ setup, respectively.

Baseline. We implemented the state-of-the-art MIMO backscatter system (MOXcatter [68]) as our baseline. Because it neither employs the space-time coding nor introduces any backscatter channel estimation. We also implemented a $1 \times 1 \times 1$ Single Antenna setup (SA), which only employs the backscatter channel estimation technique. Comparing it with MOXcatter, the performance of the backscatter channel estimation is evaluated. Comparing it with VMscatter, the performance of space-time coding is evaluated.

5.3 VMscatter in SIMO

In this section, we show the evaluation results of VMscatter with one transmitting antenna (i.e., single data stream).

5.3.1 Bit Error Rate

Fig. 13 shows the BER of VMscatter under the low bit error rate mode. The performance of VMscatter is much better than that of MOXcatter. When the distance between backscatter and the receiver is as low as $6ft$, the BER for VMscatter with 4 antennas is around 0.00002, which is reduced by a factor of 366 compared to MOXcatter (0.007). As the distance increases to $66ft$, the BER of VMscatter is still low enough to conduct communication while the BER of MOXcatter is 1. The reasons why VMscatter shows dominant performance is because VMscatter uses a novel backscatter channel estimation technique and leverages the spatial diversity for communication, which eliminates the errors introduced by cumulative clock drift or oscillator instability, etc and significantly reduce the BER. In addition, we can also observe that by simply using channel estimation, the BER of a $1 \times 1 \times 1$ single antenna setup (SA) is better than that of MOXcatter with multiple antennas. In contrast, although MOXcatter can backscatter a single stream from the WiFi sender, it does not leverage the spatial diversity in the reflected signals and channel estimation techniques, which increases the BER.

5.3.2 Packet Reception Ratio

Fig. 14 shows the Packet Reception Ratio (PRR) of VMscatter (low bit error rate mode) under different distances between backscatter and receiver. The PRR of MOXcatter drops rapidly as the distance increases from $6ft$ to $30ft$ while the performance of SA is still better than that of MOXcatter. For the distances larger than $30ft$, nearly all the packets transmitted from MOXcatter cannot be correctly decoded at the receiver side. On the contrary, since SA utilizes channel estimation, it can still conduct communication until the distance reaches $50ft$. Our VMscatter shows great advantages as distance increases. The curves are much more stable for both the 2 antennas and 4 antennas configurations. For the first $30ft$, the PRR of VMscatter is more than 90%, which is much higher than that of MOXcatter.

As shown in Figure 15, we also study the Packet Reception Ratio (PRR) of VMscatter (low bit error rate mode) with the packet length varying from 50 bits to 150 bits. Since the experiments reveal similar trends, we only show the results of the 4 antennas configuration (1x4x4). We can observe that the PRR decreases with the increasing of the packets length while VMscatter is more robust against different packet lengths. As shown in this figure, the PRR reaches nearly 0 as the distance increases to $70ft$. For MOXcatter, it does not use any space-time coding and channel estimation techniques. As a result, the PRR is nearly 0 when the distance increases to $30ft$ for the 50 bits packet length. However, when the packet lengths are 100 and 150 bits, the PRR is nearly 0 as the distance increases to $24ft$. Therefore, VMscatter can effectively increase the communication range of backscatter.

5.3.3 Throughput

We show the throughput of VMscatter under the high throughput mode with the increasing of the distance between backscatter and receiver. As we can see from Fig. 16, the throughput of VMscatter with two antennas is around 2 times as high as that of MOXcatter. This is because VMscatter takes advantages of the MIMO communication techniques. Specifically, the antennas on VMscatter are transmitting different data, which doubles the throughput. As the number of transmitting antennas increases to 4, the throughput of VMscatter is around 4 times as high as that of MOXcatter. On the contrary, the antennas on MOXcatter are transmitting the same data, which wastes the communication resources. In addition, due to the lack of channel estimation, the throughput is further hampered. As a result, the performance of MOXcatter is even worse than that of single antenna setup (SA).

5.4 VMscatter in MIMO

In this section, we evaluate the performance of VMscatter with two transmitting antennas (i.e., multi-data stream).

5.4.1 Bit Error Rate

As shown in Fig. 17, similar to a single data stream, the BER of VMscatter is still much lower than that of MOXcatter and SA. When the distance is as low as $6ft$, the BER of VMscatter is around 0.000011, which is reduced by a factor of 862 compared to the BER of MOXcatter. When comparing with

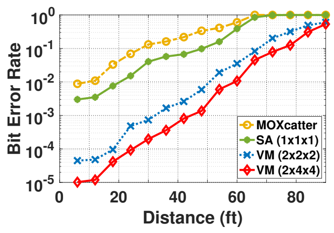

Figure 17: BER

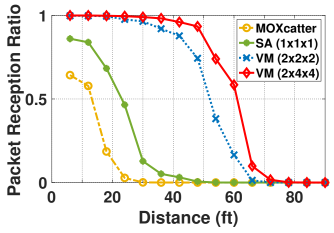

Figure 18: PRR vs. Distance

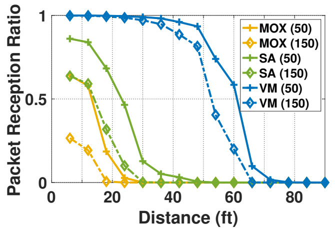

Figure 19: PRR vs. Packet Length

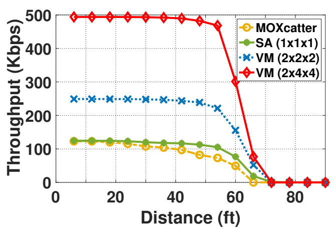

Figure 20: Throughput

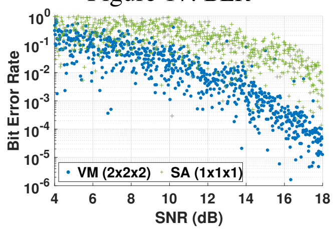

Figure 21: BER v.s. SNR

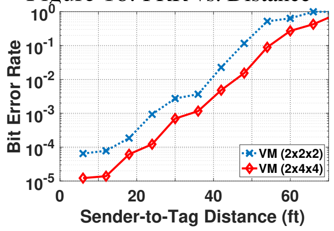

Figure 22: BER with a fixed tag-to-receiver distance

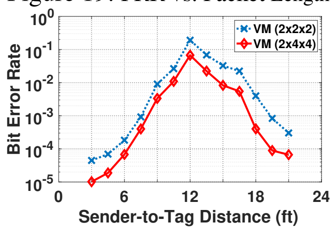

Figure 23: BER with a fixed sender-to-receiver distance

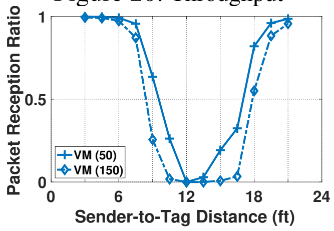

Figure 24: PRR with a fixed sender-to-receiver distance

the single data stream scenario in Fig. 13, we can also observe that the BER of VMscatter with two transmitting antennas is lower than the BER with one transmitting antenna. Interestingly, as shown in Table 1, the BER of MOXcatter shows the opposite trends, that is, the BER with two transmitting antennas is higher than the BER in the single data stream scenario and even higher than BER of the non-MIMO WiFi backscatter system FreeRider [62].

Table 1: BER Comparison

System	FreeRider (Non-MIMO)	MOXcatter (MIMO)	VMscatter (MIMO)
BER	0.002	0.0095	0.000011

This is because as the number of transmitting antennas increases, the interference and multi-path effects become more severe than the single antenna scenario, which degrades the performance of MOXcatter. In contrast, VMscatter fully leverages the feature of the MIMO spatial diversity. As the number of transmitting antennas increases, it is easier for VMscatter to conduct communication. Therefore, different from MOXcatter, VMscatter shows great advantages in this scenario.

5.4.2 Packet Reception Ratio

Fig. 18 and Fig. 19 show the Packet Reception Ratio under various distances and packet lengths, respectively. Similar to the single antenna scenario, the packet reception ratio of VMscatter is much higher than that of MOXcatter and SA. We can observe that the performance of SA with 150 bits packet length is better than that of MOXcatter with 50 bits packet length. This results prove the advances of our channel estimation technique. Moreover, we also can observe that the packet reception ratio of VMscatter is almost 100% for the first $36ft$, which shows the reliability of the low bit error rate mode of VMscatter.

5.4.3 Throughput

Fig. 20 shows the throughput of VMscatter with 2 and 4 backscatter antennas under the high throughput mode. The throughput of MOXcatter is even worse than that of the single antenna SA. This is because MOXcatter does not introduce any channel estimation techniques. As the number of transmitting antennas increases, the interference is higher, which reduces the throughput. In contrast, VMscatter can estimate the channel to minimize the interference and other unwanted errors. Moreover, VMscatter utilizes the MIMO technique to conduct backscatter communication. As the number of backscatter antennas increases to 2 and 4, the throughput of VMscatter also increases, which is around 2 and 4 times as high as that of MOXcatter.

5.4.4 BER v.s. SNR

To better understand the gain of MIMO technique for backscatter communication, we investigated the relationship between BER and SNR. In this experiment, we fixed the locations of sender, backscatter tag, and receiver while varying the transmission power of the excitation signals. Figure 21 plots the captured data points of BER over SNR for VMscatter in a $2\times2\times2$ (VM) configuration comparing with the signal antenna configuration (SA). We can observe that the BER is around 3×10^{-5} which is at least two orders of magnitude lower than that of SA.

5.5 Impact

In this section, we evaluate VMscatter under a variety of settings to further show the advantages of our design.

5.5.1 Impact of Sender-to-Tag Distance

The sender-to-tag distance is an important factor for the backscatter communication range. We evaluate its impact in two sets of experiments. In the first experiment, we fix the tag-to-receiver distance to be $1ft$ and move the tag and receiver to different locations, searching for the maximum backscatter communication range. As shown in Fig. 22, when the sender-to-tag distance increases to $45ft$, the BER for VMscatter with 4 antennas is around 0.01, which is still low enough to conduct communication.

In the second experiment, we fix the location of the sender and place the receiver at a distance of 24 ft. Then, we move the tag along the line from the sender to the receiver and measure

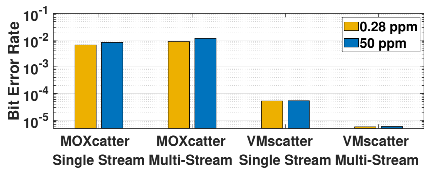

Figure 25: Impact of Oscillator Accuracy

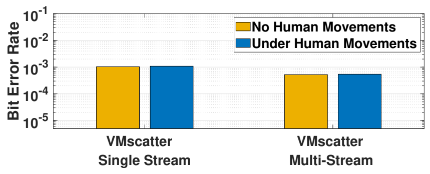

Figure 26: BER vs. Human Movement

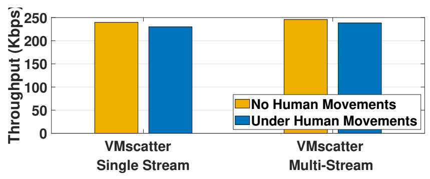

Figure 27: Throughput vs. Human Movement

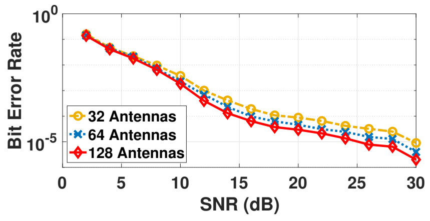

Figure 28: Number of Sender's Antennas

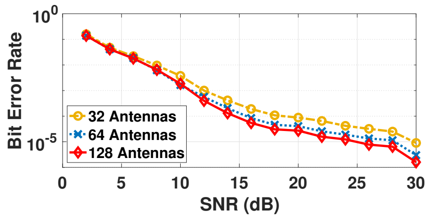

Figure 29: Number of Receiver's Antennas

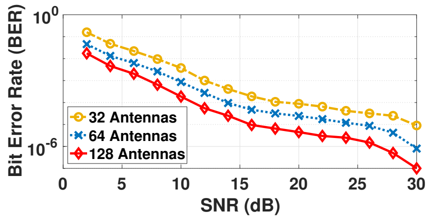

Figure 30: Number of Backscatter's Antennas

the BER and the packet reception ratio reported by VMscatter. Fig. 23 and Fig. 24 show the BER and packet reception ratio results, which can be improved either by reducing the sender-to-tag distance or the tag-to-receiver distance. This is because the signal strength at the receiver can be modeled by using Friis Transmission Equation [34, 42]. As the sender-to-tag distance or the tag-to-receiver distance decreases, the signal strength is increased at the receiver side, which means the SNR is also improved.

5.5.2 Impact of Backscatter Oscillator Accuracy

We study the impact of oscillator accuracy under VMscatter low bit error rate mode. The distance between the backscatter and the receiver is $6ft$. As shown in Fig. 25, with the decrease of crystal oscillator accuracy, the BER of MOXcatter increases while the BER of VMscatter almost remains the same. This is because MOXcatter is suffering cumulative clock drift and oscillator instability. Therefore, the performance of MOXcatter is highly related to the oscillator accuracy. In practice, an oscillator with high accuracy is more expensive and power hungry, which will limit the potential low power applications of MOXcatter. In contrast, our VMscatter utilizes a channel estimation technique, which eliminates the errors introduced by oscillator. In summary, VMscatter is stable against oscillator accuracy. A low power ring oscillator is enough for VMscatter to achieve low BER. Therefore, VMscatter has the potential to be widely adopted to real world scenarios.

5.5.3 Impact of Human Movements

Fig. 26 (low bit error rate mode) and Fig. 27 (high throughput mode) study the performances of VMscatter with human movements. During the experiments, the distance between the backscatter and the receiver is $36ft$. Two people are walking between the backscatter and the receiver. As shown in Fig. 26, the performance of VMscatter is robust against human movements. The BER remains at the level of 10^{-3} for single data stream and 10^{-4} for multi-data stream, respectively. Fig. 27 shows the throughput of VMscatter under high throughput mode. As we can see from this figure, when there are no human movements, the throughputs of VMscatter are $239.7Kbps$ and $245.9Kbps$ for single data stream and multi-data stream, respectively. For the human movements scenario, the throughputs of VMscatter still remain at $230.2Kbps$ and $238.5Kbps$, which further demonstrates the reliable communication of our VMscatter.

5.6 Simulation

To demonstrate that VMscatter can work under massive MIMO scenarios, we show the simulation results in this section. In the simulation, the physical layer configurations of the sender and receiver follow the 802.11n specification [2].

Fig. 28 and Fig. 29 study the BER with the increase of signal to noise ratio (SNR) under different number of antennas configurations. These two figures show a similar trend, that is, the BER decreases as the SNR increases. Moreover, the BER of VMscatter is lower when the number of antennas increases. When SNR reaches $30dB$, the BER results are significantly reduced (at the level of 10^{-5}). These results show that VMscatter can achieve better performance in massive MIMO scenarios, especially when the numbers of sender and receiver antennas are large.

Fig. 30 shows the results with different number of antennas on a backscatter device. When the number of antennas increases, the BER decreases. When the SNR is as low as $2dB$, the BER for 32 antennas is at the level of 10^{-1} while the BERs for 128 antennas are at the level of 10^{-2}. As SNR increases to $30dB$, the BER for 32 antennas is at the level of 10^{-5}. In contrast, the BER for 64 antennas drops to the level of 10^{-6} while the BER for 128 antennas drops below the level of 10^{-6}. These results further demonstrate that VMscatter can effectively leverage the spatial diversity to conduct reliable backscatter communication.

5.7 Energy Consumption

In this section, we first measure the power consumption of our hardware tag. We then design an integrated circuit based on the hardware and conduct power simulations to show the potential low-power capability.

5.7.1 Hardware Power Consumption Measurement

The hardware power consumption of VMscatter tag is similar to those traditional backscatter systems [61, 62, 69] that do not support MIMO communication. First, VMscatter only has $1 \sim 3$ more *passive* antennas and low-power RF switches than traditional backscatter systems. Therefore, the power consumption on the RF front is low. Second, the low-power FPGA [40] provides an internal ring oscillator to generate the clock, which consumes significantly less power than an external oscillator [64]. Third, the low-power FPGA supports the flash freeze technology. According to our lightweight modulation technique, 80% flash can be frozen.

We utilize a KEITHLEY 2701 multimeter to measure VMscatter tag's DC power draw. Under the work mode, the tag consumes as low as $464\mu W$ (it is $32\mu W$ in IC design simulation), which is $516\times$ lower than existing 802.11n MIMO chip [51]. Under the sleep mode, it consumes as little as $2.4\mu W$ of power, which is $25\times$ lower than existing 802.11n MIMO chip [51]. We can find that the work mode saves much more power than that of the sleep mode when comparing with MIMO chip. This is because the advantage of the backscatter is passive radio communication while the WiFi chip needs to generate the active radio under work mode. If the duty-cycles of the backscatter are from 1% to 10%, the overall power consumptions are around $5\mu W$ to $50\mu W$.

5.7.2 IC Design Power Consumption Simulation

To show the potential low-power capability of VMscatter, we designed an integrated circuit (IC) for VMscatter tag. The IC design consists of four main components: RF transistors, modulation logic gates, coding logic gates, and a ring oscillator. The simulation is conducted by using the HSPICE model for TMSC 55nm process. In the power consumption simulation, we considered multiple factors including operating voltages, operating temperature, system clock frequency, and power mode usage. Overall , the results show that the power consumption of VMscatter tag IC under work mode is $32\mu W$.

6 Related Work

The related work can be divided into two categories:

Backscatter Communications. Backscatter is one of the hot topics in recent years for its potential to support low-power and low-cost applications [5, 24, 38, 41, 52, 64]. Lots of work has been proposed to support various types of backscatter communications, such as WiFi [33, 59], Bluetooth [30], TV [39], FM [53]. LoRa [28, 47], or even Quantum Backscatter Communication [22] etc. Furthermore, researchers also improved backscatter to support full duplex [13]. The most related work to VMscatter is WiFi backscatter techniques. The first work of backscattering WiFi signals is WiFi Backscatter [33], which mainly modulates the CSI/RSSI information to conduct backscatter communication. Based on this work, BackFi [14] modulates phase information of the received WiFi signal and leverages the full-duplex technique to improve the throughput and communication range at the same time. HitchHike [61] introduces a codeword translation technique to make backscatter communication compatible with 802.11b radios. To support OFDM transmissions, [58] introduces a system model that analyzes the OFDM backscatter. FreeRider [62] can support backscatter communications with OFDM signals by leveraging the codeword translation to OFDM signals. MOXcatter [68] is able to backscatter MIMO signals from the WiFi MIMO sender. However, the multiple antennas on MOXcatter do not take advantage of the advanced features of MIMO technology.

MIMO Techniques. MIMO techniques have become one of the most important part in modern communication systems. Lots of projects have been proposed with focus on full duplex MIMO [10, 11, 15], Multi-User MIMO [9, 19, 35, 48–50, 56], Massive MIMO [12, 29, 32, 66], MIMO networks [21, 25, 57, 67] and novel MIMO systems [16–18, 37, 46], etc. For example, to improve the energy efficiency, CMES [46] mainly targets at finding the efficient antenna settings for MIMO 802.11 devices. To study full duplex MIMO, [15] introduces a full duplex WiFi-PHY based MIMO radios while [11] compares the capacity of multiple-antennas half-duplex MIMO with a full-duplex MIMO. Researchers have also presented lots of systems with focus on Multi-User MIMO (MU-MIMO) and Massive MIMO. MUSE [50] proposes a user selection framework on commodity devices to improve the throughput gains while Hekaton [56] combines a beamforming technique with phased-array antennas to improve the capacity gains in large-scale MU-MIMO systems. [66] introduces a scalable directional training method to obtain CSI in FDD massive MIMO systems. Surface MIMO [16] leverages the conductive paint or cloth on the surface to create an additional spatial path for communication between small devices.

Our work builds on top of the existing techniques in backscatter and MIMO. To the best of our knowledge, VMscatter is the first work that designed and implemented a versatile MIMO system. By doing this, VMscatter effectively leverages the spatial diversity feature of ambient MIMO signals, which significantly reduces the bit error rate and improves the throughput. Moreover, our design is generic and has the potential to be extended to massive MIMO.

7 Conclusion

In this paper, we present a new MIMO system on the backscatter device that can i) support various number of antennas at the sender, backscatter, and receiver; ii) significantly reduce the bit error rate or increase the throughput; and iii) achieve a similar level of energy consumption as existing backscatter systems. We built a hardware prototype and extensively evaluated our system under various real-world settings to demonstrate its extremely low BER performance. For example, the BER is reduced by a factor of 862 compared to the most related work MOXcatter [68].

Performant TCP for Low-Power Wireless Networks

Sam Kumar, Michael P Andersen, Hyung-Sin Kim, and David E. Culler
University of California, Berkeley

Abstract

Low-power and lossy networks (LLNs) enable diverse applications integrating many resource-constrained embedded devices, often requiring interconnectivity with existing TCP/IP networks as part of the Internet of Things. But TCP has received little attention in LLNs due to concerns about its overhead and performance, leading to LLN-specific protocols that require specialized gateways for interoperability. We present a systematic study of a well-designed TCP stack in IEEE 802.15.4-based LLNs, based on the TCP protocol logic in FreeBSD. Through careful implementation and extensive experiments, we show that modern low-power sensor platforms are capable of running full-scale TCP and that TCP, counter to common belief, performs well despite the lossy nature of LLNs. By carefully studying the interaction between the transport and link layers, we identify subtle but important modifications to both, achieving TCP goodput within 25% of an upper bound (5–40x higher than prior results) and low-power operation commensurate to CoAP in a practical LLN application scenario. This suggests that a TCP-based transport layer, seamlessly interoperable with existing TCP/IP networks, is viable and performant in LLNs.

1 Introduction

Research on wireless networks of low-power, resource constrained, embedded devices—low-power and lossy networks (LLNs) in IETF terms [128]—blossomed in the late 1990s. To obtain freedom to tackle the unique challenges of LLNs, researchers initially departed from the established conventions of the Internet architecture [50, 68]. As the field matured, however, researchers found ways to address these challenges *within* the Internet architecture [70]. Since then, it has become commonplace to use IPv6 in LLNs via the 6LoWPAN [105] adaptation layer. IPv6-based routing protocols, like RPL [33], and application-layer transports over UDP, like CoAP [35], have become standards in LLNs. Most wireless sensor network (WSN) operating systems, such as TinyOS [95], RIOT [24], and Contiki [45], ship with IP implementations enabled and configured. Major industry vendors offer branded and supported 6LoWPAN stacks (e.g., TI SimpleLink, Atmel SmartConnect). A consortium, Thread [64], has formed around 6LoWPAN-based interoperability.

Despite these developments, transport in LLNs has remained ad-hoc and TCP has received little serious consideration. Many embedded IP stacks (e.g., OpenThread [106]) do not even support TCP, and those that do implement only a subset of its features (Appendix B). The conventional wisdom is that IP holds merit, but *TCP is ill-suited to LLNs*. This view is represented by concerns about TCP, such as:

- "TCP is not light weight ... and may not be suitable for implementation in low-cost sensor nodes with limited processing, memory and energy resources." [110] (Similar argument in [42], [75].)
- That "TCP is a connection-oriented protocol" is a poor match for WSNs, "where actual data might be only in the order of a few bytes." [114] (Similar argument in [110].)
- "TCP uses a single packet drop to infer that the network is congested." This "can result in extremely poor transport performance because wireless links tend to exhibit relatively high packet loss rates." [109] (Similar argument in [43], [44], [75].)

Such viewpoints have led to a plethora of WSN-specialized protocols and systems [110, 117, 132] for reliable data transport, such as PSFQ [130], STCP [75], RCRT [109], Flush [88], RMST [125], Wisden [138], CRRT [10], and CoAP [31], and for unreliable data transport, like CODA [131], ESRT [118], Fusion [71], CentRoute [126], Surge [94], and RBC [142].

As LLNs become part of the emerging Internet of Things (IoT), it behooves us to re-examine the transport question, with attention to how the landscape has shifted: (1) As part of IoT, LLNs must be interoperable with traditional TCP/IP networks; to this end, using TCP in LLNs simplifies IoT gateway design. (2) Popular IoT application protocols, like MQTT [39] and ZeroMQ [8], assume that TCP is used at the transport layer. (3) Some IoT application scenarios demand high link utilization and reliability on low-bandwidth lossy links. Embedded hardware has also evolved substantially, prompting us to revisit TCP's overhead. In this context, **this paper seeks to determine: Do the "common wisdom" concerns about TCP hold in a modern IEEE 802.15.4-based LLN? Is TCP (still) unsuitable for use in LLNs?**

To answer this question, we leverage the fully-featured TCP implementation in the FreeBSD Operating System (rather than a limited locally-developed implementation) and refactor it to work with the Berkeley Low-Power IP Stack (BLIP), Generic Network Stack (GNRC), and OpenThread network stack, on two modern LLN platforms (§5). Naïvely running TCP in an LLN indeed results in poor performance. However, upon close examination, we discover that this is not caused by the expected reasons, such as those listed above. The *actual* reasons for poor TCP performance include (1) small link-layer frames that increase TCP header overhead, (2) hidden terminal effects over multiple wireless hops, and (3) poor interaction between TCP and a duty-cycled link. Through

Challenge	Technique	Observed Improvement
Resource Constraints	Zero-Copy Send	Send Buffer: 50% less mem.
	In-Place Reass.	Recv Buffer: 38% less mem.
Link-Layer Properties	Large MSS	TCP Goodput: 4–5x higher
	Link Retry Delay	TCP Seg. Loss: 6% $\to$ 1%
Energy Constraints	Adaptive DC	HTTP Latency: $\approx$ 2x lower
	L2 Queue Mgmt.	TCP Radio DC: 3% $\to$ 2%

Table 1: Impact of techniques to run full-scale TCP in LLNs

a systematic study of TCP in LLNs, we develop techniques to resolve these issues (Table 1), uncover why the generally assumed problems do not apply to TCP in LLNs, and show that TCP perfoms well in LLNs once these issues are resolved:

We find that **full-scale TCP fits well within the CPU and memory constraints of modern LLN platforms** (§5, §6). Owing to the low bandwidth of a low-power wireless link, a small window size ($\approx$ 2 KiB) is sufficient to fill the bandwidth-delay product and achieve good TCP performance. This translates into small send/receive buffers that fit comfortably within the memory of modern WSN hardware. Furthermore, we propose using an atypical Maximum Segment Size (MSS) to manage header overhead and packet fragmentation. As a result, **full-scale TCP operates well in LLNs, with 5–40 times higher throughput than existing (relatively simplistic) embedded TCP stacks** (§6).

Hidden terminals are a serious problem when running TCP over multiple wireless hops. We propose adding a delay d between link-layer retransmissions, and demonstrate that it effectively reduces hidden-terminal-induced packet loss for TCP. We find that, because a small window size is sufficient for good performance in LLNs, **TCP is quite resilient to spurious packet losses, as the congestion window can recover to a full window quickly after loss** (§7).

To run TCP in a low-power context, we *adaptively* duty-cycle the radio to avoid poor interactions with TCP's self-clocking behavior. We also propose careful link-layer queue management to make TCP more robust to interference. We demonstrate that **TCP can operate at low power, comparable to alternatives tailored specifically for WSNs**, and that **TCP brings value for real IoT sensor applications** (§8).

We conclude that TCP is entirely capable of running on IEEE 802.15.4 networks and low-cost embedded devices in LLN application scenarios (§9). Since our improvements to TCP and the link layer maintain seamless interoperability with other TCP/IP networks, we believe that a TCP-based transport architecture for LLNs could yield considerable benefit.

In summary, this paper's contributions are:

1. We implement a full-scale TCP stack for low-power embedded devices and reduce its resource usage.
2. We identify the actual issues causing poor TCP performance and develop techniques to address them.
3. We explain why the expected insurmountable reasons for poor TCP performance actually do not apply.
4. We demonstrate that, once these issues are resolved, TCP performs comparably to LoWPAN-specialized protocols.

Table 1 lists our techniques to run TCP in an LLN. Although prior LLN work has already used various forms of link-layer delays [136] and adaptive duty-cycling [140], our work shows, where applicable, how to adapt these techniques to work well with TCP, and demonstrates that they can address the challenges of LLNs within a *TCP-based* transport architecture.

2 Background and Related Work

Since the introduction of TCP, a vast literature has emerged, focusing on improving it as the Internet evolved. Some representative areas include congestion control [9, 51, 62, 76], performance on wireless links [15, 27], performance in high-bandwidth environments [11, 30, 53, 65, 78], mobility [124], and multipath operation [115]. Below, we discuss TCP in the context of LLNs and embedded devices.

2.1 Low-Power and Lossy Networks (LLNs)

Although the term *LLN* can be applied to a variety of technologies, including LoRa and Bluetooth Low Energy, we restrict our attention in this paper to **embedded networks using IEEE 802.15.4**. Such networks are called LoWPANs [93]—Low-Power Wireless Personal Area Networks—in contrast to WANs, LANs (802.3), and WLANs (802.11). Outside of LoWPANs, TCP has been successfully adapted to a variety of networks, including serial [77], Wi-Fi [27], cellular [25, 100], and satellite [15,25] links. While an 802.15.4 radio can in principle be added as a NIC to any device, we consider only *embedded* devices where it is the primary means of communication, running operating systems like TinyOS [68], RIOT [24], Contiki [45], or FreeRTOS. These devices are currently built around microcontrollers with Cortex-M CPUs, which lack MMUs. Below, we explain how LoWPANs are different from other networks where TCP has been successfully adapted.

Resource Constraints. When TCP was initially adopted by ARPANET in the early 1980s, contemporary Internet citizens—typically minicomputers and high-end workstations, but not yet personal computers—usually had at least 1 MiB of RAM. 1 MiB is tiny by today's standards, yet the LLN-class devices we consider in this work have *1-2 orders of magnitude less RAM than even the earliest computers connected with TCP/IP*. Due to energy constraints, particularly SRAM leakage, RAM size in low-power MCUs does not follow Moore's Law. For example, comparing Hamilton [83], which we use in this work, to TelosB [113], an LLN platform from 2004, shows only a 3.2x increase in RAM size over 16 years. This has caused LLN-class embedded devices to have a different balance of resources than conventional systems, a trend that is likely to continue well into the future. For example, whereas conventional computers have historically had roughly 1 MiB of RAM for every MIPS of CPU, as captured by the 3M rule, Hamilton has $\approx$ 50 DMIPS of CPU but only 32 KiB of RAM.

Link-Layer Properties. IEEE 802.15.4 is a low-bandwidth, wireless link with an MTU of only 104 bytes. The research community has explored using TCP with links that are *separately* low-bandwidth, wireless [27], or low-MTU [77], but addressing these issues *together* raises new challenges. For example, RTS-CTS, used in WLANs to avoid hidden terminals, has high overhead in LoWPANs [71, 136] due to the small MTU—control frames are comparable in size to data frames. Thus, LoWPAN researchers have moved away from RTS-CTS, instead carefully designing application traffic patterns to avoid hidden terminals [71, 88, 112]. Unlike Wi-Fi/LTE, LoWPANs do not use physical-layer techniques like adaptive modulation/coding or multi-antenna beamforming. Thus, they are directly impacted by link quality degradation due to varying environmental conditions [112, 127]. Additionally, IEEE 802.15.4 coexists with Wi-Fi in the 2.4 GHz frequency band, making Wi-Fi interference particularly relevant in indoor settings [99]. As LoWPANs are *embedded* networks, there is no human in the loop to react to and repair bad link quality.

Energy Constraints. Embedded nodes—the "hosts" of an LLN—are subject to strict power constraints. Low-power radios consume almost as much energy listening for a packet as they do when actually sending or receiving [20, 83]. Therefore, it is customary to *duty-cycle* the radio, keeping it in a low-power sleep state, in which it cannot send or receive data, most of the time [70, 112, 139]. The radio is only *occasionally* turned on to send/receive packets or determine if reception is likely. This requires *Media Management Control (MMC)* protocols [70, 112, 139] at the link layer to ensure that frames destined for a node are delivered to it only when its radio is on and listening. Similarly, the CPU also consumes a significant amount of energy [83], and must be kept idle most of the time.

Over the past 20 years, LLN researchers have addressed these challenges, but only in the context of special-purpose networks highly tailored to the particular application task at hand. The remaining open question is how to do so with a general-purpose reliable transport protocol like TCP.

2.2 TCP/IP for Embedded LLN-Class Devices

In the late 1990s and early 2000s, developers attempted to bring TCP/IP to embedded and resource-constrained systems to connect them to the Internet, usually over serial or Ethernet. Such systems [32, 80] were often designed with a specific application—often, a web server—in mind. These TCP/IP stacks were tailored to the specific applications at hand and were not suitable for general use. uIP ("micro IP") [42], introduced in 2002, was a standalone *general* TCP/IP stack optimized for 8-bit microcontrollers and serial or Ethernet links. To minimize resource consumption to run on such platforms, uIP omits standard features of TCP; for example, it allows only a single outstanding (unACKed) TCP segment per connection, rather than a sliding window of in-flight data.

Since the introduction of uIP, embedded networks have changed substantially. With *wireless* sensor networks and IEEE 802.15.4, various low-power networking protocols have been developed to overcome lossy links with strict energy and resource constraints, from S-MAC [139], B-MAC [112], X-MAC [34], and A-MAC [49], to Trickle [96] and CTP [59]. Researchers have viewed TCP as unsuitable, however, questioning end-to-end recovery, loss-triggered congestion control, and bi-directional data flow in LLNs [44]. Furthermore, WSNs of this era typically did not even use IP; instead, each WSN was designed specifically to support a particular application [89, 102, 138]. Those that require global connectivity rely on application-specific "base stations" or "gateways" connected to a TCP/IP network, treating the LLN like a peripheral interconnect (e.g., USB, bluetooth) rather than a network in its own right. This is because the prevailing sentiment at the time was that LLNs are too different from other types of networks and have to operate in too extreme conditions for the layered Internet architecture to be appropriate [50].

In 2007, the 6LoWPAN adaptation layer [105] was introduced, enabling IPv6 over IEEE 802.15.4. IPv6 has since been adopted in LLNs, bringing forth IoT [70]. uIP has been ported to LLNs [48], and IPv6 routing protocols, like RPL [33], and UDP-based application-layer transports, like CoAP [35], have emerged in LLNs. Representative operating systems, like TinyOS and Contiki, implement UDP/RPL/IPv6/6LoWPAN network stacks with IEEE 802.15.4-compatible MMC protocols for 16-bit platforms like TelosB [113].

TCP, however, is not widely adopted in LLNs. The few LLN studies that use TCP [47, 60, 67, 70, 72, 86, 144] generally use a simplified TCP stack (Appendix B), such as uIP.

In summary, despite the acceptance of IPv6, LLNs remain highly tailored at the transport layer to the application at hand. They typically use application-specific protocols on top of UDP; of such protocols, CoAP [31] has the widest adoption. In this context, this paper explores whether adopting TCP—and more broadly, the ecosystem of IP-based protocols, rather than IP alone—might bring value to LLNs moving forward.

3 Motivation: The Case for TCP in LLNs

As explained in §2, LLN design has historically been highly tailored to the specific application task at hand, for maximum efficiency. For example, PSFQ broadcasts data from a single source node to all others, RMST supports "directed diffusion" [73], and CoAP is tied to REST semantics. But embedded networks are not just isolated devices (e.g., peripheral interconnects like USB or bluetooth)—they are now true Internet citizens, and should be designed as such.

In particular, the recent megatrend of IoT requires LLNs to have a greater degree of *interoperability* with regular TCP/IP networks. Yet, LLN-specific protocols lack a clear separation between the transport and application layers, requiring *application-layer gateways* to communicate with TCP/IP-based services. This has encouraged IoT applications to develop as vertically-integrated silos, where devices cooperate only within an individual application or a particular manufacturer's ecosystem, with little to no interoperability *between* applications or with the general TCP/IP-based Internet. This phenomenon, sometimes called the "CompuServe of Things," is a serious obstacle to the IoT vision [57,97,104,133,141]. In contrast, other networks are seamlessly interoperable with the rest of the Internet. Accessing a new web application from a laptop does not require any new functionality at the Wi-Fi access point, but running a new application in a gateway-based LLN *does* require additional application-specific functionality to be installed at the gateway.

In this context, TCP-enabled LLN devices would be first-class citizens of the Internet, natively interoperable with the rest of the Internet via TCP/IP. They could use IoT protocols that assume a TCP-based transport layer (e.g., MQTT [39]) and security tools for TCP/IP networks (e.g., stateful firewalls), without an application-layer gateway. In addition, while traditional LLN applications like environment monitoring can be supported by unreliable UDP, certain applications do require high throughput and reliable delivery (e.g., anemometry (Appendix D), vibration monitoring [81]). TCP, *if it performs well in LLNs*, could benefit these applications.

Adopting TCP in LLNs may also open an interesting research agenda for IoT. TCP is the default transport protocol outside of LLNs, and history has shown that, to justify other transport protocols, application characteristics must offer substantial opportunity for optimization (e.g., [55,134,135]). If TCP becomes a viable option in LLNs, it would raise the bar for application-specific LLN protocols, resulting in some potentially interesting alternatives.

Although adopting TCP in LLNs could yield significant benefit and an interesting agenda, its feasibility and performance remain in question. This motivates our study.

4 Empirical Methodology

This section presents our methodology, carefully chosen to ground our study of full-scale TCP in LLNs.

4.1 Network Stack

Transport layer. That only a few full-scale TCP stacks exist, with a body of literature covering decades of refining, demonstrates that developing a feature-complete implementation of TCP is complex and error-prone [111]. Using a well-tested TCP implementation would ensure that results from our measurement study are due to the TCP *protocol*, not an artifact of the TCP *implementation* we used. Thus, we leverage the TCP implementation in FreeBSD 10.3 [56] to ground our study. We ported it to run in embedded operating systems and resource-constrained embedded devices (§4.2).

To verify the effectiveness of full-scale TCP in LLNs, we compare with CoAP [123], CoCoA [29], and unreliable UDP. CoAP is a standard LLN protocol that provides reliability on top of UDP. It is the most promising LLN alternative to TCP, gaining momentum in both academia [29,38,90,119,121,129] and industry [3,79], with adoption by Cisco [5,41], Nest/Google [4], and Arm [1,2]. CoCoA [29] is a recent proposal that augments CoAP with RTT estimation.

It is attractive to compare TCP to a variety of commercial systems, as has been done by a number of studies in LTE/WLANs [55,135]. Unfortunately, multihop LLNs have not yet reached the level of maturity to support a variety of commercial offerings; only CoAP has an appreciable level of commercial adoption. Other protocols are research proposals that often (1) are implemented for now-outdated operating systems and hardware or exist only in simulation [10,75,88], (2) target a very specific application paradigm [125,130,138], and/or (3) do not use IP [75,88,109,130]. We choose CoAP and CoCoA because they are not subject to these constraints.

	TelosB	Hamilton	Firestorm	Raspberry Pi
CPU	MSP430	Cortex-M0+	Cortex-M4	Cortex-A53
RAM	10 KiB	32 KiB	64 KiB	256 MB
ROM	48 KiB	256 KiB	512 KiB	SD Card

Table 2: Comparison of the platforms we used (Hamilton and Firestorm) to TelosB and Raspberry Pi

Layers 1 to 3. Because it is burdensome to place a border router with LAN connectivity within wireless range of every low-power host (e.g., sensor node), it is common to transmit data (e.g., readings) over *multiple* wireless LLN hops. Although each sensor must be battery-powered, it is reasonable to have a wall-powered LLN router node within transmission range of it.[1] This motivates Thread[2] [64,87], a recently developed protocol standard that constructs a multihop LLN over IEEE 802.15.4 links with *wall-powered, always-on* router nodes and *battery-powered, duty-cycled* leaf nodes. We use OpenThread [106], an open-source implementation of Thread.

Thread decouples routing from energy efficiency, providing a full-mesh topology among routers, frequent route updates, and asymmetric bidirectional routing for reliability. Each *leaf node* duty cycles its radio, and simply chooses a core router with good link quality, called its *parent*, as its next hop to all other nodes. The duty cycling uses *listen-after-send* [120]. A leaf node's parent stores downstream packets destined for that leaf node, until the leaf node sends it a *data request* message. A leaf node, therefore, can keep its radio powered off most of the time; infrequently, it sends a data request message to its parent, and turns on its radio for a short interval afterward to listen for downstream packets queued at its parent. Leaf nodes may send upstream traffic at any time. Each node uses CSMA-CA for medium access.

4.2 Embedded Hardware

We use two embedded hardware platforms: Hamilton [83] and Firestorm [18]. Hamilton uses a SAMR21 SoC with a 48 MHz Cortex-M0+, 256 KiB of ROM, and 32 KiB of RAM. Firestorm uses a SAM4L 48 MHz Cortex-M4 with 512 KiB of ROM and 64 KiB of RAM. While these platforms are more powerful than the TelosB [113], an older LLN platform widely

[1]The assumption of powered "core routers" is reasonable for most IoT use cases, which are typically indoors. Recent IoT protocols, such as Thread [64] and BLEmesh [63], take advantage of powered core routers.

[2]Thread has a large amount of industry support with a consortium already consisting of over 100 members [6], and is used in real IoT products sold by Nest/Google [7]. Given this trend, using Thread makes our work timely.

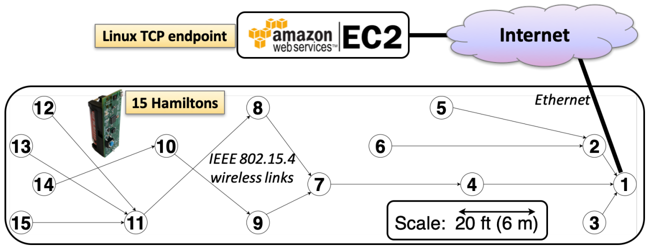

Figure 1: Snapshot of uplink routes in OpenThread topology at transmission power of -8 dBm (5 hops). Node 1 is the border router with Internet connectivity.

used in past studies, they are heavily resource-constrained compared to a Raspberry Pi (Table 2). Both platforms use the AT86RF233 radio, which supports IEEE 802.15.4. We use its standard data rate, 250 kb/s. We use Hamilton/OpenThread in our experiments; for comparison, we provide some results from Firestorm and other network stacks in Appendix A.

Handling automatic radio features. The AT86RF233 radio has built-in hardware support for link-layer retransmissions and CSMA-CA. However, it automatically enters low-power mode during CSMA backoff, during which it does not listen for incoming frames [20]. This behavior, which we call *deaf listening*, interacts poorly with TCP when radios are always on, because TCP requires bidirectional flow of packets—data in one direction and ACKs in the other. This may initially seem concerning, as deaf listening is an important power-saving feature. Fortunately, this problem disappears when using OpenThread's listen-after-send duty-cycling protocol, as leaf nodes never transmit data when listening for downstream packets. For experiments with always-on radios, we do not use the radio's capability for hardware CSMA and link retries; instead, we perform these operations in software.

Multihop Testbed. We construct an indoor LLN testbed, depicted in Figure 1, with 15 Hamiltons where node 1 is configured as the border router. OpenThread forms a 3-to-5-hop topology at transmission power of -8 dBm. Embedded TCP endpoints (Hamiltons) communicate with a Linux TCP endpoint (server on Amazon EC2) via the border router. During working hours, interference is present in the channel, due to people in the space using Wi-Fi and Bluetooth devices in the 2.4 GHz frequency band. At night, when there are few/no people in the space, there is much less interference.

5 Implementation of *TCPlp*

We seek to answer the following two questions: (1) Does full-scale TCP fit within the limited memory of modern LLN platforms? (2) How can we integrate a TCP implementation from a traditional OS into an embedded OS? To this end, we develop a TCP stack for LLNs based on the TCP implementation in FreeBSD 10.3, called *TCPlp* [91], on multiple embedded operating systems, RIOT OS [24] and TinyOS [95]. We use *TCPlp* in our measurement study in future sections.

Although we carefully preserved the protocol logic in the FreeBSD TCP implementation, achieving correct and performant operation on sensor platforms was a nontrivial effort. We had to modify the FreeBSD implementation according to the concurrency model of each embedded network stack and the timer abstractions provided by each embedded operating system (Appendix A). Our other modifications to FreeBSD, aimed at reducing memory footprint, are described below.

	Protocol	Socket Layer	`posix_sockets`
ROM	19972 B	6216 B	5468 B
RAM (Active)	364 B	88 B	48 B
RAM (Passive)	12 B	88 B	48 B

Table 3: Memory usage of *TCPlp* on RIOT OS. We also include RIOT's `posix_sockets` module, used by *TCPlp* to provide a Unix-like interface.

5.1 Connection State for *TCPlp*

As discussed in Appendix B, *TCPlp* includes features from FreeBSD that improve standard communication, like a sliding window, New Reno congestion control, zero-window probes, delayed ACKs, selective ACKs, TCP timestamps, and header prediction. *TCPlp*, however, omits some features in FreeBSD's TCP/IP stack. We omit dynamic window scaling, as buffers large enough to necessitate it ($\geq$ 64 KiB) would not fit in memory. We omit the urgent pointer, as it not recommended for use [61] and would only complicate buffering. Certain security features, such as host cache, TCP signatures, SYN cache, and SYN cookies are outside the scope of this work. We do, however, retain challenge ACKs [116].

We use separate structures for *active sockets* used to send and receive bytes, and *passive sockets* used to listen for incoming connections, as passive sockets require less memory.

Table 3 depicts the memory footprint of *TCPlp* on RIOT OS. The memory required for the protocol and application state of an active TCP socket fits in a few hundred bytes, less than 1% of the available RAM on the Cortex-M4 (Firestorm) and 2% of that on the Cortex-M0+ (Hamilton). Although *TCPlp* includes heavyweight features not traditionally included in embedded TCP stacks, it fits well within available memory.

5.2 Memory-Efficient Data Buffering

Existing embedded TCP stacks, such as uIP and BLIP, allow *only one TCP packet in the air*, eschewing careful implementation of send and receive buffers [86]. These buffers, however, are key to supporting TCP's sliding window functionality. We observe in §6.2 that *TCPlp* performs well with only 2-3 KiB send and receive buffers, which comfortably fit in memory even when naïvely pre-allocated at compile time. Given that buffers dominate *TCPlp*'s memory usage, however, we discuss techniques to optimize their memory usage.

5.2.1 Send Buffer: Zero-Copy

Zero-copy techniques [28, 40, 82, 98, 101] were devised for situations where the time for the CPU to copy memory is a significant bottleneck. Our situation is very different; the radio, not the CPU, is the bottleneck, owing to the low bandwidth of IEEE 802.15.4. By using a zero-copy send buffer,

start
end

(b) Receive buffer with in-place reassembly queue. In-sequence data (yellow) is kept in a circular buffer, and out-of-order segments (red) are written in the space past the received data.

Figure 2: Naïve and final TCP receive buffers

however, we can avoid allocating memory to intermediate buffers that would otherwise be needed to copy data, thereby reducing the network stack's total memory usage.

In TinyOS, for example, the BLIP network stack supports vectored I/O; an outgoing packet passed to the IPv6 layer is specified as an `iovec`. Instead of allocating memory in the packet heap for each outgoing packet, *TCPlp* simply creates `iovec`s that point to existing data in the send buffer. This decreases the required size of the packet heap.

Unfortunately, zero-copy optimizations were not possible for the OpenThread implementation, because OpenThread does not support vectored I/O for sending packets. The result is that the *TCPlp* implementation requires a few kilobytes of additional memory for the send buffer on this platform.

5.2.2 Receive Buffer: In-Place Reassembly Queue

Not all zero-copy optimizations are useful in the embedded setting. In FreeBSD, received packets are passed to the TCP implementation as `mbufs` [137]. The receive buffer and reassembly buffer are `mbuf` chains, so data need not be copied out of `mbufs` to add them to either buffer or recover from out-of-order delivery. Furthermore, buffer sizes are chosen dynamically [122], and are merely a *limit* on their actual size. In our memory-constrained setting, such a design is dangerous because its memory usage is nondeterministic; there is additional memory overhead, due to headers, if the data are delivered in many small packets instead of a few large ones.

We opted for a flat array-based circular buffer for the receive buffer in *TCPlp*, primarily owing to its determinism in a limited-memory environment: buffer space is reserved at *compile-time*. Head/tail pointers delimit which part of the array stores in-sequence data. To reduce memory consumption, we store out-of-order data in the same receive buffer, at the same position as if they were in-sequence. We use a bitmap, not head/tail pointers, to record where out-of-order data are stored, because out-of-order data need not be contiguous. We call this an *in-place reassembly queue* (Figure 2).

6 TCP in a Low-Power Network

In this section, we characterize how full-scale TCP interacts with a low-power network stack, resource-constrained hardware, and a low-bandwidth link.

6.1 Reducing Header Overhead using MSS

In traditional networks, it is customary to set the Maximum Segment Size (MSS) to the link MTU (or path MTU) minus the size of the TCP/IP headers. IEEE 802.15.4 frames, however, are *an order of magnitude smaller* than frames in traditional networks (Table 4). The TCP/IP headers consume more than half of the frame's available MTU. As a result, TCP performs poorly, incurring more than 50% header overhead.

	Fast Ethernet	Wi-Fi	Ethernet	802.15.4
Capacity	100 Mb/s	54 Mb/s	10 Mb/s	250 kb/s
MTU	1500 B	1500 B	1500 B	104–116 B
Tx Time	0.12 ms	0.22 ms	1.2 ms	4.1 ms

Table 4: Comparison of TCP/IP links

Header	802.15.4	6LoWPAN	IPv6	TCP	Total
1st Frame	11–23 B	5 B	2–28 B	20–44 B	38–107 B
*n*th Frame	11–23 B	5–12 B	0 B	0 B	16–35 B

Table 5: Header overhead with 6LoWPAN fragmentation

Earlier approaches to running TCP over low-MTU links (e.g., low-speed serial links) have used TCP/IP header compression based on per-flow state [77] to reduce header overhead. In contrast, the 6LoWPAN adaptation layer [105], designed for LLNs, supports only *flow-independent* compression of the IPv6 header using shared link-layer state, a clear departure from per-flow techniques. A key reason for this is that the compressor and decompressor in an LLN (host and border router) are separated by several IP hops[3], making it desirable for intermediate nodes to be able to determine a packet's IP header without per-flow context (see §10 of [105]).

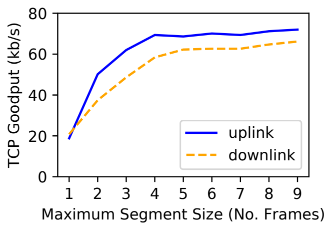
That said, compressing TCP headers separately from IP addresses using per-flow state is a promising approach to further amortize header overhead. There is preliminary work in this direction [22, 23], but it is based on uIP, which has one in-flight segment, and does not fully specify how to resynchronize compression state after packet loss with a multi-segment window. It is also not officially standardized by the IETF.

Therefore, this paper takes an approach orthogonal to header compression. We instead choose an MSS larger than the link MTU admits, *relying on fragmentation at the lower layers to decrease header overhead*. Fragmentation is handled by 6LoWPAN, which acts at Layer 2.5, between the link and network layers. Unlike end-to-end IP fragmentation, the 6LoWPAN fragments exist only within the LLN, and are reassembled into IPv6 packets when leaving the network.

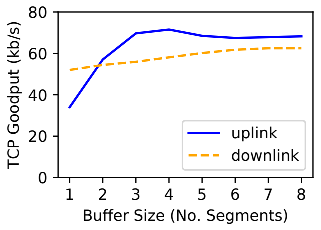
Relying on fragmentation is effective because, as shown in Table 5, TCP/IP headers consume space in the first fragment, but not in subsequent fragments. Using an excessively large MSS, however, decreases reliability because the loss of one fragment results in the loss of an entire packet. Existing work [21] has identified this trade-off and investigated it in simulation in the context of power consumption. We investigate it in the context of goodput in a live network.

Figure 3a shows the bandwidth as the MSS varies. As

[3]Thread deliberately does not abstract the mesh as a single IP link. Instead, it organizes the LLN mesh as a set of *overlapping link-local scopes*, using IP-layer routing to determine the path packets take through the mesh [70].

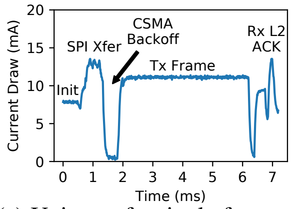


(a) Effect of varying MSS

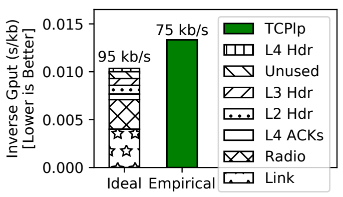


(b) Effect of varying buffer size

Figure 3: TCP goodput over one IEEE 802.15.4 hop



(a) Unicast of a single frame, measured with an oscilloscope



(b) *TCPlp* goodput compared with raw link bandwidth and overheads

Figure 4: Analysis of overhead limiting *TCPlp*'s goodput

expected, we see poor performance at a small MSS due to header overhead. Performance gains diminish when the MSS becomes larger than 5 frames. We recommend using an MSS of about 5 frames, but it is reasonable to decrease it to 3 frames if more wireless loss is expected. **Despite the small frame size of IEEE 802.15.4, we can effectively amortize header overhead for TCP using an atypical MSS.** Adjusting the MSS is orthogonal to TCP header compression. We hope that widespread use of TCP over 6LoWPAN, perhaps based on our work, will cause TCP header compression to be separately investigated and possibly used together with a large MSS.

6.2 Impact of Buffer Size

Whereas simple TCP stacks, like uIP, allow only one in-flight segment, full-scale TCP requires complex buffering (§5.2). In this section, we vary the size of the buffers (send buffer for uplink experiments and receive buffer for downlink experiments) to study how it affects the bandwidth. In varying the buffer size, we are directly affecting the size of TCP's flow window. We expect throughput to increase with the flow window size, with diminishing returns once it exceeds the bandwidth-delay product (BDP). The result is shown in Figure 3b. **Goodput levels off at a buffer size of 3 to 4 segments (1386 B to 1848 B), indicating that the buffer size needed to fill the BDP fits comfortably in memory.** Indeed, the BDP in this case is about $125\text{kb/s} \cdot 0.1\text{s} \approx 1.6\text{KiB}$.[4]

Downlink goodput at a buffer size of one segment is unusually high. This is because FreeBSD does not delay ACKs if the receive buffer is full, reducing the effective RTT from ≈ 130 ms to ≈ 70 ms. Indeed, goodput is very sensitive to RTT when the buffer size is small, because TCP exhibits "stop-and-wait" behavior due to the small flow window.

[4]We estimate the bandwidth as 125 kb/s rather than 250 kb/s to account for the radio overhead identified in §6.3.

6.3 Upper Bound on Single-Hop Goodput

We consider TCP goodput between two nodes over the IEEE 802.15.4 link, over a single hop without any border router. Using the Hamilton/OpenThread platform, we are able to achieve 75 kb/s.[5] Figure 4b lists various sources of overhead that limit *TCPlp*'s goodput, along with the ideal upper bounds that they admit. **Link** overhead refers to the 250 kb/s link capacity. **Radio** overhead includes SPI transfer to/from the radio (i.e., packet copying [107]), CSMA, and link-layer ACKs, which cannot be pipelined because the AT86RF233 radio has only one frame buffer. A full-sized 127-byte frame spends 4.1 ms in the air at 250 kb/s, but the radio takes 7.2 ms to send it (Figure 4a), almost halving the link bandwidth available to a single node. This is consistent with prior results [107]. **Unused** refers to unused space in link frames due to inefficiencies in the 6LoWPAN implementation. Overall, we estimate a 95 kb/s upper bound on goodput (100 kb/s without TCP headers). Our 75 kb/s measurement is within 25% of this upper bound, substantially higher than prior work (Table 6). The difference from the upper bound is likely due to network stack processing and other real-world inefficiencies.

7 TCP Over Multiple Wireless Hops

We instrument TCP connections between Hamilton nodes in our multi-hop testbed, without using the EC2 server.

7.1 Mitigating Hidden Terminals in LLNs

Prior work over traditional WLANs has shown that hidden terminals degrade TCP performance over multiple wireless hops [58]. Using RTS/CTS for hidden terminal avoidance has been shown to be effective in WLANs. This technique has an unacceptably high overhead in LLNs [136], however, because data frames are small (Table 4), comparable in size to the additional control frames required. Prior work in LLNs has carefully designed application traffic, using rate control [71, 88] and link-layer delays [136], to avoid hidden terminals.

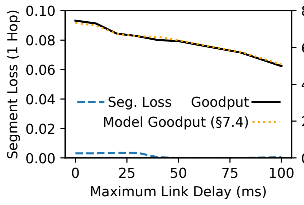
But prior work does not explore these techniques in the context of TCP. Unlike protocols like CoAP and simplified TCP implementations like uIP, a full-scale TCP flow has a *multi-segment sliding window* of unacknowledged data, making it unclear *a priori* whether existing LLN techniques will be sufficient. In particular, rate control seems sufficient because of bi-directional packet flow in TCP (data in one direction and ACKs in the other). So, rather than applying rate control, we attempt to avoid hidden terminals by adding a delay d between link-layer retries in addition to CSMA backoff. After a failed link transmission, a node waits for a random duration between 0 and d, before retransmitting the frame. The idea is

[5]Appendix A.4 provides the corresponding goodput figures for Hamilton/GNRC and Firestorm/BLIP platforms, for comparison.

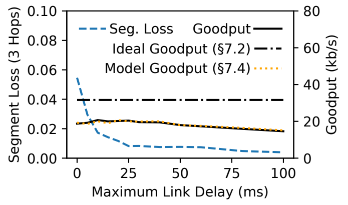
[6]One study [47] achieves ≈ 16 kb/s over multiple hops using the Linux TCP stack. We do not include it in Table 6 because it does not capture the resource constraints of LLNs—it uses traditional computers (PCs) for the end hosts—and does not consider hidden terminals—each hop uses a different wireless channel. It also uses TCP as a workload to evaluate a new link-layer protocol (burst forwarding), instead of evaluating TCP in its own right

	[144]	[22]	[67]	[86]	[69, 70]	This Paper (Hamilton Platform)
TCP Stack	uIP	uIP	uIP	BLIP	Arch Rock	*TCPlp* (RIOT OS, OpenThread)
Max. Seg Size	1 Frame	1 Frame	4 Frames	1 Frame	1024 bytes	5 Frames
Window Size	1 Seg.	1 Seg.	1 Seg.	1 Seg.	1 Seg.	1848 bytes (4 Seg.)
Goodput (One Hop)	1.5 kb/s	≈ 6.4 kb/s	≈ 12 kb/s	≈ 4.8 kb/s	15 kb/s	75 kb/s
Goodput (Multi-Hop)	≈ 0.55 kb/s	≈ 1.9 kb/s	≈ 12 kb/s	≈ 2.4 kb/s	9.6 kb/s	20 kb/s

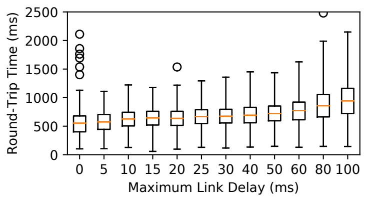
Table 6: Comparison of *TCPlp* to existing TCP implementations used in network studies over IEEE 802.15.4 networks.[6] Goodput figures obtained by reading graphs in the original paper (rather than stated numbers) are marked with the ≈ symbol.



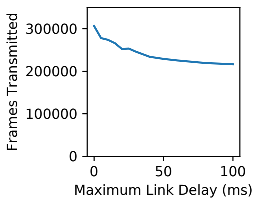
(a) TCP goodput, one hop



(b) TCP goodput, three hops



(c) RTT, three hops (outliers omitted)



(d) Total frames sent, three hops

Figure 5: Effect of varying time between link-layer retransmissions. Reported "segment loss" is the loss rate of TCP segments, not individual IEEE 802.15.4 frames. It includes only losses not masked by link-layer retries.

that if two frames collide due to a hidden terminal, the delay will prevent their link-layer retransmissions from colliding.

We modified OpenThread, which previously had no delay between link retries, to implement this. As expected, single-hop performance (Figure 5a) decreases as the delay between link retries increases; hidden terminals are not an issue in that setting. Packet loss is high for the multihop experiment (Figure 5b) when the link retry delay is 0, as is expected from hidden terminals. **Adding a small delay between link retries, however, effectively reduces packet loss.** Making the delay too large raises the RTT (Figure 5c).

We prefer a smaller frame/segment loss rate, even if goodput stays the same, in order to make more efficient use of network resources. Therefore, we prefer a moderate delay ($d = 40$ ms) to a small delay ($d = 5$ ms), even though both provide the same goodput, because the frame and segment loss rates are smaller when d is large (Figures 5b and 5d).

7.2 Upper Bound on Multi-Hop Goodput

Comparing Figures 5a and 5b, goodput over three wireless hops is substantially smaller than goodput over a single hop. Prior work has observed similar throughput reductions over multiple hops [86, 107]. It is due to radio scheduling constraints inherent in the multihop setting, which we describe in this section. Let B be the bandwidth over a single hop.

Consider a two-hop setup: $S \to R_1 \to D$. R_1 cannot receive a frame from S while sending a frame to D, because its radio cannot transmit and receive simultaneously. Thus, the maximum achievable bandwidth over two hops is $\frac{B}{2}$.

Now consider a three-hop setup: $S \to R_1 \to R_2 \to D$. By the same argument, if a frame is being transferred over $R_1 \to R_2$, then neither $S \to R_1$ nor $R_2 \to D$ can be active. Furthermore, if a frame is being transferred over $R_2 \to D$, then R_1 can hear that frame. Therefore, $S \to R_1$ cannot transfer a frame at that time; if it does, then its frame will collide at R_1 with the frame being transferred over $R_2 \to D$. Thus, the maximum bandwidth is $\frac{B}{3}$. We depict this ideal upper bound in Figure 5b, taking B to be the ideal single-hop goodput from §6.3.

In setups with more than three hops, every set of three adjacent hops is subject to this constraint. The first hop and fourth hop, however, may be able to transfer frames simultaneously. Therefore, the maximum bandwidth is still $\frac{B}{3}$. In practice, goodput may fall slightly because transmissions from a node may *interfere* with nodes multiple hops away, even if they can only be received by its immediate neighbors.

We made empirical measurements with $d = 40$ ms to validate this analysis. Goodput over one hop was 64.1 kb/s; over two hops, 28.3 kb/s; over three hops, 19.5 kb/s; and over four hops, 17.5 kb/s. This roughly fits the model.

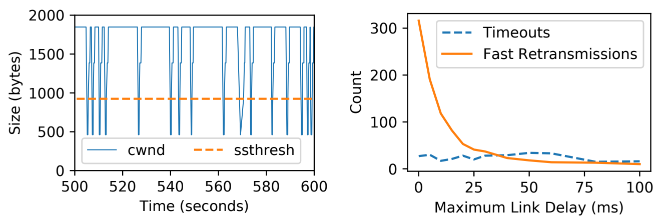
This analysis justifies why the same window size works well for both the one-hop experiments and the three-hop experiments in §7.1. Although the RTT is three times higher, the bandwidth-delay product is approximately the same. **Crucially, this means that the 2 KiB buffer size we determined in §6.2, which fits comfortably in memory, remains applicable for up to three wireless hops.**

7.3 TCP Congestion Control in LLNs

Recall that small send/receive buffers of only 1848 bytes (4 TCP segments) each are enough to achieve good TCP performance. This profoundly impacts TCP's congestion control mechanism. For example, consider Figure 5b. It is remarkable that throughput is almost the same at $d = 0$ ms and $d = 30$ ms, despite having 6% packet loss in the first case and less than 1% packet loss in the second.

Figure 6a depicts the congestion window over a 100 second interval during the $d = 0$ ms experiment.[7] Interestingly,

[7] All congestion events in Figure 6a were fast retransmissions, except for one timeout at $t = 569$ s. `cwnd` is temporarily set to 1 MSS during fast retransmissions due to an artifact of FreeBSD's implementation of SACK recovery. For clarity, we cap `cwnd` at the size of the send buffer, and we remove fluctuations in `cwnd` which resulted from "bad retransmissions" that the FreeBSD implementation corrected in the course of its normal execution.



(a) TCP cwnd for $d = 0$, three hops (b) TCP loss recovery, three hops

Figure 6: Congestion behavior of TCP over IEEE 802.15.4

the cwnd graph is far from the canonical sawtooth shape (e.g., Figure 11(b) in [26]); cwnd is almost always maxed out even though losses are frequent (6%). This is specific to small buffers. In traditional environments, where links have higher throughput and buffers are large, it takes longer for cwnd to recover after packet loss, greatly limiting the sending rate with frequent packet losses. In contrast, **in LLNs, where send/receive buffers are small, cwnd recovers to the maximum size quickly after packet loss, making TCP performance robust to packet loss.**

Congestion behavior also provides insight into loss patterns, as shown in Figure 6b. Fast retransmissions (used for isolated losses) become less frequent as d increases, suggesting that they are primarily caused by hidden-terminal-related losses. Timeouts do not become less frequent as d is increased, suggesting that they are caused by something else.

7.4 Modeling TCP Goodput in an LLN

Our findings in §7.3 suggest that, in LLNs, cwnd is limited by the buffer size, not packet loss. To validate this, we analytically model TCP performance according to our observations in §7.3, and then check if the resulting model is consistent with the data. Comprehensive models of TCP, which take window size limitations into account, already exist [108]; in contrast, our model is *intentionally simple* to provide intuition.

Observations in §7.3 suggest that we can neglect the time it takes the congestion window to recover after packet loss. So, we model a TCP connection as *binary*: either it is sending data with a full window, or it is not sending new data because it is recovering from packet loss. According to this model, a TCP flow alternates between *bursts* when it is transmitting at a full window, and *rests* when it is in recovery and not sending new data. Burst lengths depend on the packet loss rate p and rest lengths depend on RTT. This approach leads to the following model (full derivation is in Appendix C):

$$B = \frac{\text{MSS}}{\text{RTT}} \cdot \frac{1}{\frac{1}{w} + 2p} \qquad (1)$$

where B, the TCP goodput, is written in terms of the maximum segment size MSS, round-trip time RTT, packet loss rate p $(0 < p < 1)$, and window size w (sized to BDP, in packets). Figures 5a and 5b include the predicted goodput as dotted lines, calculated according to Equation 1 using the empirical RTT and segment loss rate for each experiment. **Our model of TCP goodput closely matches the empirical results.**

An established model of TCP outside of LLNs is [92, 103]:

$$B = \frac{\text{MSS}}{\text{RTT}} \cdot \sqrt{\frac{3}{2p}} \qquad (2)$$

Equation 2 fundamentally relies on there being many competing flows, so we do not expect it to match our empirical results from §7.3. But, given that existing work examining TCP in LLNs makes use of this formula to ground new algorithms [72], the differences between Equations 1 and 2 are interesting to study. In particular, Equation 1 has an added $\frac{1}{w}$ in the denominator and depends on p rather than $\sqrt{p}$, explaining, mathematically, how TCP in LLNs is more robust to small amounts of packet loss. We hope Equation 1, together with Equation 4 in Appendix C, will provide a foundation for future research on TCP in LLNs.

8 TCP in LLN Applications

To demonstrate that TCP is practical for real IoT use cases, we compare its performance to that of CoAP, CoCoA, and unreliable UDP in three workloads inspired by real application scenarios: web server, sense-and-send, and event detection. We evaluate the protocols over multiple hops with duty-cycled radios and wireless interference, present in our testbed in the day (§4.2). In our experiments, nodes 12–15 (Figure 1) send data to a server running on Amazon EC2. The RTT from the border router to the server was ≈ 12 ms, much smaller than within the low-power mesh (≈ 100-300 ms).

In our preliminary experiments, we found that in the presence of simultaneous TCP flows, tail drops at a relay node significantly impacted fairness. Implementing Random Early Detection (RED) [54] with Explicit Congestion Notification (ECN) support solved this problem. Therefore, we use RED and ECN for experiments in this section with multiple flows. While such solutions have sometimes been problematic since they are implemented in routers, they are more natural in LLNs because the intermediate “routers” relaying packets in an LLN typically also participate in the network as hosts.

We generally use a smaller MSS (3 frames) in this section, because it is more robust to interference in the day (§6). We briefly discuss how this affects our model in Appendix C, but leave a rigorous treatment to future work.

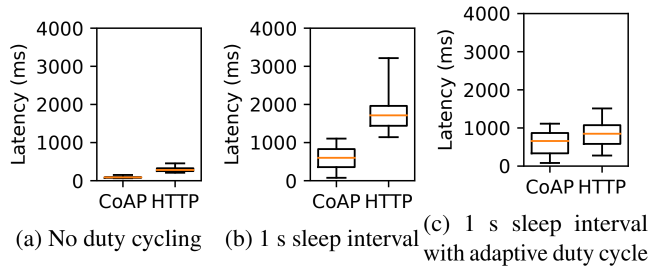
Running TCP in these application scenarios motivates **Adaptive Duty Cycle** and **Finer-Grained Link Queue Management**, which we introduce below as they are needed.

8.1 Web Server Application Scenario

To study TCP with multiple wireless hops and duty cycling, we begin with a web server hosted on a low-power device. We compare HTTP/TCP and CoAP/UDP (§4.1).

8.1.1 Latency Analysis

An HTTP request requires two round-trips: one to establish a TCP connection, and another for request/response. CoAP requires only one round trip (no connection establishment) and has smaller headers. Therefore, CoAP has a lower latency



(a) No duty cycling (b) 1 s sleep interval (c) 1 s sleep interval with adaptive duty cycle

Figure 7: Latency of web request: CoAP vs. HTTP/TCP

than HTTP/TCP when using an always-on link (Figure 7a). Even so, the latency of HTTP/TCP in this case is well below 1 second, not so large as to degrade user experience.

We now explore how a duty-cycled link affects the latency. Recall that leaf nodes in OpenThread (§4.1) periodically poll their parent to receive downstream packets, and keep their radios in a low-power sleep state between polls. We set the *sleep interval*—the time that a node waits between polls—to 1 s and show the latency in Figure 7b. Interestingly, HTTP's minimum observed latency is much higher than CoAP's, more than is explained by its additional round trip.

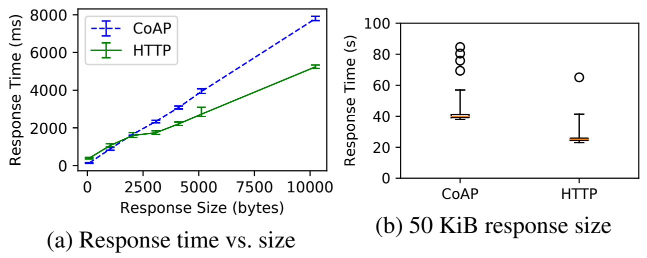
Upon investigation, we found that this is because **the self-clocking nature of TCP [76] interacts poorly with the duty-cycled link**. Concretely, the web server receives the SYN packet when it polls its parent, and sends the SYN-ACK immediately afterward, at the *beginning* of the next sleep interval. The web server therefore waits for the *entire* sleep interval before polling its parent again to receive the HTTP request, thereby experiencing the worst-case latency for the second round trip. We also observed this problem for batch transfer over TCP; TCP's self-clocking behavior causes it to consistently experience the worst-case round-trip time.

To solve this problem, we propose a technique called **Adaptive Duty Cycling**. After the web server receives a SYN, it *reduces the sleep interval* in anticipation of receiving an HTTP request. After serving the request, it restores the sleep interval to its old value. Unlike early LLN link-layer protocols like S-MAC [140] that use an adaptive duty cycle, we use *transport-layer state* to inform the duty cycle. Figure 7c shows the latency with adaptive duty cycling, where the sleep interval is temporarily reduced to 100 ms after connection establishment. **With adaptive duty-cycling, the latency overhead of HTTP compared to CoAP is small, despite larger headers and an extra round trip for connection establishment.**

Adaptive duty cycling is also useful in high-throughput scenarios, and in situations with persistent TCP connections. We apply adaptive duty cycling to one such scenario in §8.2.

8.1.2 Throughput Analysis

In §8.1.1, the size of the web server's response was 82 bytes, intentionally small to focus on latency. In a real application, however, the response may be large (e.g., it may contain a batch of sensor readings). In this section, we explore larger response sizes. We use a short sleep interval of 100 ms. This



(a) Response time vs. size (b) 50 KiB response size

Figure 8: Goodput: CoAP vs. HTTP/TCP

is realistic because, using adaptive duty cycling, the sleep interval may be longer when the node is idle, and reduced to 100 ms only when transferring the response.

Figure 8a shows the total time from dispatching the request to receiving the full response, as we vary the size of the response. It plots the median time, with quartiles shown in error bars. HTTP takes longer than CoAP when the response size is small (consistent with Figure 7), but CoAP takes longer when the response size is larger. This indicates that while HTTP/TCP has a greater fixed-size overhead than CoAP (higher y-intercept), it transfers data at a higher throughput (lower slope). TCP achieves a higher throughput than CoAP because CoAP sends response segments one-at-a-time ("stop and wait"), whereas TCP allows multiple segments to be in flight simultaneously ("sliding window").

To quantify the difference in throughput, we compare TCP and CoAP when transferring 50 KiB of data in Figure 8b. **TCP achieves 40% higher throughput compared to CoAP, over multiple hops and a duty-cycled link.**

8.1.3 Power Consumption

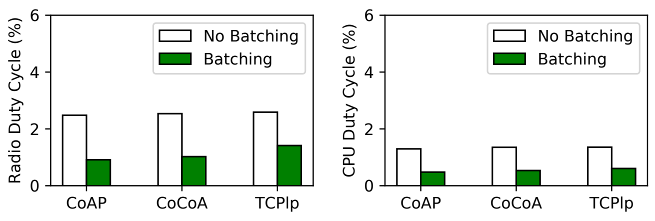
TCP consumes more energy than CoAP due to the extra round-trip at the beginning. In practice, however, a web server is interactive, and therefore will be *idle* most of the time. Thus, the idle power consumption dominates. For example, TCP keeps the radio on 35% longer than CoAP for a response size of 1024 bytes, but if the user makes one request every 100 seconds on average, this difference drops to only 0.35%.

Thus, we relegate in-depth power measurements to the sense-and-send application (§8.2), which is non-interactive.

8.2 Sense-and-Send Application Scenario

We turn our focus to the common *sense-and-send* paradigm, in which devices periodically collect sensor readings and send them upstream. For concreteness, we model our experiments on the deployment of anemometers in a building, a real-world LLN use case described in Appendix D. Anemometers collect measurements frequently (once per second), making heavy use of the transport protocol; given that our focus is on transport performance, this makes anemometers a good fit for our study. Other sensor deployments (e.g., temperature, humidity, building occupancy, etc.) sample data at a lower rate (e.g., 0.05 Hz), but are otherwise similar. Thus, *we expect our results to generalize to other sense-and-send applications.*

Nodes 12–15 (Figure 1) each generate one 82-byte reading every 1 second, and send it to the cloud server using either



(a) Radio duty cycle (b) CPU duty cycle

Figure 9: Effect of batching on power consumption

TCP or CoAP. We use most of the remaining RAM as an *application-layer queue* to prevent data from being lost if CoAP or TCP is in backoff after packet loss and cannot send out new data immediately. We make use of adaptive duty cycling for both TCP and CoAP, with a base sleep interval of four minutes (OpenThread's default) and decreasing it to 100 ms[8] when a TCP ACK or CoAP response is expected.

We measure a solution's *reliability* as the proportion of generated readings delivered to the server. Given that TCP and CoAP both guarantee reliability, a reliability measurement of less than 100% is caused by overflow of the application-layer queue due to poor network conditions preventing data from being reliably communicated as fast as they are generated. Generating data more slowly would result in higher reliability.

8.2.1 Performance in Favorable Conditions

We begin with experiments in our testbed at night, when there is less wireless interference. We compare three setups: (1) CoAP, (2) CoCoA, and (3) *TCPlp*. We also compare two sending scenarios: (1) sending each sensor reading right away ("No Batching"), and (2) sending sensor readings in batches of 64 ("Batching") [89]. We ensure that packets in a CoAP batch are the same size as segments in TCP (five frames).

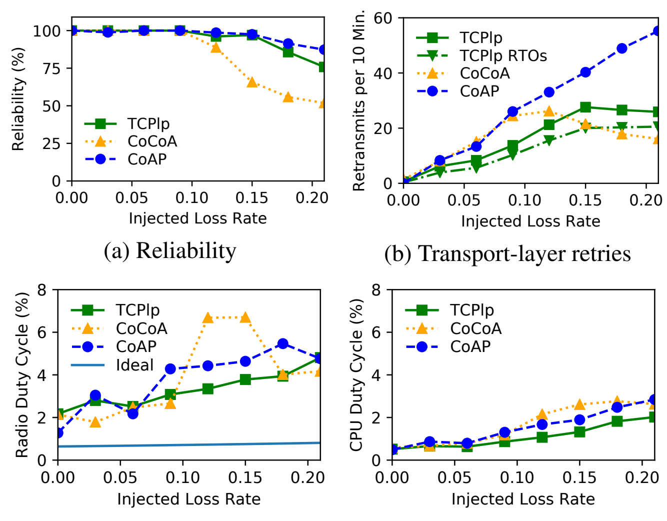
All setups achieved 100% reliability due to end-to-end acknowledgments (figures are omitted for brevity). Figures 9a and 9b also show that all the three protocols consume similar power; *TCP is comparable to LLN-specific solutions*.

Both the radio and CPU duty cycle are significantly smaller with batching than without batching. By sending data in batches, nodes can amortize the cost of sending data and waiting for a response. Thus, batching is the more realistic workload, so we use it to continue our evaluation.

8.2.2 Resilience to Packet Loss

In this section, we inject uniformly random packet loss at the border router and measure each solution.The result is shown in Figure 10. Note that the injected loss rate corresponds to the *packet-level* loss rate *after* link retries and 6LoWPAN reassembly. Although we plot loss rates up to 21%, *we consider loss rates > 15% exceptional; we focus on the loss rate up to 15%*. A number of WSN studies have already achieved > 90% end-to-end packet delivery, using only link/routing layer techniques (not transport) [46, 84, 85]. In our testbed environment, we have not observed the loss rate exceed 15% for an extended time, even with wireless interference.

[8] 100 ms is comparable to ContikiMAC's default sleep interval of 125 ms.



(a) Reliability (b) Transport-layer retries

(c) Radio duty cycle (d) CPU duty cycle

Figure 10: Performance with injected packet loss

Both CoAP and TCP achieve nearly 100% reliability at packet loss rates less than 15%, as shown in Figure 10a. At loss rates greater than 9%, CoCoA performs poorly. The reason is that CoCoA attempts to measure RTT for retransmitted packets, and conservatively calculates the RTT relative to the first transmission. This results in an inflated RTT value that causes CoCoA to delay longer before retransmitting, causing the application-layer queue to overflow. Full-scale TCP is immune to this problem despite measuring the RTT, because the TCP timestamp option allows TCP to unambiguously determine the RTT even for retransmitted segments.

Figures 10c and 10d show that, overall, **TCP and CoAP perform comparably in terms of radio and CPU duty cycle**. At 0% injected loss, *TCPlp* has a slightly higher duty cycle, consistent with Figure 9. At moderate packet loss, *TCPlp* appears to have a slightly lower duty cycle. This may be due to TCP's sliding window, which allows it to tolerate some ACK losses without retries. Additionally, Figure 10b shows that, although most of TCP's retransmissions are explained by timeouts, a significant portion were triggered in other ways (e.g., duplicate ACKs). In contrast, CoAP and CoCoA rely exclusively on timeouts, which has intrinsic limitations [143].

With exceptionally high packet loss rates (>15%), CoAP achieves higher reliability than TCP, because it "gives up" after just 4 retries; it exponentially increases the wait time between those retries, but then resets its RTO to 3 seconds when giving up and moving to the next packet. In contrast, TCP performs up to 12 retries with exponential backoff. Thus, TCP backs off further than CoAP upon consecutive packet losses, witnessed by the smaller retransmission count in Figure 10b, causing the application-layer queue to overflow more. This performance gap could be filled by parameter tuning.

We also consider an *ideal* "roofline" protocol to calculate a fairly loose lower bound on the duty cycle. This ideal protocol has the same header overhead as TCP, but learns which

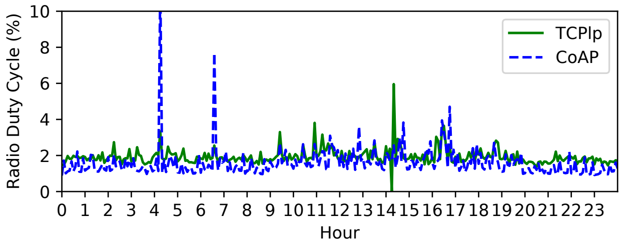


Figure 11: Radio duty cycle of TCP and CoAP in a lossy wireless environment, in one representative trial (losses are caused by natural human activity)

packets were lost for "free," without using ACKs or running MMC. Thus, it turns on its radio only to send out data and retransmit lost packets. The real protocols have much higher duty cycles than the ideal protocol would have (Figure 10c), suggesting that a significant amount of their overhead stems from determining which packets were lost—polling the parent node for downstream TCP ACKs/CoAP responses. This gap could be reduced by improving OpenThread's MMC protocol. For example, rather than using a fixed sleep interval of 100 ms when an ACK is expected, one could use exponential backoff to increase the sleep interval if an ACK is not quickly received. We leave exploring such ideas to future work.

8.2.3 Performance in Lossy Conditions

We compare the protocols over the course of a full day in our testbed, to study the impact of real wireless interference associated with human activity in an office. We focus on *TCPlp* and CoAP since they were the most promising protocols from the previous experiment. To ensure that *TCPlp* and CoAP are subject to similar interference patterns, we (1) run them simultaneously, and (2) hardcode adjacent *TCPlp* and CoAP nodes to have the same first hop in the multihop topology.

Improving Queue Management. OpenThread's queue management interacts poorly with TCP in the presence of interference. When a duty-cycled leaf node sends a data request message to its parent, it turns its radio on and listens until it receives a reply (called an "indirect message"). In OpenThread, the parent finishes sending its current frame (which may require link retries in the presence of interference), and then sends the indirect message. The duty-cycled leaf node keeps its radio on during this time, causing its radio duty cycle to increase. This is particularly bad for TCP, as its sliding window makes it more likely for the parent node to be in the middle of sending a frame when it receives a data request packet from a leaf node. Thus, **we modified OpenThread to allow indirect messages to preempt the current frame *in between link-layer retries***, to minimize the time that duty-cycled leaf nodes must wait for a reply with their radios on. Both TCP and CoAP benefitted from this; TCP benefitted more because it suffered more from the problem to begin with.

Power Consumption. To improve power consumption for both TCP and CoAP, we adjusted parameters according to the lossy environment: (1) we enabled link-layer retries for indirect messages, (2) we decreased the data request timeout and performed link-layer retries more rapidly for indirect messages, to deliver them to leaves more quickly, and (3) given the high level of daytime interference, we decreased the MSS from five frames to three frames (as in §8).

Protocol	Reliability	Radio DC	CPU DC
TCPlp	99.3%	2.29%	0.973%
CoAP	99.5%	1.84%	0.834%
Unrel., no batch	93.4%	1.13%	0.52%
Unrel., with batch	95.3%	0.734%	0.30%

Table 7: Performance in the testbed over a full day, averaged over multiple trials. The ideal protocol (§8.2.2) would have a radio DC of ≈ 0.63%–0.70% under similarly lossy conditions.

Figure 11 depicts the radio duty cycle of TCP and CoAP for a trial representative of our overall results. **CoAP maintains a lower duty cycle than *TCPlp* outside of working hours, when there is less interference; *TCPlp* has a slightly lower duty cycle than CoAP during working hours, when there is more wireless interference.** *TCPlp*'s better performance at a higher loss rate is consistent with our results from §8.2.2. At a lower packet loss rate, TCP performs slightly worse than CoAP. This could be due to hidden terminal losses; more retries, on average, are required for indirect messages for TCP, causing leaf nodes to stay awake longer. Overall, CoAP and *TCPlp* perform similarly (Table 7).

8.2.4 Unreliable UDP

As a point of comparison, we repeat the sense-and-send experiment using a UDP-based protocol that *does not provide reliability*. Concretely, we run CoAP in "nonconfirmable" mode, in which it does not use transport-layer ACKs or retransmissions. The result is in the last two rows of Table 7. Compared to unreliable UDP, reliable approaches increase the radio/CPU duty cycle by 3x, in exchange for nearly 100% reliability. That said, the corresponding decrease in battery life will be *less* than 3x, because other sources of power consumption (reading from sensors, idle current) are also significant.

For other sense-and-send applications that sample at a lower rate, TCP and CoAP would see higher reliability (less application queue loss), but UDP would not similarly benefit (no application queue). Furthermore, the power consumption of TCP, CoAP, and unreliable UDP would all be closer together, given that the radio and CPU spend more time idle.

8.3 Event Detection Application Scenario

Finally, we consider an application scenario where multiple flows compete for available bandwidth in an LLN. One such scenario is event detection: sensors wait until an interesting event occurs, at which point they report data upstream at a high data rate. Because such events tend to be correlated, multiple sensors send data simultaneously.

Nodes 12-15 in our testbed simultaneously transmit data to the EC2 instance (Figure 1), which measures the goodput

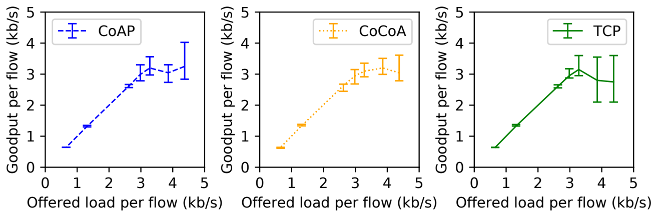

Figure 12: CoAP, CoCoA, and TCP with four competing flows

of each flow. We use the same duty-cycling policy as in §8.2. We divide each flow into 40-second intervals, measure the goodput in each interval, and compute the median and quartiles of goodput across all flows and intervals. The median gives a sense of aggregate goodput, and the quartiles gives a sense of fairness (quartiles close to the median are better).

Figure 12 shows the median and quartiles (as error bars) as the offered load increases. For small offered load, the per-flow goodput increases linearly. Once the aggregate load saturates the network, goodput declines slightly and the interquartile range increases, due to inefficiences in independent flows competing for bandwidth. **Overall, TCP performs similarly to CoAP and CoCoA, indicating that TCP's congestion control remains effective despite our observations in §7.3 that it behaves differently in LLNs.**

9 Conclusion

TCP is the *de facto* reliability protocol in the Internet. Over the past 40 years, new physical-, datalink-, and application-layer protocols have evolved alongside TCP, and supporting good TCP performance was a consideration in their design. TCP is the obvious performance baseline for new transport-layer proposals. To warrant adoption, novel transports must be *much* better than TCP in the intended application domain.

In contrast, when LLN research flourished two decades ago, LLN hardware could not run full-scale TCP. The original system architecture for networked sensors [68], for example, targeted an 8-bit MCU with only 512 *bytes* of memory. It naturally became taken for granted that TCP is too heavy for LLNs. Furthermore, contemporary research on TCP in WLANs [27] suggested that TCP would perform poorly in LLNs even if the resource constraints were surmounted.

In revisiting the TCP question, after the resource constraints relaxed, we find that the expected pitfalls of wireless TCP actually do not carry over to LLNs. Although naïve TCP indeed performs poorly in LLNs, this is not due to fundamental problems with TCP as were observed in WLANs. Rather, it is caused by incompatibilities with a low-power link layer, which likely arose because canonical LLN protocols were developed in the absence of TCP considerations. We show how to fix these incompatibilities while preserving seamless interoperability with other TCP/IP networks. This enables a viable TCP-based transport architecture for LLNs.

Our results have several implications for LLNs moving forward. First, **the use of lightweight protocols that emulate part of TCP's functionality, like CoAP, needs to be reconsidered.** Protocol stacks like OpenThread should support full-scale TCP as an option. TCP should also serve as a benchmark to assess new LLN transport proposals.

Second, **full-scale TCP will influence the design of networked systems using LLNs.** Such systems are presently designed with application-layer gateways in mind (§3). Using TCP/IP in the LLN itself would allow the use of commodity network management tools, like firewalls and NIDS. TCP would also allow the application-layer gateway to be replaced with a network-layer router, allowing clients to interact with LLN applications in much the same way as a Wi-Fi router allows users to interact with web applications. This is much more flexible than the status quo, where each LLN application needs application-specific functionality to be installed at the gateway [141]. In cases where a new LLN transport protocol is truly necessary, the new protocol may be wise to consider the byte-stream *abstraction* of TCP. This would allow the application-layer gateway to be replaced by a *transport-layer gateway*. The mere presence of a transport layer, distinct from the application layer, goes a long way to providing interoperability with the rest of the Internet.

Third, **UDP-based protocols will still have a place in LLNs, just as they have a place in the Internet.** UDP is used for applications that benefit from greater control of segment transmission and loss response than TCP provides. These are typically real-time or multimedia applications where losing information is preferable to late delivery. It is entirely seemly for some sensing applications in LLNs, particularly those with similar real-time constraints, to transfer data using UDP-based protocols, even if TCP is an option. But TCP *still* benefits such applications by providing a reliable channel for control information. For example, TCP may be used for device configuration, or to provide a shell for debugging, without yet another reliability protocol.

In summary, LLN-class devices are ready to become first-class citizens of the Internet. To this end, we believe that TCP should have a place in the LLN architecture moving forward, and that it will help put the "I" in IoT for LLN-class devices.

Acknowledgments

We thank the anonymous reviewers, including in prior submissions, and our shepherd, Keith Winstein, for their invaluable feedback. We are thankful to researchers in the BETS research group, including Kaifei Chen, Gabe Fierro, and Jack Kolb, for their feedback on early drafts of this paper, and to Prabal Dutta and Sylvia Ratnasamy for their advice and discussion. We also thank Albert Goto for his help with the LLN testbed.

A Impact of Network Stack Design

As mentioned in §5, we made nontrivial modifications to FreeBSD's TCP stack to port it to each embedded operating system and embedded network stack. Below we provide additional information about these changes, and about our implementations for platforms other than Hamilton/OpenThread.

A.1 Concurrency Model

GNRC and OpenThread (RIOT OS). RIOT OS provides threads as the basic unit of concurrency. Asynchronous interaction with hardware is done by interrupt handlers that preempt the current thread, perform a short operation in the interrupt context, and signal a related thread to perform any remaining operation outside of interrupt context. Then the thread is placed on the RIOT OS scheduler queue and is scheduled for execution depending on its priority.

The GNRC network stack for RIOT OS runs each network layer (or module) in a separate thread. Each thread has a priority and can be preempted by a thread with higher priority or by an interrupt. The thread for a lower network layer has higher priority than the thread for a higher layer.

The port of OpenThread for RIOT OS handles received packets in one thread and sends packets from another thread, where the thread for received packets has higher priority [83]. The rationale for this design is to ensure timely processing of received packets at the radio, which is especially important in the context of a high-throughput flow.

To adapt *TCPlp* for GNRC, we run the FreeBSD implementation as a single TCP-layer thread, whose priority is between that of the application-layer thread and the IPv6-layer thread. To adapt *TCPlp* for OpenThread on RIOT OS, we call the TCP protocol logic (`tcp_input()`) at the appropriate point along the receive path, and send packets from the TCP protocol logic (`tcp_output()`) using the established send path. As explained in Appendix A.2, we also use an additional thread for timer callbacks in RIOT OS.

Given that TCP state can be accessed concurrently from multiple threads—the TCP thread (GNRC) or receive thread (OpenThread), the application thread(s), and timer callbacks—we needed to synchronize access to it. The FreeBSD implementation allows fine-grained locking of connection state to allow different connections to be serviced in parallel on different CPUs. Given that low-power embedded sensors typically have only one CPU, however, we opted for simplicity, instead using a single global TCP lock for *TCPlp*.

BLIP (TinyOS). TinyOS uses an event-driven concurrency model based on split-phase operations, consisting of an event loop that executes on a *single* stack. For concurrency, TinyOS provides three types of unique operations: *commands* and *events*, which are executed immediately, and *tasks*, which are scheduled for execution after all preceding tasks are completed. An interrupt handler may preempt the current function, perform a short operation in the interrupt context using *asynchronous* events and commands, and *post* a task to perform any remaining computation later. To adapt the thread-based FreeBSD implementation to the event-driven TinyOS, we execute the primary functions of FreeBSD, such as `tcp_output()` and `tcp_input()`, within *tasks* outside of interrupt context. Because tasks in TinyOS cannot preempt each other, we remove the locking present in the FreeBSD TCP implementation.

A.2 Timer Event Management

Given that many TCP operations are based on timer events, achieving correct timer operation is important. For example, if an RTO timer event is dropped by the embedded operating system, the RTO timer will not be rescheduled, and the connection may hang.

For a simple and stable operation, many existing embedded TCP stacks, including the uIP, lwIP, and BLIP TCP stacks, rely on a periodic, fixed-interval clock in order to check for expired timeouts. Instead, *TCPlp* uses one-shot tickless timers as FreeBSD 10.3 does [74], which is beneficial in two ways: (1) When there are no scheduled timers, the tickless timers allow the CPU to sleep, rather than being needlessly woken up at a fixed interval, resulting in lower energy consumption [83]. (2) Unlike fixed periodic timers, which can only be serviced on the next tick after they expire, tickless timers can be serviced as soon as they expire. To obtain these advantages, however, an embedded operating system must robustly manage asynchronous timer callbacks.

TinyOS has a single event queue maintained by the scheduler. The semantics of TinyOS guarantee that a task can exist in the event queue only once, even if it is *posted* (i.e., scheduled for execution) multiple times before executing. Therefore, the event queue can be sized appropriately at compile-time to not overflow. Furthermore, TinyOS handles received packets in a separate queue than tasks. This ensures that TCP

	Protocol	Event Sched.	User Library
ROM	21352 B	1696 B	5384 B
RAM (Active)	488 B	40 B	36 B
RAM (Passive)	16 B	16 B	36 B

Table 8: Memory usage of *TCPlp* on TinyOS. Our implementation of *TCPlp* spans three modules: (1) protocol implementation, (2) event scheduler that injects callbacks into userspace, and (3) userland library.

timer callbacks will not be dropped.

This is not the case for RIOT OS. Timer callbacks either handle the timer entirely in interrupt context, or put an event on a thread's message queue, so that the thread performs the required callback operation. Each network protocol supported by RIOT OS has a single thread. Because a thread's message queue in RIOT OS is used to hold both received packets and timer events, there is no guarantee when a timer expires that there is enough space in the thread message queue to accept a timer event; if there is not enough space, RIOT OS drops the timer event. Furthermore, if a timer expires multiple times before its event is handled by the thread, multiple events for the same timer can exist simultaneously in the queue; *we cannot find an upper bound on the number of slots in the message queue used by a single timer*. To provide robust TCP operation on RIOT OS, we create a second thread used exclusively for TCP timers. We handle timers similarly to TinyOS' *post* operation, by preventing the message queue from having multiple callback events of a single timer. This eliminates the possibility of timer event drops.

A.3 Memory Usage: Connection State

To complement Table 3, which shows *TCPlp*'s memory footprint on RIOT OS, we include Table 8, which shows *TCPlp*'s memory footprint on TinyOS.

A.4 Performance Comparison

We consider TCP goodput between two embedded nodes over the IEEE 802.15.4 link, over a single hop without any border router, as we did in §6.3. We are able to produce a 63 kb/s goodput over a TCP connection between two Hamilton motes using RIOT's GNRC network stack. For comparison, we are able to achieve 71 kb/s using the BLIP stack on Firestorm, and 75 kb/s using the OpenThread network stack with RIOT OS on Hamilton. **This suggests that our results are reproducible across multiple platforms and embedded network stacks.** The minor performance degradation in GNRC is partially explained by its greater header overhead due to implementation differences, and by its IPC-based thread-per-layer concurrency architecture, which has known inefficiencies [36]. This suggests that the implementation of the underlying network stack, particularly with regard to concurrency, could affect TCP performance in LLNs.

	uIP	BLIP	GNRC	*TCPlp*
Flow Control	Yes	Yes	Yes	Yes
Congestion Control	N/A	No	Yes	Yes
RTT Estimation	Yes	No	Yes	Yes
MSS Option	Yes	No	Yes	Yes
OOO Reassembly	No	No	Yes	Yes
TCP Timestamps	No	No	No	Yes
Selective ACKs	No	No	No	Yes
Delayed ACKs	No	No	No	Yes

Table 9: Comparison of core features among embedded TCP stacks: uIP (Contiki), BLIP (TinyOS), GNRC (RIOT), and *TCPlp (this paper)*

B Comparison of Features in Embedded TCP Implementations

Table 9 compares the featureset of *TCPlp* to features in embedded TCP stacks. The TCP implementations in uIP and BLIP lack features core to TCP. uIP allows only one unACKed in-flight segment, eschewing TCP's sliding window. BLIP does not implement RTT estimation or congestion control. The TCP implementation in GNRC lacks features such as TCP timestamps, selective ACKs, and delayed ACKs, which are present in most full-scale TCP implementations.

Benefits of full-scale TCP. In addition to supporting the protocol-level features summarized in Table 9, *TCPlp* is likely more robust than other embedded TCP stacks because it is based on a well-tested TCP implementation. While seemingly minor, some details, implemented incorrectly by TCP stacks, have had important consequences for TCP's behavior [111]. *TCPlp* benefits from a thorough implementation of each aspect of TCP.

For example, *TCPlp*, by virtue of using the FreeBSD TCP implementation, benefits from a robust implementation of congestion control. *TCPlp* implements not only the basic New Reno algorithm, but also Explicit Congestion Notification [52], Appropriate Byte Counting [12, 13] and Limited Transmissions [14]. It also inherits from FreeBSD heuristics to identify and correct "bad retransmissions" (as in §2.8 of [16]): if, after a retransmission, the corresponding ACK is received very soon (within $\frac{\text{RTT}}{2}$ of the retransmission), the ACK is assumed to correspond to the originally transmitted segment as opposed to the retransmission. The FreeBSD implementation and *TCPlp* recover from such "bad retransmissions" by restoring `cwnd` and `ssthresh` to their former values before the packet loss. Aside from congestion control, *TCPlp* benefits from header prediction [37], which introduces a "fast code path" to process common-case TCP segments (in-sequence data and ACKs) more efficiently, and Challenge ACKs [116], which make it more difficult for an attacker to inject an RST into a TCP connection.

Enhancements such as these make us more confident that our observed results are fundamental to TCP, as opposed to artifacts of poor implementation. Furthermore, they allow us to focus on performance problems arising from the challenges of LLNs, as opposed to general TCP-related challenges that the research community has already solved in the context of traditional networks and operating systems.

C Derivation of TCP Model

This appendix provides the derivation of Equation 1, the model of TCP performance proposed in §7.4.

We think of a TCP flow as a sequence of bursts. A *burst* is a sequence of full windows of data successfully transferred, which ends in a packet loss. After this loss, the flow spends some time recovering from the packet loss, which we call a *rest*. Then, the next burst begins. Let w be the size of TCP's flow window, measured in segments (for our experiments in §7.3, we would have $w = 4$). Define b as the average number of windows sent in a burst. The goodput of TCP is the number of bytes sent in each burst, which is $w \cdot b \cdot \mathrm{MSS}$, divided by the duration of each burst. A burst lasts for the time to transmit b windows of data, plus the time to recover from the packet loss that ended the burst. The time to transmit b windows is $b \cdot \mathrm{RTT}$. We define t_{rec} to be the time to recover from the packet loss. Then we have

$$B = \frac{w \cdot b \cdot \mathrm{MSS}}{b \cdot \mathrm{RTT} + t_{\mathrm{rec}}}. \tag{3}$$

The value of b depends on the packet loss rate. We define a new variable, p_{win}, which denotes the probability that at least one packet in a window is lost. Then $b = \frac{1}{p_{\mathrm{win}}}$.

To complete the model, we must estimate t_{rec} and p_{win}.

The value of t_{rec} depends on whether the retransmission timer expires (called an RTO) or a fast retransmission is performed. If an RTO occurs, the total time lost is the excess time budgeted to the retransmit timer beyond one RTT, plus the time to retransmit the lost segments. We denote the time budgeted to the retransmit timer as ETO. So the total time lost due to a timeout, assuming it takes about 2 RTTs to recover lost segments, would be $(\mathrm{ETO} - \mathrm{RTT}) + 2 \cdot \mathrm{RTT} = \mathrm{ETO} + \mathrm{RTT}$. After a fast retransmission, TCP enters a "fast recovery" state [17, 66]. Fast recovery requires buffer space to be effective, however. In particular, if the buffer contains only four TCP segments, then the lost packet, and three packets afterward which resulted in duplicate ACKs, account for the entire send buffer; therefore, TCP cannot send new data during fast recovery, and instead stalls for one RTT, until the ACK for the fast retransmission is received. In contrast, choosing a larger send buffer will allow fast recovery to more effectively mask this loss [122].

As discussed in §7.3, these two types of losses may be caused by different factors. Therefore, we do not attempt to distinguish them on basis of probability. Instead, we use a very simple model: $t_{\mathrm{rec}} = \ell \cdot \mathrm{RTT}$. The constant ℓ can be chosen to describe the number of "productive" RTTs lost due to a packet loss. Based on the estimates above, choosing $\ell = 2$ seems reasonable for our experiments in §7 which used a buffer size of four segments.

To model p_{win}, we assume that, in each window, segment losses are independent. This gives us $p_{\mathrm{win}} = 1 - (1-p)^w$, where p is the probability of an individual segment being lost (after link retries). Because p is likely to be small (less than 20%), we apply the approximation that $(1-x)^a \approx 1 - ax$ for small x. This gives us $p_{\mathrm{win}} \approx wp$.

Applying these equations for t_{rec} and p_{win}, along with some minor algebraic manipulation to put our equation in a similar form to Equation 2, we obtain our model for TCP performance in LLNs, for small w and p:

$$B = \frac{\mathrm{MSS}}{\mathrm{RTT}} \cdot \frac{1}{\frac{1}{w} + \ell p} \tag{4}$$

Equation 1, stated in §7.4, takes $\ell = 2$, as discussed above.

Generalizing the model. In §8, we generally use a smaller MSS (3 frames) than we used in §7. Furthermore, duty-cycling increases the RTT. It is natural to ask whether our conclusions in §7, on which the model is based, still hold in this setting. With a sleep interval of 100 ms, we qualitatively observed that, although `cwnd` tends to recover more slowly after loss, due to the smaller MSS and larger RTT, it is still "maxed out" past the BDP most of the time. Therefore, we expect our conclusion, that TCP is more resilient to packet loss, to also apply in this setting.

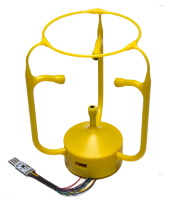
One may consider adapting our model for this setting by choosing a larger value of ℓ to reflect the fact that `cwnd` recovers from loss less quickly due to the smaller MSS. It is possible, however, that one could derive a better model by explicitly modeling the phase when `cwnd` is recovering, similar to other existing TCP models (in contrast to our model above, where we assume that the TCP flow is binary—either transmitting at a full window, or in backoff after loss). We leave exploration of this idea to future work.

D Anemometry: An LLN Application

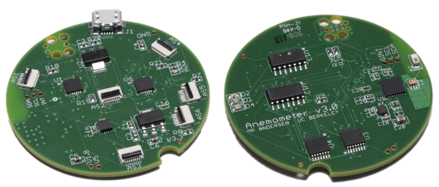
An *anemometer* is a sensor that measures air velocity. Anemometers may be deployed in a building to diagnose problems with the Heating, Ventilation, and Cooling system (HVAC), and also to collect air flow measurements for improved HVAC control. This requires anemometers in difficult-to-reach locations, such as in air flow ducts, where it is infeasible to run wires. Therefore, anemometers must be battery-powered and must transmit readings wirelessly, making LLNs attractive.

We used anemometers based on the Hamilton platform [19], each consisting of four ultrasonic transceivers arranged as vertices of a tetrahedron (Figure 13). To measure the air velocity, each transceiver, in turn, emits a burst of ultrasound, and the impulse is measured by the other three transceivers. This process results in a total of 12 measurements.

Calculating the air velocity from these measurements is computationally infeasible on the anemometer itself, because Hamilton does not have hardware floating point support and the computations require complex trigonometry. Measurements must be transmitted over the network to a server that



(a) Anemometer



(b) Hamilton-based PCB (bottom and top)

Figure 13: Hamilton-based ultrasonic anemometer

processes the data. Furthermore, a specific property of the analytics is that it requires a contiguous stream of data to maintain calibration (a numerical integration is performed on the measurements). Thus, the application requires a high sample rate (1 Hz), and is sensitive to data loss. A protocol for *reliable* delivery, like TCP or CoAP, is therefore necessary.

We note that the 1 Hz sample rate for this application is much higher than the sample rate of most sensors deployed in buildings. For example, a sensor measuring temperature, humidity, or occupancy in a building typically only generates a single reading every few tens of seconds or every few minutes. Furthermore, each individual reading from the anemometer is quite large (82 bytes), given that it encodes all 12 measurements (plus a small header). Given the higher data rate requirements of the anemometer application, we plan to use a higher-capacity battery than the standard AA batteries used in most motes. The higher cost of such a battery is justified by the higher cost of the anemometer transducers.

Comb Decoding towards Collision-Free WiFi

Shangqing Zhao, Zhe Qu, Zhengping Luo, Zhuo Lu, Yao Liu
University of South Florida, Tampa FL 33620.

Abstract

Packet collisions happen every day in WiFi networks. RTS/CTS is a widely-used approach to reduce the cost of collisions of long data packets as well as combat the hidden terminal problem. In this paper, we present a new design called comb decoding (CombDec) to efficiently resolve RTS collisions without changing the 802.11 standard. We observe that an RTS payload, when treated as a vector in a vector space, exhibits a comb-like distribution; i.e., a limited number of vectors are much more likely to be used than the others due to RTS payload construction and firmware design. This enables us to reformulate RTS collision resolution as a sparse recovery problem. We create algorithms that carefully construct the search range for sparse recovery, making the complexity feasible for system design and implementation. Experimental results show that CombDec boosts the WiFi throughput by 33.6% – 46.2% in various evaluation scenarios.

1 Introduction

CSMA/CA is fundamental for WiFi to coordinate multiple nodes to access the wireless channel. RTS/CTS is a widely-used mechanism in WiFi, which uses short RTS packets for fast collision inference, transmission path check as well as combating the hidden terminal problem [5]. In many early WiFi products, RTS/CTS was disabled due to the concern of overhead [32]. With the substantial increase of data demand in recent years, WiFi data packets become longer and longer, and today's WiFi devices send an RTS packet when the size of a data packet exceeds a given threshold. The threshold is usually set to around 2,300 bytes [1, 4, 6, 7, 9] to balance the performance and the overhead. RTS/CTS is also used in advanced WiFi functionalities, such as beamforming and MU-MIMO [5]. In addition, global RTS/CTS [41, 45, 64] has also been proposed for cross-technology communications.

The essence in the RTS/CTS mechanism is to trade a small cost of the RTS collision for a potentially large cost of data collision. In this paper, we revisit the RTS collision problem and present the comb decoding (CombDec) system to resolve RTS collisions without changing the 802.11 standard and thus improve the wireless channel utilization as well as the network throughput.

The observation behind designing CombDec is that the data payload of an RTS packet, when treated as a vector in a vector space, exhibits a comb-like distribution. Specifically, the RTS content consists of 160 bits, which leads to 2^{160} possibilities. We find that the standard-structured data fields in RTS actually result in at most around 2^{21} possible contents in today's WiFi networks. Therefore, the probability distribution of such contents will exhibit a comb-like shape: only up to 2^{21} out of 2^{160} contents having non-zero probabilities.

As a result, we reformulate the RTS collision problem as a weighted sum problem: we consider the received signal due to an RTS collision is the sum of all 2^{21} RTS contents transmitted at the same time, but with different channel weights. An RTS content has a non-zero channel weight if it is actually transmitted, and zero weight otherwise. Then, resolving the collision is equivalent to solving for the channel weight for each RTS content. The key observation to solve the problem is that a vast majority of the 2^{21} channel weights should be zeros because a collision involves only a few RTS packets in a real-world network. In other words, the vector that includes all channel weights is sparse, which opens a path to use sparse recovery [18, 19, 47] to resolve RTS collisions.

One significantly challenging issue around collision resolution based on sparse recovery is the computational complexity because we start from around 2^{21} possibilities of RTS signals to resolve a collision. To cope with this issue, we analyze how a key RTS data field, `Duration` (that specifies the time duration an RTS packet reserves), is constructed in state-of-the-art 802.11 firmware. A comprehensive set of 802.11ac packet traces are also collected to understand the distribution of `Duration` in various scenarios. It is found that today's firmware imposes extra restrictions on `Duration` and is biased towards a limited number of value selections, and the distribution of `Duration` in real-world packets is highly uneven and patterned. Based on this observation, CombDec is designed with two key components: (α, β)-construction and γ-decimation, which adaptively narrow down the search range in sparse recovery to a set of only hundreds of potential RTS signals, making system design of collision resolution practical for WiFi networks.

We implement CombDec in a 20-node network testbed, and evaluate it in different scenarios. Experimental results demonstrate that our design has both direct and indirect impacts on today's WiFi systems and setups.

Direct Impact: Today's WiFi devices usually adopt a conservative RTS threshold (i.e., around 2300 bytes), which results in 30% - 45% data transmissions initiated by RTS (according to our packet trace collection and analysis). By directly using CombDec with current RTS settings, we find via experiments that CombDec is able to decode 98% of two-RTS collisions and improve the network throughput by up to 23.3%.

Indirect Impact: CombDec offers a new capability of decoding RTS collisions and in fact encourages changing today's WiFi setups for more RTS transmissions. Therefore, by reducing the RTS threshold to zero and letting every device always send RTS before data (indicating that most collisions in the network become RTS collisions), CombDec significantly improves the network throughput by up to 46.6% in experimental evaluations.

The design of CombDec is the first systematic work towards resolving RTS collisions in WiFi networks. It is non-invasive and redefines the role of the RTS functionality and pushes WiFi towards a collision-free environment.

2 Motivation and Design Intuition

In this section, we introduce the motivation and key idea of reformulating the problem of packet collisions.

2.1 Packet Collision and Resolution

We use a noise-free, flat-fading uplink scenario as a simple motivating example: Alice and Bob send their packets to the AP at the same time. Alice's and Bob's packets consist of L time-domain baseband symbols, represented by vectors[1] $\mathbf{x}_A \in \mathcal{X}$ and $\mathbf{x}_B \in \mathcal{X}$, respectively, where $\mathcal{X} \subset \mathbb{C}^{L\times 1}$ denotes the set of all possible baseband symbol vector for $\mathbf{x}_A$ and $\mathbf{x}_B$, and $\mathbb{C}^{L\times 1}$ is the L-dimensional complex vector space.

Then, the received signal at the AP can be written as

$$\mathbf{y} = h_A\mathbf{x}_A + h_B\mathbf{x}_B, \tag{1}$$

where $h_A, h_B \in \mathbb{C}$ ($\mathbb{C}$ denotes the complex plane) are the channel gains from Alice and Bob to the AP, respectively.

If we look at the collision (1) and assume that Alice's and Bob's signals go through similar channel conditions to the AP, Alice's or Bob's signal will have an SNR around 0dB due to mutual interference. Simply given (1), the AP is less likely to recover Alice's or Bob's signal due to two major reasons.

- If the AP adopts a traditional decoding design, it cannot decode a signal with SNR around 0dB, because an acceptable SNR is usually 10dB or above [29] for WiFi.
- Although multi-user detection [59] has been developed as a vital solution to decode multiple user's signals, this technique in general requires that users employ distinct spread spectrum codes [60] to differentiate themselves at the signal level. Nonetheless, there is no such code design in WiFi.

Apparently, additional information is needed to resolve the collision (1). Our key observation is that the RTS packet format itself provides valuable information for collision resolution in a WiFi network.

2.2 Anatomy of RTS in WiFi

The RTS/CTS mechanism lets a sender reserve the channel by sending an RTS packet first. Once the receiver replies with a CTS packet, the sender transmits the data packet. The RTS packet specifies a network allocation vector (NAV), which is the total time duration it wants to reserve, including the time durations of the CTS, the data and the ACK.

The data payload in an RTS packet consists of 20 bytes or 160 bits, and we denote it as an RTS data vector $\mathbf{b} \in [0,1]^{160}$, where $[0,1]^{160}$ is the space for all vectors with length 160, whose element is either 0 or 1. At the PHY layer, the data vector $\mathbf{b}$ is interleaved, coded and modulated into a signal vector $\mathbf{x} \in \mathcal{X}$, where $\mathcal{X}$ is the set of all values of $\mathbf{x}$. These processes together can be denoted as a one-to-one function mapping $f : [0,1]^{160} \to \mathcal{X}$, which converts the RTS data vector $\mathbf{b}$ to the RTS signal vector $\mathbf{x} = f(\mathbf{b})$. As f is one-to-one correspondence, $|\mathcal{X}| = 2^{160}$ ($|\cdot|$ denotes the cardinality, or the number of elements, of a set).

We observe that all RTS data vectors in $[0,1]^{160}$ are not equally probable in the real world because all data fields in RTS are well structured and specified.

- `FrameControl` contains 2 bytes specified in 802.11.
- `Duration` is the 2-byte NAV in microseconds. The last bit is set to 0 and thus it holds up to 2^{15} values.
- `RA` and `TA` (6 bytes each) are the destination and source addresses, respectively. As today's WiFi is widely used for Internet access, stations communicate mostly with the AP. The AP knows that `RA` in an RTS packet sent to it is its own address and `TA` should be the address of one of its stations. Suppose that a dense network can support 2^6 stations (e.g., Linksys EA8500 firmware supports up to 51 stations [11]) and the number of possible values of `TA` in RTS is 2^6.
- `FCS` (4 bytes) is for error detection and relies on other data fields. It provides no additional information.

Thus, from the AP's perspective, the number of RTS data vectors of interest is 2^{15} (from `Duration`) $\times$ 2^6 (from `RA`/`TA`) = 2^{21} in the full RTS vector space $[0,1]^{160}$. As a result, the

[1]Throughout this paper, a vector is by default a column vector instead of a row vector, unless otherwise specified.

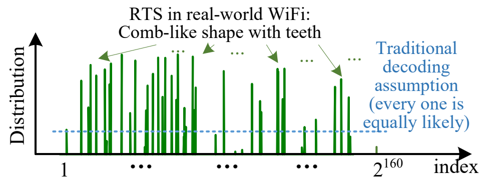


Figure 1: Example: distribution of RTS signal vectors.

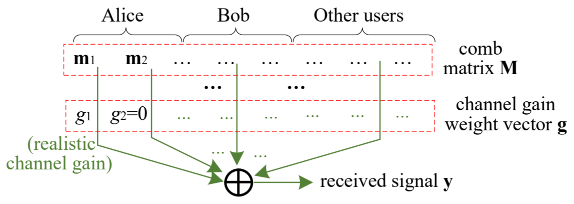

Figure 2: Reformulation of network collision.

number of RTS signal vectors of interest is also 2^{21} in the signal vector space $\mathcal{X}$ with $|\mathcal{X}| = 2^{160}$. If we index all vectors in $\mathcal{X}$ from 1 to 2^{160} and measure via the probability distribution how each vector is likely to be seen in the real world, we will obtain a comb-shaped distribution similar to the example shown in Figure 1. We call an RTS signal vector a *tooth vector* if the probability that it can be seen at the AP is positive. Although the index goes from 1 to 2^{160} in Figure 1, the number of tooth vectors should be no less than 2^{21} according to our analysis. The comb-shaped distribution is in evident contrast to the traditional decoding assumption (also illustrated in Figure 1) that all potential values of a signal vector are equally probable [31]. This opens a door for us to go beyond traditional decoding to resolve RTS collisions.

2.3 Idea of Collision Resolution

Based on the observation from Figure 1, we present the basic idea regarding how to resolve an RTS collision.

2.3.1 Problem Reformulation

Denote by $\mathcal{M} = \{\mathbf{m}_i\}_{i\in[1,M]}$ ($M = |\mathcal{M}|$) the set of tooth vectors. Define the comb matrix $\mathbf{M} = [\mathbf{m}_1, \mathbf{m}_2, \cdots, \mathbf{m}_M]$ (i.e., each column in $\mathbf{M}$ is a tooth vector). The AP can preconstruct the comb matrix $\mathbf{M}$ by inserting all possible RTS to $\mathbf{M}$ to form the columns. The AP's goal is to find exactly which ones in $\mathbf{M}$ are actually involved in the collision.

Mathematically, we reformulate the collision problem to an equivalent one: assume that all tooth vectors in $\mathbf{M}$ are transmitted to the AP, but they go through different wireless channels. In particular, the tooth vectors involved in the actual collision go through the wireless channels with realistic channel gains, but those not involved in the collision go through the channels with zero channel gains. For example, in Figure 2, Alice, Bob and other users have different tooth vectors. The received signal $\mathbf{y}$ is considered as the sum of all these tooth vectors weighted by different channel gains. The channel gain weight of a tooth vector is the realistic channel gain if it is indeed transmitted, and zero otherwise. If Alice's transmitted signal is $\mathbf{m}_1$, the channel gain weight g_1 for $\mathbf{m}_1$ is the real channel gain between Alice and the AP, and the weights for the rest of Alice's tooth vectors are all zeros (e.g., $g_2 = 0$ as Alice transmits $\mathbf{m}_1$ not $\mathbf{m}_2$). As such, the received signal $\mathbf{y}$ can be reformulated as

$$\mathbf{y} = \sum_{i=1}^{M} \mathbf{m}_i g_i = \underbrace{[\mathbf{m}_1, \mathbf{m}_2, \cdots, \mathbf{m}_M]}_{\text{comb matrix } \mathbf{M}} \ \underbrace{[g_1, g_2, \cdots, g_M]}_{\text{channel gain weight vector } \mathbf{g}}{}^{T}, \tag{2}$$

where $\mathbf{g}$ is called the channel gain weight vector and $\cdot^T$ denotes the matrix transpose. Based on (2), collision resolution is equivalent to solving for unknown $\mathbf{g}$ given $\mathbf{y}$ and $\mathbf{M}$. Then, the tooth vectors actually involved in the collision correspond to non-zero elements in the solved $\mathbf{g}$.

2.3.2 Solution based on Reformulation

There are two key observations on the reformulation in (2).

- The unknown channel gain weight vector $\mathbf{g}$ is sparse in a real-world network because of two reasons: (i) There is no self-collision. As shown in Figure 2, if Alice sends a tooth vector $\mathbf{m}_1$, we have $g_1 \neq 0$; and any other tooth vector belonging to Alice will have a zero channel gain weight (e.g., $g_2 = 0$) since there is no way Alice transmits both $\mathbf{m}_1$ and $\mathbf{m}_2$. (ii) Because of the random backoff in WiFi, a collision is likely caused by only several users transmitting at the same time. Thus, $\mathbf{g}$ should include only several non-zero elements.
- The comb matrix $\mathbf{M}$ should exhibit a nearly random matrix property. Each tooth vector $\mathbf{m}_i$ in $\mathbf{M}$ is mapped from an RTS data vector through interleaving and error-correction coding. Their main purpose is to scramble and re-map all bits into a larger bit space in a (nearly) random way such that the error-correction performance approaches the random coding performance in Shannon's capacity [24].

Given the sparse property and nearly random matrix property, the channel gain weight vector $\mathbf{g}$ should be recovered with high probability by $\mathcal{L}_1$-norm minimization according to the theory of compressive sensing [26, 28, 38]. Thus, resolving an RTS collision leads to the following optimization.

$$\begin{aligned} \text{Given:}\quad & \text{comb matrix } \mathbf{M} \text{ and received signal } \mathbf{y}, \\ \text{Objective:}\quad & \mathbf{g}_{\text{solution}} = \arg\min \|\mathbf{g}\|_1, \text{ subject to } \mathbf{y} = \mathbf{M}\mathbf{g}, \end{aligned} \tag{3}$$

where $\|\mathbf{g}\|_1$ is the $\mathcal{L}_1$-norm of $\mathbf{g}$ (i.e., $\|\mathbf{g}\|_1 = \sum_{g_i \in \mathbf{g}} |g_i|$).

The theoretical framework lays out a promising path towards resolving RTS collisions. Although the $\mathcal{L}_1$-norm minimization in (3) can be solved by many efficient algorithms

[17–19, 27, 62], directly applying (3) to collision resolution incurs an unbearable cost because the comb matrix **M** consists of up to $2^{21} = 2,097,152$ tooth vectors according to our initial analysis in Section 2.2. Thus, significant challenges exist to make collision resolution meaningful and practical.

3 Construction of Comb Matrix

The initial step towards our CombDec design is to find a way to reduce the size of the comb matrix **M** (that can include 2^{21} tooth vectors) for a low-cost solution. In this section, we analyze the 802.11 standard, firmware and packet traces to show that there is a feasible way to significantly reduce the size of 2^{21}. Then, we design two algorithms, (α, β)-construction and γ-decimation, to reduce 2^{21} to only a few hundreds, while maintaining the high performance for collision resolution. The use of (α, β)-construction and γ-decimation clears the major hurdle towards system implementation.

3.1 Standard and Firmware based Analysis

As aforementioned in Section 2.2, **M** consists of 2^{21} tooth vectors because of `Duration` and `RA/TA` fields in RTS. The `Duration` field specifies the 15-bit NAV in microseconds with $2^{15} = 32,768$ potential values, which largely contribute to the size of **M**. 802.11 specifies that the NAV is computed as one data packet duration, plus one CTS, one ACK, and three SIFS durations. Given a network setup, SIFS, CTS and ACK durations are usually fixed (e.g., SIFS is fixed to be 16 μs in 802.11ac at 5GHz). Thus, the value space of the NAV depends dominantly on the value space of the time duration of a data packet. In 802.11, the time duration of a data packet is bounded by aPPDUMaxTime, the maximum time duration of a data packet (in μs), and indirectly bounded by aPSDUMaxLength, the maximum payload length of a data packet (in bytes). As aPPDUMaxTime for 802.11ac is $5,484\mu s$, the space size of the NAV is reduced from 32,768 to at most 5,484 in the 802.11ac network.

Today's WiFi chipsets may still avoid transmitting a long packet (close to $5,484\mu s$) due to the cost consideration or hardware limitations. Hence, drivers implement their own packet length constraints on a data packet, which is usually less than the standard-defined aPSDUMaxLength or aPPDUMaxTime. We perform comprehensive code analysis on WiFi drivers and find that different vendors indeed pose different constraints on their own chipset, further limiting the value selection of the NAV. The detailed firmware analysis can be found in Appendix A.

As a result, we can leverage these constraints to further reduce the value space of the NAV in RTS. However, many WiFi drivers (in particular 802.11ac ones) are still proprietary and distributed in the binary form. It is not practical to study every WiFi chipset/firmware and optimally minimize the value space of the NAV in RTS packets. In what follows, we analyze real-world packet traces to develop a generic way to narrow down the value space.

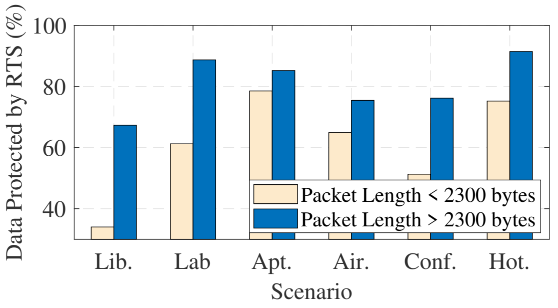

Figure 3: Percentages of data packets protected by RTS.

3.2 Packet Trace based Analysis

The key to reducing the size of the comb matrix is through shrinking the value space of NAV in RTS. We have shown that a WiFi driver can restrain the value space of NAV. Moreover, implementation-dependent rate control and data aggregation in proprietary WiFi drivers are not likely to produce uniformly distributed NAV values, but may be more biased towards certain selections and yield a NAV distribution similar to Figure 1. Our objective is to collect massive packet traces to understand the NAV distribution. Then, we create generic algorithms to select those NAVs that are the most likely to be seen for constructing the comb matrix **M**.

The first step towards understanding the NAV distribution in real-world RTS packets is to collect a substantially large number of packet traces for analysis. As no set of 802.11ac packet data is publicly available, we conducted our own measurements and collected in total 1.3 TB packet trace data with 2.33 billion packets in realistic environments[2], including (i) a public library (65.21 GB), (ii) three academic conferences (31.14 GB), (iii) five residential communities (65.69 GB), (iv) three major-brand hotels (109.48 GB), (v) four major US airports (88.5 GB), (vi) a university research lab (938.81 GB). The library, conference, and airport data traces were measured only within the business hours (i.e., 9am–5pm).

Figure 3 shows the the percentages of data packets that are protected by RTS among all data packets collected in different scenarios. Although a typical RTS threshold is set to around 2300 bytes [1, 4, 6, 7, 9], we see from Figure 3 that data packets of less than 2300 bytes are still likely to be protected by RTS. For example, in the hotel scenario, 78.55% data packets are initiated by RTS even when their lengths are less than 2300 bytes. Moreover, around 70% - 90% data packets of over 2300 bytes are protected by RTS in different scenarios. Overall, we observe from Figure 3 that RTS is still

[2]Note that the payloads of all data packet were removed after the collection to avoid the privacy concern.

intensively used in today's Wi-Fi networks.

Looking into the NAV values in RTS packets, we observe that these values are unevenly distributed. For example, Figure 4(a) shows the NAV distribution of RTS packets in the airport dataset, which reveals that many NAV values (particularly around 230 μs) are much more likely to be observed than the others. The NAV distribution also depends on a WiFi driver. For example, Figure 4(b) plots the distribution of the Belkin WiFi driver measured from RTS packets sent by Belkin devices (recognized by MAC addresses) in all datasets. The figure shows that the distribution is quite patterned, indicating that the driver has several NAV levels to construct payloads. We observe uneven or patterned distributions in all datasets and offer a more detailed analysis in Appendix B.

Thus, if we only choose the most likely NAV values (instead of all possible values) to construct the comb matrix M, the size of M should be substantially reduced. In addition, our design should not be device/firmware specific. For example, it may be possible to select NAV values based on the pattern of Belkin devices in Figure 4(b). But this method is too cumbersome because we have to examine the behaviors of all different WiFi devices. Our strategy is to use an online algorithm that actively computes the NAV distribution of a device, and then selects the most likely NAV values from the computed distribution to construct the comb matrix **M**.

3.3 The (α, β)-Construction Algorithm

To select the most likely NAV values to construct **M**, a node (either the AP or a station) should store the distribution of the NAV values in RTS packets from every other node in a network. In addition, the node should keep updating the storage to account for nodes joining or leaving the network. To this end, we propose the (α, β)-construction algorithm running at individual nodes to construct **M**.

3.3.1 Algorithm Design

For a node that runs the algorithm, it records the frequency (i.e. the number of appearances) of a NAV value in RTS packets transmitted by every other node in the network. When a new RTS packet with a NAV value is decoded, the node will increase the frequency of that NAV value by one in its local storage. There are two key factors α and β in the algorithm.

- Coverage factor α: For every other node in the network, the algorithm selects the α NAV values with the highest frequencies to form the tooth vectors and the comb matrix.
- Forgetting factor β: The algorithm decreases the frequencies of all NAV values by β every minute. The minimum frequency is always set to be zero. And if the frequencies of all NAV values associated with a node become zero, the node's information will be all removed from the storage as it is considered no longer active or out of the network.

The (α, β)-construction algorithm works differently for the AP and stations. Figure 5 shows how it works at the AP: the AP stores the frequency of each possible NAV value from each station. When a collision happens at the AP, it knows the collision must be due to at least two stations (which could be Alice, Bob, or others) transmitting to it. Thus, the AP selects the α most likely NAV values from Alice, constructs an RTS data vector using each of these values, together with Alice's MAC address as `TA` and its own MAC address as `RA`, then maps each RTS data vector by function f (including interleaving, error-correction coding, modulation, IFFT) in Section 2.2 to a signal vector (which is a tooth vector in the comb matrix **M**). Then, the AP repeats the same process for Bob and all other stations to finally obtain the full **M**.

A station's construction of the comb matrix differs from the AP. For example, as shown in Figure 6, Alice observes a collision (a) when two other stations Bob and Carol are transmitting to the AP, (b) when one other station Bob is transmitting to the AP and at the same time the AP is transmitting to a third station Carol, or (c) when the AP is transmitting to Alice while Bob and Carol are transmitting to the AP. In all three cases, collision resolution is only meaningful for Alice in case (c) because the collision in case (c) includes the AP's

Table 1: Miss rate and average size of **M**.

α=600 β=10	Miss rate	Ave. # of nodes	# of tooth vectors in **M**
Library	6.9 %	12.8	7680
Conferences	3.6 %	11.6	6960
Apartments	1.5 %	6.5	3900
Hotels	0.7 %	10.3	6180
Airports	8.8 %	18.8	11280
Lab	5.7 %	6.3	3780

signal intended for Alice. Even when Alice successfully resolves cases (a) and (b), Alice only knows that there is no signal of interest and then stops. Therefore, the construction is sufficient for Alice as long as case (c) can be resolved by Alice. According to case (c), a station should construct the comb matrix by using RTS signal vectors from the AP to itself and other RTS signal vectors from other stations to the AP. The construction process is similar to Figure 5.

3.3.2 Selections of (α,β) and Cost Evaluations

The size of the resultant comb matrix **M** depends on both α and β. In particular, α is the number of tooth vectors from one node, and β in fact determines how many nodes will be used in constructing **M** because (i) all frequencies are decreased by β every minute and (ii) a node will be removed from the construction when all its frequencies become zero. The algorithm with a larger β forgets nodes faster, thereby reducing the number of nodes used for constructing **M**.

The performance of (α,β)-construction can be evaluated by the miss rate, defined as the probability that when an RTS packet arrives at a node, **M** constructed by the algorithm at the node does not include the NAV value in the RTS packet. A large α and a small β are able to reduce the miss rate, but at the same time increase the size of **M**, incurring more cost.

Our objective is to find the pair of (α,β) to balance the miss rate and the complexity for general WiFi scenarios. To this end, we simulate a WiFi network in each of the packet datasets, replay all collected packets to simulate RTS arrivals at each node, and measure the miss rate of the algorithm with different values of α and β. Table 1 shows one selection of (α,β)=$(600,10)$ for all scenarios that achieves a good balance between the miss rate and the size of **M** (measured by α multiplying the average number of nodes used for constructing **M**). We can see that all miss rates are below 9% with around 4,000–12,000 tooth vectors in **M**.

3.4 The γ-Decimation Algorithm

Through 802.11 standard analysis, firmware analysis, packet trace analysis and (α,β)-construction, we have dramatically shrink the size of **M** from the initial 2,097,152 tooth vectors to 12,000 or fewer vectors. All these push the optimization in (3) to the practice. However, finding the $\mathcal{L}_1$-norm minimization with $12,000$ vectors in (3) still incurs a substantial cost. We propose γ-decimation to further reduce such a cost while maintaining the high performance.

Denote by M the number of tooth vectors in **M** constructed by (α,β)-construction. The basic idea of the γ-decimation algorithm ($\gamma > 1$ is called decimation rate) is to select, based on the received signal vector **y**, M/γ vectors out of all M tooth vectors in **M** to form a decimated comb matrix $\mathbf{M}'$.

The design intuition is that the received signal **y** contains only several tooth vectors in **M** that we aim to find out. If we compute the correlation between **y** and each tooth vector $\mathbf{m}_i$ in **M**, defined as $C(\mathbf{y},\mathbf{m}_i) = \|\mathbf{m}_i^H\mathbf{y}\|_2$ ($\cdot^H$ denotes conjugate transpose and $\|\cdot\|_2$ denotes the $\mathcal{L}_2$-norm), we then obtain M correlation values. Due to the property of correlation, we should observe a high correlation value if a tooth vector is indeed included in **y**, and a low correlation value otherwise. However, due to channel noise and limited length of tooth vectors, some tooth vectors not in **y** may also exhibit high correlation values. But it is not necessary to exactly identify which tooth vectors with high correlation values are indeed in **y** at this stage, γ-decimation just chooses M/γ tooth vectors that have the highest correlation values to form the decimated comb matrix $\mathbf{M}'$. It is very likely that tooth vectors involved in the collision are included in $\mathbf{M}'$ as long as M/γ is sufficiently large. We provide theoretical analysis for the performance of γ-decimation and show that all RTS signals involving a collision will survive the decimation and be included in $\mathbf{M}'$ with high probability in Appendix C.

As a result, the final comb matrix for (3) is constructed as follows: (i) (α,β)-construction constructs the comb matrix **M** with M tooth vectors (this steps ensures a low miss rate), (ii) γ-decimation decimates **M** into the decimated comb matrix $\mathbf{M}'$ with only M/γ tooth vectors (this steps ensures that tooth vectors involving the actual collision are preserved with high probability), and (iii) the decimated comb matrix $\mathbf{M}'$ is used in (3) for collision resolution to finally identify which tooth vectors are included in the collided signal **y**.

To make (3) feasible for today's systems, $\mathbf{M}'$ should have only hundreds of tooth vectors. As (α,β)-construction maintains up to around $12,000$ vectors (shown in Table 1), the decimation rate γ should be around 12 or more.

3.5 Complexity Analysis

In the following, we estimate the computational complexity and storage complexity of CombDec.

3.5.1 Computational Complexity

We evaluate CombDec's complexity by comparing it with a benchmark, which is the complexity to decode a typical 802.11 data packet with 40MHz bandwidth, 3/4 convolu-

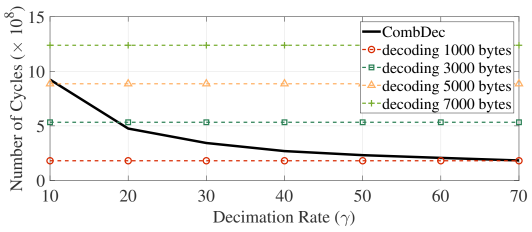

Figure 7: Number of cycles: CombDec vs benchmark.

tional coding, and 64QAM. We describe the major computational operations involved in the benchmark and CombDec.

• The benchmark complexity is proportional to the data payload length, denoted by N bytes. Decoding a data packet requires the FFT and Viterbi algorithms. The packet contains $0.0247N$ OFDM symbols plus 4 PHY headers symbols. The FFT on each symbol requires $64\log(128)$ complex multiplications and $128\log(128)$ complex additions [10]. In addition, the Viterbi algorithm incurs $4^K(10.67N+252)$ real additions and $2^K(10.67N+252)$ real comparisons, where K is the constraint length of convolutional code [12].

• In CombDec, suppose (α,β)-construction maintains M tooth vectors of length L, the correlation of the received signal with each of the tooth vector in γ-decimation needs a total of ML complex additions and multiplications. Among all correlation values, selecting the M/γ largest values incurs $M+M\log(M)/\gamma$ comparisons by using the max heap tree approach [3]. The complexity of $\mathcal{L}_1$ minimization depends on an iterative algorithm and is bounded by the cubic polynomial complexity [62]. In order to estimate an exact computational cost, we use simulations to run the primal-dual interior-point algorithm [47] to solve the $\mathcal{L}_1$-norm minimization in M/γ tooth vectors and compute the average numbers of additions, multiplications and comparisons.

As the complexity involves different types of operations, including additions, multiplications and comparisons. We need to have a unified cost utility metric to measure the overall costs of CombDec and the benchmark. We use the number of general CPU cycles as the utility metric [2]. In particular, one real addition or comparison is counted as one cycle and one multiplication is 4 cycles [2]; and a complex operation is 4 times the number of cycles incurred by its real counterpart [10]. Note that an algorithm or a computational operation can be specifically optimized on a particular signal processing software or hardware platform. Our estimation using CPU cycles is not intended to be exactly accurate for an implementation platform, but serves as an approximate way to demonstrate what computational complexity level CombDec is at when compared with the benchmark.

Figure 7 shows the total numbers of cycles incurred by CombDec and the benchmark. In Figure 7, we let (α,β)-construction form $M = 12,000$ tooth vectors to accommodate the airport scenario in Table 1 and set a typical constraint length $K = 7$ in the Viterbi Algorithm. It is observed from Figure 7 that choosing γ to be in [20, 50] leads to the complexity of CombDec roughly equivalent to decoding a packet with 1000–3000 bytes, which makes CombDec ready for system implementation.

3.5.2 Storage Complexity

CombDec also incurs a storage cost. First, CombDec for a device must store the frequency of each NAV value for any other active device in the network. The cost of storing all NAV frequencies is equal to the NAV space size multiplying the average number of active devices. There are 5,484 possible NAV values in 802.11ac and around 18.8 active nodes under (α,β) construction for the airport scenario (shown in Table 1). Hence, the storage cost is $5484 \times 18.8 \times 1 = 101$ KB when the frequency value is a one-byte integer. Second, after γ-decimation, all tooth vectors should be stored for $\mathcal{L}_1$-minimization. The storage cost is the number of tooth vectors multiplying the length of a tooth vector. When $\gamma \in [20,50]$, the number of decimated tooth vectors in the airport scenario is 240 to 600. If a typical RTS packet is transmitted at 12 Mbps (4 64-subcarrier OFDM symbols) and the element in tooth vector is a 4-byte complex number, the length of a tooth vector is $64\times4\times4 = 1$ KB. Thus, the cost of storing all these tooth vectors is in the range of $[240,600]$ KB.

Overall, the major storage cost is around [341, 701] KB. This cost is also reasonable for today's WiFi systems. For example, Qualcomm's 802.11ac chipset IPQ4018 has an on-chip memory of 256 MB [50] and related APs cost as low as tens of dollars [8, 13].

4 CombDec System Design

The (α,β)-construction and γ-decimation algorithms pave the way for a feasible system solution to (3). In this section, we present CombDec system design. We first introduce the system architecture, then describe each key component.

We design CombDec as an independent decoder in addition to the traditional 802.11 decoder. Figure 8 shows four major components in CombDec: the prologue module, (α,β)-construction, γ-decimation, collision resolution, and the epilogue module. As shown in Figure 8, CombDec is triggered only when decoding of either the PHY header or the PHY payload fails. In the following, we present the designs of individual CombDec Components.

The Prologue Module: The prologue module does all preprocessing before collision resolution.

Combining Multi-path Signal Components: The received signal may include a number of multi-path components with different time offsets. To improve the performance of CombDec under multi-path fading, we use the maximum ratio combining (MRC) [31] to combine the multi-path signal components. Specifically, denote by $s(n)$ the n-th time-domain

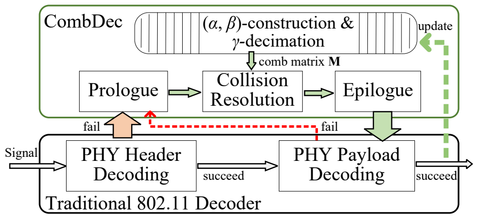

Figure 8: Architecture of CombDec decoder.

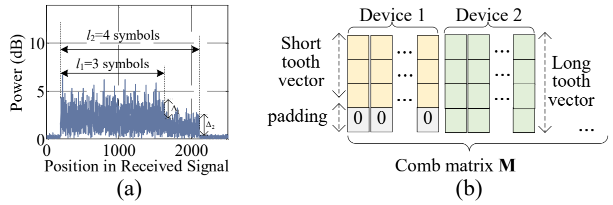

Figure 9: (a) Power level changes in the received signal. (b) Padding in comb matrix construction.

symbol in the received signal. Based on the 802.11 packet preamble, we use a matched filer [32, 58] to detect the time offset and estimate the channel gain of each signal component. Given K components found, we use the MRC [31] to coherently sum all K time-shifted copies of $s(n)$ and obtain $s'(n) = \sum_{k=1}^{K} h_k^* s(n+\delta_k)$, where k-th component having time offset δ_k and channel gain h_k, and h_k^* is the complex conjugate of h_k. Note that signal components may be from different senders in a collision, CombDec does not differentiate them in the prologue module.

Collision Recognition and Early Stop: Next, CombDec decides if $s'(n)$ can be potentially resolved. There are three types of collisions: RTS-only, RTS-data (involving at least one RTS packet and one data packet), and data-only collisions. CombDec will stop if the collision belongs to data-only collision. Note that the recognition does not need to be 100% accurate, it simply provides a way to exclude obvious data-only collisions that cannot be resolved by CombDec.

In WiFi networks, the beginnings of collided packet transmissions are roughly aligned because of CSMA/CA (if we do not consider the hidden terminal problem). Thus, we measure the time durations of different power levels of the received signal to identify the type of a collision. According to 802.11, the data rate for RTS is selected by a station from a limited set of basic rates defined by the AP (e.g., 12 Mbps and 24 Mbps are widely observed in our packet traces). Thus, a RTS time duration can be measured by a very limited number of OFDM symbol durations, e.g., 3 (or 4) OFDM symbol durations for 24 (or 12) Mbps. We record the time duration l_i, from the beginning of the signal $s'(n)$, to the position in $s'(n)$ where the i-th signal power change happens and is larger than a threshold Δ. When the power level reaches the noise floor, we stop and obtain a set of time durations $\mathcal{L} = \{l_i\}_{i\in[1,|\mathcal{L}|]}$. We consider a collision as (i) RTS-only if each value in $\mathcal{L}$ is close to one of the RTS durations corresponding to the basic rate set defined by the AP, (ii) RTS-data if one value is close to an RTS duration and any other value is not close to any of the RTS durations, and (iii) data-only otherwise. Figure 9(a) shows an example of RTS-only collision, where two measured time durations occupy 3 and 4 OFDM symbol durations, respectively, which is recognized as the collision of two RTS packets with different rates.

The Collision Resolution Module: The prologue module outputs either RTS-only or RTS-data signals for collision resolution, (α, β) construction will construct every tooth vectors for the comb matrix. As devices in a network may use different basic rates to transmit RTS packets (leading to different lengths of tooth vectors), CombDec zero-pads the shorter tooth vectors with higher data rates to form the complete comb matrix $\mathbf{M}$ used for collision resolution. Figure 9(b) shows an example of constructing the comb matrix $\mathbf{M}$ by zero-padding shorter tooth vectors. Then, $\mathbf{M}$ is γ-decimated to $\mathbf{M}'$, which is used in the primal-dual algorithm [47] that solves the $\mathcal{L}_1$-minimization in (3). Note that if a collision is RTS-data, the module resolves the collided RTS signal vectors by treating any data signal as the noise, and then leaves the potential decoding of data for the epilogue module.

The Epilogue Module: The collision resolution module yields a small set of potential RTS signal vectors involved in the collision, denoted by $\mathcal{R}$. There are still important questions left: (i) Which RTS in $\mathcal{R}$ a receiver should choose to reply with CTS? (ii) Can we decode the data in the presence of an RTS-data collision? (iii) Moreover, we also need an error detection mechanism to ensure the collision is correctly resolved because errors may happen in CombDec. We first describe how CombDec chooses data or RTS. The AP and stations have different decision making processes.

Decision Making at AP: The AP observes a collision when multiple stations transmit to the AP at the same time.

- Choosing the RTS with the largest NAV: if the collision is RTS-only, the AP chooses the RTS of the largest NAV to reply with CTS. Note that we intend to maximize the channel utilization in this way. A more advanced policy (e.g., considering the utilization and fairness) can be designed and adopted going beyond the main scope of this paper.
- Choosing data over RTS: If the collision is RTS-data, the AP first decodes all RTS packets in the collision resolution module, then proceeds to decode the data. If the data is successfully decoded, the AP chooses data over RTS and sends back the ACK to the sender of the data. This is because data packets are usually longer than RTS packets. Giving priority to data should improve the channel utilization.

Decision Making at Stations: A station observes a collision when multiple other nodes (either other stations or the AP) transmit at the same time. As shown in Figure 6(c), a station only cares about the AP's signal transmitted to it.

• If $\mathcal{R}$ includes an RTS vector from the AP to the station, the collision is due to the AP transmitting to the station and at the same time at least one other station transmitting to the AP, the station always sends CTS to the AP.

• Otherwise, there is no RTS in $\mathcal{R}$ intended for the station. If the collision is RTS-data, the station proceeds to decode the data because the data may be intended for it; otherwise, the station stops.

Error Checking and Data Decoding: Once a decision is made (choosing RTS or data), we must ensure there is no error with the chosen RTS or we must proceed to decode the data. How to proceed with error checking and data decoding? We find that a traditional 802.11 receiver, as shown in Figure 8, already has a PHY payload decoder with the cyclic redundancy check (CRC) mechanism. Thus, we should leverage the existing architecture to perform the decoding and error checking to minimize the complexity of CombDec.

As a result, if CombDec decides to act on a particular RTS signal or to decode a data signal, it uses interference cancelation to remove all other signals from the collided signal. Specifically, if a decision is to decode the data, CombDec removes all RTS signal vectors in $\mathcal{R}$ from the received signal $s'(n)$ and write the resultant signal as $s'_c(n) = s'_c(n) - \sum_{i=1}^{|\mathcal{R}|} r_i(n)g_i$, where $r_i(n)$ and g_i are the n-th element and the channel gain weight of the i-th RTS tooth vector in $\mathcal{R}$, respectively. Similarly, if the decision is to act on the j-th RTS vector (i.e., choose the j-th RTS in $\mathcal{R}$ to reply with CTS), CombDec removes all other RTS tooth vectors from the $s'(n)$ and the resultant signal becomes $s'_c(n) = s'_c(n) - \sum_{i=1,i\neq j}^{|\mathcal{R}|} r_i(n)g_i$.

Finally, the signal $s'_c(n)$ goes from CombDec into the traditional PHY payload decoder, which performs decoding and error checking, then passes the correct RTS or data to the MAC layer for protocol processing (e.g., replying with CTS). In addition, the MAC address and data rate information of a correct RTS packet is stored and its NAV value is also updated in (α, β)-construction as shown in Figure 8.

5 Evaluation

In this section, we evaluate the performance of CombDec. We first introduce the experimental setups, then measure the performance benefits CombDec brings to WiFi networks.

5.1 Setups

Testbed Implementation: We have implemented the prototype of CombDec on 20 USRP X310/300 devices. Each device is equipped with two UBX-160 daughterboards and two VERT 2450 antennas. We implement a basic 802.11ac PHY-MAC architecture with 20-MHz settings: 64 OFDM subcarriers (including 48 data subcarriers), BPSK, QPSK, 16QAM, and 64QAM modulations, Alamouti code based MIMO, and convolutional coding at the PHY layer, and CSMA/CA scheme with an initial contention window size of 8 [5] at the MAC layer. Control packets including RTS, CTS, and ACK are also implemented.

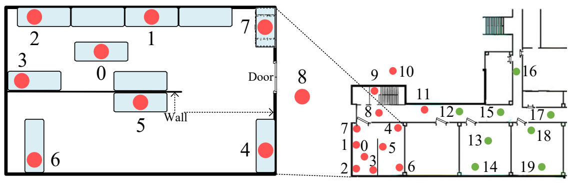

Figure 10: Environment for experiments.

Experimental Settings: We aim to measure the performance of CombDec in a realistic indoor environment inside a campus building shown in Figure 10. Network nodes are placed at various locations and transmit packets whose contents are generated according to our collected 802.11ac packet traces.

Note that we do not implement the 256QAM modulation as we found no single packet using a data rate associated with 256QAM in all collected packet traces. This does not severely affect the performance evaluation since 256QAM is intended only for very high SNR conditions.

We use the following default settings for experiments (unless otherwise specified): (i) all nodes are saturated; i.e., they always have packets to transmit; (ii) α=600, β=10, and γ=20 for CombDec; (iii) the airport dataset is used to generate packets as it represents the most crowded condition in all datasets; (iv) all nodes have the same transmit power.

Evaluation Metrics: We use the following metrics to evaluate the real-time performance of CombDec.

• Success probability of collision resolution is defined as the probability that CombDec recovers exactly all collided RTS signals. The recovery will be considered as a failure if CombDec recovers only a subset of collided RTS signals or mis-identifies an RTS signal not involved in the collision.

• Normalized throughput (or utilization efficiency), is defined as the percentage of the time duration on the wireless channel that is used to deliver data packets. An ideal network should have a normalized throughput of 1. However, control signals (e.g., RTS/CTS) and collisions deteriorate the throughput. We aim to show how much channel utilization efficiency CombDec can improve via resolving RTS collisions.

• Throughput gain ratio, defined as the ratio between the increased normalized throughput from traditional 802.11 decoding to CombDec and the normalized throughput under traditional decoding. Throughput gain ratio can directly reflect how CombDec improves the network performance.

5.2 Success Probability

We first evaluate the success probability of CombDec for collision resolution. In this evaluation, multiple nodes only

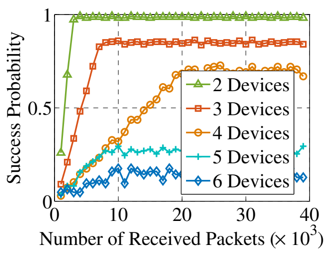

Figure 11: Success probabilities under 2-6 transmitters.

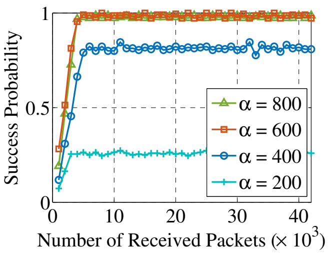

Figure 12: Impact of value of α in (α, β)-construction.

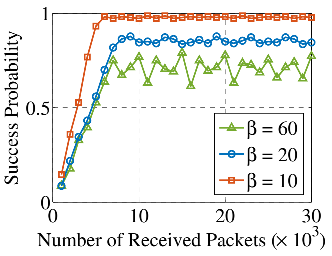

Figure 13: Impact of value of β in (α, β)-construction.

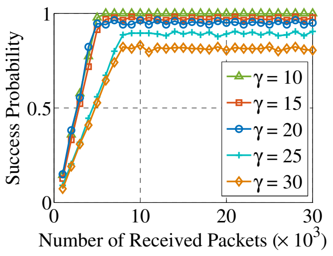

Figure 14: Impact of value of γ in γ-decimation.

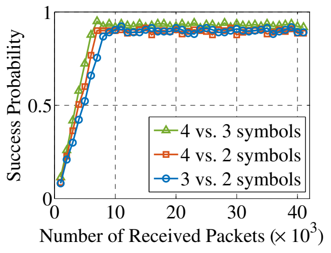

Figure 15: Resolving collisions with different rates.

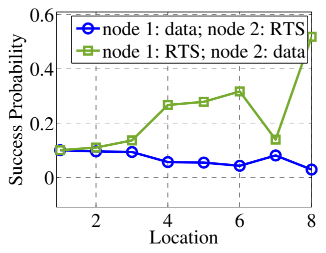

Figure 16: Resolving RTS-data collisions.

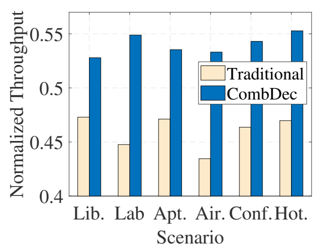

Figure 17: Throughputs under different scenarios.

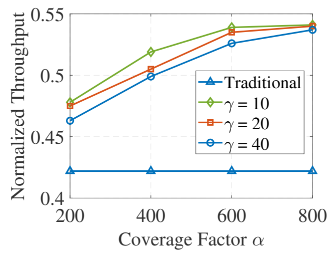

Figure 18: Throughputs with different α and γ.

transmit RTS packets to the AP placed at location 0 in Figure 10, where the success probability is measured.

Impact of Number of Transmissions: We evaluate CombDec's ability to resolve collisions due to two and more transmissions. To this end, we place multiple transmitters at location 1, which send RTS packets at the same time to the AP at location 0. Figure 11 shows the success probabilities that the AP resolves the collision under 2–6 transmitters. The success probability is computed for every 1,000 packets received. It is noted from Figure 11 that as the total number of received packets at the AP increases, CombDec gradually gains the NAV information in RTS packets, and thus the success probability also increases and finally remains stable. It is also observed that CombDec is able to resolve 98% of two-node collisions and 86% of three-node collisions. The performance degrades when the number of transmitters increases. However, a collision caused by 5 or more WiFi nodes is much less frequent because of the random backoff in CSMA/CA.

Values of α and β: We evaluate the impacts of α and β on the success probability. We place two nodes at location 1 that transmit RTS packets at the same time to the AP at location 0. Figure 12 shows that as α goes from 200 to 600, the success probability increases from 0.28 to 0.98; and further increase of α will not substantially improve the success probability. Figure 13 shows the impact of β on the success probability. We observe that when β increases from 10 to 60 (i.e., CombDec forgets the history faster), the success probability reduces from 0.98 to 0.77. From both figures, we can see that the uniform selection of $\alpha = 600$ and $\beta = 10$ yield very high performance for the airport scenario, and accordingly are also suitable for other less crowded scenarios.

Value of γ: We adopt the same setup in Figure 13 to evaluate the impact of γ. Figure 14 illustrates that gradually increasing γ does not severely decrease the success probabilities. For example, when γ becomes 30, the success probability reduces to 0.831. This indicates that adjusting γ can smoothly balance the performance and the implementation cost.

Impact of Zero-Padding: In each of our packet datasets, we find that a majority of RTS packets are transmitted at the same data rate; however, RTS packets with different rates do exist. These packets have different lengths of 2, 3, or 4 OFDM symbols. Therefore, a minority of collisions involving RTS packets with different rates. CombDec uses zero-padding to solve this issue as discussed in Section 4. We measure the ability of CombDec to resolve such a type of collisions. Hence, we place two nodes at location 1 sending RTS packets with different lengths to the AP. Figure 15 shows that the success probabilities remain approximately the same when RTS packets have different lengths in a collision. From Figure 15, we conclude that CombDec has no difficulty in resolving this type of collisions.

RTS-Data Collisions: CombDec also attempts to resolve an RTS-data collision via canceling the RTS signal from the received signal and then performing decoding. To evaluate such an ability, we place one node (node 1) at location 1 to send RTS to the AP, and place another node (node 2) at one

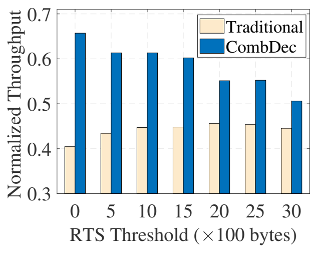

Figure 19: Throughputs with different thresholds

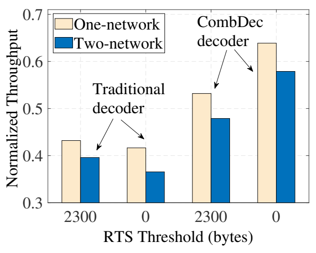

Figure 20: Throughputs in collocated networks.

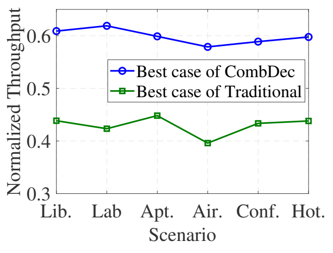

Figure 21: Throughputs in collocated networks.

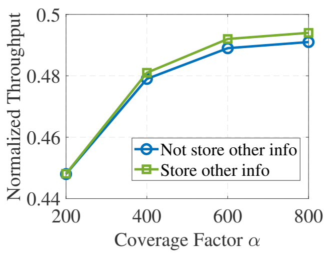

Figure 22: Storing information of other network.

of locations 1–8 to send data to the AP for the first round of experiments, and then let node 1 send data and node 2 send RTS for the second round. The first and second rounds represent the scenarios in which the receiving power of RTS is greater than and less than that of data, respectively. We consider the collision is resolved when both RTS and data packets are decoded successfully. Figure 16 depicts the success probability of collision resolution as node 2's location changes. The figure shows that generally, the success probability is higher when the receiving power of RTS is higher than that of data. This is because CombDec first treats any data packet as the noise to recover any RTS packet from the receiving signal. The results demonstrate that CombDec, primarily designed to handle RTS-only collisions, is capable of resolving RTS-data collisions in some scenarios.

5.3 Network Performance Evaluation

We then evaluate the benefits of CombDec for the network performance. Note that it is impossible to measure the network performance with CombDec under different setups at the same time because the resolution of a collision directly affects follow-on network dynamics. We have to measure the performance under different setups over non-overlapping measurement periods. Therefore, we conduct experiments during off-business hours to minimize the impact of environmental factors on different measurement periods.

5.3.1 Single Network Scenario

We first consider a single-network scenario: 12 nodes are placed at locations 0–11, in which the AP is at location 8, as shown in Figure 10. The network does not run in the MU-MIMO mode (i.e., the AP does not transmit data via MU-MIMO to multiple stations in the downlink). The RTS threshold is set to be 2,300 bytes for all nodes (i.e., RTS is triggered only when a data packet to be transmitted has a length over 2,300 bytes). The value of 2,300 is typical for today's WiFi products (e.g., the default value in Cisco APs is 2347 [9]).

Throughput Improvement: Figure 17 demonstrates the comparisons of normalized throughputs under traditional 802.11 decoding and CombDec. Note that the throughput performance is always measured at the AP. We can see that CombDec is able to uniformly boost the performance of traditional 802.11 decoding. For example, the normalized throughput for the airport scenario increases from 0.43 to 0.53, leading to a throughput gain ratio of (0.53 - 0.43)/0.43 = 23.3%. In all different scenarios, we observe that the throughput gain ratio under CombDec is 11.6%–23.3%.

Improvement by Tuning α and γ: We aim to find if we can improve the performance by tuning α and γ, which are important factors to balance the performance and complexity. Figure 18 shows the normalized throughputs for various α and γ values in the airport scenario. The figure shows that keeping increasing α and decreasing γ do not always lead to evident improvement. For example, when α goes from 600 to 800 and γ decreases from 20 to 10, the throughput under CombDec only increases from 0.491 to 0.494.

Improvement by Reducing RTS Threshold: It is still possible to further improve the network performance. Our observation is that traditionally, an RTS collision is considered not resolvable; therefore, many WiFi devices are conservative to set the RTS threshold. The transmission of a data packet triggers an RTS transmission only when its data size is greater than the threshold. In all previous experiments, the threshold is set as a typical value of 2,300 for today's networks. Now CombDec has the capability of decoding RTS collisions; therefore, it can be beneficial to encourage more RTS transmissions by reducing the threshold. Figure 19 compares the normalized throughputs under traditional 802.11 decoding and CombDec for different RTS thresholds. The figure shows that reducing the threshold generally decreases the throughput performance under traditional decoding; however and interestingly, it substantially boosts the performance under CombDec. The best case for traditional decoding is to set the threshold as 2000–2500, resulting in a normalized throughput of 0.456. By contrast, the best case for CombDec is to remove the threshold and let everyone always send RTS before data, yielding a higher throughput of 0.657. The throughput gain ratio is computed as (0.657-0.456)/0.456 = 44.08%. This encouraging result shows that CombDec has an immediate impact on today's practice of setting the RTS threshold, and significantly reducing this threshold can push WiFi towards a collision-free environment.

5.3.2 Collocated Networks

Next, we place a new network close to the single network used in previous experiments. In the new network, 8 nodes are placed at locations 12–19 and the AP is at location 15, as shown in Figure 10. The two networks use the same frequency and thus interfere with each other. We call the APs in the original and new networks AP 1 and AP 2, respectively.

Figure 20 shows the throughput performance under different settings in the airport scenario. In Figure 20, the one-network performance is the performance measured at AP 1 in the previous single-network scenario (without the new network); and the two-network performance is measured as the average of the throughputs measured at AP 1 and AP 2. We can observe from Figure 20 that when the new network is placed, the throughput performance degrades due to mutual interference. CombDec still performs better than traditional 802.11 decoding. In the two-network scenario, the best case for CombDec is setting the RTS threshold to 0 (which is also beneficial to solving the hidden terminal problem), yielding a throughput of 0.579; and the best case for traditional decoding has a throughput of 0.396. The throughput gain ratio is thus (0.579 - 0.395)/0.395 = 46.6%, which is also a substantial throughput improvement. Figure 21 compares the best case throughput performance between CombDec (removing the RTS threshold) and traditional coding (setting the threshold to 2,300) in different scenarios. It can be seen that the throughput gain ratio of CombDec is 33.6% – 46.2%.

As discussed in Section 3, CombDec is designed to only store information of its own network. In the two-network scenario, it is possible to enhance the performance of CombDec by letting (α,β)-construction store the information (including MAC addresses, NAVs, and RTS rates) of the other network. Figure 22 shows that storing other network information can further yet slightly improve the throughput performance of CombDec with a fairly large α.

6 Related Work

Interference Cancelation and Mitigation: In the literature, successive interference cancelation (SIC) has been proposed to decode collisions by using either pre-coded signatures or different receiving powers [15, 33, 35, 36, 39, 40, 53, 66]. The time offsets in different packet collisions (e.g., in the presence of hidden terminals) has also been leveraged to resolve collisions [32, 42, 63]. In addition, interference cancelation was widely studied in the full-duplex mode [20,22,23,56,66]. In cross-technology communication, corrupted packets may also be decoded by detecting the interference type [21,37]. A number of studies have also proposed interference alignment and nulling with or without channel state information [43,46]. These approaches cannot be readily adapted to regular WiFi scenarios considered in this paper, where RTS packets collide at the beginning of each transmission.

Multi-user Detection: CombDec is related to multi-user detection that attempts to decode multiple users' signals from the overlapped signal [25, 44, 61]. In cellular networks, CDMA has been widely used to assign distinct spread spectrum codes to different users [60]. However, there is no such code design in RTS packets. Constructive interference [25] is able to receive multiple synchronized transmissions. Nevertheless, it requires all packets have the same content, which is impossible for RTS signals. The work in [51] applied the time division technique to the byte level such that multiple users can share the same packet. This method needs a strict coordination among all users. A multi-user system is built in [44] through sharing multiple channels to users who are allowed to duplicate the signal into these channels. Applying these designs to WiFi requires modification of the standard; in contrast, CombDec is a non-invasive design.

Improving WiFi Performance: Substantial efforts have been devoted to improving the WiFi link performance [14, 16,30,34,48,49,55,57,65]. For example, [14,30,57] focused on optimizing the user selection algorithm in MU-MIMO and [16, 54, 65] aimed to improve the beamforming related techniques. Different algorithms were also investigated to improve the rate adaptation in WiFi [34, 49]. Recently, a rapid picocell switching has also been proposed for wireless transit networks [55]. CombDec is orthogonal to these studies that aim to improve WiFi performance in different aspects. We show that CombDec makes it possible to resolve RTS collisions and pushes WiFi towards a collision-free environment.

7 Conclusion

This paper provides a systematic study to resolve RTS collisions in WiFi networks. Our core contribution is a new decoding system CombDec that uses (α,β)-construction, γ-decimation and sparse recovery to resolve RTS collisions. CombDec does not require changing the 802.11 standard and redefines the role of the RTS functionality in WiFi. We show via system implementation and extensive evaluation that CombDec has a beneficial impact on WiFi networks and substantially improves the throughput performance by 33.6% – 46.2% in various scenarios.

APPENDIX A

We analyze popular WiFi drivers and AP firmware to understand these practical constraints: (i) Linux kernel drivers: ath9k (Qualcomm/Atheros 802.11n chipsets), brcmsmac (Broadcom 802.11n chipsets), and iwlwifi (Intel 802.11n/ac chipsets); (ii) 802.11ac AP firmware in Linksys EA8500, EA9500, TP-Link AC1200, C5400, and AD7200.

In particular, ath9k allows the maximum length of a data payload to be either 8,192 or 65,535 bytes (aPSDU-MaxLength for 802.11n is 65,535) based on its version number (as shown in Listing 1); brcmsmac uses the maximum duration of 5,000 μs (aPPDUMaxTime for 802.11n is 10,000 μs) (as shown in Listing 2); iwlwifi allows the maximum duration to be 4,000 μs (aPPDUMaxTime for 802.11ac is 5,484), as the excerpted code shown in Listing 3. In addition, Linksys EA8500, EA9500, and TP-Link AC1200, C5400 and AD7200 share the same code: the maximum length of a data payload is 65,535 bytes (aPSDUMaxLength for 802.11ac is 4,692,480)(as shown in Listing 4).

APPENDIX B

Our comprehensive data collections capture WiFi packet traces under a diversity of traffic load conditions over long time periods. For each transmitter in the packet traces, we compute the NAV distribution in its RTS packets. We find that the NAV distribution is highly patterned or uneven in its value space. Figure 23 shows the NAV distributions of top five devices that send the largest numbers of RTS packets in different measurement environments. We observe from Figure 23 that each device's NAV values almost concentrate in the small value regions. For example, in the lab scenario, 92.1% NAV values in RTS packets from device 3 is 156.

We also notice that, interestingly, WiFi devices from the same manufacturer (identified by their MAC addresses) do exhibit similar NAV distribution in their RTS packets. Figure 24 illustrates the distributions of all NAV values in RTS packets transmitted by devices from 15 common manufacturers. It is seen from Figure 24 that the distributions exhibit different patterns by manufacturers, mainly due to their distinct firmware designs. Similar to Figure 23, Figure 24 shows the NAV distributions are highly uneven and patterned with a small number of NAV values much more likely to show up in RTS packets than the others.

In addition to NAV, we also measure the data rates of RTS packets. Figure 25 depicts the distribution of RTS dta rates in different environments. We can see that a large number of devices adopt 12 Mbps and 24 Mbps data rates to send RTS. Furthermore, in the conference and hotel scenarios, most devices even only use the 24 Mbps data rate.

Based on the packet trace analysis, if we select the NAV values that are most likely in RTS packet from each device to construct the comb matrix **M**, we should be able to decrease the size of **M** at the cost of a small performance penalty.

APPENDIX C

Performance of γ-decimation: For the tooth vector set $\mathcal{M} = \{\mathbf{m}_i\}_{i\in[1,M]}$, where $M = |\mathcal{M}|$ and $\mathbf{m}_i \in \mathbb{C}^{L\times 1}$, γ-decimation selects M/γ tooth vectors with largest correlation values to form a new comb matrix. Denote by $\mathcal{M}'$ the set consisting of these selected M/γ tooth vectors by γ-decimation. Without loss of generality, we assume the collided signal $\mathbf{y}$ contains the first S tooth vectors, i.e., $\mathbf{m}_1, \cdots, \mathbf{m}_S$. In this section, notations are summarized as follows: (i) $o(1)$ denotes a function that converges to 0 as $L \to \infty$; (ii) $\mathsf{E}(\cdot)$ and $\mathsf{Var}(\cdot)$ denote the expectation and variance operators, respectively; (iii) for a complex number m, m^* is the complex conjugate of m, and $|m|$ is the magnitude of m. Now we state the following theorem to show the performance of γ-decimation:

Theorem 1 *Define event A as the event that $\mathbf{m}_1$, $\mathbf{m}_2$, $\cdots$, $\mathbf{m}_s$ are all selected by γ-decimation in $\mathcal{M}'$. Then, it holds that $\mathsf{P}(A) = 1 - o(1)$ (i.e., event A happens with high probability).*

Proof: We first normalize the correlation between comb matrix **M** and the received vector **y**. From (2), we have

$$\mathbf{z} = \frac{1}{L}\mathbf{M}^H\mathbf{y} = \frac{1}{L}\begin{bmatrix} \mathbf{m}_1^H\mathbf{m}_1 & \mathbf{m}_1^H\mathbf{m}_2 & \cdots & \mathbf{m}_1^H\mathbf{m}_M \\ \mathbf{m}_2^H\mathbf{m}_1 & \mathbf{m}_2^H\mathbf{m}_2 & \cdots & \mathbf{m}_2^H\mathbf{m}_M \\ \vdots & \vdots & \vdots & \vdots \\ \mathbf{m}_M^H\mathbf{m}_1 & \mathbf{m}_{M-1}^H\mathbf{m}_2 & \cdots & \mathbf{m}_M^H\mathbf{m}_M \end{bmatrix}\begin{bmatrix} g1 \\ g2 \\ \vdots \\ g_M \end{bmatrix}. \tag{4}$$

Let $\mathbf{z} = [z_1, z_2, \cdots, z_M]^H$. It holds that $\forall z_i \in \mathbf{z}$,

$$z_i = \frac{1}{L}\sum_{s=1}^{M} g_s \mathbf{m}_i^H \mathbf{m}_s = \frac{1}{L}\sum_{s=1}^{M}\sum_{k=1}^{L} g_s m_{i,k}^* m_{s,k}. \tag{5}$$

Because each tooth vector $\mathbf{m}_i$ has the random property by coding, for any entry $m_{j,i} \in \mathbf{m}_i$, we have $\mathsf{E}(m_{j,i}) = 0$ and let $\mathsf{E}(|m_{j,i}|^2) = \sigma^2$.

Since tooth vectors $\mathbf{m}_1, \mathbf{m}_2, \cdots, \mathbf{m}_S$ are the ones to be resolved, we know the first S members in $\mathbf{g}$ are not zeros. Define Y as

$$Y = \sum_{m=S+1}^{M} \mathbf{1}_{\{|z_m|>h\}}, \tag{6}$$

denoting the number of false alarms (i.e., noise exceeding the threshold), where h is a threshold, and $\mathbf{1}_{\{|z_m|>h\}}$ is the indicator function defined as

$$\mathbf{1}_{\{|z_m|>h\}} = \begin{cases} 1, & \text{if } |z_m| > h \\ 0, & \text{otherwise.} \end{cases} \tag{7}$$

To evaluate the performance of γ-decimation, we define another event

$$B = \left(\bigcap_{s=1}^{S}\{|z_s| > h\}\right)\bigcap\{Y \le (\gamma M - S)\},$$

where the first part denotes that the correlation values z_1, z_2, $\cdots, z_S$ are all above the given threshold h and the second part indicates that there are at most $(\gamma M - S)$ other correlation values above h. If event B happens, $\mathbf{m}_1$, $\mathbf{m}_2$, $\cdots$, $\mathbf{m}_S$ will be selected by γ-decimation and thus event A must happen. This means $\mathsf{P}(A|B) = 1$ and $\mathsf{P}(A) \ge \mathsf{P}(B)$. Therefore, according to Fréchet inequalities, we obtain

$$\begin{aligned} \mathsf{P}(A) &\ge \mathsf{P}\left(\left(\bigcap_{s=1}^{S}\{|z_s| > h\}\right)\bigcap\{Y \le (\gamma M - S)\}\right) \\ &\ge \mathsf{P}\left(\bigcap_{s=1}^{S}\{|z_s| > h\}\right) - \mathsf{P}\left(Y > (\gamma M - S)\right). \end{aligned} \tag{8}$$

From (8), we need two steps to finish the proof:

- **Step 1:** prove $\mathsf{P}\left(\bigcap_{s=1}^{S}\{|z_s| > h\}\right) = 1 - o(1)$.
- **Step 2:** prove $\mathsf{P}\left(Y > (\gamma M - S)\right) = o(1)$.

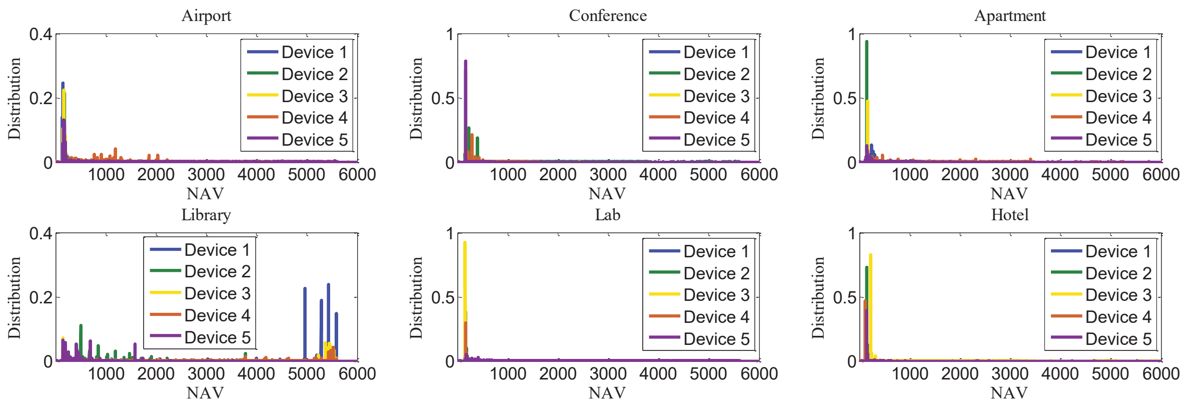

Figure 23: NAV distributions at different locations.

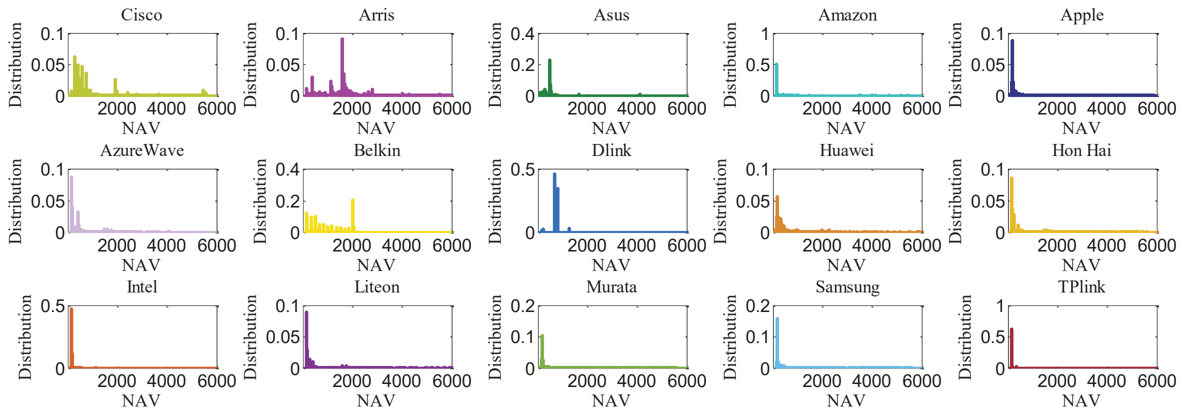

Figure 24: NAV distributions of different vendors.

Step 1:

By Fréchet inequalities, we have that

$$\mathsf{P}\left(\bigcap_{s=1}^{S}\{|z_s|>h\}\right)\geq\sum_{s=1}^{S}\mathsf{P}(|z_s|>h)-(S-1). \quad (9)$$

According to Cantelli's inequality [52], for $1\leq s\leq S$, we have the probability

$$\mathsf{P}(|z_s|>h)\geq 1-\frac{\mathsf{Var}(|z_s|)}{\mathsf{Var}(|z_s|)+(h-\mathsf{E}(|z_s|))^2}. \quad (10)$$

Next we derive $\mathsf{E}(|z_s|)$ and $\mathsf{Var}(|z_s^2|)$ respectively. Because $1\leq s\leq S$, without loss of generality, we consider the first element z_1. From (5), by leveraging Lemma 1, we have

$$\mathsf{E}(|z_1|)=\mathsf{E}(\frac{1}{L}g_1\mathbf{m}_1^H\mathbf{m}_1+\frac{1}{L}\sum_{s=2}^{S}g_s\mathbf{m}_1^H\mathbf{m}_s)=g_1\sigma^2, \quad (11)$$

and

$$\begin{aligned}\mathsf{E}(|z_1|^2)&=\mathsf{E}\left(\frac{1}{L^2}\left(\mathbf{m}_1^H\sum_{s=1}^{S}g_s\mathbf{m}_s\right)^2\right)\\&=\frac{1}{L^2}\mathsf{E}\left(\sum_{s=1}^{S}\sum_{k=1}^{L}g_sm_{1,k}^*m_{s,k}\sum_{s'=1}^{S}\sum_{k'=1}^{L}g_{s'}m_{1,k'}^*m_{s',k'}\right)\\&=\frac{1}{L^2}\sum_{s=1}^{S}\sum_{k=1}^{L}\sum_{s'=1}^{S}\left(\sum_{k'=1,k'\neq k}^{L}g_sg_{s'}\mathsf{E}(m_{1,k}^*m_{s,k})\right.\\&\qquad\left.\times\mathsf{E}(m_{1,k'}^*m_{s',k'})+g_sg_{s'}\mathsf{E}(m_{1,k}^*m_{s,k}m_{1,k}^*m_{s',k})\right).\\&=g_1^2\sigma^4+\frac{1}{L}\Xi_1,\end{aligned} \quad (12)$$

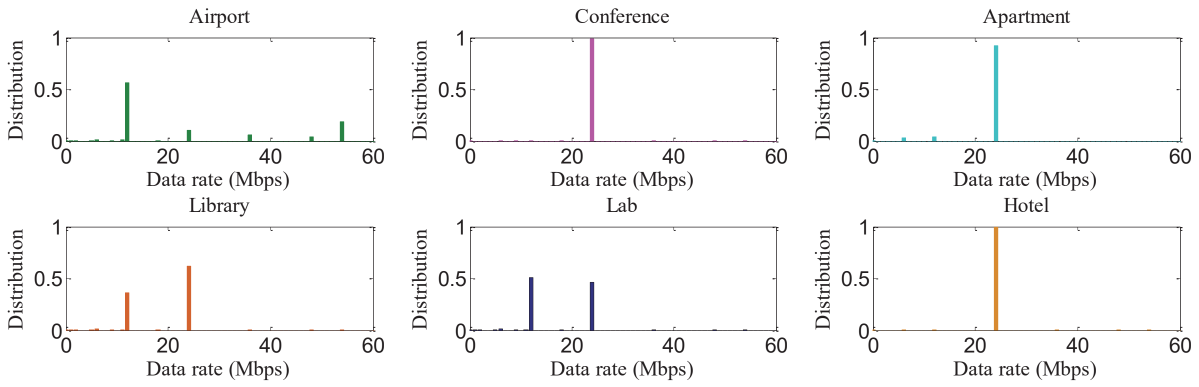

Figure 25: RTS data rate distributions.

where

$$\Xi_1 = \left(g_1^2(\mathsf{E}(|m_{1,k}|^4) - \sigma^4) + \mathsf{E}((m_{1,k}^*)^2)\mathsf{E}(m_{1,k}^2)\sum_{s=2}^{S} g_s^2 \right).$$

From (11) and (12), we obtain the variance of z_1 as

$$\mathsf{Var}(|z_1|) = \mathsf{E}(|z_1|^2) - (\mathsf{E}(|z_1|))^2 = \frac{1}{L}\Xi_1. \tag{13}$$

Replacing (13) into (10), we have

$$\mathsf{P}(|z_1| > h) \geq 1 - \frac{\Xi_1}{\Xi_1 + L(h - g_s\sigma^2)^2}. \tag{14}$$

Then, (9) can be rewritten as

$$\begin{aligned}\mathsf{P}\left(\bigcap_{s=1}^{S}\{|z_s| > h\}\right) &\geq 1 - \sum_{s=1}^{S}\frac{\Xi_s}{\Xi_s + L(h - g_s\sigma^2)^2} \\ &\geq 1 - S\frac{\Xi_{\max}}{\Xi_{\max} + L(h - g_{\max}\sigma^2)^2},\end{aligned} \tag{15}$$

where $\Xi_{\max} = \max\{\Xi_s\}_{s\in[1,S]}$, and $g_{\max} = \max\{g_s\}_{s\in[1,S]}$. When $L \to \infty$, the probability converges to 1.

Step 2:

Letting $y = \gamma M - S$, by Markov's inequality, we have

$$\mathsf{P}(Y > y) \leq \frac{1}{y}\mathsf{E}(Y), \tag{16}$$

then from (6), we have

$$\mathsf{E}(Y) = \mathsf{E}\left(\sum_{m=S+1}^{M} \mathbf{1}_{\{|z_m|>h\}}\right) = \sum_{m=S+1}^{M} \mathsf{P}(|z_m| > h). \tag{17}$$

According to Chebyshev's inequality, we can obtain

$$\mathsf{P}(||z_m| - \mathsf{E}(|z_m|)| > h) \leq \frac{\mathsf{Var}(|z_m|)}{h^2}. \tag{18}$$

Next, we derive $\mathsf{E}(|z_m|)$ and $\mathsf{Var}(|z_m|)$. Without loss of generality, we consider the last element z_M. Similarly, we have

$$\mathsf{E}(|z_M|) = \frac{1}{L}\mathsf{E}\left(\sum_{s=1}^{S}\sum_{k=1}^{L} g_s m_{M,k}^* m_{s,k}\right) = 0, \tag{19}$$

and

$$\begin{aligned}\mathsf{E}(|z_M|^2) &= \frac{1}{L^2}\mathsf{E}\left(\sum_{s=1}^{S}\sum_{k=1}^{L} g_s m_{M,k}^* m_{s,k}\right)^2 \\ &= \frac{1}{L^2}\sum_{s=1}^{S}\sum_{k=1}^{L}\sum_{s'=1}^{S} g_s g_{s'}\mathsf{E}(m_{M,k}^* m_{s,k} m_{M,k}^* m_{s',k}) \\ &= \frac{1}{L}\sum_{s=1}^{S} g_s^2\mathsf{E}((m_{M,k}^*)^2)\mathsf{E}(m_{s,k}^2).\end{aligned} \tag{20}$$

Let $\Psi_M = \sum_{s=1}^{S} g_s^2\mathsf{E}((m_{M,k}^*)^2)\mathsf{E}(m_{s,k}^2)$, then we can obtain

$$\mathsf{Var}(|z_M|) = \mathsf{E}(|z_M|^2) - (\mathsf{E}(|z_M|))^2 = \frac{1}{L}\Psi_M. \tag{21}$$

Replacing (19) and (21) into (18), we have

$$\mathsf{P}(|z_M| > h) \leq \frac{\Psi_M}{Lh^2}. \tag{22}$$

Thus (17) can be rewritten as

$$\mathsf{E}(Y) \leq \sum_{m=S+1}^{M}\frac{\Psi_M}{Lh^2} \leq (M - S - 1)\frac{\Psi_{\max}}{Lh^2}, \tag{23}$$

where $\Psi_{\max} = \max\{\Psi_m\}_{m\in[S+1,M]}$. Finally,

$$\mathsf{P}(Y > y) \leq \frac{1}{y}\mathsf{E}(Y) \leq \frac{(M - S - 1)\Psi_{\max}}{Lyh^2}. \tag{24}$$

When $L \to \infty$, $\mathsf{P}(Y > y)$ converges to 0, which completes the proof. □

Lemma 1 *Given tooth vectors $\mathbf{m}_i$ and $\mathbf{m}_j$, for all $m_{k,i} \in \mathbf{m}_i$ and $m_{s,j} \in \mathbf{m}_j$ satisfying $\mathsf{E}(m_{k,i}) = \mathsf{E}(m_{s,j}) = 0$ and $\mathsf{E}(|m_{k,i}|^2) = \mathsf{E}(|m_{s,j}|^2) = \sigma^2$, the following two statements are true: (i) if $i \neq j$, $\mathsf{E}(\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j) = 0$ and $\mathsf{E}(|\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j|^2) = \frac{1}{L}\sigma^4$; (ii) if $i = j$, $\mathsf{E}(\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_i) = \mathsf{E}(\frac{1}{L}\mathbf{m}_j^H\mathbf{m}_j) = \sigma^2$ and $\mathsf{E}(|\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_i|^2) = \frac{1}{L}(L-1)\sigma^4 + \frac{1}{L}3\sigma^4$.*

Proof: Let $z = \frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j = \frac{1}{L}\sum_{k=1}^{L} m_{i,k}^* m_{j,k}$.

For statement (i), since $\mathsf{E}(m_{i,k}) = \mathsf{E}(m_{j,k}) = 0$, we have

$$\mathsf{E}(\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j) = 0.$$

Furthermore, as we know $\mathsf{E}(|m_{i,k}|^2) = \mathsf{E}(|m_{s,k}|^2) = \sigma^2$, we can obtain

$$\begin{aligned}\mathsf{E}(|\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j|^2) &= \frac{1}{L^2}\mathsf{E}\left(\sum_{k=1}^{L} m_{i,k}^* m_{j,k} \sum_{q=1}^{L} m_{i,q}^* m_{j,q}\right) \\ &= \frac{1}{L}\sigma^4\end{aligned} \tag{25}$$

For statement (ii), it is easy to know that

$$\mathsf{E}(\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_j) = \mathsf{E}(\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_i) = \sigma^2$$

and

$$\begin{aligned}\mathsf{E}(|\frac{1}{L}\mathbf{m}_i^H\mathbf{m}_i|^2) &= \mathsf{E}\left(\frac{1}{L}\sum_{k=1}^{L} m_{i,k}^* m_{i,k}\right)^2 \\ &= \frac{1}{L^2}L(L-1)\sigma^4 + \frac{1}{L^2}\sum_{k=1}^{L}\mathsf{E}(|m_{i,k}|^4) \\ &= \frac{1}{L}(L-1)\sigma^4 + \frac{1}{L}3\sigma^4.\end{aligned} \tag{26}$$

Therefore, we complete the proof. □

Plankton: Scalable network configuration verification through model checking

Santhosh Prabhu, Kuan-Yen Chou, Ali Kheradmand, P. Brighten Godfrey, Matthew Caesar
University of Illinois at Urbana-Champaign

Abstract

Network configuration verification enables operators to ensure that the network will behave as intended, prior to deployment of their configurations. Although techniques ranging from graph algorithms to SMT solvers have been proposed, scalable configuration verification with sufficient protocol support continues to be a challenge. In this paper, we show that by combining equivalence partitioning with explicit-state model checking, network configuration verification can be scaled significantly better than the state of the art, while still supporting a rich set of protocol features. We propose Plankton, which uses symbolic partitioning to manage large header spaces and efficient model checking to exhaustively explore protocol behavior. Thanks to a highly effective suite of optimizations including state hashing, partial order reduction, and policy-based pruning, Plankton successfully verifies policies in industrial-scale networks quickly and compactly, at times reaching a 10000× speedup compared to the state of the art.

1 Introduction

Ensuring correctness of networks is a difficult and critical task. A growing number of network verification tools are targeted towards automating this process as much as possible, thereby reducing the burden on the network operator. Verification platforms have improved steadily in the recent years, both in terms of scope and scale. Starting from offline data plane verification tools like Anteater [19] and HSA [13], the state of the art has evolved to support real-time data plane verification [15, 12], and more recently, analysis of configurations [6, 5, 7, 1, 25].

Configuration analysis tools such as Batfish [6], ERA [5], ARC [7] and Minesweeper [1] are designed to take as input a given network configuration, a correctness specification, and possibly an "environment" specification, such as the maximum expected number of failures, external route advertisements, etc. Their task is to determine whether, under the given environment specification, the network configuration will always meet the correctness specification. As with most formal verification domains, the biggest challenge in configuration analysis is scalability. Being able to analyze the behavior of multiple protocols executing together is a nontrivial task. Past verifiers have used a variety of techniques to try to surmount this scalability challenge. While many of them sacrifice their correctness or expressiveness in the process, Minesweeper maintains both by modeling the network using SMT constraints and performing the verification using an SMT solver. However, we observe that this approach scales poorly with increasing problem size (4+ hours to check a 245-device network for loops, in our experiments). So, this paper addresses the following question: *Can a configuration verification tool have broad protocol support, and also scale well?*

We begin our work by observing that scalability challenges in configuration verification stem from two factors — the large space of possible packet headers, and the possibly diverse outcomes of control plane execution, particularly in the presence of failures. We believe that general purpose SAT/SMT techniques are not as well equipped to tackle these challenges as domain-specific techniques specifically designed to address them. In fact, these challenges have been studied extensively, in the domains of data plane verification and software verification. Data plane verification tools analyze the large header space to determine all possible data plane behaviors and check their correctness. Software verification techniques explore the execution paths of software, including distributed software, and identify undesirable executions that often elude testing. Motivated by the success of the analysis algorithms in these domains, we attempted to combine the two into a scalable configuration verification platform. The result — Plankton — is a configuration verifier that uses equivalence partitioning to manage the large header space, and explicit-state model checking to explore protocol execution. Thanks to these efficient analysis techniques, and an extensive suite of domain-specific optimizations, Plankton delivers consistently high verification performance.

Figure 1: Comparison of configuration verification systems

Our key contributions are as follows:

- We define a configuration verification paradigm that combines packet equivalence computation and explicit-state model checking.
- We develop optimizations that make the design feasible for networks of practical scale, including optimizations to reduce the space of event exploration, and techniques to improve efficiency of exploration.
- We implement a Plankton prototype with support for OSPF, BGP and static routing, and show experimentally that it can verify policies at practical scale (less than a second for networks with over 300 devices). Plankton outperforms the state of the art in all our tests, in some cases by as much as 4 orders of magnitude.

2 Motivation and Design Principles

Configuration verifiers take as input the configuration files for network devices, and combine them with an abstraction of the lower layers — the distributed control plane, which executes to produce data plane state, and the forwarding hardware that will use that state to process traffic. They may additionally take an *environment specification*, which describes interactions of entities external to the network, such as possible link failures, route advertisements, etc. Their task is to verify that under executions enabled by the supplied configuration and environment, correctness requirements are never violated. Configuration verifiers thus help ensure correctness of proposed configurations prior to deployment.

Figure 1 illustrates the current state of the art in configuration verification. As the figure shows, only Minesweeper [1] can reason about multiple possible converged data plane states of the network (e.g., due to topology changes or control plane non-determinism), while also having the ability to support more than just a specific protocol, and maintaining soundness of analysis. All other tools compromise on one or more key features. ARC [7], for example, uses graph algorithms to compute the multiple converged states enabled by failures, but only for shortest-path routing. As a result it cannot handle common network configurations such as BGP configurations that use LocalPref, any form of recursive routing, etc. The reason for the mismatch in Minesweeper's functionality in contrast to others is that it makes a different compromise. By using an SMT-based formulation, Minesweeper is able to achieve good data plane coverage and feature coverage, but pays the price in performance. As experiments show [2], Minesweeper scales poorly with network size, and is unable to handle networks larger than a few hundred devices in reasonable time. Our motivation for Plankton is simple — can we design a configuration verification tool without compromising scale or functionality?

Achieving our goal requires tackling two challenges: packet diversity and data plane diversity. Packet diversity, which refers to the large space of packets that needs to be checked, is easier to handle. We leverage the notion of *Packet Equivalence Classes* (PECs), which are sets of packets that behave identically. Using a trie-based technique similar to VeriFlow [15], we compute PECs as a partitioning of the packet header space such that the behavior of all packets in a PEC remains the same throughout Plankton's exploration. A more interesting aspect of PECs is how to handle dependencies across PECs without compromising performance. In Plankton, this is done by a dependency-aware scheduler designed to maximize independent analysis (§ 3.2).

Data plane diversity refers to the complexity of checking every possible converged data plane that an input network configuration may produce. It is the task of the control plane model to ensure coverage of these possible outcomes. Simulation-based tools (the best example being Batfish [6]) execute the system only along a single non-deterministic path, and can hence miss violations in networks that have multiple stable convergences, such as certain BGP configurations. ARC's graph-based approach accounts for possible failures, but can support only shortest-path routing. In order to overcome these shortcomings, Minesweeper, the current state of the art in terms of functionality, uses an SMT solver to search through possible failures and non-deterministic protocol convergence, to find any converged state that represents a violation of network correctness.

A key intuition behind our approach is that the *generic search technique employed by SMT solvers makes the core of the configuration verification problem much more difficult than it has to be*. Network control planes operate using simple algorithms which can not only be easily modeled in software, but can also find a protocol's outcome much more quickly than general-purpose SMT solving. In fact, the common case is that the control plane computes some variant of shortest or least-cost paths. To illustrate this point, we implemented simple single-source shortest path solvers in SMT (Z3) and a model checker (SPIN). The SMT formulation is implemented as constraints on the solution, while the model checker explores execution paths of the Bellman-Ford algorithm; and in this simplistic case the software has deterministic execution. The result is that the model checker approach is similar to a normal execution of software, and is around 12,000× faster even in a moderate-sized fat tree network of $N = 180$ nodes (Figure 2).

Of course, this is intentionally a simplistic, fully-

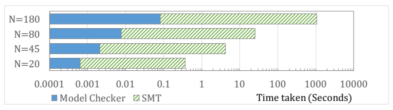

Figure 2: Comparison of two ways to compute shortest paths.

deterministic case with simple implementations. The point is that the model checking approach begins with a huge advantage — so huge that it could explore many non-deterministic execution paths and still outperform SMT. This leads to our next key intuition: *the effect of non-determinism is important, but the amount of "relevant" non-determinism is limited*. Networks can experience "relevant" non-determinism like the choice of what failures occur, and protocol execution; as well as "irrelevant" non-determinism like message timing that ultimately doesn't affect the outcome. Configurations and protocols are usually designed to keep the outcome mostly deterministic, with non-deterministic branch points ultimately leading to one or a small number of different converged states.

Motivated by this intuition, we create a control plane model that incorporates the possible non-deterministic behaviors, but we also implement optimizations so that when the *outcome* of the executions is actually deterministic, the "irrelevant" non-determinism is pruned enough that performance is comparable to simulation. This model is exhaustively explored by SPIN, a model checker designed for Promela programs. SPIN performs a depth-first search on the state space of the program, looking for states that violate the policy being checked. We further assist SPIN through optimizations that minimize the size of individual states, thus making the traversal process more efficient. Thanks to these two types of optimizations, Plankton achieves our goal of scalable, general-purpose configuration verification.

3 Plankton Design

We now present Plankton's design, illustrated in Figure 3.

3.1 Packet Equivalence Classes

The first phase in Plankton's analysis is the computation of Packet Equivalence Classes. As we discussed in § 2, Plankton uses a trie-based technique inspired by VeriFlow. The trie in Plankton holds prefixes obtained from the configuration, including any prefixes that are advertised (explicitly or automatically), any prefixes appearing in route maps, any static routes, etc. Each prefix in the trie is associated with a config object, that describes any configuration information that is specific to that prefix. For example, consider Figure 4, which illustrates a highly simplified example where the prefixes `128.0.0.0/1` and `192.0.0.0/2` are being advertised over OSPF in a topology with 3 devices. The trie holds three config objects — the default, and one for each advertised prefix.

Once the trie is populated, Plankton performs a recursive traversal, simultaneously keeping track of where the prefix boundaries define division of the header space. For each known partition, it stores the most up-to-date network-wide config known. When the end of any new prefix is reached, the config object that is associated with it is merged with the network-wide config for the partition that

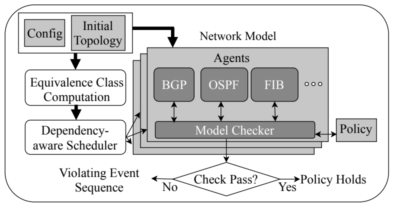

Figure 3: Plankton design

denotes the prefix. In our simple example, the traversal produces three classes defined by ranges — `[192.0.0.0, 255.255.255.255]` with two nodes originating prefixes, `[128.0.0.0, 191.255.255.255]` with only one origin, and `[0.0.0.0, 127.255.255.255]` without any node originating any prefix. As the example shows, each PEC-specific configuration computed this way will still include information about the original prefixes contributing to the PEC. Storing these prefixes may seem redundant. However, note that even within a PEC, the lengths of the prefixes that get advertised or get matched in route filters play a role in decision making.

3.2 Dependency-aware Scheduling

It is tempting to believe that Packet Equivalence Classes could be analyzed fully independently of each other, and that an embarrassingly parallel scheme could be used in the verification process. While this is indeed true sometimes, there can often be dependencies between various PECs. For example, consider a network that is running iBGP. For the various peering nodes to be able to communicate with each other, an underlying routing protocol such as OSPF should first establish a data plane state that forwards packets destined to the devices involved in BGP. In such a network, the manner in which OSPF determines the forwarding behavior for the device addresses will influence the routing decisions made in BGP. In other words, the PECs that are handled by BGP depend on the PECs handled by OSPF. In the past, configuration verification tools have either ignored such cases altogether, or, in the case of Minesweeper, modeled these classes simultaneously. Specifically, for a network of with n routers running iBGP, Minesweeper creates $n+1$ copies of the network, searching for the converged solution for the n loopback addresses and also BGP. Effectively, this turns the verification problem into one quadratically larger than the original. Given that configuration verification scales significantly worse than linearly in input size, such a quadratic increase in input size often makes the problem intractable.

Plankton goes for a more surgical approach. Once the PECs are calculated, Plankton identifies dependencies between the Packet Equivalence Classes, based on recursive routing entries, BGP sessions, etc. The dependencies are stored as a directed graph, whose nodes are the PECs, and directed edges indicate which PECs depend on which others. In order to maximize parallelism in verification runs across PECs, a dependency-aware scheduler first identifies strongly

Packet Equivalence Classes

Figure 4: Packet Equivalence Class computation

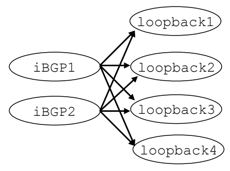

Figure 5: PEC Dependency Graph

connected components in the graph. These SCCs represent groups of PECs that are mutually dependent, and hence need to be analyzed simultaneously through a single verification run. In addition, if an SCC is reachable from another, it indicates that the upstream SCC can be scheduled for analysis only after the one downstream has finished. Each verification run is a separate process. For an SCC S, if there is another SCC S' that depends on it, Plankton forces all possible outcomes of S to be written to an in-memory filesystem (S will always gets scheduled first). Outcomes refer to every possible converged state for S, together with the non-deterministic choices made in the process of arriving at them. When the verification of S' gets scheduled, it reads these converged states, and uses them when necessary.

Minesweeper's technique of replicating the network roughly corresponds to the case where all PECs fall into a single strongly connected component. We expect this to almost never be the case. In fact, in typical cases, the SCCs are likely to be of size 1, meaning that every PEC can be analyzed in isolation, with ordering of the runs being the only constraint*. For example, Figure 5 illustrates the dependency graph for a typical case where two PECs are being handled in iBGP on a network with 4 different routers. The only constraint in this case is that the loopback PECs should be analyzed before the iBGP PECs can start. In such cases, Plankton's keeps the problem size significantly smaller, and maximizes the degree of parallelism that can be achieved.

When a PEC needs the relevant converged states of past PECs for its exploration, the non-deterministic choices may need to be coordinated across all these PECs. In particular, consider the choice of link failures: if we hypothetically executed one PEC assuming link L has failed and another PEC assuming L is working, the result represents an invalid execution of the overall network. Therefore, our current prototype matches topology changes across explorations. A second class of non-deterministic choices is protocol non-determinism. In our experiments, we have not seen cases of protocol non-determinism that requires matching across PECs. OSPF by its nature has deterministic outcomes, but on networks which have non-determinism in their internal routing (e.g., non-deterministically configured BGP for internal routing) and where message timing is correlated across PECs (e.g., via route aggregation), the system would need to coordinate this non-determinism to avoid false positives.

*An example where the SCCs are bigger than one PEC is the contrived case where there exists a static route for destination IP A whose next hop is IP B, but another static route for destination IP B whose next hop is IP A.

3.3 Explicit-state Model Checker

The explicit state model checker SPIN [9] provides Plankton its exhaustive exploration ability. SPIN verifies models written in the Promela modeling language, which has constructs to describe possible non-deterministic behavior. SPIN's exploration is essentially a depth-first search over the possible states of the supplied model. Points in the execution where non-deterministic choices are made represent branching in the state space graph.

Plankton's network model is essentially an implementation of the control plane in Promela. Our current implementation supports OSPF, BGP and static routing. Recall from § 3.1 that Plankton partitions the header space into Packet Equivalence Classes. For each SCC, Plankton uses SPIN to exhaustively explore control plane behavior. In order to improve scalability, Plankton also performs another round of partitioning by executing the control plane for each prefix in the PEC separately. This separation of prefixes is helpful in simplifying the protocol model. However, it does limit Plankton's support for route aggregation. While features such as a change in the routing metric can be supported, if there is a route map that performs an exact match on the aggregated prefix, it will not apply to the more specific routes, which Plankton models. Once the converged states of all relevant prefixes are computed, a model of the FIB combines the results from the various prefixes and protocols into a single network-wide data plane for the PEC.

In what follows, we present Plankton's network model that will be executed by SPIN. We will initially present a simple, unoptimized model, which is functionally correct but has significant non-determinism that is irrelevant to finding different converged states. Subsequently, in § 4, we discuss how Plankton attempts to minimize irrelevant non-determinism, making the execution of the deterministic fragments of the control plane comparable to simulation.

3.4 Abstract Protocol Model

To define a control plane suitable for modeling real world protocols such as BGP and OSPF, we look to the technique used by Minesweeper wherein the protocols were modeled as instances of the stable paths problem. Along similar lines, we consider the Simple Path Vector Protocol [8], which was originally proposed to solve the stable paths problem. We first extend SPVP to support some additional features that we wish to model. Based on this, we construct a protocol we call the *Reduced Path Vector Protocol*, which we show to be sufficient to correctly perform model checking, if we are interested only in the converged states of the network. We use RPVP as the common control plane protocol for Plankton. We begin with a brief overview of SPVP, highlighting our extensions to the protocol. Appendix A contains the full details of the protocol and our extensions.

3.4.1 SPVP and its extension

SPVP is an abstract model of real-world BGP, replacing the details of BGP configurations with abstract notions of import/export filters and ranking functions. For each node n and peer n', the import and export filters dictate which advertisements (i.e. the advertiser's best path to the *origin*) n can receive from and send to n', respectively. The ranking function for n dictates the preference among all received advertisements. These notions can be inferred from real-world configurations.

We slightly extend the original SPVP [8] to support more features of BGP. The extensions are as follows: we allow for multiple origins instead of a single one; the ranking function can be a *partial order* instead of a total one to allow for time based tie breaking; and to be able to model iBGP, we allow the ranking function of any node to change at any time during the execution of protocol.

It is well known that there are configurations which can make SPVP diverge in some or all execution paths. However, our goal is only to check the forwarding behavior in the converged states, through explicit-state model checking. So, we define a much simpler model that can be used, without compromising the soundness or completeness of the analysis (compared to SPVP).

3.4.2 Reduced Path Vector Protocol (RPVP)

We now describe RPVP, which is specifically designed for explicit-state model checking of the converged states of the extended SPVP protocol.

In RPVP, the message passing model of SPVP is replaced with a shared memory model. The network state only consists of the values of the best known path of each node at each moment (best-path). In the initial state, the best path of all nodes is $\perp$, except origins, whose best path is ε. At each step, the set of all enabled nodes (E) is determined (Algorithm 1, line 5). A node n is considered enabled if either i) the current best path p of n is invalid, meaning that the next hop in p has a best path that is not a prefix of p.

$$\text{invalid}(n) \triangleq \text{best-path}(\text{best-path}(n).\text{head}) \neq \text{best-path}(n).\text{rest}$$

Algorithm 1 RPVP

```
1:  procedure RPVP(:)
2:      Init : $\forall n \in N - Origins.\ \text{best-path}(n) \leftarrow \perp$
3:      Init : $\forall o \in Origins.\ \text{best-path}(o) = \varepsilon$
4:      while true do:
5:          $E \leftarrow \{n \in N \mid \text{invalid}(n) \vee \exists n' \in \text{peers}(n).\ \text{can-update}_{\text{n}}(n')\}$
6:          if $E = \emptyset$ then:
7:              break
8:          end if
9:          $n \leftarrow \text{nondet-pick}(E)$
10:         if $\text{invalid}(n)$ then
11:             $\text{best-path}(n) \leftarrow \perp$
12:         end if
13:         $U \leftarrow \text{best}(\{n' \in \text{peers}(n) \mid \text{can-update}_{\text{n}}(n')\})$
14:         $n' \leftarrow \text{nondet-pick}(U)$
15:         $p \leftarrow \text{import}_{n,n'}(\text{export}_{n',n}(\text{best-path}(n')))$
16:         $\text{best-path}(n) \leftarrow p$
17:     end while
18: end procedure
```

Or ii) there is a node n' among the peers of n that can produce an advertisement which will change the current best path of n. In other words, n' has a path better than the current best path of n, and the path is acceptable according to the export and import policies of n' and n respectively.

$$\text{can-update}_{\text{n}}(n') \triangleq \text{better}(\text{import}_{\text{n,n'}}(\text{export}_{\text{n',n}}(\text{best}(n'))), \text{best}(n))$$

Where $better_n(p, p')$ is true when path p is preferred over p' according to the ranking function of n.

At any step of the execution, if there is no enabled node, RPVP has reached a converged state. Otherwise a node n is non-deterministically picked among the enabled set (line 9). If the current best path of n is invalid, the best path is set to $\perp$. Among all peers of n that can produce advertisements that can update the best path of n, the neighbors that produce the highest ranking advertisements are selected (line 13). Note that in our model we allow multiple paths to have the same rank, so there may be more than one elements in the set U. Among the updates, one peer n' is non-deterministically selected and the best path of n is updated according to the advertisement of n' (lines 14-16). By the end of line 16, an iteration of RPVP is finished. Note that there are no explicit advertisements propagated; instead nodes are polled for the advertisement that they would generate based on their current best path when needed. The the protocol terminates once a converged state for the target equivalence class is reached. RPVP does not define the semantics of failure or any change to the ranking functions. Any topology changes to be verified are made before the protocol starts its execution and the latest version of the ranking functions are considered.

A natural question is whether or not performing analysis using RPVP is sound and complete with respect to SPVP. Soundness is trivial as each step of RPVP can be simulated using a few steps of SPVP. If we are only concerned about the converged states, RPVP is complete as well:

Theorem 1. *For any converged state reachable from the initial state of the network with a particular set of links L failing at certain steps during the execution of SPVP, there is an* *execution of RPVP with the same import/export filters and ranking functions equal to the latest version of ranking functions in the execution of SPVP, which starts from the initial state in which all links in L have failed before the protocol execution starts, and reaches the same converged state. Particularly, there is a such execution in which at each step, each node takes a best path that does not change during the rest of the execution.*

Proof. The proof can be found in the Appendix. □

Theorem 1 implies that performing model checking using the RPVP model is complete. Note that RPVP does not preserve all the transient states and the divergent behaviors of SPVP. This frees us from checking unnecessary states as we are only interested in the converged states. Yet, even the reduced state space has a significant amount of irrelevant non-determinism. Consequently, we rely on a suite of other domain-specific optimizations (§ 4) to eliminate much of this non-determinism and make model checking practical.

Note that our presentation of RPVP has assumed the that a single best path is picked by each node. This matches our current implementation in that we do not support multipath in all protocols. In a special-case deviation from RPVP, our implementation allows a node running OSPF to maintain multiple best paths, chosen based on multiple neighbors. While we could extend our protocol abstraction to allow multiple best paths at each node, it wouldn't reflect the real-world behavior of BGP which, even when multipath is configured, makes routing decisions based on a single best path. However, such an extension is valid under the constrained filtering and ranking techniques of shortest path routing. Our theorems can be extended to incorporate multipath in such protocols. We omit that to preserve clarity.

3.5 Policies

We primarily target verification of data plane policies over converged states of the network. Similar to VeriFlow [15], we don't implement a special declarative language for policies; a policy is simply an arbitrary function computed over a data plane state and returning a Boolean value. Plankton implements a Policy API where a policy supplies a callback which will be invoked each time the model checker generates a converged state. Plankton gives the callback the newly-computed converged data plane for a particular PEC, as well as the relevant converged states of any other PEC that the current PEC depends on. Plankton checks the callback's return value, and if the policy has failed, it writes a trail file describing the execution path taken to reach the particular converged state.

Our API allows a policy to give additional information to help optimize Plankton's search: *source nodes* and *interesting nodes*. We define two converged data plane states for a PEC to be *equivalent* if their paths from the source nodes have the same length and the same interesting nodes are in the same position on the path. Plankton may suppress checking a converged state if an equivalent one (from the perspective of that policy) has already been checked (§ 4.2 and § 4.3 describe how Plankton does this). If source and interesting nodes are not supplied, Plankton by default assumes that all nodes might be sources and might be interesting.

As an example, consider a waypoint policy: traffic from a set S of sources must pass through firewalls F. The policy specifies sources S, interesting nodes F, and the callback function steps through each path starting at S and fails when it finds a path that does not contain a member of F. As another example, a loop policy can't optimize as aggressively: it has to consider all sources.

In general, this API enables *any policy that is a function of a single PEC's converged data plane state*. We have found it simple to add new policies, currently including: Reachability, Waypointing, Loop Freedom, BlackHole Freedom, Bounded Path Length and Multipath Consistency [1]. We highlight several classes of policies that fall outside this API: (i) Policies that inspect the converged control plane state, as opposed to the data plane: while not yet strictly in the clean API, this information is easily available and we implemented a representative example, Path Consistency (§5), which asserts that the control plane state as well as the data plane paths for a set of devices should be identical in the converged state (similar to Local Equivalence in Minesweeper [1]). (ii) Policies that require multiple PECs, e.g., "packets to two destinations use the same firewall". This would be an easy extension, leveraging Plankton's PEC-dependency mechanism, but we have not performed a performance evaluation. (iii) Policies that inspect dynamic behavior, e.g., "no transient loops prior to convergence", are out of scope just as they are for all current configuration verification tools.

4 Optimizations

Although Plankton's RPVP-based control plane greatly reduces the state space, naive model checking is still not efficient enough to scale to large networks. We address this challenge through optimizations that fall into two major categories — reducing the search space of the model checker, and making the search more efficient.

4.1 Partial Order Reduction

A well-known optimization technique in explicit-state model checking, Partial Order Reduction (POR) involves exploring a set of events only in one order, if the various orderings will result in the same outcome. In general, precisely answering whether the order of execution affects the outcome can be as hard as model checking itself. Model checkers such as SPIN provide conservative heuristics to achieve some reduction. However, in our experiments, this feature did not yield any reduction. We believe this is because our model of the network has only a single process, and SPIN's heuristics are designed to apply only in a multiprocess environment. Even if we could restructure the model to use SPIN's heuristics, we do not expect significant reductions, as evidenced in past work [4]. Instead, we implement POR heuristics, based on our knowledge of the RPVP control plane[†].

4.1.1 Explore consistent executions only

To describe this optimization, we first introduce the notion of a *consistent* execution: For a converged state S and a partial execution of RPVP π , we say that π is consistent with S iff at each step of the execution, a node picks a path that is equal to it its best path in S and never changes it.

Readers may notice that Theorem 1 asserts the existence of a consistent execution leading to each converged state of the network, once any failures have happened. This implies that if the model checker was to explore only executions that are consistent with some converged state, completeness of the search would not be compromised (soundness is not violated since every such execution is a valid execution). Of course, when we start the exploration, we cannot know the exact executions that are consistent with some converged state, and hence need to be checked. So, we conservatively assume that every execution we explore is relevant, and if we get evidence to the contrary (like a device having to change a selected best path), we stop exploring that execution.

4.1.2 Deterministic nodes

Even when there is the possibility of non-deterministic convergence, the "relevant" non-determinism is typically localized. In other words, after each non-deterministic choice, there is a significant amount of *essentially* deterministic behavior before the opportunity for another non-deterministic choice, if any, arises. (We consider it analogous to endgames in chess, but applicable at any point in the protocol execution.) However, this is obscured by "irrelevant" non-determinism – particularly, ordering between node execution that doesn't impact the converged state. Our goal is to prune the irrelevant non-determinism to reduce the search space for Plankton's model checker.

For an enabled node n in state S with a single best update u, we say n is *deterministic* if in all possible converged states reachable from S, n will have the path selected after n processes u. Of course, with the model checker having only partially executed the protocol, it is highly non-obvious which nodes are deterministic! Nevertheless, suppose for a moment we have a way to identify at least *some* deterministic nodes. How could we use this information? At each step of RPVP, after finding the set of enabled nodes, if we can identify at least one deterministic enabled node, we choose *one* of these nodes and instruct SPIN to process its update. (More specifically, we pick one arbitrarily.) This avoids the costly non-deterministic branching caused by having to explore the numerous execution paths where *each one* of the enabled nodes is the one executed next. The following theorem shows this is safe.

[†]Since we wish to check all converged states of the network, it can be argued that any reduction in search space is essentially POR. But here, we are referring optimizations that have a localized scope.

Theorem 2. *Any partial execution of RPVP consistent with a converged state can be extended to a complete execution consistent with that state.*

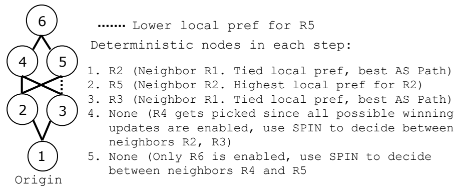
Proof. The proof can be found in the Appendix. □

By definition, choosing *any* deterministic node as the single node to execute next produces a new state that remains consistent with all possible converged states reachable from the prior state. Thus, Theorem 2 implies this deterministic choice does not eliminate any converged states from being reachable, preserving completeness. Note that this optimization does not require the entire network to have one converged state; it can apply at every step of the execution, possibly between non-deterministic choices.

What remains is the key: how can we identify deterministic nodes? Perfect identification is too much to hope for, and we allow our heuristics to return fewer deterministic nodes than actually exist. We build heuristics that are specific to each routing protocol, prioritizing speed and simplicity above handling atypical cases like circular route redistribution.

For OSPF, our detection algorithm runs a network-wide shortest path computation, and picks each node only after all nodes with shorter paths have executed. We cache this computation so it is only run once for a given topology, set of failures, and set of sources.

For BGP, the detection algorithm performs the following computation: For each node which is enabled to update its best path, it checks whether there exists a pending update that would never get replaced, because the update would definitely be preferred over other updates that are enabled now or may be in the future. To check this, we follow the node's BGP decision process, so if the update is tied for most-preferred in one step it moves to the next. For each step of the decision process, the preference calculation is quite conservative. For local pref, it marks an update as the winner if it matches an import filter that explicitly gives it the highest local pref among all import filters. For AS Path, the path length of the current update must be the minimum possible in the topology. For IGP cost, the update must be from the peer with minimum cost. If at any node, any update is found to be a clear winner, the node is picked as a deterministic node, and is allowed to process the update. If no node is found that has a clear winner but there is a node that has ≥ 2 updates tied for the most preferred, then we deterministically pick any one such node and have SPIN non-deterministically choose which of the multiple updates to process. Figure 6 illustrates these scenarios on a BGP network, highlighting one sequence of node selections (out of many possible).



```
Deterministic nodes in each step:

2. R5 (Neighbor R2. Highest local pref for R2)
3. R3 (Neighbor R1. Tied local pref, best AS Path)
4. None (R4 gets picked since all possible winning
   updates are enabled, use SPIN to decide between
   neighbors R2, R3)
5. None (Only R6 is enabled, use SPIN to decide
   between neighbors R4 and R5
```

Figure 6: Step-by-step choice of deterministic nodes (Each node has a different AS number).

The detection algorithm may fail to detect some deterministic nodes. For instance, suppose node N is deterministic but its import filter from neighbor M sets the highest local pref for updates with a particular community attribute, and M can never assign that attribute. Then the detection algorithm will fail to mark N as deterministic. But successfully identifying *at least one* deterministic node in a step will avoid non-deterministic branching at that step. As long as this happens frequently, the optimization will be helpful.

Even if the decision on a node is ambiguous in a particular state, the system will often make progress to a state where ambiguities can be resolved. In the example above, once M selects a path (and therefore will never change its path as described in § 4.1.1), the detection algorithm no longer needs to account for a possible more-preferred update from it, and may then be able to conclude that N is deterministic.

4.1.3 Decision independence

If node A's actions are independent of any future decisions of node B and vice versa, then the execution ordering between A and B does not matter. We check a sufficient condition for independence: any route advertisements passed between these nodes, in either direction, must pass through a node that has already made its best path decision (and therefore will not transmit any further updates). In this case, we pick a single arbitrary execution order between A and B.

4.1.4 Failure ordering

As stated in § 3.4.2, the model checker performs all topology changes before the protocol starts execution. We also enforce a strict ordering of link failures, reducing branching even further.

4.2 Policy-based Pruning

Policy-based pruning limits protocol execution to those parts of the network that are relevant to the satisfaction/failure of the policy. When a policy defines a set of source nodes (§ 3.5), it indicates that the policy can be checked by analyzing the forwarding from those nodes only. The best example for this is reachability, which is checked from a particular set of starting nodes. When an execution reaches a state where all source nodes have made their best-path decision, Plankton considers the execution, which is assumed to be consistent, to have finished. In the cases where only a single prefix is defined in a PEC, Plankton performs a more aggressive pruning, based on the influence relation. Any device that cannot influence a source node is not allowed to execute. With some additional bookkeeping, the optimization can be extended to cases where multiple prefixes contribute to a PEC, but our current implementation does not support this. The optimization is also not sound when applied to PECs on which other PECs depend. A router that does not speak BGP may not directly influence a source node, but it may influence the routing for the router IP addresses, which in turn may affect the chosen path of the source node. So, the optimization is not applied in such cases.

4.3 Choice of Failures

In addition to the total ordering of failures described in § 4.1.4, Plankton also attempts to reduce the number of failures that are explored, using equivalence partitioning of devices as proposed by Bonsai [2]. Bonsai groups devices in the network into abstract nodes, creating a smaller topology overall for verification. Plankton computes Device Equivalence Classes (DECs) similarly, and defines a Link Equivalence Class (LEC) as the set of links between two DECs. For each link failure, Plankton then explores only one representative from each LEC. When exploring multiple failures, we refine the DECs and LECs after each selection. Note that this optimization limits the choice of failed links, but the verification happens on the original input network. In order to avoid remapping interesting nodes (§ 3.5), they are each assigned to a separate DEC. Since the computed DECs can be different for each PEC, this optimization is done only when there are no cross-PEC dependencies.

4.4 State Hashing

During the exhaustive exploration of the state space, the explicit state model checker needs to track a large number of states simultaneously. A single network state consists of a copy of all the protocol-specific state variables at all the devices. Maintaining millions of copies of these variables is naturally expensive, and in fact, unnecessary. A routing decision at one device doesn't immediately affect the variables at any of the other devices. Plankton leverages this property to the reduce memory footprint, storing routing table entries as 64-bit pointers to the actual entry, with each entry stored once and indexed in a hash table. We believe this optimization can be applied to other variables in the network state too, as long as they are not updated frequently. Picking the right variables to optimize this way, and developing more advanced hash-based schemes, can be explored in the future.

5 Evaluation

We prototyped Plankton including the equivalence class computation, control plane model, policy API and optimizations in 373 lines of Promela and 4870 lines of C++, excluding the SPIN model checker. We experimented with our prototype on Ubuntu 16.04 running on a 3.4 GHz Intel Xeon processor with 32 hardware threads and 188 GB RAM.

We begin our evaluation with simple hand-created topologies incorporating protocol characteristics such as shortest path routing, non-deterministic protocol convergence, redistribution, recursive routing, etc. Among these tests, we incorporated examples of non-deterministic protocol execution from [8], as well as BGP wedgies, which are policy violations which can occur only under some non-deterministic execution paths. In each of these cases, Plankton correctly finds any violations that are present.

Having tested basic correctness, we next evaluate performance and compare to past verifiers. What sets Plankton apart from tools other than Minesweeper is its higher data plane coverage and ability to handle multiple protocols (Figure 1). We therefore compare primarily with Minesweeper but also include ARC in some tests.

We also evaluated Bonsai [2], a preprocessing technique that helps improve the scalability of configuration verification, for specific policies. Bonsai could assist any configuration verifier. We integrated Bonsai with Plankton, and experimentally compare the performance of Bonsai+Minesweeper and Bonsai+Plankton. However, it is important to study the performance of these tools without Bonsai too: Bonsai's network compression cannot be applied if the correctness is to be evaluated under link failures, or if the policy being evaluated is not preserved by Bonsai.

Experiments with synthetic configurations

Our first set of performance tests uses fat trees. We construct fat trees of increasing sizes, with each edge switch originating a prefix into OSPF. Link weights are identical. We check these networks for routing loops. In order to cause violations, we install static routes at the core routers. In our first set of experiments, the static routes match the routes that OSPF would eventually compute, so there are no loops. Then, we change the static routes such that some of the traffic falls into a routing loop. Figure 7(a) illustrates the time and memory consumed, using Plankton running on various numbers of cores, and using Minesweeper. We observed that under default settings, Minesweeper's CPU utilization keeps changing, ranging from 100% to $1,600\%$. In this experiment and all others where we run both Minesweeper and Plankton, the two tools produced the same policy verification results. This serves as an additional correctness check for Plankton. Bonsai is not used, because its currently available implementation does not appear to support loop policies.

As the results show, Plankton scales well with input network size. The speed and memory consumption varies as expected with the degree of parallelism. Even on a single core, Plankton is quicker than Minesweeper for all topologies. For larger networks, Plankton is several orders of magnitude quicker. On the memory front, even on 16 cores, Plankton's footprint is smaller than Minesweeper's.

Encouraged by the good performance numbers, we scale up to very large fat trees (Figure 7(b)). Here, Minesweeper doesn't finish even in 4 hours, even with a 500-device network (in the case of passing loop check, even in a 245-device network). So, we did not run Minesweeper on the larger networks. We run Plankton with a single CPU core only, to illustrate its time-memory tradeoff: since the analyses of individual PECs are fully independent and of identical computational effort, running with n cores would reduce the time by $n\times$, and increase memory by $n\times$. For example, in the 2,205-device network, Plankton uses about 170 GB per process. Policies that check a single equivalence class are much cheaper: for example, single-IP reachability finishes in seconds or minutes even on the largest networks (Figure 7(b)).

Next, we test Plankton with a very high degree of non-determinism. We evaluated a data center setting with BGP, which is often employed to provide layer 3 routing down to the rack level in modern data centers [17]. We configure BGP as described in RFC 7938 [17] on fat trees of various sizes. Furthermore, we suppose that the network operator intends traffic to pass through any of a set of acceptable *waypoints* on the aggregation layer switches (e.g., imagine the switches implement a certain monitoring function). We pick a random subset of aggregation switches as the waypoints in each experiment. However, we create a "misconfiguration" that prevents multipath and fails to steer routes through the waypoints[‡]. Thus, in this scenario, whether the selected path passes through a waypoint depends on the order in which updates are received at various nodes, due to age-based tie breaking [16]. We check waypoint policies which state that the path between two edge switches should pass through one of the waypoints. Plankton evaluates various non-deterministic convergence paths in the network, and determines a violating sequence of events. Time and memory both depend somewhat on the chosen set of aggregation switches, but even the worst-case times are less than 2 seconds (Figure 7(c)). We consider this a success of our policy-based pruning optimization: the network has too many converged states to be verified in reasonable time, but many have equivalent results in terms of the policy.

Experiments with semi-synthetic configurations

We use real-world AS topologies and associated OSPF link weights obtained from RocketFuel [24]. We pick a random ingress point that has more than one link incident on it. We verify that with any single link failure, all destination prefixes are reachable from that ingress. Here, Minesweeper's SMT-based search algorithm could be beneficial, due to the large search space created by failures. Nevertheless, Plankton performs consistently better in both time and memory (Figure 7(d)). Both tools find a violation in each case. The time taken by Plankton with 16 and 32 cores are often identical, since a violation is found in the first set of PECs. Note

[‡]This setup is convenient for practical reasons, as our current Plankton prototype implementation does not support BGP multipath.

Figure 7: Plankton experiments. Bars and lines/points denote time and memory consumption, respectively.

that in this experiment and the next, we did not use Bonsai, because (i) it cannot be used for checks involving link failures, and (ii) the topology has hardly any symmetry that Bonsai could exploit.

To evaluate our handling of PEC dependencies, we configure iBGP over OSPF on the AS topologies. The iBGP prefixes rely on the underlying OSPF routing process to reach the next hop. We check that packets destined to the iBGP-announced prefixes are correctly delivered. It is worth noting that this test evaluates a feature that, to the best of our knowledge, is provided only by Plankton and Minesweeper. Thanks to the dependency-aware scheduler, Plankton performs multiple orders of magnitude better (Figure 7(e)). This is unsurprising: Minesweeper's approach of duplicating the network forces it to solve a *much* harder problem here, sometimes over $300\times$ larger.

Integration with Bonsai

We integrated Plankton with Bonsai to take advantage of control plane compression when permitted by the specific verification task at hand. We test this integration experimentally by checking Bounded Path Length and Reachability policies on fat trees running OSPF. The symmetric nature of fat trees is key for Bonsai to have a significant impact. We measure the time taken by Plankton and Minesweeper, *after* Bonsai preprocesses the network. Plankton still outperforms Minesweeper by multiple orders of magnitude (Figure 7(f)).

Comparison with ARC

Having evaluated Plankton's performance in comparison with Minesweeper, we move on to comparing the performance of Plankton and ARC. ARC is specifically designed to check shortest-path routing under failures, so we expected the performance to be much better than the more general-purpose Plankton, when checking networks compatible with ARC. We check all-to-all reachability in fat trees and AS topologies running OSPF, under a maximum of 0, 1 and 2 link failures. Similar to Minesweeper, ARC's CPU utilization ranges from 100% to 600% under default settings. We allocate 8 cores to Plankton. Plankton is multiple orders of magnitude faster in most cases (Figure 7(g)).[§] This is genuinely surprising; one reason that *may* explain the observation is that ARC always computes separate models for each source-destination pair, whereas Plankton computes them based only the destination, when verifying destination address routing. Nevertheless, we do not believe that there is a fundamental limitation in ARC's design that would prevent it from outperforming Plankton on the networks that can be checked by either tool. Interestingly, while ARC's resiliency-focused algorithm doesn't scale as easily as Plankton for larger networks, its performance actually sometimes slightly *improves* when the number of failures to be checked increases. Plankton on the other hand scales poorly when checking increasing levels of resiliency. We do not find this concerning, since most interesting checks in the real world involve only a small number of failures. When we performed these experiments with Minesweeper, no check involving 2 failures ran to completion except the smallest fat tree.

Testing with real configurations

We used Plankton to verify 10 different real-world configurations from 3 different organizations, including the publicly available Stanford dataset. We first check reachability, waypointing and bounded path length policies on these networks, with and without failures. All except one of these networks use some form of recursive routing, such as indirect static

[§]Our numbers for ARC are similar to those reported by its authors for similar sized networks, so we believe we have not misconfigured ARC.

Experiment	Optimizations	Time	Memory

AS 1221 iBGP	All	27.54 s	254.22 MB
	All but deterministic node opt.	25.43 s	254.34 MB
Fat tree, BGP, 20 nodes	All	46 ms	137 MB
	All but deterministic node opt.	> 5 min	> 6144 MB
	All but policy-based pruning	> 5 min	> 6144 MB

Figure 8: Experiments with optimizations disabled/limited

routes or iBGP. We feel that this highlights the significance of Plankton's and Minesweeper's support for such configurations. Moreover, the PEC dependency graph for these networks did not have any strongly connected components larger than a single PEC, which matches yet another of our expectations. Interestingly, we did find that the PEC dependency graph had *self loops*, with a static route pointing to a next hop IP within the prefix being matched. It is also noteworthy that in these experiments, the only non-determinism was in the choice of links that failed, which substantiates our argument that network configurations in the real world are largely deterministic. Figure 7(h) illustrates the results, which indicate that Plankton can handle the complexity of real-world configuration verification.

In our next experiment with real world configs, we identify three networks where Loop, Multipath Consistency and Path Consistency policies are meaningful and non-trivial to check. We check these policies with and without link failures. Figure 7(i) illustrates the results of this experiment. The results indicate that the breadth of Plankton's policies scale well on real world networks. The Batfish parser, which is used by Minesweeper, was incompatible with the configurations, so we could not check these configs on Minesweeper (checking the Stanford dataset failed *after* parsing). However, the numbers we observe are significantly better than those reported for Minesweeper on similar-sized networks, for similar policies.

Optimization Cost/Effectiveness

To determine the effectiveness of Plankton's optimizations, we perform experiments with some optimizations disabled or limited. Figure 8 illustrates the results from these experiments. When all optimizations are turned off, naive model checking fails to scale beyond the most trivial of networks. The optimizations reduce the state space by $4.95\times$ in smaller networks and by as much $24{,}968\times$ in larger ones.

To evaluate device-equivalence based optimizations in picking failed links, we perform loop check on fat trees running OSPF under single link failure with the optimization turned off. We observed a $15\times$ reduction in speed, and a $38\times$ increase in memory overhead, indicating the effectiveness of the optimization in networks with high symmetry.

Experiment	No Bitstate Hashing	Bitstate Hashing
180 Node BGP DC Waypoint (Worst Case)	202 MB	67 MB
320 Node BGP DC Waypoint (Worst Case)	428 MB	215 MB
AS 1239 Fault Tolerance (2 cores)	7.33 GB	4.52 GB
AS 1221 Fault Tolerance (1 core)	163.53 MB	60 MB

Figure 9: The effect of bitstate hashing on memory usage

In the next set of experiments, we measure the impact of our partial order reduction technique of prioritizing deterministic nodes (§ 4.1.2). We first try the iBGP reachability experiment with the AS 1221 topology, with the detection of deterministic nodes in BGP disabled. We notice that in this case the decision independence partial order reduction produces reductions identical to the disabled optimization, keeping the overall performance unaffected. In fact, the the time improves by a small percentage, since there is no detection algorithm that runs at every step. We see similar results when we disable the optimization on the edge switches in our BGP data center example. However, this does not mean that the deterministic node detection can be discarded — in the BGP data center example, when the optimization is disabled altogether, the performance falls dramatically. The next optimization that we study is policy-based pruning. On the BGP data center example, we attempt to check a waypoint policy, with policy-based optimizations turned off. The check times out, since it is forced to generate every converged data plane, not just the ones relevant to the policy.

SPIN provides a built-in optimization called *bitstate hashing* that uses a Bloom filter to keep track of explored states, rather than storing them explicitly. This can cause some false negatives due to reduced coverage of execution paths. We find that bit state hashing provides significant reduction in memory in a variety of our test cases (Figure 9). According to SPIN's statistics our coverage would be over 99.9%. Nevertheless, we have not turned on bitstate hashing in our other experiments in favor of full correctness.

6 Limitations

Some of the limitations of Plankton, such as the lack of support for BGP multipath and limited support for route aggregation, have been mentioned in previous sections. As discussed in § 3.2, Plankton may also produce false positives when checking networks with cross-PEC dependencies, because it expects that every converged state of a PEC may coexist with every converged state of other PECs that depend on it. However, such false positives are unlikely to happen in practice, since real-world cases of cross-PEC dependencies (such as iBGP) usually involve only a single converged state for the recursive PECs. Our current implementation of Plankton assumes full visibility of the system to be verified, and that any dynamics will originate from inside the system. So, influences such as external advertisements need to be modeled using stubs that denote entities which originate them. Plankton's technique is not suited for detecting issues in vendor-specific protocol implementations, a limitation that all existing formal configuration analysis tools share. As with most formal verification tools, one needs to assume that Plankton itself is correct, both in terms of the theoretical foundations as well as the implementation. Correct-by-construction program synthesis could help in this regard.

7 Related Work

Data plane verification: The earlier offline network verification techniques [19, 13] have evolved into more efficient and real-time ones (e.g., [15, 12, 10, 26, 3, 11]), including richer data plane models (e.g., [21, 14]). These techniques however, cannot verify configurations prior to deployment.

Configuration verification: We discussed the state of the art of configuration verification in § 2, and how Plankton improves upon the various tools in existence. CrystalNet [18] emulates actual device VMs, and its results could be fed to a data plane verifier. However, this would not verify non-deterministic control plane dynamics. Simultaneously improving the fidelity of configuration verifiers in *both* dimensions (capturing dynamics as in Plankton and implementation-specific behavior as in CrystalNet) appears to be a difficult open problem.

Optimizing network verification: Libra [27] is a divide-and-conquer data plane verifier, which is related to our equivalence class-based partitioning of possible packets. The use of symmetry to scale verification has been studied in the data plane [22] and control plane (Bonsai [2]). We have discussed how Plankton uses ideas similar to Bonsai, as well as integrates with Bonsai itself.

Model checking in the networking domain: Past approaches that used model checking in the networking domain have focused almost exclusively on the network software itself, either as SDN controllers, or protocol implementations [4, 23, 20]. Plankton uses model checking not to verify software, but to verify configurations.

8 Conclusion and Future Work

We described Plankton, a formal network configuration verification tool that combines equivalence partitioning of the header space with explicit state model checking of protocol execution. Thanks to pragmatic optimizations such as partial order reduction and state hashing, Plankton produces significant performance gains over the state of the art in configuration verification. Improvements such as checking transient states, incorporating real software, partial order reduction heuristics that guarantee reduction, etc. are interesting avenues of future work.

A Extended SPVP

In extended SPVP, for each node n, and for each peer $n' \in \text{peers}(n)$, $\text{rib-in}_n(n')$ keeps track of the most recent advertisement of n' to n. In addition, $\text{best-path}(n)$ keeps the best path that n has to one of the *multiple* origins. Peers are connected using reliable FIFO message buffers to exchange advertisements. Each advertisement consists of a path from the advertising node to an origin. In each step (which we assume is performed atomically) a node n takes an advertisement

p from the buffer connected to peer n', and applies an import filter on it ($\mathrm{import}_{n,n'}(p)$). n then updates $\text{rib-in}_n(n')$ with the new imported advertisement. In our extension, we assume that each node has a ranking function λ that provides a *partial order* over the paths acceptable by the node. n then proceeds by updating its best-path to the highest ranking path in rib-in_n. If the best path in rib-in_n have the same rank as the current best path and that path is still valid, $\text{best-path}(n)$ will not change. If the best path is updated, n advertises the path to its peers. For each peer n', n applies the export filter on the path ($\mathrm{export}_{n,n'}(\text{best-path}(n))$) before sending the advertisement.

The import filter, the export filter, and the ranking functions are abstract notions that will be inferred from the configuration of the node. We make reasonable assumptions about these notions (Appendix B). Attributes such as local pref, IGP cost, etc. are accounted for in the the ranking function and the import/export filters.

If a session between two peers fails, the messages in the buffer are lost and the buffer cannot be used anymore. We assume that when this happens, each peer gets $\perp$ as the advertised path. Additionally, to be able to model iBGP, in extended SPVP we allow the ranking function of any node n to change at any time during the execution of the protocol. This is to model cases in which for example a link failure causes IGP costs to change. In such cases we assume that n receives a special message to recompute its best-path according to the new ranking function.

The state of network at each point in time consists of the values of best-path, rib-in, and the contents of the message buffers. In the initial state S_0, the best path of the origins is ε and the best path of the rest of the nodes are $\perp$ which indicates that the node has no path. Also for any $n, n' \in V$, $\text{rib-in}_n(n')$ is $\perp$. We assume that initially the origins put their advertisements in the message buffer to their peers, but the rest of the buffers are empty.

An (partial) execution of SPVP is a sequence of states π which starts from S_0 and each state is reachable by a single atomic step of SPVP on the state before it. A converged state in SPVP, is a state in which all buffers are empty. A complete execution is an execution that ends in a converged state. It is well known that there are configurations which can make SPVP diverge in some or all execution paths. However, our goal is to only to check the forwarding behavior in the converged states, through explicit-state model checking. So, we define a much simpler model that can be used, without compromising the soundness or completeness of the analysis (compared to SPVP).

B Assumptions

We make the following assumptions in in our theoretical model.

- Both import/export filters return $\perp$ if the filter rejects the advertisement according to the configuration.
- All import filters reject paths that cause forwarding loops. They also do not alter the path (unless the path is rejected).
- All export filters for each node n not rejecting an advertisement, will append n at the end of the advertised path. No other modification is made to the path.
- Path $\perp$ has the lowest ranking in all ranking functions.
- The import/export filters never change during the execution of the protocol. Note that we do not make such assumption for the ranking functions.

Note that these are reasonable assumptions with respect to how real world protocols (especially BGP) work.

C Proof of Theorems

Proof of Theorem 1. For a complete execution $\pi = S_0, S_1, ..., S_c$ of SPVP and a state S_i in that execution, for any node n, we say that n is converged in S_i for execution π iff n has already picked the path it has in the converged state (S_c) and does not change it:

$$\mathrm{converged}_\pi(n, S_i) \triangleq \\ \forall j. i \le j \le c : \text{best-path}_{S_j}(n) = \text{best-path}_{S_c}(n)$$

It it clear that when a node converges in an state, it remains converged (according to the definition above).

Lemma 1. *In any complete execution $\pi = S_0, S_1, ..., S_c$ of SPVP, for any sate S_i, for any two nodes n and n', if $\exists l : n' = \text{best-path}_{S_i}(n)[l]$ [¶] , and $\text{best-path}_{S_i}(n') \neq \text{best-path}_{S_i}(n)[l :]$, there is a j ($i < j \le c$) such that $\text{best-path}_{S_j}(n) \neq \text{best-path}_{S_i}(n)$.*

Proof. This can be shown by a simple induction on the length of the prefix of the best path of n from n to up to n' (l). If $l = 1$ (i.e the two nodes are directly connected) then either n' will advertise its path to n and n and will change its path or the link between n and n' fails in which case n will receive an advertisement with $\perp$ as the path (Section 3.4.1), which causes n to change its path. Note that the argument holds even if the ranking function of n or n' changes. If $l > 1$, assuming the claim holds for lengths less than l, for $n'' = \text{best-path}_{S_i}(n)[0]$, either $\text{best-path}_{S_i}(n'') \neq \text{best-path}_{S_i}(n)[1 :]$ in which case due to induction hypothesis the claim holds, or $\text{best-path}_{S_i}(n'') = \text{best-path}_{S_i}(n)[1 :]$ in which case we note that $n' = \text{best-path}_{S_i}(n'')[l-1]$, and since the length of the path n'' to n' is less than l, by induction hypothesis we know that eventually (i.e for a $j > i$) $\text{best-path}_{S_j}(n'') \neq \text{best-path}_{S_j}(n)[1 :]$ and by induction hypothesis this will lead to a change in the best path of n.

[¶]For a path $P = p_0, p_1, ..., p_n$, we denote p_i by $P[i]$ and $p_i, p_{i+1}, ..., p_n$ by $P[i :]$.

□

Corollary 1. *For any complete execution π of SPVP , for any node n, any node along the best path of n in the converged state converges before n.*

Now consider a complete execution $\pi = S_0, S_1, ..., S_c$ of SPVP. We will construct a complete execution of RPVP with $|N|$ steps (where N is set of all nodes) resulting in the same converged state as S_c. We start with a topology in which all the links that have failed during the execution of SPVP are already failed. For any node n, we define $C_\pi(n) = min\{i | \text{converged}_\pi(n, S_i)\}$. Consider the sequence $n_1, n_2, ..., n_{|N|}$ of all nodes sorted in the increasing order of C_π. Now consider the execution of RPVP $\pi' = S'_0, S'_1, ..., S'_{|N|}$ which starts from the initial state of RPVP and in each state S'_i, (a) either node n_{i+1} is the picked enabled node and the node $p_i = \text{best-path}_{S_c}(n_{i+1})[0]$ is the picked best peer, or (b) in case $p_i = \perp$, nothing happens and $S'_{i+1} = S'_i$.

First, note that (modulo the repeated states in case *b*), π' is a valid execution of of RPVP: at each state S'_i (in case *a*), n_{i+1} is indeed an enabled node since its best path at that state is $\perp$ and according to corollary 1, p_i has already picked its path: Also p_i will be in the set of best peers of n_{i+1} (line 13 in RPVP). Assume this is not the case, i.e there exists another peer p' that can advertise a better path. This means that in S_c of SPVP, p' can send an advertisement that is better (according to the version of ranking functions in S_c) than the converged path of n_{i+1}. This contradicts the fact that S_c is a converged path.

Second, note that $S'_{|N|}$ is a converged state for RPVP, because otherwise, using similar reasoning as above, S_c can not be converged. Also it is easy to see that $\text{best-path}_{S'_{|N|}} = \text{best-path}_{S_c}$

Finally, note that in π', once a node changes its best path from $\perp$, it does not change its best path again.

□

Proof of Theorem 2. We begin by making two observations about RPVP that are key to the proof:

- RPVP for a prefix can never converge to a state having looping paths.
- If a node u adopts the best path of a neighbor v, v will be next hop of u.

Consider any converged state S. The theorem states that any partial execution that is consistent with S can be extended to a full execution that leads to S. We prove the theorem by induction on the length of the longest best path in S.

Base case: If in a network a converged state exists where the best path at each node is of length 0, that means that each node is either an origin or doesn't have a best path for the prefix. Since any execution apart from the empty execution (where no protocol event happens) is not consistent with this state, the theorem holds.

Induction hypothesis: If a converged state exists in a network such that all best paths are of length k or less, then any partial execution that is consistent with the converged state can be extended to a full execution that reaches the converged state.

Induction step: Consider a network with a converged state S such that the longest best path is of length $k + 1$. We first divide the nodes in the network into two classes — N, which are the nodes with best paths of length k or less, and N', which are nodes with best paths of length $k + 1$. Consider a partial execution π that is consistent with S. We identify two possibilities for π:

Case 1: Every node that has executed in π falls into N. In this case, we define a smaller network which is the subgraph of the original network, induced by the nodes in N. In this network, the path selections made in S will constitute a converged state. This is because in the original network, in the state S, the nodes in N are not enabled to make state changes. So, we can extend π such that we get an execution π' where nodes in N match the path selections in S. Now, we further extend π' with steps where each node in N' reads the best path from the node that is its nexthop in S and updates its best path. When every node in N has done this, the overall system state will reach S.

Case 2: At least one node in N' has executed in π. In this case, we observe that since π is consistent with S, by the definition of a consistent execution, no node in the network has read the state of any node in N'. So, we can construct an execution π' which has the same steps as π, except that any step taken by a node in N' is skipped. As in the previous case, π' can be extended to reach a converged state in the subgraph induced by N. We extend π, first by using the steps that extend π', and if necessary, taking additional steps at nodes from N' to reach S. □

Config2Spec: Mining Network Specifications from Network Configurations

Rüdiger Birkner[1] Dana Drachsler-Cohen[2*] Laurent Vanbever[1] Martin Vechev[1]

[1]*ETH Zürich* [2]*Technion*

Abstract

Network verification and configuration synthesis are promising approaches to make networks more reliable and secure by enforcing a set of policies. However, these approaches require a formal and precise description of the intended network behavior, imposing a major barrier to their adoption: network operators are not only reluctant to write formal specifications, but often do not even know what these specifications are.

We present *Config2Spec*, a system that automatically synthesizes a formal specification (a set of policies) of a network given its configuration and a failure model (e.g., up to two link failures). A key technical challenge is to design a synthesis algorithm which can efficiently explore the large space of possible policies. To address this challenge, *Config2Spec* relies on a careful combination of two well-known methods: data plane analysis and control plane verification.

Experimental results show that *Config2Spec* scales to mining specifications of large networks (>150 routers).

1 Introduction

Consider the task of a network operator who—tired of human-induced network downtimes—decides to rely on formal methods to verify her network-wide configurations [4,14,22,30] or to synthesize them automatically [5,9,10,28,29]. The operator quickly realizes that both verifiers and synthesizers require a specification of the correct intended network-wide behavior. A few generic requirements quickly come to mind: surely she wants her network to ensure reachability. At the same time, she realizes that her network does *way* more than just ensuring reachability. Among others, it needs to enforce load balancing for popular destinations, provide isolation between customers, drop traffic for suspicious prefixes, and reroute business traffic via predefined waypoints—all these under failures and over hundreds of devices. Writing the precise specification seems daunting, especially as most of it has been homegrown over years, by a team of network engineers (some of which do not even work there anymore).

This situation illustrates the difficulty of writing network specifications. Akin to software specifications, formal specifications are hard to write (as hard as writing the program in the first place [20]), debug, and modify [2,21]. Yet, without easier ways to provide network specifications, network verification and synthesis are unlikely to get widely deployed.

Config2Spec We introduce *Config2Spec*, a system that automatically mines a network's specification from its configurations and a failure model (e.g., up to *k* failures). *Config2Spec* is precise: it returns *all* policies that hold under the failure model (no false negatives) and *only* those (no false positives).

Challenges Mining precise network specifications is challenging as it involves exploring two exponential search spaces: *(i)* the space of all possible policies, and *(ii)* the space of all possible network-wide forwarding states. The challenge stems from the fact that individually exploring each of the search spaces can be prohibitive: a search for the true policies is hard since they are a small fraction of the policy space, while a search for the violated policies is hard since these require witnesses (data planes), which are often sparse.

Insights *Config2Spec* addresses the above challenges by combining the strengths of data plane analysis and control plane verification. Data plane analysis enables us to compute the set of policies that hold for a single data plane, thereby providing an efficient way of *pruning* policies. On the other hand, control plane verification is an efficient way of *validating* that a single policy holds for all the data planes. *Config2Spec* combines the two approaches to prune the large space of policies through sampling and data plane analysis and then, to avoid the need of exploring all data planes, validating the remaining policies with control plane verification. The key insight is to dynamically identify the approach providing for better progress. We design predictors which rely on past iterations and the failure model to switch between the two approaches.

[*]Work done while at ETH Zürich.

Scalability While this approach scales, we identify three domain-specific techniques to improve it even further. First, to better utilize the pruning through data plane analysis, we design a *policy-aware* sampler of data planes. We experimentally show that our approach outperforms a random sampler: with typically fewer samples, it leads to pruning substantially more policies. Second, to reduce the number of queries posed to the verifier, we group queries to the control plane verifier. Third, we analyze the network topology to prune policies that are physically not feasible due to poor connectivity of the routers. For large networks and permissive failure models, this technique makes the difference between *Config2Spec* completing in few hours instead of days.

System We implemented *Config2Spec*, which leverages two state-of-the-art data plane analysis and control plane verification tools, Batfish [13] and Minesweeper [4]. As the implementation relies on these two tools, it is tied to configurations and features supported by them. The approach itself, is not limited to any specific type of configuration.

Config2Spec provides a substantial improvement over baselines that use each of the above tools in isolation (up to 8.3x against the best baseline). Further, *Config2Spec* often mines a precise network specification within an hour, and for large networks (> 150 routers) within 2.7 hours (for OSPF configurations) or 13.7 hours (for BGP configurations). We also illustrate that *Config2Spec* can handle real network configurations by running it successfully on Internet2's configurations.

Contributions Our main contributions are:

- A novel approach to automatically mine the specification of a network by leveraging both data plane analysis and control plane verification (§3).
- A dynamic predictor to decide which approach provides for better progress (§4).
- A policy-aware sampler to find data planes that are likely to prune more policies (§5).
- Policy grouping and topology-based trimming to reduce the number of queries posed to the verifier (§6, §7).
- An end-to-end implementation and an extensive evaluation across different topologies and baselines, showing that *Config2Spec* scales to large networks and significantly outperforms possible baselines (§8).

Novelty Several previous works [6, 7, 31] have looked into mining a network's specification by observing the content of the data plane. All of these works are limited to reachability policies and unlike *Config2Spec*, they either approximate the specification or do not consider the impact of failures on the specification. Concretely, they only produce the network's policies which hold when all links and routers are up. In contrast, *Config2Spec* is able to mine precise network specifications for a given failure model.

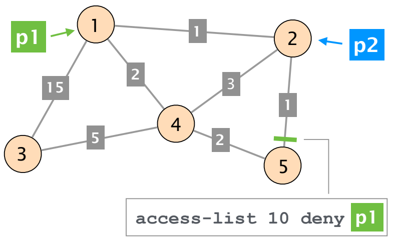

Figure 1: An OSPF network with five routers and two destinations. An ACL at router `5` blocks traffic destined to prefix `p1`, attached to router `1`.

Usefulness In general, the network's specification can be used for many different applications, such as configuration synthesis/verification and network management (e.g., analyzing the effects of configuration changes). Further, having the specification at hand allows network operators to check whether the policies they intend to enforce are indeed enforced.

In multiple discussions, network operators confirmed that a tool like *Config2Spec* is indeed useful. One operator mentioned that the adoption of a new monitoring tool fell through because it required the network's specification to detect flawed configuration changes. Another operator mentioned that having the network's specification at hand would greatly help them better understand their configurations that accumulated over years. Especially, since short-term fixes to problems that need immediate attention (e.g., congestion and hardware problems) are often forgotten and persist even long after the responsible engineer left the company. In addition, the specification can be used to streamline network's configuration by refactoring it, while keeping the same specification.

2 Motivation and Problem Definition

Obtaining a specification for how a network behaves can be useful in a variety of scenarios beyond network verification and synthesis, including helping the operator identify unexpected behaviors and inconsistencies, as well as enabling a smoother transition to (updated) configurations upon new requirements. To define the problem of mining specifications, we rely on two concepts: a *network specification*, composed of a set of *policies*, and a *failure model*, specifying under which failures the network specification should hold. We next define these concepts and illustrate them on a running example. Then, we introduce the network specification mining problem and discuss several baseline approaches together with their shortcomings, thus motivating our solution.

Running example Throughout the paper, we refer to the example shown in Fig. 1. Here, we have a network that consists of five routers and seven links. There are two host networks, `p1` and `p2`, attached to routers `1` and `2`. All routers

Policy	Meaning
`reachability(r, p)`	Traffic from `r` can reach `p`.
`isolation(r, p)`	Traffic from `r` is isolated from `p`.
`waypoint(r, w, p)`	Traffic from `r` to `p` passes through `w`.
`loadbalancing(r, p)`	Traffic from `r` to `p` is load balanced on at least two paths.

Table 1: Network policies (`r` and `w` are routers, `p` is a prefix).

are in the same OSPF area and the OSPF weights are depicted on the links. An IP access control list (ACL) on the interface from router `5` to `2` drops all packets destined to prefix `p1`.

Failure models A failure model consists of a *symbolic environment* and a number k. The symbolic environment defines which links are up or down, and which links may fail. Technically, a symbolic environment is a partition of the network links L into three subsets L_{up}, L_{down}, and $L_{symbolic}$ (i.e., given L_{up} and L_{down}, we can derive $L_{symbolic} = L \setminus (L_{up} \cup L_{down})$). The number k is a bound on the total number of links which can be simultaneously down. A *concrete environment* is a partition of the network links L into two subsets L_{up} and L_{down}. Namely, all links are fixed to a concrete state: up or down. We say that a failure model with a symbolic environment L^{SE}_{up}, L^{SE}_{down}, $L^{SE}_{symbolic}$ and a bound k, captures a concrete environment with L^{CE}_{up} and L^{CE}_{down} if $L^{SE}_{up} \subseteq L^{CE}_{up}$, $L^{SE}_{down} \subseteq L^{CE}_{down}$, and $|L^{CE}_{down}| \leq k$. Intuitively, a failure model captures all concrete environments for which the links in L^{SE}_{up} are up, the links in L^{SE}_{down} are down, and there are at most k links which are down.

For example, a failure model for our running example is $L_{symbolic} = L$ (i.e., L_{up} and L_{down} are the empty sets) and $k = 1$. This model describes any concrete environment with at most one link failure. There are eight concrete environments which meet this failure model: one where no link is down, and seven in which each of the links fails once. Another failure model is $L_{up} = \{$`2-4`$\}$, $L_{down} = \{$`2-5`$\}$, $L_{symbolic} = L \setminus (L_{up} \cup L_{down})$, and $k = 2$. This model describes any concrete environment whose link between routers `2` and `4` is up, the link between `2` and `5` is down, and the rest may be up or down. Since $k = 2$, another failed link is allowed in addition to `2-5`. There are six concrete environments that meet this failure model.

Network specification and policies A *network specification* consists of a set of policies. A *policy* captures a specific behavior in the network (e.g., reachability of two routers). It is modeled with a predicate (a constraint) which, given a concrete environment, evaluates to true if the policy holds for that concrete environment, and false otherwise. For our running example, the `reachability(5, p2)` policy evaluates to true for the concrete environment in which all links are up, and to false for the concrete environment where all links are down. We say a policy holds for a failure model if it holds for all concrete environments captured by the failure model.

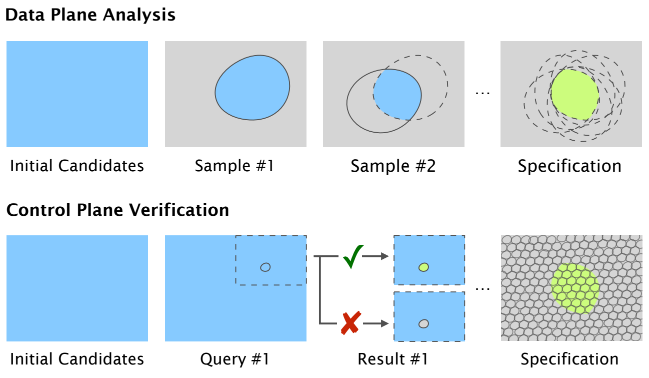

Figure 2: Illustration of the baseline approaches.

For example, the policy `reachability(5, p2)` holds for the failure model $L_{symbolic} = L$ and $k = 1$, but not for $k = 3$.

In our work, we focus on reachability, isolation, waypoint, and load balancing policies (summarized in Table 1). The reachability, isolation, and load balancing policies are defined as predicates over a router `r` and a subnet in the network `p`. These evaluate to true if, for the given concrete environment, traffic from router `r` can reach the prefix `p`, is isolated from `p`, or load balanced on at least two paths to `p`, respectively. The waypoint policy is defined over two routers `r` and `w`, and evaluates to true if, for the given concrete environment, traffic from `r` destined to prefix `p` passes through `w`. We note that our approach is extensible to any policy that is defined over the forwarding state (e.g., equal length paths).

Problem definition We now define the problem of mining a network specification:

Given a network configuration and a failure model, mine the network specification, i.e., the set of all policies which hold under the failure model.

For our running example and the failure model $L_{symbolic} = L$ and $k = 1$ (modeling up to one link failure), the network specification consists of the following policies:
`reachability(1, p1)`, `reachability(1, p2)`,
`reachability(2, p1)`, `reachability(2, p2)`,
`reachability(3, p1)`, `reachability(3, p2)`,
`reachability(4, p1)`, `reachability(4, p2)`,
`reachability(5, p2)`, `loadbalancing(4, p2)`.

Baseline solutions To address the above problem, one may consider two baseline approaches: *(i)* data plane analysis and *(ii)* control plane verification.

Data plane analysis Data plane analysis tools (e.g., [13, 17, 18]) enable reasoning of policies that hold for a certain concrete environment. Today, such tools are scalable enough to reason about all of our considered policies within seconds or minutes (mostly depending on the size of the network). Thus, one could use such tools to mine a specification by iterating over all concrete environments captured by the failure model, computing a data plane for each (from the configuration), and analyzing them to infer the set of policies which hold for each concrete environment. The solution is then the intersection of all obtained policy sets. Fig. 2 (top) visualizes this approach. Initially, every policy is a candidate which can be part of the network specification (blue area). With every sampled data plane, the set of policies that hold for it are computed (shown in circle). These are then intersected with the policies of the previous samples (dashed circles). At the end, the remaining candidate policies are those that hold for all samples, and thus form the network specification (green area). Unfortunately, for large topologies or failure models with many concrete environments, this approach does not scale (see §8.2).

Control plane verification Control plane verification tools (e.g., [4]) enable checking individual policies for a given failure model. Technically, this can be accomplished by symbolically encoding the network, its configuration, the failure model and a policy into a formula, and then checking the satisfiability of this formula. Fig. 2 (bottom) visualizes this approach. Initially, all policies are part of the set of candidates of the specification. At every step, one policy (circle) is picked and posed as a query to the verifier. The verifier either returns that the policy holds (green) or shows a counterexample to disprove it (gray). In the end, every policy has either been verified or disproved. As in data plane analysis, while control plane verification tools scale to the policies that we consider, enumerating all possible policies and checking them one by one in the above manner is prohibitive (see §8.2).

3 Our Approach: *Config2Spec*

In this section, we first present our key insight of combining the two baseline approaches from §2 and explain the reasoning behind it. Then, we provide an overview of the system (details are provided in the following sections).

3.1 Key Insight

We address the problem of mining a network specification by combining the baseline approaches and leveraging their respective strengths: data plane analysis is efficient at pruning policies, while control plane verification is efficient at validating policies. The key idea of our combination is to reduce the space of policies by sampling forwarding states and pruning policies using data plane analysis, and then running control plane verification to verify a small set of remaining policies.

This combination works well because many policies which do not hold are *dense violations*. That is, they are violated for many of the concrete environments captured by the failure model. For example, in our running example and the failure model $L_{symbolic} = L$ with $k = 1$ (up to one failure), the policy `waypoint(3, 1, p2)` only holds for the concrete environment in which all links are up, but the one from router `3` to `4`. Thus, by sampling any other concrete environment (e.g., $L_{down} = \{$`2-5`$\}, L_{up} = L \setminus L_{down}$), and computing all policies that hold for it, we can prune `waypoint(3, 1, p2)`.

On the other hand, there are *sparse violations*, which are policies that do not hold for the failure model, but are violated only by very few concrete environments. For example, in our running example and the same failure model, the policy `isolation(5, p1)` is violated only by two concrete environments: *(i)* $L_{down} = \{$`2-5`$\}, L_{up} = L \setminus L_{down}$ and *(ii)* $L_{down} = \{$`1-2`$\}, L_{up} = L \setminus L_{down}$. Unless we check these particular environments, this policy cannot be pruned by data plane analysis. Thus, we prune sparse violations during the step of control plane verification. Since the overall number of true policies and sparse violations is often significantly smaller than the number of concrete environments, control plane verification is an efficient solution for this.

3.2 The *Config2Spec* System

We build on this insight to design *Config2Spec* (Fig. 3), which takes as input the network configuration (of all devices) and a failure model and outputs the network specification.

Config2Spec runs in a loop which dynamically switches between the two approaches until the specification is mined. To achieve this, *Config2Spec* relies on three main components: *(i)* predictors, *(ii)* data plane analysis, and *(iii)* control plane verification. In addition, *Config2Spec* maintains two sets of policies, `cands` which overapproximates the specification, and `verified` which underapproximates it. We next explain these sets, the algorithm flow and the three components. We provide the full algorithm of *Config2Spec* in Appendix A.

Cands and verified *Config2Spec* keeps two sets: *(i)* `cands`, containing the current candidate policies, i.e., the policies that are known to hold or have not been pruned yet, and *(ii)* `verified`, containing the policies that are known to hold. `cands` initially contains all possible policies (blue area in Fig. 3), while `verified` is initially empty (green area in Fig. 3). We note that in practice, to avoid storing all policies in `cands`, only to prune many of them upon the first iteration of data plane analysis, *Config2Spec* directly initializes `cands` to the set of policies that holds for some concrete environment.

An invariant of the execution is that `cands` is a superset of the network specification, i.e., it contains at least all the policies that hold, while `verified` is a subset of it, i.e., it contains only policies that hold. *Config2Spec* terminates when these sets are equal – implying both equal the network specification – and then returns `verified`. Precision is ensured as *Config2Spec* does not miss any policy thanks to the invariant that `verified` contains only true policies (no false positives), while `cands` cannot miss a true policy (no false negatives).

Flow At each iteration, *Config2Spec* checks if `cands` equals `verified`. If so, it terminates. Otherwise, it checks two predictors to decide which approach is the more promising one to pursue: data plane analysis or control plane verification.

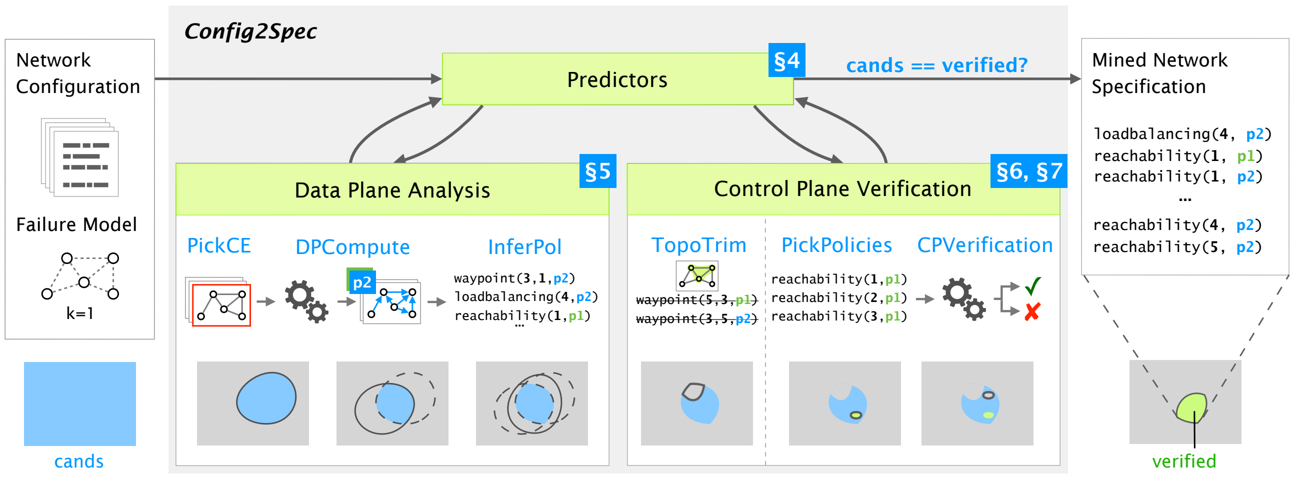

Figure 3: *Config2Spec* mines the specification from the network configuration and the failure model. It relies on three components: predictors, data plane analysis, and control plane verification. It maintains two sets: `cands`, consisting of the current candidate policies, and `verified`, consisting of the verified policies. During the execution, policies are removed from `cands` or added to `verified`. When `cands` equals `verified`, both equal the network specification, and then `verified` is returned.

Predictors (§4) We design two predictors to heuristically estimate which approach is likely to be more effective and dynamically transition between them. The predictors consider the execution times and the number of pruned and verified policies. The first predictor checks the effectiveness of each approach in classifying policies by measuring the time it needs to classify a single policy. The second predictor estimates the remaining time to mine the full specification.

Data plane analysis (§5) In every iteration of data plane analysis, *Config2Spec* samples a concrete environment, computes the policies that hold for it, and removes from `cands` any other policy. To sample a concrete environment, it executes `PickCE`, which employs a novel policy-aware sampler to find a concrete environment likely to prune more policies. Then, *Config2Spec* computes the data plane of that sample via `DPCompute`, which relies on prior tools (e.g., [13]). Next, it executes `InferPol` to compute all policies which hold for this data plane, and updates `cands` accordingly. Finally, *Config2Spec* checks whether all data planes have been analyzed. If so, it sets `verified` to `cands`, as the entire failure model has been covered and the full specification has been mined.

Control plane verification (§6) In each iteration of control plane verification, *Config2Spec* verifies a set of policies. For this, *Config2Spec* first executes `PickPolicies` to pick the next set of policies to verify. It then calls `CPVerification`, which relies on prior tools (e.g., [4]). The verifier either determines that all policies hold or returns a counterexample. In the former case, *Config2Spec* adds all the policies to `verified`, while in the latter case *Config2Spec* removes the ones violated by the counterexample from `cands`. Before the first iteration of control plane verification, *Config2Spec* invokes `TopoTrim` to reduce the verification overhead.

Topology-based trimming (§7) `TopoTrim` analyzes the topology and the failure model to trim (i.e., prune) policies which cannot hold regardless of the configuration (e.g., due to a lack of connectivity). It relies on graph algorithms to prune `reachability`, `waypoint`, and `loadbalancing` policies.

4 *Config2Spec*'s Predictors

In this section, we describe how *Config2Spec* dynamically decides whether to run the data plane analyzer or the control plane verifier. This decision relies on two predictors that capture the effectiveness of the approaches and the expected time remaining. Accordingly, *Config2Spec* infers which approach is more likely to make better progress. The predictors are: *(i)* the *Time-per-policy (TP) predictor*, favoring the approach more likely to classify more policies in a single execution, and *(ii)* the *Remaining-time (RT) predictor*, favoring the approach more likely to complete faster. If the predictors disagree on the approach, *Config2Spec* runs the data plane analyzer, we explain the reason for this choice shortly.

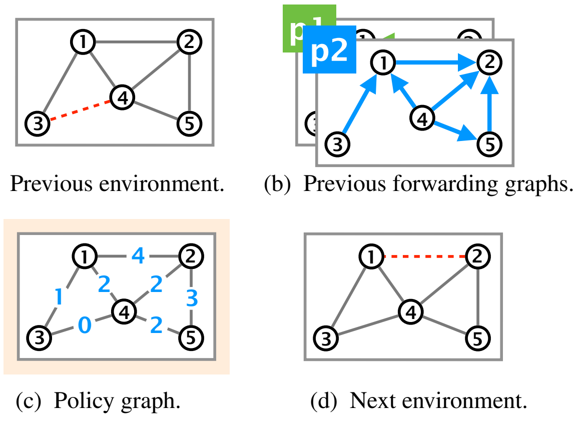
High-level behavior The predictors dynamically identify the different stages of the algorithm. In the beginning, sampling concrete environments is likely to provide the fastest progress, as at this stage the dense policies have not been pruned yet. Therefore, the TP predictor prefers data plane analysis initially. After most of the dense policies have been pruned, sampling environments may not significantly decrease the number of candidate policies anymore. At this point, the TP predictor starts to prefer control plane verification. Thus, the choice is then up to the RT predictor. It determines whether *Config2Spec* switches to control plane verification. If running data plane analysis for the remaining concrete environments is likely to be faster than running control plane verification on the remaining unclassified policies, the RT predictor prefers data plane analysis. Otherwise, it prefers control plane verification. This choice depends on the failure model: if it captures a small number of concrete environments, enumerating all of them can be faster than verifying the remaining set of candidate policies. In our running example and the failure model $L_{symbolic} = L$ and $k = 1$, this is the case. To conclude, the joint behavior of the predictors is to prefer control plane verification whenever *(i)* there is a large number of concrete environments and *(ii)* most remaining policies are true policies (i.e., part of the specification) or sparse violations.

Computation The predictors rely on statistics of the previous runs. The TP predictor is implemented by tracking two times: $T^{TP}_{analysis}$ and T^{TP}_{verify}, which record the average time to classify a single policy through analysis or verification (respectively). For $T^{TP}_{analysis}$, this time is computed by taking the ratio of the execution time of the last run of the data plane analysis and the number of policies which were pruned as a result of this analysis. For T^{TP}_{verify}, this time is computed similarly by taking the ratio of the execution time of the last run of the verifier and the number of policies which were classified by the verifier. The latter number is one of the following. If the verifier proved all policies hold, it equals the number of policies. Otherwise, if the verifier returned a counterexample, this number equals to the number of policies which were discovered as violations (i.e., the counterexample violated them). The TP predictor prefers the data plane analyzer if $T^{TP}_{analysis} < T^{TP}_{verify}$.

The RT predictor is implemented by tracking two (different) times: $T^{RT}_{analysis}$ and T^{RT}_{verify}, which record the execution time of a single run of the analyzer and verifier (respectively). The RT predictor prefers the data plane analyzer if the remaining time of the analyzer, obtained by multiplying $T^{RT}_{analysis}$ with the number of non-analyzed concrete environments is smaller than the remaining time of the verifier, given by multiplying $T^{RT}_{verifier}$ with the remaining number of unclassified policies.

Initialization To initialize T^{TP}_{verify} and T^{RT}_{verify}, *Config2Spec* executes the verifier on M policy sets (in our implementation, $M = 10$). It then sets T^{RT}_{verify} to the average execution time of the verifier, and T^{TP}_{verify} to the average ratio of execution time and policies verified or pruned. The estimates $T^{TP}_{analysis}, T^{RT}_{analysis}$ are initially 0, to guide *Config2Spec* to begin by data plane analysis. This captures our premise that initially data plane analysis is likely to classify more policies (the dense violations, which are the vast majority of the policies).

Windows To smoothen the behavior of the predictors, the times are averaged over the last N runs of the analyzer or verifier (in our implementation, $N = 10$).



(a) Previous environment. (b) Previous forwarding graphs. (c) Policy graph. (d) Next environment.

Figure 4: The policy graph is computed from the forwarding graphs of a previously analyzed concrete environment and guides us to an environment likely to prune more policies.

5 Data Plane Analysis

In this section, we present the key ingredients of running the data plane analysis in *Config2Spec*: the selection of the next concrete environment to analyze (`PickCE`), the computation of the data plane for that environment (`DPCompute`) and the inference of the policies from the data plane (`InferPol`).

5.1 Selection of Concrete Environments

At every iteration, one concrete environment is analyzed. The choice of this environment has a great impact on the overall runtime of the system. Thus, we design a sampling technique to pick the next concrete environment to prune a large number of policies from the set of candidates (`cands`). We call this technique *policy-aware sampling* as the next environment is picked based on the *policy graph*, a concept reflecting the current set of candidate policies, which we describe next.

Policy graph The *policy graph* for a given concrete environment is a copy of the network topology, augmenting the links with the number of policies that forward traffic along them. We say a `reachability(r,p)` policy forwards traffic along a link, if that link is part of a path in the forwarding graph of `p` from `r` to `p`. We define it similarly for the other policies. The policy graph allows us to identify the links on which large numbers of policies depend. Thus, we can pick a concrete environment in which these links are down. If the policies indeed hold only thanks to these links, they will be discovered as violations when analyzing this concrete environment.

We next define the policy graph. Given a network topology, a configuration, and a concrete environment, the policy graph extends the network topology with a mapping of links to weights (integers). The weight of a link represents the number of unclassified policies whose traffic is forwarded along that link. The weight is computed from the *forward-*

ing graphs of the concrete environment. Fig. 4 illustrates the concept of the policy graph using our running example (Fig. 1). Here, we are given an (already analyzed) concrete environment where all links are up, but the one between routers `3` and `4` (Fig. 4a). In this example, there are two destinations (`p1` and `p2`) and hence two forwarding graphs (Fig. 4b). For simplicity's sake, consider the following unclassified policies for destination `p2`: `reachability(i, p2)`, where `i` ranges over all five routers, and `loadbalancing(4, p2)`, which holds since router `4` has three paths to router `2` in the forwarding graph of `p2`. In this setting, the policy graph (Fig. 4c) maps, for example, link `1-3` to 1 (as only `reachability(3, p2)` depends on this link), link `2-5` to 3 (for `reachability(4, p2)`,`reachability(5, p2)` and `loadbalancing(4, p2)`), `1-2` to 4 (for `reachability(1, p2)`, `reachability(3, p2)`, `reachability(4, p2)` and `loadbalancing(4, p2)`), and `1-2` (which is down) to 0.

Policy-aware sampling Based on the idea of the policy graph, we design a policy-aware sampler for `PickCE`. The policy-aware sampler picks the next concrete environment to analyze based on the policy graph of the previously analyzed concrete environment and the current set of unclassified policies (`cands\verified`). This is done by selecting the links to add to L_{down} based on a probability distribution proportioned to the links' weights in the policy graph. The links' weights are computed by iterating over all unclassified policies (`cands\verified`) and counting, for each link, the number of policies that are forwarded along it. The probability distribution is needed to avoid getting stuck: a deterministic approach which adds the heaviest links to L_{down} can result in an oscillation between two concrete environments which already have been analyzed (we observed this phenomenon in practice). Adding non-determinism mitigates this issue, and in case it cannot, `PickCE` resorts to returning a random concrete environment which has not yet been analyzed. In the beginning, *Config2Spec* starts by analyzing the concrete environment in which all symbolic links are up.

For our running example and the policy graph in Fig. 4c, it assigns the link `1-3` to the probability $\frac{1}{14}$, `2-5` to $\frac{3}{14}$, and `1-2` to $\frac{4}{14}$. Assuming the usual failure model ($L_{symbolic} = L$ and $k = 1$), it then picks the next concrete environment by choosing one link that is down based on the distribution. For example, it picks the link `1-2` (Fig. 4d).

5.2 Analysis of a Concrete Environment

We now explain `DPCompute` and `InferPol`, which together compute all policies that hold for a given concrete environment and configuration.

The `DPCompute` algorithm executes two steps. First, for each router in the network, it computes the router's forwarding state. The forwarding state of a router is a list of destination prefix and next hop pairs. A pair `(p,w)` in the forwarding state of router `r` indicates that traffic reaching `r` for destination `p` is sent to router `w`. Computing the forwarding state of the routers is not trivial, however, there are solutions to efficiently compute them (e.g., [13]).

In the second step, `DPCompute` builds from the routers' forwarding states the forwarding graphs. It builds one forwarding graph for each equivalence class of destination prefixes (i.e., prefixes which can be captured via some prefix and have the same forwarding graph). The forwarding graph of a prefix `p` is a directed graph in which we have a link from router `r` to `w` if, according to `r`'s forwarding state, traffic for `p` is sent to `w`.

From the forwarding graphs, `InferPol` computes the policies by leveraging graph algorithms. For `reachability` and `waypoint` policies, it builds the *dominator tree* of all forwarding graphs. A dominator tree is a tree rooted at the destination of the forwarding graph. Its nodes are all routers that have at least one path to the destination. A router `a` is a child of a router `b` if *(i)* traffic from router `a` to the destination must pass through router `b` and *(ii)* for any other router `c` such that traffic from `a` must pass through it, traffic from `b` must also pass through it. `InferPol` infers a `reachability(r, p)` policy for every node `r` in the dominator tree of `p`. It further infers `waypoint(r,w,p)` for all routers `r` which are dominated by a waypoint `w` in the dominator tree of `p`. For `loadbalancing`, it computes the shortest paths in the network and infers `loadbalancing(r,p)` for routers `r` with multiple paths of the same cost available to reach destination `p`. For `isolation`, it infers `isolation(r,p)` for every router `r` and prefix `p` for which it has not inferred `reachability(r,p)`.

6 Control Plane Verification

Here, we present the two ingredients of the control plane verification in *Config2Spec*: the selection of policies to verify next (`PickPolicies`) and their verification (`CPVerification`).

CPVerification We begin with `CPVerification`, which takes as input a set of policies, the network configuration and the failure model. It checks whether all policies hold for any concrete environment meeting the failure model (for the given network configuration), or returns a counterexample.

Technically, the verifier symbolically encodes the configuration and the failure model as logical constraints: φ_{net} and φ_{fmodel}. The set of policies is encoded as a conjunction over formulas encoding the policies: $\varphi_{pols} = \bigwedge_{pl \in pols} \varphi_{pl}$. The verifier checks the satisfiability of $\varphi_{net} \wedge \varphi_{fmodel} \wedge \neg\varphi_{pols}$. If it is unsatisfiable, then all policies in *pols* hold. If the formula is satisfiable, then there is a counterexample, i.e., a concrete environment captured by the failure model, which under the given configuration violates φ_{pols} (i.e., at least one policy is violated). While the challenge of verifying network policies is not trivial, there are effective solutions (e.g., [4]).

PickPolicies This procedure takes the set of candidate policies (cands) and verified policies (verified) and returns the next set of policies to verify (from cands $\setminus$ verified). Since verifying is computationally expensive, the goal is to minimize the overall execution time of the verifier. By choosing a set of policies which have a dependency, the overall execution time of verifying them can be smaller than if they were verified one by one. Towards this goal, PickPolicies returns a maximal set of policies with the same destination prefix p.

We pick p arbitrarily, as once *Config2Spec* chooses to run the verifier, usually most policies are true policies.

Our grouping approach is always at least as good as verifying the policies one by one. The reason is that at each query to the verifier, at least one policy is classified. In the worst case, only one policy is classified as violation (if the verifier returned a counterexample which satisfies all policies but one). In a better case, several policies are classified as violation. In either of these cases, the violated policies are removed from cands, while the other policies in the set remain in cands (and will be verified in a later execution of CPVerfication). In the best case, all policies are classified as true policies. Namely, we can only gain from verifying multiple policies in the same execution of the verifier. Further, our grouping is maximal – grouping of policies with different prefixes is not helpful, as each prefix has a different forwarding graph, and so the verifier does not gain from grouping such policies.

7 Topology-based Trimming

In this section, we describe TopoTrim, a technique which reduces the load on the control plane verification by analyzing the failure model and the network topology. TopoTrim classifies policies as violations if their minimal connectivity requirements are not met under the given failure model.

TopoTrim is executed the first time *Config2Spec* chooses to run the verifier. It relies on the insight that some policies can be classified as violations directly from the network topology and failure model. For example, consider the network in Fig. 1 and the failure model with $L_{symbolic} = L$ and $k = 2$ (i.e., up to two link failures). We can infer that reachability(3, p1) cannot hold as 3 can become disconnected from the rest of the network if both links connected to it fail. For the same reason, any waypoint or loadbalancing policy where 3 is involved can be classified as violation.

To prune such policies, TopoTrim computes the $(k+1)$-edge-connected components of the topology for a failure model with k permitted failures. A $(k+1)$-edge-connected component is a set of nodes which remain connected even after removing any k edges. For example, for the network in Fig. 1 and the same failure model (where $k = 2$), the following routers are in a 3-edge-connected component: $\{1,2,4\}$.

There are efficient algorithms to compute $(k+1)$-edge-connected components, however they do not support links that must be up or down (L_{up} or L_{down}). To take these into account, TopoTrim first removes from the topology all links in L_{down}, updates k to $k - |L_{down}|$, and then, for each link in L_{up}, it adds k additional links between the routers to simulate that these routers are $(k+1)$-edge-connected. For example, for $L_{up} = \{(1,3)\}$, $L_{down} = \emptyset$ and $k = 2$, it adds two more edges between 1 and 3, so they are considered 3-edge-connected.

Based on this, TopoTrim classifies the following policies as violations (which are thus removed from cands). The policies reachability(r,p) and loadbalancing(r,p), for any router r and prefix p such that (r, r_p) is not in a $(k+1)$-edge-component, where r_p is the router attached to p. The policy waypoint(r,w,p) is classified as violation for any routers r and w and a prefix p such that *(i)* (r, w) is not in a $(k+1)$-edge-component or *(ii)* (w, r_p) is not in a $(k+1)$-edge-component, where r_p is the router attached to p.

8 Experimental Evaluation

In this section, we evaluate *Config2Spec* on multiple topologies to address the following research questions:

RQ1 How does *Config2Spec* scale to realistic topologies? We show that even for large networks with 158 routers and 189 links, it completes within 2.7 hours for OSPF configurations and 13.7 hours for BGP configurations.

RQ2 How does *Config2Spec* compare to the baselines? We show it improves the best one by up to a factor of 8.3.

RQ3 How do the domain-specific techniques contribute to *Config2Spec*? We show that *(i)* the policy-aware sampler leads to smaller candidate sets by up to a factor of 2 compared to random, and obtains them with fewer samples, and *(ii)* topology-based trimming and policy grouping reduce the queries by up to a factor of 2'500.

RQ4 Can *Config2Spec* be run on a real network configuration? We illustrate this on the Internet2 configuration.

Implementation *Config2Spec* is implemented in 5k lines of Python and Java code.[1] It computes the routers' forwarding states (§5.2) using Batfish [13], and verifies policies using Minesweeper [4]. We extended Minesweeper with the waypoint and loadbalancing policies. We note that while our implementation supports only configurations and features supported by these two third-party tools, our approach is not limited to specific configuration types or features.

Config2Spec takes as input the routers' configurations and a failure model. It outputs all policies that hold for the provided input. For large networks, we assume the network operator provides a list of devices that act as waypoints (e.g., middleboxes). In our experiments, we simulate it by randomly picking 20% of the routers to serve as waypoints.

Experiment setup To study how *Config2Spec* scales as a function of the topology size, we picked three topologies (small, medium, and large) from the Topology Zoo collec-

[1]Code is available at https://github.com/nsg-ethz/config2spec.

Topology	k	Config	Overall	DPA	CPV
BICS	1	OSPF	38.8 s	100%	0%

	2	85'021.0	702.8	0.8%
	3	98'837.6	6.8	0.01%

Table 3: The number of candidate policies and the number of policies in the specification *Config2Spec* returns. Percent shows the fraction of the policies of all candidate policies.

tion [19]: BICS with 33 routers connected by 48 links, Columbus with 70 routers and 85 links, and US Carrier with 158 routers and 189 links. We used NetComplete [10] to synthesize OSPF and BGP configurations using its path-ordering specifications for 2, 4, 8 and 16 prefixes. For each configuration type and topology, we generated 5 configuration sets.

For each set of router configurations, *Config2Spec* computes all policies which hold, for all four policy types in Table 1. We consider three failure models, where k is 1, 2, or 3, and we fix $L_{up} = L_{down} = \emptyset$ and $L_{symbolic} = L$ (i.e., any link can be up or down). The reported results are averaged over these runs and the two configuration types (i.e., OSPF and BGP). We ran all experiments in virtual machines with 32 GB of RAM and 12 virtual cores running at 2.3 GHz.

8.1 Scalability of *Config2Spec*

We begin by studying how *Config2Spec* scales to realistic topologies. To this end, we ran experiments on all three topologies and three failure models, and measured the time *Config2Spec* spent on the data plane analysis part – including `PickCE`, `DPCompute` (which invoked Batfish), and `InferPol` – and the control plane verification part – including `PickPolicies` and `CPVerification` (which invoked Minesweeper). The other parts completed in negligible times and were thus ignored (e.g., `TopoTrim` completed within five seconds for US Carrier and less than a second for BICS).

Table 2 shows the overall execution time (*Overall*) and how it is split between data plane analysis (*DPA*) and control plane verification (*CPV*) as a function of the topology, the number of failures (k), and the configuration type (*Config*). For example, for the US Carrier topology with $k = 3$ and OSPF configurations, *Config2Spec* completed within 43 minutes, where 59% of that time was spent on data plane analysis.

The results show that even for the US Carrier topology with its 158 routers and 189 links, *Config2Spec* mined the specification in a reasonable time (within 2.7 hours, for OSPF, and 13.7 hours, for BGP). The results also demonstrate that the runtime mainly depends on the network size, secondly on the failure model, and lastly on the configuration type. This is expected: the larger the network, the larger the set of candidate policies and the set of concrete environments (whose size also depends on the failure model). In contrast to the effect of the network size on the execution times, the permissiveness of the failure model shows a different trend: execution times increase from $k = 1$ and $k = 2$, but drop for $k = 3$. This is thanks to the topology-based trimming (§7), which becomes very significant for $k = 3$ (or higher values of k). For the evaluated topologies, most router pairs are not 4-edge-connected, thus many policies are pruned. We provide more details on trimming in §8.3. The results show also that for $k = 1$, *Config2Spec* only performs data plane analysis. This is because the number of concrete environments is significantly smaller than the number of candidate policies throughout execution, leading the RT predictor to favor data plane analysis. Lastly, results show that for BGP configurations, the execution time is higher than for OSPF configurations. This is mainly due to Minesweeper, for which we observe a five to ten times increase in the verification time for BGP compared to OSPF.

Table 3 reports the number of candidate policies and the number of policies in the specification, for each topology and failure model, averaged across the different configuration sets and the configuration types. The reported number of candidate policies is the number of policies that hold for the first concrete environment picked by *Config2Spec* (*Config2Spec* always begins with data plane analysis). We consider this set as the initial set of candidates, rather than all instantiations

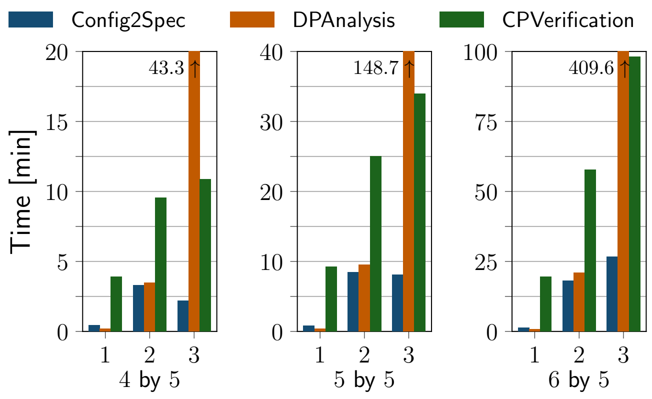

Figure 5: *Config2Spec* compared to the baselines of data plane analysis and control plane verification on grid topologies and different failure models. The bars of DPAnalysis and $k = 3$ are cut, and their maximum value is denoted next to them.

of the four policy types (Table 1), as the latter contains many policies which no concrete environment satisfies.

The results indicate that as the network size increases, the number of candidate policies increases, while the specification size (i.e., the number of policies that hold for all concrete environments) significantly drops. This demonstrates the challenge of *Config2Spec* to search in the large space of candidate policies for the small set of policies that hold.

8.2 Comparison to Baselines

We compare *Config2Spec* to the two baselines in §2: *(i)* a data plane analysis approach, which enumerates all data planes to infer the specification, and *(ii)* a control plane verification approach, which verifies the candidate policies one by one. As neither of the baselines scales to the larger networks considered in the last section, in this experiment, we use three grid topologies of sizes: 4 by 5, 5 by 5 and 6 by 5. We generated five sets of OSPF configurations per topology and used the failure model $L_{symbolic} = L$ with k ranging from 1 to 3.

Fig. 5 shows the execution time of each approach as a function of the topology and failure model. For $k = 2$ and $k = 3$, *Config2Spec* outperforms the baselines: the data plane analysis by 10.2x on average and up to 41.0x, and the control plane verification by 3.8x on average and up to 8.3x. For $k = 1$, data plane analysis is faster than *Config2Spec* because of *Config2Spec*'s setup time (i.e., the verification of few policies when initializing the predictors' times, see §4). Still, the overhead of *Config2Spec* is small (data plane analysis was faster on average by 24 seconds and by up to 37 seconds).

The results also show that both baselines have benefits. For less permissive failure models, data plane analysis performs better than control plane verification, whereas for permissive failure models it is the other way around. This demonstrates the advantage of the dynamic combination of *Config2Spec*.

8.3 Domain-specific Techniques

We next study how the domain-specific techniques improve *Config2Spec*'s performance. We study the following aspects: *(i)* how the policy-aware sampler (§5.1) helps reducing the number of concrete environments *Config2Spec* analyzes, and *(ii)* how topology-based trimming (§7) and policy grouping (§6) decrease the number of queries posed to the verifier.

Policy-aware sampler We compare the policy-aware sampler (called Policy-Aware) to a baseline which randomly picks a new concrete environment (called Random). We compare them by instantiating `PickCE` with each approach and running *Config2Spec* on the Topology Zoo topologies with the failure model $L_{symbolic} = L$ and $k = 3$, and with five sets of OSPF configurations and five sets of BGP configurations.

Table 4 shows the results. The first four columns show, for each approach, how many concrete environments were analyzed before *Config2Spec* transitioned to the verifier, and how many policies remained to verify (i.e., the percentage of remaining policies out of the policies that hold for the first sample). For example, for BICS, Policy-Aware required on average 36.4 samples before *Config2Spec* switched to verification, and at this point the size of the candidate policy set was reduced to 36.5% of the initial policy set (i.e., the set of policies which hold for the first sample).

Generally, the smaller the set of remaining policies (i.e., the closer the candidate set to the network specification is), the better. As a secondary goal, the number of analyzed concrete environments should be relatively small. Results indicate that Policy-Aware always obtains a better reduction in the size of the candidate set compared to Random. They also show that on average Policy-Aware typically required fewer samples than Random. However, we note that in 6 out of the 30 experiments, Random switched to verification before Policy-Aware did. This is not because Random made better progress. In contrary, the TP predictor decided to switch, as it observed that the concrete environments picked by Random were not effectively pruning policies anymore.

The next two columns of Table 4 provide more statistics. We checked, for each experiment, the relative size of the candidate sets for both approaches when *Config2Spec* with Policy-Aware transitioned to verification. For example, in one experiment using BICS, Policy-Aware transitioned to verification after 32 samples, and at that point the number of candidate policies was 970, while for Random, after 32 samples, there were 1'124 candidate policies, making the ratio 86.3%. In Table 4, Cands Ratio shows the average over the ten runs. We also checked how many additional samples Random required to reduce the candidate policies to (at most) the size obtained with Policy-Aware. For example, in that experiment for BICS, Policy-Aware required 32 samples to reduce the candidates to 970 policies, while Random required 43. Hence, Random needed 11 additional samples. In Table 4, Added Samples shows the average of this number. The re-

Topology	Policy-Aware Samples	Policy-Aware Candidates	Random Samples	Random Candidates	Cands Ratio	Added Samples	Policy-Aware PickCE	Policy-Aware DPAnalysis	Random PickCE	Random DPAnalysis
BICS	36.4	36.5%	42.1	39.5%	89.7%	45.7	22.1 ms	1.4 s	0.5 ms	1.3 s
Columbus	71.0	16.6%	79.0	26.4%	60.5%	109.0	63.1 ms	8.3 s	0.7 ms	7.7 s
US Carrier	113.8	9.6%	122.1	18.6%	51.6%	>500	358.2 ms	57.8 s	1.4 ms	51.6 s

Table 4: Comparison of the policy-aware sampler in `PickCE` (§5.1) and a random baseline. Samples is the number of samples before *Config2Spec* switched to verifier. Candidates is the percentage of remaining candidate policies at that point. Cands Ratio is the ratio of the candidate set sizes for Policy-Aware and Random when *Config2Spec* with Policy-Aware transitioned to verification. Added Samples is the number of samples Random needed to reduce the candidate set to the size of the candidate size with Policy-Aware. PickCE is the time to pick the next environment. DPAnalysis is the overall time to analyze a data plane.

sults indicate that Policy-Aware not only obtains a smaller candidate set, but reaches it significantly faster.

The last four columns of Table 4 show execution times: PickCE shows the execution time of the sampler, while DP-Analysis shows the overall execution time of a single data plane analysis (i.e., `DPCompute` and `InferPol`). Results show that while Policy-Aware takes more time than Random (as expected), the overhead is negligible compared to the overall execution time of the data plane analysis.

Topology-based trimming and policy grouping We next evaluate the topology-based trimming and policy grouping in reducing the number of queries to the verifier. We ran the experiments for the three topologies and the failure model with $k = 2$ and $k = 3$ (for $k = 1$, *Config2Spec* only performs data plane analysis §8.1). We measured how many queries to the verifier each technique saved. In every experiment, we recorded the number of policies *Config2Spec* had the first time it transitioned to the verification. This number, denoted B (for baseline), provides the number of queries to the verifier if we did not use either technique. We also recorded how many policies were pruned thanks to topology-based trimming. We count each policy that has been pruned as one saved query for the verifier, and denote the overall saved queries by T (for trimming). Also, we recorded how many queries were posed to the verifier (when employing policy grouping), and denote the number of queries by G (for grouping).

Fig. 6 shows the percentage of remaining queries after each optimization: $\frac{B-T}{B}\%$ for trimming and $\frac{G}{B}\%$ for policy grouping. For example, for BICS and $k = 2$, trimming pruned 51.1% of the policies. Policy grouping saved 41.5% and reduced the overall queries to the verifier to 9.6%. Overall, the reduction was 90.3%. The results show that the combination of trimming and policy grouping can reduce the number of queries to as little as 0.04%. Trimming is especially powerful for the larger topologies and for more permissive failure models ($k = 3$). The policy grouping also significantly reduces the number of queries to the verifier. The best case is for the largest network, where trimming reduced the number of queries to 1.15% and then policy grouping reduced it to 0.04%, compared to the baseline.

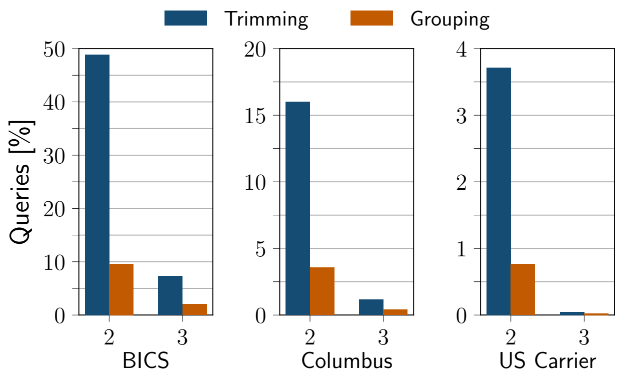

Figure 6: Reduction in the number of queries to the verifier thanks to topology-based trimming and policy grouping.

8.4 Running *Config2Spec* on Internet2

Finally, we demonstrate that *Config2Spec* can handle real configurations. For this, we took a publicly available configuration of the Internet2 network from May 2015 [8]. For Batfish to be able to parse this configuration, we had to remove multiple lines from it. Mostly, these parts concerned logging (e.g., `system dump-on-panic;`), anonymization leftovers (e.g., `Firewall Stanza Removed`) and other (for our purposes) irrelevant parts (e.g., `bfd-liveness-detection no-adaptation;`). For Minesweeper to be able to verify our queries, we had to remove parts of the BGP route-maps (community-matches and empty prefix-list matches). This does not affect the output, as we only mine the specification for internal prefixes, since no external peers are connected. In total, we had more than 90k lines of configuration. The topology consisted of 10 routers and 18 links. For a failure model with $L_{symbolic} = L$ and k from 1 to 3, *Config2Spec* required 32, 314, and 1'805 seconds to infer the network specification. It consisted of 3'962, 3'405, and 3'339 policies. The high number of policies, even for $k = 3$, stems from the fact that the five routers on the east-coast almost form a clique.

9 Related Work

In this section, we survey related work across five dimensions: specification mining, data plane analysis, control plane verification, network specification languages, and counterexample-guided inductive synthesis.

Specification mining Our work is inspired by works on specification mining [1], where high-level specifications are automatically inferred from low-level execution of programs. One example is Daikon [11], which dynamically detects program invariants (e.g., $x \neq 0$) by running the program and observing the values the program computes. For computer networks, Xie et al. [31] show how to compute the reachability specification for a given failure model based on the network's configuration. They compute the reachability upper bound – all policies that hold for at least one concrete environment – and lower bound – all policies that hold for all concrete environments. To scale, only an approximation of the bounds is computed. In contrast, *Config2Spec* computes the exact lower bound of reachability, as well as other policies, and thereby obtains a precise specification. Benson et al. [6] show how to mine reachability *policy units*, a high-level abstraction of pair-wise reachability, from network configurations for a single concrete environment. Like *Config2Spec*, it relies on data plane analysis. Unlike *Config2Spec*, failure models are not supported. Other works [7, 15] assess the complexity of managing the network and its overall health, i.e., the frequency of performance and availability problems, by analyzing its configurations.

Data plane analysis *Config2Spec* relies on a data plane analyzer. Several works exist and they differ mostly in their input. There are tools that require the forwarding state as input [16–18, 23], and others that compute the forwarding state from the network configuration [13]. These tools enable to check various properties, such as reachability and isolation, for the single forwarding state being analyzed.

Network verification *Config2Spec* also relies on a control plane verifier. Several works offer solutions for network verification, supporting different kinds of queries. Minesweeper [4] relies on an SMT-solver, and is currently the most general solution: it supports various properties (e.g., reachability, loop-freedom, router equivalence) and multiple (interacting) routing protocols. ERA [12] creates a unified control plane model that mainly allows to reason about reachability properties under multiple routing protocols. ARC [14] constructs an abstract graph representation of the data plane computation and supports various properties: reachability, isolation, waypointing and control plane equivalence. Many other tools focus on a single protocol such as Bagpipe [30].

Network specifications Many works introduce different network specification languages, varying in their expressiveness. Some allow to capture traffic classes at the path-level [3, 5, 27], while others use a higher-level abstraction describing traffic classes and high-level policies such as reachability and waypointing [24]. Despite the differences, *Config2Spec*'s output can be used by other tools, such as NetKAT [3], whose language can accommodate the policies we consider.

Counterexample-guided inductive synthesis (CEGIS) CEGIS is a technique in program synthesis in which examples guide the search for the target program [25, 26]. Technically, from an initial set of examples (which may be empty), the synthesizer proposes a candidate program consistent with the examples, and introduces it to a validator. The validator either confirms the candidate is the target program or returns a counterexample. The counterexample is added to the set of examples, guiding the synthesizer to look for a different candidate. *Config2Spec* can be seen as a synthesizer looking for (all) policies that hold for a given network configuration and failure model. Like CEGIS, it is guided by examples (the data planes) and a validator (the verifier). Unlike CEGIS, *Config2Spec* looks for *all* valid policies (and not a single one). This poses a greater challenge, both in terms of the search space and the burden on the validator. To cope, *Config2Spec* cleverly samples examples to prune the search space (without the help of the validator), trims and groups policies to save queries to the validator, and dynamically switches between sampling and verifying to expedite the search.

10 Conclusion

We introduced *Config2Spec*, a scalable approach for mining a network's specification from its configuration and a failure model. The key insight is to dynamically switch between data plane analysis and control plane verification. To scale further, we integrated three domain-specific techniques: *(i)* policy-aware sampling to pick concrete environments which are more promising for policy pruning, *(ii)* policy grouping to group queries and thereby reduce verification overhead, and *(iii)* topology-based trimming to prune policies infeasible for the given topology and failure model. We evaluated *Config2Spec* on different topologies and against two baselines. The results show that *Config2Spec* scales to large networks, unlike the baselines, and that our domain-specific techniques significantly contribute to the scalability.

26 return verified
```

A Main Algorithm of *Config2Spec*

Here, we present the main algorithm of *Config2Spec* (Algorithm 1). Our algorithm takes as input the configuration `conf` and a failure model $\mathcal{F}$ consisting of $L_{up}, L_{down}, L_{symbolic}$ and k. It outputs all policies which hold for this setting. The algorithm maintains the time estimates presented in §4 as well as a few sets. We next present these sets and the initialization of the time estimates, and afterwards the algorithm flow.

Main data structures The algorithm maintains four sets: `cands`, `verified`, `prevEnvs`, and `lastFwds`.

The `cands` set contains all policies that are still candidates for the network specification (i.e., unclassified policies and verified policies). That is, it is a superset of the network specification. When the algorithm terminates, `cands` is exactly the set of policies which hold. During the execution, policies which are discovered as violations are removed from `cands`. Initially, this set consists of all reachability, isolation, load balancing, and waypoint policies. Although we focus on these policies, our algorithm easily extends to any policy supported by the data plane analyzer and control plane verifier.

The `verified` set is the set of all policies that the verifier proved to be part of the network specification. That is, it is a subset of the set of policies which hold. When the algorithm terminates, `verified` is exactly the network specification. During the execution, policies which are discovered as true policies are added to it.

The `prevEnvs` set contains all previously analyzed concrete environments, while the `lastFwds` set contains the forwarding graphs of the last analyzed concrete environment, which is used to pick the next concrete environment.

Initialization of predictors' times As discussed in §4, our predictors rely on four time estimates: $T^{TP}_{analysis}$, $T^{TP}_{verifier}$, $T^{RT}_{analysis}$, and T^{RT}_{verify}. These are initialized as discussed in §4, where to initialize T^{TP}_{verify} and T^{RT}_{verify}, *Config2Spec* executes the verifier on M policy sets by running M times Line 18–Line 25, which are shortly explained.

Flow After initialization, *Config2Spec* runs in a loop which terminates when `verified` equals `cands`, indicating that both are equal to the network specification. At each iteration of the loop, *Config2Spec* first computes the predictors to pick between the data plane analyzer and the control plane verifier. The TP predictor checks $T^{TP}_{analysis} < T^{TP}_{verify}$. The RT predictor checks *DP-RT* < *CP-RT*, where *DP-RT* and *CP-RT* are the remaining times of the analyzer and verifier.

If the data plane analysis is chosen to be executed (Line 10–Line 16), *Config2Spec* invokes `PickCE` to pick the next concrete environment. It then calls `DPCompute`, to compute the forwarding graphs, and `InferPol`, to compute all policies from `cands` that hold for this environment. Afterwards, it updates the time estimates $T^{RT}_{analysis}$ (to the execution time of `DPCompute`) and $T^{TP}_{analysis}$ (to the execution time per policy which was pruned in this iteration). Then, it retains in `cands` only the policies that hold for the given environment and updates `prevEnvs` with the new environment. Finally, it checks whether there are still more concrete environments to analyze. If not, then `cands` contains only true policies, and so it sets `verified` to `cands`.

If the control plane verification is chosen (Line 18–Line 25), *Config2Spec* picks a set of policies to verify via `PickPolicies`. It then calls the verifier via `CPVerification`. The result is a counterexample `cex`, which may be ⊥, to indicate that all policies hold, or a concrete environment if some of the policies are violated. If `cex` is ⊥, all policies are added to `verified` and T^{TP}_{verify} is set to the ratio of the execution time and all policies (since all have been classified). If `cex` is not $\perp$, then *Config2Spec* removes from `cands` the policies which are violated by `cex`, and sets T^{TP}_{verify} to the ratio of the execution time and violated policies (since only they are classified).

Correctness We next discuss the correctness of *Config2Spec*. First, *Config2Spec* is precise. That is, it returns *all* policies which hold and *only* the policies which hold. The correctness argument relies on the data plane analysis and control plane verification being precise with respect to their tasks: the data plane analysis returns all and only those policies which hold for the given concrete environment, while the control plane verification returns a counterexample if and only if some of the given policies do not hold. With this assumption, we can prove the invariant that *(i)* `cands` always contains the network specification (i.e., the specification is a subset of it) and *(ii)* `verified` is always contained in the network specification. Because the algorithm terminates when these sets are equal, we get the guarantee.

Second, *Config2Spec* always terminates. For this, we rely on the data plane analysis and control plane verification to always terminate. We then make the claim that at each iteration either a new concrete environment is analyzed (guaranteed by `PickCE`) or at least one policy is classified (guaranteed by the control plane verification). Since the number of concrete environments and policies is finite, at some point either all policies are classified – at which point `cands=verified` and the algorithm terminates – or all concrete environments have been analyzed – at which point, *Config2Spec* sets `verified` to `cands` (Line 16), thereby terminating the algorithm.

Network Error Logging: Client-side measurement of end-to-end web service reliability

Abstract

We present NEL (Network Error Logging), a planet-scale, client-side, network reliability measurement system. NEL is implemented in Google Chrome and has been proposed as a new W3C standard, letting any web site operator collect reports of clients' successful and failed requests to their sites. These reports are similar to web server logs, but include information about failed requests that never reach serving infrastructure. Reports are uploaded via redundant failover paths, reducing the likelihood of shared-fate failures of report uploads. We have designed NEL such that service providers can glean no additional information about users or their behavior compared to what services already have visibility into during normal operation. Since 2014, NEL has been invaluable in monitoring all of Google's domains, allowing us to detect and investigate instances of DNS hijacking, BGP route leaks, protocol deployment bugs, and other problems where packets might never reach our servers. This paper presents the design of NEL, case studies of real outages, and deployment lessons for other operators who choose to use NEL to monitor their traffic.

1 Introduction

Maintaining high availability is a matter of utmost importance for the operator of any popular web service. When users cannot access a web service, this may not only result in loss of revenue for the service provider but may also impact the service's reputation, causing users to shift to competing services. Therefore, it is critical that a web service operator detect and react in a timely manner when its service is inaccessible for any sizable population of users.

The primary challenge in doing so is that network traffic faces many threats as it traverses the Internet from clients to servers, most of which are outside the control of the service operator. Rogue DNS resolvers can serve hijacked results [2], ISP middleboxes can surgically alter traffic [27], bad router policy can silently drop packets [24], misconfigured BGP can take entire organizations offline [1], and more. Even though each of these issues is caused by systems that are not under the web service operator's control, the operator must bear primary responsibility for detecting and responding to them.

To address this challenge, a range of approaches have been developed over the years. For instance, server-side request logs (*e.g.*, the Apache web server's access.log and error.log files [31]) give fine-grained information about the success or failure of each incoming request. After annotating these logs with additional information, like the ISP or geographic location of the end user, operators can identify when interesting populations of end users are all affected by the same reliability issues [5, 4]. Alternative approaches rely on a dedicated monitoring infrastructure comprising a globally distributed set of vantage points. These approaches either actively probe the service to detect unreachability [6, 20] or passively monitor BGP feeds to identify routing issues [7].

Unfortunately, these existing solutions suffer from two fundamental limitations.

- First, they are typically capable of only detecting large, systemic outages. For example, with server-side monitoring, a major problem (*e.g.*, a global outage of a major service, or a regional outage affecting a large enough region) might show up as a noticeable drop in total request volume [28], but operators typically only learn of smaller problems when users manually report them.[1] These user reports are often frustratingly vague, and collecting additional information from nonexpert users is next to impossible, so investigation may take hours or even days.
- Second, and more importantly, existing approaches are incapable of precisely quantifying how many clients are affected, if any. For example, active probing from dedicated probing infrastructure can only probe from a handful of locations relative to the number of real users, and probe traffic is not always representative of what actual users experience (*e.g.*, probers may not use real web browsers and might receive different network configuration than actual end users). Without knowing how many users are affected, the operator is unable to judge whether it should prioritize the troubleshooting of a detected problem over other ongoing issues that deserve its attention.

To overcome these challenges in detecting and scoping instances of service unreachability, we need a system that (1)

[1]While sites like https://downdetector.com crowdsource such reports, historically we have often only learned of problems via social media.

passively monitors *actual* end user traffic to any target web service; (2) has visibility into reliability issues regardless of where on the end-to-end path they occur; and (3) requires little to no custom engineering work on the part of the operator.

With these goals in mind, we have designed, implemented, and deployed NEL (Network Error Logging). The key intuition behind NEL's design is that clients have ground truth about their ability to access a web service. Therefore, NEL leverages end users' browsers to collect reliability information about the service. NEL is implemented directly in the browser's network stack, collecting metadata about the outcome of requests, without requiring any custom per-site JavaScript instrumentation. The browser then uploads these reports to a redundant set of collection servers, which aggregates reports from users around the globe to detect and scope network outages.

This paper describes our contributions, based on the following three tracks:

First, we present our solutions to the various engineering and policy challenges that arise in using client-side data to detect reachability issues. When clients are unable to talk to a service, how do we still ensure successful collection of unreachability reports from these clients? What should uploaded reports contain so that they aid in diagnosing and estimating the impact of outages? How do we prevent abuse of the system, given that clients are free to upload fraudulent reports and service operators can attempt to learn about clients' reachability to other services? Our primary consideration in answering these questions has been to preserve user privacy; we ensure that NEL does not reveal more about clients than what service operators would learn during normal operation.

Second, we describe our experiences in using NEL to monitor reachability to Google's services since 2014. In that time, as we relay in Section 4, it has been instrumental in detecting and mitigating a wide variety of network outages including routing loops, BGP leaks, DNS hijacks, and protocol misconfigurations. In particular, without NEL, it would have been hard, if not impossible, to estimate the number of clients affected by each outage. Thus, NEL has proved invaluable in helping us identify which problems warrant immediate investigation due to their large impact and which ones we can afford to ignore or attend to later.

Third, after several years of experience with an initial implementation that could only monitor Google services, we describe our recent efforts to promote this capability as a new proposed W3C standard [11]. Standardizing this work has two benefits: (1) it allows all service operators to take advantage of this new collection ability, and (2) it allows operators to collect reliability data from any user agent that complies with the standard, and not just Chrome.

NEL is not a panacea for painstaking problem detection and diagnosis. It cannot report problems when clients are completely disconnected from the network or cannot reach at least one of a redundant set of collectors. It reports only coarse-grained summaries about entire requests, and is no substitute for lower-level network diagnostics like traceroutes and packet captures. (For example, it can detect when clients experience connection timeouts, but cannot tell you much more about why.) Nonetheless, NEL has proven a valuable tool for detecting and scoping network outages that are invisible to other monitoring infrastructure.

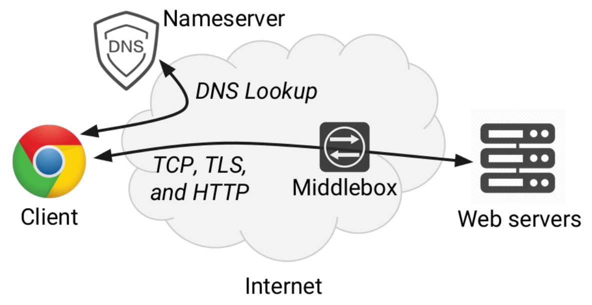

Figure 1: Steps and entities involved in enabling a client to access a web service.

2 Background and Motivation

We begin by listing several causes that may render a web service inaccessible, solutions that exist to detect service reachability problems, and the limitations of these solutions that motivated us to develop NEL.

2.1 Causes of service inaccessibility

As Figure 1 shows, a typical communication between a client and a web service offered over HTTPS involves the following steps: the client performs a DNS lookup of the service's hostname, establishes a TCP connection to the IP address it obtains, performs a TLS handshake with the server, and then sends its HTTP request.[2]

Given these steps, a client may be unable to communicate with a web service due to any of the following reasons:

- **DNS failure:** The client will be unable to execute any of the subsequent steps if its attempt to resolve the service's hostname fails. This can happen either if the nameserver that the client uses is unresponsive, or if the service provider's DNS setup is misconfigured.
- **DNS hijack:** The client could get an incorrect IP address in response to its DNS request if either the nameserver that the client uses is compromised or if the client is compromised to use a malicious nameserver.
- **IP unreachability:** When the client does get a correct IP address, the Internet may be unable to route packets from the client to that IP, either due to problems with BGP (*e.g.*, misconfiguration or convergence delays) or because of active blocking by network operators.

[2]Note that this only considers the user's communication with a "front-end" server. Modern services typically require many back-end service calls to generate the final response, which are hidden behind the interaction with the front-end server, and invisible to the client (and by extension, NEL).

- **Prefix hijack:** Alternatively, if the prefix which contains the IP address has been hijacked, the client's requests will be directed to servers not controlled by the service provider. The client will hence be (hopefully) unable to complete TLS connection setup.
- **Faulty middlebox:** When IP-level reachability between the client and the service is functional, the client's attempt to connect to the service may still fail due to a misconfigured or malicious middlebox enroute.
- **Service faulty/down:** Lastly, even if the client's DNS lookup succeeds and both IP-level and TLS-level connectivity are unhindered, the client will be unable to access a service that is down or misconfigured.

2.2 Existing solutions and limitations

To detect unreachability caused by the above-mentioned problems, a wide range of solutions have been developed over the years. This body of prior work falls broadly into four categories.

Monitoring from distributed vantage points. A popular approach is to monitor reachability from a dedicated set of distributed vantage points. Solutions that use this approach either actively probe services from devices that mimic real clients [3, 6]—probing can either be at the application level (*e.g.*, in the form of HTTP requests) or at the routing level (*e.g.*, in the form of traceroutes)—or passively monitor BGP updates (*e.g.*, to detect prefix hijacks [22, 19]), or use some combination of the two [20, 35]. Such approaches can detect problems that have wide impact. Localized problems are, however, likely to go unnoticed because a set of vantage points typically cannot match the global coverage of a service's clients. Moreover, when unreachability is detected, it is hard to estimate how many real clients are affected.

Monitoring service logs. To ensure broad coverage, service providers can monitor their service's usage either by analyzing server-side logs or by augmenting pages on their site with JavaScript that performs and uploads client-side measurements (popularly referred to as Real User Monitoring, or RUM for short [9]). With either strategy, operators must infer reachability problems from the *absence* of traffic. Requests from affected users will never arrive at the server and therefore are absent from server-side logs, whereas users unable to fetch even the HTML of a web page will not execute any JavaScript included on the page, even if cached. For any population of users, a significant drop in requests compared to what is typically expected (given historical traffic volumes) may indicate a reachability problem being experienced by these users. The challenge here is: how to distinguish between localized reachability problems and intrinsic volatility in traffic volumes? While traffic in aggregate across a large population of users is typically fairly predictable (*e.g.*, same from a particular hour in a week to that hour next week), the smaller the subset of users considered, the larger the unpredictability. As a result, drops in traffic volumes for small populations of users are not adequate evidence for service operators to take action.

Data source	**Enable timely detection**	**Detect localized outages**	**Estimate # of affected clients**
Distributed monitoring infrastructure	✓	×	×
Service logs	✓	×	×
Backscatter traffic	×	×	×
User reports	×	✓	×
NEL	✓	✓	✓

Table 1: Properties satisfied by different approaches for detecting service reachability problems at scale.

Monitoring backscatter traffic. Similar limitations exist with solutions that rely on backscatter traffic—traffic that clients send to unused portions of the IP address space—to detect reachability issues [12]. Here too, one has to infer (for example) censorship based on the absence of traffic. Consequently, problems can be reliably detected only when they are large in scope. Moreover, even when backscatter traffic shows an absence of traffic from a large population, those users likely cannot reach *any* IP address.

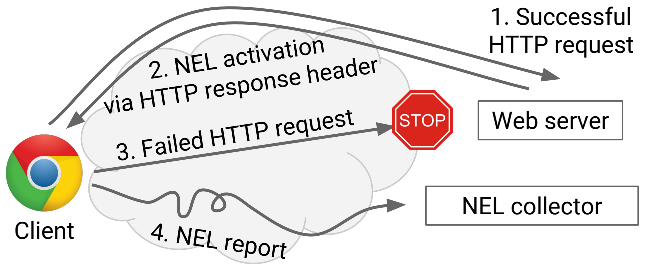
Leveraging user reports. An approach which can detect localized problems, unlike the previous categories of solutions, is to rely on complaints/reports from users. However, such solutions are typically incapable of detecting reachability problems in a timely, reproduceable, representative, and consistent manner. For example, users in some regions may be less likely to notify service operators about problems, due to language or cultural barriers.

Table 1 summarizes the limitations of these existing solutions. The overriding one, which motivated our development of NEL, is the inability to accurately estimate *how many clients are currently affected by an outage*. In our experience, a high confidence estimate of the scope of a problem is the top criterion to warrant investigation by a service operator. Lacking such data, it is hard to triage and prioritize human effort to troubleshoot the large number of issues that a service provider has to deal with at any point in time.

3 Design

This section presents the design of NEL, our browser-based mechanism for collecting information about a web service's availability, as seen by its clients. By using the client as the vantage point, the operator gains *explicit* information about the impact of reliability problems, rather then having to *estimate* the impact based on either the absence of traffic or by extrapolating from a small set of clients.

Google has twice implemented the ideas behind NEL: first as a proof of concept that could only monitor reachability to Google properties, and again as a proposed public W3C stan-



1. Successful HTTP request
2. NEL activation via HTTP response header
3. Failed HTTP request

Web server
NEL collector
Client
4. NEL report

Figure 2: When a client successfully communicates with a service, collection of client-side reports is activated via a NEL policy in the service's response headers. The client reports the success and failure of its subsequent requests to that service to collectors referenced in the NEL policy.

dard [11] available to all service operators. Here, we focus on the latter due to its general availability. We also summarize important differences between the two implementations.

3.1 Approach and challenges

When stated at a high level, NEL's approach is fairly simple and intuitive: clients upload reports summarizing their ability to either successfully or unsuccessfully access target services. In aggregate, such reports enable the provider to piece together the ground truth as to how many, and which, of its clients are unable to access its service.

Realizing this approach in practice requires us to answer several questions:

- How do clients know which services to collect reliability information about?
- What should clients include in reports they upload?
- In order to reliably report that information, where should clients upload reports to?

Before describing our answers to these questions (summarized in an illustration of NEL's architecture in Figure 2), we first list the properties required of such a system, which motivate our design choices.

3.2 Security, privacy, and ethics

When designing NEL, we have to balance collecting enough information to enable quick detection of reliability issues versus satisfying the security and privacy expectations of both service owners and their end users. There are four principles in particular that we must follow:

1. We cannot collect any information about end users, their device/user agent, or their network configuration, that the server does not already have visibility into. That is, we should not collect *new information* relative to existing server logs; only existing information in a *different place*.
2. We can only collect information about requests that user agents issue when users voluntarily access services on the Web. We cannot issue requests in the background (*i.e.*, outside of normal user activity), even though this prevents us from proactively ascertaining service reachability.
3. End users can opt out of collection at any time, either globally or on a per-site basis. Support for respecting opt-outs must be implemented by NEL-compliant user agents, so that users do not need to trust service providers for opt-outs to take effect.
4. Modulo that end-user opt-out, it is *only* the site owner who gets to decide whether reports are collected about a particular site, and if so, where they are sent. Third parties (including browser vendors) must not be able to use NEL to monitor sites that they do not control.

These principles have clear ramifications on the design of the system, as we discuss below in our description of NEL's design; Table 2 provides a summary.

3.3 When do clients generate reports?

Configuration via response headers. How does a user agent know which requests to collect reports about? An operator needs a way to instruct client browsers to collect reports about requests to services they control, along with any configuration parameters about that collection.

HTTP response headers provide exactly what we need: service operators insert policy configuration headers (Report-To and NEL) into their outgoing responses; Figure 3(a) shows an example. The user agent's network stack intercepts these policy headers as part of the normal processing of the response. NEL is limited to secure connections—HTTPS connections with validated certificates—ensuring that (in the absence of a subversion of the certificate trust validation mechanism) third parties cannot inject NEL policies into the responses of servers not under their control.

If an attacker does somehow subvert connection security, they could inject NEL's HTTP headers and can obtain NEL monitoring data. For example, a malicious or compromised CDN provider could siphon NEL logs off to their own collector. But such an attacker could obtain the same data by other means (*e.g.*, by injecting additional JavaScript).

Scope of activation. We need to ensure that client-side collection of NEL reports does not allow third parties to collect information about sites they do not control. The cleanest way to do this is to follow the existing Same-Origin Policy (SOP) [8], and to have report collection be scoped to the origin (domain name, scheme, and port) of the request. That is, collection would be activated (or deactivated) for all requests to an origin; any collection policy configured for origin A would have no effect on requests to origin B, even if both origins happen to be owned and operated by the same entity.

Note that NEL does not preclude user agents from generating NEL reports even when the user is in private browsing mode. In such cases, any service's server-side logs do reflect the user's use of its service. NEL is simply collecting the same information at the client and uploading it via redundant paths to the same service provider. As we describe later in this section, the contents of any NEL report ensure

Goal	Approach	Refinements/Experience
Securely **activate client-side collection** of reachability reports	• Include NEL policy header in HTTP responses • Enforce Same-Origin Policy • Limit to HTTPS connections	• With include_subdomains option, one successful communication with an origin suffices for a user agent to start collecting (some) reports for all subdomains of that origin
Ensure report content **preserves user privacy**, yet **aids diagnosis**	• Only include information that is visible to service during normal operation • Limited set of hierarchically organized error types	• Upload reports even for successful requests to establish baseline request rate and to reduce burstiness of collection workload
Enable secure and timely **collection of NEL reports** from clients	• Causes that can render collectors unreachable should be disjoint from those that can affect the service's reachability • Client downgrades report (removing sensitive information) if service's IP address is not one from which it has received NEL policy for this origin	• Specify weight and priority per collector to balance load and to enable failover across collectors • Configurable sampling rates to reduce load on both clients and collectors • Host collectors on cloud infrastructure to deter censorship of report collection

Table 2: Summary of the approach taken in NEL to address different design decisions, along with experience-based refinements.

that the service provider can glean no additional information about its users than it can from its server-side logs.

Preventing DNS rebinding attacks. On its own, SOP is not enough to prevent a malicious actor from using NEL to learn about the reachability of origins that they do not control. Consider a *rebinding* attack, where an attacker who owns bad.example wishes to learn about the availability of good.example. They start by configuring DNS to resolve bad.example to a server that they control (using a short TTL), and getting an end user to make a request to bad.example. The server returns a NEL policy instructing the user agent to send NEL reports to a collector run by the attacker. They then update DNS to resolve bad.example to good.example's IP address(es), and cause the user to make another request to bad.example. Even though the request *looks* like it will go to the original bad.example server, it will instead be routed to good.example's server; if there are any errors with the connection, NEL reports about those errors will be sent to the attacker's collector. In this way, the attacker has been able to collect error reports about good.example, even though they do not own it. This kind of attack could also be used to port scan an internal network, by repeatedly rebinding bad.example to several different internal IP addresses.

NEL prevents such attacks by having user agents *downgrade* the quality of a report when the server IP address that a user agent contacts is not one from which it previously received the NEL policy header for this origin. In this case, instead of reporting whether the request succeeded or not (and the error type if not), the report simply states that the user agent's DNS lookup yielded a different IP address. This information is safe to report to the attacker, since it is information that they already knew; and, because it relates to what addresses bad.example resolves to, the attacker is actually the legitimate party to deliver this information to. Note that this can limit the utility of NEL's reports for domains that resolve to many IP addresses (*e.g.*, CDNs).

Subdomain reports. A consequence of activating NEL via headers in HTTP responses and enforcing SOP is that NEL cannot help an operator discover a client's inability to access their service unless the client has successfully communicated with the service at least once in the past. To minimize the impact of this constraint on service providers, a NEL policy can include the include_subdomains field, which tells the user agent to collect and upload reports for both the origin as well as all of its subdomains.

At first glance, this is a clear violation of SOP: there is no guarantee that the web sites hosted at each subdomain are owned by the same entity.[3] To maintain our privacy properties, a user agent can only use an include_subdomains policy to report *DNS errors* about requests to a subdomain, since the author of the policy has only been able to establish ownership of that portion of the domain name tree. Subdomain reports about successful requests, and about any errors that occur during or after connection establishment, are *downgraded* to reports only containing information visible in DNS. Such reports suffice for the service provider to discover unreachability due to DNS misconfiguration, *e.g.*, the provider may have forgotten to add a DNS entry for a new subdomain.

3.4 What do clients upload?

Report content. The most important part of a NEL report (Figure 3(b) shows an example) is the type, which indicates whether the underlying request succeeded or failed. If the request succeeded, the report's type will be `ok`; if it failed, it will describe what error condition caused the request to fail. The full set of predefined error types is given in the specification [11, §6]; examples include `http.error`, `dns.name_not_resolved`, `tcp.reset`, and `tcp.timed_out`. These predefined types are categorized hierarchically, so that one can find, for example, all TCP-related failures by looking for any type that starts with `tcp`.

We have found it useful to collect NEL reports even for successful requests, despite the fact that these requests also show up in server-side logs. Reporting on successful re-

[3]Consider a PaaS cloud offering like Google App Engine, where independent cloud applications are hosted at subdomains under appspot.com.

Figure 3: Examples of (a) a service's use of NEL headers in its HTTPS response to activate report collection by a user agent, and (b) a report uploaded by a user agent. Comments are not included in real headers and reports.

quests lets us directly compare error ratios from successful and failed reports, without having to join the NEL logs with server-side logs. Comparing successful reports to web server logs also lets us estimate the relationship between NEL report volumes and actual request volumes.

In addition to the type, NEL reports can only contain a fixed set of additional information, as defined by the public specification. This helps ensure that implementors do not accidentally include additional information that would violate our desired privacy properties. In authoring the specification, our primary constraint when determining which fields to include is to ensure that every field in the report contains information that the server can already see during its normal processing of the request.

Given this constraint, NEL reports include basic information about the request: URL (with user credentials and fragment identifiers removed), HTTP request method (`GET`, `POST`, etc.), application and transport protocol (HTTP/1.1, HTTP/2, QUIC, etc.), User-Agent string, and referrer. The reports also include the HTTP status code of the response, if one was received, and how long the request took to complete.

Reports also contain the IP address of the server that the user agent attempted to connect to. For most requests, this is the public IP address of the service's front-end server that directly accepts incoming connections from end users. Inclusion of this IP address in reports is crucial to enable detection of DNS hijacking; though the error type in the report may indicate successful TCP connection setup, the server IP address mentioned in the report will not be one used by any of a service's front-end servers.

As mentioned above, there are several situations where a NEL report is *downgraded* for privacy reasons; for instance, when the server IP of the request is not one that the corresponding NEL policy was received from. In these cases, any privacy-sensitive fields are modified or removed from the report, to maintain the property that the report only contains information that the policy author already had access to. The NEL specification [11] contains more detail about precisely which fields are modified or removed, and when.

What do reports *not* contain? There are many details about the client that we explicitly exclude from NEL reports, even at the expense of hampering diagnosis. For example, if a user agent is using a client-configured proxy server, the IP address that the user agent attempts to connect to would be the IP address of that proxy server. Since that proxy configuration is not intended to be visible to the server, we cannot include the IP address in the report. Note that this restriction only applies to proxies configured *by the end user*. If their ISP is using a transparent proxy for all of its customers' requests, any individual user agent won't easily be able to detect this. That means that the server IP reported by the user agent will still be the actual address of the origin server, while the client IP address seen by the server and any NEL collectors will be the address of the transparent proxy.

Similarly, we cannot include the IP address of the DNS resolver that the client uses. For DNS-related network outages, this would be useful information to collect, since it would help the service owner determine whether a rogue or misconfigured DNS resolver is at fault for an outage; however, since this information is not visible to the server when processing a request, we cannot include it in a NEL report.

NEL reports also do not include details about HTTP requests that are immaterial to diagnosing reachability problems. For example, user agents exclude cookies and URL parameters from reports. A NEL report does include the full path that a request was issued for, not just the hostname to which the request was issued. We have not found much use for this information so far, but it may prove useful to an operator whose service configuration varies across different pathnames under the same origin.

Sampling rates. For high-volume sites, it is undesirable to have clients generate NEL reports about *every* attempted request, since that could double the number of requests a client must make and would require the site's collection infrastructure to be able to deal with the same full volume of request traffic as the actual site. NEL allows service operators to define a *sampling rate*, instructing user agents to only generate reports about a random subset of requests. Moreover, they can provide separate sampling rates for successful and failed requests. Typically, one will want to configure a very high sampling rate for failed requests, since those requests are more operationally relevant and more important to collect as much information about as possible. The utility of collecting reports for successful requests is largely to estimate their total number, so lower sampling rates (*e.g.*, 1–10%) are typically sufficient. Each NEL report includes the sampling rate in effect when that particular report was generated, which allows collectors to weight each report by the inverse of its sampling rate when determining totals.

To reduce overhead, it may be tempting to adaptively vary the sampling rate over time. However, the need to increase sampling rates will arise precisely when an outage occurs. At that point, it will be infeasible for the service provider to update the NEL policy being used by affected clients.

Google uses a 5% sampling rate for successes and 100% for failures. We chose these numbers based on our experience working with NEL: (1) we find a lower sampling rate dilutes our data too much when examining small user populations (*e.g.*, when investigating outages in small ISPs), and (2) we want a relatively consistent report traffic volume, rather than massive spikes in load during major outages.

3.5 Where do clients upload reports to?

Once a user agent has generated reports about requests to an origin, those reports must somehow be sent back to the service operator's monitoring infrastructure. To do this, the service operator defines a set of *collectors*, giving an upload URL for each one (see Figure 3(a)). Since the set of collectors is defined in the NEL policy included in HTTP response headers, service operators have full control over where NEL reports about their origins are sent to.

User agents will periodically batch together reports about a particular origin, and upload those reports to one of the origin's configured collectors. The report upload is a simple `POST` request, with the JSON-serialized batched report content in the request payload.

Report uploads are subject to Cross-Origin Resource Sharing (CORS) [32] checks. If the origin of the collector is different than the origin of the requests that the NEL reports describe, the user agent will perform a CORS preflight request to verify that the collector is willing to receive NEL reports about the origin. If the CORS preflight request fails, the NEL report will be silently discarded. Reports are only uploaded over HTTPS to prevent leaking their content to passive in-network monitors.

Collector failure modes. For an operator to detect outages in a timely manner, it is crucial that clients be able to upload NEL reports even when they are unable to reach the monitored service. This requires that the collection path differ from the request path in as many ways as possible. As a consequence, not only must the collectors be hosted differently than the monitored service, but it is desirable that there be significant hosting diversity among those collectors. Examples of the ways in which collectors might differ from the monitored service include: different IP address (to learn about the service's IP being unreachable); different version of IP (if IPv4 is reachable, but not IPv6); different AS number (to account for BGP/routing issues); different transport protocol (*e.g.*, for QUIC-specific problems); and different hostname, registrar, and DNS server[4] (if the service's nameserver is unreachable). Later, in Section 4, we recount the kinds of collector diversity that have proved to be most valuable in our experience.

Given the effort necessary to ensure that collectors for a service do not share the same failure modes as the service itself, one may wonder whether the collectors could be used to improve the availability of the service, beyond collecting evidence of its (un)reachability. However, a NEL collector requires significantly fewer resources than necessary to run the monitored service. In particular, NEL collectors typically do not need to make the same latency guarantees as interactive web requests. Therefore, a service's collection infrastructure is unlikely to have the necessary capacity for an operator to serve affected users from the collectors when these users are unable to access the service normally.

Load balancing and failover. NEL enables service operators to define arbitrary load balancing and failover behavior for their collectors. Inspired by the DNS `SRV` record [17], a NEL policy can specify an optional weight and priority for each collector. When choosing which collector to upload a report to, a user agent will randomly select a collector from those with the smallest priority value, weighted by their weight values. The user agent keeps track of whether uploads to a particular collector fail too frequently; if so, that collector is marked as *pending*, and taken out of rotation. This ensures that collectors with higher priority are only attempted if *all* collectors with lower priority have failed. This mechanism gives service operators maximum flexibility in determining how to configure their collection infrastructure.

If *all* of the collectors are unreachable, the user agent will retain the reports in memory for a small amount of time (typically 15 minutes). When this happens, it often indicates a complete loss of connectivity on the part of the user. During this time, the user agent will continue attempting to deliver the reports (typically once per minute, with exponential backoffs). If the reports have still not been delivered after several attempts, they are dropped. The short interval ensures that we have visibility into temporary connectivity losses, while not requiring much storage in the user agent.

Note that a NEL user agent will also upload reports summarizing the success or failure of its attempts to upload a NEL report to a collector; after all, attempts to upload NEL reports are also HTTP requests. We refer to these as *meta reports*. Such meta reports help a service provider detect problems that clients face in contacting its collectors. To prevent infinite recursion, user agents generate meta reports only for uploads of NEL reports that are not meta reports.

[4]Note that all of these must be different for the client to use a completely different set of nameservers to resolve the collector's hostname.

Feature	Domain Reliability	NEL W3C standard
Adoption model	Opt-in	Opt-out
Activation time	Browser start	After first successful request to an origin
Activation overhead	None	HTTP response headers
Coverage	Google origins	Any HTTPS origin

Table 3: Comparison of the two implementations of NEL: the version that monitors reachability from Chrome's users to Google's services versus the W3C standard. The latter incurs additional overhead to be generic.

Censorship resistance. Although we have found NEL useful in detecting and investigating state-sponsored censorship, NEL itself is not particularly resistant to censorship. An attacker who can block access to an origin can also trivially enumerate all NEL collectors for the origin, and block access to those collectors. Service operators could try to introduce a modicum of censorship resistance by hosting NEL collectors in cloud providers, thereby tying the fate of report collection to the cloud provider as a whole. An operator could also make it harder for an adversary to identify all of its collectors by returning different subsets of collectors to different clients [34]; however, a NEL collector may be discernable via network traffic analysis [14].

Report authenticity. Since NEL reports are generated by user agents running on untrusted client devices, there is nothing preventing clients from generating and uploading fraudulent reports. A service provider can account for this challenge by only reacting to problems that affect a large enough population of unique client IP addresses (typically dozens). This measure ensures that a malicious entity can only cause a service operator to react to fake outages if they control a large number of client devices (*e.g.*, a botnet operator). However, making NEL robust to fraud in this manner comes with the risk of minimizing the impact of an outage which affects a few IP addresses shared by many client devices, *e.g.*, when many devices are behind a shared NAT.

3.6 Domain Reliability

Thus far, this section has described the public standard [11] which is usable by all services and browsers, and available in Chrome as of version 69. We also implemented these ideas in an earlier proof-of-concept called *Domain Reliability*, which could only monitor reachability from Chrome users to Google services. There are some important differences between Domain Reliability and NEL (see Table 3).

- Since Domain Reliability was not generally available to all service operators and only monitored Google properties, it required users to explicitly opt in to report collection. With NEL, any user agent which implements the standard collects reports by default for origins which include NEL policies in their responses. A user can opt out of NEL either globally or on a per-origin basis.
- One consequence of NEL being opt-out is that its users will represent a more uniform sample of a service's userbase. Because of this, we expect to more confidently generalize results from NEL to non-NEL clients.
- With Domain Reliability, the list of origins for which clients generate reachability reports and the list of collectors to which they upload these reports was hard-coded into Chrome. Any updates to these lists were delivered as part of Chrome's regular update process, resulting in a multiple-week lead time to push any monitoring changes to our users. In contrast, with NEL, any web service gets to bootstrap the origins to monitor and the collector domains by including this information as headers in the service's HTTP responses. This allows monitoring changes to be picked up immediately, with the cost of increased overhead in client-server traffic.
- An implication of the previous point is that NEL can enable a client to upload reachability reports for a particular origin only after that client has successfully communicated with that origin at least once. Without doing so, the client would neither know that it must generate and upload reports for this origin, nor know which collectors to upload these reports to. Because its configuration was hard-coded in Chrome, Domain Reliability enabled monitoring of a client's reachability to Google's services even if that client had never successfully been able to communicate with any Google origin.
- Since Domain Reliability was only implemented in Chrome, it could not reveal reachability issues faced by users of other browsers. With NEL, a service can collect reports from any HTTP client that implements the proposed W3C standard [11].
- Because Domain Reliability's configuration was encoded in source code, we relied on the existing code review process to ensure that the configuration adhered to our desired security and privacy properties. Because this configuration was restricted (by policy) to Google properties, we did not have to downgrade Domain Reliability reports like is needed for NEL in some situations; instead, we ensured that Domain Reliability's hard-coded policy prevented reports from being sent at all in those situations.

4 Deployment Experiences

This section relays some of our experiences with the techniques described in the previous section. In each case, data alerted us to the presence of a problem and hinted at a cause based on the population of users reporting that problem (*i.e.*, the "shape" of the problem); however, these techniques are most useful in concert with other network diagnostic tools that can dig deeper into specific problems and provide "smoking gun" evidence of a particular cause.

Note that this section deals with Domain Reliability, the initial prototype of these concepts that we developed to mon-

Figure 4: (a) Traceroute to the affected IP address appears to show a routing loop in the last-mile ISP, and (b) traceroute from the same vantage point to an adjacent IP address exits the ISP within a few hops. Hostnames and IP addresses are anonymized.

itor traffic only to Google's services. We have monitored Google's services with it since Chrome 38 in 2014 and are currently migrating our monitoring to use NEL. Although Domain Reliability and NEL are not qualitatively different, Section 3.6 explains how one might expect our experiences to differ once we fully migrate to NEL.

4.1 Unreachability of a single IP address

In December of 2018, Chrome clients started reporting failures of TCP connections and QUIC sessions made to a single Google IP address. The problem affected all requests to that IP from all users in every ISP in one country for the following two weeks.

Further manual investigation revealed that traceroutes from an affected host to that IP were failing inside a transit ISP which dominates wired connectivity within that country. We also occasionally noticed IPs belonging to this transit provider in high-TTL hops of the traceroute, suggesting that packets were stuck in a routing loop in that ISP's network (see Figure 4). The problem was eventually resolved after we contacted the ISP, although we never learned how they presumably fixed it.

NEL was useful in this case in several ways.

- It let us quickly detect a problem we may have never noticed otherwise. The impacted IP served content that is visible to users but is not critical (*e.g.*, thumbnail images), which may be why we received no reports about this problem on social media, and why there was no visibility on crowdsourced sites like downdetector.com.
- NEL was additionally helpful in confirming that the problem had gone away, particularly since the ISP never notified us that they fixed it.
- Diversity of our NEL collectors was trivially useful in this case; a collector hosted on *any* IP other than the one impacted could have successfully received report uploads.

Although other network monitoring tools could have caught this problem (*e.g.*, active probing of all serving IPs), it would have been difficult to assess the scale of users impacted or even to achieve dense enough probe coverage to know how many ISPs were affected. It would have been

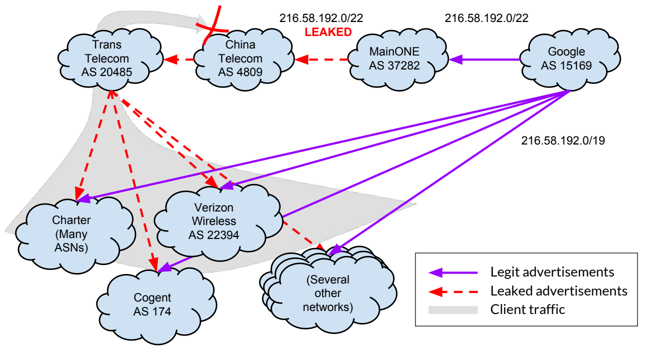

Figure 5: AS 37252 leaked prefixes to its peers, which ultimately misrouted traffic in several downstream ASNs. NEL quantified the impact of the leak on users in those downstream networks.

even more difficult to feel confident that the problem had been completely resolved.

However, NEL alone was not enough to diagnose this issue because it gave no information about the location of the problem other than the set of users affected. We needed other tools, like traceroute, to identify which network links were impacted and that most, if not all, of the Internet traffic in that country transits through one ISP.

4.2 BGP leakage

On November 12, 2018, AS 37282 leaked its routing table to its upstream providers. As shown in Figure 5, this leak rerouted traffic destined for some Google prefixes, causing packet loss for many of our users. The network operations community noticed this incident and the media widely reported on it.[5]

NEL saw this incident as an increase in connection timeouts for the leaked prefixes. Although many other monitoring tools had clear visibility of the leaked BGP routes [7], NEL directly told us the incident's impact on user traffic. In some networks, NEL reported that nearly all requests to these prefixes timed out. Moreover, diversity of our NEL collectors was useful in this case, because we had collectors running in IP prefixes not affected by the leakage.

[5]https://www.manrs.org/2018/11/route-leak-causes-major-google-outage/

On the other hand, NEL said nothing about the cause of the outage other than perhaps that the problem was localized to a specific set of prefixes. It would probably be most valuable to overlay NEL data on existing BGP leak detection tools, to distinguish relatively benign incidents of BGP leakage (*i.e.*, that do not impact much traffic) from major events like this one.

Note that BGP leaks that have no impact on the users of Google's services are likely since Google advertises and uses different IP prefixes to serve its users in different parts of the world. Hence, when an ISP erroneously advertises one of our prefixes, this has no impact on users if this ISP operates in a region far from where we use the affected prefix. NEL helps us avoid troubleshooting such inconsequential problems, whose impact would otherwise have been hard to determine only based on analysis of BGP data.

4.3 Malware-induced DNS hijacking

In February of 2018, NEL reported that users in a large ISP were resolving several of our domains to non-authoritative IP addresses belonging to a third-party cloud hosting provider. Clients could still complete requests to these domains (*i.e.*, most reports we received had type `ok`), suggesting the presence of a layer 3 proxy server. Although requests were successful, this was still concerning because a proxy could reduce performance and reliability. We could not find reports of the problem online or reproduce the issue ourselves from our CDN infrastructure in the ISP.

We later discovered a rogue DNS resolver associated with malware that was responding to DNS requests in much the same way. We theorize that either (1) an ISP DNS server had been compromised to resolve requests using the rogue resolver, or (2) many machines and/or home routers in that ISP had been similarly compromised.

This case highlights a key advantage of NEL over traditional active probing: NEL monitors actual user network conditions and configurations, which can differ from those of dedicated monitoring infrastructure. It can detect massive problems that are simply invisible to other forms of monitoring. However, this case also highlights that NEL is not necessarily very helpful in debugging problems; in this case, since NEL does not report which DNS resolver clients use, it did not help us make progress on the problem.

Note that collector diversity was unnecessary in this case because requests to these hijacked domains still worked. Nonetheless, NEL was helpful because it alerted us to the presence of a proxy server associated with malware.

4.4 Protocol-specific problems

On March, 17, 2017, NEL observed that users were having trouble connecting to Google services in two of our datacenters in the United States and Europe. On closer inspection, only clients using QUIC [23] were affected. This was corroborated by reports from users.[6]

Our operations team traced the problem back to a bad server configuration change, and mitigated it soon after. The problem caused machines in the affected datacenters to drop all traffic on established QUIC sessions. Although QUIC clients transparently fall back to TCP when QUIC cannot establish a connection, that did not help in this case because we only dropped packets *after* a connection was established.

This situation illustrates the value of black box traffic monitoring; if operations teams only monitor specific protocol-level metrics (*e.g.*, number of connections established), then there is a chance that those metrics do not tell the whole story. NEL lets operations teams know whether users' connections are healthy end-to-end.

NEL collector diversity was useful in this case because the problem was localized to a few datacenters; clients could successfully upload NEL reports to other locations.

4.5 Monitoring of NEL report uploads

In addition to discovering network outages, we have also leveraged NEL's collection infrastructure to monitor previously unmonitored infrastructure. Other operators of NEL collectors may do the same.

Domain Reliability monitors only Google's first-party services, but not customer-owned origins hosted on Google's cloud infrastructure. This is currently a blind spot in our monitoring. Moreover, NEL will not allow us to monitor customer-owned origins directly, since NEL's privacy design gives the *customer*, and not their cloud provider, control over whether reports are collected and where they are sent.

To help ameliorate this limitation, in addition to our existing diverse set of NEL collectors, we run another set of collectors hosted on our cloud infrastructure. As a result, whenever a user makes a request to a Google service, the user agent generates a NEL report and attempts to upload it to one of our cloud collectors with a probability based on the values of the weight fields in our NEL policy. The user agent then generates and uploads a *meta report* about the upload of the original report.

Although this technique does not grant us visibility into problems affecting individual cloud tenants (*e.g.*, a misconfigured tenant firewall), it at least lets us detect problems affecting our entire cloud infrastructure, even if those problems are localized to a small number of clients. For example, this helped us quickly confirm that the BGP leak in Section 4.2 also impacted our cloud infrastructure.

One caveat to meta reports is that they are not representative. Any sampling rates defined in the NEL policy are compounded for meta reports, making it more difficult to get a large enough collection of meta reports to derive a statistically meaningful signal. Clients with unreliable connectivity are more likely to attempt to send NEL reports, and to fail

[6]https://news.ycombinator.com/item?id=13892431

doing so. So, we see higher baseline error rates for NEL report traffic from such clients compared to the global set of NEL reports. As a result, we cannot compare NEL error rates for our cloud infrastructure and our non-cloud infrastructure; but, trend analysis on meta reports remains useful.

5 Deployment Challenges

This section discusses several practical challenges we encountered when deploying NEL. Other web service operators are likely to encounter similar hurdles.

5.1 Collector diversity

As seen in some of our case studies (§4), diversity in the deployment of collectors has been crucial to collect client unreachability reports in a timely manner. For example, in the BGP leak case, it was crucial that we had a collector in a different prefix from those leaked.

While such diversity existed in Google's infrastructure even prior to our deployment of NEL, hosting collectors across the globe, in multiple prefixes and AS numbers, and supporting multiple IP versions is unlikely to be straightforward for an arbitrary web service. Therefore, to ease the use of NEL by other web services, we envision public cloud providers offering "NEL collectors as a service." Like Google, other large cloud providers also have a rich diversity of global infrastructure that naturally lends itself for use as NEL collectors.

5.2 Overhead

NEL increases network traffic for both clients and service providers in two ways: 1) the additional header that the service provider must include in its responses to clients' HTTP requests, and 2) reports that clients upload to NEL collectors.

Response header overhead. As shown in Figure 3, servers must send two headers to activate NEL: NEL and Report-To. Although exact sizes vary depending on the number of collectors and the presence of non-default options, headers are typically several hundred bytes long and are uncompressed unless the client is using HTTP/2. Furthermore, there is currently no way for clients to tell the server whether they support NEL or already have activated NEL for an origin, so servers typically include headers on all requests to all clients. This could be particularly problematic when serving many small objects, in which case NEL headers could constitute a significant fraction of the total response size.

Service operators have several ways to curtail NEL's bandwidth usage. Operators could (1) only serve NEL on a fixed fraction of responses, (2) try to predict which clients support NEL based on their User-Agent header, or (3) only serve NEL headers on HTTP/2 connections, under the assumption that (due to NEL's relatively young age) all clients that support NEL also support HTTP/2.

Report upload overhead. NEL also incurs overhead whenever clients upload reports. Reports we receive from our clients are 532 ± 34 bytes long; clients batch these into uploads that contain an average of 1.3 reports each. Clients upload a batch of reports about an origin once per minute.

Clients pay additional bandwidth overhead for failed uploads: 1) Clients incur connection establishment overhead multiple times as they retry an upload to different collectors, and 2) each failed upload may itself generate a NEL report.

Service operators can control these overheads with sampling rates in the NEL header. In particular, because *most* requests succeed, the success_fraction field can have a large impact on total upload traffic. For example, over 90% of requests to our services succeed and reports about those requests do not contribute much to our ability to reason about network outages other than by establishing proper baselines. We set success_fraction to 0.05, but success reports are still almost 40% of our upload traffic.

5.3 Provisioning for bursty workloads

We could further reduce success_fraction, but at a cost. Although request failures are much rarer than successes, failures are very bursty. Major network outages can cause large networks to send tens or hundreds of times more NEL reports than they normally would. A service's NEL collection infrastructure must be provisioned to handle these cases or risk data collection failing at exactly when it is most needed.

NEL client retry logic compounds this by causing clients to retry uploads to collectors when they are overloaded. We currently mitigate this by having our collectors always return HTTP 200, which prevents clients from retrying uploads when the collection infrastructure is overloaded. If more explicit control is needed, the NEL specification requires user agents to stop sending reports to a collector entirely when that collector returns an HTTP 410 (*Gone*) response.

5.4 Application-layer retries

It can be tempting to compare error rates across different kinds of applications, domains, and URLs. For example, one might suspect that if one domain has four times the error rate of another then something must surely be wrong with the former domain. Although this *might* be true, application-layer retry logic could also explain the discrepancy.

For example, if a Web application makes a lot of AJAX requests to example.com and *retries those requests when they fail*, then the overall NEL error rate for example.com will appear higher. This is because successive request failures are likely not independent; if a request fails once, it is much more likely that a second request will also fail.

This logic also applies to user-initiated retries. If a particular request is more likely to elicit a retry (*e.g.*, a browser reload) from a user when it fails, that can also inflate the NEL error rate. For example, a user may be more likely to retry requests that are very important to them whereas they may simply abandon more trivial requests.

6 Future Work

End-to-end report encryption. As mentioned in Section 5.1, one easy way operators can increase the likelihood that clients can successfully upload NEL reports is to host collectors in cloud providers. However, NEL clients currently assume that operators trust collectors and therefore do not encrypt reports beyond uploading them using HTTPS. If an operator does not trust a cloud, their only option currently is to use the cloud as a layer 3 proxy and terminate HTTPS elsewhere. Future versions of NEL could encrypt reports end-to-end (*e.g.*, using PGP), which would decouple collectors (which would see reports as opaque blobs) and report analyzers (which could decrypt reports).

Automated triage. Individual NEL reports are rarely useful; we derive utility from examining collections of reports and identifying patterns in those collections. For example, if we see many timeouts of requests to many IPs in a prefix, that may indicate a problem with that entire prefix. We currently look for problems in a manually curated set of dimensions based on our past experience, but in the future could try to automatically identify problematic user populations without *a priori* knowledge of likely problems. Based on the "shape" of a given problem (*i.e.*, the distribution of different types of NEL reports), we could attempt to automate triage of the problem. For example, if we detect that all users in just one ISP are having difficulty accessing a domain, then we could automatically notify that ISP, since their network configuration is a likely culprit.

Reducing overhead. Future versions of NEL might add several mechanisms to reduce the overhead of NEL policy headers. For example, we might let services specify NEL policies in external URLs, using a mechanism like the proposed Origin Policy [33] or Site-Wide HTTP Headers [26] standards. By making their NEL policy object cacheable, service providers can preclude clients from having to fetch the policy from the external URL after every successful request. We may also let clients include request headers which indicate when the server should send NEL policy headers, using a mechanism similar to HTTP Client Hints [16]. This would prevent servers from needlessly sending NEL headers to clients that will ignore them.

7 Related Work

Earlier in Section 2, we reviewed prior work which shares NEL's aim of detecting and diagnosing service unreachability. Here, we compare NEL to other systems which also rely on client-side measurements.

There have been a number of previous client-side measurement systems focused on one of the following goals: continual collection of passive measurements [30], enabling users to measure their network [21], or orchestration of measurement campaigns [29, 25, 13]. All of these efforts aim to gather measurements with the aim of compiling performance distributions, characterizing middleboxes, measuring network topologies, etc. Since none of this data needs to be compiled in a timely manner, uploading via redundant paths has been unnecessary in these efforts, unlike in NEL. Moreover, since the measurements gathered in these systems do not contain application traffic, protecting user privacy has not been a concern.

Windows Error Reporting (WER) [15] is most similar in spirit to NEL in that it too uploads error reports gathered at the client. WER does have to pay attention to privacy by pruning crash reports before uploading them. However, since uploaded crash reports are analyzed at a later point in time [18], failover on the upload path was unnecessary in this case too.

Odin [10] enables Microsoft to gather measurements from their clients to their CDN. By incorporating active measurement logic into client applications, Odin preempts concerns regarding coverage associated with dedicated monitoring infrastructure. Like NEL, Odin too attempts to make report uploading fault-tolerant via proxies in third-party networks. Unlike NEL, since Odin only relies on measurements that it actively issues, purging reports to protect privacy is not a significant concern. Odin also cannot be used by services not managed by Microsoft.

8 Conclusion

Despite the wide range of solutions available today to detect and diagnose reachability issues over the Internet, service operators lack an important capability: the ability to quantify the number of clients affected by any particular outage. To fill this void, we presented NEL, which equips service providers with timely collection of reachability reports generated at the client. Incorporation of NEL's techniques into Chrome has proved invaluable over the last few years in monitoring reachability to Google's domains. Motivated by our experience, we have proposed NEL as a W3C standard to spur support for it in other user agents and to enable other service providers to benefit from this capability.

Acknowledgements

We thank the anonymous reviewers and our shepherd, KyoungSoo Park, for their valuable feedback. Many people at Google have contributed to this project, particularly through their experiences investigating problems NEL has detected. In particular, we thank Emma Christie, Fred Douglas, Logan Ingalls, Martijn Stevenson, Matthew Steele, Steve Wang, Wesley Darlington, and Yan Avlasov for investigating issues that NEL has detected over the years. Debashish Chatterjee, Francesco Marabotto, Jelmer Vernooij, and Mitchell Jeffrey have provided valuable support from Google's SRE organization. We thank Chris Bentzel for initial sponsorship of the project. Harsha Madhyastha's participation was funded in part by the National Science Foundation via award CNS-1563849.

Abstract

Network verification to detect router configuration errors typically requires an explicit correctness *specification*. Unfortunately, specifications often either do not exist, are incomplete, or are written informally in English. We describe an approach to infer likely network configuration errors without a specification through a form of automated *outlier detection*. Unlike prior techniques, our approach can identify outliers even for complex, structured configuration elements that have a variety of intentional differences across nodes, like access-control lists, prefix lists, and route policies.

Given a collection of configuration elements, our algorithm automatically infers a set of parameterized *templates*, modeling the (likely) intentional differences as variations within a template while modeling the (likely) erroneous differences as variations across templates. We have implemented our algorithm, which we call *structured generalization*, in a tool called SELFSTARTER and used it to automatically identify configuration outliers in a collection of datacenter networks from a large cloud provider, the wide-area network from the same cloud provider, and the campus network of a large university. SELFSTARTER found misconfigurations in all three networks, including 43 previously unknown bugs, and is in the process of adoption in the configuration management system of a major cloud provider.

1 Introduction

Router configuration errors are a major cause of network outages [1, 17, 19, 30, 35, 37]. Accordingly, researchers have developed a variety of techniques to automatically identify such errors and/or to prove their absence. Techniques that began in academic research [16, 23, 24, 29] have migrated to industry via cloud vendors [2, 20], router vendors [3], and startups [4]. However, these approaches have an important practical limitation: users must provide an explicit, formal *specification* of the network's intended behaviors (e.g., reachability requirements) [14, 18, 23, 29]. In practice, such specifications often do not exist, and when they do exist, they tend to be informal, incomplete, and ambiguous. A few tools do not require a specification [15, 16] but then are limited to identifying *generic* configuration errors (e.g., forwarding loops, duplicate IP addresses), independent of the network's particular policy intent.

In this paper, we develop an approach to identify *network-specific* misconfigurations without a specification, through a form of outlier detection. The *bugs as outliers* paradigm [13] is natural for network configurations, since, by design, many nodes' configurations are intended to be highly similar to one another (e.g., all nodes playing the same *role* in the network). We refer to any logical unit of a configuration, such as a BGP session configuration or access-control list, as a *segment*. Given a set of configuration segments that are intended to be similar, our goal is to automatically identify likely misconfigurations and provide actionable feedback to fix them.

Prior work in outlier detection (§ 8) for network configurations [12, 28] assumes that configuration segments are intended to be *exactly equivalent* to one another. Such approaches can identify outliers in the simpler aspects of a configuration, such as the set of DNS servers and the MTU values on interfaces. However, exact equivalence is much too strong an assumption for detecting useful outliers for complex configuration segments like access-control lists and route policies. Such segments often have a variety of intentional policy differences across nodes (e.g., the treatment of local hosts or services). Hence, outlier detection must be able to distinguish intentional differences from ones that represent likely errors.

We describe a general approach to outlier detection that addresses this limitation. Given a set of configuration segments, our algorithm, which we call *structured generalization*, infers one or more segment *templates*. Each template is a segment definition that is optionally parameterized by various pieces of data (e.g., the IP address used on a particular line). These templates serve as a compact summary of the differences across network policies and induce an equivalence relation on the nodes: two nodes are considered "equivalent" if they are instantiations of the same template. In other words, we model the (likely) intentional differences between nodes as variations *within a template* while modeling the (likely) erroneous differences as variations *across templates*.

The key challenge is to infer templates that result in useful equivalence relations. This requires a delicate balance between templates that cover too few or too many configurations. Parameterization is necessary to account for intentional differences between segments. However, supporting arbitrary parameterization would lead to overly-general templates that mask important differences. Similarly, the ordering of some configuration lines (e.g., consecutive `permit` lines in an ACL) is semantically transparent. Hence, a single template should admit such reordering. However, a single template that admits arbitrary reordering (e.g., arbitrary ACL `permit` and `deny` lines) may result in masking semantic differences, thus potentially hiding critical configuration errors.

Our structured generalization meets this challenge through a novel two-level approach to matching segments with one another. *Sequence alignment* is used to align *blocks* of segment lines with one another, thereby admitting insertions and deletions but ensuring that the order of blocks is respected. However, the similarity measure for this alignment employs *bipartite matching* to match the lines within the blocks, thereby admitting line reordering and also naturally inducing template parameters wherever two matched lines differ. Our algorithm is parameterized by the definition of blocks and the cost function for bipartite matching, which respectively control the amount of reordering and parameterization. We also provide instantiations of this generic algorithm for access-control lists, prefix lists, and route policies.

We have implemented structured generalization in a tool called SELFSTARTER. We applied SELFSTARTER to identify configuration outliers in three different kinds of networks: a large number of datacenters in a cloud provider network, totaling on the order of $O(10000)$ routers; the wide area network (WAN) of a large cloud provider, containing hundreds of routers; and the department routers of a large university campus network, containing $\sim$100 routers. In these networks, we applied SELFSTARTER to three heavily-used segment types: *access-control lists* (ACLs), which contain a sequence of `permit` and `deny` lines that determine which packets to accept; *prefix lists*, which have a similar structure as ACLs and are used to determine which route announcements to accept during routing; and *route policies*, which flexibly match sets of route announcements and update them in various ways (e.g., to add a community tag).

For the datacenter, SELFSTARTER identified 1168 outliers, of which 630 were investigated and all determined to be true positives. For the wide area, SELFSTARTER identified 56 route policy outliers, of which 33 were investigated and all were determined to be true positives. As SELFSTARTER found new bugs that were previously unknown to operators, it is in the process of being adopted in the configuration management process of the WAN. However, SELFSTARTER was much less successful in identifying true positives for prefix lists in the wide area; the reasons are explained in §6. For the university network, SELFSTARTER identified 6 ACL outliers, of which 3 were investigated and all were determined to be true positives. SELFSTARTER's metatemplates made it easy for the network operators to quickly classify outliers as true/-false positives and to remediate the actual misconfigurations. Further, the templates that SELFSTARTER generated closely matched any existing "golden" templates or configurations for these networks.

We make the following contributions:

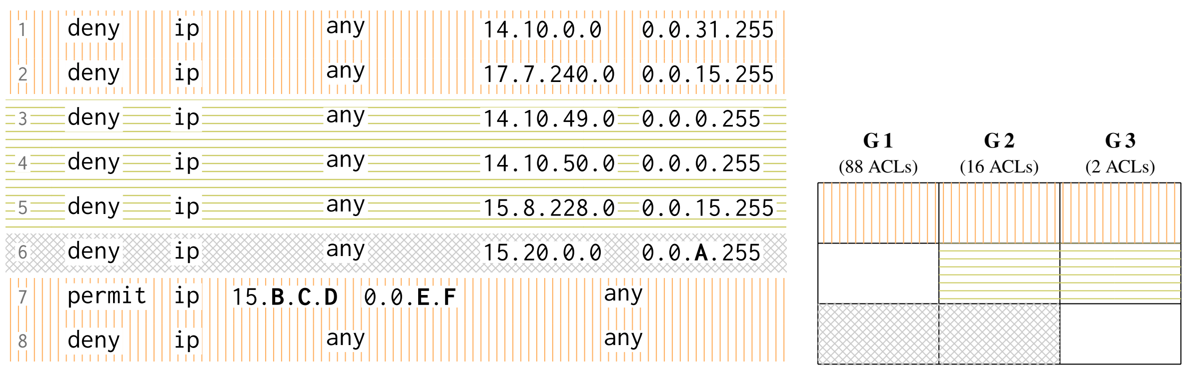
1. **Automatic Template Inference:** To our knowledge, we are the first to propose the idea of automatic template inference for network configuration segments and to employ it to identify network misconfigurations (§2).
2. **Structured Generalization:** We present a novel algorithm for automatic inference of parameterized templates for network configuration segments that combines sequence alignment and bipartite matching in a two-level structure to support controlled forms of parameterization and reordering (§3 and §4).
3. **Implementation:** We have implemented structured generalization in a practical tool called SELFSTARTER (§5).
4. **Evaluation:** We describe our empirical evaluation of SELFSTARTER on several large real-world production networks, demonstrating that in most cases it generates high-quality outliers with a low false positive rate (§6).

2 Using SELFSTARTER

We describe an example of SELFSTARTER's output and its use in finding misconfigurations in the campus network of a large university. SELFSTARTER was given as input the configurations of 106 *building routers* (one of the roles in the network), along with a regular expression capturing the name(s) of an access-control list (ACL) of interest used on the routers.[1] Given this input, SELFSTARTER automatically inferred three templates, each of which is an ACL definition that is parameterized by zero or more parameters.

Figure 1 shows SELFSTARTER's output for this example. Figure 1(a) shows a *metatemplate*, which is a concise representation of the three inferred templates, highlighting their commonalities and differences. A metatemplate is a sequence of parameterized configuration lines. Capital letters like `A` and `B` are *parameters*, representing values that differ across ACLs that contain the corresponding line. The metatemplate is *complete*: every line that appears in some ACL is represented by a line in the metatemplate.

[1]We allow regular expressions instead of simple strings since some organizations append metadata to ACL names, so two ACLs with slightly different names may still be intended to be similar.



```
1  deny    ip              any                14.10.0.0     0.0.31.255
2  deny    ip              any                17.7.240.0    0.0.15.255
3  deny    ip              any                14.10.49.0    0.0.0.255
4  deny    ip              any                14.10.50.0    0.0.0.255
5  deny    ip              any                15.8.228.0    0.0.15.255
6  deny    ip              any                15.20.0.0     0.0.A.255
7  permit  ip  15.B.C.D  0.0.E.F                       any
8  deny    ip              any                          any
```

(a) ACL Metatemplate

(b) Groups

Figure 1: SELFSTARTER output for an ACL Regex in a university network. Groups 2 and 3 are confirmed to be anomalous.

Figure 1(b) identifies the three templates that SELFSTARTER inferred. Each column represents a *group* of nodes that share a common template. Colors allow users to easily see which lines of the metatemplate belong to each template. For example, the template for the 88 ACLs in Group 1 contains the metatemplate lines that are colored orange (vertical bars) and gray (crosshatching), i.e., lines 1, 2, 6, 7, and 8. Similarly, the template for Group 2 consists of lines 1-8, and the template for Group 3 consists of lines 1-5, 7, and 8.

Though each of the example ACLs contains at most eight lines, manually scanning the configurations from all 106 routers to find outliers would be onerous and error-prone. Furthermore, partitioning the ACLs based on *exact equivalence* would result in 53 different groups, since each building has two routers with an identical ACL, but parameter values differ from building to building. In contrast, SELFSTARTER's output makes it easy for network engineers to identify outliers and to understand exactly how they differ from non-outliers. Specifically, SELFSTARTER helps engineers to identify two types of outliers, which we now describe.

Group Outliers. If SELFSTARTER produces multiple groups, the network engineer can compare the templates for these groups to decide whether one or more groups are misconfigured. Groups that are relatively small in size are particularly likely to be the results of misconfiguration. For example, in Figure 1(b) the vast majority of the ACLs are in Group 1, indicating that Groups 2 and 3 are suspect.

In fact, for this example, the network engineers have confirmed that Groups 2 and 3 represent misconfigurations. Group 3 erroneously omits line 6, allowing some flows that should be denied. Further, both Groups 2 and 3 erroneously include lines 3-5. While these lines used to be required to prevent access to certain infrastructure servers, those servers were phased out and the lines were supposed to be removed. Further, some of the denied IP addresses had since been reassigned to servers that are intended to be accessible. Hence these lines deny some flows that should be allowed.

Parameter Outliers. Structured configuration segments, like ACLs, often differ across nodes. Hence, the ability to parameterize is critical for generating templates that identify similarities without requiring exact equivalence. For each parameter, SELFSTARTER maintains a mapping from nodes to parameter values for the engineer to inspect.

A parameter error is present if some field in a line is supposed to be constant across all the routers, but it is not. SELFSTARTER guarantees that a parameter in some field of a line in the metatemplate indicates that there must be at least two different values for that field across the given configuration segments. Thus, a parameter error is identified in the metatemplate by a field that contains a parameter instead of a constant. In our example, out of the 104 ACLs that contain line 6, 94 use the mask 255 for parameter A, while 10 of them use the mask 127. The network engineers confirmed that the 10 ACLs are erroneous, permitting more traffic than intended.

SELFSTARTER is useful for finding errors and inconsistencies in networks that are managed through manual creation of individual node configurations. Perhaps surprisingly, we have also found SELFSTARTER to be useful for networks that employ forms of automation to manage configurations.

First, many network engineers employ *configuration templates*, with one parameterized template per role in the network. This simplifies network management since node configurations can be created by instantiating the relevant template with node-specific parameter values. For example, the university network described above has a template for all building routers. However, this network still suffered from multiple misconfigurations identified by SELFSTARTER. The problem is that node configurations tend to drift over time from their original templates. Such *template drift* happens for several reasons. First, operators often must manually edit a node's configuration, for example to quickly address a problem or to perform maintenance of various kinds. Second, the templates themselves get updated over time, and often operators are relied upon to manually perform the necessary configuration updates. Hence there is typically still considerable manual configuration in practice, which can easily lead to errors.

Second, some networks employ automated scripts to deploy, update, and validate configurations consistently. In this situation, SELFSTARTER is useful to protect against bugs in the automation software itself. Automation may actually *increase* the need for validation tools like SELFSTARTER, since small errors in the automation can lead to large, network-wide misconfigurations. The wide-area network (WAN) that we analyzed employs automation scripts for various purposes, and SELFSTARTER discovered misconfigurations that were due to previously unknown script errors. Once reported, the network engineers promptly confirmed and fixed the errors.

3 Structured Generalization

Our *structured generalization* algorithm takes as input a collection of configuration segments and outputs a metatemplate for these segments in the form shown in Figure 1. After an overview of the key challenges, we present the generic algorithm and then describe how it is instantiated for ACLs, prefix lists, and route policies.

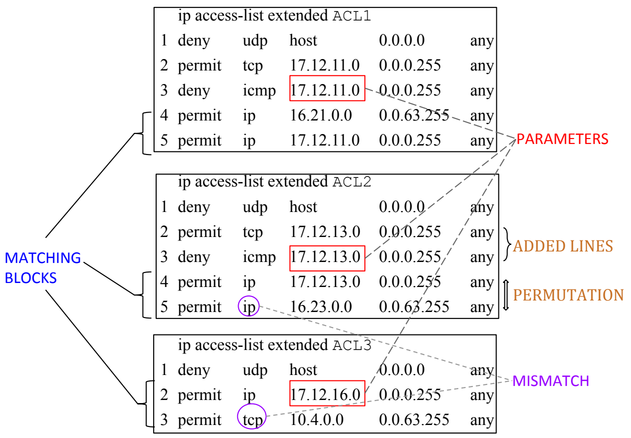
To provide high-quality outliers, the algorithm must be given configuration segments that are intended to be similarly structured. For example, it is common for routers to be partitioned into *roles* (e.g., border routers, core routers) and for the routers within a role to be configured similarly. We rely on the user to provide an appropriate set of configuration segments to be templated. In our experience (see §6), operators know the roles in their network and can quickly identify the segments that are intended to be similar, so this requirement does not pose a large burden in practice.

3.1 Challenges

Suppose that we wish to create a metatemplate for the three different configurations of the same ACL shown in Figure 2. We use this example to illustrate the challenges that our algorithm must address.

Consider the first two ACLs in Figure 2. Their first lines are identical, so clearly they should be matched to one another. However, their second lines differ — they apply to different source IP addresses. A naive approach is to simply not match these lines to one another. However, such an exact-matching criterion is much too strong, as it is common for corresponding ACLs to be similar but not identical across nodes, for example to treat local addresses specially. Therefore, the algorithm must be able to match non-identical lines to one another. This requirement is met using *parameterization*. In this example, we can introduce a parameter to represent the third octet in the source IP address, indicating that this octet differs in each ACL while the rest of the line is identical.

While limited parameterization is necessary, arbitrary parameterization would yield undesirable results. For example, it would not be useful if the metatemplate matches a `permit`



```
  ip access-list extended ACL1
1 deny    udp   host       0.0.0.0     any
2 permit  tcp   17.12.11.0 0.0.0.255   any
3 deny    icmp  17.12.11.0 0.0.0.255   any
4 permit  ip    16.21.0.0  0.0.63.255  any
5 permit  ip    17.12.11.0 0.0.0.255   any

  ip access-list extended ACL2
1 deny    udp   host       0.0.0.0     any
2 permit  tcp   17.12.13.0 0.0.0.255   any
3 deny    icmp  17.12.13.0 0.0.0.255   any
4 permit  ip    17.12.13.0 0.0.0.255   any
5 permit  ip    16.23.0.0  0.0.63.255  any

  ip access-list extended ACL3
1 deny    udp   host       0.0.0.0     any
2 permit  ip    17.12.16.0 0.0.0.255   any
3 permit  tcp   10.4.0.0   0.0.63.255  any
```

Figure 2: Configurations of the ACLs matching the `ACL*` regex from three different routers highlighting the challenges.

line with a `deny` line, as their behavior is not at all similar. As a more subtle example, consider the last line in `ACL3` in Figure 2. This line is similar to the last line in `ACL2`. However, since the two lines specify different protocols (tcp vs. ip), it is unlikely that they are intended to serve the same function in the ACLs. Hence, despite being similar, it may not make sense to match these two lines. Therefore, there is a need for an ability to specify different constraints on what can and cannot be parameterized for different segment types.

Now consider lines 4 and 5 in `ACL1` and `ACL2`. Line 4 in `ACL1` is similar to line 5 in `ACL2`. To match these lines to one another, the algorithm must support *reordering* of configuration lines. Doing so requires a scoring metric to determine which line pairs are the best matches. Such a scoring metric also naturally handles missing lines, as in `ACL3`, resulting in there being multiple options for how to match the lines present in `ACL3` to those in the other ACLs.

As with parameterization, allowing arbitrary line reordering would yield undesirable results. Specifically, reordering a `permit` line and a `deny` line can, in general, change the semantics of an ACL. Therefore, matching lines across ACLs in a way that requires such a reordering can potentially mask important differences between ACLs. Thus, as with parameterization, we need the ability to specify constraints on the allowable reorderings for different segment types.

Our structured generalization algorithm, described below, meets these challenges through a novel two-level approach.

3.2 Algorithm

The algorithm partitions segments into *blocks* of lines that must not be reordered with one another and hence are matched using sequence alignment. However, when matching two blocks with one another, the algorithm employs bipartite matching on their lines, thereby supporting line reordering within blocks and also inducing parameters wherever two

Algorithm 1 STRUCTURED GENERALIZATION

```
Input: $S_1, S_2, \ldots S_n$ - Sequence of segments to be templated
Output: Metatemplate for $S_1, S_2, \ldots S_n$
1: Metatemplate $T \leftarrow S_1$
2: for $S_i \leftarrow \{S_2, \ldots, S_n\}$ do
3:     Block sequence $B_1 \leftarrow$ GETBLOCKSEQUENCE($T$)
4:     Block sequence $B_2 \leftarrow$ GETBLOCKSEQUENCE($S_i$)
5:     Alignment $A \leftarrow$ ALIGNSEQUENCES($B_1$, $B_2$, MISMATCHSCORE)
6:     $T \leftarrow$ GENERATEMETATEMPLATE($A$, $B_1$, $B_2$)
7: end for
8: $T \leftarrow$ MINIMIZEPARAMETERS($T$)
9: return $T$
```

matched lines differ. The amount of reordering and parameterization are respectively controlled through a function that partitions segments into blocks and a function that determines edge weights for bipartite matching.

The structured generalization algorithm is shown in Algorithm 1. The algorithm starts by treating the first segment S_1 as the initial metatemplate (Line 1). It then iteratively combines the current metatemplate with each remaining configuration segment, one at a time, to produce the final metatemplate.

At each iteration the algorithm performs three main steps:

1. Block Generation: A *block* is a contiguous sequence of lines within a segment that can be reordered with one another. The GETBLOCKSEQUENCE function partitions each segment into blocks (Lines 3 to 4) and is specific to a particular segment type. For example, for ACLs the GETBLOCKSEQUENCE function partitions a segment into maximal sequences of lines that have the same action (`permit` or `deny`). The block abstraction and corresponding GETBLOCKSEQUENCE function provide a natural way to admit reorderings within a block while forbidding those across blocks.

2. Block Alignment and Line Matching: Blocks are matched in the two block sequences B_1 and B_2. To prevent cross-block reorderings, a standard *sequence alignment* algorithm is employed at the block level (Line 5). Such an algorithm finds a minimum-cost alignment between the two block sequences, allowing gaps but not reorderings.

To meet the need to support within-block reorderings, our algorithm leverages the fact that the sequence alignment algorithm requires a function MISMATCHSCORE that provides the cost of matching two blocks to one another.[2] The MISMATCHSCORE function is shown in Algorithm 2. The function first breaks the two blocks into lines, and then it performs a minimum-weight bipartite matching between the two line sequences using a standard matching algorithm, thereby supporting line reordering. The function returns the score for the best matching and also the matching itself.

The MISMATCHSCORE function uses another function, LINESCORE, to assign weights to each edge in the bipartite graph (between a pair of lines). This function is specific

[2]Sequence alignment algorithms also require a function to provide the cost of introducing a gap; we use a simple metric for this cost based on the size of the unmatched block.

Algorithm 2 MISMATCHSCORE

```
Input: $\{b_1, b_2\}$ - Blocks to be matched
Output: A score for aligning $b_1, b_2$ and a matching between their lines
1: Line sequence $L_1 \leftarrow$ GETLINESEQUENCE($b_1$)
2: Line sequence $L_2 \leftarrow$ GETLINESEQUENCE($b_2$)
3: Score $S$, Matching $M \leftarrow$ MINIMUMWEIGHTBIPARTITEMATCHING($L_1$,
   $L_2$, LINESCORE)
4: return $S$, $M$
```

to each type of segment and provides a flexible way to prevent undesired line matchings and to prioritize among different possible line matchings.

3. Parameterization: Once the two block sequences have been aligned, the metatemplate is generated (Line 6). As described above, for each pair of blocks that are aligned with one another, the MISMATCHSCORE function also provides a matching at the line level. For each pair l_1 and l_2 of matched lines, the metatemplate includes their *least general generalization* (lgg) [34]. Intuitively, this is simply a version of l_1 where a parameter is introduced in each field where it differs from l_2. For example, the lgg of the second lines in the first two ACLs in Figure 1 is `permit tcp 17.12.P.0 0.0.0.255 any`, where `P` is a new parameter.

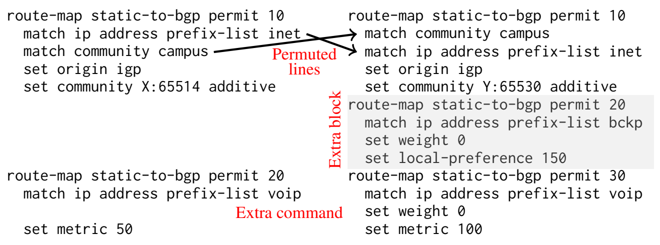
As a final step, the number of parameters in the metatemplate is globally minimized (Line 8). Specifically, let $P(S)$ denote the value that parameter P takes in segment S. If two parameters P_0 and P_1 in the metatemplate have the property that $P_0(S_i) = P_1(S_i)$ for each segment S_i, then the parameters are merged into a single parameter.

3.3 Instantiation for ACLs and Prefix Lists

This subsection discusses how the structured generalization algorithm is instantiated for ACLs and prefix lists, which are handled identically. Doing so requires providing specific GETBLOCKSEQUENCE and LINESCORE functions to the generic algorithm above. The goal is to take advantage of the particular properties of ACLs and prefix lists to both allow for flexible templating and ensure that generated templates are *actionable*, i.e., they facilitate the identification of common configuration errors.

The GETBLOCKSEQUENCE function partitions an ACL or prefix list into maximal sequences of lines that have the same action (`permit` or `deny`). This allows reorderings guaranteed to have no behavioral effect. The notion of blocks can be relaxed to admit more reorderings. For example, reordering a `permit` line with a `deny` line does not change behavior when the sets of packets that they handle are disjoint. However, in practice, we have not encountered the need to support such reorderings, so the extra complexity is not warranted.

The LINESCORE function for ACLs and prefix lists prohibits matching lines that differ in either their action (`permit` or `deny`) or protocol by returning an infinite weight. All other differences (e.g., in source or destination IP addresses) are



```
route-map static-to-bgp permit 10            route-map static-to-bgp permit 10
  match ip address prefix-list inet            match community campus
  match community campus                       match ip address prefix-list inet
  set origin igp                               set origin igp
  set community X:65514 additive               set community Y:65530 additive
                                             route-map static-to-bgp permit 20
                                               match ip address prefix-list bckp
                                               set weight 0
                                               set local-preference 150
route-map static-to-bgp permit 20            route-map static-to-bgp permit 30
  match ip address prefix-list voip            match ip address prefix-list voip
                                               set weight 0
  set metric 50                                set metric 100
```

Figure 3: Example: Two route policies.

allowed but are penalized by an increase in overall score. Specifically, consider some field of the two lines that is allowed to differ (e.g., the first octet of the source IP address). If the lines agree on the value of this field, then the overall score is unchanged. If one field contains a constant while the other contains a parameter name (which must have been introduced in an earlier iteration), then the overall score is increased by 1, since an exact match is preferable. Finally, if the lines contain different constant values in this field, then the overall score is increased by 2, since a new parameter must be introduced in order to match the lines, so either of the above two cases is preferable. Despite its simplicity, this scoring function works well across all of our experiments (§6).

§4 contains a detailed example of the structured generalization algorithm applied to the ACLs in Figure 2.

3.4 Instantiation for Route Policies

Route policies are flexible configuration segments used in several contexts, including route redistribution filtering, policy-based routing, and BGP policy implementation. A route policy is defined as a sequence of *route map clauses*, each of which contains an action (e.g., `permit`), a list of `match` lines, and a list of `set` lines.[3] The `match` lines provide a flexible way to select route announcements of interest based on the route attributes. The `set` lines then update matching announcements (e.g., to add a particular community tag). Figure 3 shows two example route policies.

The GETBLOCKSEQUENCE function for route policies puts each clause in one block, so the left and right route policies in Figure 3 respectively contain two and three blocks. This allows the `match` lines within a route map to be reordered with respect to one another, and similarly for the `set` lines.[4] Since all `match` lines have to succeed for a route announcement to match the route map, reordering them has no effect. In principle, reordering `set` lines can change behavior, specifically if one `set` line reads a value that was updated by a previous `set` line. In our experience, however, order dependence is rare: we have encountered only one such situation (where the deletion to a community attribute was followed by an addition). Therefore we opted to allow reordering of `set` lines within route maps to handle the common case properly.

The LINESCORE function for route policies allows two lines to be matched in the bipartite matching only if they refer to the same *attribute* of the route announcement. For example, the `match community campus` line in the left route policy of Figure 3 can only match against other `match community` lines, and the following `set origin igp` line can only match against other `set origin` lines.

With route policies it is common for `match` lines to refer to prefix lists and access lists defined elsewhere in the configuration. For example, the first `match` line in the left route policy refers to the prefix list named `inet`. When scoring two lines that refer to a named segment, we choose to perform a *shallow* comparison that considers them to exactly match if they refer to same-named segments. An alternative would be to perform a *deep* analysis that ignores the names and instead expands the definitions of these segments in order to recursively compare them. From our experiments on a large cloud provider network, we found that simple name comparison works well, since the network names segments identically across configurations. Further, if two same-named segments do differ in their definitions, that will be caught during metatemplating of those segments.

Figure 3 illustrates the best alignment of the two route policies, based on the GETBLOCKSEQUENCE and LINESCORE functions described above. Specifically, the second clause of the left policy is aligned with the third clause of the right policy. That is the lowest-cost alignment since these route maps match on the same-named prefix list announce and both have a line to set the `metric`.

4 A Templating Example

This section describes how Algorithms 1 and 2 generate a metatemplate for the three ACLs in Figure 2. Figure 4 shows `ACL1` and `ACL2` side by side; we use superscripts to uniquely refer to each `permit` and `deny` line. The STRUCTURED GENERALIZATION algorithm designates `ACL1` as the initial metatemplate (Line 1) and iteratively incorporates `ACL2` and `ACL3` to produce the final metatemplate (Lines 2 to 7).

In the first iteration, the "Block Generation" step partitions `ACL1` (Line 3) and `ACL2` (Line 4) into blocks. For `ACL1`, the algorithm generates the block sequence B_1 consisting of four blocks — $\mathsf{D_a}$, $\mathsf{P_a}$, $\mathsf{D_b}$, and $\mathsf{P_b}$ — where $\mathsf{D_a}$ contains deny^1, $\mathsf{P_a}$ contains permit^1, $\mathsf{D_b}$ contains deny^2, and $\mathsf{P_b}$ contains permit^2 and permit^3. The algorithm generates an analogous block sequence B_2 for `ACL2`, with four blocks that we denote $\mathsf{D_x}$, $\mathsf{P_x}$, $\mathsf{D_y}$ and $\mathsf{P_y}$.

Next, in the "Block Alignment and Line Matching" step, the algorithm uses the sequence alignment algorithm, which in turn relies on the MISMATCHSCORE(b_1, b_2) function in Algorithm 2. It turns out that the following alignment A is the

[3]Here we have used the syntax from Cisco IOS; the JunOS syntax from Juniper uses different keywords but is semantically similar.

[4]Technically it also allows `match` and `set` lines to be reordered with one another, but that is not syntactically legal so will never arise.

```
ip access-list extended ACL1
 deny^1   udp  host        0.0.0.0     any
 permit^1 tcp  17.12.11.0  0.0.0.255   any
 deny^2   icmp 17.12.11.0  0.0.0.255   any
 permit^2 ip   16.21.0.0   0.0.63.255  any
 permit^3 ip   17.12.11.0  0.0.0.255   any
```

```
ip access-list extended ACL2
 deny^3   udp  host        0.0.0.0     any
 permit^4 tcp  17.12.13.0  0.0.0.255   any
 deny^4   icmp 17.12.13.0  0.0.0.255   any
 permit^5 ip   17.12.13.0  0.0.0.255   any
 permit^6 ip   16.23.0.0   0.0.63.255  any
```

```
ip access-list extended ACL*
 deny         udp  host        0.0.0.0     any
 permit       tcp  17.12.A.0   0.0.0.255   any
 deny         icmp 17.12.B.0   0.0.0.255   any
 permit^3,5   ip   17.12.C.0   0.0.0.255   any
 permit^2,6   ip   16.D.0.0    0.0.63.255  any
```

```
ip access-list extended ACL3
 deny      udp  host        0.0.0.0     any

 permit^7  ip   17.12.16.0  0.0.0.255   any
 permit^8  tcp  10.4.0.0    0.0.63.255  any
```

Figure 6: Comparing the metatemplate for ACL1 and ACL2 with ACL3

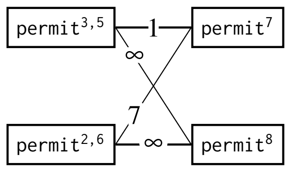

Figure 7: Bipartite graph of last permit block

optimal alignment for the two sequences.

$$(D_a, P_a, D_b, P_b)$$
$$(D_x, P_x, D_y, P_y)$$

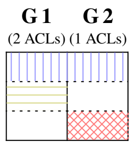
The single line in D_a is matched with the single line in D_x, and similarly for the next two pairs of blocks in the alignment. For the last pair of blocks (P_b, P_y), the algorithm constructs the bipartite graph shown in Figure 5 to determine line matchings. The LINESCORE(l_1, l_2) function assigns the edge weight of permit^2 and permit^6 as 2 since the lines differ in the second octet of the source IP, but the edge weight of permit^2 and permit^5 is assigned as 8 since they differ in four octets total across the source IP and source mask. Therefore, the minimum weight matching (Line 3) matches permit^2 with permit^6 and permit^3 and permit^5, thereby performing the allowable reordering.

The "Parameterization" step generates the metatemplate by introducing parameters based on the produced sequence alignment and line matchings (Line 6). The resultant metatemplate of ACL1 and ACL2 is shown on the left side in Figure 6. The two ACLs have a common template; the line produced by merging permit^3 with permit^5 is shown as permit^{3,5} in the metatemplate, and similarly for permit^{2,6}.

The next iteration incorporates ACL3. The metatemplate from the first iteration and ACL3 are both partitioned into blocks, and then these blocks are aligned in the same way as described above. The best block alignment and line matching are shown in Figure 6. As an example, the bipartite graph constructed to calculate the MISMATCHSCORE of the last block in each block sequence is shown in Figure 7. The edge weight of permit^{3,5} and permit^7 is 1 since there is already a parameter in the metatemplate for the source IP address octet where the two lines disagree. The LINESCORE function gives the edge between permit^{3,5} and permit^8 a score of ∞ since lines with different protocols cannot be matched. The minimal-weight matching matches permit^{3,5} with permit^7 and leaves lines (permit^{2,6} and permit^8) unmatched. This

```
ip access-list extended ACL*
 deny           udp   host        0.0.0.0     any
 permit         tcp   17.12.A.0   0.0.0.255   any
 deny           icmp  17.12.B.0   0.0.0.255   any
 permit^3,5,7   ip    17.12.C.0   0.0.0.255   any
 permit^2,6     ip    16.D.0.0    0.0.63.255  any
 permit^8       tcp   10.4.0.0    0.0.63.255  any
```

(a) Metatemplate of all three ACLs



(b) Groups

```
ACL1: [A = 11, B = 11, C = 11, D = 21]
ACL2: [A = 13, B = 13, C = 13, D = 23]
ACL3: [C = 16]
```

(c) Router parameter value map

Figure 8: Result of templating ACL1, ACL2 and ACL3

example demonstrates the need to match blocks but also to identify gaps due to missing/extra lines.

The resultant metatemplate for the three ACLs is shown in Figure 8(a), the ACL groups are shown in Figure 8(b), and the parameter-value map is shown in Figure 8(c). Finally, as explained in §3.2, the algorithm can create more parameters than necessary. For example, in Figure 8, parameters A, B and C are redundant: for every router *R* that requires all of these parameters, *R* instantiates the parameters with the same value. Therefore, the parameter minimization step (Line 8) merges A, B and C into a single parameter.[5]

5 Implementation

SELFSTARTER[6] takes as input a set of router configurations and a segment name or regular expression. It outputs a

[5]A degenerate case occurs when two parameters are never required together by any router; in that case we do not merge the parameters since they are likely to be logically unrelated.

[6]https://github.com/SivaKesava1/SelfStarter

metatemplate for all segments that match the given name or regular expression, a partitioning of each segment into groups that share a common template, and a parameter mapping for each segment, as shown in Figure 8.

SelfStarter is written in Python. It uses PyBatfish,[7] a client for the Batfish network configuration analysis tool [16], to parse the raw vendor-specific configuration files into Batfish's vendor-agnostic format. This format provides a structured representation of the configuration data, and our algorithm works directly on this representation. Batfish can parse many different configuration formats, including those from Cisco, Juniper, and Arista, so in turn SelfStarter can infer templates for segments from all of these vendors.

Our structured generalization algorithm uses a standard algorithm for sequence alignment based on dynamic programming, in order to align block sequences. Lines within a block are matched using the Python library `munkres`, which implements Munkres' improvement on the standard Hungarian matching algorithm to be (strongly) polynomial [25, 26, 33]. We also perform one major optimization over the algorithm. Given the collection of segments to template, SelfStarter first removes all duplicates from the collection — segments whose representation in Batfish's format are identical to that of some existing segment in the collection. Since there are often subsets of the configurations in a role that are meant to be exactly identical, this optimization can significantly improve the efficiency of structured generalization by reducing the number of calls to the expensive matching algorithms.

The order in which segments are considered for templating can affect the final metatemplate and groups produced. Our implementation uses a simple heuristic. The segments are partitioned based on their line counts. The segments in the largest partition (i.e., the partition containing the most segments) are templated first, choosing segments randomly from that partition until it is empty. The remaining segment partitions are then processed in order of decreasing partition size. Intuitively this heuristic tries to template segments that are likely to be outliers last, so that their impact on the templates of other segments is minimized.

The structured generalization algorithm produces a metatemplate in Batfish's vendor-agnostic format, but SelfStarter must output the metatemplate in some vendor-specific format in order to be understandable to network engineers. Currently SelfStarter outputs metatemplates in Cisco's IOS format. This has been sufficient to get feedback for our experiments (§6), since the majority of nodes use that format, and it is similar enough to the other formats for the engineers to understand the results. It would be straightforward to add pretty printers to output the metatemplate in other vendor-specific formats in the future.

Given the results of the structured generalization algorithm, SelfStarter finally produces the output visualization as shown in Figure 8. First the metatemplate lines are partitioned, where two lines are placed in the same subset if and only if for every segment, either both lines are in the segment or neither is. Then a color is chosen for each subset, each inferred template is mapped to the set of colors of its lines, and the colored tables are created and output as HTML files.

6 Evaluation

To evaluate SelfStarter, we applied it to a collection of datacenter networks from a large cloud provider, a wide area network from the same cloud provider, and the campus network of a large university. These networks differ widely in their structure, scale, and management style. Yet SelfStarter identified misconfigurations in all of them; in two of the three networks SelfStarter identified previously unknown errors. Further, SelfStarter's inferred templates closely match any manually written templates that exist for these networks. A dominant cause of the errors that SelfStarter identified were planned configuration updates not yet applied or inconsistently applied. We ran SelfStarter on a 3.6 GHz quad-core machine with 32 GB of RAM.

Methodology: For each network, we obtained a snapshot of the router configurations and partitioned them into roles based on router names, sometimes with the help of the network operator. We then parsed the configurations with Batfish and ran SelfStarter on the output once per *triple*, where a triple is a tuple of a segment type (e.g., ACL), role (e.g., the border routers), and segment name or regular expression (e.g., `border-out-1`). SelfStarter produces a metatemplate for each triple.

Network	Number of routers	Number of roles	Number of triples	Batfish parsing time	SelfStarter running time
Datacenter	$O(10000)$	$O(1000)$	25475	150 min	90 min
WAN	$O(100)$	$O(100)$	21011	14 min	20 min
Campus	106	1	6	2 min	<2 min

Table 1: Networks' parsing and running times

Table 1 shows the order of magnitude of each network in number of routers and roles, along with the number of triples on which we ran SelfStarter[8] and the time for Batfish parsing as well as the total time to run on all triples.

We define a **consistent triple** to be one whose metatemplate consists of only a single group (i.e., all segments meet the same template). Similarly, an **inconsistent triple** is one for which SelfStarter generates a metatemplate with at least two groups. We consider *all* inconsistent triples to be group outliers, and we report the number of such outliers as well as the number that are true/false positives, by comparing with the ground truth (either a "golden" configuration or the

[8] For confidentiality, we cannot disclose the exact number of routers and roles for the cloud provider.

network operator). Perhaps surprisingly, this very coarse way of identifying group outliers is quite effective in identifying real errors in practice, as we show below.

We tried to automatically identify parameter outliers, where a parameter value is considered an outlier if the value's frequency is below a threshold. We considered different threshold functions – $X\%$ of max frequency, $X\%$ of average frequency, etc. — and used an existing technique [28] to identify a good threshold value by finding the point at which the number of outliers spikes as X is varied. However, in the cloud provider networks nearly all parameter outliers that we investigated using this approach were false positives. The global nature of the cloud provider networks makes it likely that there will be many different parameter values, including some used infrequently. Therefore, our experiments do not identify parameter outliers for the cloud provider networks. For the university network, the number of metatemplates and parameters was small enough for us to manually identify parameter outliers and then validate them with the network operators.

6.1 Datacenter Networks

We applied SELFSTARTER to a large collection of production datacenter networks, totaling tens of thousands of devices and hundreds of millions of lines of configuration, from a cloud provider. The datacenters are set up in a folded Clos topology and run the eBGP routing protocol with private AS numbers, as described in an RFC [27]. We obtained a snapshot of device configurations from December 2018.

Ground truth: The configuration files for all network devices are generated automatically from a set of hand-written templates, which are kept up-to-date as "golden" templates. The templates are parameterized, and a separate database maintains the parameter values for each node (e.g., its list of SNMP monitoring servers). Both the golden templates and the parameters database are subject to periodic updates. A software service automatically generates new per-device "golden" configuration based on these updates and installs them on the running devices. However, there are constraints on when and how often it is appropriate to update a device. For example, a device that is a single point of failure must be updated only after customers that could be impacted are safely transitioned. The software service takes these constraints into account when updating the configurations.

We consider an inconsistent triple to be a true positive if the configurations of at least one group of nodes that SELFSTARTER identifies differ from their golden configurations. Because of the software service that automates configuration updates, we did not expect to (and indeed did not) find new errors with SELFSTARTER. Rather, this experiment allows us to objectively validate SELFSTARTER by comparing its results with a well-maintained source of ground truth.[9]

[9]However, in principle SELFSTARTER can still be useful for this network, to catch errors in the automation service itself.

Triples: Recall that a triple contains a segment type, role, and segment name. Since each datacenter network defines ACLs, prefix-lists, and route-policies, we include all three segment types in our triples. Each node's name includes both the name of the datacenter to which it belongs and its *tier* within the datacenter (e.g., top-of-rack); we treat each (datacenter, tier) pair as a unique role. Finally, for each segment type and role, we create a triple for each unique segment name of that type in the role, resulting in more than 20,000 triples.

Segment Type	Consistent Triples	Inconsistent Triples		
		Reported	Investigated	True positives
ACLs	9700	938	400	400
Prefix Lists	2954	0	-	-
Route Policies	11653	230	230	230

Table 2: Datacenter Results

Results: SELFSTARTER identified 1168 group outliers across the three segment types (Table 2), which is fewer than 5% of all triples. We investigated all 230 of the route-policy outliers. We randomly selected 400 ACL outliers to investigate while ensuring that this subset contains at least one triple for each different segment name that appears in the set of outliers. All 630 outliers were determined to be true positives. Specifically, in all cases, at least one of the groups of routers was correctly following the golden template and the difference between configurations was due to a configuration update had been applied to some, but not all, of the nodes in the same role. As mentioned earlier, updates are delayed for many reasons, so such differences are expected and are eventually resolved by the software service.

6.2 Wide Area Network

The WAN we analyzed is one of the largest backbone networks in the world; it interconnects North America, South America, Asia, Europe, Africa, and Oceania. The backbone consists of hundreds of thousands of kilometers of fiber, hundreds of routers, and millions of lines of router configuration. The configurations for the routers are stored in a centralized database, from which we obtained a June 2019 snapshot. All routers are JunOS-based and use the flat-juniper configuration language format.

Ground truth: The WAN does not employ explicit configuration templates. However, the network operators rely partly on scripts to manage the network; the templates are implicit in these scripts. Typically, each script performs one specific task. As an example, a script configures a set of route policies and verifies that they are consistent across a set of devices. In effect, the equivalent of "golden" configurations described for datacenters do not exist for the wide area. Thus, we asked the network operators to help classify SELFSTARTER's outliers as true/false positives.

Triples: We determined useful network roles using an iterative process. We initially divided nodes into roles based on only their network functionality from their names — edge routers, border routers, core routers, route reflector routers and so on. As in the datacenter, we then created one triple for each unique segment name, per segment type and role.

The initial results using this role scheme contained numerous false positives. Upon consulting a network operator, we immediately (within minutes) received the feedback that these roles were too coarse-grained as well as guidance on how to further refine the roles. The first refinement was to take into account the operating environment of each node. For example, two nodes, where one has external peering enabled and the other does not, should not be considered to be in the same role. Fortunately, we were able to utilize information in a file, maintained by the operator, that lists the operating environment of each node. The second refinement was to take into account geographic location. Routers have certain specializations based on geographical regions in order to meet local policies such as government-specific privacy requirements.

In the end, the number of routers is only roughly $5\times$ the number of roles. In retrospect this makes sense for the WAN due to its global spread. Devices necessarily have many policy differences across regions, for instance based on local peering relationships. Though our initial guess of roles was overly coarse, it was trivial for the operator to immediately identify the issue and provide refined role information.

The WAN defines ACLs, prefix lists, and route policies. However, to date we only have feedback from the operators about SELFSTARTER's output for prefix lists and route policies; thus we omit ACLs from the results below.

Segment Type	Consistent Triples	Inconsistent Triples		
		Reported	Investigated	True positives
Prefix Lists	10042	166	138	7
Route Policies	10969	56	33	33

Table 3: WAN Results

Results: SELFSTARTER identified 222 inconsistent triples (Table 3), which is $\sim$1% of all triples. All outliers that were flagged as true positives were previously unknown and have since been remediated by the operators. All 33 investigated triples for route policies were verified as true positives by the network operators. There were several different root causes. Interestingly, one class of errors was due to bugs in the automation scripts. Specifically, a script that checks for the existence of certain commands in a route policy accidentally did not consider the order of these commands. Since SELFSTARTER takes order into account, its metatemplate contained multiple groups and hence identified ordering errors that change the behavior and that the script missed. Another class of errors, which caused five inconsistent triples, was due to a spurious community tag being added to some route announcements in a few routers.

SELFSTARTER was much less effective at finding real errors in prefix lists, with only 7 out of 138 investigated triples determined to be true positives. In 95 out of 138 triples, the Juniper command `apply-path` is used to create a prefix list by expanding an existing set of addresses defined elsewhere in the configuration, such as the set of local IPs or NTP servers. The seven true positives represented cases where there were inconsistent sets of loopback interfaces defined on different routers, and required cleanup. For the other 88 cases, the operator informed us that it is expected that every router's prefix list will expand to a different set of IPs, and that they can have different numbers of such addresses. For the remaining prefix-lists, the operator informed us that those prefix-lists are locally significant on every router and will always be different. Since SELFSTARTER creates multiple groups whenever two segments have different numbers of lines, this led it to report these spurious inconsistent triples.

On the positive side, it was easy for the operator to quickly understand SELFSTARTER's output and identify these cases as false positives. In fact, the total operator time to classify all of SELFSTARTER's results, for both prefix lists and route policies, was under 30 minutes. Going forward, it would be simple to allow operators to suppress errors reported for segments/roles with well-known differences.

6.3 University Network

The university network consists of approximately 1000 devices, including border routers that connect to external ISPs, core routers that form the backbone, and building routers that handle connectivity for individual buildings. We obtained a snapshot from May 2019 of the network configurations.

Ground truth: Configurations in the network were created using a mix of manual setup and templates. However, even where templates exist, the configurations are still updated directly over time to meet evolving policy needs, and the original templates are not always kept up to date. Therefore, we asked the network engineers to validate our results.

Triples: Node names include a two-letter abbreviation to indicate the network role, for example *cr* for core routers and *br* for building routers. We analyzed only the 106 building routers in the network. This network role was chosen because it is the most interesting one for our purposes – it is the only role that contains many segments that are intended to be similar to one another. Specifically, the role contains six distinct ACLs that appear in nearly all routers. ACLs account for more than one third of the lines in these configurations. The building routers do not contain prefix lists or route policies.

We ran SELFSTARTER with a regular expression for each ACL rather than an exact name, since they have slightly different names in each router. Specifically, the name of each router's version of an ACL includes the router's associated building name and the date on which the ACL was created.

ACL Pattern	Number of ACLs in largest group	Number of ACLs in other groups
br_aux_mgmt_*_in_*	88	18
br_mgmt_*_in_*	82	24
br_wlan_mgmt_*_in_*	80	24
br_aux_mgmt_*_out_*	84	22
voip_*_in_*	61	22
voip_*_out_*	61	22

Table 4: May 2019 "br" router ACL results.

Results: Table 4 summarizes the results. For each ACL SelfStarter identified one dominant group of nodes that share a common template, along with one or more smaller groups of nodes that have a different template. Hence non-dominant groups potentially indicate misconfigurations.

To date the network engineers have provided feedback on the first three ACLs in the table. In all three cases the network engineers have confirmed that the group outliers that SelfStarter identified are indeed misconfigurations: every ACL that SelfStarter placed in a non-majority group has at least one misconfiguration.

For example, the metatemplate and the groups that SelfStarter inferred for the first ACL regex in Table 4 was shown in Figure 1. The 18 ACLs in Groups 2 and 3 include some old `deny` lines. Initially, IP spaces 14.10.49.0/24, 14.10.50.0/24, and 15.8.228.0/20 were allocated for infrastructure management; thus access to them was restricted using `deny` lines (ACL Lines 3 – 5). However, that allocation changed at some point to 14.10.0.0/19 and 17.7.240.0/20; thus the intent was to deny traffic to these new IP spaces (ACL Lines 1 – 2) and remove the old `deny` lines. Because it is each department's responsibility to update the ACLs for their building routers, some of the ACLs were not properly updated. The second and third ACLs in Table 4 exhibited similar misconfigurations, all of which were confirmed by the network engineers.

The network engineers have templates for these ACLs and so we manually compared the template that SelfStarter inferred for the dominant group with those templates for the first three ACLs in Table 4. For the first two ACLs, SelfStarter's template matches the network's hand-written templates. Specifically, the templates are *line-for-line identical*, except that in some cases SelfStarter's template has a concrete value where the golden template has a parameter. For example, SelfStarter might learn that a particular line uses IP address `1.2.3.A`, since all segments agree on the first three octet values, but the hand-written template treats the entire IP address as a parameter.

For the third ACL, SelfStarter's template for the dominant group does not match the network's template. Specifically, the network's template has two additional `permit` lines (one based on IP and another on ICMP). The network engineers informed us that this template was indeed stale. This shows that a possible use case for SelfStarter is to automatically identify "template drift".

Finally, we manually identified three parameter outliers in the first ACL. Earlier we said that parameter `A` in line 6 (ACL Line 6) of the metatemplate in Figure 1(a) was confirmed as a misconfiguration. We also asked the network engineers about parameters `B` and `E` (line 7). Both of these turned out to be intentional differences. For example, in the case of parameter `E` two building routers required more hosts than 255 and so were allocated a larger IP space than the other routers.

7 Discussion

Our experience applying SelfStarter to real-world networks and interacting with the operators has led to several observations, which we discuss here.

SelfStarter assumes that many router configurations in a network are *structurally similar* to one another. Our experiments largely bear out this assumption, since network operators typically employ configuration templates or common guidelines to simplify the configuration of groups of nodes. However, when this assumption does not hold, for example in the prefix lists of the WAN that we analyzed, then SelfStarter will not be as useful.

Our experimental evaluation indicates that SelfStarter can be useful in different kinds of networks, which are managed in different ways. Even where templates exist, they can become stale over time as the running configurations are updated. Even where automation exists, the automation can be incomplete or itself be a source of errors. Because SelfStarter takes as input only the final per-node configurations, it provides a useful form of redundancy for validating configurations, regardless of how they were created.

Finally, SelfStarter's structural approach to outlier detection means that it cannot determine the *behavioral* differences between outliers and non-outliers. However, in our experience a key advantage of SelfStarter is that its results are very easy for operators to understand, precisely because a metatemplate retains the structure of the original configuration segments. All of the network operators with whom we interacted were able to quickly decide whether an identified outlier was a true or false positive.

8 Related Work

To our knowledge, ours is the first technique to automatically infer templates for network configuration segments. We use these templates to identify misconfigurations, so we compare against other techniques for doing so.

Network Verification Network verification for the data plane (e.g., [6,11,23,24,29,31,39]) and control plane (e.g., [7, 14–16,18]) models the *semantics* of the network, which allows them to verify deep behavioral properties. However, they rely on the user providing a formal specification, and otherwise are limited to checking generic properties like the absence of loops. In contrast, SELFSTARTER leverages the *structural* similarity of many router configurations to identify network-specific errors without a specification, but SELFSTARTER cannot map these errors to specific undesired behaviors.

Minesweeper [7] can verify *functional equivalence* of two router configurations, which could be used to identify outliers. However, exact functional equivalence is much too strong a criterion in general and so would lead to a high false positive rate and make it harder to spot errors. For example, partitioning the 88 ACLs of Group 1 from Figure 1, all of which are correct, by functional equivalence would result in 44 groups, each of size 2. On the plus side, by modeling a segment's behavior Minesweeper can safely allow reorderings that SELFSTARTER would spuriously flag, for example swapping the order of unrelated `permit` and `deny` lines.

Outlier Detection for Network Configurations: El-Arini and Killourhy [12] use a form of Bayesian inference to identify outlier configuration lines and demonstrate that the approach can find "lone commands," lines that only appear once in the given set of configurations. Le *et al.* [28] employ a data-mining algorithm to infer association rules; configurations that violate the rules are deemed outliers. These approaches identify misconfigurations in settings of interface definition and BGP sessions, including BGP route policies.

However, these approaches share two key limitations. First, they can only find outliers based on *exact equivalence*. Specifically, neither the approach of El-Arini and Killourhy nor the inferred association rules of Le *et al.* can infer configuration *parameters*, which is necessary to account for values that differ in expected ways across devices. Second, neither approach takes into account the importance of line reorderings within a configuration segment. Our structured generalization algorithm overcomes both limitations: bipartite matching of lines induces a natural form of parameterization, and sequence alignment of blocks enforces ordering constraints.

Mining Configuration Policies: Benson *et al.* show how to infer reachability policies for a network data plane [9]. Recently, Birkner *et al.* show how to infer similar policies that also take into account the control plane, ensuring that policies hold even in the presence of failures [10]. These *semantic* policies, which pertain to the end-to-end behavior of the network, are orthogonal and complementary to SELFSTARTER's *structural* policies for network configurations.

Benson *et al.* also introduce metrics and techniques to gauge the *complexity* of configurations [8]. Closest to our work is their technique to infer network *roles*. Their algorithm replaces field values with dummy entries — for example, IP addresses with the string "IPADDRESS" — and then employs an off-the-shelf clone detection tool [22] to find similar configurations. Our structured generalization is similar in spirit but provides several refinements necessary for template inference, including fine-grained support for parameterization and reordering. However, their work is complementary to ours, as we require the user to provide network role information.

Diagnosing Misconfigurations: Another line of work focuses on diagnosing the cause of misconfigurations. For example, NetPrints [5] does this through a form of decision tree learning, and PeerPressure [38] does this through a statistical analysis. Unlike SELFSTARTER, these tools start from a set of known or suspected misconfigurations, which the user must supply. Further, these tools diagnose misconfigurations in terms of a set of simple configuration features, while SELFSTARTER leverages the full structure of the configuration segments through template inference.

Automatic Differencing: Many algorithms exist for "diffing," for example, text comparison [32], clone detection [21, 22], and sequence alignment [36]. Our *structured generalization* algorithm combines some of these techniques in a novel manner, based on our domain requirements. We employ bipartite matching at the line level to support permutation and parameterization, but we introduce the *block* abstraction and perform sequence alignment on blocks to restrict certain reorderings while admitting insertions and deletions.

9 Conclusion

We presented an approach to identify misconfigurations in complex configuration segments, such as ACLs and route policies, without a specification. Such segments are typically intended to be similar across nodes playing the same *role*, yet they often have many intentional differences. We address this challenge by automatically inferring *templates*, modeling the (likely) intentional differences as variations within a template and the (likely) erroneous differences as variations across templates. Our *structured generalization* algorithm employs a novel two-level matching technique to allow controlled forms of parameterization and reordering within templates. To our knowledge this is the first approach to automatic template inference for network configuration segments.

Unlike the majority of work in network verification, which reasons about the *semantics* of networks, SELFSTARTER's analysis instead reasons about the *structure* of their configurations. While SELFSTARTER by design cannot understand packet behavior, it makes up for this lack by providing concise, actionable feedback directly in terms of the configurations. As a result, it has helped operators find and fix previously unknown network misconfigurations in three very different types of networks: datacenter, WAN, and campus.

Acknowledgments

Thanks to the NSDI reviewers and our shepherd Laurent Vanbever for their insightful comments, to the anonymous network operators for their feedback on SELFSTARTER's results, and to Shuang Zhang for help with SELFSTARTER's output visualization. Abstract

When designing, understanding, or optimizing a computer network, it is often useful to identify and rank common patterns in its usage over time. Often referred to as a network traffic pattern, identifying the patterns in which the network spends most of its time can help ease network operators' tasks considerably. Despite this, extracting traffic patterns from a network is, unfortunately, a difficult and highly manual process.

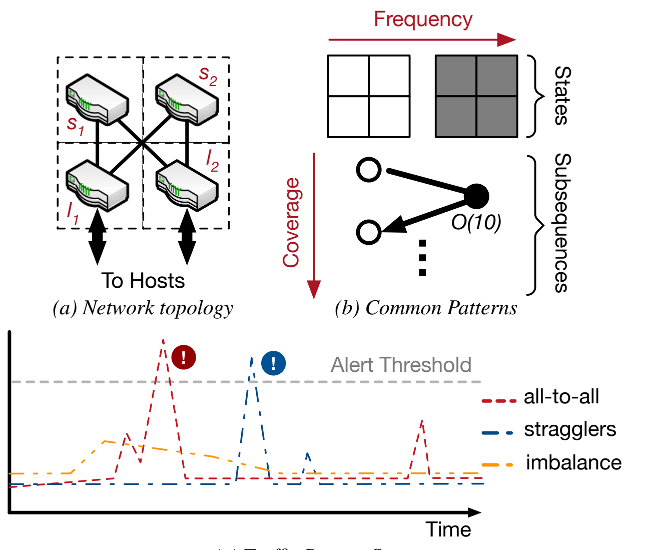
In this paper, we introduce `tpprof`, a profiler for network traffic patterns. `tpprof` is built around two novel abstractions: (1) network states, which capture an approximate snapshot of network link utilization and (2) traffic pattern subsequences,which represent a finite-state automaton over a sequence of network states. Around these abstractions, we introduce novel techniques to extract these abstractions, a robust tool to analyze them, and a system for alerting operators of their presence in a running network.

1 Introduction

When designing, understanding, or optimizing a computer network, it is often useful to identify common patterns in its usage over time. Often referred to as a **network traffic pattern**, identifying the patterns in which the network spends most of its time can result in useful insights:

- *All-to-all traffic*, which might manifest as uniform utilization of all paths between a set of application nodes, might suggest the importance of bisection bandwidth and guide future provisioning decisions.
- *Chronic stragglers*, where we expect all-to-all traffic but a significant amount of time is spent with only a few flows active, might suggest the need for better sharding and mitigation techniques.
- *Elephant flow dominance*, in which utilization is dominated by isolated path-level hotspots, might guide future provisioning decisions.
- Finally, *synchronized requests/responses*, indicated by repeated bursts of cross-network communication all originating at a single node, might motivate changes in the application or network architecture.

While there are a number of existing tools that capture flow- and switch-level trends (e.g., heavy hitter analysis [68], network tomography [28], or the vast array of network analytics suites on the market [1–6, 30]), identifying prevalent *network*-level patterns typically requires a significant amount of manual effort and specialized analyses. To determine the presence of synchronized requests/responses, for instance, an operator might need to instrument the start and stop times of all flows in the system, correct for the time drift of different machines, compute the cluster tendencies of the data (e.g., with a Hopkins statistic or heuristic), and distinguish it from all-to-all traffic by examining the sources and destinations of synchronized flows. To determine whether this pattern is a particularly common one would require additional analyses.



(c) Traffic Pattern Scores

Figure 1: `tpprof`'s visualizations for b common traffic patterns and c the TPS score over time for a simple leaf-spine topology, a. We describe these in more detail later, but in b, states are heatmaps of common utilization patterns over the network in a; darker is hotter. Subsequences are common transition patterns between the aforementioned states. These are ranked by their frequency of occurrence and their cumulative coverage of the profiled run, respectively. The subsequence shows an all-to-all pattern: the network starts unutilized (left state), becomes fully utilized (right state) for 10s of samples, then returns. In c, `tpprof` is tracking three different known traffic patterns. When the score of any of them crosses the alerting threshold (twice in the figure), `tpprof` deduces that the pattern has occurred in the network.

Our goal in this work is a tool for the automatic identification of the most prevalent traffic patterns in a network. To that end, we present the design and implementation of `tpprof`, a network traffic pattern profiler.

Similar to traditional application profilers like gprof [27] or Oprofile [22] that have helped programmers understand and improve their software for decades, `tpprof` automatically measures, extracts, and ranks common traffic patterns of individual applications within running networks. It also facilitates the monitoring of known patterns so that, when specific patterns appear in the network, the operator is informed. It does both of these things without modifying applications and without affecting existing network traffic—the only changes we require are to switch monitoring configurations. Examples of both of the above tools in action are shown in Figure 1.

Traffic patterns are, unfortunately, significantly more challenging to profile than applications. Traditional profilers benefit from well-defined building blocks (functions or lines of code) connected by well-defined call graphs. In contrast, networks offer little such structure: switch and link utilizations are noisy and measured in real values (Bps); their evolution over time is even less constrained. In the end, two different instances of something as simple as all-to-all traffic will never look exactly the same.

Thus, `tpprof` is built around two novel abstractions: (1) *network states*, which capture an approximate snapshot of a network's device-level utilization and (2) *traffic pattern subsequences*, which represent a finite-state automaton over a sequence of network states. As hinted above, subsequences serve as both output and input to our system: output in the case of profiling an existing network, input in the case of specifying a traffic pattern alert. In both cases, classification of network states and sub-sequences is approximate and implemented through specialized clustering techniques.

We implement and deploy `tpprof` to a small hardware testbed in order to monitor and profile the traffic patterns of real distributed applications like memcache, Hadoop, Spark, Giraph, and TensorFlow. We demonstrate that, using `tpprof`, we can find meaningful patterns and issues in their behavior. Further, we demonstrate `tpprof`'s utility on larger and more complex networks by profiling a trace taken from one of Facebook's frontend clusters. While our evaluation focuses on data center networks (where interesting and impactful distributed applications are plentiful), `tpprof` and its techniques generalize to arbitrary networks.

Specifically, this paper makes the following contributions:

- **Novel abstractions for describing common traffic patterns:** We introduce two abstractions, network states and traffic pattern subsequences, that together enable network operators to easily describe and reason about common traffic patterns. Network states capture similar configurations of approximate utilization of a specific application or set of applications running in a network. Subsequences are then strings of states with bounded repetition that summarize traffic pattern changes over time.
- **Domain-specific algorithms for clustering and ranking both network states and subsequences:** Through empirical analysis of a variety of application traffic patterns, we identify and design algorithms that transform a network trace into the building blocks of traffic patterns. Specifically, we demonstrate through PCA and waypoint analysis of real application traffic that GMMs are well-suited to capturing first-order similarities between different network utilization patterns. In the case of subsequences, we create a domain-specific clustering algorithm that extracts sequences that are both common and that provide broad coverage of the measured network traces.
- **A language and mechanism for expressing and fuzzily matching known traffic patterns in observed traces:** Finally, to complement the above, we develop a simple grammar for describing traffic patterns and introduce an algorithm that automatically identifies approximate occurrences of known traffic patterns within network traces. Our scoring engine outputs a confidence score that can be used to generate alerts when known traffic patterns appear in observed traces.

Taken together, `tpprof` is, to the best of out knowledge, the first profiling tool for network-wide traffic patterns. Our implementation is in Python and the code is open source.[1]

2 The Anatomy of a Traffic Pattern

We begin by introducing the definitions and abstractions on which `tpprof` is built. First and foremost, we define the overall traffic pattern of a network as follows:

NETWORK TRAFFIC PATTERN — A function $f(x,t)$ that represents, for an entire network N across a time span $[t_0, t_1]$, the utilization of device $x \in N$ at time $t_0 \leq t \leq t_1$.

We also define, for each application in the network:

APPLICATION-SPECIFIC TRAFFIC PATTERN — $f_A(x,t)$, equivalent to the network traffic pattern, but only accounting for a single application or set of applications, A.

For the purposes of our clustering and ranking algorithms, the distinction is unimportant; unless otherwise specified, we use 'traffic pattern' to refer to both. Instead, the choice of whether to filter by application is entirely the user's (with the mechanisms in Section 4); Regardless, for a given network and overall workload, we note that the traffic pattern of both the network and its constituent applications will typically exhibit predictable and repeated characteristics given a sufficiently long measurement period. These patterns can occur over short time spans of individual packets and flows, or over longer time spans in the form of diurnal or weekday/weekend effects.

A contribution of this paper is the decomposition of traffic patterns into a more convenient low-level primitive:

[1] https://github.com/eniac/tpprof.

Network Sample — $|N|$ real values that capture an approximate snapshot of $f(x,t)$ for all devices $x \in N$, at a particular time t, and averaged over the last t_Δ seconds.

Network Sample Sequence — A chain of network samples that sample $f(x,t)$ over increments of t_Δ, where t_Δ is bounded by the measurement granularity of the system.

Any traffic pattern can be described in these terms. For the network in Figure 1a, the all-to-all pattern in Figure 1b is one example. Another is chronic stragglers, which we can describe as a transition between two configurations, assuming a load balanced network: (1) all switches at high utilization and (2) only l_1, l_2 and s_1 at high utilization; or the same but replacing s_1 with s_2.

We can perform a similar exercise for all of the many (possibly application-specific) traffic patterns in the literature, e.g., rack-level hotspots in data centers [24, 29, 44, 58], synchronized behavior of distributed applications [9, 20, 67], and stragglers in data-intensive applications [21, 41, 43]. We do the same for the link- and switch-level traffic patterns that are the focus of most existing automated profiling tools [1–6, 30].

While not necessarily the way these patterns were described originally, sequences of network samples provide a general primitive with which we can represent arbitrary patterns.

3 `tpprof` Design Overview

Our goal in this paper is the design and implementation of a *profiler* for network and application-specific traffic patterns. Our system, `tpprof`, is intended to identify traffic patterns, rank them in prevalence, and assist network operators in monitoring for their recurrence. Like other profiling tools, `tpprof` is not intended to improve networks directly; rather, its focus is on assisting users with designing, understanding, and optimizing them.

On that note, we take inspiration from traditional sampling profilers like gprof [27], Oprofile [22], and Valgrind [48]. These profilers take an unmodified application and they periodically sample system state (e.g., stack traces) to produce a statistical profile of the target application. Early instantiations solely sampled program counters; over time, they expanded to capture trends in function utilization and call graph traversal.

`tpprof` uses a similar approach to construct profiles of traffic patterns. To that end, network samples and sequences of samples present an attractive substrate. In principle, a sequence of network samples create a statistical profile of an application's network utilization. Unfortunately, these samples are unlikely to ever repeat: small differences in application processing time, workload, and background traffic can cause substantive differences in traffic, as can slight noise in the sampling frequency of the measurement framework. Extracting patterns from raw samples is challenging.

Core abstractions. To address this challenge, we introduce two additional abstractions:

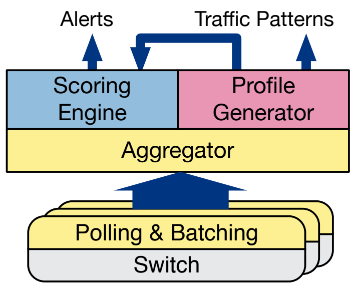


Figure 2: The overall architecture of `tpprof`. `tpprof` polls, batches, and aggregates switch counters from the network. These are fed into (1) a scoring engine that alerts on detection of known patterns and (2) a profile generator that extracts common traffic patterns from the gathered trace.

Network State — A class of network samples defined by a single, n-device network sample, S, and n variance values, $\bar{v}$ such that S is a centroid of the multivariate normal distribution with shape defined by $\bar{v}$.

Network State Subsequences — A class of sequences of network states that allows for bounded repetition of states. A state subsequence can be represented as a regular expression or finite state automata of network states.

Multiple network samples can be mapped to a single network state and multiple sample sequences can be mapped to a single state subsequence. These abstractions are tolerant to noise by design: variations of link utilization from sample to sample are smoothed by our method of extracting network states; variations in the evolution of those samples over time are smoothed by our method of extracting subsequences. The precise construction of both of the above elements is described in Sections 5.1 and 5.2.

Components. `tpprof` consists of three primary components:

1. A configurable *sampling framework* that periodically samples the device-level utilization of a specified application, set of applications, or the full network (Section 4).
2. A *profiling tool* for the automatic extraction and visualization of the most common states and state subsequences in the captured data (Section 5).
3. An *alerting system* that scores incoming traces against a set of user-defined patterns using a fuzzy string search in order to facilitate network automation (Section 6).

Of the above, only (1) affects the network itself; (2) and (3) occur out-of-band. As such, the overhead of `tpprof` is minimal: in the case of an non-application-specific traffic pattern, little is required beyond an SNMP poller; application-specific patterns only require simple `iptables` and switch configuration changes on top of that.

Our current implementation leverages programmable switches and a recently proposed network-wide monitoring framework [63]. This provides slightly more control and accuracy than an implementation based on top of traditional switches, but it is not a strict requirement; we detail both approaches in Section 4.

Workflow. `tpprof` profiles production networks. A typical workflow thus proceeds as follows. First, users specify three configuration parameters: the start time a, the end time b, and the sampling interval i. The network can optionally be configured to track certain applications separately. Regardless, a centralized service periodically polls the byte counters of the entire network between time a and b, with interval i.

The centralized service will stream the data through a set of scoring algorithms that quantify the prevalence of a set of target patterns in the measured trace. If the score of the trace exceeds a threshold for a given pattern, an alert will be generated. By default, the measurement data is not stored. This changes when users request a profile, i.e., a visualization, of common traffic patterns in the network. In this case, raw network samples are stored for a specified profiling duration for clustering and analysis. The resulting profile can be used to construct additional pattern alerts or analyzed separately. The remainder of this paper describes each of the three components of `tpprof` in more detail.

4 Sampling Framework

`tpprof`'s sampling framework continually polls a custom set of switch counters to capture traffic patterns. Most production networks already implement some form of this—`tpprof` can piggyback on these existing polling suites. `tpprof` is, however, parameterized by at least two configuration options.

- *Application filters:* To profile application-specific traffic patterns, users must provide a proper filter for the traffic in question. In `tpprof`, this takes the form of `iptables` rules. Any filter that can be expressed as an `iptables` rule is allowed. Thus, multiple applications can be captured by a single filter and different flows from the same application can be split into different filters by port, packet type, etc. All traffic matching installed filters are marked with a special set of bits, e.g., in the DSCP field of the packet header. We term the value of these bits a *filterid*.
- *Sampling interval:* Users must also specify an interval, t_Δ, at which `tpprof`'s sampling framework will poll all devices in the network. This interval is common to the entire system, so the network and all application-specific traffic patterns will be read at this rate. Though this is a user-defined value, we anticipate that it should be set to the minimum value feasible for the target network without incurring sample loss. We note that, because the raw data is discarded after alert pattern matching, measurement data storage capacity is not a bottleneck in `tpprof`.

4.1 Counter Implementation and Sampling

Network devices in a `tpprof`-enabled network track a set of device-level application-specific byte counters corresponding to the space of possible *filterid*s. For every packet traversing the switch, the counter associated with the specified *filterid* is incremented by the size of the packet; all categories summed will give the cumulative byte counter of the device. In this design, the network is never reconfigured; instead, users associate applications to *filterid*s directly through the `iptables` rules at every end host.

`tpprof` samples these counters at an interval of t_Δ via a recently proposed measurement primitive, Speedlight. For brevity, we omit the details of its operation and refer interested readers to its non-channel-state variant [62, 63]. At a high level, the primitive is that of a synchronized, causally consistent snapshot of network-wide switch counters. Compared to SNMP and other naïve poling tools, Speedlight provides increased accuracy and low minimum sampling interval, both of which are useful when profiling network traffic patterns.

Alternative implementations. We note that, at its core, the only requirement of `tpprof` is for configurable counters and a method to periodically poll all such counters in the network. There are other implementations that satisfy this requirement.

For instance, most modern switches typically include support for configurable ACL entries with per-entry counters. This approach has the advantage that it can be implemented without end host cooperation. Class of Service (CoS) counters are similarly promising. Note that, if application-specific tracking is not required, periodic SNMP polling is sufficient.

4.2 Batching and Aggregation

While it is possible to directly transmit polled counter results to a centralized profiling service, the scale of measurement data collected by `tpprof` necessitates careful handling. In particular, there are two issues we must address: decreasing overhead and handling sample loss.

For the first, to decrease the number of messages and the overhead per sample, `tpprof` agents running on each network device assemble results locally before shipping batches of size B in the following format:

```
sampleBatch: {
  switch: <SWITCH_ID>,
  indexes: [i : <SAMPLE_ID> for i from 0 to B],
  app1_bytes: [i : <BYTE_COUNT> for i from 0 to B],
  ...
  appM_bytes: [i : <BYTE_COUNT> for i from 0 to B]}
```

`indexes[k]` and `*_bytes[k]` should correspond to a single network sample. Gaps in the samples, e.g., from failures or measurement packet drops, will manifest as gaps in the `indexes` array. In these cases, `tpprof` attempts to interpolate values by taking the difference between byte counters before and after any gap and averaging the difference over the length of the gap. If the device has rebooted or if it stays down for too long, we will treat the device as 'failed' during the missing measurement intervals. 'Failed' devices are excluded from

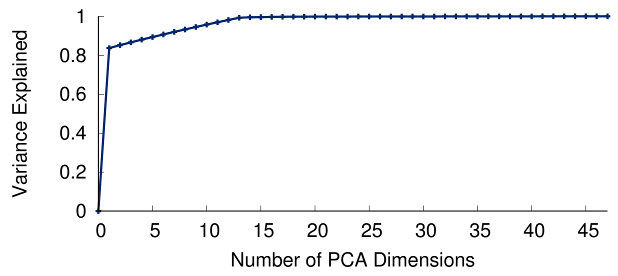

Figure 3: Covariance explained by different numbers of PCA dimensions. Dataset is a trace of utilization over 48 ToR switches in a Facebook frontend cluster.

profiling and treated as wildcards during alerting. Note that reboots are also excluded from interpolation as we do not know how much traffic was sent before the counter was reset.

Storing data for profiling. While `tpprof` does not store raw counter values in the common case, raw values are necessary for generating profiles. Profiles are, therefore, executed on-demand using the API:

```
start_profile(start, end, filter_id)
```

The duration of collection should be long enough to capture a representative slice of behavior. In general, longer is better, but this may be subject to limitations of sample storage space and the user's timeline. `filter_id` $= -1$ indicates the sum of all application-specific counters.

5 The `tpprof` Profiling Tool

We first discuss how `tpprof` extracts and ranks traffic patterns before delving into the scoring and alerting system in Section 6. To that end, the output of the previous subsection (4.2) is a network sample sequence, i.e., a sequence of n-device samples of network utilization. Using that, the output of the `tpprof` profiler is a ranked list of network states and a ranked list of state subsequences, as sketched by Figure 1b and demonstrated in Section 7. `tpprof` achieves this using a pair of domain-specific clustering techniques that are designed to capture first-order patterns in network traffic.

5.1 Network States

The first challenge in identifying meaningful traffic patterns is the inherent noise present in a trace of network samples. Small variations in workload, TCP effects, background traffic, or any number of other factors mean that, most likely, no two network samples will look exactly alike.

To de-noise the data, `tpprof` summarizes network samples into a small number of distinct network states. We can naturally frame this as a clustering problem, where the points to be clustered are the n-element vectors representing network samples. Clustering has been used to great effect in a number of fields, from image segmentation to recommendation systems and anomaly detection; each of these has their own set of challenges and associated clustering algorithms.

Network state extraction is no different in that regard. In this work, we leverage empirical analysis of a variety of applications and traces to identify and design algorithms suited to the domain. Applications observed include Hadoop, Giraph, TensorFlow, Spark, Memcache, and a trace from a production Facebook frontend cluster (see Section 7 for their details).

Dimensionality reduction. Before delving into `tpprof`'s clustering algorithm, we note that, in general, networks present a particular challenge to clustering because of their high device counts. Profiling the ToRs of a 48-rack data center cluster, for instance, might result in a 48-feature input vector, which prior work has indicated might be too many dimensions for typical distance metrics [17].

The general solution to this well known 'curse of dimensionality' [15] is transforming the data into a lower dimensional space before clustering. The simplest approach is to cluster on only a subset of features. While this works in other domains, it is not well suited for our problem because the load on *every* device may be important. Instead, `tpprof` preprocesses data with Principle Component Analysis (PCA) [25], which derives a small set of features that are an orthogonal linear transformation of the original features. Said differently, PCA removes redundancies in the original data by creating a new set of independent features that explain most of the variability in the original data.

PCA is most effective when features are strongly correlated, and there is good reason to believe that this is true in our domain. Recent work [21] shows that network usage is highly correlated, driven by the data-parallelism in distributed systems [31, 65]. Analysis of the Facebook traffic trace verifies this: each ToR had strong and statistically significant correlations ($r > .7$, $p < .001$) with an average of 3.25 other ToRs. The applications we profiled showed similar results.

Figure 3 measures the effect of PCA on that data, gauged by plotting number of PCA dimensions (i.e., features) versus explained variance. All other traces we obtained showed similar results. A value of 1 means that a PCA transformation to K dimensions preserved all the information contained in the original data with 48 dimensions. Even for this large and complex trace, one dimension already explains over 80% of the variance and two dimensions explain ∼85%. Striking a balance between clustering efficacy and explained variance, `tpprof` projects all data into 2D by default. This can be adjusted depending on the data.

Gaussian Mixture Models (GMMs) for sample classification. `tpprof` clusters around typical network variations through its use of GMMs. To demonstrate this effect, we consider the 2D PCA projections described above and visualized, for our set of profiled applications and traces, in Figure 4. To help interpret points in the PCA space, we also plot network load at 4 extreme *waypoints* along the convex hull of each trace. We observe two general cluster shapes in the projected

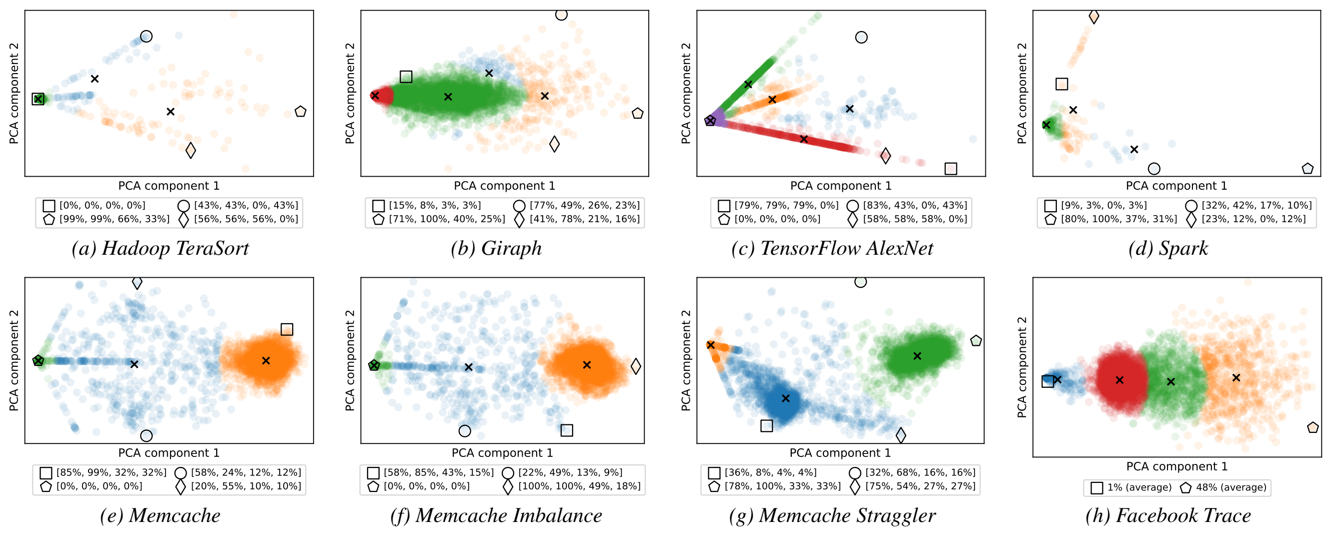

Figure 4: Network samples projected into a 2-dimensional PCA space. Cluster centers are marked with x's. Shaped-markers map points in the space to sample vectors [l1, l2, s1, s2] (see Figure 1a) or, for the Facebook trace, average utilization.

data: 'rays' and 'clouds'.

- **Rays**, like the ones prominent in Figures 4a and 4c, are typically associated with rising or falling utilization on a set of highly correlated nodes. We can see this effect most clearly in Figure 4c through the relationship between ⬠, ◇, and □. Compare their utilizations with that of ○.
- **Clouds**, like the ones in Figures 4b and 4g, typically characterize samples that are similar in configuration, but separated by noise that offsets points by a small amount in all directions of the PCA space. These clouds can be more or less dense, depending on the coherence of the pattern. The memcache variants, for instance, exhibit strong all-to-all behavior, which manifests as dense clouds to the right of the PCA plots.

Synchronized behavior and noise around a specific configuration capture most of the key behavior in our empirical tests. For these two types of clusters, GMMs are known to perform well. GMMs model a cluster as a multivariate Gaussian with independent parameters for each dimension of the data. This independence provides the flexibility for clusters to fit both types of clusters with arbitrary densities. We fit GMMs to the data using the expectation-maximization algorithm from Scikit-learn [51], which finds clusters that are each defined by a centroid sample and a vector of per-feature variances.

Automated detection of cluster count. GMMs are defined in terms of a fixed number of clusters, K. `tpprof` selects K automatically by using a Bayesian Information Criteria (BIC) score. Informally, a better (lower) BIC score means that a specific clustering, if used as a generative function, is more likely to produce the observed data.

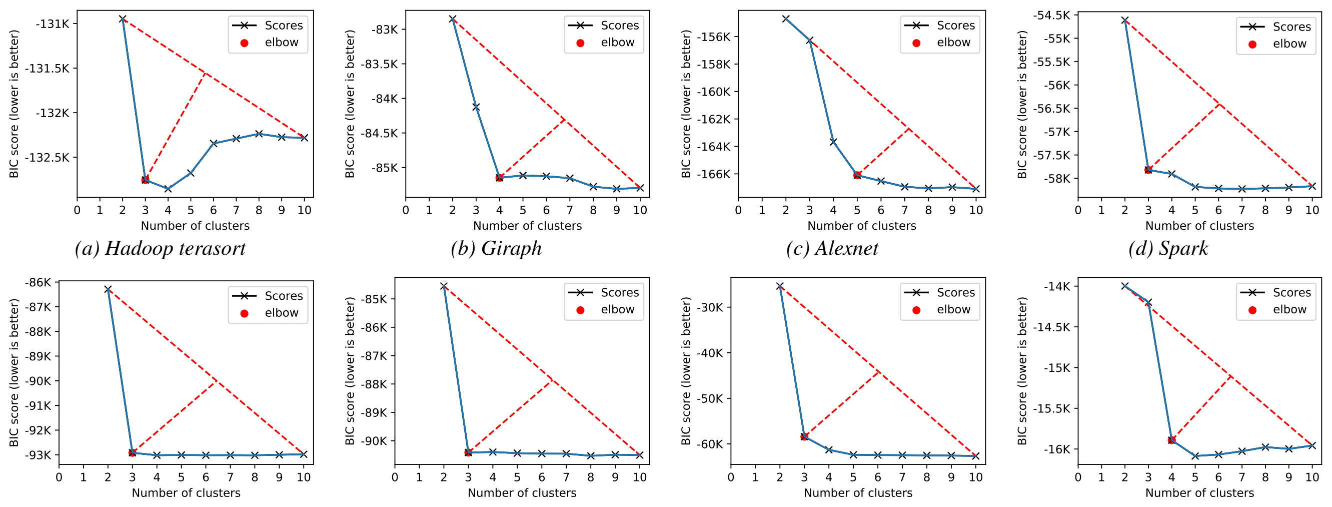
We note, however, that BIC scores tend to improve as K increases, but a high number of clusters can overfit the data. To overcome this issue, we select a K value at which the benefit gained by adding an extra cluster starts to diminish. Finding such "elbows", or points of maximum curvature, is a common problem in machine learning and systems research. We use the Kneedle method [56], a simple but general algorithm based on the intuition that the point of maximum curvature in a convex and decreasing curve is its local minima when rotated θ degrees counter-clockwise about (xmin, ymin) through the line formed by the points (xmin, ymin) and (xmax, ymax). Specifically, we plot the *BIC* score versus K and draw a line segment connecting the points for $K = 2$ and a configured maximum of $K = 10$, which we set based on the typical working set capacity of humans. The optimal value of K is given by the point furthest from that line. Figure 5 shows the results of this analysis for the applications and traces introduced above.

5.2 Network State Subsequences

Network state subsequences extend network states to capture temporal patterns in traffic. Like states, subsequences require compression of the the full sequence of samples taken during the profiling run into a small set of representative patterns. Unlike states, existing sequence-based clustering algorithms are a poor fit for network traffic patterns.

To see why identifying and ranking network state subsequences is challenging, consider a strawman solution: take all possible subsequences of the trace and count their frequencies, e.g., the trace ABC would result in the following subsequences $\{A \times 1, B \times 1, C \times 1, AB \times 1, BC \times 1, ABC \times 1\}$.

Challenge 1: (a) $A^5 = AAAAA$ versus (b) $A^5B \dots AAB \dots AAB$
Intuitively, the interesting bit of sequence (a) is that there is a long run of A's. The strawman solution will instead output that the most common subsequence and frequency is the single state $A \times 5$, followed by $AA \times 4$, etc. With the naïve approach, short subsequences will always take



(a) *Hadoop terasort* (b) *Giraph* (c) *Alexnet* (d) *Spark*
(e) *Memcache* (f) *Memcache imbalance* (g) *Memcache straggler* (h) *Facebook cluster*

Figure 5: Selecting the number of clusters with Bayesian Information Criteria (BIC) and the elbow heuristic.

```
param stateSequence[# samples in the trace]: Full sequence of

param minFreq: The minimum number of subsequence
  occurrences before it is counted as a 'common' subsequence.
1  Function getSubSequences:
2      for targetLength : len(stateSequence) to 2 do
3          maxStart ← len(stateSequence) − targetLength
4          for start : 0 to maxStart do
5              end ← start + targetLength
               /* Skip taken ranges */
6              if [start,end] contained in takenRanges then
7                  continue
               /* Add if it meets minFreq */
8              subseq ← log10Merge(stateSequence[start:end])
9              if (# subseq observations) ≥ minFreq then
10                 Add (start, end) to takenRanges after loop
11                 Increment subseqs[subseq]
12             else
13                 Hold subseq until the threshold is reached
14     subsequenceCoverage ← computeCoverage(subseqs)
15     totalCoverage ← computeTotalCoverage(subseqs)
16     return subseqs, subsequenceCoverage, and totalCoverage
```

Figure 6: Pseudocode for finding common subsequences in a sequence of network states.

priority; in fact, we can prove that subsequences will *never* beat their member states. On the other hand, sequence (b) demonstrates a case where it might be useful to be able to observe the shorter subsequences. In this case, greedily setting aside the A^5 would miss the third occurrence of AAB, which is arguably the more important pattern.

Challenge 2: $XA^{39}Y \dots XA^{40}Y \dots XA^{41}Y$
The strawman solution also performs poorly with similar, but not identical ranges. While it may find here that there are long strings of As, or even that X is typically followed by As, or that Y is typically preceeded by As, it will fail to find that As are typically sandwiched between X and Y. Variance in duration is common in networks, where measurement timing, available capacity, and workload size changes frequently.

Challenge 3: $(AB)^3(CDEFGHIJKLMNOPQRSTUVXYZ)^2$
Finally, we note that frequency itself is not an ideal metric. Consider the above trace. The longer trace is much rarer and more interesting, but a pure frequency analysis will rank AB higher in importance.

`tpprof`'s subsequence extraction (outlined in Figure 6) addresses these challenges through a series of rules, which we describe below. Line numbers reference Figure 6.

Only consider subsequences of length 2+ [Line 2]. While knowing the most frequent single states is useful, the goal of extraction is to capture patterns in traffic. We, therefore, prune subsequences of length 1 from consideration and list the relative frequency of single states separately.

Ignore strict subsequences [Lines 6–7]. To better summarize cases like Challenge 1(a), we exclude any subsequence that is wholly contained within another subsequence. We implement this efficiently using two data structures: (1) *takenRanges*, a list of existing subsequences sorted by *start*, and (2) a *heap*-based index of the currently overlapping subsequences, sorted by *end* (not shown).

Frequency threshold before a subsequence is counted [Lines 9–13]. The above rule, applied directly, might produce a single subsequence encompassing the entire trace. To account for this, we set a minimum frequency threshold, *minFreq*, before which the subsequence is not counted. We note that a lower value of *minFreq* promotes the inclusion of longer but sparser subsequences, while a higher value favors many, shorter subsequences. `tpprof` automatically tunes this value using the `hyperopt` library to optimize for 'total coverage', a metric we describe at the end of this section.

Log10 repetition frequencies [Line 8]. To handle cases like

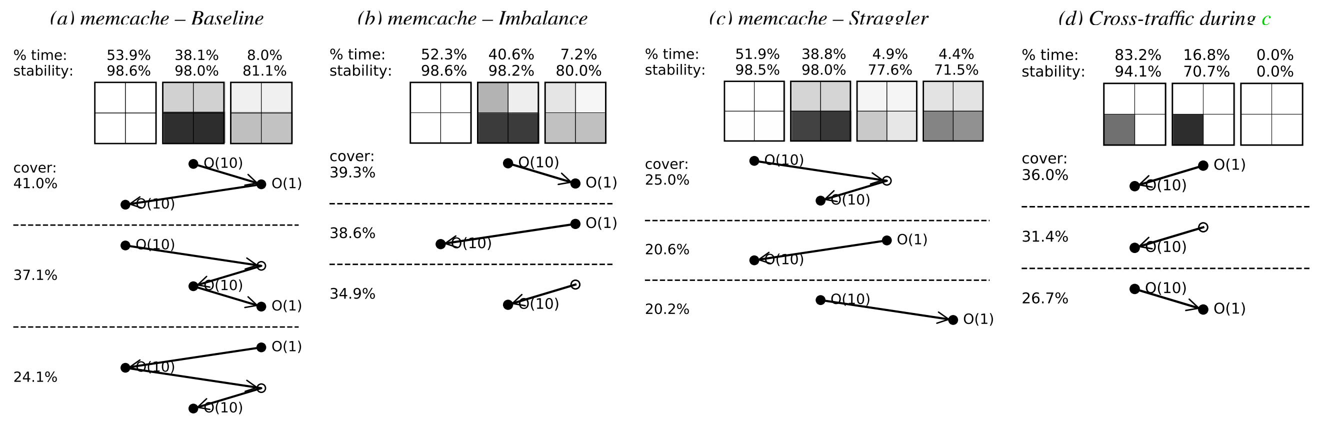

Figure 7: `tpprof` profiles of memcache in three different environments (a–c), plus a profile of cross-traffic (d) active during c.

that of Challenge 2, common in network traces, we compress repetitive states into the nearest power of 10. Doing so ignores small differences in duration while still retaining the length's rough magnitude.

Coverage rather than frequency [Lines 14–15]. As evidenced in Challenge 3, differences in the length of subsequences and the ability of subsequences to overlap diminish the utility of frequency as a way to reason about the relative importance of different subsequences. Instead, we propose *coverage* as a metric for ranking subsequences and for hyperparameter-tuning minFreq. Coverage measures, for either a single subsequence or the union of all subsequences, the cumulative fraction of states in the stateSequence that are included in at least one subsequence.

We encourage the reader to step through several short examples of network state sequences to see why the above rules produce intuitive results.

5.3 Example Visualization: memcached

To tie the above discussion together and showcase the utility of `tpprof`, we present to the reader several real profiles produced by the `tpprof` tool suite. See Section 7 for a description of the hardware testbed used in these tests.

As a baseline, we first look at a memcache workload generated using the `memaslap` [7] benchmarking utility, running in isolation. Each machine in the testbed was configured as a memcache server with 64 B keys and 1024 B values. Gets and sets were randomly generated from two machines—one in each rack—with a ratio of 9:1. In this simple test, the two memcache clients, every 6 s, will simultaneously begin performing 290k get/set operations.We profiled this behavior, collecting a total of 7000 network samples at a 50 ms interval.

Visualization structure. Figure 7a shows the `tpprof` profile for this run. Like Figure 1b, heatmaps of *network state* are at the top of the figure and the most common *network state subsequences* are below. Each heatmap shows the centroid of the sample clusters it represents. We add to this the state's % *time* (the amount of time the network spends in the state) as well as its *stability* (the probability that the network, once in the state, will stay there); states are sorted by % time.

For subsequences, we include the top three by coverage; more can be generated on demand. Subsequences are depicted with a series of points (representing states) connected by arrows (denoting transitions between states). The points align horizontally with the states they represent. Solid points accompanied with an O(x) label indicate an x–$10x$ repetition of that state. The number on the left of each subsequence is the percentage of the trace that it covers. Note that coverage can add to more than 100% due to overlapping subsequences.

Observations. We can observe several characteristics in Figure 7a. First, we can see that there are three states in which the network spends its time. In the one that accounts for more than half the trace, the network is unutilized. The other two show different states of even leaf and even spine utilization, indicating that the network is relatively balanced when it is being used. Note that the leaves of the network are consistently hotter than the spines due to rack-internal communication.

As expected of the workload, the subsequences of the profile show a trace composed of *on-off* periods of *all-to-all* traffic. We can also deduce from the duration of repetitions that the on and off periods both last on the order of seconds. Further, we can infer that the network takes time to ramp up/down from full utilization. This is inferred from the presence of the (L-to-R) 3rd state and the absence of direct transitions between states 1 and 2. Ramp ups seem to be an order of magnitude faster than ramp downs.

`tpprof`'s observations can inform network and application changes. For example, if an operator were to see a similar profile in practice, she could conclude that load balancing is not an issue. Instead, a more promising approach would be to either desynchronize traffic to spread out utilization over time or augment the leaf switches with additional capacity.

5.3.1 Case Study #1: Detecting Load Imbalance

`tpprof` can also help to detect acute problems in networks. As as a case study, we artificially introduced an ECMP miscon-

$\langle signature \rangle$ ::= **{ (**$\langle target\ state\ set \rangle$**) ;** $\langle target\ sequence \rangle$ **}**

$\langle target\ state\ set \rangle$ ::= $\langle target\ state \rangle$ **,** $\langle target\ state\ set \rangle$

$\langle target\ state \rangle$ ::= $\overrightarrow{utilization}$

$\langle target\ sequence\ (P) \rangle$ ::= $\langle target\ state \rangle$ | ~$\langle P \rangle$
  | $\langle P \rangle \wedge \langle P \rangle$ | $\langle P \rangle \vee \langle P \rangle$
  | $\langle P \rangle^*$ | $\langle P \rangle$**{** min repetitions **,** max repetitions**}**

Figure 8: Definition of a traffic pattern signature.

figuration [69] into the network. Specifically, we configured one of the ToR switches to only use the left spine; otherwise, the workload is identical to Figure 7a. Figure 7b shows the output of our tpprof's Python-based visualizer. An operator comparing this profile to that of the baseline would be able to see the new and stark differences between the two spines in all states with load, and conclude that ECMP was not doing its job. While imbalance can also be due to elephant flows and hash collisions, the fact that this happens consistently and always with the same spine points to a structural issue.

5.3.2 Case Study #2: Debugging a Noisy Neighbor

As another case study, we use tpprof to debug an apparent straggler in the system. In this experiment, we add a heavy background flow between two hosts connected to the lower-left leaf, l_1. Figure 7c shows the profile in question. From this profile, an operator can observe that, in 5–10% of samples, there is a slight bias toward l_1 while the other leaf is largely un-utilized. These samples are summarized in the right two network states. If the operator is expecting an even all-to-all pattern like the one in Figure 7a, these states would lead her to suspect that a task in the system is straggling.

tpprof's ability to profile concurrent applications independently can also help to diagnose this issue. In particular, she can view the profile of non-memcache traffic present during the same profiling period. In this case, tpprof would provide her with Figure 7d, which clearly shows a competing flow or set of flows within l_1.

6 Traffic Pattern Scoring

The tpprof components described in prior sections allow users to profile their networks and find prominent traffic patterns. In many cases, after finding certain patterns, users are likely to want to know if (or when) they occur in the future. The tpprof traffic pattern scoring engine solves this problem. The key challenge is designing both a language that makes it simple for users to specify pattern signatures and also an algorithm efficient enough to detect those patterns in realtime.

Traffic pattern signatures. A traffic pattern signature describes the approximate spatial and temporal characteristics of a traffic pattern. It is defined by the grammar in Figure 8 and has two components.

- A set of *target network states* describe the approximate samples that are likely to be observed during the traffic pattern. These can be generated from prior profiling runs or manually specified.
- A *target subsequence*, written as a regular expression, that estimates how the network transitions between the target states during the pattern.

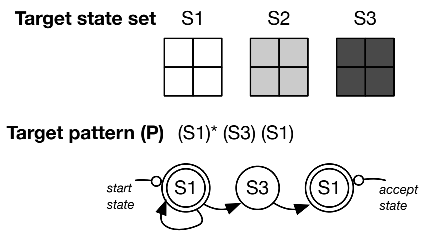

Figure 9: An example traffic pattern signature that detects a synchronized all-to-all burst.

As an example, Figure 9 illustrates a signature to detect a synchronized all-to-all burst of traffic in our example topology. The target states in the signature are: S_1, 0% utilization on all links; S_2, 50% utilization on all links; and S_3, 100% utilization on all links. The signature's target subsequence is, thus, one in which the network is in S_1 before transitioning to S_3 (i.e., high, all-to-all utilization) and immediately going back to S_1, signaling a quick end to the all-to-all utilization.

Scoring signatures. tpprof's Traffic Pattern Score (TPS) algorithm quantifies a signature's prominence in a network sample sequence by finding and scoring subsequences that are similar to it. This amounts to a streaming fuzzy string search. Figure 10 illustrates the scoring algorithm for the all-to-all signature in Figure 9, while Figure 11 provides psuedocode of our streaming implementation. There are three steps.

1. *State matching:* The TPS algorithm first maps each incoming sample to the most similar target state, transforming the stream of samples into an *intermediate stream*.
2. *Pattern matching:* It then scans the intermediate stream for the target subsequence using a finite automata [34]. A match occurs when the automaton reaches an accept state, at which point it is executed in reverse to identify the start point of the longest matching subsequence.
3. *Match scoring:* A match indicates that the exact target subsequence has been found in the intermediate stream; however, how this relates to the underlying sample stream is unclear. Thus, the final step is to score match strength by calculating the average similarity between the two streams during the subsequence.

Writing signatures. There are two sources for signatures. First, they can be automatically generated by the profiler, from the network state subsequences it identifies. This allows the TPS algorithm to automatically identify future reoccurrences of events identified with the tpprof profiler.

Second, users can manually write signatures that characterize the most important attributes of a traffic pattern. Since TPSes use a fuzzy algorithm, patterns do not need to be exact. Instead, they can be defined programmatically. With the

            emit sum(scoreBuf[begin-offset:end-offset]
```

Figure 11: The streaming TPS algorithm.

three primitives described below, users can express simple but powerful signatures.

- *State definition*, e.g., `(x:v, y:u)`, which defines a state with switch `x` having utilization `v` and switch `y` having utilization `u`.
- *Set assignment*, e.g., `X:v`. This sets every switch `x` ∈ `X` to utilization value `v`.
- *Iteration (over sets or switches)* e.g., `{(x:v) for x ∈ X}`, which defines a set of states: one state for each switch in `X`, defining that switch to utilization value `v`.

Table 1 lists five example signatures written with these primitives. We evaluate them later in Section 7.3.

7 Implementation and Evaluation

`tpprof` is implemented in Python/C++ as a standalone service that aggregates samples, profiles them, and scores them for the presence of known traffic patterns, as described in the previous sections. Each of the profiles shown in this section are real outputs of `tpprof`, generated programmatically

Pattern	Signature	State Definitions
Short all-all	$S_1^* S_2\{1,10\} S_1$	$\{S_1\}$=`N:0.0`,$\{S_s\}$=N`:0.5`
Long all-all	$S_1^* S_2\{10,100\} S_1$	$\{S_1\}$=`N:0.0`,$\{S_s\}$=N`:0.5`
Hotspots	$(S_1\|S_2\|S_3\|S_4)\{10,100\}$	$\{S_1, ..., S_4\}$=`{(x:1.0, -x:0.0) for x ∈` N`}`
Imbalance	$S_1^*\|S_2^*$	$\{S_1,S_2\}$=`{(x:1.0, -x:0.0) for x ∈ (`s_1`,` s_2`)}`
Stragglers	$(S_1\|S_2\|S_3)^* S_3$	$\{S_1,S_2,S_3\}$=`{(`l_1`:v, -`l_1`:0.0) for v ∈ (0.1,0.01,0.0)}`

Table 1: Traffic pattern signatures for a leaf-spine network N with spines (s_1, s_2) and leaves (l_1, l_2).

using Python and Matplotlib 3.1.1. The requisite counters and polling/batching components that run on each device are implemented in P4 and Python, respectively. Traffic Pattern Scoring is implemented in C++ using `hyperscan` [34].

Hardware testbed. To verify the utility of `tpprof` and its outputs, we used it to profile and score the traffic patterns of real applications running on a small hardware testbed consisting of a Barefoot Wedge100BF-32X programmable switch connected to six servers with Intel(R) Xeon(R) Silver 4110 CPUs via 25 GbE links. The testbed is configured to emulate a small leaf-spine cluster like the one in Figure 1a. To implement this network, we split the Wedge100BF switch into 4 fully isolated logical switches. Each logical switch runs ECMP to balance load across paths.

Application workloads. On our hardware tested, we profile four popular networked applications, in addition to the memcache evaluation in Section 5.3:

1. Hadoop running a TeraSort [11] benchmark workload with 5B rows of data. Our Hadoop instance ran version 2.9.0 with YARN [12] on 10 mappers and 8 reducers spread across the 5 servers (and 1 master).
2. Spark's GraphX [13] running a connected components benchmark workload with 1.24M vertices. We ran Spark 2.2.1 with Yarn on 5 servers (and 1 master).
3. Giraph [10] running a PageRank synthetic benchmark workload with 120,000 vertices and 3,000 edges on each vertex. We used 23 workers in total across our 6 servers.
4. TensorFlow running the AlexNet [38] image processing model with 1 server managing parameters and 5 workers. We used ILSVRC 2012 data for training.

Unless otherwise specified, these applications were run in the presence of background TCP traffic derived from a well-known trace of a large cluster running data mining jobs [8]. Profiles are of of the target application only.

Large-scale trace. To augment our small testbed, we also profile packet traces of 48 Top-of-Rack switches from three of Facebook's production clusters: a frontend cluster, a database cluster, and a Hadoop cluster. As the datasets are sampled by a factor of 30,000, we divide the timestamps by 30,000

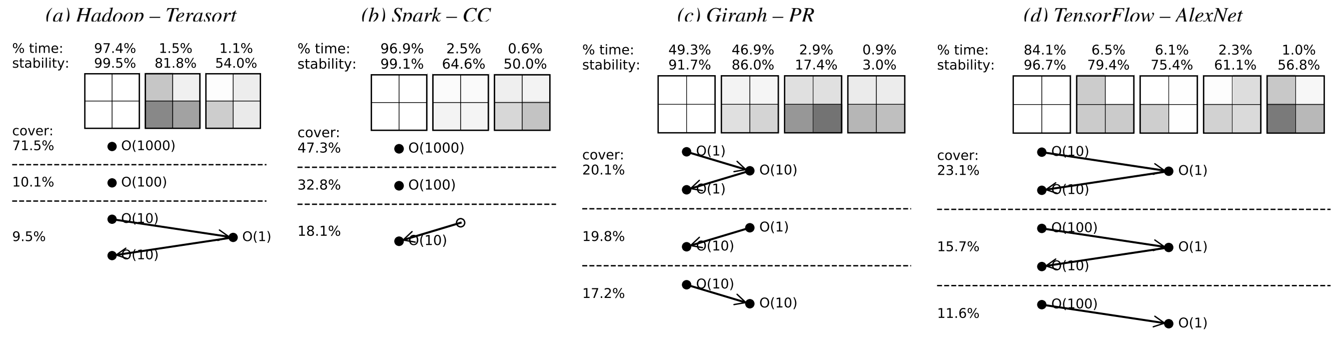

Figure 12: *Profiles of more complex applications running with realistic background traffic.*

to obtain an approximate representation of a full trace. Note that multiplying traffic by 30,000 would have given a more accurate distribution, but resulted in artificially stable patterns.

7.1 Profiling More Complex Applications

To evaluate how `tpprof`'s algorithms deal with more complex applications, we profile each of the application workloads we introduced earlier in this section. These applications all ran in the presence of background traffic, but we only show profiles of the application-specific traffic.

From the resulting profiles in Figure 12, we can see that, for the most part, the network was only lightly utilized during these tests. In Hadoop and Spark, for instance, the network spent $>96\%$ of the time in a unutilized, indicating that our particular testbed tends to be CPU-bound. Giraph is the notable exception, spending about equal time utilized and not.

The states reveal some interesting behavior of the applications. For Hadoop and TensorFlow, we see heavy skew in spine utilization, but not to a consistent spine. This likely indicates the presence of a few large flows that dominate the network and sidestep ECMP's flow-level balancing. We also see in these two workloads a slight bias toward the lower-left switch. This is due to task placement: for Hadoop, that switch is home to the controller and name server; for TensorFlow, it holds both the chief worker and the parameter server.

7.2 Profiling Large Production Networks

`tpprof` is able to profile more complex networks as well. To demonstrate this, we run `tpprof`'s profiler over large-scale traces of the combined traffic for three production Facebook clusters and show the output in Figure 13. We separate the states and subsequences for readability.

Figure 13a shows the profile for the frontend cluster. As in the original paper describing this trace (Figure 5 of [54]), we can observe a clear split between the average utilization of cache, multifeed, and web servers. States A–C show memcache at full utilization, webservers at low utilization, and varying levels of multifeed traffic. Diverging from the original paper, we find an additional network state (occurring 3.8% of the time) in which the multifeed server utilizations spike. The stability of this state indicates that this may manifest as small, but intense and correlated bursts. Subsequences further show frequent transitions between states A and B, with state C representing a short-lived relative lull in multifeed traffic.

Signature	Accuracy	Precision	Recall
Straggler	0.943	0.867	0.720
Imbalance	0.936	1.000	0.868

Table 2: *Classification performance of signatures in the memcached testbed.*

Figure 13b and Figure 13c show the profiles of a database and Hadoop cluster, respectively. Notably, the database cluster is very uniform and stable across the trace, indicating a steady workload and good load balancing properties. The Hadoop profile is also notable in that it diverges substantially from the averaged results in Figure 5 of the original paper, which showed balanced utilization across racks. While the traffic is balanced across longer timescales, our results match more closely with their more granular findings of on-off periods and significant variance at medium timescales.

7.3 Efficacy of the TPS Module

We showcase Traffic Pattern Scores by demonstrating how they can help answer an important question: *is my network performing poorly due to load imbalance or stragglers?* For this, we use the straggler and network imbalance signatures from Table 1 to diagnose issues in the memcache deployment from Section 5.3. We run the deployment in baseline, noisy neighbor, and ECMP misconfiguration scenarios. We then generate labeled network sample traces by manually identifying the precise time windows during which each undesired behavior occurred. Finally, we run `tpprof` on each of the traces and compare signature scores against ground truth scores calculated from sample labels.

Figure 14 plots the rolling average of ground truth and signature scores in each of the three scenarios. The signature scores are highly correlated with the ground truth. Table 2 lists the classification performance. Both signatures have high accuracy and precision, with slightly lower recall—a desirable tradeoff in an alerting system. We note that `tpprof`'s per-scenario precision and recall are 100%: no signature's score is high in the baseline scenario; only the straggler sig-

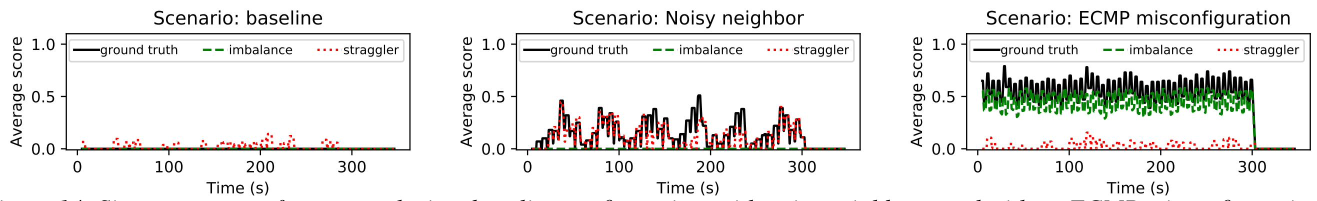

Figure 14: Signature scores for memcache in a baseline configuration, with noisy neighbors, and with an ECMP misconfiguration.

Filter count	0	128	256	512	1024
CPU Util (%)	0.44	0.65	0.84	1.18	1.77

Table 3: `tpprof`'s `iptables` CPU utilization.

nature's score is high in the noisy neighbor scenario; and only the imbalance signature's score is high in the ECMP misconfiguration scenario.

7.4 Overhead and Performance of `tpprof`

Finally, `tpprof` is designed for efficiency and minimal overhead. Only two components in the sampling framework can potentially impact traffic: sample collection and `iptables` tagging. Analytically, snapshots of all ports on a 128 port switch at a 50 ms interval generate only 0.1 Mb/s of measurement data. As Table 3 shows, the `iptables` rules used to construct application-specific profiles also have low overhead.

In addition to measuring overhead, we also benchmark the Hyperscan [34]-based TPS scoring engine, which operates online in parallel with the network. Specifically, we measure average CPU load while operating on the Facebook trace. Figure 15 shows single-core CPU load. It increases linearly with number of signatures, but even in this large network with 100 signatures and a 50 ms sampling frequency, average load for real-time processing is only around 10%.

8 Related Work

Traffic pattern inference. We note that the concept of a network traffic pattern is not novel. Many prior works have both identified and used traffic patterns to great benefit [20, 29, 40, 54, 55, 67]. Unfortunately, these insights have typically been limited to situations were the pattern can be measured at a single link/device [40, 55, 67, 68] or have been a result of property-specific analyses, often with a large dose of manual effort [16, 20, 29, 54]. The goal of `tpprof` is instead

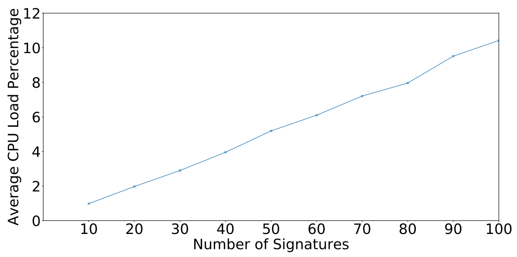

Figure 15: Signature vs CPU Load

the automatic extraction and ranking of common patterns from running networks.

Network monitoring and visualization tools. We also acknowledge the vast array of existing network monitoring and visualization tools, both commercial [1–5, 26, 37, 49, 52] and academic [30, 45, 47, 57, 61, 68]. We lack sufficient space to discuss them all, but one worth mentioning is Cisco's recent Tetration platform [52]. Among other features, Tetration can extract the control flow of a distributed application by clustering hosts based on the partners with which they communicate. Other work has attacked similar problems [36]. To the best of our knowledge, `tpprof` is the first tool that extracts common *network-wide traffic patterns*, rather than application-level communication patterns or packet/flow-level behavior. Broadly speaking, `tpprof` operates at a higher-level of abstraction than these existing systems.

Wee note, however, that `tpprof` is compatible with some infrastructure monitoring frameworks like Nagios [37] that collect monitoring data from across the network. By default, none of these provide the same abstraction as `tpprof`, but many allow custom measurement configurations and plugins, of which `tpprof` could be one.

Application performance profilers. Our work draws inspiration from a long history of work in application performance profiling [19, 22, 27, 46, 53, 60, 64]. Some of which are even able to profile distributed applications [32, 33, 42, 50]. While `tpprof` borrows its approach from the subset of these that profile stochastically, it does this for traffic patterns, which have their own unique set of challenges.

Anomaly detectors. Our alerting mechanisms are related to prior work in anomaly detection. Compared to unsupervised anomaly detection [18, 66], however, `tpprof` provides a much more accurate and fine-grained detection method. Compared to traditional profiling-based anomaly detection in which a user provides a 'correct' trace and the system determines whether the current system diverges [39, 59], `tpprof` can distinguish between different anomalies and does not require the user to obtain a correct trace. More generally, `tpprof`'s scoring engine presents a natural, declarative interface for the user tell the detector, via traffic pattern signatures, the approximate characteristics of relevant traffic patterns.

Clustering and compression. Finally, we note that our techniques for compressing network states borrow from or are related to the rich literature on clustering and compression [14, 23, 25, 35]. Our network state extraction techniques, in particular, leverage existing algorithms. The contribution of this work is instead the choice and tuning of these clustering algorithms to the domain of network traffic pattern analysis.

9 Discussion

Other metrics. While we focus on utilization in this paper, we note that `tpprof` easily extends to any metric collectable from the network. These include simple extensions like packet counts to more advanced metrics like buffer depth and high-water marks. As these metrics are generally correlated with utilization, we anticipate that `tpprof`'s techniques will extend intrinsically, but we leave an exploration of these extensions to future work.

Canned reactions. We also note that the ability of `tpprof`'s scoring engine to distinguish different traffic patterns presents an attractive substrate for building network-level reactions to different traffic patterns. This can also work in reverse: `tpprof` can identify common patterns for which operators should pre-compute reactions. We leave an investigation of this class of applications to future work as well.

10 Conclusion

We present `tpprof`, a network traffic pattern profiler. Just as tools like gprof made it easy for programmers to design, understand, and optimize their programs, `tpprof` does the same for profiling the utilization of large networks. `tpprof` leverages recent advancements in programmable networks and network-wide measurement to capture packet-accurate snapshots of utilization over time. On top of that, `tpprof` builds user-centric profiling, visualization, and automation tools. `tpprof` is agnostic to the application set running over the network and can profile networks in situ, making it an ideal fit for multi-tenant or transit networks. We profile several classic applications in order to demonstrate its utility.

TinySDR: Low-Power SDR Platform for Over-the-Air Programmable IoT Testbeds

Mehrdad Hessar[†], *Ali Najafi*[†], *Vikram Iyer and Shyamnath Gollakota*
University of Washington
[†]Co-primary Student Authors

Abstract

Wireless protocol design for IoT networks is an active area of research which has seen significant interest and developments in recent years. The research community is however handicapped by the lack of a flexible, easily deployable platform for prototyping *IoT endpoints* that would allow for ground up protocol development and investigation of how such protocols perform at scale. We introduce tinySDR, the first software-defined radio platform tailored to the needs of power-constrained IoT endpoints. TinySDR provides a standalone, fully programmable low power software-defined radio solution that can be duty cycled for battery operation like a real IoT endpoint, and more importantly, can be programmed over the air to allow for large scale deployment. We present extensive evaluation of our platform showing it consumes as little as 30 uW of power in sleep mode, which is 10,000x lower than existing SDR platforms. We present two case studies by implementing LoRa and BLE beacons on the platform and achieve sensitivities of -126 dBm and -94 dBm respectively while consuming 11% and 3% of the FPGA resources. Finally, using tinySDR, we explore the research question of whether an IoT device can demodulate concurrent LoRa transmissions in real-time, within its power and computing constraints.

1 Introduction

Recent years have seen development of numerous wireless protocols for Internet of Things (IoT) devices. In addition to longtime standards such as Bluetooth and Zigbee, a number of new protocols including LoRa, Sigfox, NB-IoT and LTE-M have been developed that achieve long ranges of more than a few kilometers. Due to the lack of a de-facto standard, this space remains an active area of research for both industry and academia. The rapid advances in this space however present practical challenges for researchers: each of these protocols requires a dedicated radio chipset to evaluate, and these proprietary solutions often leave little room for protocol modification. The academic community is therefore severely handicapped by the lack of a *flexible* platform, as even a complex multi-radio prototype cannot adapt to evaluate new protocols or even customize existing solutions. The current ecosystem therefore discourages researchers from investigating the important questions that arise when scaling up IoT networks, and more importantly taking a systematic approach to developing new protocols from the ground up.

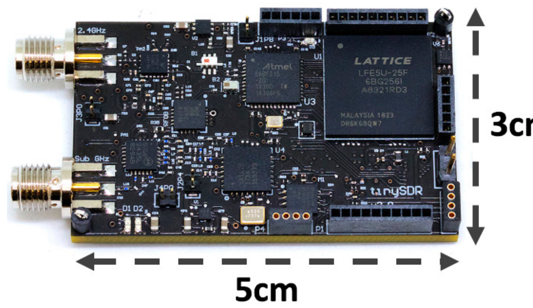

Figure 1: **TinySDR Hardware Platform.** It has two antenna ports for running IoT PHY and MAC protocols at 2.4 GHz and 900 MHz. This image is the actual size of the platform on printed paper.

Ideally, we would like a large scale IoT network testbed with the flexibility to run *any* IoT protocol at the PHY and MAC layers. Further, since many of these IoT testbeds can span hundreds of endpoints across a large campus or even a city, we need the ability to push changes to the PHY and MAC layers, using simple over-the-air software updates. This would allow for performance comparisons on a single testbed to investigate the trade-offs between existing standards as well as showcase the advantages of an entirely new custom protocol. Moreover, to make such a system representative of real-world deployments, individual network nodes should model the constraints of IoT endpoints. Specifically, these devices should have appropriate power controls and options to duty cycle transmissions, have an ultra-low power sleep mode and also have interfaces to connect sensors. Finally, the ability to run these endpoints on batteries would also allow for flexibility of deployment in spaces without dedicated power access, or even in mobile scenarios.

Realizing this vision however is challenging with existing software defined radio (SDR) platforms. Specifically, we require an SDR for the flexibility of implementing differ-

ent PHY protocols; but there is currently no SDR platform that meets the requirements of IoT endpoints (see Table 1). Existing SDR systems consume large amounts of power for transmitting data, do not support ultra-low power sleep modes, require wired infrastructure and often a dedicated computer and furthermore, are expensive. More importantly, none of the existing SDR platforms support over-the-air programming to update PHY or MAC protocols. Finally, IoT devices prioritize power consumption and communication range and hence use limited radio bandwidth — LoRa, Sigfox, NB-IoT, LTE-M, Bluetooth and ZigBee use only 500 kHz, 200 Hz, 180 kHz, 1.4 MHz, 2 MHz and 2 MHz respectively. In contrast, existing SDR platforms focus on achieving high performance in terms of bandwidth because *they are tailored to the needs of gateway devices and not for IoT endpoint devices.*

Driven by a need for such a platform in our own research, we design tinySDR as shown in Fig. 1, the first SDR platform tailored to the needs of IoT endpoints. TinySDR provides an entirely standalone solution that incorporates a radio front-end, FPGA and microcontroller for custom processing, over-the-air FPGA and microcontroller programming capabilities, a micro SD card interface for storage, ultra-low power sleep modes and highly granular power management options to enable battery-powered operation. It is capable of transmitting and receiving in both the 900 MHz and 2.4 GHz ISM bands, supports 4 MHz of bandwidth which is sufficient for most IoT protocols including Bluetooth, Zigbee, LoRa, Sigfox, NB-IoT and LTE-M, and can achieve the high sensitivities of commercial solutions such as LoRa chips [24]. Additionally it includes multiple analog and digital I/O options for connecting sensors.

Designing such an SDR platform required addressing multiple systems, architecture, power and engineering challenges:

• **Low-power hardware architecture.** Achieving a small form-factor, low-power SDR requires a minimalist design approach that can satisfy the real-time needs of IoT protocols and ensure flexibility at the PHY and MAC layers. To do this, we exploit recent advances in small, low-power microcontrollers, FPGAs and flash memory to pick the right components for our platform (see §3.1). We use a low-power FPGA to run the PHY layer while the microcontroller runs the MAC protocols as well as handles the I/O operations between the FPGA, radio, memory and sensor interfaces (see §3.2).

• **Efficient power management.** Achieving highly granular power management needed for battery-powered operation and enabling ultra-low power sleep modes requires shutting down parts of SDR when not in use. This is important for IoT endpoints that perform duty-cycled operations and require an ultra-low power sleep mode to achieve a long battery life. This presents a design tradeoff between the complexity of toggling the power of each hardware component ON and OFF, and the cost of additional circuitry to do so. We address this challenge in §3.3 and achieve sleep power as low as 30 μW.

• **Over-the-air SDR programming.** Enabling a truly scalable system requires the ability to update the PHY and MAC layers on the platform, over-the-air, in a testbed deployment. This however also introduces the challenge of over-the-air FPGA and microcontroller programming as well as communicating these updates robustly to each device in the network while minimizing power consumption and network utilization. We use a dedicated wireless backbone subsystem complete with a MAC protocol and its own flash memory to program both the microcontroller and FPGA. Additionally we leverage compression and low-power decompression algorithms to minimize network downtime during the updates (see §3.4)

Fig. 2 shows the power consumption of the radio module in tinySDR compared to existing SDR platforms. We evaluate tinySDR's performance by presenting case studies of two common protocols: LoRa and BLE beacons, and also evaluate tinySDR in a campus-testbed of 20 devices.

• LoRa modulation and demodulation use 4% and 11% of the FPGA resources respectively and achieve a sensitivity of -126 dBm for 3.12 kbps, which is similar to an SX1276 [24] LoRa chip with the same configuration. Further, the FPGA supports real-time modulation and demodulation of all LoRa spreading factors from 6 to 12. A LoRa MAC implementation on our MCU is also compatible with the *The Things Network*.

• TinySDR supports 2.4 GHz BLE beacon transmissions. The full baseband packet generation on the FPGA uses 3% of its resources. The platform can perform frequency hopping with a delay of 220 us and achieves a sensitivity of -94 dBm which is comparable to the commercial BLE chipsets [21].

Finally, we present a case study of how the unique capabilities of tinySDR could be used to answer new research questions. Recent work has explored techniques to enable concurrent transmissions in LoRa networks [44, 47]; however these solutions were prototyped on USRPs and it is unclear if IoT endpoints can decode concurrent transmissions in real-time within their power and resource constraints. We implement a custom decoder on tinySDR to demonstrate for the first time that IoT endpoints *can* receive concurrent transmissions.

Contributions. To summarize, we design the first SDR platform tailored to the needs of IoT endpoint devices. By making careful design and architectural choices, our platform achieves low power, supports IoT protocols at both 900 MHz and 2.4 GHz and has computation resources to do on-board processing. We present a highly granular power management scheme that enables duty-cycled operation and 10,000x lower power sleep modes. We also develop the first over-the-air SDR programming capability to support PHY and MAC updates in a wireless testbed. We characterize and evaluate our platform with case studies of LoRa and BLE beacons. Finally, we present a research exploration of concurrently receiving multiple LoRa transmissions on our SDR platform.

Platform availability. TinySDR's hardware schematics and software are available at:

https://github.com/uw-x/tinysdr

2 SDR Requirements for IoT Nodes

To motivate the need for tinySDR and inform our design decisions, we begin by identifying the key requirements for an IoT endpoint. These include 1) operation in the 900 MHz and 2.4 GHz bands, 2) low power operation which requires the ability to transition to ultra-low power sleep mode, 3) standalone operation which requires an on-board control unit to duty cycle the radio, 4) over-the-air programming capabilities for large scale IoT testbeds, 5) low cost per node, and 6) at least 2 MHz bandwidth to support IoT protocols including LoRa, SIGFOX, LTE-M, NB-IoT, ZigBee and Bluetooth. While there are a number of commercially available SDRs such as the USRP, BladeRF, Pluto SDR, and LimeSDR [1, 3, 7, 31, 36] on the market and SDR research prototypes such as WARP, Argos, SORA, SODA, KUAR, Tick, μSDR, OpenMili, and GalioT [40, 41, 43, 46, 55–58, 60, 63, 64, 66–68, 70, 72, 73], all of them are designed as *gateway devices* and do not satisfy many of the above constraints. Here, we analyze the shortcomings of these platforms in the context of these requirements.

• **Low power operation and sleep mode.** Fig. 2 compares the power consumption of the radio module *alone* in existing SDR platforms, since each one has different peripherals. We find that most SDR platforms consume 200-300 mW in receive mode, but a lot more power when transmitting. While this may be acceptable for a gateway devices that are more often receiving, typical IoT endpoints do the opposite and are required to transmit data like sensor information. Moreover, real IoT nodes spend a very short time transmitting before transitioning to ultra-low power sleep modes. Although IoT

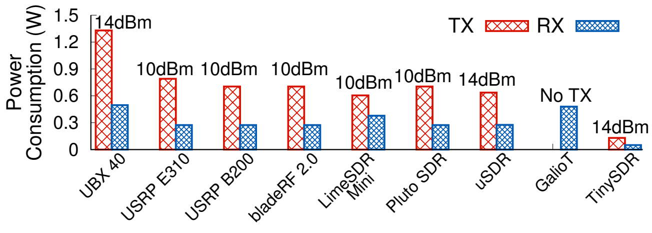

Figure 2: **Radio Module Power Consumption for Each Platform.** The TX output power of each radio module is shown on top of it.

radios often consume tens to hundreds of milliwatts of power, the key to achieving long battery lifetimes is exploiting their microwatt power sleep modes. Table 1 shows that none of the other platforms can benefit from duty cycling as they consume more power in sleep mode than tinySDR does when transmitting; tinySDR's microwatt power consumption in sleep mode enables dramatic power savings with duty cycling.

• **Standalone operation and cost.** We observe that some of these platforms do not allow for standalone operation, i.e., they cannot be used in a testbed deployment without an external computer. Among the ones that do, the Embedded USRP and bladeRF cost $700 or more per unit making large scale deployments expensive. μSDR allows for standalone operation but only operates at 2.4 GHz and cannot support protocols like LoRa. GalioT [63] uses the low cost RTL2832U radio [5] connected to a Raspberry Pi computer which allows for standalone operation, however it does not support 2.4 GHz band. Moreover, this platform is *receiver only* and cannot be used to prototype a typical IoT node that transmits data.

• **Over-the-air (OTA) programming.** As shown in Table 1, all existing SDR platforms rely on wired interfaces for programming. This means that even if one of these systems were connected to a battery, running an experiment would require either tethering each one to a wired network or individually programming them. An OTA programming system is crucial to realizing the goal of a large scale wide area testbed as without it, researchers have to decide between limiting themselves to deployment scenarios with wired infrastructure that are not representative of real IoT use cases or traveling over *kilometer* distances to update individual nodes for *each* minor protocol modification, which would be unmanageable at scale.

3 TinySDR Platform

We first describe our design choices for the different components of our hardware shown in Fig. 3 and explain the interfaces between them. Next we present the power management module which enables our ultra-low-power sleep mode. Finally, we describe our over-the-air update protocol including decompression algorithms and over-the-air reprogramming.

3.1 Hardware Design

We seek to minimize power consumption and cost while offering the flexibility of an SDR to process raw samples.

3.1.1 Designing the Software Radio

The core block on our platform is the software-defined radio, a programmable PHY layer that processes and converts bits to radio signals and vice versa. We begin by explaining our choices for the primary components of an SDR which are a radio chip that provides an interface for sending and receiving raw samples of an RF signal as well as an FPGA that can process these signals in real time. We then discuss the supporting peripherals for these devices such as a power amplifier (PA) to boost the output of the radio chip and non-volatile memory for the FPGA to read and write data from.

Choosing a radio chip. We begin by choosing a radio chip as its specs define the requirements for the FPGA and other blocks. Our primary requirement is that the chip supports reading and writing raw complex I/Q samples of the RF signal. As shown in Table 2, current SDR systems use I/Q radio chips that are designed to cover a multi-GHz spectrum and have high ADC/DAC sampling rates to support large bandwidth. For example, the AD936x [17] series which is used in USRP and Pluto SDR can transmit up to 3.8 GHz and supports sampling rates as high as tens of MHz. Each of these specs such as wide bandwidth, low noise, and high sampling rate represent fundamental trade offs of power for performance, and therefore these chips consume watts of power. Moreover, some of these radio chips costs more than \$100.

We instead take a different approach: identify the minimum required specs and find a radio that supports them. Specifically, a radio chip for an IoT platform must be able to operate in at least the 900 MHz and 2.4 GHz ISM bands, have 4 MHz of bandwidth, while otherwise minimizing power and ideally costing less than \$10. We analyze all of the commercially available radio chips that provide baseband I/Q samples and list them in Table 2, where only the AT86RF215 supports all of our requirements. In addition to its lower cost and support for both frequency bands, it also consumes less power than the MAX2831 and the SX1257. Moreover, the AT86RF215 integrates all the necessary blocks including an LNA, programmable receive gain, automatic gain control (AGC) and low pass filter, ADC on the RX chain, as well as a DAC and programmable PA with a maximum power of 14 dBm on the TX side. In terms of noise, the RF front-end has a 3-5 dB noise figure which is even better than the noise figure of the front-end used in Semtech SX1276 LoRa chipset, suggesting it should be able to achieve long range performance. It consumes 5x less power than the radios used on other SDRs as shown in Fig. 2 and has built in support for common modulations such as MR-FSK, MR-OFDM, MR-O-QPSK and O-QPSK that can save FPGA resources or power by bypassing the FPGA entirely.

Picking an FPGA. Now that we have chosen a radio chip, the next step in our design process is to find an FPGA that can interface with it. Aside from minimizing power and cost, we would also like to maintain a small form factor and short wake-up time. Although flash-based FPGAs are capable of fast wake-ups, they are more expensive compared to SRAM-based FPGAs with the same number of logic elements. We use LFE5U-25F [33] FPGA from Lattice Semiconductor for baseband processing which is SRAM-based and has 24k logic units. This chip provides a greater number of look up tables (LUTs) than the FPGAs on the Pluto SDR and LimeSDR mini, and at a lower cost. Moreover, it is significantly cheaper than the flash-based FPGA used in uSDR [56].

Table 2: **Existing Off-the-Shelf I/Q Radio Modules.**

I/Q Radio	Frequency (MHz)	RX Power (mW)	Cost
AD9361 [17]	70∼6000	262	\$282
AD9363 [18]	325∼3800	262	\$123
AD9364 [12]	70∼6000	262	\$210
LMS7002M [25]	10∼3500	378	\$110
MAX2831 [10]	2400∼2500	276	\$9
SX1257 [35]	862∼1020	54	\$7.5
AT86RF215 [20]	**389.5∼510 779∼1020 2400∼2483**	**50**	**\$5.5**

Adding a power amplifier (PA). AT86RF215 only supports a maximum transmit power of 14 dBm which is traditionally used by IoT radios but is less than the 30 dBm maximum allowed by the FCC. To provide flexibility, we add optional PAs. Given the high cost and power requirements of wide-band PAs that could operate at both 900 MHz and 2.4 GHz we instead select two different chips: the SE2435L [23] for 900 MHz and SKY66112 [28] for 2.4 GHz. Our 900 MHz PA supports up to 30 dBm output power, and the 2.4 GHz PA can output up to 27 dBm. Both chips also include an LNA for receive mode and a built in circuit to bypass either of these components for power savings. In receive mode, we can either pass the incoming signal through the LNA and then connect it to the radio or completely bypass the LNA and connect the signal directly. The maximum bypass current is 280 uA and the sleep current of both power amplifiers is only 1 uA. In transmit operation we can pass the signal through the PA and amplify the signal or turn off the PA and pass the signal directly to the antenna for transmit power $<$ 14 dBm.

Picking the microcontroller. We use a microcontroller to control all the individual chips and toggle all of these power saving options. In addition to having a low sleep current it must be able to support multiple control interfaces, have enough memory resources to support IoT MAC protocols and also be able to run a decompression algorithm for our OTA system. We select the MSP432P401R [27] a 32-Bit Cortex M4F MCU which meets all of our requirements with less than 1 uA sleep current, has 64 KB of onboard SRAM and 256 KB of onboard flash memory. In addition to controlling the I/Q and backbone radio parameters, and reprogramming of the FPGA, the MCU performs the important function of power management. It is responsible for toggling ON and OFF the power amplifiers, as well as performing power-gating by turning ON and OFF different voltage regulators in §3.3.

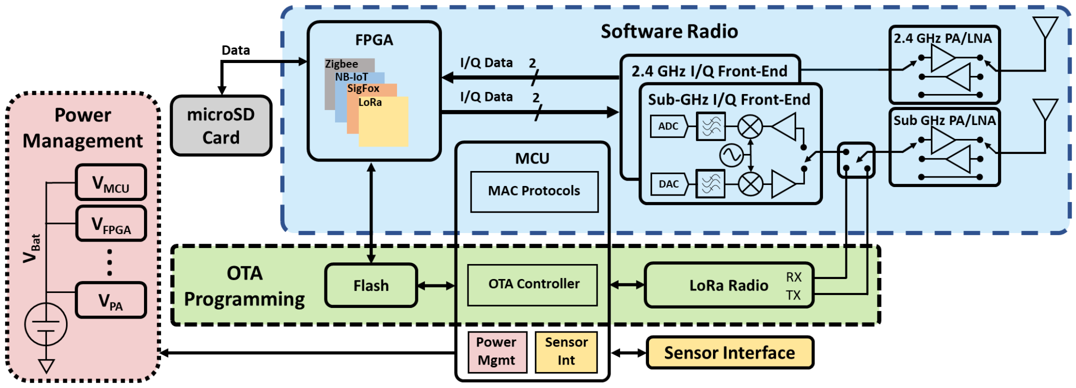

Figure 3: **TinySDR System Block Diagram.** A complete system diagram showing all of the components of tinySDR. This includes the software radio consisting of the radio, amplifiers, and FPGA, OTA programmer which uses a LoRa radio and flash memory to store programs, and a power managment system with the flexibility to turn off power consuming components. Each of these subsystems are controlled in software running on the MCU.

3.1.2 Designing OTA Update Hardware

While the above discussion enables a small, low power, low cost SDR for easy deployment, FPGAs and microcontrollers typically require a wired interface for reprogramming. There are two options for enabling wireless reprogramming: i) using the existing I/Q radio and FPGA and ii) using a dedicated wireless communication chipset. We chose the second option since it provides a fail-safe mode for updating the firmware. Moreover, a dedicated wireless communication chipset would consume less power compared to the first option.

OTA wireless chipset. A key question when designing an OTA update system is, what wireless protocol should be used? To support wide area networking, we focus on protocols designed for long range operation. We analyze all of the available long range protocols and select LoRa for our OTA system for a number of reasons. First, LoRa receivers have a high sensitivity which enables kilometer ranges. LoRa also support a wide range of data rates from 11 bps to 37 kbps which allows us to trade off rate for range depending on the deployment scenario. Moreover, LoRa is becoming more and more wide-spread in the US. We use the SX1276 Semtech chipset [24] which is available for \$4.5, minimizing cost.

Flash Memory. Our FPGA is SRAM based and does not include on-chip non-volatile memory for storing programming data. We instead store the firmware bitstream on a separate flash memory chip. The FPGA programming bitstream is 579 KB and the MCU programs require a maximum of 256 KB. We chose the MX25R6435F flash chip with 8 MB memory. Although this is far more than the size required, it allows tinySDR to store multiple FPGA bitstreams and MCU programs to quickly switch between stored protocols without having to re-send the programming data over the air.

3.2 Interfacing Between Blocks

3.2.1 Reading and Writing I/Q Samples

The AT86RF215 radio chipset samples baseband signals at 4 MHz with a 13 bit resolution for both I and Q. Operating at the full rate therefore requires an interface which can support a throughput of over 100 Mbps without consuming a large amount of power to meet our design objectives. To do this we use low-voltage differential signaling (LVDS) [4] which is a high-speed digital interface that reduces power by using lower voltage signals but maintains good SNR by sending data over two differential lines to reduce common mode noise.

I_SYNC (0b10)	I_Data (13 bits)	Control (1 bit)	Q_SYNC (0b01)	Q_Data (13 bits)	Control (1 bit)

Figure 4: **I/Q Word Structure Used by I/Q Radio.**

Receiving serial I/Q data. Our system communicates over LVDS to the FPGA in serial mode to transfer I/Q data with a physical interface consisting of 4 I/O lines, pairs of which are used to send data and clock signals. The radio outputs 32-bit serial data words at 4 Mwords/s using the format in Fig. 4. Each data word starts with the *I_SYNC* pattern which indicates the start of the *I* sample which we use for synchronization. Next, it has 13 bits of *I_Data* followed by a control bit. The same format follows for *Q*, beginning with a synchronization pattern *Q_SYNC* and then 13 bits for *Q_Data* and the final control bit. The required 128 Mbps data rate is achieved using a 64 MHz clock provided by the radio operating at double data rate by sampling at both the rising and falling edges of the clock. We implement an I/Q deserializer on the FPGA to read the data which samples the input at both the rising and falling edges of the clock, uses the *I_SYNC* and *Q_SYNC* to detect the beginning of the data fields and loads the *I* and *Q* values into 13 bit registers for parallel processing.

Transmitting I/Q samples. In TX mode we need to do the opposite of the above sequence to convert from the parallel representation on the FPGA to a serialized LVDS stream. To do this, we use the FPGA's onboard PLL to generate the 64 MHz clock signal. Next to create our double data rate output signal that varies on both the positive and negative edges of this clock signal using a dual-edge D flip-flop design [48] resulting in the desired 128 Mbps data rate. We use this to generate the same I/Q word structure described above.

3.2.2 Memory Interfaces

After reading the raw data from the LVDS lines using the I/Q deserializer described above, we store the samples into a FIFO buffer implemented using the FPGA's embedded SRAM. We implement a simple memory controller to write data to the FIFO which generates the memory control signals and writes a full data word on each cycle. The embedded memory can run at rates significantly greater than 4 MHz meaning it is not a limiting factor for real-time processing. The SRAM can buffer up to 126 kB. The data stored in the FIFO can then be sent to signal processing blocks to implement filters, cryptographic functions, etc. or to non-volatile flash memory. For flash memory, we use a micro SD card which enables us to collect raw I/Q data and analyze the spectrum. The micro SD card supports two modes: native SD mode and standard SPI mode. In native SD mode, micro SD card's interface uses 4 parallel data lines to read/write data to/from the micro SD card. This mode supports a higher data rate compared to the SPI mode which only supports a 1-bit serial interface. However, we implement SPI mode since it supports the 104 Mbps data rate which we need to write data in real time. This allows us to re-use the same, simpler SPI block for multiple functions and save resources on the FPGA.

3.2.3 RF, Control and Sensor Interfaces

The AT86RF215 provides differential RF signals for both 900 MHz and 2.4 GHz and has an integrated TX/RX switch for both. At 2.4 GHz, the differential signal is transformed to a single-ended output using the 2450FB15A050E [8] balun and fed to the SKY66112 [28] front-end with the bypassable LNA and PA. Finally, after passing through a matching network, the 2.4 GHz signal is connected to an SMA output.

On the 900 MHz side, the differential output of the AT86RF215 is connected to 0896BM15E0025E [32] to convert it to a single-ended output. This must be shared between the backbone radio's two separate RF paths for transmit and receive and AT86RF215's 900 MHz single-ended signal. We choose between them using a ADG904 [19] SP4T RF switch. The single port side is connected to the SE2435L [23] 900 MHz front-end which is similar to the 2.4 GHz front-end. The MCU communicates with the I/Q radio, backbone radio, FPGA and Flash memory through SPI which it uses to send commands for changing the frequency, selecting the outputs, etc. It also has control signals for FPGA programming, 900 MHz and 2.4 GHz front-end modules, RF switch and voltage regulators for active power control. TinySDR supports common digital interfaces like SPI and I2C to communicate with digital sensors and two analog to digital converters (ADC) for interfacing with analog sensors. We leverage the internal flash memory of the MCU ($\approx$ 256 kB) and external flash memory ($\approx$ 8 MB) to store sensor data.

Table 3: **Power Domains in TinySDR.**

Component	Voltage [V]	Power Domain
MCU	1.8V	V1
FPGA	1.1, 1.8, 2.5, Vlvds	V2, V3, V4, V5
I/Q Radio	1.8< V5 <3.6	V5
Backbone Radio	1.8< V5 <3.6	V5
sub-GHz PA	3.5V	V6
2.4 GHz PA	1.8, 3.0	V3, V7
FLASH Memory	1.8	V3
Micro SD Memory	3.0	V7

3.3 Power Management Unit

Next, we present the design of our power management unit which seeks to maximize the system lifetime when running off of a 3.7 V Lithium battery. To enable long battery lifetimes we need to be able to duty-cycle our system and allow the MCU to toggle each of the above blocks ON and OFF when they are not in use. Further, different components have different supply voltage requirements and we wish to provide each one with the lowest voltage possible to minimize power usage.

Ideally we would want separate controllable voltage regulators for each component in the system. However, having many different regulators with individual controls significantly increases the complexity, number of components, and price. Moreover, it complicates the PCB design by requiring many control signals and a multitude of power planes. Therefore, there exists a trade-off between the granularity of power control and the price/complexity of a design. We outline the supply voltages needed for each component and the power domain supporting it in Table 3. Below, we show how we group components to balance power and complexity.

- **Power domain V1 (MCU).** Since the MCU is the central controller that implements power management, it needs to be powered at all times and therefore has its own power domain. To minimize its sleep current we need to use a voltage regulator with a low quiescent current. Although switching voltage regulators have higher conversion efficiency when active, they also have high quiescent currents so we instead select the TPS78218 linear regulator.
- **Power domains V2, V3, V4, V6 and V7.** These power domains provide power to blocks such as the FPGA, memory blocks, and PAs. Since these components can all be turned off when not operating, the voltage regulators for these domains should have low shut-down current during sleep and high efficiency when active. We therefore choose the TPS62240 which has a shutdown current of only 0.1 uA. It is highly efficient and is rated to support the current draw required by all components except the 900 MHz PA. To support this PA at its maximum output power we use the TPS62080 switching regulator which supports the required current.
- **Power domain V5.** V5 is a shared power domain for I/Q radio, backbone LoRa radio and FPGA I/O bank. This power domain is initially set to 1.8V to minimize power consumption, however components such as the radio chips can require higher voltage to achieve maximum output power. Therefore,

Figure 5: **LoRa Packet Structure.**

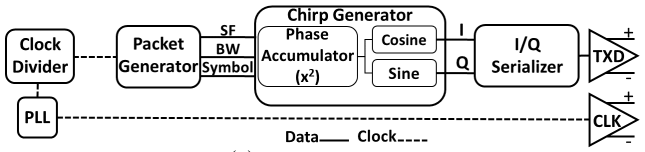
in addition to high efficiency and low shut-down current like the others, this domain should be programmable. To do this, we use Semtech SC195ULTRT [15] which provides an adjustable output that can be set from 1.8 V to 3.6 V.

3.4 Over-the-Air Programming protocol

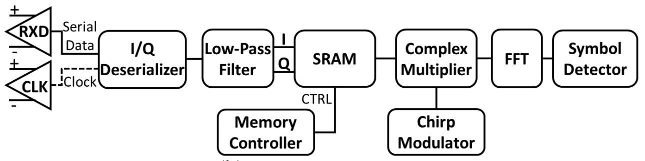
OTA AP and MAC protocol. To update a network of tinySDR devices, we use an AP with a LoRa radio to communicate with each device sequentially. In order to propagate updates throughout a testbed or to specific tinySDR nodes, we design a MAC layer for the LoRa PHY. We pre-program a timer on the MCU to periodically turn off the FPGA and switch from IQ radio mode to the backbone radio to listen for new firmware updates. If there is an update, the AP sends a programming request as a LoRa packet with specific device IDs indicating the nodes to be programmed along with the time they should wake up to receive the update. Upon processing this packet and detecting its ID, the tinySDR node switches into update mode and sends a ready message to the AP at the scheduled time. Then, the AP transmits the firmware update as a series of LoRa packets with sequence numbers. Upon receiving each packet, the tinySDR node checks the sequence number and CRC. For a correct packet it writes the data to its flash memory and transmits an ACK to indicate correct reception. In the case of failure no ACK is sent and the AP re-transmits the corrupted packet after a timeout. After sending all the firmware data, the AP sends a final packet indicating the end of firmware update which tells the tinySDR node to reprogram itself and switch back to normal operation.

To maintain the OTA timing, we use a programmable timer that operates with a 20 PPM low-frequency crystal oscillator source. This will result in timing drift between the tinySDR node and the AP over time. However, with each update we compensate the error by sending the correct time to the tinySDR.

Compressing and decompressing the bitstream. Our system compresses data to reduce update times, however this compression must be compatible with the resources available on tinySDR. We choose the miniLZO compression algorithm [34], which is a lightweight subset of the Lempel–Ziv–Oberhumer (LZO) algorithm. Our implementation of miniLZO only requires a memory allocation equal to the size of the uncompressed data. We perform compression on the AP. The compression ratio of bitstream file varies based on the content of the bitstream, and in the worst case the compressed file could have almost the same size of the original file. This would require a maximum memory allocation of 579 kB which we cannot afford on a low-cost MCU. Instead, we first divide the original update file into blocks of 30 kB that will fit in the MCU memory. Then we compress each



(a) **LoRa Modulator**



(b) **LoRa Demodulator**

Figure 6: **LoRa Implementation Block Diagrams.**

block separately and transmit them to the tinySDR node one by one. Considering the LoRa radio takes more power than the MCU, we immediately write the data to our dedicated programming flash memory using an SPI interface.

After receiving all the data we turn off the LoRa radio and decompress data. First, we allocate memory on the MCU's SRAM equal to the block size and load a block of data from flash. Next, we perform decompression and write the data in the allocated SRAM memory. Finally, we write the decompressed data back to the flash beginning at the corresponding address of the programming boot file. We repeat these steps until we decompress the full firmware update.

Over-the-air FPGA programming. After storing uncompressed programming data in flash memory, we program the FPGA. We use the MCU to set the FPGA into programming mode. When the FPGA switches to programming mode, it automatically reads its firmware directly from the flash memory using a 62 MHz quad SPI interface and programs itself. Reading from flash using quad SPI achieves programming times of 22 ms which is similar to FPGAs with embedded flash memory and results in minimal system down time. After programming is complete, it resumes operation and begins running the new firmware.

3.5 TinySDR's Architectural Considerations

We design tinySDR to achieve three main goals: i) low-power ii) low-cost and iii) over-the-air programmability. To do this, we use a low-power I/Q radio with lower bandwidth support compared to previous platforms. Since this radio is optimized for low bandwidths and in turn low sampling rates, it consumes less power during TX/RX operations. Previous platforms [31, 56] use hardware architectures that support high-bandwidth protocols such as Wi-Fi. However, we use a low-power radio and build our hardware architecture for IoT protocols around it. In addition, we design a power management system to be able to power cycle different parts of tinySDR's architecture in each operation to further reduce the power consumption. To achieve this, we use an MCU chip that enables full control of the tinySDR's blocks and power domains. We achieve minimum power consumption during sleep mode by turning off power-hungry components.

In contrast, previous architectures such as uSDR [56] use an MCU integrated with an FPGA which forces the FPGA to be always ON and increases the power consumption during sleep mode. This is because uSDR is not designed for IoT endpoints but for gateways and hence does not provide any of the architectural optimizations required for the low-power sleep operation required by IoT devices. Furthermore, by using a lower bandwidth radio and also a low-cost SRAM-based FPGA, we minimize the cost compared to platforms such as uSDR [56], Pluto SDR [31] and LimeSDR [2]. Finally, we design tinySDR to operate completely standalone on battery without the need for a wired connection to a network or a computer. To do this, we design an OTA system on tinySDR to be able to re-program the FPGA and MCU on tinySDR wirelessly. This capability does not exist on prior SDR platforms.

4 Case Studies: LoRa and BLE Beacons

4.1 LoRa Protocol with tinySDR

We choose LoRa as it is gaining popularity for IoT solutions due to its long range capabilities. Since LoRa is a proprietary standard, we begin by describing the basics of its modulation and packet structure followed by the implementation details of our modulator, demodulator and MAC protocol.

LoRa Protocol Primer. LoRa achieves long ranges by using Chirp Spread Spectrum (CSS) modulation. In CSS, data is modulated using linearly increasing frequency upchirp symbol. Each upchirp symbol has two main features: Spreading Factor (SF) and Bandwidth (BW). SF determines the number of bits in each upchirp symbol [44, 47, 69] and BW is the difference between upper and lower frequency of the chirp which together with SF determines the length of an upchirp symbol. SF and BW trade data rate for range. Data is modulated by 2^{SF} cyclic-shifts of an upchirp symbol. The starting point of the symbol in frequency domain, which is the cyclic shift of the upchirp symbol, determines its value [16]. LoRa uses SF values from 6 to 12 and BW values from 7.8125 KHz to 500 KHz to achieve PHY-layer rates of $\frac{BW}{2^{SF}} \times SF$.

Fig. 5 shows the LoRa packet structure which begins with a preamble of 10 zero symbols (upchirps with zero cyclic-shift). This is followed by the Sync field with two upchirp symbols. Next, a sequence of 2.25 downchirp symbols (chirp symbol with linearly decreasing frequency) indicate the beginning of the payload. The payload then consists of a sequence of upchirp symbols which encode a header, payload and CRC.

LoRa Modulator. Fig. 6a shows the block diagram of our LoRa modulator. We use our FPGA to implement a LoRa modulator in Verilog and stream data to AT86RF215 in I/Q mode. The modulator begins with the *Packet Generator* module which reads data either from FPGA memory for transmitting fixed packets or from the MCU, as well as LoRa

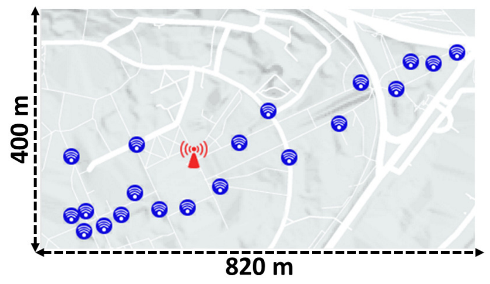


Figure 7: **Evaluation Testbed Map.**

configuration parameters such as SF, coding and BW. This module determines each symbol value and its corresponding cyclic-shift. Next, the *Packet Generator* sends these parameters along with the symbol values to the *Chirp Generator* module, which generates the I/Q samples of each chirp symbol in the packet using a squared phase accumulator and two lookup tables for *sine* and *cosine* function [69]. We then feed these I/Q samples into an I/Q Serializer to stream them over the LVDS interface to the I/Q radio. We generate the 64 MHz transmission clock using internal PLL of the FPGA.

LoRa Demodulator. Fig. 6b shows the block diagram of our LoRa demodulator. It begins by reading data from the I/Q radio into the *I/Q Deserializer* module on the FPGA which converts the serial I/Q stream to parallel I/Q for further signal processing. Next, we run the data through a 14 tap FIR low-pass filter to suppress high frequency noise and interference. We store the filtered samples in a buffer implemented using the FPGA's memory blocks. To decode the data, we use the *Chirp Generator* module from the *LoRa Modulator* described above to generate a baseline upchirp/downchirp symbol, and then we multiply that with the received chirp symbol using our *Complex Multiplier* unit. The output of the multiplication then goes to an FFT block implemented using a standard IP core from Lattice. Finally the *Symbol Detector* scans the output of the FFT for peaks and records the frequency of the peak to determine the symbol value. To detect the chirp type (upchirp/downchirp), we multiply each chirp symbol with both an upchirp and downchirp and then compare the amplitudes of their FFT peaks. The higher peak in the FFT shows higher correlation which indicates the chirp type.

LoRa MAC Layer. To demonstrate that our LoRa implementation on tinySDR is compatible with existing LoRa networks such as the LoRa Alliance's [26] The Things Network (TTN) [38], we adopt their LoRa MAC design from TTN's Arduino libraries [39] and implement it on tinySDR's MCU. TTN uses two methods for device association; Over-the-air activation (OTAA) and activation by personalization (ABP). In OTAA, each node performs a join-procedure during which a dynamic device address is assigned to a node. However, in ABP we can hard-code the device address in the device which makes it simpler since the node skips the join procedure. Our platform can support both OTAA and ABP methods.

Table 4: **Different Operation Timing for TinySDR.**

Operation	Duration (ms)
Sleep to Radio Operation	22
Radio Setup	1.2
TX to RX	0.045
RX to TX	0.011
Frequency Switch	0.220

4.2 BLE Beacons with tinySDR

To demonstrate tinySDR's 2.4 GHz capabilities we implement Bluetooth beacons which are commonly used by IoT devices.

BLE Beacon Primer. We implement non-connectable BLE advertisements (ADV_NON_CONN_IND) which are broadcast packets used for beacons. These packets allow a low power device to broadcast its data to any listening receiver within range without the power overhead of exchanging packets to setup a connection. These packets have a bit rate of 1 Mbps in Bluetooth 4.0 or up to 2 Mbps in Bluetooth 5.0 and are generated using GFSK with a modulation index of 0.45-0.55. The GFSK modulation is binary frequency shift keying (BFSK) with the addition of a Gaussian filter to the square wave pulses to reduce the spectral width.

Generating a BLE Packet. Bluetooth advertisements consist of 6-37 octets, beginning with fixed preamble and access address fields indicating the packet type set to 0xAA and 0x8E89BED6 respectively. This is followed by the packet data unit (PDU) beginning with a 2 byte length field and followed by a manufacturer specific advertisement address and data. The final 3 bytes of the packet consist of a CRC generated using a 24-bit linear feedback shift register (LFSR) with the polynomial $x^{24}+x^{10}+x^9+x^6+x^4+x^3+x+1$. The LFSR is set to a starting state of 0x555555 and the PDU is input LSB first. The final LFSR state after inputting the PDU becomes the CRC. Data whitening is then performed over the PDU and CRC fields to eliminate long strings of zeros or ones within a packet. This is also done using a 7-bit LFSR with polynomial x^7+x^4+1. The LFSR is initialized with the lower 7 bits of the channel number the packet will be transmitted on, and each byte is input LSB first. We implement both these blocks in Verilog on the FPGA.

Packet Transmission and MAC Protocol. From this bitstream, we need to generate the I/Q samples to feed to the I/Q radio. First, we upsample and apply a Gaussian filter to the bitstream. This gives us the desired changes in frequency which we integrate to get the phase. We then feed the phase to *sine* and *cosine* functions to get the final I and Q samples, which are passed to I/Q serializer and sent to the I/Q radio. BLE divides the 2.4 GHz band into channels, each spaced 2 MHz apart, but BLE beacons are only transmitted on three advertising channels without carrier sense, typically in sequential order separated by a few hundred microseconds. This sequence is re-transmitted every advertising interval [37].

5 Evaluation

We deploy a testbed of 20 tinySDR devices across our institution's campus as shown in Fig. 7. To see if tinySDR meets the requirements for IoT endpoint devices, we characterize its power, computational resource usage, delays and cost when operating in different modes and running different protocols.

5.1 Benchmarks and Specifications

Sleep mode power. Many IoT nodes perform short, simple tasks allowing them to be heavily duty cycled which allows them to achieve battery lifetimes of years. We design tinySDR with this critical need in mind such that the MCU can actively toggle on and off power consuming components such as the radio, PAs, and FPGA to enter a low power sleep mode.

We do this by first turning off the the I/Q transceiver and LoRa radios. To reduce the static power consumption of the FPGA, we shut it down by disabling the voltage regulators that provide power to its I/O banks and core voltage. Similarly, we also turn off the PAs. Finally, we put the MCU in sleep mode LPM3 running only a wakeup timer. The measured total system sleep power in this mode was 30 uW.

The low sleep power allows for significant power savings, but also introduces latency. Table 4 shows the time required to wake up from sleep mode until the radio is active. Because we can perform the I/Q radio setup in parallel with booting the FPGA, the total wakeup time for RX and TX is 22 ms. The I/Q radio setup takes 1.2 ms, so the wakeup time is dominated by booting up the FPGA which itself takes 22 ms. We compare this to a SmartSense Temperature sensor [14] and find that tinySDR has only a 4x longer wakeup time even though it requires programming unlike commercial products that use a custom single protocol radio. Additionally many IoT devices operate at low duty cycles waiting in sleep mode for seconds or more making tinySDR's wakeup latency insignificant.

Switching delays. We also measure the switching delays for different operations on the I/Q radio as this is an important parameter for meeting MAC and protocol timing requirements. Table 4 shows that it takes 45 μs and 11 μs to switch from TX to RX mode and RX to TX mode respectively. As we see later, this is sufficient to meet the timing requirements of IoT packet ACKs and MAC protocols. Further, the delay for switching between different frequencies is only 220 us. To measure this number, we switch between 2.402 GHz, 2.426 GHz and 2.480 GHz. This switching delay is again sufficient to meet the requirements of frequency

Table 5: **TinySDR Cost Breakdown for 1000 Units.**

Components		Price
DSP	FPGA	$8.69
	Oscillator	$0.9
IQ Front-End	Radio	$5.08
	Crystal	$0.53
	2.4 GHz Balun	$0.36
	Sub-GHz Balun	$0.3
Backbone	Radio	$4.5
	Crystal	$0.4
	Flash Memory	$1.6
MAC	MCU	$3.89
	Crystals	$0.68

Total	–	**$54.53**

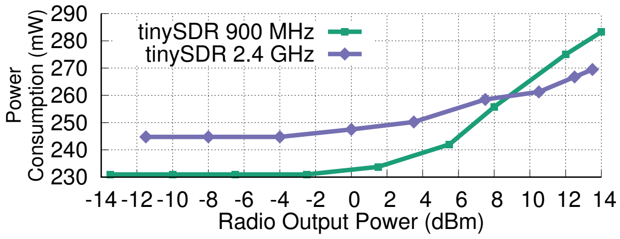

Figure 9: **Single-Tone Transmitter Power Consumption.** We show the total power consumption of tinySDR including I/Q radio, FPGA, MCU and regulators at different transmitter output power. This is 15-16 times lower power consumption than the USRP E310 embedded SDR.

hopping during Bluetooth advertising.

Transmitter performance. First, we implement a single-tone modulator on the FPGA that generates the appropriate I/Q samples and streams them over LVDS to the radio. We connect the output to an MDO4104b-6 [11] spectrum analyzer and observe a single tone, shown in Fig. 8, with no unexpected harmonics introduced by the modulator.

Next we measure the end-to-end DC power consumption of our system including the I/Q radio, FPGA, MCU and regulators to see how it scales with RF output power. We vary our radio output power while transmitting a single tone and use a Fluke 287 multimeter to measure its DC power draw. Fig. 9 shows the power consumption of tinySDR for 900 MHz and 2.4 GHz operation. Interestingly, we observe the DC power is constant at low RF power but increases as expected beyond some RF power level. TinySDR consumes 231 mW when transmitting at 0 dBm, and for comparison the end-to-end power consumption of the USRP E310 is 16x higher under the same conditions. Similarly tinySDR consumes 283 mW at its 14 dBm setting while the USRP E310 is 15x higher. In addition, we measure the peak current consumption of tinySDR while transmitting a single-tone on the I/Q radio. The peak current consumption is 105 mA when tinySDR boots up the FPGA and then starts transmitting using the I/Q radio. This current is less than the maximum current supported by a typical LiPo 1200 mAh battery [13].

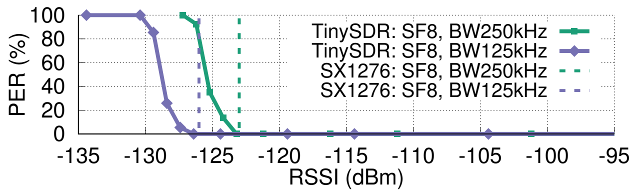

Figure 10: **LoRa Modulator Evaluation.** We evaluate our LoRa modulator in comparison with Semtech LoRa chip.

Cost. We also analyze the cost which is an important practical consideration for real world deployment at scale. Table 5 shows a detailed breakdown of cost including each component as well as PCB fabrication and assembly based on quotes for 1000 units [22], where the overall cost is around $55 each.

5.2 Evaluating the Case Studies

LoRa using tinySDR. We evaluate various different components of tinySDR using LoRa as a case study.

LoRa modulator. To evaluate this, we use our LoRa modulator to generate packets with three byte payloads using a spreading factor of $SF = 8$ and bandwidths of 250 kHz and 125 kHz which we transmit at -13 dBm. We receive the output of tinySDR on a Semtech SX1276 LoRa transceiver [35] which we use to measure the packet error rate (PER) versus RSSI and plot the results in Fig. 10. We compare our LoRa modulator to transmissions from an SX1276 LoRa transceiver. The plots show that we can achieve a comparable sensitivity of -126 dBm which is the LoRa sensitivity for $SF = 8$ and $BW = 125kHz$ configuration. This is true for both configurations, which shows that our low-power SDR can meet the sensitivity requirement of LPWAN IoT protocols.

LoRa demodulator. Next we evaluate our LoRa demodulator on tinySDR. To test this, we use transmissions from a Semtech SX1276 LoRa transceiver and use tinySDR to receive these transmissions. The LoRa transceiver transmits packets with two configurations using a spreading factor of 8 and bandwidths of 250 kHz and 125 kHz. We record the received RF signals in the FPGA memory and run them through our demodulator to compute a chirp symbol error rate. Note that the Semtech LoRa transceiver does not give access to its symbol error rate, but since we have access to I/Q samples, we can compute it on our platform. We plot the results in Fig. 11 as a function of the LoRa RSSI values. Our LoRa demodulator can demodulate chirp symbols down to -126 dBm which is LoRa protocol sensitivity at $SF = 8$ and $BW = 125kHz$. Both the LoRa modulator and demodulator run in real-time.

Resource allocation. Next, we evaluate the resource utilization of our LoRa PHY implementation on the FPGA. Table 6 shows the size for implementing the modulator and demodulator on our FPGA using different SFs. Our LoRa modulator supports all LoRa configurations with different SF with no additional cost. However, in the LoRa demodulator, we need

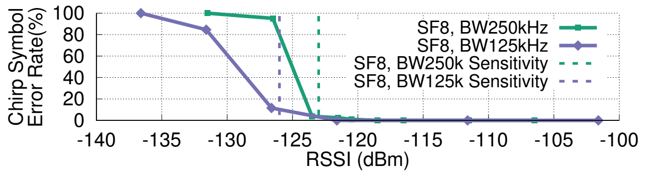

Figure 11: **LoRa Demodulator Evaluation.** We evaluate our LoRa demodulator by demodulating chirp symbols at different RSSI.

Table 6: **FPGA Utilization for LoRa Protocol.**

SF	LoRa TX (LUT)	LoRa RX (LUT)
6	976 (4%)	2656 (10%)
7	976 (4%)	2670 (10%)
8	976 (4%)	2700 (11%)
9	976 (4%)	2742 (11%)
10	976 (4%)	2786 (11%)
11	976 (4%)	2794 (11%)
12	976 (4%)	2818 (11%)

FFT blocks with different sizes to support different SF configurations. This table shows that our FPGA has sufficient resources to support multiple configurations of LoRa and still leave space for other custom operations.

LoRa MAC. We implement the LoRa MAC based on TTN's Arduino libraries [39]. TTN protocol together with control for the I/Q radio, backbone radio, FPGA, PMU and decompression algorithm for OTA take only 18% of MCU resources. Also, as shown in Table 4, our timings are well within the requirements for LoRaWAN specifications [26].

We also measure the power consumption of our platform for LoRa packet transmission and reception. LoRa packet transmission with $SF = 9$ and $BW = 500\ kHz$ and radio output power of 14 dBm consumes a total power of 287 mW from which 179 mW is for the radio and the rest is from the FPGA and MCU. LoRa packet reception consumes 186 mW with radio taking 59 mW.

BLE using tinySDR. Next, we evaluate tinySDR using BLE beacons as a case study. First, we measure the impact of our BLE beacons transmitted from tinySDR using the TI CC2650 [21] BLE chip as a receiver. We do this by configuring tinySDR to transmit BLE beacons at a rate of 1 packet per second. We transmit 100 packets and set the CC2650 BLE chip to report bit error rate (BER). Fig. 12 shows the BER as a function of the received RSSI as reported by the CC2650 BLE chip. The plot shows that we achieve a sensitivity of -94 dBm. This is within 2 dB of the CC2650 BLE chipset's sensitivity, defined by a BER threshold of 10^{-3}.

Next we evaluate the latency of our BLE implementation as BLE beacons are typically transmitted in sequence by hopping between three different advertising channels. We measure the minimum time tinySDR takes to switch between these frequencies by connecting its output to a 2.4 GHz envelope detector and using an MDO4104B-6 oscilloscope to measure the time delay between transmissions. Fig. 13 plots the envelope of three BLE beacons in the time-domain transmitted on the different advertising channels and shows that our system can transmit packets with as little as 220 us delay

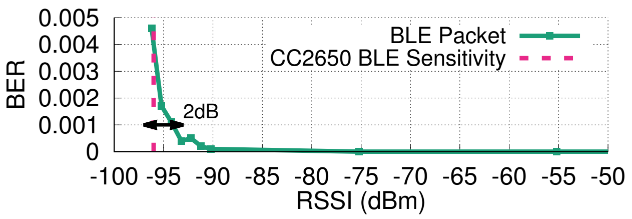

Figure 12: **BLE evaluation.** BLE beacons at different power levels.

between beacons. The corresponding result when a iPhone 8 transmits beacons is 350 us. Finally, generating BLE beacons requires only 3% of the FPGA resources on the tinySDR and it could run for over 2 years on a 1000 mAh battery when transmitting once per second.

5.3 Over-the-Air Programming

An effective OTA programming system should both minimize use of system resources such as power as well as network downtime. Considering the time to reprogram the FPGA and microcontroller from flash is fixed, the downtime for programming a node depends on the amount of data sent and the throughput which varies with SNR.

Raw programming files for our FPGA are 579 kB, however we compress our data using miniLZO. While the exact compression ratio depends on FPGA utilization, our LoRa program compresses to 99 kB and BLE to 40 kB. Our microcontroller programs for both LoRa and BLE are approximately 78 kB and are both compressed to 24 kB. When dividing the files into packets, we would ideally minimize the preamble length and maximize packet length to reduce overhead, however long packets with short preambles lead to higher PER. We choose a preamble of 8 chirps and packets of 60 B which we find balances the trade-off of protocol overhead versus range in our experiments.

To see the impact on a real deployment, we evaluate the time required to program tinySDR nodes in our 20 device testbed shown in Fig. 7. We set up a LoRa transceiver configured with $SF = 8$, $BW = 500\ kHz$ and $CodingRate = 6$ connected to a patch antenna transmitting at 14 dBm as an AP and measure the time it takes to program the tinySDR devices at each location, according to our protocol. We transmit the compressed FPGA and MCU programming data for LoRa and BLE and plot the results as a CDF in Fig. 14. The plots show that the LoRa FPGA requires an average programming time of 150 s while BLE, FPGA, and MCU require 59 s and 39 s respectively due to their smaller file size. Decompressing these received files only takes a maximum of 450 ms. The variation of the programming time between different nodes is caused by the variation in the wireless channel and hence the number of re-transmissions for each tinySDR node is different.

Our OTA programming system components, backbone radio and MCU, consume an average energy of 6144 mJ for receiving a LoRa FPGA update and 2342 mJ for a BLE FPGA update when using 14 dBm output power. Using a 1000 mAh

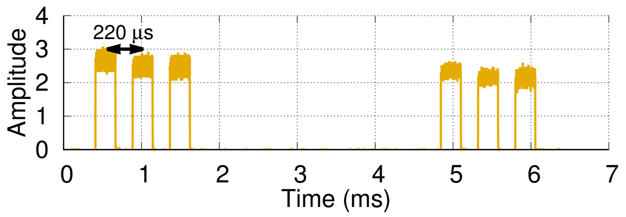

Figure 13: **BLE Beacons Signal.** We show BLE beacon transmissions on three advertising channels from tinySDR using an envelope detector.

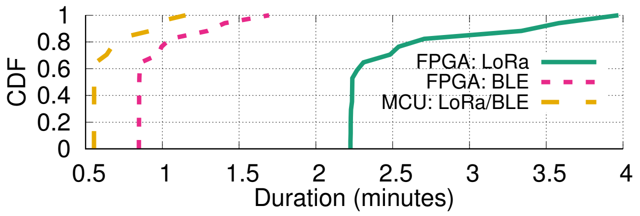

Figure 14: **OTA Programming Time.** We show CDF of OTA programming time for programming LoRa and BLE implementations on tinySDR.

LiPo battery, we could OTA program each tinySDR node with LoRa 2100 times and BLE 5600 times. Assuming OTA programming of once per day, the average power consumption would be 71 uW and 27 uW respectively for LoRa and BLE.

6 Research Study: Concurrent Reception

An SDR designed for IoT endpoints that can provide I/Q transmission and reception capability opens up opportunities for addressing multiple research questions in IoT networks.

In this section, we focus on the following question: Can a *low-power IoT endpoint* device decode multiple concurrent LoRa transmissions at the same time? LoRa supports long range communication for IoT devices and is gaining popularity as a low-power wide area networking (LPWAN) standard. Supporting long ranges introduces new challenges since it increases the probability of collisions in large scale city-wide deployments. While recent works [44, 47] have explored the feasibility of enabling concurrent LoRa transmissions, they have been designed for decoding on a gateway-style USRP device. In fact, most concurrent transmission techniques in our community [44, 45, 52] have been prototyped on USRPs and it is unclear if a low-power IoT endpoint device can decode concurrent transmissions in real-time within its stringent power and resource constraints. TinySDR enables us to explore such questions and design MAC protocols for decoding concurrent transmissions on IoT endpoints.

Using orthogonal LoRa codes. Here we explore a specific way of enabling concurrent transmissions in LoRa: using orthogonal codes. Specifically, to allow multiple LoRa nodes to communicate at the same time, we exploit LoRa's support for orthogonal transmissions [16] which can occupy the same frequency channel without interfering with each other. Two chirp symbols are orthogonal when they have a different chirp slope. For a chirp with a spreading factor of SF and bandwidth of BW, the chirp slope is given by: $\frac{BW^2}{2^{SF}}$ [47].

Decoding concurrent transmissions on tinySDR. In order to receive concurrent LoRa transmissions, tinySDR must be able to demodulate LoRa upchirp symbols with different slopes. Suppose we have two LoRa transmissions that use different spreading factor and bandwidth configurations: SF_1, BW_1 and SF_2, BW_2. To decode them concurrently, we implement decoders similar to Fig. 6b for each chirp configuration in parallel on our FPGA. Specifically, we first generate a corresponding downchirp symbol for each configuration in real-time using our chirp generator. Note that we generate each chirp with its corresponding configuration on the FPGA and we do not use pre-generated chirps on the FPGA. We then correlate the received signals with their corresponding downchirp symbols using time domain multiplication. After correlation, we take the appropriate length FFT of the result.

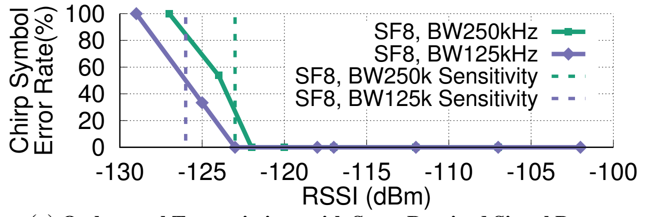
Evaluation. We evaluate three key aspects of our design: 1) the platform's effectiveness in decoding concurrent transmissions across a range of RSSI values, 2) the power consumption at the endpoint device while decoding concurrent transmissions and 3) the computational resources required.

We use two SX1276 LoRa transceivers as our transmitters and set them to transmit continuously at two different settings: they both use a spreading factor of $SF = 8$ but have two different bandwidth setups, $BW_1 = 125kHz$ and $BW_2 = 250kHz$. We set the two to send random chirp symbols. The tinySDR platform decodes these two concurrent transmissions and computes the chirp symbol error rate for each transmission. We evaluate two scenarios: 1) when the two transmitters have a similar power level at the receiver, 2) fix the power of one of the transmitters and increase the power of the other one.

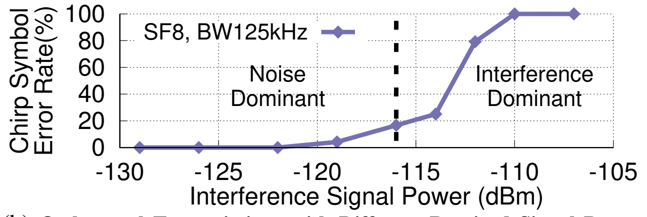
Fig. 15a shows the results when the two transmissions have similar power at the receiver. We lose around 2 dB and 0.5 dB sensitivity for concurrent demodulation of LoRa configurations with $BW_1 = 125kHz$ and $BW_2 = 250kHz$. This is because while in theory the two chirps are orthogonal, in practice, the chirps are created in the digital domain with discrete frequency steps which introduces some non-orthogonality.

Fig. 15b shows the results when the first LoRa transmitter $BW_1 = 125kHz$ is received near its sensitivity of -123 dBm and and the second LoRa transmitter changes its power. Here, the chirp symbol error rate is affected when the other transmission's power is higher than -116 dBm. When two concurrent transmissions are present, one acts as an interferer when decoding the other. The combined power of noise and the interferer, $P_{I,N}$, determines the error rate. When sweeping the power of interferer, at first the $P_{I,N}$ is dominated by noise and we should not see much effect on error rate. Then at some point their power would be equal which results in a 3 dB increase of $P_{I,N}$ and hence 3 dB sensitivity loss after which the error rate is determined by the interferer power. This demonstrates the need for power control for concurrent transmissions to be received on IoT endpoints.

Our parallel demodulation implementation, uses only 17% of the FPGA resources. This concurrent demodulation imple-



(a) **Orthogonal Transmissions with Same Received Signal Power.**



(b) **Orthogonal Transmissions with Different Received Signal Power**. We set the power of LoRa transmission with $BW_1 = 125kHz$ to -123 dBm and increase the power of the other one.

Figure 15: **Orthogonal LoRa Demodulation Evaluation**

mentation consumes 207 mW. Note that Semtech gateway solutions such as the SX1308 [29] can receive multiple transmissions. But, to the best of our knowledge we are the first to show that concurrent LoRa transmissions can be decoded on an IoT endpoint while meeting its power and computational requirements. This would have been difficult to do without tinySDR.

7 Conclusion and Research Opportunities

This paper presents the first SDR platform specifically tailored to the needs of IoT endpoints that can be used for large scale IoT network deployments. The goal of tinySDR is to provide a platform that can catalyze research in IoT networks.

Research on PHY/MAC protocols. TinySDR presents an opportunity for researchers to avoid the time consuming endeavor of building their own custom hardware and instead focus on PHY/MAC protocol innovations across the stack: What is the trade-off between packet length and overall throughput? Are there benefits of rate adaptation? What about concurrent transmissions from IoT devices? One could also create multi-hop IoT PHY/MAC innovations, which have not been explored well given the lack of a flexible platform.

Research on IoT localization. TinySDR could also be used to build localization systems as it gives access to I/Q signals and therefore phase across the 2.4 GHz and 900 MHz bands, which forms the basis for many localization algorithms [62]. One could also explore distributed localization solutions that combine the phase information across a distributed set of sensors to create a large MIMO sensing system.

Machine learning on IoT devices. The FPGA on tinySDR opens up exciting opportunities [42] for exploring machine learning algorithms on-board. This would allow researchers to explore trade-offs between the power overhead of running an on-board classifier versus sending data to the cloud. This could also enable use of high bandwidth sensors such as cameras and microphones where the power bottleneck may be communication rather than sensing.

Low power backscatter readers. Recent work on ambient backscatter [51, 53, 54, 59, 71] aims to achieve ultra-low power communication for IoT devices. Many of these proposals require either a single-tone generator [54] or a custom receiver to decode the backscatter transmissions [49, 50, 61, 65]. TinySDR can be used as a building block to achieve a battery-operated backscatter signal generation and receiver.

Better programming interface and protocols. In addition to IoT research opportunities, we can also improve our platform in multiple ways. TinySDR currently requires users to write Verilog or VHDL to program the FPGA and C code for programming the microcontroller. Future versions can incorporate a pipeline to use high level synthesis tools or integrate with GNUradio for easy prototyping. Further, tinySDR uses a simple MAC protocol for programming with a focus on using minimal system resources to allow for other custom software; however we could explore modified MAC protocols that simultaneously broadcast the updates across the network to reduce programming time.

Acknowledgments. We thank Aaron Schulman, Mohamad Katanbaf, and the anonymous reviewers for their helpful feedback on the paper. This work was funded in part by NSF awards CNS-1812554, CNS-1452494, CNS-1823148 and Google Faculty Research Awards.

RFocus: Beamforming Using Thousands of Passive Antennas

Venkat Arun and Hari Balakrishnan
MIT, CSAIL
{venkatar, hari}@csail.mit.edu

Abstract

To reduce transmit power, increase throughput, and improve range, radio systems benefit from the ability to direct more of the transmitted power toward the intended receiver. Many modern systems beamform with antenna arrays for this purpose. However, a radio's ability to direct its signal is fundamentally limited by its size. This limitation is acute on IoT and mobile devices, which are small and inexpensive, but even access points and base stations are typically constrained to a modest number of antennas.

To address this problem, we introduce *RFocus*, which moves beamforming functions from the radio endpoints to the environment. RFocus includes a two-dimensional surface with a rectangular array of simple RF switch elements. Each switch element either lets the signal through or reflects it. The surface does not emit any power of its own. The state of the elements is set by a software controller to maximize the signal strength at a receiver, with a novel optimization algorithm that uses signal strength measurements from the receiver. The RFocus surface can be manufactured as an inexpensive thin "wallpaper". In one floor of an office building (at MIT CSAIL), our prototype improves the median signal strength by $9.5\times$ and the median channel capacity by $2.0\times$.

1 Introduction

Many radio systems use directional or sectorized antennas and beamforming to improve the throughput or range of a wireless communication link. Beamforming ensures that a larger fraction of transmitted energy reaches the intended receiver,while reducing unintended interference. A radio with many antennas spread densely over a large area can fundamentally beamform better than a smaller radio [1, 4]. However, there are many practical challenges to making radio systems with large antenna arrays. First devices such as IoT sensors and handhelds must be small in size. Second, connecting each antenna in an array to full-fledged radio transmit/receive circuitry increases cost and power. Third, large, bulky systems are hard to deploy, even in infrastructure base stations or access points.

To address these challenges and achieve the equivalent of a large number of antennas, we propose *RFocus*. RFocus includes a *software-controlled surface* placed in the environment, made up of thousands of simple switching elements. RFocus also has a *controller* that configures each element so that the surface, as a whole, directs a signal from a transmitter to a receiver without any signal amplification (i.e., no extra power) or knowledge of the locations of the transmitter or receiver. This approach moves the task of beamforming from the transmitter to the surface. Any device in the vicinity of the surface can reap the benefits of RFocus without itself being large or consuming additional energy.

The RFocus surface is made up of thousands of simple elements organized in a rectangular array. To reduce cost and energy, each element is a single simple 2-way RF switch. Each element in the RFocus surface can be in one of two states. When "on", the element reflects the signal; otherwise, the signal passes through. Each receiver periodically sends measurements of the received signal strength to the RFocus controller. The controller uses these to configure the elements on the RFocus surface to maximize the received signal strength. This optimization has two steps: a training phase, where the controller configures test states on the surface and monitors the changes in the reported measurements to collect data, and an optimized phase where the controller uses this data to set the on/off state for each element. RFocus can switch between optimized states to maximize signal strength between different pairs of endpoints.

RFocus can work both as a "mirror" or a "lens", with the controller choosing the right mode. That is, radio endpoints can be on the same side of the surface, or on opposite sides.

We have built an RFocus prototype with 3,200 inexpensive[1] antennas on a 6 square-meter surface. This configuration may well be the largest published number of antennas ever used for a single communication link.

The controller's optimization algorithm solves three key challenges. First, indoor environments exhibit complex multi-path, and the direct path may be blocked. Therefore the optimal configuration might not correspond to directing the signal along a single direction, but can depend on the environment. Second, the effect of an individual element on the channel is usually miniscule, and hence hard to measure (§6.2.3). Third, the phase of a channel is hard to

[1] At scale, the cost of each element is a few cents.

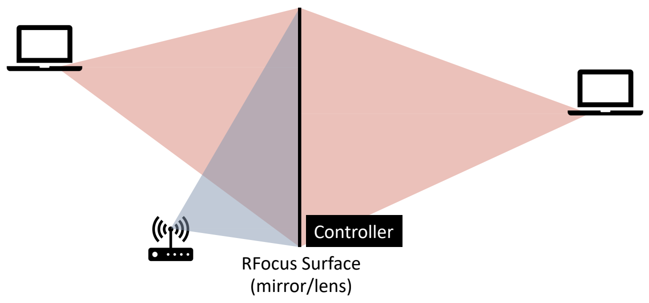

Figure 1: RFocus is an electronically configurable mirror/lens that focuses the transmitter's signal on the receiver.

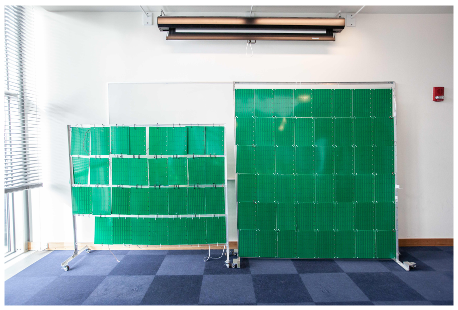

Figure 2: Our prototype of the RFocus surface.

measure when the signal is weak, due to carrier frequency offset and radio-clock jitter. And last but not least, commodity radio receivers usually don't report phase.

The contributions of this paper include:

1. The RFocus controller, incorporating two key ideas. First, it modulates all elements at once to boost the effect of the RFocus surface on the channel, hence making the change large enough to be measurable. Second, it relies only on signal strength measurements, sidestepping difficulties in measuring phase. We provide an analysis of the algorithm under some assumptions, that suggests that it finds a solution that is close to optimal.

2. Experiments, which show that in a typical indoor office environment, RFocus achieves a median $9.5\times$ improvement in signal strength and $2.0\times$ improvement in channel capacity. Moreover, RFocus is robust to element failure; even when one-third the elements fail, the relative performance improvement does not plummet to 0, but drops by 50%.

2 Related Work

Passive reflective surfaces to control incident radiation, called "meta-surfaces" have been studied extensively by applied physicists in the microwave, terahertz, and optical frequencies [2, 6–8, 13]. These works focus on hardware design to control the incident radiation efficiently. Some of these metasurfaces are configurable. Here, given the incident wave and desired reflected/transmitted wave direction(s), they develop algorithms to determine good configurations, for example to create programmable holograms. Recently there has been interest in using metasurfaces, called "reconfigurable intelligent surfaces", to improve communication channels. Most papers explore the idea with theory and simulation [12, 17–19, 28] except for a few papers providing small-scale experimental results [11, 15, 29] that evaluate channel improvement between one fixed pair of endpoints that are close to each other and to the surface.

In prior work, the method to determine a good configuration works by varying the state of the elements *one at a time* and measuring its effect on the channel. This approach is linear in the number of elements, but requires the receiver to be able to accurately measure the impact of the change in a single element. If the transmitter and receiver are very close to the surface, the effect is measurable, but not otherwise because the strength of the signal attenuates as at least $1/(d_s d_r)^2$, where d_s and d_r are the distances from the element to the sender and receiver, respectively. For a large surface with thousands of antennas, the effect becomes hard to measure because some elements will necessarily be at long distances from the transmitter or receiver §6.2.3. The reason is that the size of each element is between one-quarter to one-half of the wavelength of the signal (at 2.4 GHz, the wavelength is 15 cm), so thousands of elements require a surface area of a few square meters, and at a distance of a few meters, measuring a single-element change is inaccurate especially on commodity radio receivers. Our algorithm overcomes this problem and scales to larger surfaces by varying many elements at once and boosting the signal strength changes being measured.

LAIA [16, 32] is a recent project that also achieves gains at larger distances, but with a different setup and design from RFocus. LAIA helps endpoints whose line-of-sight path is blocked by a wall. LAIA elements collect radio energy from one side of the wall, phase-shift them, and take them to the other side of the wall via wires traversing holes in the wall. Because they go through the wall with wires, individual LAIA elements have a much larger impact on the channel than RFocus elements, allowing LAIA to function with fewer elements than RFocus, and without RFocus's optimization algorithm.

Another line of related work improves wireless coverage by analyzing the indoor space, and custom-designing a 3D reflector for that space. When 3D-printed and placed behind an access point (AP), the reflector reflects energy in specific directions to maximize signal strength at previously uncovered areas [5, 33]. Once deployed, this reflector has a low operational cost because it is just a passive metal-coated object. But a new reflector needs to be designed for each new location and whenever the space changes or the AP is moved or a new AP is added. Moreover, a single solution has to be designed for all pairs of endpoints, whereas RFocus dynamically and automatically configures a new pattern for each pair.

RFocus can be thought of as a phased array [25, 26] that uses the air instead of transmission lines to distribute signals from the transmitter to the antennas. We believe this allows larger antenna arrays to be deployed more ubiquitously. Transmission lines tend to be expensive and bulky. Even PCB-trace transmission lines, which are easy to manufacture, depend on properties of the dielectric and cannot be manufactured as a paper-thin sheet. This is unlike the wires used in RFocus, which are digital and do not carry high-speed signals. Due to its simplicity, RFocus can be readily incorporated into the environment (§7). On the other hand, for the same number of antennas, RFocus achieves a lower gain than phased arrays because it doesn't harness all of the transmitted energy (§7).

Digital Light Processors (DLPs) and Digital Micromirror Devices (DMDs) [22, 23, 27] are micro-electro-mechanical systems (MEMS) devices that have a large array of small (microns or smaller) mirrors on a single silicon chip. The mirrors can be toggled between two angles, controlling which ones reflect light onto the object, and which reflect it elsewhere. They are used for steering lasers and in display projectors. RFocus could be thought of as a DMD for radio.

Range extenders increase signal strength at the receiver. However, by rebroadcasting signals, they increase interference and reduce transmission opportunities. By precisely focusing energy already available, RFocus decreases interference while increasing signal strength. That said, RFocus complements range extenders and both could be used together if necessary.

Reconfigurable antennas [10] and reflectarray antennas [14] have RF switches and phase shifters, which allow them to dynamically change their characteristics such as operating frequency, input impedance, and directionality. These approaches modify an antenna to improve characteristics. By contrast, RFocus leaves the transmit and receive antennas unmodified, instead modifying the environment to improve communication for all nearby devices. Additionally, like phased arrays, it is difficult to use wires to scale to a large number of radiating elements.

3 Background

3.1 System Model and Notation

In most environments, there are multiple paths between a sending and receiving antenna. For a narrow-band signal, the effect of each path can be represented by a complex number. The net effect of the channel is the sum of the effects of all the paths. A subset of the paths pass via each of the N elements on the RFocus surface. Denote the contribution of the elements by $c_1, \ldots, c_N$. We combine all the paths *not* going via RFocus into one complex number c_E (E for environment). The net channel, h, is equal to $c_E + \sum_{i=1}^{N} \alpha_i c_i$, where α_i represents the amplitude change and phase shift introduced by element i.

RFocus controls the channel, h, by adjusting α_i. c_E and c_i are functions of the path lengths. α_i depends on three factors: the state of the i^{th} element and its neighbors; the shape of the antennas composing the element, and the angles at which the path enters and leaves the i^{th} element. Since the elements are passive and lack power, $|\alpha_i| \leq 1$.

Maximizing $|h|$ maximizes the received signal strength. The maximum possible value of $|h|$, the sum of several complex numbers, is the sum of the magnitudes of the summands:

$$|h_{\max}| = |c_E| + \sum_{i=1}^{N} |c_i| \tag{1}$$

This maximum is achievable if we had full control over each α_i by setting $\alpha_i = \frac{c_E}{|c_E|}\frac{c_i^*}{|c_i|}$, where c_i^* denotes conjugation. Unfortunately, we do not have full control over α_i. Each element can only be on or off. If we assume that α_i is a function of only the i^{th} element's state and not its neighbors (we validate this assumption with experiments in §6.2.1), then we can write the channel as

$$h = h_Z + \mathbf{h} \cdot \mathbf{b} = h_Z + \sum_{i=1}^{N} \mathbf{h}^{(i)} \mathbf{b}^{(i)} \tag{2}$$

Here $\mathbf{b}^{(i)} \in \{0, 1\}$ denotes whether the i^{th} element is off or on; h_Z is the channel when all elements are off; and $\mathbf{h}^{(i)}$ is the effect of turning the i^{th} element on. Here, we have folded the complexities of α_i into c_i to get $\mathbf{h}^{(i)}$. We in prove in §5.2 that having the ability to set *any* $|\mathbf{b}^{(i)}| \leq 1$ (i.e., fine-grained control over the phase) instead of only 0 or 1 gives only a factor-of-π advantage in optimizing $|h|$.

3.2 How Size Helps Communication

To get a qualitative understanding of the benefits of RFocus, we use some well known results from physics. First, RFocus can only control the portion of transmitted energy that falls on it. This is given by the solid angle, Ω, subtended by the surface on the transmitter. The Abbe diffraction limit tells us how well the surface can focus the energy at the receiver. If the surface modulates the incident energy perfectly, the spot onto which the energy is focused will have an area a proportional to $\lambda^2\left(1 + 4\frac{d^2}{A}\right)$, where A is the area of the RFocus surface and d is the distance of the receiver from it [20]. Thus a fraction $\Omega/(4\pi)$ of the transmitted energy is now spread over an area $\approx a$, and hence peak energy will be proportional to Ω/a. RFocus works best when either the transmitter or the receiver is close to the surface, and therefore Ω is large (as a rule of thumb, about 3 meters for a surface 2-3 meters in length/width). Note, the Abbe diffraction limit is only an approximate result.

A/d^2 is proportional to the angle subtended by the surface on the receiver. There are two regimes depending on how large this angle is. If the radio is far away from the surface (i.e. $d^2 \gg A$), then $a \underset{\sim}{\propto} d^2/A$ and energy falls as $A\Omega/d^2$. This is still a $1/d^2$ fall, but the constant is improved by a factor of $A\Omega$. If

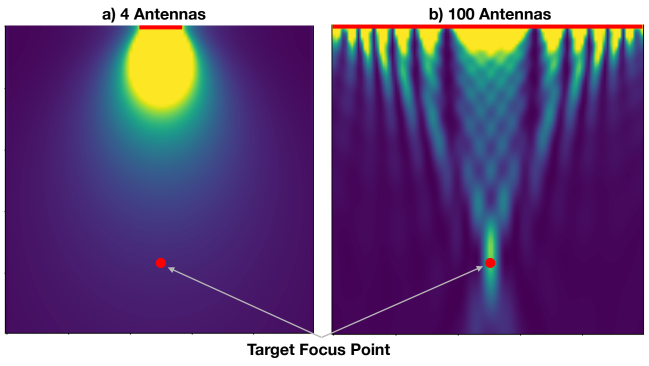

Figure 3: A simulation of how signal strength (brighter is higher) is distributed when an antenna array tries to maximize signal strength at the target point. The antennas are on the top horizontal line (red). With four antennas the signal quickly begins to diffuse. The 100 antennas subtend a large angle at the target, and are hence able to focus energy there, avoiding attenuation due to spreading.

the radio is closer, then $d^2 \sim A$, and the first term dominates. In this regime, a can be made quite small, on the order of a few λ^2. Hence almost all of the transmitted energy can be incident on the receiver.

In traditional beamforming, A is typically small, hence $d^2 \gg A$ and we are always in the first regime where the signal experiences a $1/d^2$ attenuation as it spreads out. The difference between the two regimes is illustrated in Figure 3.

4 Optimization Algorithm

The RFocus controller uses measurements from the radio endpoints to maximize signal strength at the receiver. In this section we first describe the challenges in measuring changes in the channel, and why we rely only on RSSI measurements (§4.1). Then we describe our algorithm (§4.2) before giving a preliminary theoretical analysis showing that it converges to a near-optimal solution (§4.3).

4.1 Measuring the Channel

A direct, but naive, method: When all the elements are turned off, the channel is h_Z, by definition. Ideally, to measure each $\mathbf{h}^{(i)}$, we could turn just the i^{th} element on, and measure the difference from h_Z. But this change is usually too feeble to measure because an element is just a small piece of metal lying somewhere in the environment (§6.2.3). In many cases, we cannot statistically tell the difference between an element being on or off, even with hundreds of samples. This is also the reason why gradient descent to find an optimal configuration is untenable.

Boosting the signal. Each $\mathbf{h}^{(i)}$ may be small, but all the elements together can have a large effect. To make the change measurable, we generate several configurations of the surface by randomly choosing the state of each element. If we vary N elements, the change in the channel will have an expected magnitude of $O(\bar{h}\sqrt{N})$ (due to the central limit theorem), where $\bar{h}$ is the average magnitude of $\mathbf{h}^{(i)}$. This gives us a $O(\sqrt{N})$ boost in amplitude (and $O(N)$ boost in signal strength) over flipping just one element.

Challenges in measuring phase. One might consider a method that would measure the (complex) channel for many random configurations of the surface, and solve the linear equations to obtain all the $\mathbf{h}^{(i)}$. But this is difficult because it needs to measure changes in the *phase* of the channel, which commodity wireless devices don't provide. More importantly, the change in the channel, even after this $O(\sqrt{N})$ boost, remains small. Measuring small changes in phase is hard because the clocks of the transmitter and receiver are never perfectly synchronized, leading to carrier frequency offset (CFO) and jitter in phase measurements. Correcting for CFO over long periods of time is non-trivial, since CFO drifts over time.

Using RSSI. Our method uses only signal-strength measurements, ignoring phase information altogether. RSSI is not always an absolute metric, and may vary due to automatic-gain control changes or temperature changes at the amplifier. Hence we measure RSSI of a test state *relative* to a baseline state; e.g., to the all-zeros state where all elements are turned off. We call this quantity the *RSSI-ratio*.

4.2 RFocus's Optimization Algorithm

Algorithm 1 The majority voting algorithm (described below)

```
procedure MajorityVote([$\mathbf{b}_1,\ldots,\mathbf{b}_K$], RSSI)
    // RSSI[$j$] gives the measured RSSI-ratio for state $\mathbf{b}_j$
    $\mathbf{b}_\perp \leftarrow$ blank-vector            ▷ The final optimized state
    $m \leftarrow$ Median(RSSI)
    for $i := 0$ to $N$ do
        VoteOn $\leftarrow 0$, VoteOff $\leftarrow 0$
        for $j := 0$ to $K$ do
            if
                ($\mathbf{b}_j^{(i)} == 1$ and RSSI[$j$] $> m$) or
                ($\mathbf{b}_j^{(i)} == 0$ and RSSI[$j$] $< m$) then
                VoteOn $\leftarrow$ VoteOn $+ 1$
            else
                VoteOff $\leftarrow$ VoteOff $+ 1$
        $\mathbf{b}_\perp^{(i)} \leftarrow$ (VoteOn $>$ VoteOff)
    return $\mathbf{b}_\perp$
```

Given the measured RSSI-ratio for a set of K random configurations, the idea is to compare the RSSI-ratio of each measurement to the median value: if the RSSI-ratio when the i^{th} element is on (off) is higher than the median, then we add a vote for the element to be on (off) in the optimized configuration. The i^{th} element's optimized state is the state that received more votes for that element. Algorithm 1 gives the pseudo-code for how the controller determines the optimized state for each bit, i.

We use the median instead of the mean of the RSSI-ratio samples because it is more robust to one-shot noise, which may occur due to people moving or amplifier changes. We expect this algorithm to be robust to element failure and occluded elements, since elements' states are determined independently of each other. We evaluate how the received signal strength of the optimized configuration degrades with element failures in Section 6.4.

4.3 Theoretical Analysis

We show that if each $\mathbf{h}^{(i)}$ is small and the collection has uniformly-distributed phases, the optimization algorithm will find a near-optimal solution with high probability.

4.3.1 Assumptions

The proof relies on the following assumptions:

Assumption 1. *The phases of* $\mathbf{h}^{(i)}$ *are uniformly distributed random variables in* $(-\pi,\pi]$.

This is reasonable because the paths to different elements are of different lengths, so all phases are equally likely to be represented. To remove any spatial correlations, we can randomize the indices of $\mathbf{h}^{(i)}$.

Assumption 2. *For uniformly random* $\mathbf{b}$, $|\mathbf{b}\cdot\mathbf{h}| \ll h_Z$ *with high probability.*

The average of $\mathbf{h}^{(i)}$ is 0 when phases are uniformly random. Hence, assumption 1 implies that for uniformly random $\mathbf{b}$, $|\mathbf{h}\cdot\mathbf{b}|$ is $O(\frac{1}{\sqrt{N}}\sum_{i=1}^{N}\left|\mathbf{h}^{(i)}\right|)$ due to the central limit theorem.

Though $|\mathbf{h}\cdot\mathbf{b}|$ is small for random $\mathbf{b}$, an *optimal* assignment to $\mathbf{b}$ can cause $|\mathbf{h}\cdot\mathbf{b}|$ be large relative to $|h_Z|$, since it will be $O(N)$ times bigger than the average $|\mathbf{h}^{(i)}|$ (see theorem 2). On the other hand, for random $|\mathbf{b}|$, $|\mathbf{h}\cdot\mathbf{b}|$ is only $O(\sqrt{N})$ times bigger than the average $|\mathbf{h}^{(i)}|$.

Assumption 3. $|\mathbf{h}^{(i)}|$ *is bounded above by a constant, even as* $N\to\infty$.

With this assumption, $\left|\mathbf{h}^{(i)}\right| \ll \sum_{j=i}^{N}\left|\mathbf{h}^{(j)}\right|$, capturing the intuition that, since all elements are small, there is no dominating element. Many elements must contribute to create a large effect.

Note that an RFocus element is only half a wavelength long when on. This implies that, individually, an element cannot be very directional [9]. Hence, the reflections are not specular. Rather, each element diffracts waves to a wide range of angles. Hence, we would expect all the $\mathbf{h}^{(i)}$ to have a similar (likely, small) magnitude. However, acting together, the elements form a large structure which which c which and can beconfigured to achieve directionality (§3.2). In addition, we assume that equation 2 is accurate, which we later verify experimentally (see §6.2.1). Our analysis is in the limit where the number of elements and the number of measurements go to infinity.

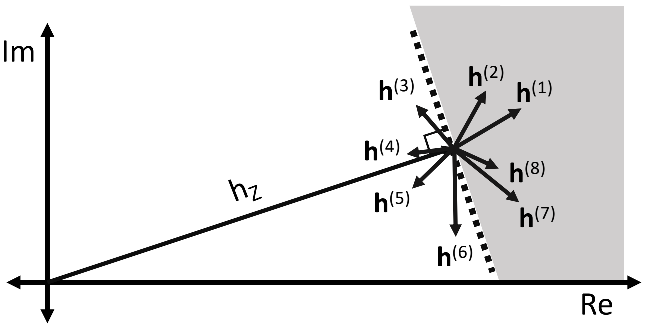

Figure 4: h_Z and the $\mathbf{h}^{(i)}$ in the complex plane. To maximize signal strength, we should pick the $\mathbf{h}^{(i)}$ in the shaded region and remove the others.

4.3.2 Proof Outline

Consider h_Z and $\mathbf{h}^{(i)}$ on the complex plane as shown in Figure 4. The signal strength is $|h_Z+\sum_i \mathbf{h}^{(i)}\mathbf{b}^{(i)}|^2$. If all the elements are turned on, the $\mathbf{h}^{(i)}$ interfere destructively with each other. To increase signal strength, we should eliminate this destructive interference. To do so, we should pick a half-plane (the dotted line), turn on all elements on one side of it and turn the others off. We show in Lemma 1 that the optimal solution takes this form.

Next, if the phases of $\mathbf{h}^{(i)}$ are randomly distributed, it doesn't matter which half-plane we pick; they will all produce roughly the same $|\mathbf{b}\cdot\mathbf{h}|$ (Lemma 2). Hence, we can maximize alignment with h_Z by picking the half-plane perpendicular to it (pictured in the figure).

The controller needs to determine for each element i if $\mathbf{h}^{(i)}$ is aligned with h_Z. Or equivalently, whether $\Re(\mathbf{h}^{(i)}h_Z^*) > 0$ where $\Re(\cdot)$ denotes the real component of a complex number and * denotes complex conjugation. The algorithm takes advantage of the fact that if $\Re(\mathbf{h}^{(i)}h_Z^*) > 0$, the signal strength is slightly more likely to be higher than the median signal strength when $\mathbf{h}^{(i)}$ is turned on (Theorem 1).

4.3.3 A Near-Optimal Solution

We show that all the chosen $\mathbf{h}^{(i)}$ in an optimal solution lie on one side of a line in the complex plane, formalized as follows:

Lemma 1. *Under assumptions 2 and 3, let* $\mathbf{b}_{OPT}$ *be an optimal state assignment. Then,* $\mathbf{b}_{OPT}^{(i)} = 1$ *if and only if* $\Re(\mathbf{h}^{(i)}\cdot H(\mathbf{b}_{OPT})^*) > 0$, *where* $H(\mathbf{b}) = h_Z + \mathbf{h}\cdot\mathbf{b}$.

Proof. If this were not the case, we could flip $\mathbf{b}_{OPT}^{(i)}$ to get

$$\begin{aligned}
&|H(\mathbf{b}_{OPT})-\mathbf{b}_{OPT}^{(i)}\mathbf{h}^{(i)}+\left(1-\mathbf{b}_{OPT}^{(i)}\right)\mathbf{h}^{(i)}| \\
&=\left|H(\mathbf{b}_{OPT})+\left(1-2\mathbf{b}_{OPT}^{(i)}\right)\mathbf{h}^{(i)}\right| \qquad (3)\\
&\geq |H(\mathbf{b}_{OPT})|
\end{aligned}$$

To prove the last inequality, note

$$\begin{aligned}
&\left|H(\mathbf{b}_{OPT})+\left(1-2\mathbf{b}^{(i)}\right)\mathbf{h}^{(i)}\right|^2-|H(\mathbf{b}_{OPT})|^2 \\
&=\left|\left(1-2\mathbf{b}^{(i)}\right)\mathbf{h}^{(i)}\right|^2+2\Re\left(\left(1-2\mathbf{b}^{(i)}\right)\mathbf{h}^{(i)}\cdot H(\mathbf{b}_{OPT})^*\right) \qquad (4)\\
&\approx 2\Re((1-2\mathbf{b}^{(i)})\mathbf{h}^{(i)}\cdot H(\mathbf{b}_{OPT})^*)\\
&\geq 0
\end{aligned}$$

The second-last approximation follows because $|\mathbf{h}^{(i)}|$ is bounded and hence $|\mathbf{h}^{(i)}| \ll h_Z \leq |H(\mathbf{b}_{OPT})|$. The last inequality holds if our condition on $\mathbf{b}_{OPT}^{(i)}$ is not satisfied. If so, the solution can be improved, which contradicts our assumption that $\mathbf{b}_{OPT}$ is optimal. □

The next lemma states that the solution pictured in Figure 4 is close to optimal with high probability as the number of elements $N \to \infty$.

Lemma 2. *Let $\mathbf{b}_{OPT}$ be the optimal assignment that maximizes $|h_Z+\mathbf{h}\cdot\mathbf{b}|$ and $\mathbf{b}_\perp$ be such that the i^{th} component $\mathbf{b}_\perp^{(i)}=1$ if and only if $\Re(\mathbf{h}^{(i)}\cdot h_Z^*)>0$. As $N\to\infty$, if assumptions 1 and 3 hold, then $|H(\mathbf{b}_{OPT})|/|H(\mathbf{b}_\perp)|<1+\varepsilon\ \forall\varepsilon>0$, with high probability.*

The proof is in Appendix A. We give the outline here. Let $\mathbf{b}_\theta$ be the state such that $\mathbf{b}_\theta^{(i)}=1$ iff $\Re(\mathbf{h}^{(i)}e^{-j\theta})>0$. We show that, since the phases of $\mathbf{h}$ are uniformly distributed, it does not matter what θ we pick. That is, $\max_\theta|\mathbf{b}_\theta\cdot\mathbf{h}|$ isn't very different from $\min_\theta|\mathbf{b}_\theta\cdot\mathbf{h}|$. Hence, we can pick θ to be the phase of h_Z to prove the theorem.

4.3.4 Analysis of the Algorithm

We prove that Algorithm 1 finds the near-optimal solution discussed in Lemma 2.

Theorem 1. *Let assumptions 1, 2, and 3 hold. Then, as $N\to\infty$ and $K\to\infty$, the configuration returned by Algorithm 1 finds a near-optimal solution.*

Proof. According to Equation 2, when we randomly vary $\mathbf{b}^{(i)}$, h becomes a random variable, H, with mean $h_Z+S/2$, where $S=\sum_{i=1}^N\mathbf{h}^{(i)}$ is the sum of the contributions of the rest of the elements. The $S/2$ term appears because we include each element with probability $1/2$. Figure 5(a) shows this probability distribution. Consider an element i that hasn't yet been fixed. If we condition the probability distribution on the $i$thelement being on, then the PDF shifts by $\mathbf{h}^{(i)}/2$ as

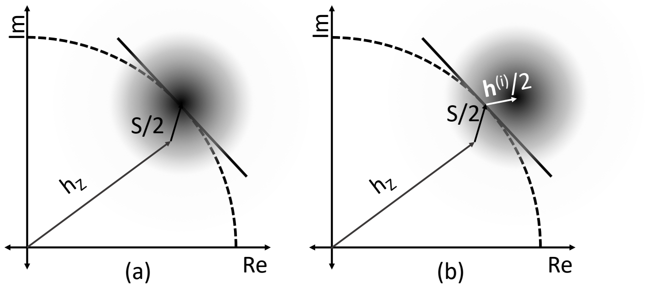

Figure 5: (a) Shows the probability density function of the channel when all bits are chosen uniformly at random. (b) Shows the PDF conditioned on the i^{th} bit being 'on'. The dashed circle is centered at the origin with radius $|h_Z+S/2|$, where $S=\sum_{i=1}^N\mathbf{h}^{(i)}$. Depending on which side of the circle h_i takes the mean, the mean magnitude will be greater or lesser than that of the unconditional PDF.

shown in Figure 5(b), because the $i$thelement's value is fixed in these samples (it shifts by $\mathbf{h}^{(i)}/2$ and not $\mathbf{h}^{(i)}$ since we have already included the other $\mathbf{h}^{(i)}/2$ in $S/2$). If we condition on the element being off, then the mean shifts by $-\mathbf{h}^{(i)}/2$.

The central limit theorem implies that $H/\sqrt{N}$ is Gaussian as $N\to\infty$. Hence, if $\mathbf{h}^{(i)}/2$ (or $-\mathbf{h}^{(i)}/2$) shifts the mean to be outside the circle, then when the element is on (or off) the RSSI-ratio is more likely to be greater than the unconditional mean. If $\mathbf{h}^{(i)}/2$ shifts the mean inside the circle, then the opposite holds. Here, we use assumption 2, which implies that H isn't shifted far from $h_Z+S/2$. Hence, as $K\to\infty$, Algorithm 1 determines with confidence tending to 100%, whether the conditional mean is inside or outside the circle, by looking at RSSI alone. Note that mean equals median in this case.

Assumption 2 implies that $|\mathbf{h}^{(i)}|\ll|h_Z|$. Thus, the mean shifts outside the circle if and only if it shifts to the outer side of the tangent line shown in figure 5. That is, $\mathbf{b}_\perp^{(i)}=1$ if and only if $\Re\left(\mathbf{h}^{(i)}\cdot(h_Z+S/2)^*\right)$. But $h_Z+S/2\approx h_Z$, because of assumption 2. Hence $\mathbf{b}_\perp^{(i)}=1$ if and only if $\Re\left(\mathbf{h}^{(i)}\cdot h_Z^*\right)>0$. From Lemma 2, we know that this produces a near-optimal solution. □

To a first order approximation, the RSSI-ratio is linear in $\mathbf{b}$.[2] Hence linear regression is an alternative to majority voting. Majority voting has three advantages. First, unlike linear regression, majority voting is robust to outliers. Second, it is conceptually and computationally simpler, which is particularly important when the controller is an embedded device. Third, when the votes for a particular element determine its value with high confidence (say, $>95\%$), it can be fixed for the rest of the training

[2] RSSI-ratio, $|h/h_Z|=|1+\mathbf{b}\cdot\mathbf{h}/h_Z|\approx 1+\sum_i\Re(\mathbf{b}^{(i)}\mathbf{h}^{(i)}/h_Z)$ because $|\mathbf{b}\cdot\mathbf{h}|\ll h_Z$ for random $\mathbf{b}$ and $|1+x|\approx 1+\Re(x)$ for small x.

period. This allows the channel to be improved even before the training ends. Fixing elements also removes the confounding effect they have on determining values for other elements. An earlier version of this paper used this idea [3]. However due to a performance optimization (§6.1), we do not implement it here.

5 Antenna Array Design

We have made two key design choices in the physical design of our antenna array. First, each element has only two states: one that reflects the signal, another that lets it through. Second, each element is half a wavelength tall and $1/10$ of a wavelength wide. In this section we explore the tradeoffs in these choices.

5.1 How Big Should Each Element Be?

An array with many small antennas gives better control over the reflected signal, while one with fewer but larger antennas is cheaper and simpler. If the inter-antenna spacing is larger than half a wavelength, there will be grating lobes where the signal is sent in directions other than the one desired [4].

Designing antennas that are much smaller than a wavelength[3] is challenging. Small antennas are either inefficient, absorbing only a small fraction of incident energy, or they are efficient only over a small bandwidth [21, 31]. Further, when placed close to each other, antennas interact strongly with each other in a way that is often hard to model.

Fortunately, a well understood result states that controlling the reflected wave at a granularity finer than half a wavelength gives only marginal benefits. Consider two infinite parallel planes a distance d apart, separated by a homogeneous medium. Variations in electric/magnetic fields in one plane that are faster than once per wavelength, will have a negligible effect on the fields on the other plane; it decays exponentially with d [24]. Hence any fine-grained variations we introduce in the surface will be lost as soon as the signal propagates a few wavelengths in either direction. Thus we can design an array with antennas comparable to a wavelength and still get most of the benefits. Metasurfaces [6] may enable a more efficient design, but that is out of scope of this work.

5.2 How Many States for an Element?

We chose elements that can be in only one of two states. But we could have chosen a design that offers greater control. Ideally we would be able to control the exact phase and amplitude with which each element reflects its energy. In terms of our model in equation 2, we would have been able to set any $\mathbf{b}^{(i)} \in \mathbb{C}, |\mathbf{b}^{(i)}| \leq 1$, instead of being restricted to $\mathbf{b}^{(i)} \in \{0,1\}$. Denote the amount of energy that can be directed by the surface in the two cases as h_{IDEAL} and h_{REAL}. In the ideal system, we would be able to align the phases of all $\mathbf{h}^{(i)}$ to get $|h_{IDEAL}| = \sum_i |\mathbf{h}^{(i)}|$. We show here that $|h_{REAL}| \geq |h_{IDEAL}|/\pi$.

Here $|h_{REAL}|$ and $|h_{IDEAL}|$ include only the signal due to the surface ($|\mathbf{h}\cdot\mathbf{b}|$) and not the rest of the environment (h_Z). To maximize signal strength, we would need to align the phases with h_Z too. If we assume that phases are random (assumption 1), we can also prove the result when $|h_{REAL}|$ and $|h_{IDEAL}|$ include h_Z. We discuss this as a corollary of lemma 3 in Appendix A.

Theorem 2. *Under assumptions 2 and 3,* $|h_{REAL}| \geq \frac{|h_{IDEAL}|}{\pi}$ *as* $N \to \infty$.

Proof. Define $A = \int_{-\pi}^{\pi} \sum_{i=1}^{N} |\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta})| d\theta$. $\Re(\cdot)$ denotes the real part of a complex number. The variable A expresses the sum of components of $\mathbf{h}^{(i)}$ along angle θ and integrates over all θ. Each θ corresponds to a perpendicular to a half-plane, as discussed before in Lemma 1. At least one of these, θ_0, corresponds to the optimal half-plane, wherein the optimal solution contains all the $\mathbf{h}^{(i)}$ such that $\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta_0}) > 0$. These contribute $\mathbf{h}^{(i)}$ toward h_{REAL}. Thus,

$$|h_{REAL}| \geq \sum_{i=1}^{N} \max\left\{0, \Re\left(\mathbf{h}^{(i)} \cdot e^{-j\theta_0}\right)\right\} \geq \frac{1}{2}\sum_{i=1}^{N}\left|\Re\left(\mathbf{h}^{(i)} \cdot e^{-j\theta_0}\right)\right| \tag{5}$$

The first inequality holds because the absolute value (LHS) is greater than the real component (RHS). The second inequality holds because otherwise we could have chosen $\pi + \theta_0$ and obtained a better $|h_{REAL}|$. Hence $|h_{REAL}| \geq \frac{1}{2}\max_{\theta\in[\pi,\pi)} \sum_{i=1}^{N} |\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta})| \geq \frac{1}{2}\frac{1}{2\pi}\int_{-\pi}^{\pi}\sum_{i=1}^{N} |\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta})|\, d\theta = \frac{A}{4\pi}$, since the maximum is greater than the average.

Separately, we can rearrange the sum as $A = \sum_{i=1}^{N} \int_{-\pi}^{\pi} |\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta})|\, d\theta = \sum_{i=1}^{N} |\mathbf{h}^{(i)}| \left(\int_{-\pi}^{\pi} |\cos\theta|\, d\theta\right)$. The second step is possible, because $\cos\theta$ expresses the dot product of $\mathbf{h}^{(i)}$ over a unit complex number with phase θ. Since we are integrating over all angles, it doesn't matter which angle we start from. Now we can evaluate the integral to get $A = 4\sum_{i=1}^{N} |\mathbf{h}^{(i)}| = 4|h_{IDEAL}|$. Since $|h_{REAL}| \geq \frac{A}{4\pi}$, $|h_{REAL}| \geq \frac{|h_{IDEAL}|}{\pi}$. □

Alternate designs. We could design an alternate system where $\mathbf{b}^{(i)} \in \{-1, 1\}$ instead of $\mathbf{b}^{(i)} \in \{0, 1\}$. That is, the elements either reflect signal directly or with a 180^o phase difference. In this case, we'd get a $2/\pi$-approximation, which is better than the $1/\pi$ factor we get now. This is because we would have had $\max\{\Re(\mathbf{h}^{(i)} \cdot e^{j\theta_0}), \Re(\mathbf{h}^{(i)} \cdot e^{-j\theta_0})\}$, which removes the $1/2$ factor in equation 5. On the other hand, while our setup can function as both a mirror and a lens (i.e. it can be selectively transparent), this alternate design can only operate as one of the two. A four-state system could potentially offer the benefits of both, a good topic for future work.

5.3 Our Design

Our surface design consists of a panel of metal rectangles of size $\lambda/4 \times \lambda/10$ as shown in Figure 6, where λ denotes

[3]These are called "electrically small antennas".

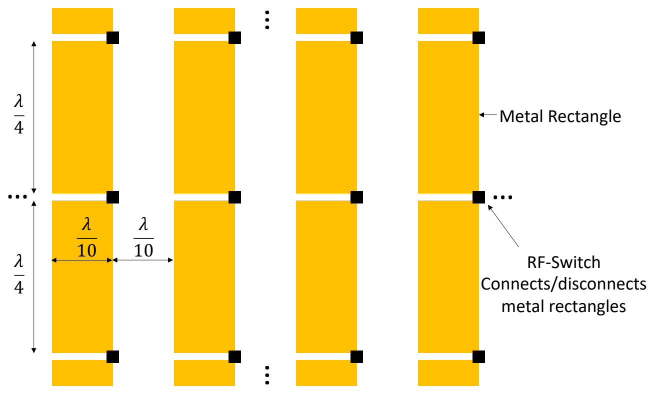

Figure 6: Schematic of the design of our antenna array. This array of rectangles continues in both directions.

the wavelength. They are connected by RF switches, which determine whether or not the rectangles are connected (the switches are placed off-center for practical PCB-design reasons). This design works only for vertically polarized radiation. It can be generalized to all polarizations by having an identical copy perpendicular to this one.

There are two principles of operation. First, the rectangles by themselves are small and hence interact weakly with radiation. If the switches are all off, the surface would be semi-transparent. However, when an RF switch is turned on, it joins two rectangles to form a $\lambda/2 \times \lambda/10$ rectangle. This forms a half-dipole antenna and interacts strongly with incident radiation. We made the strips wide to support a wider bandwidth of operation, since the width allows more modes of oscillation.

Second, if a plate of metal has small holes in it, then radio behaves as if the holes weren't there. This effect is used in Faraday cages, such as those in microwave ovens. A common rule-of-thumb says that the holes need to be smaller than $\lambda/10$, the size of the gaps between rectangles. When switches in adjacent columns are turned on, their rectangles will behave as a continuous sheet of metal, rather than individual columns, almost completely reflecting incident waves. Because neighbors act in a simple way, we expect that the neighbors' state wouldn't change the phase of the currents induced in the rectangle, only the magnitude. Hence the linear model in Equation 2 is approximately correct.

The above reasoning is merely the conjecture that motivated our design. We conduct two experiments to partially validate it. §6.2.1 demonstrates that the linear model is approximately correct, and §6.2.2 shows that the surface can significantly change its opacity. Validating this design in an anechoic chamber would offer more insights. We leave that for future work.

6 Evaluation

6.1 Experiment Setup

Our antennas are fabricated on custom printed circuit boards, with 40 antennas per board. We mount 80 of these boards on two frames and place it next to a wall in our lab. Since metal would interfere with the antennas, the frames are partially built from acrylic. The boards are connected in series with a single SPI serial-to-parallel bus composed of shift registers, allowing our Raspberry Pi controller to serially set the state of each individual element.

To set element state, the controller pushes values through the shift registers at 1 Mbit/s. Higher speeds are impeded by distortion due to the long wires in our setup. Hence pushing a new random state to the surface is the most time-consuming part of measuring it. To alleviate this problem, instead of pushing 3200 bits for each state, we push just 8 bits at a time, which shifts all the bits in the surface by 8 positions. Though the new state isn't completely fresh, each element still gets a new random value that is independent of the previous one. If we were to solve for $\mathbf{h}^{(i)}$ from the system of linear equations, the measurement matrix is still full rank. Hence we expect Algorithm 1 to work. This modification reduces the mean time to measure a state from 7 ms to 0.22 ms. Better engineering will improve performance further. To measure the channel, we use a USRP programmable radio operating in the 2.4 GHz ISM band.

Measurement method. The results in the main evaluation (Figures 10 and 11) are reported as the ratio of the signal strength when RFocus is in its optimized state to the strength when the surface is not present (i.e., *it is physically removed*, not just set to off). We measure this ratio as follows. Let R_I be the improved signal strength, R_0 be the signal strength when the surface is in the all-zeros state (i.e. it is semi-transparent), and R_B be the baseline signal strength when RFocus isn't present. We separately measure R_I/R_0 and R_0/R_B and multiply them to obtain R_I/R_B as desired.

After optimizing the state, we measure R_I/R_0 100 times by repeatedly flipping between the two states every 5 ms and calculating the mean improvement. We find that 1σ error is $< 2\%$ in all cases. To measure R_0/R_B, we first measure R_0. Then we remove the surface and measure R_B. We do this over ≈ 10 transmitter positions in a neighborhood around the original point, and use the median R_0/R_B to correct R_I/R_0. The median helps account for the *systematic* effects of the RFocus surface. It ignores random fading effects that may occur since the RFocus surface, people, or objects will have moved in the meanwhile. The mean absolute correction we had to introduce was 0.6 dB, while the maximum was 1.5 dB.

Total prediction error	Error due to noise
5.4%	2.0%

Figure 7: A linear model predicts the channel due to a state with 5.4% accuracy. If the surface were perfectly linear, the error would have been 2.0% due to noise. Hence the RFocus is approximately, but not fully, linear.

6.2 Microbenchmarks

6.2.1 Linearity

Our analysis of the optimization algorithm (see §4.3) assumes that the elements are not coupled with each other. Hence we used a linear model formalized in Equation (2), where $\mathbf{h}^{(i)}$ are independent of the states of the other elements. We wouldn't expect elements that are far away from each other (say, more than a wavelength) to couple strongly, especially since the elements are flat and radiate perpendicularly away from the surface. However, we packed the elements tightly to more densely cover the surface and beamform more precisely. We hypothesized that the non-linearity due to any resulting coupling will be small (§5.3). We now test this hypothesis.

We prepare several random "test-triples" of states of the form $(\mathbf{b}_A, \mathbf{b}_B, \mathbf{b}_{AB})$. Let (h_A, h_B, h_{AB}) be the corresponding channels. The states are drawn uniformly from the triples where $\mathbf{b}_A \& \mathbf{b}_B = 0$ and $\mathbf{b}_{AB} = \mathbf{b}_A | \mathbf{b}_B$; here states are represented as bit-strings and & and | are bitwise operators. That is, no element is on in both $\mathbf{b}_A$ and $\mathbf{b}_B$, and any element that is on in either $\mathbf{b}_A$ or $\mathbf{b}_B$ is also on in $\mathbf{b}_{AB}$.

If the linear model in Equation (2) is correct, then $h_A/h_Z + h_B/h_Z - 1 = h_{AB}/h_Z$. If an element's effect on the channel ($\mathbf{h}^{(i)}$) depends on whether its neighbors are on, this relation will not hold, since many more pairs of neighbors are on in $\mathbf{b}_{AB}$ than in $\mathbf{b}_A$ or $\mathbf{b}_B$. Since the neighborhoods are substantially different, $\mathbf{h}^{(i)}$ will be different for different states if our assumption is wrong.

Hence, to test linearity, we measure $(|h_A/h_Z|, |h_B/h_Z|, |h_{AB}/h_Z|)$ for several random states and test our ability to predict $|h_{AB}/h_Z|$ given $|h_A/h_Z|$ and $|h_B/h_Z|$ using the above relation. Using $|\cdot|$ doesn't invalidate the relation since for any random state X, $h_X/h_Z = |1 + \Delta h_X/h_Z| \approx 1 + \Re(h_X/h_Z)$ since $\Delta h_X \ll h_Z$. We measure each state 100 times. If Equation (2) were correct, the error in prediction due to measurement noise would have been 2.0%. Our error is 5.4% as shown in Figure 7. We conclude that although RFocus is not perfectly linear, the nonlinearities are small. They *are*, however, large enough that linear regression on $|h_X/h_Z|$ doesn't produce a good predictor.

6.2.2 Controllability and Bandwidth

We expect that the RFocus surface can control its opacity to radio. To test this, we kept the surface in between two wide-bandwidth directional (Vivaldi) antennas pointed at each other.

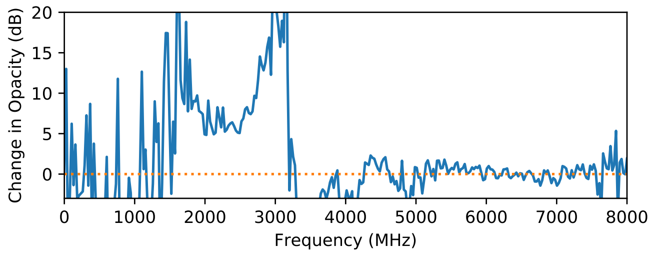

Figure 8: The ability to control the surface's opacity to radio as a function of frequency. This also indicates RFocus's bandwidth of operation.

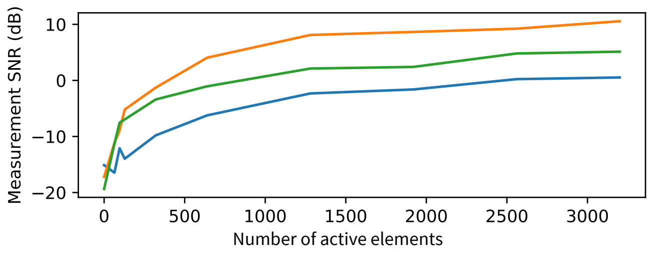

Figure 9: Measurability of the effect random configurations of the RFocus surface on the channel, as a random subset of them are deactivated, for three representative transmitter locations. It demonstrates why boosting (§4.1) is important for RFocus to function.

Using a Vector Network Analyzer (VNA), we compare the signal strength between the antennas when all the elements are turned on to when they are all turned off. We expect that, when the elements are all on, the surface will be much more opaque to radiation, reflecting a large fraction of it. The ratio of signal strength in these configurations is shown in Figure 8: it is consistently greater than 6 dB between 1600 and 3100 MHz. Hence, RFocus can change its opacity by over 75% over a large bandwidth. The peak is closer to 3000 MHz, where the change is well over 10 dB (90% control). But all of our other results are in the 2450 MHz ISM band, in order to conform to FCC rules. Frequency of operation can be tuned by scaling the sizes of the components. (Antenna design is not the focus of this paper.)

The y-axis is cropped at -3 dB for clarity in showing our frequency range of interest. The change falls after 3000 MHz because our RF switch is only rated up to that frequency. At < 1500 MHz, the rectangles, even after joining, are too small to interact with radiation.

6.2.3 Measurability

To find a good configuration, the controller needs to measure $\mathbf{h}$. However, the effect of each individual element, $\mathbf{h}^{(i)}$, is tiny and hard to measure. To aid measurement, we vary all elements randomly and at once (§4.1). This gives us an $O(\sqrt{N})$ boost in

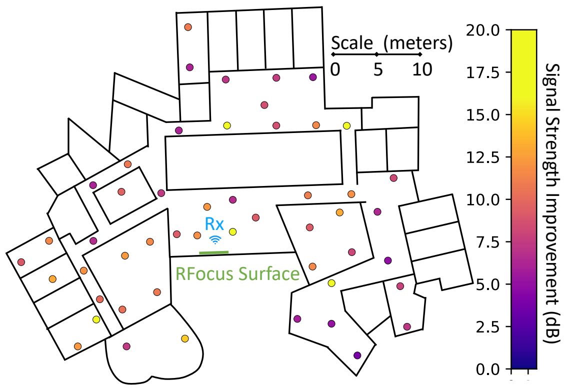

Figure 10: Ratio (in dB) of signal strength without and without the surface. The colored circles represent the improvement when the transmitter was placed at those locations, with the receiver and RFocus placed as shown. The CDF of improvements are shown in Figure 11.

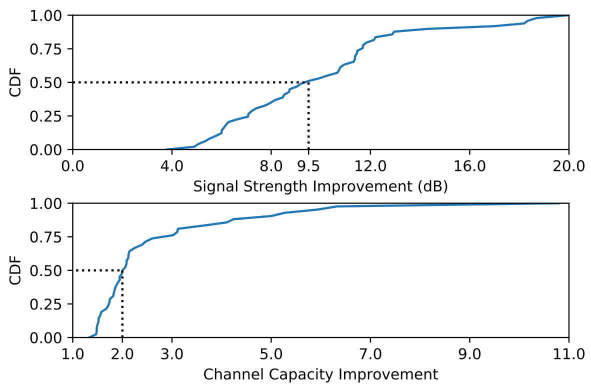

Figure 11: CDF of Improvement in the signal strength and channel capacity

the change in the channel amplitude ($O(N)$ in signal strength), which is easier to measure. To experimentally study the effect of this boost, we compute the Signal to Noise Ratio (SNR) of the *change in the channel due to a random state* as a function of the number of elements in the array. We artificially reduce the size of our array, by deactivating a random subset of it.

We choose 165 different random configurations, and measure the RSSI-ratio for each configuration ≈ 1000 times. The definition of "measurability SNR" is as follows. The "signal" in SNR is the variance in the average RSSI-ratio across all configurations, and the "noise" is the average variance in the RSSI-ratio measurements within each individual configuration. With the receiver and RFocus surface in the locations shown in Figure 10, we place the transmitter at three representative locations covering the full range of signal strengths.

Figure 9 shows the measurability SNR as a function of the number of active elements for these points. We can see that SNR is increases when more elements are varied. Note that when only a few elements are varied, the SNR is very low. This is why boosting the signal by varying all elements at once is critical, especially when the transmitter is far from the receiver.

The impact of random configurations on the channel is still small, because elements can interfere destructively. An optimized state eliminates destructive interference and produces an $O(N)$ effect on the channel ($O(N^2)$ in signal strength). Hence it produces significant gains in signal strength, even though a random state has little impact.

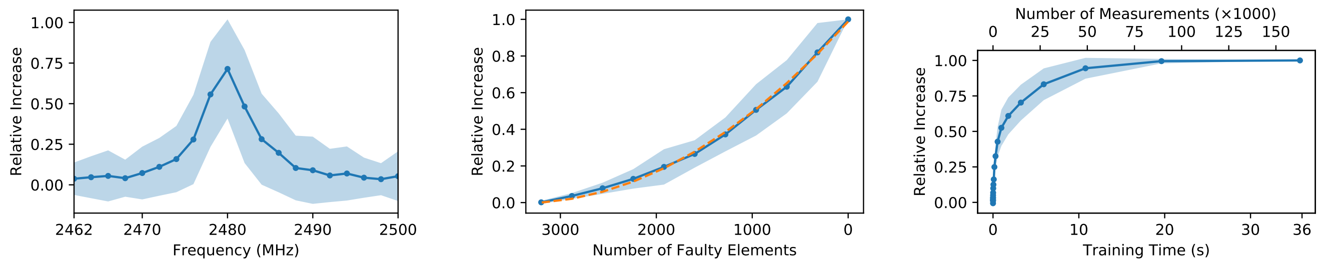
6.3 Signal Strength Optimization

We placed the receiver and the RFocus surface at a constant location as marked in Figure 10. Then we placed the transmitter at various positions in an indoor environment (our lab), and ran the optimization algorithm to maximize signal strength at the receiver. We measure the ratio of the improved signal strength to the signal strength when the surface is physically removed. We plot these on a map in Figure 10. The corresponding CDFs are shown in Figure 11. RFocus provides benefits throughout an entire floor of our building. The minimum, median and maximum improvements across all locations are 3.8 dB, 9.5 dB, and 20.0 dB, respectively.

The five points with the highest improvement had among the smallest unimproved RSSI. Further, they appear in apparently random locations, which makes us postulate that their unimproved RSSI is low due to fading, where destructive interference drastically decreases signal strength. Due to its size, RFocus is unlikely to suffer from fading at all its antennas. Hence, RFocus provides significant benefits for weak channels in such situations.

RFocus's large area allows it to focus energy from the transmitter to the receiver. This is particularly helpful when the transmitters are power constrained, since even a "whisper" will be "heard" clearly at the receiver. Yet, interference does not increase because the transmit power isn't increased. This could enable a new regime of low-power, high throughput IoT sensor devices. Whenever a sensor wants to transmit, it can ask the controller to tailor the surface for that particular endpoint (using a brief high-power transmission). Then it can make its high-bandwidth transmission at low power. Since sensors tend to be stationary, the same trained configuration can be used for extended periods of time. We evaluate this scenario in 6.4.1. Once trained, setting a state takes ≈ 3 ms.

Alternately, radios can use the additional signal strength to increase their channel capacity to obtain higher bitrates, as shown in Figure 11. Channel capacity increases logarithmically with signal strength, and hence the improvement decreases with increasing transmitting power. We set our transmitter to the highest power level (≈ 20 dBm) and adjust the receiver's gain accordingly to avoid saturation.



(a) Improvement for different frequencies, when RFocus was optimized for 2480 MHz. (b) Improvement when some antennas are faulty and flip randomly. Dotted line shows the best quadratic fit. (c) Improvement as a function of training time (and number of measurements)

Figure 12: To understand the trends as we vary different parameters, we plot the mean ± standard deviation of the improvement across all locations pictured in Figure 10. To normalize for differences in absolute improvement for different locations, we plot $\frac{I-1}{Max(I)-1}$. I is the ratio of the improved signal strength to the baseline strength. We normalize relative to the maximum improvement (across all values of the parameter) for that location. Note: $I = 1$ means no improvement. Hence we subtract 1 in our metric, so that positive values denote an improved channel.

6.4 Understanding the Improvement

Neighboring frequencies. Our optimization algorithm only seeks to improve the signal strength at a single frequency (we leave generalizing to multiple frequencies as future work). Nevertheless, we find that it also provides improvement in a 10 MHz neighborhood as shown in Figure 12(a). Multi-path rich environments often have very different signal strength for different frequencies, due to fading [30]. To maximize gain, RFocus could preferentially improve frequencies with the lowest signal strength.

In some cases the frequency that improved the most is different from the target frequency. This could be because that frequency had a much lower baseline signal strength in the un-improved channel due to fading. Hence, the center frequency doesn't have a value of 1. Far away from the target frequency, sometimes the signal strength decreases slightly due to the surface.

Fault tolerance. RFocus is intended to be a large array of inexpensive elements. Hence individual elements are expected to fail, and the system must be robust to failure. To test this, we artificially make a random subset of elements flip randomly, and not as per the controller's instructions, during both training and testing. Figure 12(b) shows the improvement against the number of 'faulty' elements.

Our model of the system suggests that the signal strength increases quadratically with the number of elements (§3.2). This is because each element contributes linearly to the channel amplitude, and the signal strength is the square of the amplitude. Under this model, we expect the normalized mean plotted to have the form $\alpha n^2 + \beta n$, where n is the number of non-faulty elements, and (α, β) are constants. This is the best-fit line pictured.

Note that, this does not imply that gain increases quadratically with the area of the surface, since a larger surface will have more elements that are far away from the source, and hence a smaller $\mathbf{h}^{(i)}$. In the above experiment, we don't change the distribution of $\mathbf{h}^{(i)}$ since we disable a random subset of elements. Hence, the quadratic model works.

Optimization speed. To understand the rate at which the optimization progresses, we plot the signal strength improvement as a function of the training time/number of measurements. As shown in Figure 12(c), 50% of the improvement occurs within 1 sec, with 4500 measurements and 90% improvement occurs within 10 seconds. Note, RFocus has 3200 elements, and we'd expect to need at-least 3200 measurements before the problem is well determined, even ignoring noise. RFocus exploits additional measurements to contend with the fact that measurements are noisy (§6.2.3). RFocus provides some (smaller) benefit with fewer than 3200 measurements, since, at any point in time, RFocus has a hypothesis state that it believes is optimal.

6.4.1 Stability Across Time

Once optimized, how long does an optimized state work? How often do we need to re-optimize our state? To test this, we keep our transmitter in our office on a typical workday, where around 10 people work. We optimized the state at 10AM and measured the improvement due to *that* state till 4PM that day. The top graph in figure 13 shows this. The initial improvement, shown as a dotted line, was 12.6 dB for about 3 minutes before it increased (without re-optimizing the state) for the next ≈ 20 minutes, and then decreased again. We also do a 100 second experiment (in a different location), where two people walk between the endpoints and the surface, intentionally trying to block the direct paths. The bottom graph in figure 13 shows this. Note, the people move only in the middle portion. At other times, the improvement reverts to the baseline.

RFocus's optimized state is robust to motion in the

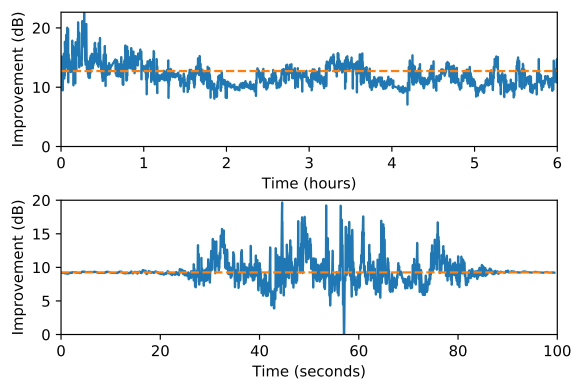


Figure 13: Improvement across time due to a state optimized in the beginning of the time window. This shows that the same optimized state can be used for a long time. The dotted line shows the improvement immediately after the state was optimized. Note the unit change in the x-axis (hours/seconds).

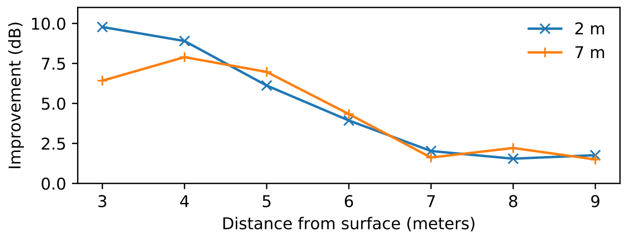

Figure 14: Signal strength improvement when *both* transmitter and receiver are at increasing distances from the surface. In other experiments, the receiver stays close to the surface. The radios endpoints are 2 m and 7m away from each other, in front of the surface, on the same side.

environment. Since optimization takes only 1 to 10 seconds, endpoints can benefit from RFocus for a large fraction of time. RFocus does not support continuous motion and needs to re-optimize the state if the endpoints move.

6.4.2 Moving both endpoints away from the surface

RFocus works best when either (or both) the transmitter and receiver is close to the surface. Performance degrades when both are moved away. Figure 14 shows that RFocus provides benefits up to a few meters from either transmitter or receiver. If ubiquitously deployed, such as on a wall, floor, or ceiling in every room, RFocus allows small devices to realize the benefits of a large antenna array. Alternately, surfaces could be placed close to APs or embedded in building fixtures.

7 Discussion

Efficiency In theory, an N-antenna phased array can achieve an $N\times$ gain in signal strength. RFocus achieves a median $10\times$ gain with 3200 antennas. RFocus suffers from two sources of loss in efficiency. First, only a fraction of the transmitted energy reaches the surface[4]. Second, RFocus can only direct a fraction of the energy that reaches it. This can be improved with better antenna design (§5.2) and metasurfaces [6].

RFocus's gain is qualitatively different from that of a 10 antenna phased array. RFocus precisely focuses a fraction of the transmitted energy, whereas the phased array coarsely directs all of the transmitted energy. Hence, near the receiver, RFocus's beam is more spatially concentrated while the phased array's coarse beam will interfere with nearby endpoints. Nevertheless, we believe these methods are complementary. Phased arrays can direct signals toward RFocus, which can then focus it precisely onto the receiver.

Wireless Controller In our prototype, elements are powered and controlled with wires. This isn't necessary. We envision a design where each element is powered and controlled wirelessly, like a passive RFID tag. The controller acts like a RFID controller that sets the state of each element. RFocus's fault tolerance allows deployment with failure-prone RFID tags (§6.4).

In such a setup, buildings could prefabricate their walls with RFocus elements. Carpets and wallpapers could be sold with RFocus elements already embedded in them. Users can separately buy a controller to control and obtain the benefits of the elements already present in the environment.

8 Conclusion

This paper presented RFocus, a system that moves beamforming functions from the radio transmitter to the environment. RFocus includes a two-dimensional surface with a rectangular array of simple elements, each of which contains an RF switch. Each element either lets the signal through or reflects it. The state of the elements is set by a software controller to maximize the signal strength at a receiver, using a majority-voting-based optimization algorithm. The RFocus surface can be manufactured as an inexpensive thin wallpaper, requiring no wiring. Our prototype implementation improves the median signal strength by $9.5\times$, and the median channel capacity by $2.0\times$.

Human Safety. Because RFocus doesn't emit any energy of its own, it does not increase the total radiation. It cannot focus energy to an area smaller than the size of a wavelength, since any device's ability to focus energy to an area smaller than a wavelength drops exponentially with distance from it. Hence RFocus is no riskier than being near the transmitter.

Ethics Statement. This work raises no ethical concerns.

[4]In most of our experiments, RFocus subtends $\approx 0.4\pi$ steradian on the receiver (equivalently, the transmitter). Hence it controls $\approx 10\%$ of the energy.

A Proof of Lemma 2

First, we prove another intermediate result.

Lemma 3. *Let $\mathbf{b}_\theta$ be the state such that $\mathbf{b}_\theta^{(i)} = 1$ iff $\Re(\mathbf{h}^{(i)} \cdot e^{-j\theta}) > 0$. If assumption 1 holds, then for any θ, the expected value of $\mathbf{h} \cdot \mathbf{b}_\theta$ is $\frac{e^{j\theta}}{\pi}\sum_i |\mathbf{h}^{(i)}|$.*

Proof.

$$E[\mathbf{h}\cdot\mathbf{b}_\theta] = \sum_i E[\mathbf{h}^{(i)}\mathbf{b}_\theta^{(i)}] = \sum_i E[e^{j\theta}\max^{\Re}\{0, \mathbf{h}^{(i)}\cdot e^{-j\theta}\}]$$
$$= \frac{e^{j\theta}}{2}\sum_i E[\Re(\mathbf{h}^{(i)}\cdot e^{-j\theta})] = \frac{e^{j\theta}}{\pi}\sum_i |\mathbf{h}^{(i)}|$$

Here, $\max^{\Re}$ compares the real component, and chooses $\mathbf{h}^{(i)} \cdot e^{-j\theta}$ if its real component is positive. The second step comes from our definition of $\mathbf{b}_\theta$. The third step notes that half of the values are expected to be non-zero and the sum of the remaining values is expected to have a phase of 0, and hence only the real part remains. For the final step, we compute the expected magnitude of the real part of a complex number with random phase in $(-\pi/2, \pi/2]$, given by the factor $\frac{1}{\pi}\int_{-\pi/2}^{\pi/2}\cos(\theta)d\theta = 2/\pi$. □

A corollary of this is that, if $\phi = \text{Arg}(h_Z)$, $|E[h_Z + \mathbf{h}\cdot\mathbf{b}_\phi]| = |h_Z| + \frac{1}{\pi}\sum_i |\mathbf{h}^{(i)}|$. As discussed in §5.2, in an ideal system where we can choose any $\mathbf{b}^{(i)} \in \mathbb{C}, |\mathbf{b}^{(i)}| \le 1$, the optimal assignment achieves a signal strength of $|h_Z| + \sum_i |\mathbf{h}^{(i)}|$. This gives us the same $1/\pi$ bound on what our system can achieve relative to the ideal when we account for h_Z and are willing to assume that phases are random (assumption 1).

Now, we restate and prove lemma 2 here.

Lemma 2. *Let $\mathbf{b}_{OPT}$ be the optimal assignment that maximizes $|h_Z + \mathbf{h}\cdot\mathbf{b}|$ and $\mathbf{b}_\perp$ be such that the i^{th} component $\mathbf{b}_\perp^{(i)} = 1$ iff $\Re(\mathbf{h}^{(i)} \cdot h_Z^*) > 0$. If assumptions 1 and 3 hold, then as $N \to \infty$, $|H(\mathbf{b}_{OPT})|/|H(\mathbf{b}_\perp)| < 1 + \varepsilon \forall \varepsilon > 0$ with high probability.*

Proof. We will argue that $\mathbf{h}\cdot\mathbf{b}_\theta$ is roughly the same as the expected value (with high probability) for any θ. For any $\varepsilon > 0$ and $\theta, \phi \in (-\pi, \pi]$, let A_θ denote the event that $R_\theta = \frac{|\mathbf{h}\cdot\mathbf{b}_\theta|}{|E[\mathbf{h}\cdot\mathbf{b}_\phi]|} > 1 + \varepsilon$. We now show that for any $\varepsilon > 0$, the probability that $\frac{\text{Max}_{\theta\in(-\pi,\pi]}|\mathbf{h}\cdot\mathbf{b}_\theta|}{|E[\mathbf{h}\cdot\mathbf{b}_\phi]|} > 1 + \varepsilon$ goes to zero as $N \to 0$. Let p denote this probability. Note, there are only N distinct values of $\mathbf{b}_\theta$ (say for $\theta_1, ..., \theta_N$), since it only changes when we include/exclude a new $\mathbf{h}^{(i)}$. Hence we need to take a maximum over only N values. Hence p is the probability that $\exists i$ such that that A_{θ_i} happens. That is, $p = P[\cup_{i=1}^N A_{\theta_i}] \le \sum_{i=1}^N P[A_{\theta_i}] = NP[A_\theta]$, for any θ, since the expression is symmetric in θ (note: we need not assume A_{θ_i} are independent here). Let $\bar{h} = \sum_i |\mathbf{h}^{(i)}|/N$, be the mean of the magnitude individual components . Then $|E[\mathbf{h}\cdot\mathbf{b}_\theta]| = N\bar{h}/\pi$ and $R_\theta = \frac{\pi}{\bar{h}}|\sum_{i=1}^N \mathbf{h}^{(i)} \cdot \mathbf{b}_\theta^{(i)}|/N$. From the central limit theorem and lemma 3, we have

$$R_\theta = \frac{\pi}{\bar{h}}\left|\frac{\bar{h}}{\pi} + \mathcal{N}(0, \sigma^2/N)\right| = \left|1 + \frac{\pi}{\bar{h}}\mathcal{N}(0, \sigma^2/N)\right|$$

where σ is the standard deviation in $\mathbf{b}_\theta^{(i)}\mathbf{h}^{(i)}\cos\theta$ for a random θ and $\mathcal{N}$ is a symmetric complex normal distribution with given mean and variance. Note, σ and $\bar{h}$ are bounded as $N \to \infty$, since assumption 3 tells us8 that $\mathbf{h}^{(i)}$ is bounded. Hence $P[A_\theta] = P\left[\mathcal{N}(0, \sigma^2/N) > \varepsilon\bar{h}/\pi\right]$ goes to zero as $N \to \infty$ for any $\varepsilon > 0$. $p = NP[A_\theta]$ also goes to zero as $N \to \infty$, since $P[A_\theta]$ decreases faster than $1/N$. We can follow a similar argument to show that for any $\varepsilon > 0$, the probability that $\frac{|\text{Min}_{\theta\in(-\pi,\pi]}\mathbf{h}\cdot\mathbf{b}_\theta|}{|E[\mathbf{h}\cdot\mathbf{b}_\phi]|} < 1 - \varepsilon$ goes to zero. And hence for any $\varepsilon' > 0$, the probability that $\frac{|E[\mathbf{h}\cdot\mathbf{b}_\phi]|}{|\text{Min}_{\theta\in(-\pi,\pi]}\mathbf{h}\cdot\mathbf{b}_\theta|} > 1 + \varepsilon'$ goes to zero.

Lemma 1 shows that $\exists\theta$ such that $\mathbf{b}_{OPT} = \mathbf{b}_\theta$. Hence

$$H(\mathbf{b}_{OPT}) = \text{Max}_\theta|h_Z + \mathbf{h}\cdot\mathbf{b}_\theta| \le |h_Z| + |\text{Max}_\theta(\mathbf{h}\cdot\mathbf{b}_\theta)|$$

Also $\mathbf{b}_\perp = \mathbf{b}_\phi$ for $\phi = \text{Arg}(h_Z)$. Hence

$$H(\mathbf{b}_\perp) = |h_Z + \mathbf{h}\cdot\mathbf{b}_\phi| = |h_Z| + |\mathbf{h}\cdot\mathbf{b}_\phi| \ge |h_Z| + \text{Min}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|$$

The second step is true since the two terms have the same phase as $N \to \infty$. Thus,

$$\frac{H(\mathbf{b}_{OPT})}{H(\mathbf{b}_\perp)} \le \frac{|h_Z| + \text{Max}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|}{|h_Z| + \text{Min}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|} \le \frac{\text{Max}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|}{\text{Min}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|}$$
$$= \frac{\text{Max}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|}{E[|\mathbf{h}\cdot\mathbf{b}|]}\frac{E[|\mathbf{h}\cdot\mathbf{b}|]}{\text{Min}_\theta|\mathbf{h}\cdot\mathbf{b}_\theta|} < 1 + \varepsilon$$

with high probability for any $\varepsilon < 0$. This proves the theorem. □

CarMap: Fast 3D Feature Map Updates for Automobiles

Abstract

Autonomous vehicles need an accurate, up-to-date, 3D map to localize themselves with respect to their surroundings. Today, map collection runs infrequently and uses a fleet of specialized vehicles. In this paper, we explore a different approach: near-real time *crowd-sourced* 3D map collection from vehicles with advanced sensors (LiDAR, stereo cameras). Our main technical challenge is to find a lean representation of a 3D map such that new map segments, or updates to existing maps, are compact enough to upload in near real-time over a cellular network. To this end, we develop CarMap,[1][2] which finds a parsimonious representation of a feature map, contains novel object filtering and position-based feature matching techniques to improve localization robustness, and incorporates a novel stitching algorithm to combine *map segments* from multiple vehicles for unmapped road segments and an efficient map-update operation for updating existing segments. Evaluations show that CarMap takes less than a second to update a map, reduces map sizes by 75× relative to competing strategies, has higher localization accuracy, and is able to localize in corner cases when other approaches fail.

1 Introduction

Autonomous vehicles use a three-dimensional (3D) map of the environment to position themselves accurately with respect to the environment. A 3D map contains *features* in the environment (§2), and their associated positions. As a vehicle drives, it perceives these features using advanced depth perception sensors (such as LiDAR and stereo cameras), then *matches these to features in the map*, and using the feature positions, triangulates its own position.

Maps need to be updated whenever there are significant changes to the environment. Changes to the environment can impact the set of features visible to a vehicle. For example, road or lane closures due to construction or accidents, parked delivery vans impeding traffic flow, parked vehicles on the road-side, or closures for sporting events can cause the set of features in the map to be different from the set of features visible to the vehicle. This impacts feature matching, and can reduce localization accuracy. Figure 1 quantifies this in a simple scenario. In the image on the left, a street has been closed due to an accident. With an outdated map, a car is unable to position itself; an updated map is necessary for accurate positioning.

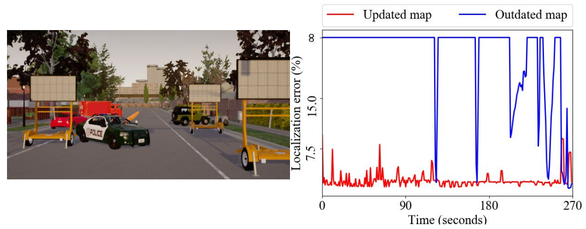

Figure 1: If short timescale events like traffic accidents (left) are not updated in maps, a vehicle cannot localize itself (blue line) because it cannot match the scene with the map. On the other hand, vehicles with updated maps (red line) can localize themselves accurately.

Keeping this map up to date can be tedious. Today, large companies (*e.g.,* Waymo [56], Uber [14], Lyft [12], Here [31], Apple [6], Baidu [7], Kuandeng [11], Mapper [5]) employ fleets of vehicles equipped with expensive sensors (LiDAR, Radar, stereo cameras) and GPS devices. For instance, Apple Map [1] uses vans equipped with a high-precision GPS device, 4 Lidar Arrays, and 8 cameras beside other equipment for capturing mapping data. These vehicles scan neighborhoods periodically with a frequency determined by cost considerations, which could be up to several thousand dollars per kilometer [4]. The scan frequency determines the timescale of environmental changes captured by the map [2]. To capture these changes, vehicle fleets have to continuously traverse the mapped area at very fine timescales [8], which can be prohibitively expensive.

In this paper, we take a first step towards answering the question: *What techniques and methods can ensure near real-time updates to 3D maps?* The most promising architectural approach to this question, which we explore in this paper, is *crowd-sourcing*.[3] In this approach, which leverages the increasing availability of depth perception sensors in vehicles, each vehicle, as it drives through a road segment, uploads *map updates* in near real-time over a cellular network to a cloud service. The cloud service, which acts as a rendezvous point, applies these updates to the map and makes these updates available to other vehicles.

Given today's cellular bandwidths, this architecture is most suitable for a class of 3D maps in which landmarks are *sparse*

[1]https://github.com/USC-NSL/CarMap
[2]Video demo

[3]Incentives for crowd-sourcing are beyond the scope of this paper. Waze has successfully employed crowd-sourcing from vehicles, by providing a navigation service and CarMap can use similar techniques.

features in the environment. Even so, today's feature-based 3D maps of the kind generated by Simultaneous Localization and Mapping (SLAM) algorithms require an order of magnitude higher bandwidth than cellular speeds (§2).

Contributions. Our first contribution (§3) is to identify the most parsimonious representation of feature maps. SLAM feature maps preserve a large number of features, even transient ones, and build indices to enable fast and effective *feature matching*. We show that it is possible to preserve fewer features, and reconstruct the indices, without impacting localization accuracy while reducing map size significantly.

Because our lean map representation throws away information, we have had to re-think feature matching. Our second contribution leverages the observation that, unlike robots, cars have approximate position information (*e.g.,* from GPS). Thus, instead of using statistics of features alone for matching, we also use position information to enable a more robust feature search, leading to improved localization accuracy.

Vehicles will use feature maps over longer time-scales than SLAM maps used by robots,[4] so we must avoid including features (*e.g.,* from parked cars, or pedestrians) that may disappear over those time-scales. We observe that *semantic segmentation* algorithms can identify such features. Our third contribution is a robust resource-aware algorithm that incorporates the semantics of objects in the scene to perform *dynamic object filtering*.

Updates to a map can be of two kinds: *map segments* representing a previously unseen road segment, and *map diffs* representing a transient in a previously-mapped road segment. Our last contribution is a collection of algorithms for map update: a fast and efficient map diff algorithm which generates compact diffs and can integrate these quickly into the map, and a robust map segment *stitching* algorithm that reliably identifies areas of overlap between the map segment and the existing map, and uses features within the overlapped region to transform the segment into the existing map's coordinate frame of reference.

We have embodied these contributions in a system called CarMap. Using experiments on an implementation (§4) of CarMap built upon the top-ranked visual open-source SLAM algorithm [41], and real traces as well as traces from a game-engine simulator [27] we show that (§5): CarMap requires 75× lower bandwidth than competing algorithms; it can generate a map update, disseminate it to a participating vehicle, and integrate the update into the vehicle's map *in less than a second*; its localization accuracy is better than state-of-the-art SLAM algorithms especially when a map is used in dramatically different conditions (*e.g.,* denser traffic) than when it was collected; it can localize a vehicle in some cases when other competitors cannot, such as when a map obtained from one lane is used in another lane in a multi-lane street; its computational overhead is comparable to, and sometimes better than competing strategies; and its feature labeling achieves upwards of 95% accuracy in distinguishing static from non-static objects even when the underlying segmentation algorithms have lower accuracy.

[4]In a robot, SLAM algorithms perform mapping and localization simultaneously. For vehicular use, a SLAM map is collected once, updated intermittently, and used often.

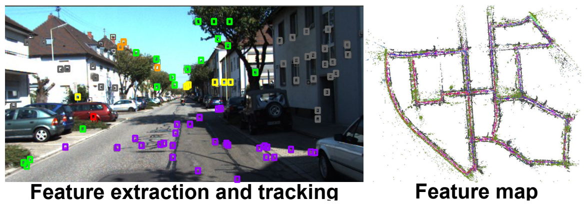

Figure 2: Localization using a feature based map. The picture on the left shows the features in an image, and the picture on the right shows the feature map generated for an area. Features are color-coded by the type of object those features belong to.

2 Background and Motivation

SLAM Principles. SLAM represents a map by a set of *landmarks* and their associated positions [19]. As a vehicle traverses the environment, its sensors (LiDAR, cameras) continuously generate *measurements* of the environment. SLAM continuously outputs (a) detected landmarks, and (b) the current *pose* (position and orientation) of the vehicle. It does this by using maximum *a posteriori* (MAP) estimation [42], finding the landmark position and vehicle pose that best explain the observed measurements.

Feature-based Maps: Terminology. SLAM maps can contain either feature-based landmarks (extracted from cameras [41] or LiDAR [57, 58]) or dense representations such as image frames [28] and occupancy grids [54]. In this paper, we explore crowd-sourcing *feature-based maps* (Figure 2), leaving denser representations for future work[5]. A *feature* is a lower-dimensional representation of some high-dimensional entity in the environment (*e.g.,* a leaf on a tree, or a part of a letter on a roadside sign), and is represented by a feature signature. Features are usually extracted from LiDAR or camera frames. For storage efficiency, SLAM implementations store features from approximately every k frames (so called *keyframes*), for small k. These implementations associate each feature in a keyframe with a relative 3D position with respect to that keyframe. They extract landmarks for the feature-based map from a subset of these features; we call these *map-features*. Maps have a single coordinate frame of reference, and map-features have 3D positions relative to the map's coordinate frame of reference.

SLAM Practice. Practical SLAM implementations are complex (Figure 3) because they have to deal with sensor and estimation errors. We briefly describe SLAM components

[5]Which map technology a vehicle uses is generally proprietary information, but we conjecture, based on anecdotal evidence that lower levels of autonomous driving [43] or vehicles that use stereo cameras will use feature-based maps [9] for cost reasons, while higher-end fully-autonomous vehicles with LiDAR will use denser maps.

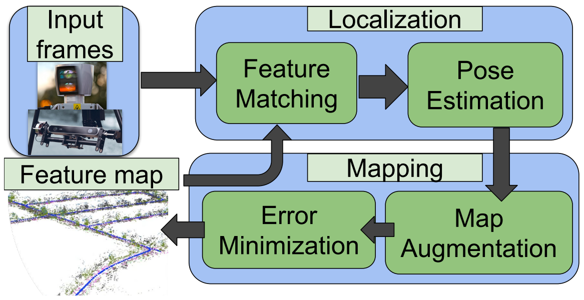

Figure 3: Components of feature-based map generators.

here, and introduce additional background in later sections.

Feature matching. Feature matching (or data association) is the process of matching features in the current frame with features seen in one or more keyframes in the map. SLAM implementations match features in a number of different ways: *e.g.,* image feature matching uses the similarity of image signatures (feature descriptors), and LiDAR 3-D features use feature geometry. Matching is a crucial building block for identifying map-features (as described below). SLAM implementations contain two data structures to speed up feature matching. A *map-feature index* associates map-features to keyframes they occur in. A *feature index* can search for the keyframe whose features most closely match the features in a given frame.

Pose estimation. This component contains algorithms that estimate the pose of the vehicle. As a vehicle traverses an environment, it first extracts features from each frame received from its sensor. Then, the vehicle matches the extracted features with those extracted in the last frame. At this point, the vehicle knows (a) the pose estimate in the previous frame, (b) the positions of the matched features in the previous frame and the current frame. It then uses MAP estimation [42] to estimate the current pose of the vehicle. If the feature matching step does not return enough features to estimate pose accurately, the vehicle uses the feature index to search the entire map for keyframes containing features matching those seen in this frame, a step called *relocalization*.

Map augmentation. Pose estimation can estimate the 3D positions of features in each keyframe. It adds some of these features as map-features, but only after filtering transient features (those that do not occur across multiple frames [41, 58]) or dynamic features (*e.g.,* features that belong to moving vehicles) whose position is not stable across frames.

Error minimization. This component minimizes the error accumulated in the feature map. *Local error minimization* rectifies error accumulation in successive frames using, for example, extended Kalman filters for LiDARs and bundle adjustment [55] for cameras. When vehicles visit a previously-traversed part of the environment, a *loop closure* algorithm finds matches between features in the current frame and features already in the map, then reconciles their position estimates (while also correcting positions of features discovered

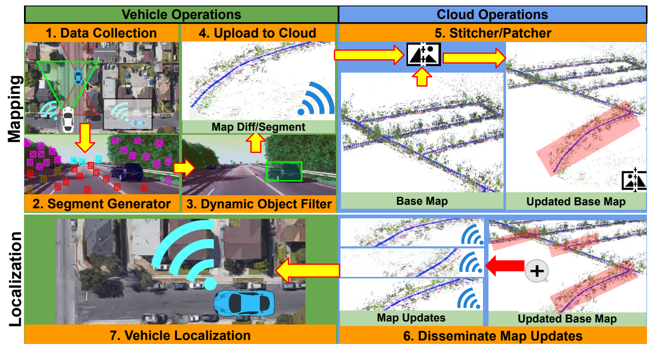

Figure 4: Architecture and workflow of CarMap

within the loop), thereby reducing error.

Challenges. CarMap faces four challenges.

Map size. CarMap could simply upload, over the cellular network, a SLAM map to the cloud, but these maps, which include map-features, keyframes, and the two indices, can be large. A 1 km stretch of our campus generates a 1.5 GB map. A car traveling at 30 kph would require a sustained bandwidth of 100 Mbps, well above achievable LTE speeds [3].[6] Our first challenge is to find a lean map representation that fits within wireless bandwidth constraints.

Environmental dynamics. CarMap maps are meant to be used over a longer timescale than SLAM maps used by robots, so they must be robust to environmental dynamics. For example, if a map includes features from a parked car that has since moved, localization error can increase.

Effective feature matching. As in SLAM, CarMap relies heavily on accurate feature matching for pose estimation, relocalization, and loop closure. However, because CarMap's lean map has less information than SLAM's, its feature matching accuracy can be lower, so CarMap must use a fundamentally different strategy.

Fast map-updates. CarMap must devise fast algorithms to (a) *stitch* additions to the map received from vehicles traversing a previously unmapped road segment (decentralized SLAM algorithms [29] have a similar capability but differ significantly in the details, §6), (b) generate and incorporate changes to the map from temporary obstructions.

3 Design of CarMap

Architecture and Workflow. As vehicles traverse streets (Step 1, Figure 4), they derive lean representations of feature maps using a *map segment generator* that runs on the vehicle (Step 2, §3.1). To this representation, CarMap applies a *dynamic object filter* to improve robustness to environmental dynamics (Step 3, §3.3). CarMap then determines whether this is a new map segment (not available in its own base map). If so, it uploads the entire map segment, else it uploads a

[6]With standard compression techniques (*e.g.,* gzip [26]) the sustained bandwidth is approximately 60 Mbps. Moreover, gzip compression adds latency: it takes approximately 25 seconds to compress a 500MB map collected over 4 minutes.

map diff (Step 4) to a cloud service. The cloud service runs a *stitcher* to add a new segment to the map, or a *patcher* to patch the diff into the existing map (Step 5, §3.4).

A vehicle receives, from the cloud service, segments or diffs contributed by other vehicles (Step 6), *reconstructs* the complete map, and uses it for localizing the vehicle (Step 7, §3.5). Diff generation, stitching, patching, and reconstruction use a *position-based feature index* for feature matching (§3.2), resulting in high feature matching accuracy.

The on-vehicle compute resources needed to run map generation, matching, diff generation, and reconstruction are comparable to those provided by commercial on-vehicle computing platforms like the NVIDIA Drive AGX [13]. CarMap uses (a) cloud storage as rendezvous for map updates from vehicles, and (b) cloud compute to integrate map updates. Extensions to this architecture to use road-side units for storage and processing are left to future work.

3.1 Map Segment Generator

The Problem. As a vehicle traverses a street, it produces map segments. The map segment generator must find the *leanest* representation of the map that respects cellular bandwidth constraints while permitting accurate localization.

As discussed in §2, a complete map contains four distinct components: (A) map-features, (B) features associated with every keyframe, (C) a map-feature index that associates map-features with keyframes used to generate the map-features (recall that a map-feature is one whose position is stable across several keyframes), and (D) a feature index that finds the most similar keyframe to the current frame. Uploading the complete map is well beyond cellular bandwidths (§2).

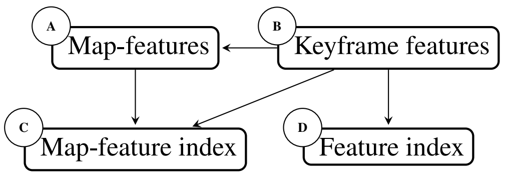

Figure 5: Dependencies between map components

CarMap's Approach. Consider Figure 5 in which an arrow from B to A indicates that B is needed to generate A. Thus, for example, map features are generated from keyframe features. Similarly, to generate the map-feature index, we need both map-features and keyframe features.

From this figure, it is clear that *all other components can be generated from keyframe features*. Thus, in theory, it would suffice for CarMap to upload only the keyframe features, thereby reducing the volume of data to be uploaded. Unfortunately, this does not provide significant bandwidth savings. For a 1 km stretch of a street on our campus (§2), the keyframe features require 400 MB. At 30 kmph, this would require an upload bandwidth of 26.67 Mbps, still above nominal LTE speeds. At higher speeds, CarMap would require proportionally greater bandwidth since the vehicle covers more of the environment (§A.3, Figure 19).

A Lean Map. CarMap uses a slightly non-intuitive choice of map representation: the *map-features* alone. Each map-feature contains the feature signature, the 3D position in the map's frame of reference, and the list of keyframes in which the map-feature appears. In §5, we show that this representation permits real-time map uploads.

Reconstruction. However, to understand why this is a reasonable representation, we describe how one can reconstruct a full SLAM map from these map-features. Map-features have, associated with them, a list of keyframes in which they appear. From these, we can generate keyframe features (a sequence of keyframes and features seen in those keyframes). From these keyframe features, it is possible to generate the feature index and the map-feature index, resulting in the complete SLAM map. §3.5 presents the details.

However, the CarMap map contains *only* map-features whereas a SLAM map contains *all* features seen in every keyframe. These fewer features can potentially impair feature matching accuracy. To address this, CarMap employs a better feature search strategy.

3.2 Robust and Scalable Feature Matching

Background. Feature matching is a crucial component in feature-based localization, and determines both the robustness of feature matching as well as scalability. Feature matching requires two operations: given a frame F, (a) find keyframes with the most similar features, and (b) given a feature f in F and a keyframe K, find those map-features m in K that are most similar to f. The first operation is used in relocalization and loop closure, and the second operation is used for these two tasks as well as fine-grained pose estimation (§2).

Similarity matching. Both of these operations use similarity matching techniques. For example, if a feature is represented by a vector, then, the most similar feature is one closest by Euclidean distance to this feature. Similarly, if a frame F can be represented by a signature in a multi-dimensional space, then the most similar keyframe K is one that is closest by some distance measure.

Scaling similarity matching. To derive scalable feature matching, many SLAM implementations arrange keyframe features in fast data structures. We have used the term feature index in §3.1 to describe these data structures. In practice, implementations construct multiple indices.

To ground the discussion, we take a concrete example from a popular visual SLAM [41] implementation. This implementation discretizes the space of features into hypercubes, and represents each hypercube by a *word*. For example, if a feature f is represented by a vector $< 1, 5 >$, and the hypercube has a side of 10 units, then, f falls into the hypercube defined at the origin. Suppose the hypercube is assigned the word "0". Then, any feature f' that is assigned "0" (*i.e.,* falls into the same hypercube) is close in feature space to f.

Search indices. The two feature matching operations can be implemented in scalable fashion using this word-based discretization. The first operation uses an *inverted index I* that maps each word to all the keyframes that it appears in. To find a keyframe closest to a given frame F, we can use the following algorithm. (i) Map each feature f in F to a word w_f. (ii) For each w_f in F, find all keyframes K associated with w_f in I. (iii) Take the intersection of all keyframes across all words w_f, then find those keyframes whose word histogram is most similar to F. The second operation requires a *word search tree per keyframe K* that maps a given w_f to those features in K that are closest to w_f in feature space.

The Problem. While these data structures work well for indoor robot navigation in relatively static environments, they can fail in more dynamic environments for outdoor vehicles. For example, keyframe word histogram matching can fail when a map's keyframe K was collected from an unobstructed view, while frame F, *taken at the same position*, had a car in front of it which obscured many of the features in K. As another example, consider a map of a 2-lane street where the map was taken from the right lane, but the vehicle using the map is on the left lane; in this case, a feature's signature may change if perceived from a different 3D position and orientation and hence result in a mismatch if the matching is based on feature similarity. In these cases, feature matching can result in *false positives*: a keyframe K far from the vehicle's current position may better match the current frame F than the correct match K' because features at completely different locations in a frame may look visually similar (*e.g.,* features from trees of the same species).

CarMap's Approach. To address these problems, instead of searching all keyframes in the map, CarMap *searches for matches in the vicinity of the vehicle's current position*. CarMap relies on a vehicle's GPS position to scope the search. However, GPS is known to be erroneous, especially in highly obstructed environments [40], so CarMap searches over a large radius around the current GPS position (in our experiments, 50 m, larger than the maximum error reported in [40]).

Keyframe matching. Specifically, in addition to using the inverted index and word histogram similarity to find matching keyframes in the base map, CarMap maintains a global k-d tree [16] of keyframes and uses it to search for all keyframes in the map within a given radius. Then, to localize a vehicle with a frame F in a given map, CarMap uses the GPS coordinates of the vehicle to get all keyframes within a large radius around the GPS position. It then finds the subset of these keyframes that most closely resemble F based on histogram matching. If it cannot find any resembling keyframes, then CarMap uses the keyframes closest to the vehicle's GPS coordinates. For each keyframe K in this subset, CarMap tries to find, for each feature f in F, the closest matching feature in K. To do this, it first performs a coordinate transformation to find the position of f in the map, assuming that F is at K's position, and then performs feature matching.

Feature matching. Based on the position hints of the features, CarMap also maintains another global k-d tree of map features, which partitions 3-D space into different regions to find all features in the map that are closest (by position) to a given feature f. Then, for each feature f in frame F, CarMap finds all map-features that are spatial neighbors, and uses feature similarity to identify the matching features. Using these matching features, it can perform pose estimation. CarMap then attempts to *refine* this pose estimate by searching nearby (in position) map-features for additional feature matches.

3.3 Dynamic Object Filter

Background. As a vehicle traverses an environment, it encounters three types of objects: a) static, b) semi-dynamic, and c) dynamic objects. Static objects are those that are at rest when perceived by the vehicle and are likely to stay in the same position for a long time *e.g.,* roads, buildings, traffic lights, and traffic signs. Dynamic objects are those that are in motion when perceived by the vehicle *e.g.,* moving vehicles and pedestrians. Semi-dynamic objects are those that have the ability to move but might not be in motion when perceived by the vehicle *e.g.,* parked vehicles, construction trucks.

The Problem. SLAM algorithms contain techniques to estimate whether a feature belongs to a dynamic object or not; if it does, that feature is not used in the map (§2). However, for a system designed for vehicles like CarMap, this is insufficient. These techniques work only if the majority of the scene is static and fail in highly dynamic environment (as we show in §5). Similarly, unlike SLAM, CarMap maps are intended to be re-used over longer time scales, during which the environment might change significantly. If a map contains a feature f, say, belonging to a semi-dynamic object such as a parked car which has moved away by the time a vehicle uses that map (before another vehicle has contributed a map diff), keyframe matching and feature matching might fail.

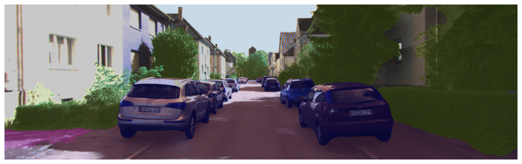

Figure 6: Semantic segmentation of an image while driving.

CarMap's Approach. To counter this, CarMap uses *semantic segmentation* to classify the whole scene into static and (semi-)dynamic objects. Semantic segmentation can be performed on camera data as well as LiDAR data, and refers to the task of assigning every pixel/voxel in a frame a semantic label (Figure 6), such as "car", "building" *etc.* In addition to motion analysis (§2), CarMap leverages these semantic labels to determine whether to add features to the map.

Specifically, CarMap extracts features (Figure 4) and uses semantic segmentation to label each point/pixel in the frame. It then associates each feature with the corresponding semantic label of the particular pixel(s) that the feature covers. As a result, when a feature is generated, besides its feature signature and 3D position, CarMap also appends a semantic label to it. If the semantic label belongs to a dynamic or semi-dynamic[7] object (*e.g.,* car, truck, pedestrian, bike *etc.*), CarMap does not add it to the map.

To detect moving objects we could have used *background subtraction*, but CarMap needs the ability to also detect semi-dynamic objects (*e.g.,* parked cars). Object detectors can generate loose bounding boxes for semi-dynamic objects, which can result in incorrect matches between features and their corresponding objects.

Challenges. Semantic segmentation poses two challenges in practice. First, it is prone to errors, especially at the boundaries of different objects. For example, a state-of-the-art segmentation tool, DeepLabv3+ [20], has an iIoU[8] score of 62.4% on a semantic segmentation benchmark (CityScapes [23]). Second, it uses deep convolutional neural networks that are computationally very expensive (*e.g.,* DeepLabv3+ runs at only 1.1 FPS on a relatively powerful desktop equipped with an NVIDIA GeForce RTX 2080 GPU).

Robust labeling. To tackle the first challenge, CarMap tracks feature labels across multiple frames and uses a majority voting scheme for deriving robust labels. Consider a feature f that is detected and tracked in multiple keyframes (only these features are likely to be added as map-features). In each keyframe, we determine the semantic label associated with the f. Instead of labeling each feature with its semantic label, we perform a coarser classification, determining whether that label belongs to a static (road surface, traffic signals, buildings, and vegetation *etc.*) or a non-static (cars, trucks, pedestrians) *etc.* This coarser classification overcomes boundary errors in segmentation: even if the segmentation algorithm identifies a pixel as belonging to a building when it actually belongs to a tree in front of the building, because both of these are static objects, the pixel would be correctly classified as static. CarMap then does a majority voting across these coarser labels to determine whether f is static or non-static. In §5, we show that this approach results in high classification accuracy.

Resource usage. Semantic segmentation CNNs can run at low frame rates. However, CarMap only needs to determine the label of a feature when creating map-features. These are assessed at keyframes, so, segmentation needs only be applied at keyframes. Depending on the vehicle's speed, SLAM algorithms [41] can generate keyframes at 1-10 frames per second. In §5, we explore a resource/accuracy trade-off: running slightly less accurate, but lower resource intensive CNNs still gives acceptable performance in our setting. When segmentation cannot run on every keyframe, we mark the missed keyframe's features as *unlabeled*.

[7]For brevity, we use the term *dynamic object filter* for this capability, but it can detect semi-dynamic objects as well.

[8]The IoU (intersection over union) metric is biased towards classes covering a large image area. Hence, for autonomous driving, the iIoU metric is preferred which is fairer towards all classes.

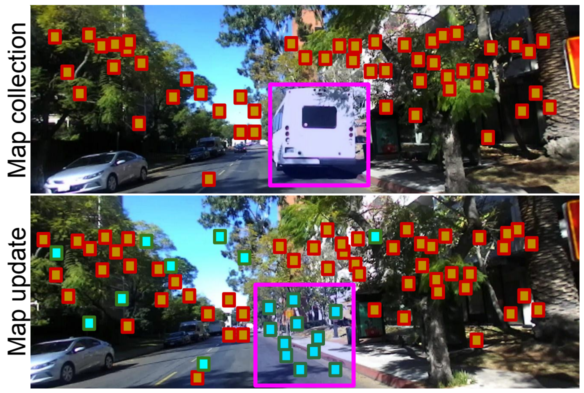

Figure 7: When adding a new region to the base map, the vehicle uploads the whole map segment (above). For updating a existing map segment, CarMap generates a map diff containing new map features (below, new map features marked in blue).

3.4 Map Updater

Map Diffs. When a vehicle traverses a segment that exists in its own map, CarMap generates a compact map diff to report newly discovered map features.

The Problem. CarMap may discover new features for two reasons. In Figure 7, if the feature map were constructed from the top image, a vehicle traveling through the same region at a later time (bottom image) might see new features previously occluded by the bus. Moreover, sparse SLAM algorithms are designed to capture only a small portion of all the features in the environment to ensure real-time operation, so a new traversal may discover additional features (Figure 7).

CarMap's Approach. A *map diff* compactly represents the newly discovered features. To explain how CarMap generates a map diff, consider a vehicle V, traversing a road segment R_A at time t_1, having an on-board map segment M_A of the same area from an earlier time t_0. CarMap loads the on-board map segment M_A into memory and marks all map elements (map-points and keyframes) as pre-loaded elements in the map. As the vehicle V traverses R_A, it localizes itself in the map segment M_A. At the same time, for every feature f_{road} the vehicle perceives, it uses CarMap's robust feature matching (§3.2) to query and match it against features f_A present in the map segment M_A in the same spatial vicinity. If the match is successful, that means the feature is already present in the map. If not, it is a new feature. This yields a set of features f_{diff} and keyframes K_{diff} that have been introduced in the time interval $\delta t = t_1 - t_0$. The vehicle uploads this *diff* map to the cloud service. The cloud service's patcher receives this and patches these map elements (f_{diff} and K_{diff}) into the base map. It also sends out the patch to all vehicles so that they can update their base maps.

Removing features no longer visible is tricky because those

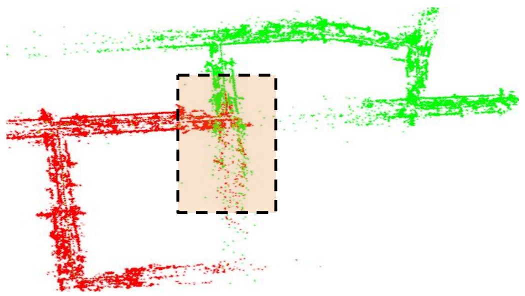

Figure 8: CarMap stitching together two feature maps. The highlighted regions represent overlapped sub-segments.

features could be, for example, occluded by a parked vehicle. It is, however, important to do this in practice (*e.g.,* features from objects present during a transient road closure). We are currently working on a robust algorithm for this.

Map Segment Stitching. When it traverses a previously unseen road segment, CarMap uploads the map segment to a *map stitcher* in the cloud.

The Problem. CarMap's stitcher adds map segments (§3.1) received from vehicles into its *base map* (Figure 8). CarMap must address three challenges while stitching a map segment into a base map. It must efficiently find potential regions of overlap between two map segments. The stitcher only has access to map-features at keyframes whereas SLAM algorithms preserve all features in each keyframe; feature matching can potentially be more difficult in CarMap. To scale well, CarMap must incrementally add new map segments to the base map without recomputing the whole map.

CarMap's Approach. Algorithm A.1 depicts the stitching algorithm. Suppose we have two map segments, the new incoming map segment M_s and the base map M_b. To stitch M_s with the base map M_b, CarMap first reconstructs (lines 4-5) (§3.5) the two map segments (R_b, R_s). Then, it uses (line 6) fast feature search (§3.2) to find the sub-segments (sequences of keyframes) that overlap (O_b, O_s). It then applies (line 7) feature matching between these sub-segments and uses these matches to compute the *coordinate transformation matrix* between M_s and M_b. It uses this matrix to transform M_s into M_b's coordinate frame of reference (lines 8-9). Finally, it removes duplicate features observed in both segments. §A.1 describes some of the details of this algorithm.

3.5 Reconstruction

Map Segment Download. Before a vehicle enters a street, it retrieves a map segment from the cloud service. This segment uses the lean representation described in §3.1.

Reconstruction Details. CarMap places map-features into keyframes, and adds them to the k-d tree structures. It then generates word histograms and per-keyframe word search trees as in SLAM. To do this, it must compute the 2D and 3D positions of each map-feature in the associated keyframe (recall that a map-feature's position in a map segment is with respect to the map's frame of reference). To reconstruct the position of a given map-feature f in a keyframe k, $P_f\left(k\right)$, CarMap uses the global 3D position of the map-feature $P_f\left(O\right)$, the respective keyframe's position $P_K\left(O\right)$ and rotation matrix $R_K\left(O\right)$ to perform an inverse transformation:

$$P_f\left(k\right) = \left[R_K^{-1}\left(O\right) * \left\{P_f\left(0\right) - P_K\left(0\right)\right\}\right] \tag{1}$$

4 Implementation of CarMap

Software we use. We have implemented CarMap by modifying a visual SLAM algorithm, ORB-SLAM2 [41], the top-ranked open-source visual odometry algorithm for mono, stereo, and RGB-D cameras in the KITTI vision-based benchmarks [30] for self-driving cars. At least one other visual SLAM implementation [45] has a very similar implementation structure, so CarMap can be ported to it. It should also be possible to incorporate CarMap ideas into LiDAR SLAM implementations, but we have left this to future work.

For semantic segmentation, we use MobileNetV2 [51], a light-weight version of DeepLabv3+ [20] designed for mobile devices. We use OpenCV [18] for image transformations, the Point Cloud Library (PCL) [50] for point cloud operations, and the C++ Boost library [52] for serializing and transferring the map files over the network.

Our Additions. On top of these, we have added a number of software modules necessary for the six components described in §3. CarMap reuses the feature extraction, index generation, and similarity-based feature matching modules in ORB-SLAM2 (ORB-SLAM2 is 9620 lines of C++ code), but even so, it requires approximately 15,000 additional lines of C++ code. §A.2 discusses these additions in detail.

5 CarMap Evaluation

In this section, we evaluate (a) real-time end-to-end latency of map update using experiments and (b) the localization accuracy of CarMap using trace-driven simulation. We then report on microbenchmarks for its lean map representation, feature map stitching, segmentation, and spatio-temporal robustness in localization, using both synthetic and real-world traces.

5.1 Methodology

Traces. For our end-to-end accuracy evaluations, we use 15 km of stereo camera traces that we curated using CarLA [27], the leading simulation platform for autonomous driving supported both by car manufacturers and major players in the computing industry. CarLA can simulate multiple vehicles driving through realistic environments — the simulator has built-in 3D models of several environments including freeways, suburban areas, and downtown streets. Each vehicle can be equipped with stereo cameras or LiDAR sensors, and the simulator produces a *trace* of the sensor outputs as the cars drive through. When curating our CarLA traces, we model a stereo camera with the same properties (stereo baseline, focal length *etc.*) used in the KITTI dataset. When evaluating

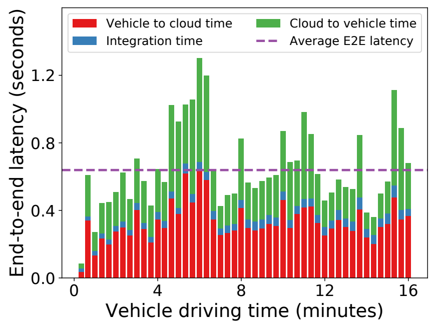

Figure 9: End-to-end latency results for CarMap's map update operation enables real-time map updates (average end-to-end latency is approximately 0.6 seconds.)

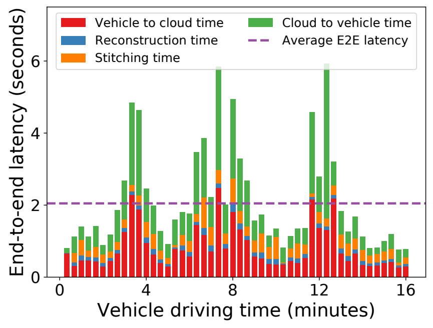

Figure 10: End-to-end latency for CarMap's map stitch operation. The stitch operation, on average, takes approximately 2.0 seconds for unmapped regions.

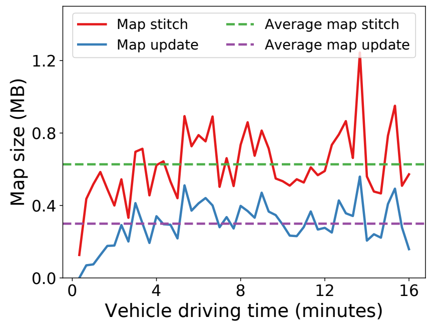

Figure 11: Vehicle map uploads for map stitch and update operations. Map updates reduce required bandwidth by 2x as compared to stitching map segments.

CarMap, we only extract the left and right images from the modeled camera after which we process the frames like we would for a real-world camera. We do not extract depth or segmentation labels from CarLA but instead generate them using ORB-SLAM2's stereo matching and a segmentation CNN respectively.

For some of our microbenchmarks, we also used 22 km of real-world traces from the KITTI odometry benchmark [30]. The KITTI benchmark traces only have a single run for each route, but for our end-to-end evaluations, we need one run to build the map, and another to use the map for localization. This is why we use traces from CarLA.

Finally, to validate real-time map updates (§5.2), we used 8 km of stereo camera data from our campus.

Metrics. For most evaluations, we are interested in end-to-end latency, localization accuracy, and map size. To calculate localization accuracy, we build a map for a region and then localize another vehicle that drives in the same region using that map. In this case, the localization error is the average translational/localization error (used in KITTI odometry benchmark [30]) between the ground truth position of the vehicle and its estimated position, averaged over the whole trace. In some experiments, we also measure compute times for various operations. These measurements were taken on an Alienware laptop equipped with an Intel i7 CPU running at 4.4 GHz with 16 GB DDR4 RAM and an NVIDIA 1080p GPU with 2560 CUDA cores.

Scenarios. For the end-to-end accuracy experiments, we generate CarLA traces to mimic three different kinds of driving conditions: a) suburban streets (light traffic and some parked vehicles), b) freeway roads (dense traffic), and c) downtown roads (dense traffic, with parked vehicles on both sides). For each of these, we generate traces for a static scene (no traffic), and for a dynamic scene (with traffic). This allows us to evaluate maps built for one kind of scene (*e.g.,* static), but used in another (*e.g.,* dynamic).

Comparison. In all these evaluations, we compare the performance of: a) maps generated by ORB-SLAM2, b) a stitched map generated by QuickSketch [15], and c) a stitched CarMap map. QuickSketch is a competing approach to map crowd-sourcing that does not attempt near real-time map updates. In QuickSketch, map segments are raw stereo camera traces, and the stitching algorithm feeds new map elements from the camera trace into an existing base map generated by ORB-SLAM2. QuickSketch uses ORB-SLAM2's relocalization and feature matching components. We repeat each experiment three times and report the average values.

5.2 Near Real-Time Map Updates

Methodology. To measure end-to-end latency of map updates, we drove a vehicle for 16 minutes (8 km) equipped with an Alienware laptop tethered to a phone with an LTE connection. The laptop sends map updates to a remote server which runs CarMap's diff integration and stitching operations, then sends the map updates back to the vehicle. The end-to-end latency includes: update generation and transmission on the sender, update processing on the cloud, and update transmission and integration on the receiver. We conducted two experiments.

Map Diffs. In the first experiment, we measure end-to-end latency when all updates are in the form of map diffs (*i.e.,* the vehicle drives through a previously mapped area). CarMap generates map diffs every 10 s. As Figure 9 shows, the *average end-to-end latency for CarMap's map update operation is 0.6 s*[9]. Update transmission times dominate the cost, since diff integration is fast (§3.4).

Map Segment Stitching. In the second real-time experiment, we measure the end-to-end latency when all updates are in the form of map segments (*i.e.,* the vehicle drives through a previously un-mapped area). As before, CarMap generates map segments every 10 s; in this case, however, the cloud service needs to perform an expensive stitch operation (§3.4).

The overall end-to-end latency for map segment updates in CarMap (Figure 10), although about 3.2× more than map-

[9] As an aside, vehicles rely on these maps only to localize themselves, not for safety-critical operations (for which they use their sensors).

updates, is *still only 2.1 seconds on average*. Two factors contribute to a higher end-to-end latency. First, map segments are about 2-4× larger than map diffs (Figure 11). Second, they require about 10× more computation than map updates. Map update integration is only 50 ms whereas the partial reconstruction (§A.1) and stitching take nearly 500 ms. Even so, transmission and reception times dominate.

In summary, in CarMap, map updates can be made available to other vehicles in under a second. Even in the rare event that a vehicle traverses an un-mapped road segment, map updates can be made available in about 2 s.

5.3 End-to-End Localization Accuracy

We now demonstrate that CarMap has comparable or better localization accuracy than ORB-SLAM2 and QuickSketch [15] for three different scenarios: static scene, dynamic scene, and multi-lane localization.

Static Scene Maps. In this scenario, we build a map from a static scene with no dynamic or semi-dynamic objects (a *static-map*). We then use this map to localize a vehicle that drives in: a) the same static scene (resulting in a *static-trace*), and b) the same scene with parked and moving vehicles (resulting in a *dynamic-trace*). Figure 12 shows the average error and map sizes for each scheme and scenario. (We show the error distributions in Figure A.9 and Figure A.11).

In all three environments (suburbia, downtown, and freeway), the localization error for the static-trace in the static-map shows that CarMap is able to *localize as accurately as ORB-SLAM2* even though the *map sizes are 23-26*× smaller. Similar results hold for CarMap when compared against recent map crowdsourcing work, QuickSketch. This is because CarMap preserves all map-features that contribute most towards accurate localization.

However, for the dynamic-trace on the static-map, CarMap has nearly *28× better localization accuracy* than ORB-SLAM2 and Quicksketch. These differences arise from two features in our scenarios: traffic, and the presence of parked cars, which impact localization accuracy in different ways.

To understand why, consider a dynamic-trace on a suburban street. If the location or number of parked cars in the dynamic-trace are different from those in the static-map, the signature of the observed frame (its word histogram) is different in the trace than in the map. Because ORB-SLAM2 relies on word-histogram matching for re-localization, it fails to find the right keyframe candidates to localize. In contrast, because CarMap filters features belonging to parked cars, the vehicle in the suburban street sees similar features as in the map, and can re-localize more accurately.

Now consider a dynamic-trace on the freeway, in which a vehicle's view can be obscured by other vehicles, so it is unable to observe many of the features in the map. This causes ORB-SLAM2's word histogram matching to fail. CarMap uses all keyframes within a 50 m radius of its current position, so it always has keyframe candidates to search from. Even when histogram matching succeeds, ORB-SLAM2 uses per-keyframe word search trees that can result in false-positive feature matches. CarMap uses feature position based search to avoid this. In this scenario, moreover, ORB-SLAM2 believes features belonging to vehicles moving in the same direction to be stable (since their relative speed is near zero), makes them map-features and uses them to track its own motion. CarMap's dynamic object filter avoids this pitfall.

Dynamic Scene Maps. In this scenario, we build a map from a dynamic scene (a *dynamic-map*) and then use the map to localize in a dynamic- or static-trace. Figure 13 summarizes the results from this experiment (Figure A.10 plots the distribution of mapping errors).

The results for the dynamic-map are more dramatic than those for the static-map. CarMap's map is 15-36× smaller than ORB-SLAM2's or QuickSketch's map. Despite this, these two approaches *fail to localize* (denoted by ∞) on static-traces in downtown and suburban streets. In the static-trace, very few of the perceived features appear in the dynamic-map, and relocalization fails completely. CarMap does well here because it filters out all cars (parked or moving). For the dynamic-trace, its accuracy is nearly 50× better than ORB-SLAM2 and QuickSketch. CarMap's accuracy is lowest for the downtown dynamic-trace (with a 5% translational error) in which parked and moving cars obscure a lot of features in the map, resulting in fewer matches.

Multi-Lane Localization. In this set of experiments, we consider a somewhat more challenging case, for each of our scenarios: building a map by traversing one lane of a multi-lane street (4 freeway lanes, or 2 lanes in the suburban and downtown streets), and then trying to localize the vehicle in each of the remaining lanes. As before, we build both static-maps (Figure 14) and dynamic-maps (Figure 15).

For the freeway static-map, ORB-SLAM2 cannot localize beyond the second lane, while CarMap can localize across all four lanes. For the dynamic-map, a more challenging case, CarMap can localize one lane over, but ORB-SLAM2 and QuickSketch cannot localize at all (denoted by ∞). In all these cases, ORB-SLAM2's search strategy fails because its keyframe search relies on the vehicle's perspective being the same as the map's perspective: in these experiments, that assumption does not hold. CarMap, by contrast, matches features by position not perspective, so is much more robust.

Similar results hold for suburban and downtown streets: ORB-SLAM2 and QuickSketch are unable to localize, but CarMap is able to localize in all cases, with low error.

In §A.4, we show that CarMap's *mapping accuracy*, which measures the inherent error introduced by mapping, is comparable to ORB-SLAM2.

5.4 Other Performance Measures

Map Sizes in Real-World Traces. §5.3 shows that CarMap's maps are lean relative to competing strategies, but these are

Mapping scheme	Freeway			Suburbia			Downtown		
	Static error (%)	*Dynamic error (%)*	*Map size (MB)*	*Static error (%)*	*Dynamic error (%)*	*Map size (MB)*	*Static error (%)*	*Dynamic error (%)*	*Map size (MB)*

Downtown	**QuickSketch**	∞	∞
	CarMap	0.93	4.91

Figure 16: Mapping errors (m) for stitching map segments from different traffic conditions. CarMap is robust to temporal changes because: a) removes dynamics, and b) robust feature search.

DCNN	**FPS**	**Label segmentation accuracy**	**Object segmentation accuracy**
DeepLabV3+	1.1	76.7	96.6
Tuned DeepLabV3+	2.2	71.6	96.4
MobileNetV2	5	72.8	97.6

Figure 17: Semantic segmentation accuracy for different DCNNs. By classifying labels into static and dynamic objects, the segmentation accuracy for all DCNNs is above 96%.

for synthetically generated traces. Figure 18 shows the map sizes for the 11 real-world KITTI sequences. Across all sequences, CarMap *reduces map size 20×*. About 20% of this savings comes from removing the reconstructible indices (the *No Index* column), and another 60% from removing keyframe-features after generating the indices (the *No Keyframe-features* column).

As a vehicle travels faster, feature maps capture more data from the environment and generate data at a higher rate. We validate this in Figure 19 by calculating the bandwidth requirements of all 11 KITTI traces. Maps generated by ORB-SLAM2 and the No-Index approach are impractical at all speeds for LTE wireless upload and impractical for LTE download at speeds over 40 kph. The No Keyframe-features alternative is impractical for LTE upload at speeds over 60 kph. CarMap requires less than 3 Mbps up to 80 kph (the highest speed in the KITTI traces). Similar results hold for CarLA-generated traces (§A.3).

Other factors determine map size, including visual richness of the environment, lighting, weather *etc.* CarMap's map size should still be an order of magnitude smaller than competing approaches; future work can validate this.

Localization Time. CarMap's accuracy comes at the cost of a slightly higher per-frame localization time. During localization, CarMap's feature search adds overhead. To quantify this, we built a map from a very large trace with 4541 frames and then tried to localize in the same trace. ORB-SLAM2 has a per-frame localization cost of 0.023 s, while CarMap's is only marginally higher (0.033 s).

Map Load Time. When it receives a map segment, CarMap needs to read the segment from disk, reconstruct the keyframe features, and the indices. Figure 20 quantifies the total cost of these operations (called the map *load time*) for each of the 11 KITTI sequences. The load times for other alternatives are normalized by those for CarMap.

Interestingly, except for sequences 00, 01 and 06, load times for CarMap *are less than ORB-SLAM2* (on average, 0.95×). For most sequences, CarMap's load time is lower than ORB-SLAM2 because the latter's map is large enough that the time to load it from disk exceeds CarMap's reconstruction overhead. Other alternatives (*No Index* and *No Keyframe-features*) have large maps and high reconstruction overhead. When CarMap's reconstruction cost is (marginally) higher than ORB-SLAM2, it is because the corresponding scenes have a dense map-feature index, leading to a slightly higher reconstruction cost. (See §A.5 for details). Denser map-feature indices are found in environments with keyframes that have a large number of common map-features (*e.g.,* freeways). We have verified both these observations (equivalent map-load times and slightly higher load times for dense map-feature indices) for CarLA sequences.

Loop Closure. Loop closure is an important component of SLAM systems. For the KITTI dataset, we have verified that, even though its maps contain only map-features, CarMap can perform all loop closures that ORB-SLAM2 can.

5.5 Robustness

Robust Feature Matching. We compare CarMap's feature matching performance to that of ORB-SLAM2's native feature matching approach (we use ORB-SLAM2's default parameters for matching). For this, we build a map segment for a static trace and then use that trace to localize: a) the same static trace, b) a static trace from a parallel lane, c) a dynamic trace from the same lane, and d) a dynamic trace from a parallel lane. We collect the trace using CarLA on a freeway, and use two metrics: a) feature matching ratio (the percentage of map-features matched in the current trace), and b) localization error (m).

Figure 21 shows that for all scenarios, robust feature matching *is able to find more matches and hence results in lower*

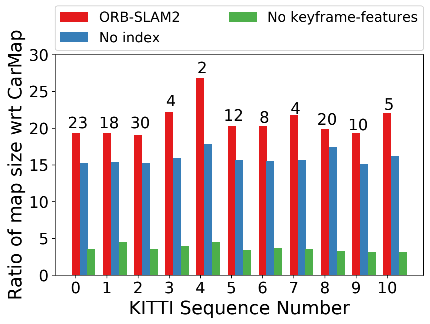

Figure 18: Map sizes on KITTI traces: for each alternative, the map size is normalized by CarMap's map size. The number on top of each group of bars shows the size in MB of CarMap's map for the corresponding KITTI trace. CarMap reduces map size by 20x for unmapped regions.

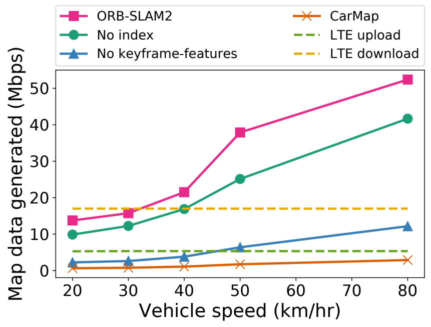

Figure 19: Bandwidth requirements for the four mapping schemes averaged over diverse environments in all 11 KITTI sequences at different speeds. CarMap can support near-real time uploads over LTE at speeds up to 80 kph whereas other schemes fail even at low speeds.

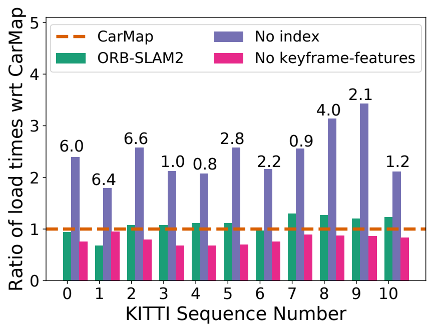

Figure 20: Load times on KITTI traces: for each alternative, the load times are normalized by CarMap's load time (whose absolute value is on top of each group of bars). CarMap loads faster than ORB-SLAM2 (*i.e.,* ORB-SLAM2's load time ratio > 1), except for 3 KITTI sequences.

Scheme	Feature matching (FM) ratio (%)	Localization error (m)
Map: Lane 1 (static) Trace: Lane 1 (static)		
Normal FM	70	0.83
Robust FM	**96**	**0.51**
Map: Lane 1 (static) Trace: Lane 1 (dynamic)		
Normal FM	49	1.4
Robust FM	**66**	**0.57**
Map: Lane 1 (static) Trace: Lane 2 (static)		
Normal FM	52	1.2
Robust FM	**74**	**0.66**
Map: Lane 1 (static) Trace: Lane 2 (dynamic)		
Normal FM	32	1.5
Robust FM	**40**	**0.6**

Figure 21: CarMap's robust feature matching finds more features in different conditions and thus localize better than ORB-SLAM2.

Base map lane	Mapping scheme	Map segment lane			
		1st	2nd	3rd	4th
1st	QuickSketch	0.67	0.90	∞	∞
	CarMap	0.70	**0.88**	∞	∞
2nd	QuickSketch	0.34	0.68	0.90	∞
	CarMap	1.1	**0.62**	0.97	**1.15**
3rd	QuickSketch	∞	5.8	0.68	3.2
	CarMap	**1.13**	**0.96**	**0.63**	**1.19**
4th	QuickSketch	∞	∞	10.83	0.67
	CarMap	∞	**1.0**	**1.0**	**0.66**

Figure 22: Mapping error (m) for multi-lane stitching. CarMap's stitching algorithm uses a more robust feature search based on position hints to stitch map segments two lanes apart where competing strategies fail (∞ shows an unsuccessful stitch operation.)

localization error as compared to ORB-SLAM2's feature matching. The base case (static-map used by a static trace) shows that normal feature matching fails to detect 30% of the features even though the same trace is used for mapping and localization. The introduction of dynamic objects reduces the feature matching ratio because features are occluded by vehicles and hence cannot be detected even with robust matching.

Making Semantic Segmentation Robust. CarMap makes segmentation robust by voting across multiple keyframes, and using a coarser static vs. non-static classification. Figure 17 shows CarMap's overall accuracy, for three different versions of DeepLabv3+. These DNNs are the DeepLabv3+ trained on the CityScape dataset pre-trained, a fined tuned DeepLabv3+ trained on the KITTI dataset and a light-weight version of DeepLabv3+ (MobileNetv2) for mobile devices. The third column shows that CarMap achieves upwards of 96% accuracy if we apply segmentation to every keyframe. Semantic segmentation, by itself, achieves only 70% accuracy in label assignment (second column).

The first column shows the frame rate these DNNs run at. The frame rate needs to be fast enough to process every keyframe, or at worst, every other keyframe (at which segmentation accuracy drops to about 85%, and below which it drops to unacceptable levels, §A.7). In the KITTI dataset, the average across the 11 sequences is 3.17 keyframes per second, well within the rate of the MobileNetv2 version. One of these sequences runs at 10 keyframes per second, so for this sequence MobileNetv2 would process every other keyframe. For more dynamic scenes, it might be necessary to devise faster semantic segmentation techniques, and we expect the vision community will make advances in this direction.

Multi-Lane Stitching. CarMap can stitch map segments collected from different lanes. For this experiment, we collect traces from four parallel lanes on a freeway in CarLA. Using each of these four traces as base maps, we try to stitch map segments from other lanes into it, then evaluate the mapping error for the new maps. Figure 22 shows the absolute mapping errors (in meters) for these stitched map segments. The first column shows the lane used to collect the base map and the last four columns show the absolute mapping error of a stitched map with each of these lanes. The ∞ sign represents a failure to stitch segments from the two lanes.

Although QuickSketch's base map has 20× more features than CarMap and it localizes a stereo camera trace in that base map instead of another map segment (CarMap), it cannot stitch two lanes away. On the other hand, CarMap's stitching algorithm uses robust feature matching (§3.2) and can stitch map segments collected two lanes away (*e.g.,* map segments from lane 1 and lane 3). CarMap's robustness comes purely from using position hints to find the set of key-frames to match, and to find matching map features, while QuickSketch uses ORB-SLAM2's built-in matching methods (in this experiment, we do not compare against ORB-SLAM2 because it does not contain a map stitch operation).

Stitching in Different Traffic Conditions. Besides being robust to spatial changes, crowdsourced map collection and update requires robustness to temporal changes as well (*e.g.,* changes in traffic during different times of day). To evaluate this, we collect stereo camera traces from CarLA in suburban and downtown areas in the same environment during different traffic conditions (no traffic and heavy traffic). Using these traces, we evaluate the ability of the mapping schemes to stitch these map segments by comparing their mapping error.

Figure 16 shows that QuickSketch is unable to stitch because it fails to relocalize a trace in different traffic conditions (§5.3). This, again, is because its stitching is solely based on appearance-based matching whereas CarMap uses position hints as well to make its stitching more robust. By contrast, CarMap is able to stitch map segments collected across different traffic conditions. We evaluate the sensitivity of stitching accuracy to the degree of map segment overlap in §A.6.

6 Related Work

Decentralized SLAM. Decentralized SLAM systems [24] leverage multiple agents to run SLAM in unknown environments. CarMap can be considered an instance of decentralized SLAM [22] with some differences. In decentralized SLAM, the agents (robots) have limited compute-power and only run visual odometry [29]. This leads to inaccurate localization whereas vehicles in CarMap localize more accurately because they run both mapping and localization. Decentralized SLAM sends all keyframe features to a central collector which performs all mapping operations [53] whereas CarMap only sends map-features to a cloud service to ensure real-time map exchanges. Similarly, in decentralized SLAM, the collector finds overlap between maps of different agents using the histogram word approach, does not remove environmental dynamics and hence is not robust like CarMap. Decentralized SLAM [47] uses features from a single keyframe overlap to compute the transformation matrix whereas CarMap is more robust and uses features from multiple keyframes.

Visual SLAM. Although we have implemented CarMap on top of ORB-SLAM2 [41], our study of other SLAM systems shows that it can be easily ported to other keyframe-based visual SLAM algorithms like S-PTAM [45]. In future work, we can extend CarMap to group features into higher-dimensional planes [32] to further improve localization accuracy. As wireless speeds increase, it might be possible to design over-the-air map updates for dense mapping systems like [38] using techniques similar to ours. We have left this to future work.

Long Term Mapping. Our implementation uses traditional computer vision-based features (ORB [49]) to build the map, but these can be replaced with better, more stable CNN-based features [25]. After running a feature extractor, CarMap uses motion tracking and semantic segmentation to select stable features to build the map. Mask-SLAM [33] proposes a similar dynamic object filter to CarMap but CarMap uses majority voting and robust labeling to account for limited on-board computational resources and boundary segmentation errors. Other approaches [17, 34] remove dynamic features from multiple maps collected along the same trace using background subtraction. Even the most static features are not persistent for larger timescales. Future work for longer timescale mapping can integrate CarMap with a persistence filter presented in [48] that estimates the life period of a feature based on an environmental evolution model. CarMap benefits from map-element culling techniques [35] that scale maps sizes by the scale of the environment rather than the number of miles driven. Mobileye [10] crowdsources collecting 3D maps for vehicles using monocular cameras whereas CarMap is designed for 3D sensors like LiDARs, and stereo cameras.

Vehicle Sensing and Communication. LiveMap [21] uses GPS and monocular cameras to automate road abnormality detection (*e.g.,* pothole detection). With its depth perception capabilities, CarMap can more accurately position roadside hazards. AVR [46] extends vehicular vision using feature maps and would benefit from CarMap. Although the bandwidth requirements for CarMap are within the LTE speeds today, it can benefit from systems [36] that schedule redundant transmissions over multiple networks. Recent work in object detection on mobile devices [39] introduces a fast object tracking method that can be used in CarMap to enable faster segmentation. For stitching map segments from rural, unmapped regions, CarMap can benefit from [44] which enables autonomous navigation in such areas.

7 Conclusion

CarMap enables near real-time crowd-sourced updates, over cellular networks, of feature-based 3D maps of the environment. It finds a lean representation of a feature map that fits within wireless capacity constraints, incorporates robust position-based feature search, removes dynamic and semi-dynamic features to enable better localization, and contains novel map update algorithms. CarMap has better localization accuracy than competing approaches, and can localize even when other approaches fail completely. Future work can explore LiDAR sensors, mapping over timescales in which even relatively static features can disappear, dense map representations, infrastructure-based sensing for map updates in low vehicle density areas, and automated update of semantic map overlays (accidents, available parking spots).

A Appendix

A.1 Map Stitching Details

Algorithm A.1 describes the details of the stitching algorithm. The following two paragraphs discuss two key aspects of stitching.

Finding Overlap. To find potential regions of overlap, CarMap uses two strategies. When the cloud service receives the new map segment M_s, it uses the GPS positions and word-histograms associated with M_s to coarsely find potentially overlapping keyframes in the base map M_b. For this, CarMap reconstructs all the data structures in M_b and only word-histograms and keyframe-features of M_s using the methods described in §3.5.

Then, CarMap finds a finer-grained overlap O_b and O_s (granularity level of map-points) between M_s and M_b. For this, CarMap uses the reconstructed keyframe features of M_s. For each keyframe k_s in O_s, it uses the k-D tree to find *all* features (§3.2) in O_b that match features in k_s, instead of only matching features belonging to the two overlapping keyframes k_s and k_b. At the end of this process, there is a pairwise matching of features between O_b and O_s.

```
Input  : Base map $M_b$ and new map segment $M_s$
Output: Stitched base map $M'_b$
1  if $M_b$ is empty then
2      $M'_b \leftarrow M_s$;
3  else
4      $R_b \leftarrow$ Reconstruct($M_b$);
5      $R_s \leftarrow$ PartialReconstruct($M_s$);
6      $O_b, O_s \leftarrow$ FindOverlap($R_b$,$R_s$);
7      $T_{bs} \leftarrow$ FindTransform($O_b$, $O_s$);
8      $M^\star_s \leftarrow T_{bs} * M_s$;
9      $M'_b \leftarrow$ Merge($M_b$, $M^\star_s$);
10 end
```

Algorithm A.1: Stitching Algorithm

Computing the transformation matrix. In the next step, CarMap computes the transform (translation and rotation) to re-orient and position M_s in M_b. To do this, it finds the keyframe k_s from the new map segment with the maximum number of matched features from the previous step. Then it uses a perspective n-point (PnP [37]) solver to derive the coordinate transformation matrix, then transforms each map feature in M_s to M_b's frame of reference. After the transformation, CarMap removes all the duplicate map-features in the overlapping region O_b of the resulting base map M'_b that originated as a result of the transformation.

A.2 Implementation Details

The following paragraphs describe how we have implemented CarMap components on top of ORB-SLAM2.

Map segment generator. This component takes the output of ORB-SLAM2 (which includes map-features, keyframe features, and the two indices), and simply strips all other components other than the map-features. We have also added the ability to periodically transmit complete *map segments*. On the receiver, we added a module to reconstruct (§3.5) the keyframe features from the received lean map, and re-generates the indices.

Fast feature search. For this, we added the k-D tree data structure, and associated code for manipulating the tree and searching in the tree, and re-used ORB-SLAM2 code for re-positioning a feature in a keyframe.

Stitcher. Stitching functionality does not exist in ORB-SLAM2. For stitching maps, we wrote our own modules for ORB-SLAM2. We also added support for finding overlapped keyframes and computing the transformation matrix.

Map updater. We wrote our own module for map updates. At the vehicle, our map update module uses a fast feature search for finding differences in the two feature sets (environment and base map). At the cloud, the module integrates these differences into the base map.

Dynamic object filter. We added a dynamic object filter to the mapping component of ORB-SLAM2 which invokes semantic segmentation and applies majority voting to decide the label associated with each map feature.

Map exchange. We added another module to allow the exchange of *map segments*, map updates, and the base map between the vehicles and the cloud service.

A.3 Bandwidth Requirements

Map Size with Change in Speed. As a vehicle's speed increases, it sees more features and hence generates larger maps. As such, we generated CarLA traces in which we increased the speed of the vehicle while keeping time constant. The goal of this experiment is to see if CarMap's maps can stay within the wireless bandwidth limits at different speeds. Figure A.1 shows that CarMap's maps are well below the wireless bandwidth limits today by a large margin and this is not true for competing strategies. ORB-SLAM2 and the No index approach's maps cannot be uploaded over current wireless networks at all speeds and cannot be downloaded for speeds greater than 10 kmph. The No keyframe-features approach is also infeasible for LTE upload for speeds over 15 kmph. We also validated this in Figure 19 for real-world traces from the KITTI dataset.

Bandwidth Savings with Map Updates. In this section, we evaluate the ability of CarMap's update operation to reduce the amount of bandwidth required to update the base map. For these experiments, we collected traces from the same area in CarLA in three different traffic conditions *i.e.,* static with no parked vehicles, semi-dynamic with only parked vehicles and dynamic with both parked and moving vehicles. We build a map for each traffic condition and then measure the amount of bandwidth required to update the existing map with features

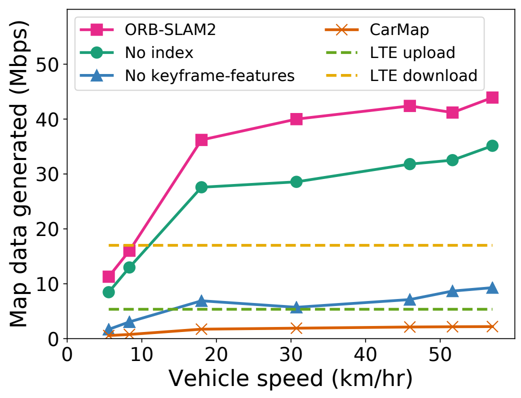

Figure A.1: Bandwidth requirements for mapping schemes at different speeds in CarLA. The bandwidth required to upload CarMap maps are well below the LTE upload limits.

Pre-loaded map	Trace	Map stitch size (MB)	Map update size (MB)
Static	Static	0.81	0.21
Static	Semi-dynamic	0.80	0.35
Static	Dynamic	0.82	0.29
Semi-dynamic	Static	0.81	0.27
Semi-dynamic	Semi-dynamic	0.80	0.08
Semi-dynamic	Dynamic	0.82	0.27
Dynamic	Static	0.81	0.24
Dynamic	Semi-dynamic	0.80	0.25
Dynamic	Dynamic	0.82	0.12

Figure A.2: Bandwidth requirements for map updates in CarMap under different traffic conditions

from a different set of conditions. The baseline we compare is with the map stitch case in which we would upload the whole map segment to the cloud service and the cloud service would only add the new map elements to the map.

The results from the experiment (Figure A.2) show that, given a base map of the area, map updates can reduce the amount of bandwidth required to integrate new features in the base map by 4-10$\times$ compared to sending the whole map segment (75$\times$ savings as compared to QuickSketch and ORB-SLAM2). This happens because the map update only sends new features whereas the map stitch sends the whole perceived map segment.

A.4 Mapping Accuracy

In this section, we evaluate how CarMap's reduced map sizes affect localization accuracy. For this experiment, we use all 11 real-world traces from the KITTI dataset. We generate maps for each of these traces, use them as base maps and localize the same trace in these maps. We compare the generated trajectory with the ground truth positions. Figure A.3 shows the average localization error divided by the length of the whole sequence for all the KITTI sequences. Even though CarMap reduces map sizes by a factor of 20, it is able to localize as accurately as ORB-SLAM2 in almost all KITTI sequences because: a) it preserves the most important map elements (map-features), and b) robust feature matching.

KITTI sequence number	Average translational error over whole trace (%)			
	ORB-SLAM2	No index	No keyframe-features	CarMap
00	0.16	0.17	0.17	0.16
01	0.69	0.69	0.68	0.74
02	0.18	0.17	0.17	0.18
03	0.31	0.32	0.32	0.36
04	0.33	0.31	0.39	0.40
05	0.07	0.07	0.07	0.08
06	0.12	0.21	0.20	0.20
07	0.14	0.15	0.14	0.15
08	0.33	0.30	0.26	0.30
09	0.32	0.32	0.30	0.29
10	0.46	0.50	0.50	0.48

Figure A.3: Localization error for CarMap over all KITTI sequences. Even though CarMap uses 20X fewer features in its map, its localization error is almost the same as ORB-SLAM2.

Total distance covered (m)	Average translational error (%)			
	ORB-SLAM2	No index	No keyframe-features	CarMap
50	3.62	3.61	3.75	2.70
100	2.25	2.15	2.22	1.85
150	1.55	1.54	1.60	1.50
200	0.88	1.22	1.27	1.30
300	0.73	0.91	0.94	0.99
400	0.66	0.75	0.78	0.80
600	0.56	0.60	0.62	0.58
800	0.53	0.55	0.53	0.49
1000	0.30	0.30	0.31	0.31
2000	0.32	0.30	0.30	0.32
3000	0.24	0.23	0.22	0.23
4000	0.18	0.17	0.17	0.18
5000	0.18	0.17	0.17	0.18

Figure A.4: Mapping accuracy of mapping schemes with varying distance, averaged over all KITTI sequences. The overall localization error decreases over longer distances and CarMap's localization error is almost the same as ORB-SLAM2's

Figure A.8 shows the error distribution of CarMap is similar to ORB-SLAM2, and QuickSketch for a map built from, and used in the first KITTI sequence, despite reducing map sizes by a factor of 20.

An important property of a map is to able to localize accurately over long distances. To study how CarMap's localization accuracy changes with the mapped area, we calculate the average translational error at different distances (*i.e.,* 50m to 5km) for all 11 KITTI sequences. We average these errors on all KITTI sequences and report the numbers in Figure A.4. As distance increases, the average translational error decreases and CarMap does as well as ORB-SLAM2 in almost all cases. The reason for this, as mentioned in §3, is that although CarMap removes keyframe-features, the robust feature matching (§3.2) makes up for the 20x fewer features with better matching.

A.5 Map Reconstruction

CarMap reduces map size by trading off compute for storage. The map load time for CarMap consists of the time to load the map from disk and the reconstruction time. After loading the map into memory, CarMap reconstructs two indices and infers the 2D and 3D position of map-features in keyframes (§3.5). Even so, as shown in Figure 20, except for sequence 00, 01 and 06, the load times for CarMap *are less than the ORB-SLAM2 baseline* (on average, 0.95×).

Figure A.5 shows the breakdown of the various map elements that contribute to map reconstruction time for all 11 KITTI sequences. In all sequences, reconstructing the feature-index takes around 40% of the overall reconstruction time. This, however, is still 2-4x less than the reconstruction time for keyframes that contain keyframe-features (in other mapping schemes) instead of just map-features. Calculating the 2D and 3D positions of map-features also takes an average 35% of the overall reconstruction time. The main reason for higher load times (Figure 20), as compared to ORB-SLAM2, in some cases (sequence 00, 01, and 06) is because of the variability map-feature index (orange bar) reconstruction times. The map-feature index is a graph that relates map-points to keyframes they were detected in. Hence, for environments like highways where the scene stays relatively constant, this graph is denser and so the reconstruction costs for the map-feature index are relatively greater. On the other hand, for environments where features change quickly *e.g.,* narrow streets, the map-feature index reconstruction times are lower because these graphs are not as dense. For instance, the feature-index reconstruction for sequence 00 (captured in narrow-streets) is approximately 3x greater than sequence 01 (captured on the highway).

A.6 Map Stitching Evaluation

In this section, we evaluate the ability of CarMap to accurately stitch map segments collected from different spatial and temporal conditions. We compare CarMap against two other map stitching schemes: progressive relocalization and QuickSketch. In progressive relocalization, as opposed to CarMap (one-shot stitching), we relocalize *every* keyframe from the incoming map segment instead of using the global transformation matrix. QuickSketch can only stitch a stereo camera trace with a QuickSketch generated map segment. So, for stitching, QuickSketch loads the QuickSketch map as a base map and then stitches by localizing the stereo camera trace in it.

We evaluate two metrics for stitching: mapping error, and stitching time. After stitching two map segments, we localize a trace in the stitched map and calculate the absolute translational error (m) for each frame. Mapping error is the mean of the translational errors over the whole trace. The stitching time is the amount of time required to do the whole stitch operation of two map segments.

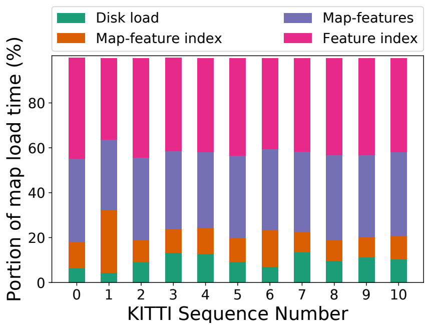

Figure A.5: Breakdown of reconstruction time for CarMap across all KITTI sequences

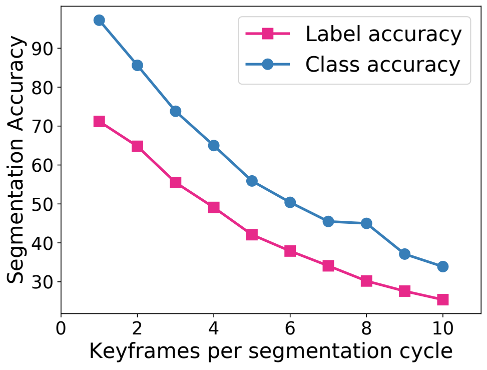

Figure A.6: Semantic segmentation accuracy at different frame rates. If CarMap segments every other keyframe, classification accuracy is 85%.

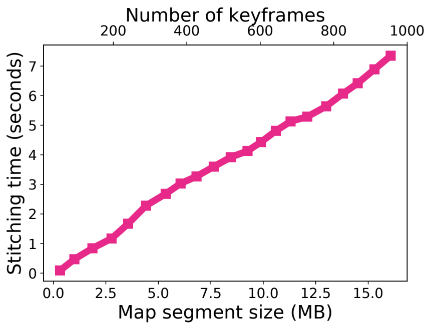

Figure A.7: Computational overhead of stitching. Even map segments as large as 1000 keyframes can be stitched in under 7 seconds.

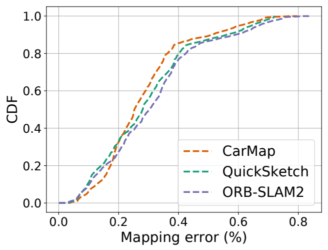

Figure A.8: For a map built, and used from a real-world trace (KITTI Trace 00) 80% of CarMap's mapping errors are less than 0.4% with respect to the length of the trace.

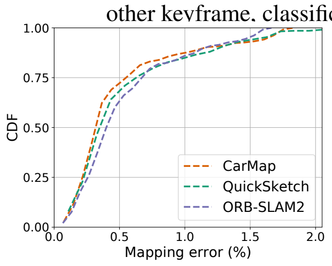

Figure A.9: For a map built, and used in a static trace collected from CarLA, 75% of the mapping errors for CarMap are less than 0.2% with respect to the length of the trace.

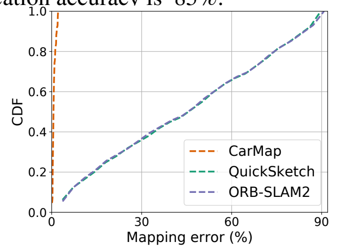

Figure A.10: For maps built, and used in CarLA's dynamic environments, CarMap has a maximum error of 2%. ORB-SLAM2 and QuickSketch have maximum errors of 90%.

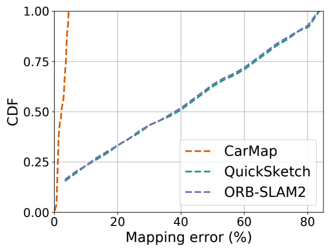

Figure A.11: For CarLA maps built from static, and used in dynamic environments, CarMap has a max error of 4%. ORB-SLAM2 and QuickSketch have maximum errors of 90%.

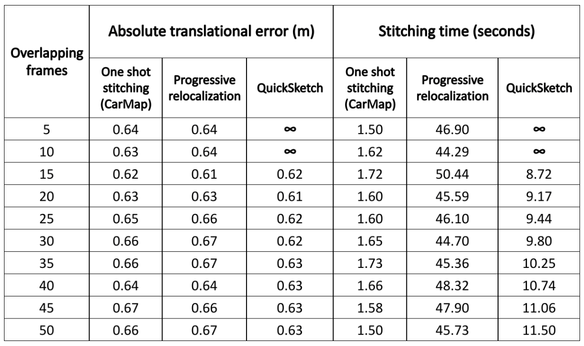


Overlapping frames	Absolute translational error (m)			Stitching time (seconds)		
	One shot stitching (CarMap)	Progressive relocalization	QuickSketch	One shot stitching (CarMap)	Progressive relocalization	QuickSketch
5	0.64	0.64	∞	1.50	46.90	∞
10	0.63	0.64	∞	1.62	44.29	∞
15	0.62	0.61	0.62	1.72	50.44	8.72
20	0.63	0.63	0.61	1.60	45.59	9.17
25	0.65	0.66	0.62	1.60	46.10	9.44
30	0.66	0.67	0.62	1.65	44.70	9.80
35	0.66	0.67	0.63	1.73	45.36	10.25
40	0.64	0.64	0.63	1.66	48.32	10.74
45	0.67	0.66	0.63	1.58	47.90	11.06
50	0.66	0.67	0.63	1.50	45.73	11.50

Figure A.12: Mapping error (m) with different overlapping regions. CarMap can stitch with fewer overlapping frames than QuickSketch and 30x faster than progressive relocalization.

Stitching Overlap. In the first experiment, we evaluate the mapping error and stitching time of the three mapping schemes as a function of the overlap between the two map segments. For this, we take a single stereo camera trace and split it into two traces with different overlaps. Figure A.12 shows that QuickSketch fails to stitch when the number of overlapping frames between the two map segments is less than 10 frames (1 second). This is because it is not able to find enough feature matches between the two map segments. On the other hand, CarMap can find enough feature matches even though it uses 20x fewer features due to its robust feature matching (§3.2). The mapping accuracy remains relatively constant irrespective of the amount of overlap because CarMap only needs to localize a single keyframe in the base map for a successful stitch operation. Although the mapping error of progressive relocalization is identical to CarMap, it takes approximately 30x more time to stitch the same area. In the stitch operation, localizing a keyframe in the base map is the most expensive operation. CarMap intelligently localizes a single keyframe in the base map and then uses a transformation matrix to shift the remaining map elements. On the other hand, progressive relocalization localizes all keyframes in the base map and hence takes a much longer time. So, as the size of the incoming map segment increases, the stitching time for progressive relocalization will increase significantly.

Stitching Overhead. To study the overhead of stitching, we take a KITTI trace and split it into two map segments (with a few overlapping frames). In doing so, we mark one as the base map and the other as the incoming map segment. We keep the size of the base map constant and vary the size of the incoming map segment. Figure A.7 shows that the stitching time increases with the size of the incoming map segment. It also shows that for map segments containing as many as 1,000 keyframes (15 MB), stitching takes only 7 seconds.

A.7 Semantic Segmentation

In this experiment, we evaluate the object label and class (static, and dynamic) estimation accuracy of CarMap against the frame rate of semantic segmentation. For this experiment, we generate stereo camera traces from CarLA. We segment these images with MobileNetV2. For ground truth, we use CarLA's own semantic segmented images.

Figure A.6 plots the accuracy of segmentation in CarMap using majority voting at different frame rates. We start by running segmentation every keyframe and evaluate till running segmentation every 10 keyframes. In the KITTI dataset, the average keyframes inserted per second is 3.17 and the worst case is 10 keyframes per second. The worse case corresponds to running segmentation every 2 keyframes *i.e.,* a class accuracy of 86% with CarMap using MobileNetv2 in a majority voting scheme.

Food and Liquid Sensing in Practical Environments using RFIDs

Unsoo Ha, Junshan Leng, Alaa Khaddaj, Fadel Adib
Massachusetts Institute of Technology

Abstract – We present the design and implementation of RF-EATS, a system that can sense food and liquids *in closed containers without opening them or requiring any contact with their contents*. RF-EATS uses passive backscatter tags (e.g., RFIDs) placed on a container, and leverages near-field coupling between a tag's antenna and the container contents to sense them noninvasively.

In contrast to prior proposals that are invasive or require strict measurement conditions, RF-EATS is noninvasive and does not require any calibration; it can robustly identify contents in practical indoor environments and *generalize to unseen environments*. These capabilities are made possible by a learning framework that adapts recent advances in variational inference to the RF sensing problem. The framework introduces an RF kernel and incorporates a transfer model that together allow it to generalize to new contents in a sample-efficient manner, enabling users to extend it to new inference tasks using a small number of measurements.

We built a prototype of RF-EATS and tested it in seven different applications including identifying fake medicine, adulterated baby formula, and counterfeit beauty products. Our results demonstrate that RF-EATS can achieve over 90% classification accuracy in scenarios where state-of-the-art RFID sensing systems cannot perform better than a random guess.

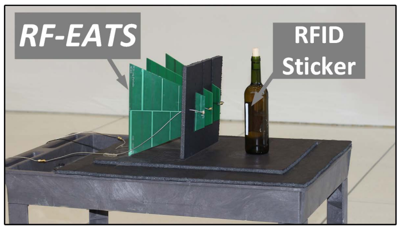
1 Introduction

The networking community has recently witnessed a surge in research that uses wireless signals for sensing liquid and food properties [25, 21, 66, 77]. This research is motivated by a desire to develop low-cost, ubiquitous solutions for food safety sensing by leveraging pervasive networking technologies. In contrast to traditional food sensing solutions which rely on expensive equipment in specialized labs, these new proposals aim to make food safety sensing accessible to lay consumers. This can help avoid widescale future health hazards like the Chinese baby milk scandal [43], the Flint water crisis [70], and the recurring alcohol poisoning problem which results in hundreds of cases of blindness and death every year [32].

Despite initial steps made toward this vision [21, 77, 66], existing proposals still have fundamental limitations that make them too invasive and/or impractical for lay consumers. Specifically, they either require users to extract liquid samples and place them in specialized containers (which often involves a complex calibration process) [21, 77, 56], or they can only operate correctly a single lab setup under strict measurement conditions [66, 25]. These limitations make it difficult for consumers to use such systems for testing products for contamination or counterfeiting before purchasing and outside pre-calibrated lab environments.

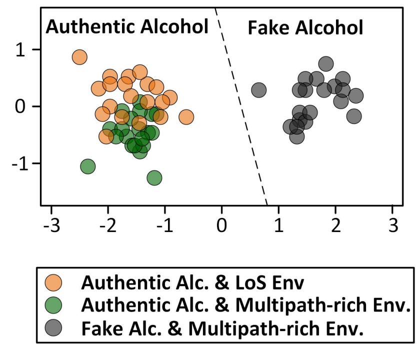
The goal of this paper is to develop a *noninvasive, zero-calibration* system for wireless sensing of food and liquids in practical environments. Such a system would enable consumers to test food and liquids without opening their containers and in different environments: supermarkets, grocery stores, or homes. Our system will rely on off-the-shelf RFIDs (Radio Frequency IDentifiers), similar to those used in some past proposals [25, 66]. RFIDs cost few cents each, and they have been widely adopted by the industry as barcode replacements for billions of items (including food products). This makes them ideal candidates for low-cost and ubiquitous food sensing. Moreover, our recent research has demonstrated that an RFID's signal changes when it is placed on containers filled with different liquids due to near-field coupling between the RFID's antenna and material inside the container [25]. However, similar to earlier wireless proposals, this RFID-based approach could not generalize to new environments.

The difficulty in extending wireless food sensing to different environments is that radio signals are not only impacted by the content of a container but also by the environment where the measurement is made. Fig. 1 illustrates this challenge by showing three experimental trials in two different setups. Each setup consists of a wireless reader that measures the RFID's signal and extracts the channel response. This response is impacted by two factors: the content inside the container (due to the near-field coupling) and the measurement environment which encompasses the location of the container with respect to the reader as well as the reflections off different objects in the environment (due to the propagation of the RFID's wireless signal before it reaches the reader). As a result, if either the environment or the content proper-

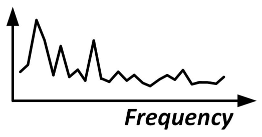


(a) First Environment (E1)

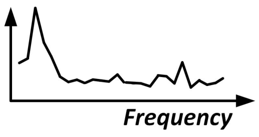
(b) Second Environment (E2)



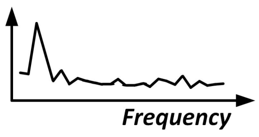
(f) Learning Results



(c) Authentic in E1



(d) Authentic in E2



(e) Fake in E2

Figure 1: **RF-EATS senses food and liquids noninvasively across different environments.** The figure shows how RF-EATS uses unmodified RFID stickers placed on authentic and fake alcohol-filled bottles to sense their contents noninvasively in two different environments shown in (a) and (b). (c)-(e) plot the RFID's wideband response from three experimental trials. Because the environment significantly impacts the measured RFID response, the frequency spectra of (d) and (e) look closer than (c) despite that (c) and (d) are from authentic alcohol bottles while (e) is from a fake alcohol one. (f) plots the classification output of RF-EATS's learning model (after dimensionality reduction), where each point represents a different experimental trial. The plot shows that trials with authentic alcohol collected across different environments are clustered together, while those with fake alcohol are in a different cluster. This shows that RF-EATS can correctly classify contents despite the environmental changes.

ties change, the response changes (see the bottom row of Fig. 1). This is why prior proposals require calibrating or constraining the measurement conditions, limiting the practicality and generalizability of their designs.

We present RF-EATS,[1] an RFID-based sensing system that is robust to environmental variations and that generalizes well to unseen environments. At the core of RF-EATS's design is a neural learning model that can learn RF features due to a container's content and discard those resulting from extraneous environmental changes. For example, if the system is trained to detect adulterated baby formula in a lab environment, it still has high detection accuracy in a supermarket-style setup with dense environmental multipath (reflections) from metal shelving and other items on the aisles.

A fundamental challenge in training any neural learning model (including for image or text classification tasks) arises from the need for very large datasets. This challenge is exacerbated in our context due to the limited availability of RF datasets for sensing. A naive solution is to collect an extensive dataset that covers various indoor environments and use it in training. However, such an approach is time-consuming, inefficient, and incapable of generalizing to unseen environments.

To efficiently generalize to different environments, RF-EATS builds on recent advances in variational autoencoders [53, 33] and adapts them to RF sensing tasks. These models are typically used to generate realistic synthetic data (e.g., images of faces of humans who do not exist). Instead, RF-EATS employs them to generate a large number of realistic multipath-affected data from a small number of real-world measurements. To do so, it introduces a *multipath kernel function*, which allows it to (approximately) decompose the wireless channel into content-dependent and environment-dependent features. Subsequently, RF-EATS can train an autoencoder to learn distributions of practical radio environments (i.e., reflections, position changes, etc.) by focusing on the environment-dependent features. This allows RF-EATS to emulate a large number of realistic measurements and use them to train its neural classifier.[2] In §3.1, we describe this technique in detail and demonstrate how its stochastic nature enables generalizing RF-EATS to unseen environments.

It is desirable to extend RF-EATS's learning framework to new contents in a sample-efficient manner. For example, if a model is trained to detect adulterated baby formula, we would like to extend it to detect fake alcohol using a small number of alcohol measurements. Said differently, we would like to harness the power of a well-trained model on a large number of measurements to achieve high accuracy on new tasks, without having to train a new model from scratch. To do so, RF-EATS employs transfer learning: it divides a multi-layered network into *common layers* (shared by all tasks) and *task-specific layers*. In order to learn a new task (e.g., detecting fake alcohol), it can inherit the common layers from a well-trained model (e.g., the baby formula model) and only needs to retrain the task-specific layers. This further reduces the number samples required to extend the model to new contents, allowing RF-EATS to achieve near-

[1]RF-EATS stands for RF-based Environment-Agnostic Transferable Sensing.

[2]In our evaluation, we demonstrate how this approach significantly outperforms using the standard ray-tracing model for generating synthetic multi-path environments [63].

optimal accuracy even when the dataset from a new content is limited. We describe this model in details in §3.2.1 and show how the common layers can serve as a pre-trained model for future classification tasks beyond those described in this paper.

We implemented a prototype of RF-EATS on USRP X310 software radios, and tested it with off-the-shelf UHF (Ultra-High Frequency) RFIDs. We adapted a recent wideband measurement technique which can extract more than half a GHz of RF measurements from off-the-shelf, passive RFIDs [40], thus providing a rich set of features for classification. We evaluated it in seven different applications and with sixteen different contents including: fake medicine, adulterated baby formula, contaminated alcohol, counterfeit perfume, wine aging, and soda classification. In each of these applications, we evaluated its ability to identify adulteration under standard contamination/adulteration levels reported in recent cases [43, 32, 50, 17, 19].

Our results from 2048 experimental trials in 20 different environments demonstrate the following:

- RF-EATS's accuracy approaches 90% across most the above applications even when tested in new and unseen environments. In contrast, the accuracy of a state-of-the-art baseline [25] drops from 90%+ when evaluated in the same environment to a random guess in unseen environments for half the applications.
- RF-EATS's transfer model enables achieving near-optimal accuracy with as little as four data samples, demonstrating the importance of this model when the dataset is limited.
- We show how RF-EATS's autoencoder can be used as an anomaly detector to generalize to contaminated or counterfeit content even if it has not been trained on the specific contaminant.
- RF-EATS's accuracy is directly impacted by the dielectric differences between the contents it wishes to classify. We show some negative results including its low accuracy in detecting fake extra-virgin olive oil due to limited dielectric differences between fake and authentic olive oil.

Contributions: RF-EATS is the first RFID-based system that can noninvasively sense food and liquids in closed containers and operate correctly in unseen environments. It employs a variational autoencoder architecture that can learn and generate realistic multipath environments, and introduces a new kernel function that can apply these generated environments to real data. It also employs transfer learning to efficiently extend its sensing capabilities to new liquids and food items. The paper also contributes a prototype implementation and evaluation of RF-EATS in practical environments.

It is important to note that RF-EATS's performance is directly impacted by the extent of dielectric differences between contents it wishes to classify. This means that if the dielectric differences are small (e.g., the olive oil application), the accuracy degrades. This degradation is likely to be mitigated as the dataset and learning models evolve. We also note that our evaluation focused on demonstrating robustness to changes in the surrounding environment while fixing the container's material (e.g., glass or plastic) and shape. Despite these limitations, RF-EATS marks an important step toward food and liquid sensing in practical environments. More generally, we hope that RF-based liquid and food sensing will follow a similar trend in accuracy improvements as that witnessed by vision and text learning tasks in recent years.

2 Background

Researchers have long recognized the need for monitoring food quality and safety. Most existing techniques rely on measuring electrochemical and electrophysical properties [42, 35, 65, 1]. The process involves extracting food samples and placing them in direct contact with chemical reagents and/or specialized sensing circuits (e.g. biotoxin sensors [15, 16, 27]) and is typically done in specialized food labs.

Given the length of the food lab testing process, recent proposals have considered building small sensing circuits in hope of incorporating them inside food containers [72, 46, 62, 51, 37]. These proposals require designing a customized sensor for every different type of food or food property of interest [72, 62] or they require coating existing circuits (e.g., LC circuits or RFIDs) with different types of polymers to increase sensitivity to specific materials of interest [46, 51]. Moreover, many of these sensors still require direct contact with food samples, which can lead to contaminating the food samples and is erosive to their sensing interfaces [47, 76, 58].

The desire for ubiquitous and general purpose solutions has led networking and mobile researchers to explore various mobile sensing modalities. These techniques rely on different kinds of wireless signals to extract material properties such as the electric permittivity [66, 21, 23, 44, 78], surface tension [60, 71, 77], or photo-acoustic signatures [57]. However, the reliance on wireless signals makes these techniques highly sensitive to measurement conditions; hence, the proposed systems require isolating food samples of interest and placing them in calibrated setups. This includes recent proposals like LiquID [21], TagScan [66], and CapCam [77]. The invasiveness of these approaches makes them unsuitable for use by consumers before they purchase counterfeit or contaminated food and liquid products. RF-EATS shares the vision of this line of work but aims to develop a non-invasive approach for food and liquid sensing.

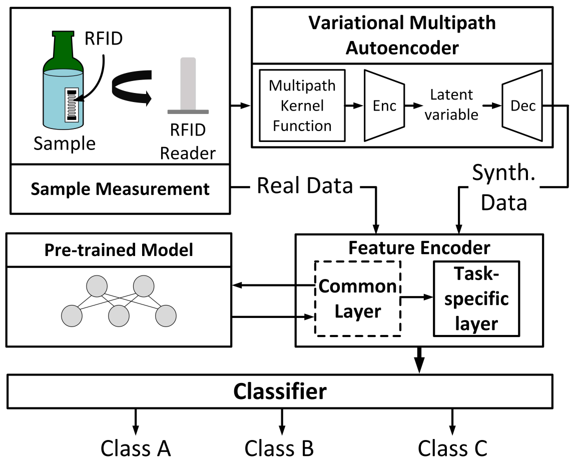


Figure 2: **RF-EATS's Learning Model.**

3 Design

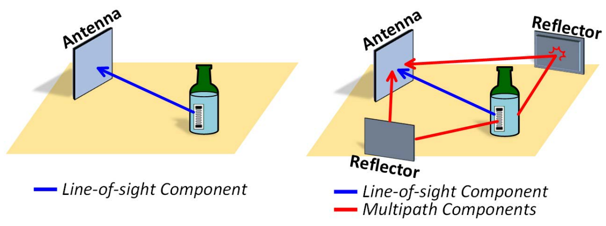
RF-EATS is a wireless system that can noninvasively sense food and liquid products in closed containers without opening them. It relies on cheap, passive UHF (Ultra-High Frequency) RFID tags placed on the containers, and exploits the near-field coupling between the RFID's antenna and the container's contents. These RFIDs may either be already affixed on the container by the manufacturer, or they may be attached as stickers to the container as shown in Fig. 1.

Fig. 2 shows the overall system architecture. From the hardware perspective (top left), it uses a modified RFID reader capable of obtaining wideband channel measurements [39, 25, 14] of unmodified RFID tags. The reader sends a downlink signal which powers up a passive tag and obtains the tag's response. It performs standard channel estimation using the packet preamble, and uses the channel estimates in training and classification.[3] Note that while our discussion focuses on a single tag, it can be easily extended to any number of tags since it adapts the standard EPC-Gen2 protocol.

RF-EATS can be used for various inference tasks (e.g., detecting adulterated baby formula, fake alcohol). Its learning architecture consists of a neural network with the following components, as shown in Fig. 2:

- *Variational Multipath Autoencoder (§3.1):* This component takes as input a small number real-world channel measurements and outputs a large number of realistic synthetic measurements. At the heart of this component is a multipath kernel function that enables learning representative distributions of RF environments while discarding the container contents' impact.
- *Feature Encoder (§3.2.1:)* This component takes as input real and synthetic data and extracts features for use in classification. It consists of multiple layers, some of which are shared among all classification tasks. These layers may be reused as a pre-trained model for extending RF-EATS to new types of contents.
- *Classifier (§4.1):* The component takes as input the features outputted by the feature encoder, and outputs the classification results. While the variational autoencoder and part of the feature encoder are shared by all tasks, this component must be retrained for each task.

[3]It relies on the *channels not the IDs* for the inference tasks.



(a) Line-of-sight environment (b) Multipath environment

Figure 3: **Typical Ray-Tracing Channel Approximations.**

The above three components together enable RF-EATS to generalize to unseen environments (through synthetic data from the autoencoder), expand to new materials using small datasets (by leveraging the shared layers of the feature encoder), and extend to untested contaminants (by using the autoencoder as an anomaly detector). The following sections explain these components in details.

3.1 Variational Multipath Autoencoder

To achieve high accuracy with a neural learning model, RF-EATS's training dataset needs to be large and representative of a variety of environments. Unfortunately, collecting large datasets for every contaminant and every multipath environment is an expensive and time-consuming [28]. Further, even if we manage to collect such datasets, there would remain unseen environments which the model may not be able to generalize to.

Below, we describe how RF-EATS overcomes this challenge by leveraging a stochastic generative model based on variational autoencoders. The model enables it to generate realistic synthetic data for use in training, which increases its accuracy despite limited datasets and enables it to generalize to unseen environments.

3.1.1 The Multipath Kernel

RF-EATS's generative model needs to realistically capture different aspects of an RFID's measured channel response. Fig. 3(a)-(b) depict common approximations of the wireless channel. In line-of-sight scenarios, the RFID's wireless signal arrives on a direct path to the reader's antenna; in multipath-rich environments, the signal arrives on multiple paths (after bouncing off various reflectors) which linearly combine at the receiver. Mathematically, the RFID's channel h at a given frequency k is typically approximated as [63]:

$$h_k = \sum_{i=0}^{N} a_i e^{-j2\pi f_k \tau_i} \tag{1}$$

where a_i and τ_i are the amplitude and time delay of the i^{th} path, f_k is the k^{th} frequency, and N is the total number of paths.

This standard approximation is problematic for RF-EATS's learning tasks because of two main reasons: 1) it ignores the impact of the RFID's antenna gain and 2) it ignores scattering and diffraction phenomena of radio signals. The first approximation is particularly detrimental since it prevents capturing the impact of the container's content on the antenna (more specifically, the impact of the content's dielectric ε). The second one is also problematic as it results in less representative channel distributions.[4] While it is possible to overcome these shortcomings by solving Maxwell's equations [64], this is undesirable since it requires precise modeling of the geometry and materials in the environment, making it practically and computationally expensive [61].

To truthfully represent the RFID's measured response, we would like RF-EATS's generative model to embrace the complexity of the wireless channel. The model must incorporate both the impact of the content dielectric (on the antenna gain) and that of the wireless signal propagation (due to reflection, scattering, and diffraction). We can achieve this by expressing the overall channel as a product of the gain $G(\varepsilon, k)$ and the propagation $P(k)$ characteristics as follows:

$$h_k = G(\varepsilon, k) \cdot P(k) \tag{2}$$

We make the following remarks:

- First, one might wonder why the presence of other nearby objects does not impact the RFID's antenna gain (i.e., why it only affects the propagation factor $P(k)$). To answer this question, we note that the electromagnetic interaction of antennas with different objects in the environment depends on the distance between the antenna and the objects [29]. If an object is in the near-field (i.e., within one wavelength[5]), it "couples" with the antenna and impacts its gain. If the object is in the far-field (i.e., larger than two wavelengths), it impacts the propagation $P(k)$. This is why RF-EATS incorporates the impact of container contents into the gain while absorbing environmental multipath into the propagation factor.[6]
- If the location and multipath environment are fixed, then any change in the measured channel h_k can be attributed to the gain $G(\varepsilon, k)$ and thus be used directly to infer the contents. Indeed, this is why past proposals for wireless food sensing required fixing and/or calibrating their setup but are unable to generalize to different multipath environments.
- Similarly, if the content of a container is fixed, then any change in the measured channel can be attributed entirely to the multipath environment $P(k)$. Let us say that we measure the RFID's channel in two scenarios: one in a line-of-sight (LOS) controlled environment with little to no multipath ($h_{k,LOS}$), and another in a multipath-rich environment ($h_{k,MPATH}$). The ratio of these measurements is entirely dependent on the multipath environment and independent of a container's contents. Specifically:

$$\frac{h_{k,MPATH}}{h_{k,LOS}} = \frac{P_{MPATH}(k)}{P_{LOS}(k)}$$

We call this the *multipath kernel function*. For simplicity, we approximate a multipath-free $P_{LOS}(k) \approx 1$.

[4]In §4.4, we empirically compare against the standard ray-tracing model and show that RF-EATS significantly outperforms it.

[5]In the UHF ISM band, the wavelength is about 30 cm. It becomes significantly smaller in liquids due to the impact of the dielectric.

[6]This approximation works well in practical because near-field backscatter power decays as $1/d^4$.

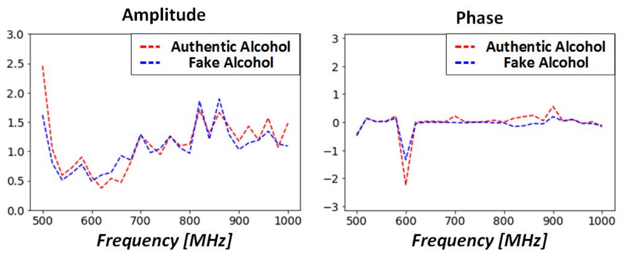


Figure 4: **Output of Multipath Kernel Function.**

To test that the multipath kernel indeed results in content-independent features, we ran experimental trials with fake and authentic alcohol in two environments representing line-of-sight and multipath-rich settings similar to those shown in Fig. 1. We computed the ratio of the channel in multipath to that in line of sight, and plot the output in Fig. 4. Since the channel is a complex number, we plot the amplitude and phase of the ratios on separate graphs, each as a function of frequency. The figure shows that the ratio is indeed independent of the content since the plots for authentic (red) and fake (blue) alcohol almost overlap for both magnitude and phase. This indicates that the kernel function enables us to extract environment-dependent content-independent features.

3.1.2 Training a Generative Model

Now that we have a mechanism to obtain environment-dependent features from real-world measurements, we can use them to train a generative model. The model takes these measurements as input and generates a large number of synthetic data representing different multipath environments. While there are various kinds of generative models [55, 53, 33], RF-EATS employs variational autoencoders (VAE) because they have the ability to generalize using a small input dataset. In what follows, we

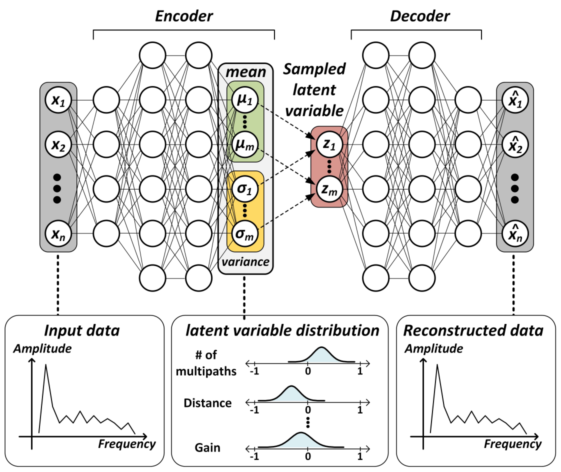

Figure 5: **RF-EATS's Variational Autoencoder.**

describe these models at a high level and in the context of our problem, and we refer the interested reader to [53] for a more detailed exposition.

VAEs assume that the input features represent a much lower dimensional space of latent variables. In the context of our learning tasks, the wireless propagation factor is indeed caused by a small number of reflectors and scatterers in the environment [34]. However, the reflectors and scatterers change across different environments, resulting in different channel responses. VAEs capture this phenomenon by assuming that the latent variables are randomly drawn from a normal distribution. Once the underlying distributions are learned, RF-EATS can draw new samples from them to generate synthetic data for unseen multipath environments.

Fig. 5 shows the overall architecture of RF-EATS's variational autoencoder. The VAE takes as input the channel ratios, each of which consists of a multi-dimensional vector $x_1, x_2, ..., x_n$, and outputs a reconstruction of these features $\hat{x}_1, \hat{x}_2, ..., \hat{x}_n$. The model consists of an encoder (which aims to compress these features into latent variables $z_1, z_2, ..., z_m$) and a decoder (which aims to reconstruct the input from the latent variables). By compressing and decompressing the input, the neural network aims to learn a representative lower-dimensional distribution of the latent variables.

Formally, the purpose of training the VAE is to learn the parameters of the neural network that can (1) minimize the reconstruction loss between the input $\mathbf{x}$ and output $\hat{\mathbf{x}}$, and (2) model the underlying distribution of the latent variables $q_\theta(z|x)$ as a normal distribution. Formally, this can be achieved by minimizing the following loss function [33]:

$$L_i(\phi, \theta, x_i) = KL(q_\theta(z|x_i)||\mathcal{N}(0,1)) + \mathcal{L}(x, \hat{x}) \quad (3)$$

where KL is Kullback-Leibler divergence, which is a measure of the difference between two probability distributions, $\mathcal{N}(0,1)$ denotes the Gaussian with zero mean and standard deviation of 1, and $\mathcal{L}$ represents the *L2 norm* of the reconstruction loss in frequency domain.

The following points are worth noting:

- The VAE input and output are independent of the content. Hence, it can be trained on any container content (or even on empty containers), and its output may be used for any classification task as we explain below.
- Our discussion focuses entirely on the RFID's channel and ignores the communication bits. This is possible because RF-EATS applies standard channel estimation on the RFID packet's preamble to extract the channel. It also uses an out-of-band sensing technique (described in §4.1) to obtain wideband estimates.

3.1.3 Embedding Dielectric Characteristics

Once the VAE has been trained, it can be used to generate synthetic multipath environments by randomly drawing samples z from the latent distributions and passing them through the decoder shown in Fig. 5. Note, however, that the VAE's synthetic output cannot be directly used to train a contamination classifier (i.e., we cannot directly use it to train a fake alcohol classifier). This is because output features are independent of the content.

In order to generate synthetic measurements that incorporate the impact of both the content and the propagation environment, we need to apply the inverse of the multipath kernel. Specifically, we need to measure $h_{k,LOS}$ of an RFID placed on fake and authentic alcohol bottles in line-of-sight settings, then multiply these measurements by the output features of the VAE. Since the generative model is capable of stochastically generating different multipath environments, we only need a small measurement dataset of $h_{k,LoS}$ to generate a large number of realistic channel measurements and feed them into the classifier. Hence, the VAE model provides a large corpus for training the classifier without requiring measurements for every multipath environment and contaminant.

3.2 Extending to New Tasks and Compositions

In this section, we describe how we can efficiently extend RF-EATS's learning framework to new tasks and unseen compositions or contaminants.

3.2.1 Transfer Learning to New Tasks

We would like to extend RF-EATS to new classification tasks in a sample-efficient manner. For example, having trained a classifier to detect fake alcohol using a large dataset, we would like to extend it to detect adulterated baby formula using a small number of samples. This would enable expanding RF-EATS to new tasks using a smaller number of measurements of the new content of interest. To do so, RF-EATS employs transfer learning in order to transfer training knowledge from a well-trained source domain (e.g., alcohol) to a new target domain (e.g., baby formula).

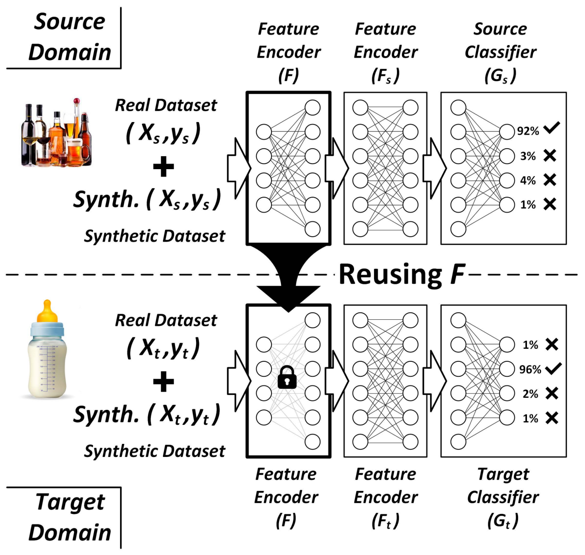

Figure 6: **RF-EATS's Transfer Learning Model.**

Fig 6 shows how this process works at a high level. Recall that neural networks consist of multiple layers, some of which are used for feature extraction or encoding, while others are used for classification. The feature extraction layers themselves may be further divided into common layers and task-specific layers. The common layers can be directly transferred as "frozen" layers F from a well-trained classifier to the target domain. This significantly reduces the number of parameters that need to be learned for the new task, thus reducing the required dataset size to achieve high accuracy.

Mathematically, each domain can be represented as

$$\begin{aligned}(X_s, y_s) &= \{(x_{s,i}, y_{s,i})\}_{i=1}^{N_s} \\ (X_t, y_t) &= \{(x_{t,i}, y_{t,i})\}_{i=1}^{N_t}\end{aligned} \tag{4}$$

where X_s and y_s are the observations and respective labels of the source content domain, X_t and y_s are the observations and labels of the target content domain, x_i represents the complex channel estimate of one observation over different frequencies, y_i represents the label (*e.g.* contaminated or not), N_s the number of samples in the source content domain and N_t the number of samples in the target content domain.

Assuming the latent space dimensionality is d, we can represent the feature encoder and source/target classifier as:

$$\begin{aligned}F &: \mathbb{R}^n \to \mathbb{R}^d \\ G_s \circ F_s &: \mathbb{R}^d \to \{0, 1, \ldots, C_s\} \\ G_t \circ F_t &: \mathbb{R}^d \to \{0, 1, \ldots, C_t\}\end{aligned} \tag{5}$$

where n comes from the dimension of the input data, and C_s, C_t represent the number of classes in the source and target content domains respectively.

After training the model on the source content domain, we fix the weights of F. We then compute $\hat{y}_t = G_t \circ F_2 \circ F(X_t)$ and minimize the standard cross-entropy loss function $\mathcal{L}_t(y_t, \hat{y}_t) = -\sum_{i=1}^{C} p(y_{t,i}) \log p(\hat{y}_{t,i})$, where $y_{t,i}$ and $\hat{y}_{t,i}$ represent the actual and predicted label for class i. Here, only the weights of F_2 and G_t are updated, while the weights of F remain intact.

Algorithm 3.1 VAE-based Anomaly Sample Detection

```
Input: Anomalous data point $x_i$, threshold $\alpha$, trained
  Encoder $E_\theta$ and Decoder $D_\phi$
Output: Reconstruction probability $P_R$
  $\mu_{z(i)}, \sigma_{z(i)} = E_\theta(x_i)$
  draw $L$ samples from $z \sim N(\mu_{z(i)}, \sigma_{z(i)})$
  for $l = 1$ to L do
    $\hat{x}_{(i,l)} = D_\phi(z_{(i,l)})$
  $P_{R(i)} = \frac{1}{L} \sum_{l=1}^{L} \mathcal{L}(x, \hat{x}_{(i,l)})$
  if $P_{R(i)} > \alpha$ then
    $x_i$ is an anomaly
  else
    $x_i$ is not an anomaly
```

3.2.2 Anomaly Detection for Unseen Compositions

So far, we have assumed that RF-EATS's classifiers have been trained on samples from all classes of interest, including counterfeit and adulterated samples. However, in many practical applications, we may not have access to counterfeit or contaminated samples, or the composition/type of contaminant may be unknown.

We can generalize RF-EATS to deal with such situations by using its VAE as an anomaly detector [13, 41]. Recall that the VAE is trained to minimize the reconstruction loss of the environment-dependent features. Hence, if the input to the VAE encodes environment-dependent features, we expect the reconstruction loss to be low. On the other hand, if the input deviates from the expected distribution, the reconstruction loss will be high, indicating an anomaly.

To see how this can be used to detect counterfeiting, consider the case of a manufacturer that creates a database of $h_{k,LOS}$ measurements of the authentic product. Subsequently, if we measure the channel $h_{k,c}$ of a counterfeit product and apply the multipath kernel to it, we obtain:

$$\frac{h_{k,MPATH}}{h_{k,LOS}} = \frac{P_{MPATH}(k)}{P_{LOS}(k)} \times \frac{G(\varepsilon', k)}{G(\varepsilon, k)}$$

Notice how in such situations, the impact of the content does not cancel out upon applying the multipath kernel, and the resulting ratio is not only dependent on the environment P, but also on the content. Thus, if this ratio is fed as input to the VAE, we expect a high reconstruction loss since the sample deviates from the learned distribution. In contrast, if the sample were authentic, the ratio will be dielectric-free and the reconstruction loss would be lower. Algorithm 3.1 summarizes the anomaly detection algorithm using the variational autoencoder.

4 Implementation and Evaluation

4.1 Implementation

Hardware. We implemented our design on USRP X310 and N210 software radios [11] by extending a two-frequency excitation prototype [40]. The radios run the EPC-Gen2 protocol and transmit two frequencies: one high power frequency (10-31dBm) inside the UHF ISM band and another low power sensing frequency which is varied within 500-1000 MHz. At the sensing frequency's receiver, we employed a low-pass filter that eliminates the impact of the power up frequency and added an LNA to boost the received signal power. To reduce the harmonics of transmission, we used a low-pass filter at the output of the transmit USRPs. We also added anti-aliasing low-pass filters at the input of the receive USRPs. The received signal is sampled (digitized) and sent over Ethernet to a computer for offline processing.

Software. RF-EATS's software package was implemented in MATLAB and python. The transmitted query requests the extended RFID preamble, and the receiver averages 50 RFID responses to boost the signal-to-noise ratio (SNR). The receiver decodes the response and performs standard channel estimation using the packet preamble. It repeats this process over 26 frequencies, separated by 20 MHz across RF-EATS's 500 MHz frequency span. This results in RF-EATS's feature vectors which include amplitude, phase, and correlation across frequencies. The multipath kernel was applied by dividing the multipath-affected data by line-of-sight measurement data ($h_k/h_{k,LoS}$). The number of datapoints used in training the classifiers is much larger than the number of measurements due to this combinatorial relationship.

To ensure the reliability of the channel measurements (i.e., that the channel estimates were not significantly distorted by noise or interference), we computed the correlation at each frequency k as:

$$corr_k = \sum_t y_t p_t^* / \sqrt{\sum_t |y_t|^2 \sum_t |p_t|^2} \qquad (6)$$

where p_t is the known preamble of the RFID packet and y_t is the received signal. We discarded points that had very low ($\leq$0.6). We used the python implementation of the PyTorch and Keras package [49] to implement RF-EATS's classifier and refiner.

Transfer Learning Classifier. The classifier was implemented as a fully-connected network with 3 hidden layers. Dropout and batch normalization layers were added to minimize overfitting. We used the Adam optimizer and set learning *rate = 1e-4, beta1=0.9, beta2=0.999, dropout rate=0.2*.

Variational Autoencoder. The encoder and decoder were implemented as fully-connected networks with 3 hidden layers each. The dimension of latent variable was set to 16. We used the Adam optimizer and set learning *rate = 1e-7,beta1=0.9, beta2=0.999, dropout rate=0.2*.

Content	Samples	Content	Samples
Pure Alcohol	218	Baby Formula (uncontaminated)	95

Table 1: Number of Samples per Material

4.2 Dataset & Applications

We tested RF-EATS in 7 different applications and collected 2,048 data samples in total. The applications demonstrate the generality of the technique to important real-world tasks. Below, we describe these applications, their motivations, and how their corresponding compositions were obtained. The dataset is detailed in Table 1.

- **Tainted Alcohol and Diluted Alcohol.** Tainted alcohol is an ongoing problem in many developing world countries including China, Indonesia, Iran, Turkey, India, and Mexico [32]. Alcohol is tainted by mixing it with cheaper methanol, and consuming it leads to hundreds of cases of blindness and death every year. Standard tainting percentages range between 30-50%. In order to stress-test for sensitivity, we prepared tainted alcohol by removing 10% of the content of an authentic bottle of GRAVES Grain Alcohol [8] and replacing it with methanol.
- **Adulterated Baby Formula.** In 2008, the Chinese milk scandal broke out after the hospitalization of 50,000 babies due to kidney damage [43]. Manufactures had watered down baby formulas up to 83% and mixed them with melamine CAS NO. 108-78-1 [24], a compound used in making plastics. The purpose of adding melamine (by manufacturers) was to conceal dilution by artificially increasing protein levels. To stress-test the sensitivity of our system, we prepared adulterated baby formula by diluting a bottle of Enfamil NeuroPro Infant Formula - Ready to Use (8 fl Oz) [6] with 50% water and mixing it with a higher concentration of melamine (1g/L).
- **Fake Medicine.** Fake medicine is also a major challenge in many developing-world countries, leading to dozens of fatalities every year [50]. A recent incident involved fake cough medicine bottles, where 90% of the active ingredient was replaced with diethylene glycol, a compound used in making antifreeze agents [54]. To prepare such samples, we removed

80% of the contents of a Tylenol bottle [3] and replaced it with diethylene glycol.

- **Fake Extra-Virgin Oil.** Recent studies have shown that 69% of US-imported Extra Virgin Olive Oil has been adulterated by mixing it with cheaper oils (*e.g.* peanut oil) [26]. This can lead to health hazards for consumers with (peanut) allergy. Standard adulteration levels range between 70-80% [26]. We prepared fake olive oil by removing 80% a bottle of GOYA Extra Virgin Olive Oil [7] and replacing it with peanut oil from Planters 100% Pure Peanut Oil.
- **Counterfeit Perfume.** Counterfeit beauty products are abound, leading Estee Lauder to confiscate over 2.6 million counterfeit items in 2016 alone [17]. Many such products are sold online. We purchased an authentic Chanel perfume (COCO MADEMOISELLE - Eau de Parfum) directly from the supplier (160$) and a knock off for $40 from an online retailer.
- **Wine Fraud.** Wine fraud takes many forms. A common one involves selling consumers wine vintages that are dated to earlier years, artificially inflating their price [19]. We purchased wine vintages of Castalia Pinot Noir from two different years: 2009 and 2012.
- **Soda Brand.** Counterfeit soft drinks are marketed under common brand names [4]. While it was difficult for us to purchase counterfeit soft drinks, we tested RF-EATS's ability to classify between common brands: Coke, Pepsi, and Diet Coke.

4.3 Evaluation

Environments & Setup. We evaluated RF-EATS in 20 environments in total including supermarket-style setups with dense metal shelving, kitchens (with sinks and fridges), open lab spaces, offices, hallways and corridors, dining table settings, etc. These environments were fully furnished with tables, chairs, and computers. People walked around during our measurements, and various wireless technologies were present (LTE, WiFi, Bluetooth, etc.). Fig. 1 shows two sample setups, one representing an open lab space and another emulating a supermarket environment.[7] In each experimental trial, a container with an RFID was placed within 10-20 cm distance and -45°-45° from RF-EATS's antennas. The device powers up the RFID and captures its response. Across our trials, we varied the measurement conditions by changing the location of the container and the number, location, and kinds of objects/reflectors around it. Note that even though the RFID is relatively close to RF-EATS's antennas,[8] the richness of the multipath environment significantly impacts the measured response.

[7]Most of our trials (aside from the line-of-sight measurements) were performed outside the clean open space environments.

[8]Beyond such distance, it is difficult to power up an RFID on liquid-filled containers.

RFIDs. We performed our experiments with a variety of commercial off-the-shelf passive UHF RFIDs, including the Alien ALN-9640 Squiggle [2] and Smartrac [59] tags. Each tag costs around 5 cents.

Ground-truth. To measure the ground truth dielectric constant, we used a vector network analyzer, the Agilent Technologies E8362B PNA Network Analyzer [5] (price∼$20,000), and connected it to an N1501A dielectric probe [9]. We measured the dielectric constants across 500-1000 MHz frequency range for each content.

Baselines. Our baseline evaluation focused on non-invasive proposals (i.e., we avoided past systems that are invasive or require isolating liquid samples, e.g., [21, 77]). We implemented the following baselines:

- *RFIQ (Gradient Boosting) [25]:* We implemented RFIQ's gradient boosting tree model. We set $eta = 0.3$, $max\_depth = 3$, $subsample = 0.5$, and $num\_boost\_round = 128$.
- *VAE with a Ray-Tracing Model:* We implemented a VAE that is trained on an analytical ray-tracing model. Specifically, rather than collecting $h_{k,MPATH}/h_{k,LOS}$ in a data-driven fashion, we modeled it using the following equation:

$$\frac{h_{k,MPATH}}{h_{k,LOS}} = \sum_i a_i e^{-j2\pi f_k \tau_i} \tag{7}$$

  where a_i and τ_i are the amplitude and time delay of the i^{th} path, and f_k is the k^{th} frequency. This model allows us to generate a large number of synthetic multipath environments and use them in training.
- *Simple Neural Network:* We also implemented a 3-layer fully-connected neural network, which has the same structure with RF-EATS's neural network (but without the transfer learning and VAE components).

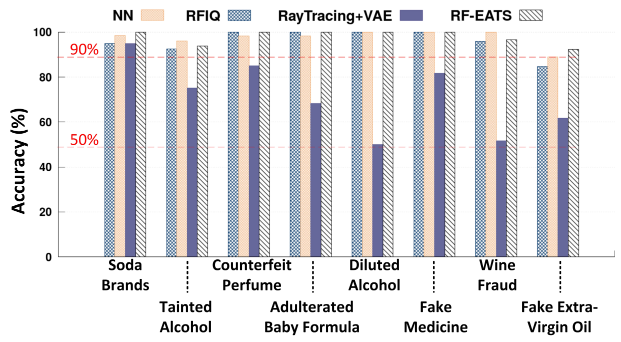
We note the following additional points:

- Across our evaluation, the dataset was divided into a training, testing, and validation sets, all mutually exclusive, i.e., none of the containers or measurements used in one of these sets was present in any other sets.
- We trained the VAE using measurements taken from an RFID placed on empty containers. Recall that the VAE is content-agnostic and general.
- Similar to standard machine learning approaches, we extensively explored the space of hyper-parameters and scaling functions in our training process.

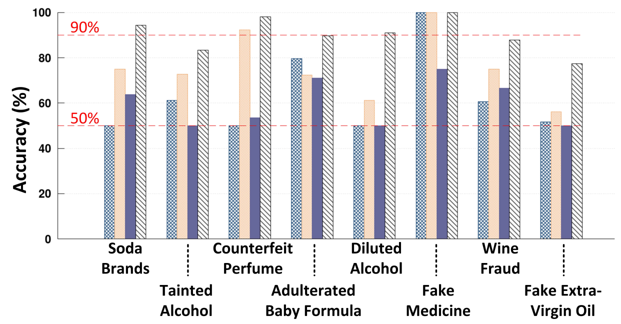
4.4 Results

4.4.1 Overall Performance

We would like to evaluate RF-EATS's overall performance in two different regimes: the first involves training and testing in the same environment, while the second involves training in one environment and evaluating in all



(a) Training and testing in the same environment.



(b) Training in one environment and testing in other environments.

Figure 7: **Overall Performance** (a) and (b) plot the accuracy for each of the applications with different experimental regimes.

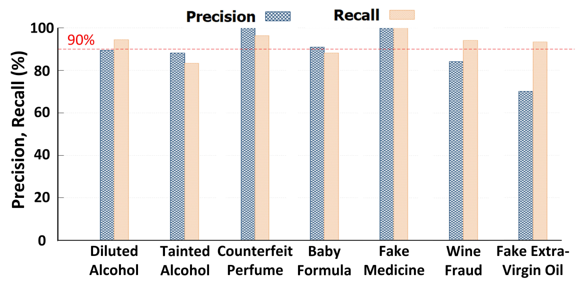


Figure 8: **Precision and Recall of Counterfeit Detection.**

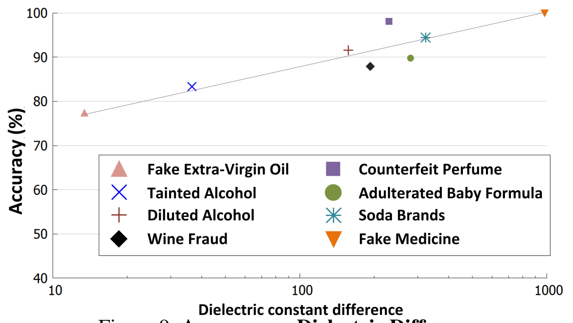

Figure 9: **Accuracy vs Dielectric Differences.**

other environments. In the first regime, the dataset from all environments was mixed and divided into mutually-exclusive training and testing sets. The split-ratio is 80% training and 20% testing for both RF-EATS and the state-of-the-art baseline, RFIQ.[9]

Fig. 7 plots the accuracy for each of the applications in both regimes, and compares them to each of the baselines described in §4.3. We make the following remarks:

- When trained and tested in the same environment, most models achieve high accuracy ($\geq$90%) across all applications. In such scenarios, RF-EATS matches or exceeds the performance of the baselines.
- When testing in new and unseen environments, the accuracy of all the baselines drop significantly, some to a random guess. On the other hand, RF-EATS's accuracy remains around or above 90% for six out of the eight applications, and above 83% for all the applications. Its median improvement over a simple neural network is 15.1%, over RFIQ is 26.5%, and over the ray-tracing model is 29.0% across these applications. This shows that RF-EATS's model can indeed learn representative multipath distributions and generalize to unseen environments.
- The neural network (VAE) trained with a ray-tracing model achieves the worst performance. As discussed in §3.1.1, this is because the ray-tracing model ignores important radio propagation characteristics. As a result, a VAE trained on such a model cannot capture representative distributions and is significantly outperformed by RF-EATS's approach which leverages the multipath kernel.

Next, we would like to gain more insight into RF-EATS's performance as a counterfeit detector. In counterfeit detection, it is important to understand the impact of false postives and false negatives. The standard metrics for quantifying them are denoted by precision and recall [10]:

$$Precision = \frac{TP}{TP+FP}, \quad Recall = \frac{TP}{TP+FN} \qquad (8)$$

where TP is true positive, FP is false positive, and FN is false negative. Fig. 8 shows the precision and recall, demonstrating that they are of the same order of RF-EATS's overall accuracy.[10] Note that these metrics are not reported for soda brand application since false positives/negatives are not meaningful in that context.

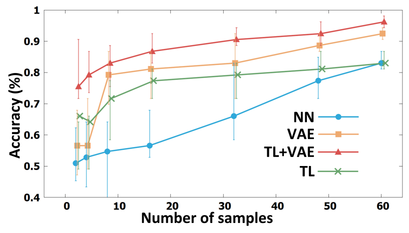
Impact of Dielectric Difference on Accuracy. Next, we would like to confirm that RF-EATS's performance depends on the dielectric differences between the contents of interest. We measured the dielectric of the various contents using the ground truth probe described in §4.3.[11] Because the dielectric constant changes with frequency, we computed the following dielectric distance metric $\sum_{i=1}^{L} \mathcal{L}\left(D_{A,i}, D_{B,i}\right)$ where $\mathcal{L}$ is *L2norm*[12] and

[9]Note that we experimented with different splitting ratios and found that RF-EATS outperformed RFIQ irrespective of the split ratio.

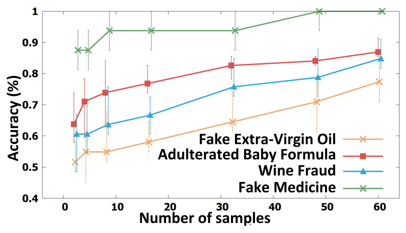
[10]The accuracy plotted in Fig. 7 can be expressed as: (TP+TN)/(TP+TN+FP+FN).

[11]Our measurements are provided in Appendix A.

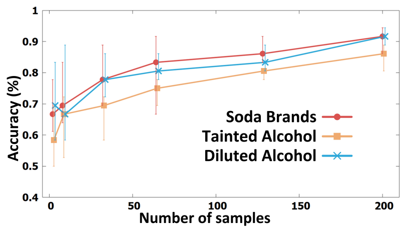
[12]Note that it is possible to use other distance metrics.



(a) Partial Implementations



(b) Performance across Applications



(c) Accuracy for Larger Datasets

Figure 10: **Micro-benchmarks** The figure plots the median accuracy as a function of the training dataset for (a) partial implementations, (b) different applications, and (c) large dataset sizes. Error bars indicate lowest and highest accuracy for different dataset splits between training and testing.

$D_{A,i}, D_{B,i}$ are the dielectric constants at *i-th* frequency component of samples A and B.

Fig. 9 plots the classification accuracy as a function of the dielectric difference for each of the tasks. The figure shows a log-linear relationship between the accuracy and the dielectric differences. When the difference is over 200, RF-EATS achieves 90+% accuracy. The figure also shows that the olive oil application has the lowest accuracy and lowest difference of 15. These results verify that RF-EATS's performance is directly impacted by extent of dielectric differences between the contents of interest.

4.4.2 Micro-benchmarks

We would like to quantify the accuracy gains arising from each of RF-EATS's subcomponents. To do so, we evaluated the accuracy of partial implementations of the overall system: (1) a simple neural network,[13] (2) with the VAE (but no transfer learning), (3) with transfer learning (but no VAE), (4) RF-EATS's full architecture with both the VAE and transfer learning. Similar to our earlier evaluation, we trained on one environment and evaluated on the rest. Additionally, when training the transfer learning model on a given task (e.g., counterfeit perfume), the source domain is obtained by training the encoder on datasets from all the other tasks.

Fig. 10(a) plots the accuracy as a function of the size of the training dataset for each of the above models. For simplicity, the figure only plots results for the counterfeit perfume application . For each dataset size, we randomly chose samples from the database for training, while the rest were used for testing. We repeated this experiment ten times, each time randomly choosing a different subset of samples. The figure plots the median accuracy, and the error bars indicate the maximum and minimum accuracies across the ten iterations.

We make the following remarks:

- Each of the subcomponents contributes to the overall system performance. The improvement in accuracy from the transfer learning classifier over a simple neural network shows that the transfer classifier has higher start point, and VAE has higher slope and asymptote. This is because when the dataset is very small, transfer learning allows extracting well-defined general features and can contribute more to the overall accuracy. However, when the data size becomes large enough, the VAE has higher accuracy because of its effectiveness in generalizing to unseen environments.
- The accuracy gains are more pronounced for smaller datasets. Moreover, the overall system has a smaller standard deviation in comparison to the simple baseline. This result demonstrates the model's ability to not just improve accuracy but also reduce the dataset size required for training.
- The accuracy of each of the models increases with the dataset size. This holds true not only for the perfume classifier but for all classification tasks as shown in Fig. 10(b)-(c), and it is expected because more data enables the learning model to better train its classifier.

[13] We also experimented with networks consisting of more than three layers, but they performed worse. This is likely due to overfitting to the small datasets, so we do not report their results.

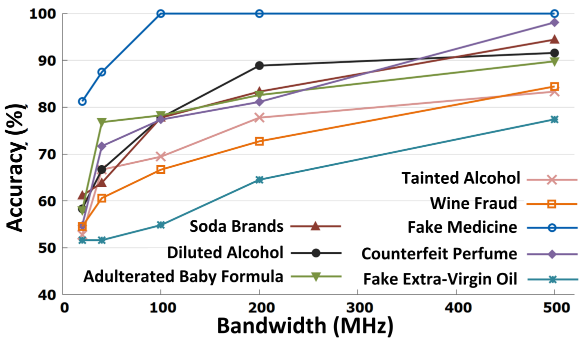


Figure 11: **Impact of Bandwidth on Accuracy.**

Next, we would like to understand the impact of the estimation bandwidth on RF-EATS's accuracy. Recall that our implementation uses two-frequency excitation to sense an RFID's response over a wide bandwidth. To evaluate the impact of bandwidth on accuracy, we used the same measurements from the experimental trials performed earlier, but we only provided varying chunks of bandwidths in training and testing the learning model.

Fig. 11 plots the accuracy on the y-axis as a function of the bandwidth for each of the classification tasks. It shows that RF-EATS's accuracy increases with bandwidth for all of the tasks. In contrast, when using a bandwidth that is constrained to the UHF ISM band (26MHz) as with a standard RFID reader, the accuracies across

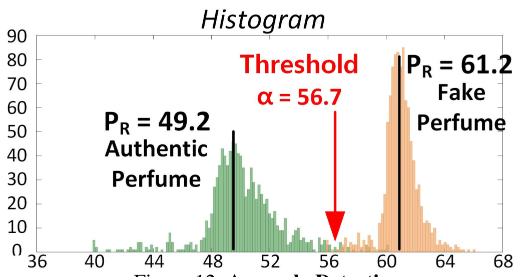

Figure 12: **Anomaly Detection**

most tasks are close to a random guess. This demonstrates the importance of wideband estimation for enabling RF-based food and liquid sensing.

4.4.3 Extending to Unseen Compositions

Finally, we would like to evaluate RF-EATS's ability to perform anomaly detection as per §3.2.2. To do so, we trained the VAE on outputs of the multipath kernel obtained from all datasets except the perfume dataset. Then, we applied the multipath kernel to both the counterfeit and non-counterfeit perfume. Specifically, we compute $h^a_{k,MPATH}/h^a_{k,LoS}$ and $h^a_{k,MPATH}/h^a_{k,LoS}$ where $h^{a/f}_{k,MPATH}$ denotes the channel of authentic/fake perfume in multipath-rich environments, and $h^a_{k,LOS}$ denotes the line-of-sight channel of authentic perfume. The detector is provided with samples of $h^a_{k,LOS}$ knowing that they are authentic. We set $L = 1000$ in Algorithm 3.1, resulting in 1,000 reconstruction loss values.

Fig. 12 shows the histogram of the reconstruction loss of authentic (green) and fake (orange) perfumes. The figure shows that the average reconstruction loss of fake (61.2) is significantly smaller than that of the authentic (49.2) perfume. If we set the threshold value α to 56.7, we would obtain 94% accuracy in counterfeit detection.

5 Other Related Work

(a) RF sensing. RF-EATS is related to a large and emerging body of literature on using wireless signals for sensing purposes, including shape-based object classification [75, 74], radio localization [73, 31], liquid level sensing [18], and human sensing [12, 52, 30]. RF-EATS's goal is orthogonal to these proposals and it focuses on food and liquid sensing. It is worth noting that while some of these proposals can generalize to new multipath environments, their problem statement is fundamentally different than RF-EATS's because the impact of the dielectric and multipath is not linearly separable as explained in §3.1.

(b) Use of Machine Learning in Wireless. Motivated by recent advances in machine learning, wireless researchers have adapted these advances to a variety of communication and sensing tasks, including end-to-end decoding [22], signal classification [48], localization [45, 68, 67, 69, 36], imaging [79], physiological sensing [80], and spectrum monitoring [38, 20]. RF-EATS is similarly motivated by recent advances in learning; however, it focuses on the liquid sensing problem and introduces new contributions that allow it to address domain-specific challenges.

Finally, prior work on human activity sensing has recognized the problem of generalizing RF learning models to different environments [28, 80]. Existing solutions require collecting datasets for each activity and label across a large number of environments. In our context, this would require collecting measurements for each label/contaminant/class across a wide variety of environments, significantly increasing the training and data collection effort over RF-EATS's approach. In contrast, RF-EATS's multipath kernel and transfer learning approach allow it to generalize to new environments and sensing tasks in a sample-efficient manner.

6 Discussion & Conclusion

RF-EATS marks an important step toward ubiquitous, low-cost food sensing using pervasive networking technologies. Our evaluation demonstrated RF-EATS's ability to deliver important applications, its resilience to changing indoor environments, and its efficiency in generalizing to new tasks and unseen environments.

RF-EATS's design and evaluation can be extended in multiple ways. First, while our evaluation focused on changes in the radio environment (multipath reflections, positions, etc.), the RFID measurements may also be impacted by other environmental factors such as the shape and material of the container itself or even the impact of temperature changes on the dielectric. It may be possible to extend RF-EATS's VAE to similarly learn the distributions of such changes and enable it to generalize to these environmental variables as well. We note that even without generalizing the model to different container shapes and materials, it can be used as-is in the context of counterfeit detection (e.g., fake perfume) since such items are typically designed to look very similar to the original products (but have different contents). Another valuable extension of RF-EATS is via miniaturization. Specifically, our current prototype is relatively bulky for direct consumer use. However, the large size is primarily due to the use of USRP software radios and log-periodic antennas for flexibility of prototyping, and can be miniaturized in future design iterations.

As the research evolves, we hope that it can continue bringing low-cost food and liquid sensing closer to the hands of lay consumers to help democratize food and product safety solutions.

Acknowledgments. We thank our shepherd Kyle Jamieson, the anonymous NSDI reviewers, and the Signal Kinetics group for their helpful feedback on the manuscript. This research is supported by a J-WAFS grant, the NSF, and the MIT Media Lab.

A Dielectric Measurements

To ensure there is a detectable difference between the real and contaminated/fake products, we measured the dielectric constants of each of the materials. We used the Keysight N1501A Dielectric Probe Kit and E8362B PNA Network Analyzer. We calibrated the dielectric probe with 20°C water and performed a linear sweep from 500MHz to 1GHz, in steps of 1 MHz. The graphs below plot the dielectric constants as a function of frequency.

Eingerprint: Robust Energy-related Fingerprinting for Passive RFID Tags

Xingyu Chen* Jia Liu* Xia Wang Haisong Liu Dong Jiang Lijun Chen

Abstract

RFID tag authentication is challenging because most advanced cryptographic algorithms cannot be afforded by passive tags. Recent physical-layer identification utilizes unique features of RF signals as the fingerprint to authenticate a tag. This approach is effective but difficult for practical use because it either requires a purpose-built device to extract the signal features or is sensitive to environmental conditions. In this paper, we present a new energy-related fingerprint called *Eingerprint* to authenticate passive tags with commodity RFID devices. The competitive advantage of Eingerprint is that it is fully compatible with the RFID standard EPC-global Gen2, which makes it more applicable and scalable in practice. Besides, it takes the electrical energy stored in a tag's resistor-capacitor (RC) circuit as the fingerprint, which is robust to environmental changes such as tag position, communication distance, transmit power, and multi-path effects. We propose a new metric called persistence time to indirectly estimate the energy level in the RC circuit. A select-query based scheme is designed to extract the persistence time by flipping and observing a flag in the tag's volatile memory. We implement a prototype of Eingerprint with commodity RFID devices without any modifications to the hardware or the firmware. Experiment results show that Eingerprint is able to achieve a high authentication accuracy of 99.4% when three persistence times are used, regardless of device diversity and environmental conditions.

1 Introduction

Radio frequency identification (RFID) is gaining increasing popularity in a wide range of applications, including warehouse inventory [15–17, 34], object tracking [13, 24, 25, 27, 30], and supply chain [22], due to its compelling features, dropping costs, and standardizations. Each RFID tag has a unique digital identity to label tagged items, brings item intelligence to our daily life, and allows the reach of the Internet to include objects as diverse as retail products, library books, debit cards, passports, driver licenses, car plates, and medical devices. In general, the RFID tags fall into two categories: active and passive. Active tags have their own power source and remain active all the time. Compared with the passive tags, they have more computational capabilities and longer read ranges. However, the built-in power source makes them bulky and expensive, which restricts these tags to high-end applications. In contrast, passive tags do not have a built-in power source and are powered by either induction or electromagnetic RF signals of the reader. They have limited computational capabilities and a lower read range than active tags. In spite of these limitations, they are common due to their low cost, small size, and longer life.

In recent years, with the proliferation of RFID systems, the problem of RFID security has attracted increasing attention. A great number of authentication protocols have been proposed to identify the authenticity of a tag [5, 8, 9, 19]. In the nascent stage, the authentication protocols check only the data (e.g., TID [4]) stored in a tag's memory, which is vulnerable to counterfeiting attacks: Adversaries can easily retrieve the data from a genuine tag with a commercial reader and forge a replica by filling its memory with the same data as the genuine tag. To address this problem, some cryptographic approaches are studied. By transmitting the ciphertext rather than the plaintext, the communication channel between a reader and a tag is protected against eavesdropping. However, this approach requires extra hardware components to support high computation overhead, which greatly increases the cost of a passive tag as well as reduces the communication range between the reader and the tag. Hence, it is rarely used by most commercial passive tags.

Motivated by the above limitations, recent research has shifted to physical-layer identification (PLI), which is commonly referred to as RF fingerprinting [10, 11, 20, 33, 35, 36]. It is the process of identifying a device based on transmission imperfections exhibited by its radio transceiver. The key appeal of applying RF fingerprint for authentication is twofold. First, RF fingerprints are unique and unpredictable, such that

*These authors contributed equally to this work they can provide high security guarantees against various protocol-layer attacks. Second, no upgrades of hardware or firmware on existing systems are required, which makes it scalable to the wide use of RFID systems. In spite of this advancement, however, PLI suffers from two problems. First, most PLI-based solutions need a specialized device to detect physical-layer signals, which cannot be deployed in commodity RFIDs. Second, some work is not resistant to environmental or signal acquisition factors, e.g., RF phase values, a widely used metric for RF fingerprinting, heavily relies on the RF channels. Two different measurements of the same tag are very likely to give rise to different RF phases.

In this paper, we explore a brand-new fingerprint called energy-related fingerprint (*Eingerprint*) to authenticate passive tags with commodity RFID systems. Eingerprint takes the electrical energy stored in the tag's circuit as the fingerprint, which is robust to environmental conditions, including tag position, tag orientation, communication distance, transmit power, and multi-path effects. The basic idea is that passive tags do not have any built-in power source and are energized by the electromagnetic RF signals issued by the reader. To ensure proper functioning, a tag needs to store some electrical energy into its microchip, which is equivalent to a resistor-capacitor (RC) charging circuit [38]. Due to manufacturing imperfection, no two tags could ever have exactly the same RC circuit. If we can detect this difference, then we are able to fingerprint each tag as desired.

However, this is not easy. Building the electronic test circuit to physically measure the RC circuit of each tag is infeasible because it destroys the tag's structure and functions. Instead, we use a new metric called *persistence time* to indirectly reflect the RC circuit. The persistence time is the time span from the initial supply voltage when the RC circuit is fully charged decaying to a very low level that cannot afford the tag to run properly, which heavily relies on the RC circuit itself. In other words, if two RC circuits differ from each other, their persistence time is very likely to be different. On the basis of this idea, we design a Gen2-compatible approach to measure the persistence time based on a one-bit inventoried flag of a tag (a one-bit register in a tag's volatile memory). The volatile memory requires power to maintain the stored information. Once the power is cut off (or is lower than a threshold), the stored data are quickly lost. By flipping the inventoried flag and continuously observing its status with Gen-2 compatible commands, we are able to extract the persistence time of a tag. Afterwards, a t-test based model is designed to validate the genuineness of the tag. In addition, instead of individual fingerprinting, we propose a quick and reliable scheme to deal with multiple tags in parallel, which greatly improves the time efficiency of tag authentication. The main contributions of this paper are threefold.

- We explore a new energy-related fingerprint called *Eingerprint* to authenticate passive tags with commodity RFID devices. The competitive advantage of Eingerprint is that it is fully compatible with the RFID standard, which makes it more applicable and scalable for practical use. Besides, it takes the electrical energy as the fingerprint, which is robust to various environmental conditions.
- We propose a new metric *persistence time* to indirectly indicate the energy level stored in a tag's RC circuit. A select-query based scheme is designed to measure the persistence time by flipping and observing a flag in the tag's volatile memory.
- We implement a prototype of Eingerprint in a commercial off-the-shelf RFID system with over 1000 tags. Extensive experiments show that our fingerprinting system is able to achieve a high accuracy of 97.3% and 99.4% when one persistence time and three persistence times are used respectively, without any changes to the hardware.

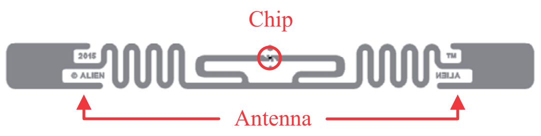

Figure 1: Alien Squiggle general-purpose RFID tag.

The rest of the paper is organized as follows. Section 2 overviews the fingerprinting model and proposes an energy-related fingerprint. Section 3 proposes a Gen2-compatible scheme to derive the fingerprint. Section 4 uses the fingerprint distribution to validate the genuineness of a tag. Section 5 evaluates the performance of the fingerprinting system. Section 6 introduces the related work. Finally, Section 7 concludes this work.

2 Overview

2.1 Fingerprinting Model

Passive tags do not have any built-in power source and are energized by the electromagnetic RF signals emitted by the reader. In general, a passive RFID tag consists of two components: the tag antenna and the microchip. As shown in Fig. 1, the microchip is usually placed right at the terminals of the tag antenna. When the RF signals are received by the tag antenna, the voltage developed on antenna terminals powers up the chip for computing and modulating the backscattered signal. The passive tag can be equivalent to a resistor-capacitor (RC) series circuit [38] that is composed of a resistor and a capacitor.

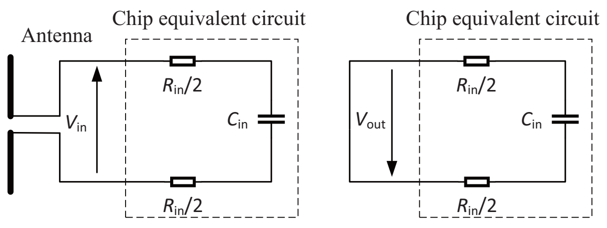
As a result of manufacturing imperfection, no two tags could ever have exactly the same microchip; the same idea applies to the electronic components (the resistor and the capacitor). If we can detect the difference of these electronic components among different tags, then we are able to fingerprint each tag from the physical-layer perspective, which forms the fingerprinting metric of this work. To achieve this goal, an intuitive solution is to set up an electronic test circuit and measure each electronic component manually. This concept works in theory but suffers from three problems in practice. First, a tag needs to be dissected (physically separating the microchip from the antenna), which damages the tag's structure and function. Second, performing measurements individually and manually is time consuming, especially when many tags need to be authenticated. Third, a purpose-built electronic test platform is needed to measure the chip circuit, which increases the cost of fingerprinting and is not scalable in commercial use. Hence, a new fingerprint that is able to reflect the attributes of the electronic components is required.

2.2 Fingerprint: Persistence Time

Consider the RC circuit of the microchip. When the tag captures the energy from the RF signals issued by the reader, it is actually an RC charging process. The equivalent charging circuit is shown in Fig. 2(a), where a capacitor C_{in} in series with a resistor R_{in} is connected across a DC battery supply (the power is obtained from the RF signals). The capacitor will gradually charge up through the resistor until the voltage across it reaches the supply voltage of the DC battery, namely, fully charged. According to the Gen2 standard, this charging process lasts for 2 ms at most. Afterwards, if we remove the voltage source (e.g., turn off the reader) from the fully charged circuit, the capacitor that is able to store the electrical energy acts like a small battery and releases the energy as required. This is referred to as an RC discharging process. As shown in Fig. 2(b), the capacitor discharges through the resistance in the opposite direction, which enables the tag to compute and communicate with the reader. As the discharge continues, the voltage goes down and there is less discharge current across the circuit. When the voltage decays to a very low level that cannot afford the tag to run properly, we say that the tag is exhausted and out of function. Assume that the initial supply voltage of the fully charged circuit is V_{in} and the minimal voltage that is needed to drive a tag is V_0. In the discharging stage, we refer to the time span from the initial supply voltage V_{in} decaying to the voltage threshold V_0 as *persistence time*, which can be derived as follows:

$$T_p = R_{in} \times C_{in} \times \ln(\frac{V_{in}}{V_{in} - V_0}), \quad (1)$$

where R_{in} and C_{in} are the resistance and capacitance of the microchip, respectively [38]. In Eq. (1), the V_0 voltage threshold is a constant when a tag chip is manufactured. For V_{in}, it varies with the available input power and thus depends on the energy captured by the tag antenna. This would be a variable in different communication conditions, e.g., different communication distances. To provide a stable voltage to the digital core, however, the commercial tag is required to carry a low dropout regulator [38], which uses a voltage reference block to produce a regulated and constant voltage V_{in}. Hence, the persistence time relies on the four constants R_{in}, C_{in}, V_0,



(a) Charging. (b) Discharging.

Figure 2: RC circuit of a tag's microchip.

and V_{in}, which are determined by the hardware of a tag, regardless of the environment factors, e.g., the communication distance, the tag location, multipath effects. By measuring the persistence time, we are able to figure out the difference of tag chips. This forms the basic idea of our method.

The energy-based fingerprint has three competitive advantages. First, any Gen2-compatible readers are able to measure the persistence time of a commodity tag with no need for any modifications to the hardware or the firmware. Hence, implementing and deploying the fingerprinting system is easy in practice. Second, the persistence time not only accurately reflects the RC circuit of the tag chip but is also robust to the environment changes (e.g., the communication distance, the tag location, multipath effects), which is a key challenge for some PLI work [11,28]). Third, a commercial tag has several independent persistence times (different RC circuits), which form different fingerprints to jointly authenticate the tag, thus making it hard to counterfeit. In spite of this advancement, measuring the persistence time of a tag is not easy. Next, we first show the system architecture of our approach and then detail how to obtain the persistence time in a Gen2-compatible commodity RFID system.

2.3 System Architecture

In general, the workflow of the fingerprinting system consists of three steps, which are shown in Fig. 3.

- *EPC Identification*: The reader interrogates a tag according to the Gen2 protocol and checks whether the EPC (i.e., tag ID) is identical to the tag to be authenticated. If no, then the tag is counterfeit. Otherwise, the system moves to the second step.
- *Fingerprint Extraction*: This step aims to extract the persistence time of the tag and treats it as the tag's energy fingerprint. Two key issues need to be solved. First, how can the persistence time be measured with the commercial RFID devices? Second, how can the time efficiency be improved and how can the measurement of multiple tags be conducted in parallel?
- *Genuineness Validation*: The system measures the persistence time and validates it with the stored records in the database. If it passes the authentication, then the tag is considered a genuine tag; otherwise, it is a counterfeit.

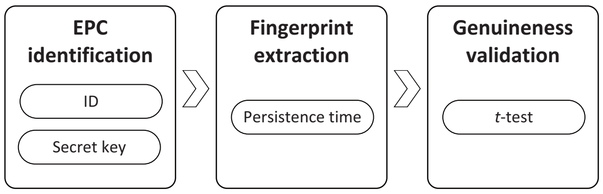


Figure 3: The workflow of the fingerprinting system.

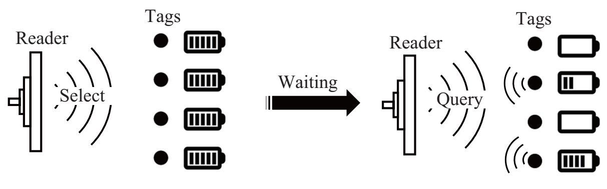

Figure 4: Basic idea of fingerprint extraction.

3 Fingerprint Extraction

3.1 Basic Idea

The basic idea of measuring the persistence time is to build a fully charged RC circuit and then run the discharging operation. This approach requires the following three steps. As shown in Fig. 4, first, we turn on the reader and let it issue the RF signals to energize the tag. Second, after the tag is fully charged, we cut off the power by turning off the reader; the discharging process starts. Third, after a period of time T_d, we check whether the tag is exhausted or not. By gradually increasing the time period T_d and repeating the above three steps, we can find a maximum of T_d that is guaranteed to help the tag work properly. This maximum is actually the persistence time to be measured.

Among above three steps, the first two, turning on and off the reader, are easy to operate. However, examining when the power of the tag is exhausted with a commodity RFID system is challenging. To address this problem, we resort to the volatile memory of a tag. Unlike non-volatile memory (e.g., NAND flash and solid-state drives), the volatile memory requires power to maintain the stored information. Once the power is cut off (or lower than a threshold), the stored data are quickly lost. In the RFID standard Gen2, we find a metric *inventoried flag*, which is a one-bit indicator in a tag's volatile memory. By flipping the inventoried flag and checking its status continuously, we are able to know when the power of the tag is exhausted. Next, we first introduce the Gen2 protocol and then detail how to measure the persistence time based on the RFID standard.

3.2 EPCglobal Gen2 Protocol

The EPCglobal Gen2 (Gen2) protocol is a worldwide UHF RFID standard that defines the physical interactions and logical operating procedures between the readers and tags [4]. On the basis of Gen2, we highlight the related functions that we will be involved by Eingerprint below.

Tag Memory. Gen2 standard specifies that the tag memory is supposed to contain four distinct memory banks (page 44—51 in [4]). MemBank-0 is reserved for kill and access passwords if encryption is implemented on the tag. MemBank-1 stores the electronic product code (EPC), i.e., tag ID that is often referred to. MemBank-2 stores TID that indicates the tag- and manufacturer-specific data at the time of manufacture, which is permalocked and unchangeable. MemBank-3 is user memory that allows customized data storage. In this work, we need to visit the tag's ID, so MemBank-1 is used.

Sessions & Inventoried Flags. Gen2 requires the readers and tags to provide four sessions (denoted as S0, S1, S2, and S3). Tags in one of these sessions shall neither use nor modify an inventoried flag for a different session. This allows two or more readers to use different sessions to independently inventory a common tag population (in different time slots). The inventoried flag is actually a one-bit indicator of a tag's volatile memory. The binary state of the inventoried flag is denoted by A and B, respectively, where A is the initial state as usual. The volatile memory requires power to maintain the stored information. Once the power is lower than a threshold, the stored data are quickly lost, that is, the inventoried flag will flip to A when the power of the tag is exhausted, no matter what the previous state is. According to Gen2, each session corresponds to an independent inventoried flag that needs different power levels to maintain its state, so the persistence time of each inventoried flag is different. Table 1 shows the persistence periods of different sessions specified by the Gen2 protocol. As we can see, when the tag is not energized, the persistence times of the inventoried flags in S2 and S3 are greater than 2 s. In contrast, the persistence time in S1 varies between 500 ms and 5 s, and no persistence time (always in A) is found for S0. This specification provides us with three persistence times by using the inventoried flags in S1, S2, and S3. Next, we take the inventoried flag in S1 as an example to show how our fingerprinting system works; the two other sessions can be used in the same way.

Select. *Select* is a mandatory command that is prior to each inventory round. It allows a reader to choose a specific subset of tags that participate in the subsequent inventoried round.

Table 1: Persistence time

G2 Session	Persistence time
S0	Tag energized: Indefinite Tag not energized: none
S1	Tag energized: 500 ms -5 sec Tag not energized: 500 ms -5 sec
S2	Tag energized: Indefinite Tag not energized: >2 sec
S3	Tag energized: Indefinite Tag not energized: >2 sec

Aside from tag selection, the *Select* command can also assert or deassert a tag's selected (SL) flag, or set a tag's inventoried flag to either A or B. These flags are used to determine whether or not a tag may respond to a reader. Specifically, a *Select* command consists six fields.

• *MemBank, Mask, Length, Pointer*. These four fields jointly determine which tags are matching or not. *MemBank* specifies which memory bank is chosen for comparison. As aforementioned, four memory banks are available, MemBank-0, MemBank-1, MemBank-2, and MemBank-3, which are indicated by 0, 1, 2, and 3, respectively. *Pointer* indicates the starting position in the chosen memory bank. *Length* determines the length of *Mask*, which is a customized bit string according to the user demands. If *Mask* is the same as the string that begins at *Pointer* and ends *Length* bits later in the memory of *MemBank*, then the corresponding tag is matched.

• *Target, Action.* The field *Target* indicates the object that *Select* will operate, which is either a tag's SL flag or an inventoried flag in any one of four sessions. The sessions are specified by the Gen2 protocol to fit the case of exclusive reading among multiple readers. Therefore, five different targets can be chosen. The selection function is actually achieved by masking the interested tags, setting the matching tags' inventoried flags or SL flag to a specific state while not-matching tags to opposite, and finally operating the tags with the same flag state. How to set the inventoried flag and the SL fag is determined by the *Action* field. As shown in Table 2, eight actions are available, where matching and not-matching tags set their inventoried flags to *A* or *B*. By combining *Target* and *Action*, the reader is able to modify the state of the inventoried flags or the SL flag for a group of tags. For example, when the *Action* is 0, the matching tags are set to *A* while the not-matching tags are set to B. The term "do nothing" means the tags keep their flags unchanged.

Query. *Query* command starts a new inventory round over the tag subpopulation, which are chosen by the previous *Select* command(s). In the inventory round, the reader will carry out a frame that consists of some time slots. Each "selected" tag randomly picks one of these time slots and transmits its tag ID to the reader in that slot. After a tag is queried by the reader, it will invert its inventoried flag, i.e., from the state *A* to *B*, or vice versa. *Query* includes three fields that we would like to focus on.

• *Session, Target*. Similar to that in *Select*, this field *Session* in *Query* specifies one of the four sessions used in the incoming inventory round. The field *Target* determines which tags will participate in the current inventory round, where 0 indicates the tags with the inventoried flag being *A* and 1 indicates *B*.

Table 2: Eight actions of *Select*.

Action	Tag Matching	Tag Not-Matching	Abbr.
000	assert **SL** or **inventoried** → *A*	deassert **SL** or **inventoried** → *B*	AB
001	assert **SL** or **inventoried** → *A*	do nothing	A-
010	do nothing	deassert **SL** or **inventoried** → *B*	-B
011	negate **SL** or *(A→B, B→A)*	do nothing	S-
100	deassert **SL** or **inventoried** → *B*	assert **SL** or **inventoried** → *A*	BA
101	deassert **SL** or **inventoried** → *B*	do nothing	B-
110	do nothing	assert **SL** or **inventoried** → *A*	-A
111	do nothing	negate **SL** or *(A→B, B→A)*	-S

• *Sel*. This field consists of two bits that determine which tags respond to *Query*: 00_2 and 01_2 indicate all matching tags in the previous Select command; 10_2 indicates tags with deasserted SL flag ($\sim SL$); and 11_2 indicates tags with asserted SL flag (SL).

On the basis of the above Gen2-compatible functions, we next detail how to jointly utilize the *Select* and *Query* commands to measure the persistence time by using the state of the inventoried flag. The method is called select-query based measurement.

3.3 Select-Query based Measurement (SQM)

The basic idea is that when the internal energy of a tag is exhausted, the inventoried flag will move back to the initial state *A* for sure, regardless of its previous state. If we set the tag's inventoried flag to *B* and keep the RC circuit fully charged, then the time period from starting discharging to the time when the inventoried flag turns to *A* can be treated as the persistence time.

3.3.1 Design of SQM

To measure the discharging time, we need to jointly use the *Select* command and the *Query* command. According to Gen2, a *Select* command can be written as follows:

$$S(\underbrace{t}_{\text{Target}}, \overbrace{a}^{\text{Action}}, \underbrace{b}_{\text{Membank}}, \overbrace{p}^{\text{Pointer}}, \underbrace{l}_{\text{Length}}, \overbrace{k}^{\text{Mask}}). \tag{2}$$

To set a tag's inventoried flag to *B*, the reader just needs to broadcast a *Select* as follows:

$$\text{Flag} \leftarrow \text{BA: } S(1,4,1,32,96,id), \tag{3}$$

where $t = 1$ (001_2) means the operating object is set to the inventoried flag in session 1 (S1), $a = 4$ indicates that the inventoried flags of matching tags will be set to *B*, while those of not-matching tags will be set to *A*, $(b,p,l,k) = (1,32,96,id)$ means the tag's ID is the same as *id* is selected (matching). Note that the first bit of the tag ID starts from the 32nd bit ($p = 32$) in MemBank-1, because the first 32 bits are a protocol-control (PC) word and the tag ID follows behind the PC word. More details can be seen in [4].

By this means, the target tag is set to *B*. Now the question is how long we can obtain a fully charged RC circuit. Gen2 specifies that the charging time should be no longer than 2 ms, which is much less than the time period (about 20 ms) for broadcasting a select command. In other words, once the select command in 3 is carried out, the target tag has the inventoried flag being B and also the RC circuit being fully charged.

Afterwards, we move to the discharging process by turning off the readers. Given that the tag cannot harvest energy from the reader anymore, the stored electric energy is consumed gradually. After a period of time T_d for discharging, the reader broadcasts a query command to check whether any tag with the inventoried flag B exists. The query command is as follows:

$$\text{Query } B: \ Q(Session = 1, Target = 1, Sel = 0). \quad (4)$$

If a tag reply is received, it means that the persistence time of this tag is longer than T_d. In this case, we need to increase T_d by a small step Δ_t and repeat the above select-query process again. For the first time period T_d that makes no tag reply, it is treated as the persistence time to be measured. That is because no tag reply means that the tag's inventoried flag has flipped to A since the power ran out. Note that, for the session 1 (S1), since the persistence time is bounded between 500 ms to 5 s, we can initialize T_d with 500 ms and increases it gradually until no tag reply occurs.

3.3.2 Multiple Tags

So far, we have discussed how to obtain the persistence time of a session for a single tag. In a practical scenario, however, authenticating multiple tags at a time is common. One intuitive solution is to fingerprint each tag in sequence, one by one. This works but suffers from high time latency. To make SQM more efficient and scalable to the multi-tag case, we need to deal with multiple tags in parallel.

An important observation is that broadcasting the select and executing the query operation take only a few milliseconds; the majority of the time overhead comes from trying the waiting period T_d. If we can let multiple tags wait concurrently, the execution time will decline sharply. Following this idea, we first set all target tags' inventoried flags to the state B, instead of individually dealing with one tag at a time. Afterwards, these target tags move to the discharging process and the energy is consumed gradually. After a period of time T_d, we query the tags with flag B as is. If a tag does not respond to the reader, its persistence time is T_d. This process repeats until all target tags are measured. In this way, the long discharging process executes in parallel, which saves a large amount of time overhead. For example, assume that we fingerprint 10 tags in parallel. We can reduce the waiting periods by about 90%; the global authentication performance is much better than the individual authentication performance.

Now the question is how to select a subset of tags and set their inventoried flags to the state B. Assume there are n tags, in which m tags are target tags. We can separate these m tags from the entire tag set via m select commands. The selection process is executed as follows. We first use the $Action = BA$ to select the first tag t_1, i.e., t_1's inventoried flag is set to B while others are A. Afterwards, for the ith tag t_i, the $Action$ is set to $B-$. We use $B-$ because this action will set the matching tag t_i to B accordingly but not change the settings of the previous tags. The commands are shown below.

$$\begin{aligned} &① \ t_1 \leftarrow BA: S(2, a = 4, 1, 32, 96, id_1) \\ &ⓘ \ t_i \leftarrow B-: S(2, a = 5, 1, 32, 96, id_i), \ \ i \in [2, m], \end{aligned} \quad (5)$$

where id_i represents the tag t_i's tag ID, $a = 5$ means the action $B-$, which can be seen in Table 2. Besides, by investigating commodity RFID readers through their data sheets and real experiments, we find that these readers allow multiple selects to be broadcast in one transmission, e.g., two by Impinj R420 [2] and four by ALR 9900+ and ALR F800 [1]. With this function, we are able to fill several selects into a single one, further saving the communication overhead.

3.4 Enhanced SQM

Although concurrently fingerprinting multiple tags can sharply shorten the authentication time, a large gap still exists between SQM and efficient authentication primarily because that the process of increasingly adjusting the waiting time T_d is time-consuming. For example, assume a tag's persistence time is 3 s and the step length is 0.1 s. The waiting time T_d is initialized to 0.5 s and SQM needs to iteratively try 0.5 s, 0.6 s, 0.7 s, ..., 3.0 s. Summing up the overhead of each try, we have the overall time cost 45.5 s. This time cost is fine for some applications without real-time requirements. However, in the applications such as access control systems, this time is too long to be applicable for practical use.

The basic reason for the low time efficiency is that when a waiting time T_d is examined, we need to reset all tags and retry the next one. A longer time is needed for checking. If we can run the measurement within only one waiting time window, the performance will be improved greatly. Through extensive experiments, we find that the query command does not charge the tag in the session S1. In other words, during the discharging process, we are able to keep querying the tags, with no need to turn off the reader. Once a tag is queried by the reader, it will be recharged again.

3.4.1 Design of Enhanced SQM

With these features, the enhanced SQM measures the tag t_1's persistence time as follows. First, similar to the basic SQM, the reader broadcasts a select command (see Eq. (3)) with action BA to set t_1's inventoried flag to B. After that, the discharging process starts and the reader queries the tag with the flag state being A. The query command is

$$\text{Query } A: \ Q(Session = 1, Target = 0). \quad (6)$$

As shown in Fig. 5, during the discharging process, the internal circuit energizes the tag and keeps the inventoried flag

B, so the reader cannot receive any response from the tag t_1. When the power level is too low to maintain the information of the volatile memory, the inventoried flag moves back to the initial state A. At that time, because the reader keeps querying tags with A, the tag t_1 satisfying this condition will reply to the reader. By observing the time span from the start of discharging to the tag reply, we are able to derive the persistence time of the tag. Clearly, enhanced SQM does not need to try different waiting times; only one time window is able to measure the persistence time, which saves a great number of overheads. For example, consider the above tag with 3 s persistence time. Enhanced SQM results in great performance improvement, reducing the time from 44.5 s to only 3 s, in comparison to the basic SQM.

After responding to the reader, the tag flips its inventoried flag to B (according to Gen2); meanwhile, the RC circuit is fully charged. With the reader continuing to query A, the tag will reply after another persistence time. Hence, if we need multiple measures of persistence time, we just need to record each time interval between two adjacent tag responses, which is shown in Fig. 5. In fact, we can also simplify the enhanced SQM by removing the select command, that is, the reader directly enters the inventory stage. By keeping querying tags with A, the reader is able to get each tag's replies. The time interval between any two adjacent tag replies is the tag's persistence time. In addition, enhanced SQM can be extended to the multi-tag case, with no need for any modifications to the measurement process.

3.4.2 Multiple Tags

In spite of advancements, the enhanced SQM faces a new challenge in which the tags beyond the target tags might have negative effects on the measurement of the persistence time, especially when a great number of these tags exist. More specifically, assume that the tag set is τ and $\tau' \subseteq \tau$ is a subset of tags to be authenticated. The problem is that, when we set the inventoried flags of τ' to B with the select command, the tags in $\tau - \tau'$ will be set to A. In the follow-up inventory stage, the reader queries tags with flags being A; these tags $\tau - \tau'$ will attend to respond. As a result, the tags in τ' cannot give a prompt reply when their flags move back to A due to lack of energy. Setting $\tau - \tau'$ to B initially does not work either because these tags will still reply to the reader after their power level is lower than a threshold.

To address this problem, we resort to another indicator: SL flag. As mentioned previously, the SL flag has two states denoted by SL and $\sim SL$. The reader can specify a set of tags in one of the two states, which will participate in the inventory round. The SL flag and the inventoried flag are independent and can be jointly used to remove the interference of $\tau - \tau'$. The solution is to set the target tags τ' to SL while others $\tau - \tau'$ to $\sim SL$. In the inventory stage, we let only the tags with SL participate in the response. By this means, even if

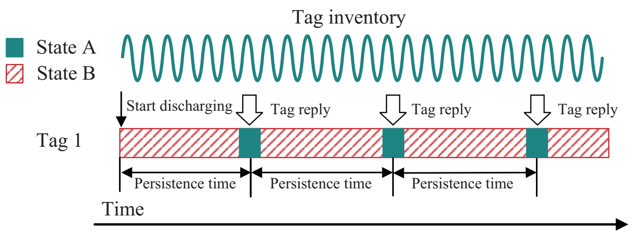

Figure 5: Enhanced SQM for obtaining the persistence time.

a tag in $\tau - \tau'$ is with the inventoried flag A, it has to keep silent to the command of querying A. Specifically, assume that $\tau' = \{t_1, t_2, ..., t_m\}$. The reader broadcasts the select commands as follows:

$$\begin{aligned} &\textcircled{1}\ t_1 \leftarrow AB : S(t = 4, 0, 1, 32, 96, id_1), \\ &\textcircled{i}\ t_i \leftarrow A- : S(t = 4, 1, 1, 32, 96, id_i), \quad i \in [2, m], \end{aligned} \tag{7}$$

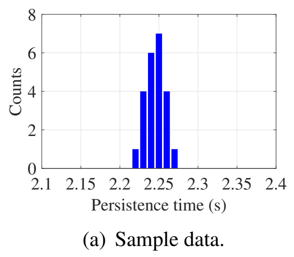
where $Target$ being set to 4 ($t = 4$) means that the operating object of the select is the SL flag. With the above select commands, the SL flags of the tags in τ' are asserted (SL), whereas those of tags in $\tau - \tau'$ are deasserted ($\sim SL$). Afterwards, we move to the inventory stage with the query command:

$$\text{Query } A \ \& \ SL: \ Q(1, Target = 0, Sel = 3), \tag{8}$$

where the fields $Sel = 3$ and $Target = 0$ mean that the reader queries only the tags with the inventoried flags being A together with asserted SL. In such a context, only the target tags of τ' have the chance to reply; other tags in $\tau - \tau'$ are silenced due to $\sim SL$. For any target tag, by recording the time interval between two adjacent replies, we can get its persistence time, which is treated as the energy-related fingerprint.

3.5 Degree of Parallelism

Simultaneous authentication of multiple tags greatly saves the time overhead. However, this is not free; it lowers the sampling rate of each tag when measuring its persistence time. That is because the read throughput of a reader model (how fast the reader can read the tags) is usually fixed. More tags correspond to reduced likelihood that a tag is read. A low sampling rate means a low resolution of measured persistence time, which further affects the authentication accuracy. To address this problem, we can partition a tag set into several small subsets if a large number of tags are to be authenticated. Afterwards, we deal with each subset of tags at a time. The process of fingerprinting a subset of tags can be seen in Section 3.3.2 (for SQM) and Section 3.4.2 (for enhanced SQM). This process repeats until all tags are validated. Note that the degree of parallelism is related to the read throughput of a reader. High read throughput ensures that more tags can be fingerprinted simultaneously. The degree of parallelism is evaluated in Section 5.3.2.



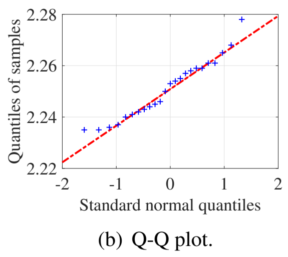


Figure 6: Gaussian distribution of persistence time.

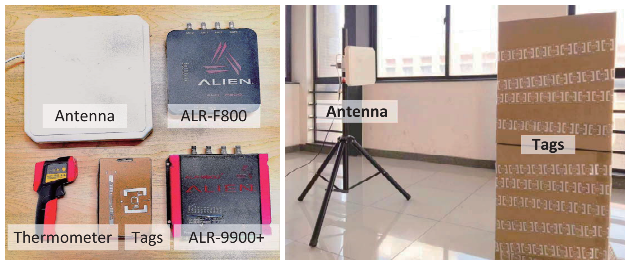

Figure 7: System deployment.

4 Genuineness Validation

To validate the genuineness of a tag, we need to compare its fingerprints under testing with those in the check-in stage. In this work, we take the distribution of the persistence time as the metric to perform the comparison. Intuitively, if a tag under testing is genuine, then its persistence time should follow the same distribution as its genuine records. Given a newly measured set X' of the persistence time and a genuine record X, the task of genuineness validation is reduced to verify whether X' and X follow the same distribution.

Now, we set up an RFID system that contains 1000 tags with eight different models supplied by three leading RFID companies: Alien [1], NXP [3], and Impinj [2]. For each tag, we run the enhanced SQM to obtain at least 20 measures of the persistence time. In Fig. 6(a), we randomly pick a tag and plot its persistence time. As we can see, the persistence time is likely to be a Gaussian distribution. We validate this conclusion through a quantile-quantile (Q-Q) plot, which is widely used to compare the similarity between two probability distributions. If two compared distributions are similar, then the points in the Q-Q plot will nearly lie on a line. As shown in Fig. 6(b), we compare the persistence time with the standard normal distribution. Clearly, the plots almost form a straight line, suggesting that the persistence time follows a Gaussian distribution.

In statistics, t-test is most commonly applied to determine whether the means of two sets of data with Gaussian distribution are significantly different from each other. Suppose the recorded data X follows a Gaussian distribution $N(\mu, \delta^2)$ and the data X' under testing follows a Gaussian distribution $N(\mu', \delta'^2)$. If the tag is a genuine tag, then μ' and δ'^2 are supposed to be very close to μ and δ^2, respectively. According to t-distribution, the mean value $\bar{X}'$ shall be

$$f(\bar{X}') = \frac{\bar{X}' - \mu}{\delta/\sqrt{n}}. \tag{9}$$

The t-test uses the significance level p as a threshold to determine whether or not accept $\bar{X}'$. The significance level p belongs to the interval [0, 1] and is typically set to 0.05 or less [23]. The setting of p will be discussed in Section 5.3.1.

Note that if the persistence time does not follow normal distribution, we can resort to a non-parametric test, e.g., Wilcoxon rank-sum test, which is valid for both non-normally distributed data and normally distributed data.

5 Implementation & Evaluation

In this section, we implement a prototype of Eingerprint in a commodity RFID system. On the basis of this system, we evaluate the performance of Eingerprint through extensive experiments in terms of the robustness to environmental changes and authentication accuracy.

5.1 System Deployment

The system setup is shown in Fig. 7. Two reader models, ALR-F800 and ALR-9900+ supplied by Alien [1], are employed in our experiment without any modifications to the hardware or the firmware. The reader is connected to a directional antenna (Laird S9028 [14], with a gain of 8.5 dBi) and operates at around 920 MHz. Over 1000 tags with 8 tag models are used in total. The model ALN-9634 [1] is adopted as the default in the experiments without explicit instructions. The development software of the fingerprinting system is Java, which adopts the Low-Level Reader Protocol (LLRP), specified by EPCglobal in its EPC Gen2 standard, to communicate. The host computer is a laptop with an Intel Core i5-8250U 1.8 GHz CPU and 8 GB RAM.

5.2 Impact of Environmental Factors

Resilience to environmental conditions is where Eingerprint shines, which is a basis for practical use. In this subsection, we investigate the impact of environmental factors on the measure of the persistence time, including the communication distance, tag orientation, communication frequency, transmit power, and temperature. All results are evaluated based on the inventoried flag in session 1 (S1) without explicit instructions. Similar conclusions can also be drawn in session 2 (S2) and session 3 (S3).

Distance. The communication distance between a reader and a tag is well known to have a great impact on the RF signals, e.g., RSSI or the phase value. To investigate the impact of the distance on Eingerprint, we vary the distance d and

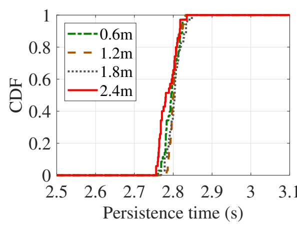

Figure 8: Impact of distance.

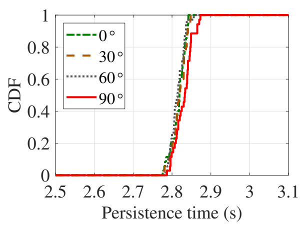

Figure 9: Impact of tag orientation.

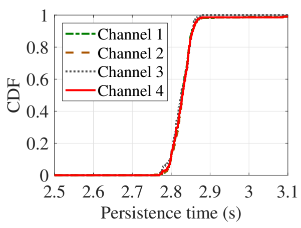

Figure 10: Impact of channel.

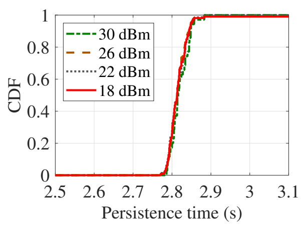

Figure 11: Impact of transmit power.

observe the changes in CDFs of persistence times. In this experiment, four distances are tested, where d_1 =0.6 m, d_2 =1.2 m, d_3 =1.8 m, and d_4 =2.4 m. As shown in Fig. 8, we can see that the CDFs are very close to each other and the means of the persistence times under the four distances are 2.797 s, 2.801 s, 2.804 s, and 2.787 s, respectively. These positive results demonstrate that the distance between a reader and a tag has little effect on the energy-related fingerprint.

Tag orientation. In some existing RF-based work [10,35], the authentication accuracy largely depends on the tag orientation. In Fig. 9, we observe the persistence time of a tag under different rotation angles, i.e., $0°, 30°, 60°, 90°$. The means of the measured persistence times are 2.817 s, 2.818 s, 2.814 s, and 2.814 s, respectively, corresponding to the four rotation angles. Similarly, the consistent results indicate that our energy-related fingerprint remains stable, regardless of the tag's rotation angles.

RF channels. A typical UHF reader has 16 channels working at 920—924 MHz ISM band. RF phase values, a widely used metric for RF fingerprinting, heavily rely on the RF channels. To examine whether the channel affects the stability of Eingerprint, we extract the persistence time from a tag under four different channels, where $channel_1$ = 920.625 MHz, $channel_2$ = 921.625 MHz, $channel_3$ = 922.625 MHz, $channel_4$ = 923.625 MHz. Fig. 10 shows the CDFs of the persistence times under the four channels. The close results demonstrate that the energy-related fingerprint is resistant to the communication channel.

Transmit power. Next, we examine the effect of the transmit power of the reader. In this experiment, we set the transmit power to 30 dBm, 26 dBm, 22 dBm, and 18 dBm respectively, and observe its impact on persistence time. As shown in Fig. 11, the CDFs of the persistence times under different transmit powers approach to each other. The positive results demonstrate that the transmit power has little impact on the energy-related fingerprint.

Temperature. In this experiment, we study the impact of the temperature on the persistence time. Four temperatures are investigated, three of which are close to each other (20 °C, 21 °C, 22 °C) and another is much higher (30 °C). Fig. 12 shows the CDFs of the persistence time under these four temperatures. As we can see, the three CDFs of temperatures 20 °C, 21 °C, 22 °C are similar, while that of 30 °C is different from the others'. This result indicates that the temperature has an impact on the persistence time. If the temperature change is slight, the impact could be negligible. Otherwise, we need to take the temperature into account if it varies considerably. This accords with the theory as temperature could affect the resistance and capacitance of electronic components. In fact, it is a blessing in disguise to some extent: each temperature corresponds to a fingerprint, which provides us with more fingerprints and higher authentication accuracy.

On top of the above experiments, we draw the conclusion that the energy-related fingerprint is resistant to various environmental conditions, including communication distance, tag orientation, communication frequency, and transmit power, except for the temperature.

5.3 Authentication Performance

In the experiments, three widely used metrics are applied to evaluate the authentication performance of Eingerprint, including false acceptance rate (FAR), false rejection rate (FRR), and authentication accuracy. FAR indicates the likelihood that the system will incorrectly accept a counterfeit. FRR indicates the likelihood that the system will fail to accept a genuine tag. For each experiment, we randomly pick two tags from 200 tags and treat one of them as a genuine tag and the other as a counterfeit. By checking whether each of them is genuine or not, we can record the number of correct checks. Repeating the above experiment 500 times, we derive the authentication accuracy that is equal to the ratio of the number of correct checks to the number of tests in total.

5.3.1 Significance Level

Eingerprint utilizes the significance level (threshold), denoted by p, to determine whether a testing fingerprint is valid or not. A large p is likely to reject a valid tag, leading to a high FRR, while a small p cannot figure out friend (genuine tag) or foe (counterfeit), increasing FAR. This dilemma requires a proper value of p to balance FRR and FAR. We extract fingerprints from 200 tags and respectively compute FRR and FAR under various p, which ranges from 0.01 to 0.06. As shown in Fig. 13, we set the value p to the value that corresponds to the intersect point of the two curves of FRR and FAR, i.e., $p = 0.03$, which is used in the following experiments.

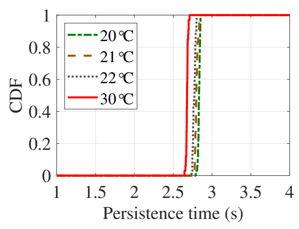

Figure 12: Impact of temperature.

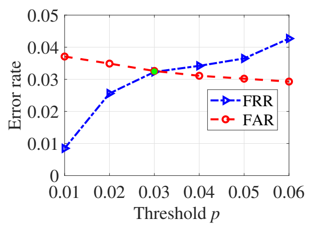

Figure 13: Threshold setting.

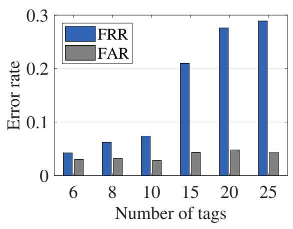

Figure 15: Multiple tags.

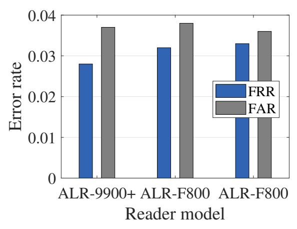

Figure 16: Device diversity.

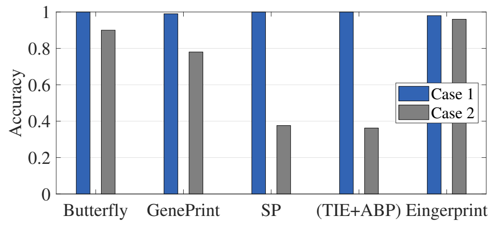

Figure 14: Performance comparison.

5.3.2 Authentication Accuracy

We now compare the authentication accuracy of Eingerprint with the state-of-the-art, including Butterfly [11], GenePrint [10], spectral feature (SP) [35], and time interval error together with the average base band power (TIE+ABP) [35]. Two cases are taken into account. In case 1, the tags are registered and authenticated at the same position. In case 2, the tags are registered and authenticated in different rooms. As shown in Fig. 14, all methods achieve a high authentication accuracy in case 1. However, the environmental changes in case 2 have a great impact on the performance of existing work. For example, the accuracy of SP drops sharply from 100% to 37.6%. By contrast, Eingerprint is resistant to these changes; the authentication accuracy in case 2 reaches 96.2%. Eingerprint is also more scalable than these approaches, which require a purpose-built device to measure the RF signals and cannot be deployed in a commercial RFID system. Notably, we just use one session to do the authentication. If more sessions are taken into account, the accuracy will be further improved, which will be shown next.

Selection of sessions. According to the Gen2 standard, three sessions with different persistence times can be used for tag authentication: session 1 (S1), session 2 (S2), and session 3 (S3). As shown in Table 3, we increasingly use these three sessions. The authentication accuracy improves as the number of sessions increases. This result is intuitive because more fingerprints reduce the probability that the system incorrectly accepts a counterfeit. Using multiple sessions, however, increases the authentication time. Hence, it is a trade-off between the accuracy and the time efficiency.

Table 3: Accuracy with different sessions

	S1	S1+S3	S1+S2+S3
Accuracy	97.3%	98.3%	99.4%

Multiple tags. We now study the performance of Eingerprint when authenticating multiple tags concurrently. We randomly choose 6, 8, 10, 15, 20, and 25 tags from 200 tags and authenticate them concurrently. As shown in Fig. 15, FRR sees a sharp rise as the number of tags increases because the large number lowers the sampling rate of each tag, which further lowers the resolution of the measured persistence time. In other words, the same tag is likely to have some persistence times apart from each other due to the low resolution, which increases the probability that a genuine tag is rejected. In contrast, the number of tags has a much lower impact on FAR because the same tag still more easily has similar persistence times than others even though the resolution is low. In addition, we can see that our method has potential in validating multiple tags in parallel. For example, when fingerprinting 10 tags, the FRR is 7.2%, the FAR is 2.3%, and the authentication accuracy is 95.2%. We assert that the degree of parallelism is related to how fast a reader can read tags. In this experiment, the read throughput of the reader is about 150 tags/s. If a faster reader is adopted, then the degree of parallelism could be higher.

Device diversity. In practice, using different devices to register and validate tags is common. To study the impact of device diversity, four readers are used, namely, three ALR-F800 readers and an ALR-9900+ reader. In the experiment, we first register 200 tags with an ALR-F800 reader and then validate the tags with the other three readers. As shown in Fig. 16, the authentication accuracy remains almost unchanged, regardless of which reader is used. This experimental result shows that device diversity has little impact on the performance of Eingerprint.

Tag model. We further study the performance of Eingerprint on different tag models. In the experiment, we test eight tag models from three leading RFID tag providers, which are Alien [1], NXP [3], and Impinj [2]. As shown in Table 4, Eingerprint achieves a high authentication accuracy (>94%) on all Alien and NXP tags. However, for Impinj tags, the accuracy experiences a sharp drop. By checking the persistence time, we find that the difference of persistence times of Impinj tags is much smaller than that of the other two. Hence, we recommend using Alien tags or NXP tags if tag authentication is required.

6 Related Work

Existing studies on RFID authentication can be divided into two categories: cryptographic-based approach [5, 8, 9, 18, 19, 32] and physical-layer identification (PLI) [6, 7, 10–12, 21, 26, 29, 31, 35–37, 40]. The former uses cryptographic technique to protect the communication between reader and tags against eavesdropping. However, existing cryptographic-based approaches suffer from two limitations. First, some cryptographic algorithms require high computation overhead, which is too heavy to be afforded by a passive tag [8]. Besides, it increases the cost of a passive tag as well as reduces the communication range between a reader and a tag. Second, some cryptographic-based methods are vulnerable to protocol-layer attacks, such as reverse engineering, side-channel, replay attack, and cloning [18, 32].

PLI is commonly referred to as RF fingerprinting, which utilizes the physical-layer information to identify digital devices. PLI has two advantages over cryptographic-based methods. First, the feature from the physical layer is unique and unpredictable, such that it can provide high security guarantees against various protocol-layer attacks. Second, no hardware or firmware upgrades on existing systems are required. Existing PLI work generally has three categories: location-based RF fingerprinting (LRF) [26, 31, 37], transient-based and preamble-based RF fingerprinting (TPF) [7, 10, 11, 29], and modulation error-based RF fingerprinting (MEF) [6, 12, 35].

LRF takes the location information as the fingerprint to authenticate a target, which works but strongly relies on the target's location. TPF fingerprints a device through the uniqueness of a certain fixed segment extracted from its transition signals and preamble signals [7, 10, 11, 29]. Since the transient-based and preamble-based features are always derived by spectral transformations, this approach is sensitive to environmental changes [29, 39]. MEF fingerprints a device through the modulation errors caused by hardware imperfection, such as SYNC correlation [6], carrier frequency offset [12], and time interval errors [35], which is channel-robust but usually requires a purpose-built device (e.g., USRP) to acquire fine-gain signal features and is thus not scalable to a commodity RFID system.

Table 4: Performance on different tag models

Company	Chip	Model	Accuracy
Alien	Higgs 3	ALN-9634	97.3%
	Higgs 4	ALN-9740	96.9%
	Higgs EC	ALN-9830	96.6%
NXP	Ucode G2iL	MiniWeb	94.4%
	Ucode G2iM	AD-380iM	94.9%
	Ucode 8	AD-238U8	94.2%
Impinj	Monza 4	H47	77.8%
	Monza R6	BLING	80.4%

7 Conclusion

In this paper, we propose a robust RFID authentication scheme by using an energy-related fingerprint. The basic idea is using the electric energy stored in a tag's circuit rather than RF signals as the fingerprint, which is resistant to the environmental changes. Directly measuring the tag's circuit to obtain the stored energy is impractical. Instead, we find an equivalent metric, namely, persistence time, that can reflect the circuit diversity indirectly. We design a Gen2-compatible select-query method to measure the persistence time. Afterwards, we use a t-test based model to validate the genuineness of a tag. We set up a prototype of the fingerprinting system, and extensive experiment results show that our system is able to achieve a high authentication accuracy of 99.4%, regardless of environmental conditions and without any hardware or firmware modifications.

Acknowledgments

We would like to thank our shepherd, Prof. Aaron Schulman, and the anonymous reviewers for their valuable feedback on an earlier draft of this paper. Abstract

Indoor localization has been studied for nearly two decades fueled by wide interest in indoor navigation, achieving the necessary decimeter-level accuracy. However, there are no real-world deployments of WiFi-based user localization algorithms, primarily because these algorithms are infrastructure dependent and therefore assume the location of the access points, their antenna geometries, and deployment orientations in the physical map. In the real world, such detailed knowledge of the location attributes of the access Point is seldom available, thereby making WiFi localization hard to deploy. In this paper, for the first time, we establish the accuracy requirements for the location attributes of access points to achieve decimeter level user localization accuracy. Surprisingly, these requirements for antenna geometries and deployment orientation are very stringent, requiring millimeter level and sub-10° of accuracy respectively, which is hard to achieve with manual effort. To ease the deployment of real-world WiFi localization, we present LocAP, which is an autonomous system to physically map the environment and accurately locate the attributes of existing wireless infrastructure in the physical space down to the required stringent accuracy of 3 mm antenna separation and 3^o deployment orientation median errors, whereas state-of-the-art algorithm reports 150 mm and 25^o respectively.

1 Introduction

Indoor navigation requires precise indoor maps and accurate user location in these maps. Google, Bing, Apple or Open Street Maps have made considerable progress towards providing precise indoor maps for notable locations like airports and shopping malls [1–4]. On the other hand, there are two decades of research on indoor localization using WiFi infrastructure that achieve decimeter accurate user locations [22, 30, 37, 39, 50, 51, 53, 58, 59, 65–69]. Despite these innovations, we still cannot use our smartphones to navigate in these indoor environments.

The key reason for this inability is the absence of the bridge

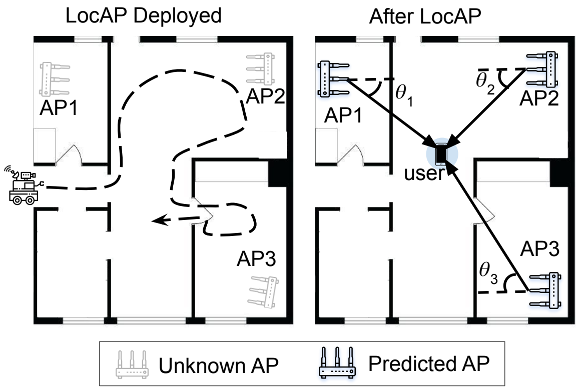

Figure 1: **Implementation of LocAP: (Left)** An unknown environment with unknown AP attributes where LocAP is deployed. **(Right)** LocAP once deployed determines the AP attributes in the physical map enabling triangulation based user localization.

providing the context of the physical map to the user locations. While there is recent work [8] that bridges this gap, it, like other state-of-the-art localization algorithms [37, 59, 66], is dependant on the accurate location attributes of the WiFi access points (APs) in the physical maps of these airports and malls. To understand what we mean by location attributes, consider the setup shown in Figure 1(right). The smartphone user is triangulated in an indoor environment by estimating the angle subtended by the user at each of the access points. This approach inherently assumes to have accurate knowledge of each access point's location and its deployment orientation (the angle at which the access point is placed in the given physical map). Further, to estimate the angle made by the user with respect to an access point, the channel state information (CSI) based WiFi localization algorithms need to know the exact antenna placements on these access points.

One can endeavor to manually locate each of these access points in the environment, but that would be labor-intensive, time-consuming and even impossible sometimes because of the following reasons. First, these access points (AP) are usually not easily visible; they may be located behind a wall or pillar. Second, even if the AP is visible, most of the access points are encased by the manufacturer, making it difficult to know the exact information of the antenna placements on the access point. Third and finally, even if we can estimate the antenna placements on the access point from the datasheet provided by the manufacturer[1], the AP's *deployment orientation* has to be carefully calibrated to the indoor maps within an error of a few degrees. Thus, we need a system that can help in accurate mapping of the existing WiFi infrastructure, which does not involve any manual labor or time.

In this paper, we present LocAP, an autonomous and accurate system to estimate access point location attributes – access point location, antenna placements, and deployment orientation. We call this process of predicting accurate access point attributes as *reverse localization*. LocAP is the first work to establish the requirements for reverse localization as follows:

Accurate Access Point Locations: As shown in Figure 2a, any error in AP location is translated to an error in the location of the user. So, any error exceeding a few tens of centimeters in access points' location is going to adversely affect the decimeter-level user localization. Thus, LocAP needs to locate the access point accurate to within tens of centimeters.

Accurate Antenna Separation: Different APs have different antenna placement configurations and the angle made by the user is measured at the access point using the spacing between antennas. So, any error in measuring antenna placements is going to cause a rotation error at the user. For example, error in antenna separation by 4 mm causes 12^o of error in the angle of user measured at the access point, which translates to up to 1 m of error for a user 5 m away from the access point. Thus, LocAP needs to predict the antenna separation accurately to within a few millimeters.

Accurate Deployment Orientation: Finally, the access points can be placed in any orientation in the environment. Any error in measurement of orientation directly translates to the predicted angle subtended by the user at the access point. Hence even 10^o of error in deployment orientation causes up to 90 cm of user location error for a user located just 5 m away from the access point. Thus, LocAP should resolve the deployment orientation of the access point accurate to less than 10^o of error.

Automation: LocAP's goal is to require no manual effort for the reverse localization, and achieve the stringent requirements discussed earlier. Furthermore, there should be zero effort to associate these positions with the existing indoor maps, ideally in an autonomous way.

LocAP achieves the aforementioned requirements and enables automated and accurate *reverse localization* of the access points. We achieve autonomy by deploying LocAP on a bot retrofitted with a multi-antenna WiFi device used in

[1]Datasheets, though publicly available do not talk about antenna placements or dimensions [6, 7, 17, 28, 47, 48, 57].

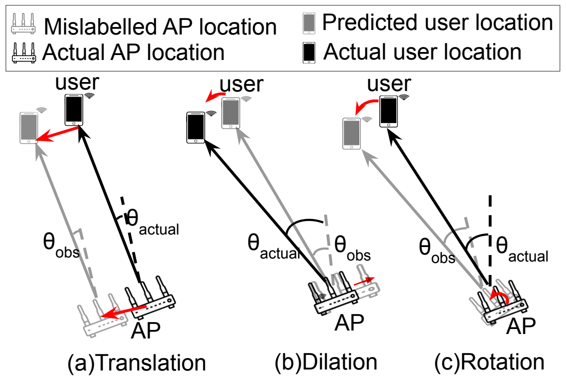

Figure 2: **LocAP's Motivation:** The user location is predicted wrong due to different errors in access point's estimated details. **(a) Translation:** Predicting the wrong location of the AP. **(b) Dilation:** Predicting wrong antenna separation on the access point results in an error in angle estimated,($\theta_{obs} \neq \theta_{exp}$) of the user. **(c) Rotation:** Predicting the wrong orientation of the AP.

[8]. When deployed in a new environment, the bot first maps the physical environment. Next, it associates with existing AP infrastructure by collecting multi-antenna channel state information, and pairing it with its predicted location in the physical map as shown in Figure 1(left). LocAP uses this information to build a database of the deployed WiFi infrastructure consisting of all the access point attributes meeting our stringent accuracy requirements. This database of accurate AP location attributes can then be used for decimeter level user localization as depicted in Fig. 1(right)

The main technical contributions of LocAP to achieve the above requirements can be summarized as follows:

cm-accurate Access Point Localization: We make an important observation that accuracy of triangulation based WiFi-localization methods improves with an increasing number of anchor points with known locations. In essence, creating an array of 100's of antennas measuring CSI at known locations achieves cm-level localization, which is not feasible in practice[2]. To overcome this, LocAP leverages the CSI data collected by the bot at 100's of predicted locations, mimicking 100's of virtual antennas with known locations. However, these *predicted* locations suffer from a varying amount of inaccuracy. Hence, LocAP designs a weighted localization algorithm, which weights each location-CSI data-point with a uniquely defined confidence metric capturing the accuracy of the predicted location.

mm-accurate Antenna Geometry Localization: We have seen earlier that both mm-error in antenna separation and error in deployment orientation lead to in-accurate Angle of Arrival (AoA) measurement at the access point, which impedes user-triangulation. Thus, LocAP tackles antenna separation and deployment orientation together by achieving millimeter-

[2]typical indoor settings are 1000-2000 sq. ft., which would imply deploying an antenna every 100 sq. ft.

level accuracy in predicting the antenna geometry. The first thought would be to use 1000's of virtual antennas to achieve cm-accurate localization [39] by locating individual antenna geometry on the AP. But, this idea can only achieve accuracy at the cm-level and will not suffice to achieve mm-level details of the antenna geometry. Our key observation is to localize the relative antenna geometry between two antennas, primarily because the relative wireless channel between the two antennas can be measured very accurately by measuring their phase information. The phase information is measured at the carrier frequency level (λ=60 mm equivalent to 360^o), hence even phase measurement accurate to 10's of degrees achieves 1-2 mm accuracy. However, this works for only relative antenna separation $d < \frac{\lambda}{2}$. LocAP designs a novel algorithm that uses relative channel information across multiple bot locations to solve for any antenna geometry, unrestricted by antenna separation, to mm-level accuracy.

Automation – Augmenting the SLAM algorithms: To avoid any manual labor and errors, LocAP is deployed on a SLAM (Simultaneous Localization and Mapping) based autonomous bot developed by us [8]. This bot provides us with a physical map and the location and heading of the bot in this physical map at all times. We pair these location-heading measurements with the CSI collected by the mounted WiFi device. However, even the best of SLAM algorithms report the location to be in-accurate up to 10-20 cm, which can have a detrimental effect on the AP location attributes. Therefore, LocAP develops a confidence metric whose core idea to look at the covariance of measurements across consecutive frames.

Further, the implementation of LocAP does not need any modification at the existing access points, as it is deployed on a custom made bot [8] that is mounted with a Quantenna client. The Quantenna client readily reports the channel-state-information (CSI) of the associated access point. We evaluate LocAP in an indoor environment of 1000 sq ft area with multiple off-the-shelf access points and 2 different antenna configurations – rectangular and linear[3] We achieved the following results satisfying the aforementioned accuracy requirements:

Relative Antenna Geometry Prediction: LocAP's relative reverse localization for the antenna separation has a median error of 3 mm (50$\times$ improvement), and a median error of 3^o(8$\times$ improvement) for deployment orientation, while state-of-the-art achieves a median error of 150 mm and 25^o respectively.

Access Point Localization: LocAP's reverse localization of the access points achieves a median localization error of 13.5 cm improving by 35% over the state-of-the-art WiFi localization algorithms [37].

Case Study-User Localization: State-of-Art user localization is deployed using the access point attributes measured manually and with LocAP. We observe user localization errors of 78 cm and 50 cm respectively, a decrease in the error of about 36%.

[3]these configurations generalize the more generic antenna deployments found on the commercial off the shelf WiFi access points.

2 Requirement and Motivation

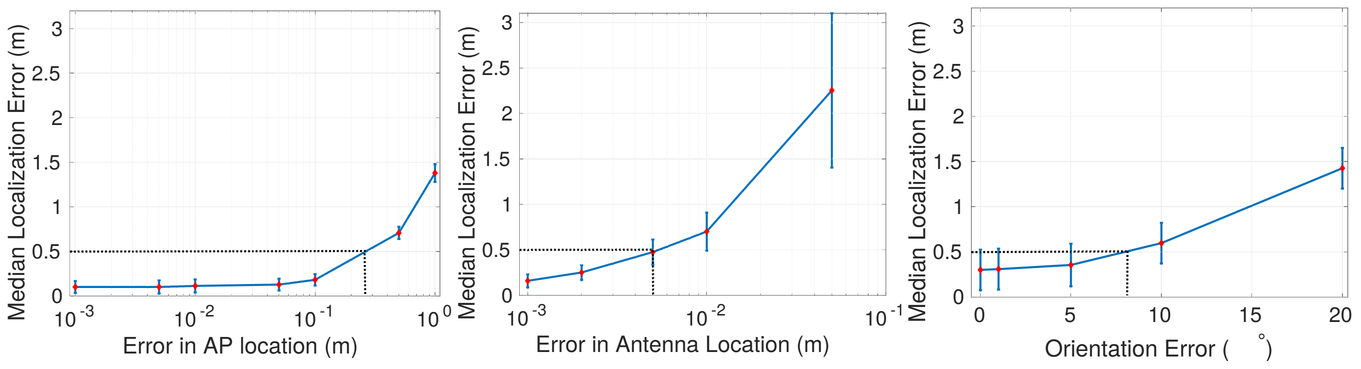
It may seem natural that user localization algorithms [37, 53, 59, 67] could be sufficient for *reverse localizing* the access point's location attributes – location, antenna geometry and deployment orientation. Surprisingly, it turns out that requirements for reverse localization of the access are stringent. To define these requirements, we conduct empirical evaluations from the standpoint on how various errors in AP attributes adversely affect the state-of-the-art decimeter level localization algorithms.

Our empirical setup contains four access points, each with 4 antennas, setup in a 25ft$\times$30ft space. The user device is placed at 100 different locations while the access points locate the user using an algorithm similar to [37]. Specifically, we aim to achieve decimeter-level localization accuracies for user WiFi localization algorithms and thus set a hardbound that no more than 50 cm median error for user localization can be tolerated.

Error in the AP's location Firstly, in the above-described setup, we incrementally increase the error in all the access points' locations. Next, we estimate the user location for each of these erroneous access point locations and calculate the user localization error. In Figure 3a, we plot the median user localization error across the access point errors reported. We can see that if the access point locations have an error of more than a few centimeters, the median localization error starts to increase. From this, we can infer that the required level of accuracy for the reverse localization of APs should be in the order of centimeters.

Error in the antenna separation Second, AoA based localization algorithms make use of the relative phase information between two antennas. Earlier, we have seen that the relative antenna position has to be estimated accurately to have exact measurements of angles. Even when the access point positions are reported correctly, we can observe that the localization error increases with just a few millimeters of errors in the reported relative antenna positions as shown in Figure 3b. This observation is intuitive because the relative antenna distances are usually of the order of a wavelength of the transmitted signal, which in the case of WiFi is 6cm. So, any error which is greater than a few millimeters is going to make a huge difference in the relative phase measured at the access point.

Error in the Deployment Orientation Finally, the antenna array can be oriented in any direction. It is also important to know the exact deployment orientation of the antenna array. Errors in this orientation will proportionately affect the angle of arrival measurements made at the access points. We observe that the greater the error in deployment orientation prediction, the higher the median localization error becomes as shown in Figure 3c. From this plot, we can see that even 7^o will degrade the median user localization accuracy to more than 50 cm.



(a) (b) (c)

Figure 3: **Robustness of localization accuracy to Access Point (AP) location errors:**(a) Shows that median localization error increases with increase in error of estimated AP location.(b) Shows how median localization error increases with increase in error of estimated antenna locations. (c) Shows how median localization error increases with increase in error of estimated antenna deployment orientation.

In summary, we should locate the access point's location with less than 30 cm of error, the antenna separation within 5 mm of error and the deployment orientation to less than 7^o of error. While these locations are typically mapped manually by humans using specialized equipment like VICON [55] or laser-based range finders [11], this process is time-consuming, labor-intensive and error-prone. So, we need a system that can accurately localize access points attributes satisfying these stringent requirements. Note that the most stringent requirements are the mm-accurate antenna separation and sub-7 degree deployment orientation. The state-of-the-art [37, 39, 53, 67] localization algorithms can locate the individual antennas to within a few 10 centimeters even by deploying hundreds of AP's in a given environment, which is insufficient to determine the antenna geometry as per required specifications established earlier in this section. Further, there are relative localization algorithms [38, 61, 64] which track the user's location across contiguous observations few millimieters apart. These ideas could potentially be used to find the relative antenna geometry. But, these tracking algorithms assume that the two relative locations are less than $\lambda/2$ apart [6, 7, 17, 28, 47, 48, 57] but the antenna separations on most access points are more than $\lambda/2$ apart, where there is an ambiguity that cannot be resolved. So, we design a system, LocAP, which fulfills these requirements and locates the access points and their antennas with the desired level of accuracy

3 Design

In this section, we present the design of LocAP. Recall that our main goal is to autonomously determine access points' location attributes within the reference coordinates of the physical map to enable easily deploy-able WiFi-localization. LocAP deploys a SLAM based autonomous bot developed in [8] to map the environment. The autonomous bot provides it's location and heading with respect to the environment's map. Simultaneously, a four antenna WiFi device retrofitted on the bot, connects with the existing WiFi infrastructure, all the while reporting the CSI information at each instance. Furthermore, to avoid changes to deployed AP infrastructure, we perform all the processing on the bot. LocAP, therefore, is provided with the location and orientation of the bot with respect to the physical map and the CSI data from the WiFi device on the bot, which connects with the existing WiFi infrastructure. We design LocAP to use these inputs to provide accurate access point attributes–location, antenna separation, and deployment orientation with respect to the physical map.

First, we discuss how to achieve the cm-level accurate location of the AP that also accounts for inaccuracies in reported bot poses. Second, we present LocAP's algorithm to estimate the antenna separation and deployment orientation of all the APs that needs to achieve the stringent requirement of mm-level accuracy. In both of these scenarios, we assume we have the CSI corresponding to the direct path and later in Section 3.3 we discuss how we tackle the presence of multipath in the environment and recover the direct path's CSI. Finally, we present the SLAM-based bot design, which does the best effort to provide the necessary measurements mentioned above. But often, these measured poses are not accurate. So, LocAP builds an algorithm which reports a confidence metric for each measured pose. This confidence metric helps us surmount the errors in the bot locations to calculate AP location attributes.

3.1 Locating the Access Point

In this subsection, we focus on identifying the position of one of the access point's antenna. This position of the antenna would then be representative of the access point's location and we refer to this as the first antenna in the subsequent text. Recall that the access point's location has to be estimated accurately to cm-level. A simple solution can be to utilize the existing WiFi localization approaches to locate one of the antennas on the access point, which would then become the access point's location. Unfortunately, state-of-

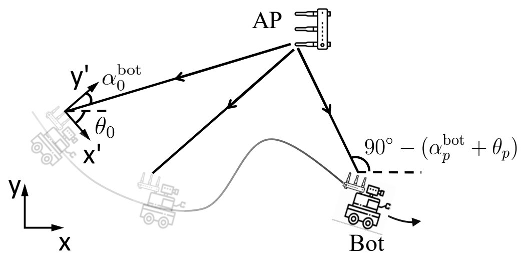


Figure 4: **First Antenna Localization:** Gives an overview of how triangulation from 10s of bot locations locates the access point accurately to within few centimeters.

the-art localization algorithms only report decimeter level location estimates. However, we make an interesting observation: these algorithms show increasing location accuracies with an increase in the number of access points deployed in an environment. In our scenario, we have a mobile bot which collects CSI data from the deployed access point at multiple anchors. This bot covers a large area setting up 100's of anchors which aids in cm-accurate first antenna localization.

Owing to this setup of LocAP, we can employ an angle of arrival estimation algorithm similar to [37] and estimate the direct path's AoA, α_p^{bot} for p^{th} bot location ($p = 1, 2, \dots, P$). We measure these AoA's with respect to the bot's local axis (X'-Y') corresponding to the first antenna's transmission for each bot location $\mathbf{u}_p = [u_p, v_p]$. To enable this AoA based first antenna triangulation, we should also know the direction of the bot's heading (θ_p) with respect to the global axis (denoted by X-Y in Figure 4), which is reported by the bot as mentioned earlier. With ($\mathbf{u}_p, \theta_p$ and α_p^{bot}) we can find the first antenna location as an intersection of P lines:

$$\text{Line}_p \equiv (y_1 - v_p) = \tan(90^\circ - (\alpha_p^{bot} + \theta_p))(x_1 - u_p) \quad (1)$$

Ironically, the AoA based triangulation accuracy is bounded by the errors in the bot's reports of its location, (u_p, v_p) and heading, θ_p^{bot}. Clearly, this creates a vicious unending loop – to predict the antenna locations we need accurate bot measurements and vice-versa to predict the bot's locations. To overcome this problem, we take advantage of SLAM algorithms [21] to get accurate ground truth estimates of the bot location and heading. Unfortunately, SLAM-based bots do not have 100% confidence in all the location estimates they report, forcing us to only cherry-pick the measurements which we believe are accurate. Based on this intuition, we design a confidence metric, $w_p \in [0, 1]$ for each bot location $\mathbf{u}_p$. Further details on the design of the confidence metric are discussed in Section 3.4. This confidence metric implies that the bot is more confident with the reported pose the closer it is to one. We thus implement a low-confidence rejection algorithm, which rejects the measurements with confidences, w_p, in the lowest 20% (Using only $\lfloor 0.8 \times P \rfloor$ lines).

We use these confidences in combination with the rest of our $\lfloor 0.8 \times P \rfloor$ line equations to define a weighted least squares problem to optimally solve for the first antenna location as follows:

$$\min_{\mathbf{x}_1} ||W(S\mathbf{x}_1 - \mathbf{t})||^2 \quad (2)$$

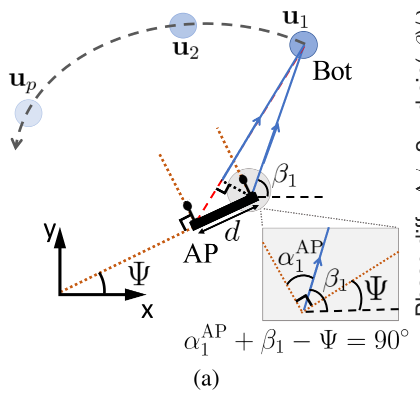
where $\mathbf{x}_1 = [x \;\; y]^T$ is the first antenna location, $W = \text{diag}(w_1, w_2, \cdots, w_{0.8P})$ is the weight matrix, $S(p,:) = [\cos(\alpha_p^{bot} + \theta_p) \;\; - \sin(\alpha_p^{bot} + \theta_p)]^T$ and $\mathbf{t}(p) = [u_p \cos(\alpha_p^{bot} + \theta_p) - v_p \sin(\alpha_p^{bot} + \theta_p)]$. Thus, we estimate of the first antenna's location $\mathbf{x}_1$ which corresponds to the access points location.

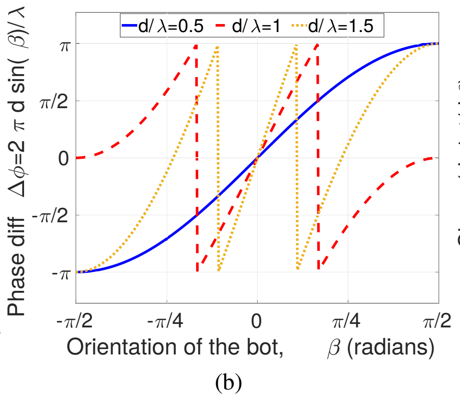
3.2 Determining Antenna Separation and Deployment orientation

As described above, we can leverage the motion of the bot to identify the accurate location of one antenna on the access point. One might wonder if it is possible to apply this algorithm iteratively to identify the location of each antenna on the access point and hence recover the relative placement of antennas. However, it is not so straightforward. In particular, the geometry prediction needs to be an order of magnitude more accurate than the location prediction. While it suffices to measure the location of the access point to cm-level, the geometry, i.e. the relative position of antennas, needs to be mm-accurate. While combining across 10s of bot locations provides antenna location accurate to cm-level, it does not extend to mm-accurate antenna geometry by combining across 100s or even 1000s of bot locations as shown in the prior art [39]. This problem occurs owing to the asynchronous clocks between the access point and the bot's WiFi device when measured at a single antenna at the access point.

To overcome this problem we make a key observation - in contrast to the phase measured at one antenna on the access point, the relative phase across two antennas is rid of synchronization errors as they share the same clock. Further, at WiFi 11ac's 5GHz carrier frequency, a wavelength of 6 cm corresponds to a phase difference of 2π radians. Empirically, we have observed that we can easily resolve phase differences up to $\pi/18$ radians (10^o), which facilitates measurement of the distance between two antennas with a resolution of 2 mm, thus enabling us to locate the antenna geometry accurately to within few millimeters. Hence, our first key insight is to measure the relative antenna separations, d_i, and deployment orientations, ψ_i, for all the N_{AP} antennas on the access point with respect to the first antenna ($i = 2, 3, \dots, N_{AP}$).

Unfortunately, although the relative phase information can resolve relative antenna separation to within 2mm, it cannot resolve for antenna separations greater than $\lambda/2$. To further understand this, consider an example scenario where the bot is moving in a circular arc about the two-antenna access point in steps of small angles as shown in Figure 5a. To avoid overcrowding of subscripts, we consider a two antenna access point and drop the access point's antenna indexing, i. Similar analysis can be performed pairwise on all the antennas on the access point with respect to the first antenna. Now, to





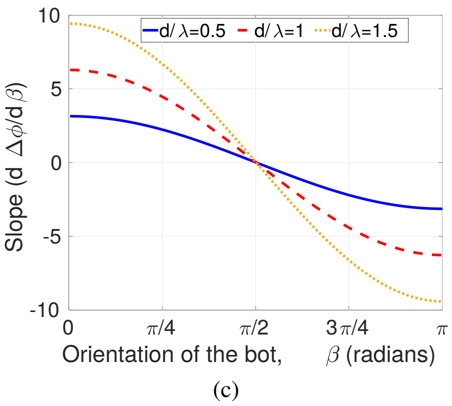


Figure 5: **Estimating AoD from phase difference:** (a) A sample case where the bot is in circular arc around the AP (b) Phase difference $\Delta\phi$ vs the orientation of the bot β assuming the deployment orientation of the AP, $\psi = 0$ (c) Slope $\frac{d\Delta\phi}{d\beta}$ vs the orientation of the bot β when compensated for the orientation of the access point.

locate the second antenna with respect to the first antenna, we analyze relative phase across these two antennas. We know that for the bot's location, $\mathbf{u}_p$, the phase difference between these two antennas corresponding to the direct path, $\Delta\phi_p$, can be estimated as:

$$\Delta\phi_p = \mod\left(\frac{2\pi d}{\lambda}\sin(90° - (\beta_p - \psi)), 2\pi\right) \quad (3)$$

where, the parameters of interest ψ and d are antenna deployment orientation (with respect to the X-axis) and antenna separation respectively. β_p is the angle subtended by the bot's location at the access point with respect to the global X-axis. From the inset in Figure 5a, we can see that the angle of departure from the AP is given by

$$\alpha_p^{AP} = 90° - (\beta_p - \psi) \quad (4)$$

and the extra distance travelled (represented by the red-dashed segment) is given by $d\sin(\alpha_p^{AP})$. This extra distance travelled induces the phase difference given in Equation 3. Thus, the phase difference across two antennas can help us estimate the antenna separation, d and deployment orientation ψ. To better understand this relation, we plot $\Delta\phi_p$ for all the bot locations along the circular arc against the angle subtended by the bot, β_p, for various antenna separations d in Figure 5b. From this plot we can see that for $d \le \lambda/2$, we have a unique mapping between the phase difference, $\Delta\phi_p$, and the bot's location, but for $d > \lambda/2$ we have ambiguous solutions that prevents us from estimating d and ψ. The ambiguity occurs because the phase difference we measured is a modulus of 2π, which means for a given $\Delta\phi_p$, the actual phase difference can be $2n_p\pi + \Delta\phi_p$, where n_p is any positive integer. This means we have three unknowns, (d, ψ, n_p) to solve for, given a single phase difference value, $\Delta\phi_p$. Furthermore, even for each additional bot location we have a new $\Delta\phi_{p+1}$ estimate, we also add an extra unknown n_{p+1} making it impossible to uniquely solve for d and ψ. LocAP's key insight is that, in contrast to the phase difference $\Delta\phi_p$, the differential phase difference with respect to the bot's angle at the AP (β_p) for optimally small increments of β_p, has a unique one-to-one mapping as shown in Figure 5c. So, the second key observation we make is that while the phase difference is not uniquely solvable for $d > \lambda/2$, the differential phase difference is uniquely solvable. Intuitively, two close bot positions will have the similar phase wrap-around's, and hence, taking the difference of the phase differences, $\Delta\phi_{p_2} - \Delta\phi_{p_1}$, can eliminate the ambiguity.

So far we have considered that the bot is moving along a circular trajectory. In fact, LocAP does not restrict the bot's motion to a circular arc and can work with arbitrary motion, as long as the CSI is measured regularly. To understand the exact implementation of LocAP's relative antenna geometry prediction, we consider a more free-flow path as shown in Figure 6. Concretely, determining the relative antenna geometry requires two parameters – the distance between antennas, d, and the deployment orientation of the antenna array, ψ, as can be seen from Figure 6. The bot moves to P distinct locations along a pre-determined trajectory about the AP and collects a series of P CSI measurements, H_p ($p = 1, 2, \cdots, P$), while simultaneously reporting the bot's locations, $\mathbf{u}_p$. The bot makes an angle β_p with respect to the global X-axis. Next, for each position of the bot, $\mathbf{u}_p$, we evaluate the differential phase difference $\frac{d\Delta\phi_p}{d\beta_p}$ between the two antennas on the access point. Differentiating Equation 3, we get

$$\frac{d\Delta\phi}{d\beta} = -\frac{2\pi d}{\lambda}\cos(90° - (\beta - \psi)) = -\frac{2\pi d}{\lambda}\sin(\beta - \psi) \quad (5)$$

But, for incremental movements of the bot, the differential phase difference in Equation 5 can be approximated as

$$\frac{d\Delta\phi_p}{d\beta_p} \approx \frac{\Delta\phi_{p+1} - \Delta\phi_p}{\beta_{p+1} - \beta_p} \quad (6)$$

The bot traces $P(> 3)$ positions as it moves, which enables us to obtain the solution from an over-determined system of equations, consequently reducing the noise level. Thus achieving highly accurate relative antenna position and orientation,

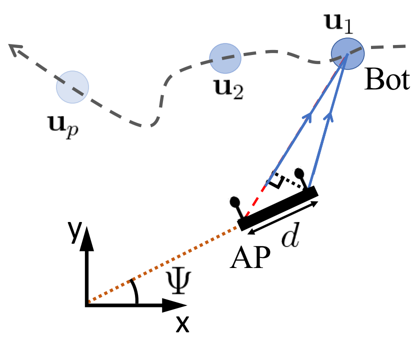

Figure 6: **Relative Geometry Prediction:** Shows the same setup as in Figure 5a with a two antenna AP making angle ψ with the positive x-axis and the bot moving about the located first antenna of the AP in an arbitrary path.

and thereby achieving millimeter-level accuracy for relative antenna localization. Now to solve for (d, ψ) uniquely as an over-determined system, it is easier to work with Cartesian co-ordinates than polar coordinates. So, we fix the location of the first antenna of the AP, the antenna on the left in Figure 6, as (x_1, y_1) and represent the second antenna (x, y) defined in the global coordinate system as:

$$(x,y) = (x_1 + d\cos(\psi), y_1 + d\sin(\psi))$$

We rewrite Equation (5) in terms of (x, y) as follows:

$$\frac{d\Delta\phi}{d\beta} = \frac{2\pi}{\lambda}[-(x-x_1)\sin(\beta_p) + (y-y_1)\cos(\beta_p)] \qquad (7)$$
$$\text{for} \quad p = 1,2,\cdots,P-1$$

Next, we represent these P set of linear equations in matrix-vector form as follows,

$$A\begin{bmatrix} x-x_1 \\ y-y_1 \end{bmatrix} = \mathbf{b} \qquad (8)$$

where A is a $(P-1)\times 2$ matrix and b is a $(P-1)$ sized column vector defined as

$$A(p,:) = \begin{bmatrix} -\sin(\beta_p) & \cos(\beta_p) \end{bmatrix} \qquad (9)$$
$$\mathbf{b}(p) = \frac{\lambda}{2\pi}\frac{\Delta\phi_{p+1} - \Delta\phi_p}{\beta_{p+1} - \beta_p}, \quad p = 1,2,\ldots,P-1 \qquad (10)$$

We further denote $\mathbf{x} = \begin{bmatrix} x & y \end{bmatrix}^T$ and $\mathbf{x}_1 = \begin{bmatrix} x_1 & y_1 \end{bmatrix}^T$. We estimate $\mathbf{x}$ to the following least squares problem:

$$\min_{\mathbf{x}} \quad ||A(\mathbf{x} - \mathbf{x}_1) - \mathbf{b}||^2 \qquad (11)$$

In this way we can uniquely solve for the cartesian coordinates of the second antenna with respect to the first antenna.

Note that the two measurements $\{\beta_p, \Delta\phi_p\}$ and $\{\beta_{p+1}, \Delta\phi_{p+1}\}$ should not be very close to avoid noise amplification. On the other hand, the measurements should not be very far apart to cause an error in the estimation of the derivative. A large separation between consecutive measurements can increase the phase difference to more than 2π, thus creating discontinuities across the series of P measurements. Our experiments suggest that around $5°$ of angular separation $(\beta_{p+1} - \beta_p)$ provides the best results for an antenna separation in $d = [0, 4\lambda]$, where $\lambda = 6$cm is the minimum wavelength in the 5GHz frequency band. We emphasize the estimated value of ψ will be in the range of $0 \le \psi \le \pi$ because the orientation of the antenna array can be defined uniquely in $0 \le \psi \le \pi$.

Generalizing Equation 11, we locate the relative location of each antenna on the access point as $\mathbf{x}_i = [x_i \quad y_i]^T$, where, $i = 2, 3, \ldots, N_{AP}$, where N_{AP} is the number of antennas on the AP. We finally find the antenna separations as $d_i = \sqrt{(x_i - x_1)^2 + (y_i - y_1)^2}$, and the deployment orientation as $\psi_i = \tan^{-1}\frac{y_i - y_1}{x_i - x_1}$, for all the antennas with respect to the first antenna, $\mathbf{x}_1$. Thus, we accurately predict the location, antenna separation and deployment orientation of the access point.

3.3 Multipath

So far, in both Section 3.1 and Section 3.2, we have assumed only one single path from the AP to the bot to solve for the access point attributes. However, the environment creates multipath which would cause the previous algorithms to fail by distorting the phase measurements. We leverage multipath rejection algorithm from [37] to estimate the direction of direct path for AP localization (Section 3.1) and build a novel algorithm to recover direct path phases as required in Section 3.2.

Recall from Section 3.1 that locating the first-antenna on the AP requires direct path AoA information at the bot. However, the received signal at the bot is usually a mix of signals arriving from different directions. We leverage multiple antennas on the bot along with the channel information across multiple subcarriers of the WiFi signal to identify the direct path and isolate it from other paths similar to prior art [37]. As first step, we collect $N_{bot} \times N_{sub}$ CSI-matrix (across N_{bot} bot client's antennas and N_{sub} subcarriers) as shown in Figure 7(a). We then apply 2D-FFT transform to estimate the AoA and Time-of-Flight (ToF) for each arriving path to the bot (Figure 7(b)). Finally, we estimate the direct path AoA by observing the signal, which has the least ToF. Intuitively, the direct path signal travels the shortest distance and thus has the lowest ToF. Thus, we can use these direct path AoA estimates to run our AP localization algorithm, as discussed in Section 3.1.

Note, however, that the direct path AoA information is not enough for estimating AP's antenna geometry (Section 3.2). In this case, our algorithm requires relative phase information across multiple AP antennas corresponding to the direct path signal. Our first insight is to estimate the direct path channel individually for each AP antenna and use them to re-

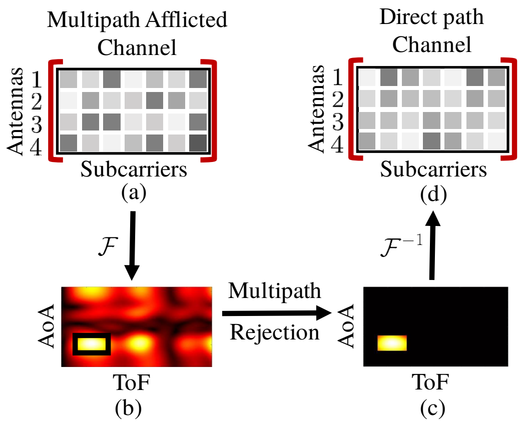

Figure 7: **Multipath rejection:** (a) Shows the measured $N_{bot} \times N_{sub}$ complex channel matrix. (b) We perform 2D FFT based transform [9] to estimate the 2D AoA-ToF profile within which we identify the direct path as the least ToF path. (c) We then perform a windowing around this peak to obtain direct path filtered AoA-ToF profile. (d) Finally, direct path's $N_{bot} \times N_{sub}$ complex channel is estimated by performing a 2D-IFFT on the windowed AoA-ToF profile.

cover the relative phase information. We take the $N_{bot} \times N_{sub}$ CSI-matrix for a fixed AP antenna and estimate the AoA-ToF profile using the same procedure as described in the previous paragraph and Figure 7(a),(b). From [37], we know that the direct path signal is concentrated around the first ToF peak (in the AoA-ToF domain). So, our insight is to apply appropriate window function in the AoA-ToF domain to remove the adulteration due to multipath (Figure 7(c)) and use this information to extract the channel corresponding to direct path. Finally, to extract the direct path signal from this windowed AoA-ToF profile, we perform 2D-IFFT on this windowed signal, as shown in Figure 7(d). As we established before, the same process can be repeated for each AP antenna to finally obtain accurate AP antenna geometries, as discussed in Section 3.2.

3.4 Autonomous Bot and Confidence Metrics

In the following section, let us look more closely at the confidence metric we mentioned in Section 3.1. We deploy RevBot largely to automate our data collection pipeline and further implementation details can be found in [8]. The key pieces of data we need to collect are the bot's pose information (provided by SLAM algorithms), and time-synchronized CSI estimates for each AP in the environment (provided by an onboard access point). Unfortunately, the position and heading reported by SLAM algorithms are not completely error-free, and the measurements can be adversely affected by the movement of the bot and the surroundings resulting in errors from 20-25 cm. These particularly worse, low-confidence measurements, need to be discarded to obtain accurate AP geometry predictions. But, most SLAM algorithms do not expose the accurate confidences of a particular reported pose. Fortunately, we can manufacture a pseudo-confidence metric by comparing the match of a current measurement with its surroundings. We make these comparisons using 3D pointclouds generated using an RGB-D camera. Pointclouds are to a 3D space what pixels are to a 2D image – each point carries an (x,y,z) coordinate and color information. We make the following observation - by looking at the registration accuracy of the point-clouds generated by consecutive pose measurements, we can estimate the quality of the relative transformation in question.

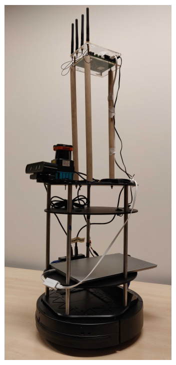
More concretely, let us consider two consecutive measurement frames $\mathcal{F}_i$ and $\mathcal{F}_{i+1}$. We determine the relative transformation T_i between the two frames by looking at their pose estimates. Hence, T_i takes us from $\mathcal{F}_i$ to $\mathcal{F}_{i+1}$. Furthermore, from the RGB-D images captured at these frames, we can generate point-clouds. By applying T_i to the point-cloud from $\mathcal{F}_i$, we get an estimate of $\mathcal{F}_{i+1}$ and we can stitch these two point-clouds together. If T_i is accurate, then we will get a perfect overlap of these pointclouds over all the points visible in both the frames. Based on this intuition, we use the covariance matrix $\mathcal{V}_i$ as implemented by [16]. Now, this covariance matrix accommodates all six degrees of freedom as found in a 3D environment, three belonging to each direction of translation and three for each axis of rotation, hence $\mathcal{V}_i \in \mathbb{R}^{6\times 6}$. The first two diagonal elements give us the variance in the x and y position and $\mathcal{V}_i[1,2]$ gives us the co-variance between x and y. The variance in $(x+y)$ tells us how much wiggle room there is for the pose in question. Hence, the larger the wiggle room, the less confident we are in our poses. Furthermore, we observe that these variances vary in orders of magnitude, and to linearize our confidence metric, we take the log of the variance. We calculate the pseudo-confidence metric for $\mathcal{F}_i$ as

$$\begin{aligned} C_i &= \log(\text{var}(x+y)) \quad (12)\\ &= \log(\text{var}(x)+\text{var}(y)-2\text{cov}(x,y)) \quad (13)\end{aligned}$$

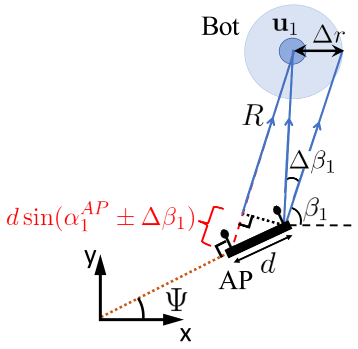
Finally, we normalize C_i, $\forall i = 1,2,\cdots,P$, between 0 and 1 to determine w_i, which are confidences we use in Equation 2 used to filter out the low confidence bot locations.

4 Micro-benchmarks

Before evaluating LocAP's performance, we must understand how the error in the ground truth locations reported by the autonomous bot is affecting the algorithm. We have utilized the robot implementation described in [8], while replacing the single antenna client Quantenna platform with a 4 antenna linear array Quantenna station as shown in Figure 8a. For that, we first estimate the bot's location error and analyze its effects on the accurate prediction of the location of the access point and the relative antenna geometry on the access point.



(a)



(b)

Figure 8: **Accuracy of the bot's ground truth movement:** (a) The bot we used for our experiments, a Turtlebot-2 equipped with a 4 antenna Quantenna board, LIDAR, RGB-D camera. (b) Depiction on how bot's error can effect the relative antenna localization algorithm.

4.1 Error in Bot's ground truth Location

Since, we are using the same bot setup described in [8] we use the median localization error reported for the bot in their experiments. We can observe that the median error Δr is around 6cm in this case. Further, we study the orientation errors within the same setup. We find that the median error $\Delta\beta$ in orientation is 3°.

Next, we quantify the effect of this error on the accuracy of locating the access point and determining the relative antenna geometry.

4.2 Effects of Bot's Error

First, we estimate the location of the access point. For this step, we use both the bot's location and orientation. Hence, we must look at the errors in both these measurements. We observe that an error of Δr in bot's location error directly corresponds to an error of Δr in the access point's location prediction, which is 6cm in our scenario. Next, assuming an orientation error of $\Delta\beta$, we observe that the error will be $R\Delta\beta$ in the access point's location, where R is the estimate of the distance to the access point. Hence, the upper-bound on the total error propagated will be $\Delta r + R\Delta\beta$, which for an average indoor distance of $R = 5$m would be 32cm.

Second, for the relative antenna location estimation, from Figure 8b we can see that the error in bot's location, Δr, translates to error in the angle estimated at the access point, $\beta_i + \Delta\beta_i$, where approximately $\Delta\beta_i = \frac{\Delta r}{R}$. Hence, we redefine A from Equation 9 as $A' = A\begin{bmatrix} 1 & \frac{\Delta r}{R} \\ -\frac{\Delta r}{R} & 1 \end{bmatrix}$, while b remains unchanged. Thus we can re-write Equation 11, assuming $\mathbf{x_1} = 0$, as

$$\min_{\mathbf{x}'} ||A'\mathbf{x}' - \mathbf{b}||^2 \tag{14}$$

where $\mathbf{x}' = \mathbf{x} + \Delta\mathbf{x}$, and $\Delta\mathbf{x} = \begin{bmatrix}\Delta x & \Delta y\end{bmatrix}^T$. Solving for $\Delta\mathbf{x}$ from the Equations 11 and 14, and simplifying by neglecting higher order error polynomial terms we can see that $\Delta x = \frac{\Delta r}{R}y, \quad \Delta y = \frac{\Delta r}{R}x$. We know that $\mathbf{x} = [x \quad y]^T$ is of the order of few centimeters, while Δr is of the order of few centimeters and R of the order of few meters, which reduces the whole expression for Δx and Δy to be of order of $\frac{1}{10}^{th}$ millimeter, which is well within limits of the tolerance for relative antenna localization. Thus we observe that the relative antenna geometry on the access points can be estimated accurately to within few millimeters using LocAP and its implementation on our autonomous system.

5 Evaluation

Now that we have seen all the components of LocAP, we evaluate LocAP's performance in a real world deployment to see if it has conformed to the stringent requirements we established in Section 2. For this we have deployed our autonomous bot in two different indoor environments, as shown in [8], that span 1000 sq. ft. in area, and have 8 different access points deployed at different locations, heights and orientation. Across these 8 different access points, we have covered two standard antenna geometries, linear and square antenna arrays, and covered 5 different antenna separations,$\{\lambda/2, \lambda, 3\lambda/2, 2\lambda, 5\lambda/2\}$, where $\lambda = 6$ cm is the minimum wavelength in the 155 channel of the 5GHz frequency band. Throughout this experiment, we collect CSI from multiple access points across space and time which is used to implement LocAP. The ground truth for all the evaluations are measured accurately with a commodity laser range finder [11], that is accurate up to 1mm, after carefully marking the axes on the ground and labeling the 1000 sq ft space of experimentation. This entire process of labeling the experimental space of 1000 sq ft takes a minimum of one hour spent by a group of at least three people. While there is two decades of CSI based WiFi localization, LocAP is the first work to tackle the problem of *reverse localization* of the WiFi access points and thus is compared with a state-of-the-art AoA based user localization algorithm [37], SpotFi, which combines data across multiple anchor locations.

With the given setup the overview of LocAP's results are as follows: LocAP achieves 5 cm of median localization error for the first antenna localization utilizing the weighted least squares formulation while a simple least-squares problem achieves just 8 cm of median localization error. Further, the relative geometry prediction algorithm of LocAP locates the access points in this setup accurately with a median antenna separation error of 3 mm and a median orientation error of 3^o, whereas the state-of-the-art localization algorithms achieve a 150 mm median error for antenna separation and 25° median deployment orientation error as shown in Fgure 9.

A final case study of user localization with the updated LocAP's AP attributes showed a reduction of 28 cm in me-

dian user localization compared to the manual AP attribute mapping.

5.1 AP Location accuracy

To evaluate the access point localization accuracy, we deploy it in 8 different test scenarios across various heights of access points, different locations, environments and distances from the bot. To get a statistically accurate estimate of these locations, we have collected the CSI corresponding to each of these manually determined locations at 20 different time instants. With this data, we have estimated the location of each individual antenna on these access points using a least-squares triangulation algorithms employing [37]. As shown in Figure 9a, we find that the median error is 5 cm, well below the established threshold. Unfortunately, manually measuring locations takes hours of manual time and thus defeats the purpose of LocAP.

Hence, we deploy LocAP on our autonomous platform [8] that collects the same amount of data within 5 minutes. We use the SpotFi algorithm [37] as a comparative baseline model for the bot data. SpotFi assumes accurate ground truth locations of the anchors unlike LocAP's implementation that smartly rejects anchor locations that are unreliable. We observed that while the baseline model provides a median AP localization error of 20.5 cm, our weighted least squares with smart-rejection achieves 13.5 cm showing an improvement of 36% in AP localization.

Further, the bandwidth assumed for these initial results is 80MHz, while the commodity WiFi access points hardly operate at these bandwidths. These WiFi access points usually use either 20MHz or 40MHz bandwidths. To mimic this, we also collect CSI data with the same setup for both 40MHz and 20MHz bandwidths. These CSI estimates have then been utilized to test our algorithm at different WiFi bandwidths. The CDF plot for variation of localization accuracy across different bandwidths can be seen in Figure 9a. It is seen that at higher bandwidths, the localization accuracy is marginally better, while LocAP still attains centimeter-level accuracy for localizing the access point.

The design of LocAP relies on the angles estimated from the CSI data received. While the above-reported results are for a 4-antenna station, a commodity off-the-shelf WiFi device does not always have 4 antennas. Hence, we performed another experiment to observe the effect of change in the number of antennas on LocAP. This was done by changing the number of antennas present on the station mounted on the mobile robot. The CDF plot for the localization error with the increasing number of antennas can be seen in Figure 9a. The localization accuracy increases with the increasing number of antennas on the client mounted on the mobile robot. This is evidenced by the lower median error observed with 3 antennas present on the mobile robot as seen in Figure 9b. We further observe that a 2 antenna WiFi device significantly hurts the performance of LocAP. This performance degradation is because for a 2 antenna system, the multipath need to be at least 90^o apart for the two different paths to be resolved.

5.2 Relative Antenna Geometry Accuracy

After the location of the first antenna of the AP is obtained, LocAP finds the positions of the other antennas of the AP relative to the first antenna. This is achieved by traversing around the reverse localized antenna of the AP, as described in Section 3.2. To test this algorithm, we deploy APs with a linear antenna array and a square antenna array AP in the two aforementioned environments. Similar to AP location estimation, we have collected data for each antenna setup at 40 different time instances to obtain statistically accurate results. The relative antenna locations on these APs were measured using LocAP and then compared with the ground truth to get the relative antenna localization errors and the deployment orientations. We further compare these results with that derived by state-of-the-art localization algorithm, SpotFi [37].

Relative Antenna Separation: We first measure the relative antenna separation of all the antennas on the access point with respect to the first antenna and the CDF plot for the

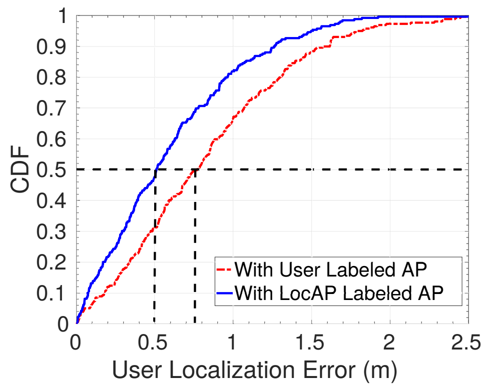

Figure 10: **User Localization accuracy:** Shows the CDF of localization accuracy after localizing the access points with LocAP and compared with those results of the manually labeled APs.

errors in relative antenna localization is shown in Figure 9c. We can see that the median error is about 3 mm for the relative antenna localization of LocAP while the state-of-the-art WiFi localization algorithm combined over multiple bot locations and time instances achieves 20 cm of median antenna separation error. Thus we show that LocAP achieves millimeter-level accuracy and meets the 5 mm error threshold set in Section 2 for predicting the antenna separation of the access point.

Deployment Orientation: We also measure the deployment orientation of all the antennas on the access point with respect to the first antenna and the CDF plot for the errors in the deployment orientation is shown in Figure 9d. We can see that while the state-of-the-art localization algorithm has a median error of 25°, LocAP's deployment orientation prediction algorithm achieves a median orientation error of just 3°, meeting the 7° limit set in Section 2.

5.3 Case Study: User Localization

So far we have seen the performance of LocAP in accurately predicting the access point attributes. We implement LocAP, to enable CSI based indoor user localization. Further LocAP is automated by deploying on a bot to remove any manual labor and time or human errors. As discussed in Section 1, human based measurements lead to high degree of errors, especially in the antenna separation measurements that are needed to be accurate to less than 5mm of errors, especially when the antennas are housed in a casing whose datasheets provided by the chip designers do not contain information regarding the antenna placements on board [28, 47, 48]. Further, the antenna placement is determined mostly by the manufacturer, and the vast cardinality of the available vendors and their models make it impossible to estimate the antenna geometry from their datasheets, which also mostly do not discuss about the antenna placements on board [6, 7, 17, 57]. Additionally, deployment orientation has to be measured accurate to less than 7° of error, which becomes extremely impossible for manual measurements. While we have shown 3mm (<5mm) error in predicting antenna separation and 3°(<7°) error in orientation deployment predictions for LocAP. To verify the effect of both LocAP mapped AP attributes and manually mapped AP attributes on the state-of-the-art indoor WiFi localization algorithms [37, 53, 67], we have asked a group of 25 people to measure the first antenna locations, relative antenna separations and the deployment orientation of the access points deployed in a realistic scenario. Users have been provided with a laser range finder [11] and compass based apps used in smartphones.

From these user measurements, we have observed that manual mapping can make their best efforts to map the AP locations accurate with 21 cm median error , the antenna separation accurate to within 4 mm of median error, and a median absolute error of about 13^o in measuring the deployment orientation of the access point.

We then deploy LocAP in a 1000 sq ft environment and locate the 4 access points' attributes. A moving user that covers 300 different marked locations in this environment is then localized using both the manually mapped and LocAP's mapped AP attributes and the corresponding CDF is shown in Figure 10c. From this plot, we can see that while human mapped AP attributes have a median localization error of 78 cm, LocAP's AP locations achieve 50 cm median error. Thus we can see that LocAP solves for the fundamental dependency of CSI based user localization algorithms by accurately predicting the AP attributes within the physical map.

6 Related Work

There has been significant work in the field of localization and LocAP's implementation work on reverse localizing the access points is closely related to the work in the following three fields:

Indoor Localization: Wide-scale deployment of WiFi based infrastructure and WiFi chips on hand-held devices makes indoor localization promising for various indoor navigation applications. There has been extensive research in WiFi based indoor localization algorithms over the past two decades [10, 15, 22, 23, 30, 37, 39, 41, 43, 45, 51, 53, 58–60, 65–69, 72, 74]. While most of the initial work was based on the Received Signal Strength Information [10, 15, 45, 60, 74] these algorithms do not achieve meter-level localization, or require extensive fingerprinting to achieve desired decimeter-level localization. Thus, most of the later work has been focused on CSI based localization algorithms [22, 30, 37, 39, 51, 53, 58, 59, 65–69]. LocAP which leverages the idea of Angle of Arrival based localization. Some such algorithms which have been developed in the past few years [37, 67] achieve decimeter-level localization and extend it to achieve centimeter-level localization accuracy. However, these WiFi based localization algorithms assume the knowledge of the location of the AP to measure the user's location with respect to the AP location. In contrast to the above work, LocAP builds a relative localization technique which provides millimeter-level accuracy for the antenna geometry on the AP. Furthermore, we also demonstrate that LocAP can solve for the antenna separation values larger than a single wavelength (λ).

Source Localization: Solving the problem of accurate knowledge of the WiFi AP locations have been attempted for RSSI based [26] and CSI based [54] systems. But these algorithms do not achieve centimeter-level localization for APs, but solve for the general regional mapping of these access points. These works are limited by the available bandwidth and thus there has also been significant work on ultra-wideband (UWB) based localization [5, 13, 14, 18, 34, 46, 49] and anchor localization algorithms [12, 19, 20, 34–36]. But these UWB systems require new infrastructure deployment. Similarly, there has been significant work towards a beacon based localization system [9, 29, 32, 33, 42, 52, 62, 63, 70, 71, 73] which have been shown to achieve decimeter-level localization but also need additional deployment of infrastructure. LocAP solves the problems of exact WiFi access point localization and exact antenna placements on WiFi Access Points.

Relative Localization: LocAP solves for millimeter-level accurate antenna placements on any given WiFi access point by borrowing and extending the principles from wireless tracking. Wireless tracking or relative localization is a well-solved problem unlike localization, with reported accuracies up to few centimeters and few millimeters [38, 61, 64]. Though all of these algorithms would need the separation between two consecutive locations to be tracked to be less than $\lambda/2$ distance apart, LocAP solves for relative localization of two antennas that are at any arbitrary distance from each other, including for distances greater than $\lambda/2$ apart. Thus LocAP can enable high mobility tracking for indoor WiFi devices.

SLAM Automation: There has been exhaustive research conducted in graph based SLAM algorithms [24]. In LocAP we employ a SLAM based autonomous bot to report ground truth and also design a metric to understand the confidence of the bot for a given ground truth. Confidences for reported measurements can be extracted from the marginal co-variances of the nodes used to describe these variables and are used to perform data association [27, 31, 44, 56]. Though these numerical methods are valid, most of them are not implemented on standard SLAM platforms, to the best of our knowledge. Furthermore, commonly used frameworks [25, 40] do not readily expose these marginal co-variances. We extend the methods described in [16] as a proxy for these internal co-variance metrics.

7 Conclusion and Future Work

We presented, LocAP, an automated reverse localization system of the existing WiFi APs that was successful in achieving the requirements for accurate localization of AP position, antenna separation and deployment orientation. After the mobile robot is allowed to traverse the unknown environment, we have a map of the indoor environment and the reverse localized positions of all the APs in this environment. If we consider the map to be part of a coordinate system, we can provide each access point with its coordinate in the environment, such that the AP becomes self-aware about its location. When a new user enters this environment, and associates with one of these APs, they can locate the user in turn almost instantaneously relative to their position.

Using the mapping and reverse localization information, we can provide accurate indoor localization and navigation for large indoor environments. These accurate AP location attributes aids many of the networking issues like user location based smart hand-off, network load balancing utilizing both AP locations and client locations and other networking services based on AP and client locations. Further, with the emergence of 5G and 11ad/ax wireless protocols, where directional beams become more and more important, these angle of arrival estimates that are provided by LocAP, can be further used to perform smart-beamforming at both the client and the AP side.

In LocAP we have analyzed the 2D scenario when the access point is in the same plane as the user to be located. In a real world deployment the access point is placed at least a meter above the user height thus subtending a non-zero polar angle at the access point. This does not affect LocAP's algorithm on relative geometry prediction as the cartesian co-ordinates defined absorb the polar angular term. Thus unchanging the formulation of the relative antenna geometry prediction algorithm enabling LocAP to perform accurately under 3D deployments.
