Message from the 24th USENIX Security Symposium Program Chair

Welcome to the 24th USENIX Security Symposium in Washington, D.C.!

I hope you enjoy the technical program, hallway track, and fun evening events in the next three days. USENIX Security has been a premier venue for security and privacy research and I look forward to seeing the lasting impact that the papers of this year will make in years to come.

After agreeing to chair USENIX Security '15 Program Committee (PC), I sought feedback on different approaches to reviewing by reaching out to former chairs of USENIX Security and to chairs of the IEEE Symposium on Security and Privacy, ACM CCS, NSDI, ACM SIGCOMM, ACM CHI, and UbiComp. I also read chair reports from ASPLOS and ICSE. While no process will ever be perfect, I hope future conferences will be able to benefit from what we learned at USENIX Security this year.

Selection of Program Committee: I was very lucky to have a fantastic set of rock stars from our field who volunteered to serve on the program committee this year. I analyzed the topics of USENIX Security 2014 submissions and grouped them into seven areas and allocated the number of PC members to invite based on the number of expected submissions per area. To diversify the PC, I had a target of at least 20% PC members from each of four categories: outside the US, not from academia, not male, and new to the USENIX Security PC. To cope with the growth of submissions, I divided the PC into those required to attend the PC meeting ("attending") and those who were not ("remote") and provisioned the PC such that the review load was kept fewer than 20 submissions per member. 36 volunteers served as attending PC members and 39 served as remote PC members.

First round of reviews (Feb. 26–Apr. 2, 2015): We received 426 submissions, a 22% increase over the past year! 19 papers were desk rejected due to a violation of submission requirements and the rest were assigned to at least two reviewers per submission. The program committee spent one week on online discussion once reviews had been collected. As in past years, we decided to finalize decisions in the first round for a subset of papers that had confident reviews and did not appear to have a chance of acceptance. While in prior years we have used a similar process to decide the outcomes of many submissions at the end of the first round, the decision to issue early notifications and provide early access to reviews is new this year. 228 papers (54%) were rejected in the first round of decisions.

Second round of reviews (Apr. 3–May 6, 2015): Most papers received at least two more reviews in the second round. After the reviewing deadline, the program committee spent an additional two weeks discussing these papers using an online forum. Each paper was assigned to a discussion lead whose responsibility was to summarize reviews and drive a consensus among the reviewers between "suggest accept," "suggest reject," and "discuss." 22 papers received a "suggest accept" recommendation; 94 "suggest reject"; and 82 "discuss."

Un-blinding papers (May 6, 2015): Outcomes and discussion points were finalized for each paper and the deputy chair and I decided on the list of 88 papers to discuss at the PC meeting based on the recommendations. At that point the author names were made visible to reviewers. The un-blinding was helpful during the meeting to clarify conflicts and to help prevent authors from being punished for failing to cite their own work or from reviewers who might have a bias based on a false assumption regarding the authors' identity.

PC meeting (May 7–8, 2015, at Microsoft Research in Redmond, WA): 35 PC members attended the PC meeting and several remote PC members called into it. The PC began with a discussion of top five ranked papers and bottom five ranked papers to calibrate. To speed up a discussion, we allocated four minutes for a paper that was suggested to accept by the reviewers and eight minutes for the rest. The PC discussed 76 papers on the first day and 12 papers on the second day. After going through the list of 88 papers, the PC spent two extra hours discussing tabled papers and 14 papers that were voted to be resurrected. After the final decisions were made, we had accepted 67 papers, 16% of the submissions: all 22 papers tagged as "suggest accept," 44 papers tagged as "discuss." and 1 paper tagged as "suggest reject."

(Continued on page xii)

(Continued from page xi)

The program committee members spent countless hours not only reviewing papers but also discussing papers with each other online and in person. For instance, one controversial submission received seven reviews (including those from two external experts) and 44 comments online. On top of that, the PC spent an hour after dinner on the first day of the PC meeting to come to a consensus.

The technical program would not have been possible without contributions from the 75 program committee members and over 100 external reviewers who provided thoughtful reviews and recommendations and had to put up with nagging emails and reminders from me especially around the review deadlines. I would also like to thank Thorsten Holz for serving as the deputy chair; Angelos Keromytis for chairing the invited talks committee; Sarah Meiklejohn and Adam Doupé for serving as the poster session chairs; Tadayoshi Kohno for serving as the WiPs chair and mentoring a new chair like me; student volunteers Anna Simpson, Peter Ney, Adam Lerner, and Philipp Koppe, for scribing at the PC meeting and checking reviews; Eddie Kohler for adding new features into the already awesome HotCRP system that made paper triaging easier; Kevin Fu for creating funny session titles; Microsoft for sponsoring the PC meeting; Stuart Schechter for hosting an ice cream social and a post-PC meeting party; the USENIX staff, especially Casey Henderson and Michele Nelson for all the support throughout the process; and the authors of 426 papers for submitting their research for consideration. Finally, I would like to thank the USENIX steering committee to allow me to have this incredible opportunity to work with so many wonderful people.

Thanks to you all.

USENIX Security '15 Program Chair

Post-Mortem of a Zombie: Conficker Cleanup After Six Years

Hadi Asghari, Michael Ciere and Michel J.G. van Eeten
Delft University of Technology

Abstract

Research on botnet mitigation has focused predominantly on methods to technically disrupt the command-and-control infrastructure. Much less is known about the effectiveness of large-scale efforts to clean up infected machines. We analyze longitudinal data from the sinkhole of Conficker, one the largest botnets ever seen, to assess the impact of what has been emerging as a best practice: national anti-botnet initiatives that support large-scale cleanup of end user machines. It has been six years since the Conficker botnet was sinkholed. The attackers have abandoned it. Still, nearly a million machines remain infected. Conficker provides us with a unique opportunity to estimate cleanup rates, because there are relatively few interfering factors at work. This paper is the first to propose a systematic approach to transform noisy sinkhole data into comparative infection metrics and normalized estimates of cleanup rates. We compare the growth, peak, and decay of Conficker across countries. We find that institutional differences, such as ICT development or unlicensed software use, explain much of the variance, while the national anti-botnet centers have had no visible impact. Cleanup seems even slower than the replacement of machines running Windows XP. In general, the infected users appear outside the reach of current remediation practices. Some ISPs may have judged the neutralized botnet an insufficient threat to merit remediation. These machines can however be magnets for other threats — we find an overlap between GameoverZeus and Conficker infections. We conclude by reflecting on what this means for the future of botnet mitigation.

1 Introduction

For years, researchers have been working on methods to take over or disrupt the command-and-control (C&C) infrastructure of botnets (e.g. [14, 37, 26]). Their successes have been answered by the attackers with ever more sophisticated C&C mechanisms that are increasingly resilient against takeover attempts [30].

In pale contrast to this wealth of work stands the limited research into the other side of botnet mitigation: cleanup of the infected machines of end users. After a botnet is successfully sinkholed, the bots or zombies basically remain waiting for the attackers to find a way to reconnect to them, update their binaries and move the machines out of the sinkhole. This happens with some regularity. The recent sinkholing attempt of GameoverZeus [32], for example, is more a tug of war between attackers and defenders, rather than definitive takedown action. The bots that remain after a takedown of C&C infrastructure may also attract other attackers, as these machines remain vulnerable and hence can be re-compromised.

To some extent, cleanup of bots is an automated process, driven by anti-virus software, software patches and tools like Microsoft's Malicious Software Removal Tool, which is included in Windows' automatic update cycle. These automated actions are deemed insufficient, however. In recent years, wide support has been established for the idea that Internet Service Providers (ISPs) should contact affected customers and help them remediate their compromised machines [39, 22]. This shift has been accompanied by proposals to treat large-scale infections as a public health issue [6, 8].

As part of this public health approach, we have seen the emergence of large-scale cleanup campaigns, most notably in the form of national anti-botnet initiatives. Public and private stakeholders, especially ISPs, collaborate to notify infected end users and help them clean their machines. Examples include Germany's Anti-Botnet Advisory Center (BotFrei), Australia's Internet Industry Code of Practice (iCode), and Japan's Cyber Clean Center (CCC, superseded by ACTIVE) [27].

Setting up large-scale cleanup mechanisms is cumbersome and costly. This underlines the need to measure whether these efforts are effective. The central question of this paper is: What factors drive cleanup rates of infected machines? We explore whether the leading national anti-botnet initiatives have increased the speed of cleanup.

We answer this question via longitudinal data from the sinkhole of Conficker, one the largest botnets ever seen. Conficker provides us with a unique opportunity to study the impact of national initiatives. It has been six years since the vulnerability was patched and the botnet was sinkholed. The attackers have basically abandoned it years ago, which means that infection rates are driven by cleanup rather than the attacker countermeasures. Still, nearly a million machines remain infected (see figure 1). The Conficker Working Group, the collective industry effort against the botnet, concluded in 2010 that remediation has been a failure [7].

Before one can draw lessons from sinkhole data, or from most other data sources on infected machines, several methodological problems have to be overcome. This paper is the first to systematically work through these issues, transforming noisy sinkhole data into comparative infection metrics and normalized estimates of cleanup rates.

For this research, we were generously given access to the Conficker sinkhole logs, which provide a unique long term view into the life of the botnet. The dataset runs from February 2009 until September 2014, and covers all countries — 241 ISO codes — and 34,000 autonomous systems. It records millions of unique IP addresses each year — for instance, 223 million in 2009, and 120 million in 2013. For this paper, we focus on bots located in 62 countries.

In sum, the contributions of this paper are as follows:

1. We develop a systematic approach to transform noisy sinkhole data into comparative infection metrics and normalized estimates of cleanup rates.

2. We present the first long term study on botnet remediation.

3. We provide the first empirical test of the best practice exemplified by the leading national anti-botnet initiatives.

4. We identify several factors that influence cleanup rates across countries.

2 Background

2.1 Conficker timeline and variants

In this section we will provide a brief background on the history of the Conficker worm, its spreading and defense mechanisms, and some milestones in the activities of the Conficker Working Group.

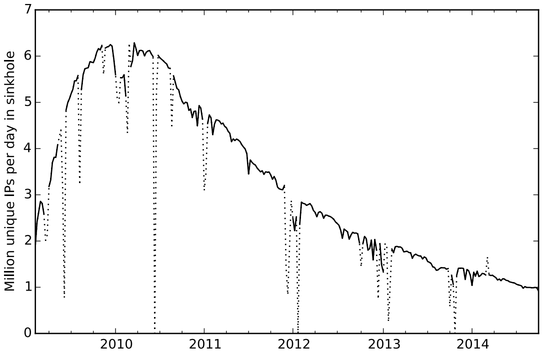

Figure 1: Conficker bots worldwide

The Conficker worm, also known as Downadup, was first detected in November 2008. The worm spread by exploiting vulnerability MS08-067 in Microsoft Windows, which had just been announced and patched. The vulnerability affected all versions of Microsoft Windows at the time, including server versions. A detailed technical analysis is available in [29]. Briefly put, infected machines scanned the IP space for vulnerable machines and infected them in a number steps. To be vulnerable, a machine needed to be unpatched and online with its NetBIOS ports open and not behind a firewall. Remarkably, a third of all machines had still not installed the patch by January 2009, a few months after its availability [11]. Consequently, the worm spread at an explosive rate. The malware authors released an update on December 29, 2008, which was named Conficker-B. The update added new methods of spreading, including via infected USB devices and shared network folders with weak passwords. This made the worm propagate even faster [7].

Infected machines communicated with the attackers via an innovative, centralized system. Every day, the bots attempted to connect to 250 new pseudo-randomly generated domains under eight different top-level domains. The attackers needed to register only one of these domains to reach the bots and update their instructions and binaries. Defenders, on the other hand, needed to block all these domains, every day, to disrupt the C&C. Another aspect of Conficker was the use of intelligent defense mechanisms, that made the worm harder to remove. It disabled Windows updates, popular anti-virus products, and several Windows security services. It also blocked access to popular security websites [29, 7].

Conficker continued to grow, causing alarm in the cybersecurity community about the potential scale of attacks, even though the botnet had not yet been very active at that point. In late January, the community — including Microsoft, ICANN, domain registries, anti-virus vendors, and academic researchers — responded by forming the Conficker Working Group [7, 31]. The most important task of the working group was to coordinate and register or block all the domains the bots would use to communicate, staying ahead of the Conficker authors. The group was mostly successful in neutralizing the botnet and disconnecting it from its owners; however, small errors were made on two occasions in March, allowing the attackers to gain access to part of the botnet population and update them to the C variant.

The Conficker-C variant had two key new features: the number of pseudo-randomly generated domains was increased to 50,000 per day, distributed over a hundred different TLDs, and a P2P update protocol was added. These features complicated the work of the working group. On April 9, 2009, Conficker-C bots upgraded to a new variant that included a scareware program which sold fake anti-virus at prices between $50–$100. The fake anti-virus program, probably a pay-per-install contract, was purchased by close to a million unwitting users, as was later discovered. This use of the botnet prompted law enforcement agencies to increase their efforts to pursue the authors of Conficker.[1] Eventually, in 2011, the U.S. Federal Bureau of Investigation, in collaboration with police in several other countries, arrested several individuals associated with this $72-million scareware ring. [21, 19]

2.2 National anti-botnet centers

Despite the successes of the cybersecurity community in neutralizing Conficker, a large number of infected machines still remained. This painful fact was recognized early on; in its 'Lessons Learned' document from 2010, the Conficker Working Group reported remediation as its top failure [7]. Despite being inactive, Conficker remains one of the largest botnets. As recent as June 2014, it was listed as the #6 botnet in the world by anti-virus vendor ESET [9]. This underlines the idea that neutralizing the C&C infrastructure in combination with automated cleanup tools will not eradicate the infected machines; some organized form of cleanup is necessary.

During the past years, industry and regulatory guidelines have been calling for increased participation of ISPs in cleanup efforts. For instance, the European Network and Information Security Agency [1], the Internet Engineering Task Force [22], the Federal Communications Commission [10], and the Organization for Economic Cooperation and Development [27] have all called upon ISPs to contact infected customers and help them clean up their compromised machines.

The main reason for this shift is that ISPs can identify and contact the owners of the infected machines, and provide direct support to end users. They can also quarantine machines that do not get cleaned up. Earlier work has found evidence that ISP mitigation can significantly impact end user security [40].

Along with this shift of responsibility towards ISPs, some countries have established national anti-botnet initiatives to support the ISPs and end users in cleanup efforts. The setup is different in each country, but typically it involves the collection of data on infected machines (from botnet sinkholes, honeypots, spamtraps, and other sources); notifying ISPs of infections within their networks; and providing support for end users, via a website and sometimes a call-center.

A number of countries have been running such centers, often as part of a public-private partnership. Table 1 lists the countries with active initiatives in late 2011, according to an OECD report [27]. The report also mentions the U.S. & U.K. as developing such initiatives. The Netherlands is listed as having 'ISP-specific' programs, for at that time, KPN and Ziggo — the two largest ISPs — were heading such programs voluntarily [39].[2] Finland, though not listed, has been a leader with consistently low infection rates for years. It has had a notification and cleanup mechanism in place since 2005, as part of a collaboration between the national CERT, the telco regulator and main ISPs [20, 25]. At the time of writing, other countries are starting anti-botnet centers as well. In the EU alone, seven new national centers have been announced [2]. These will obviously not impact the past cleanup rates of Conficker, but they do underwrite the importance of empirically testing the efficacy of this mitigation strategy.

Figure 2 shows the website of the German anti-botnet advisory center, *botfrei*. The center was launched in 2010 by eco, the German Internet industry association, and is partially funded by the German government. The center does three things. First, it identifies users with infected PCs. Second, they inform the infected customers via their ISPs. Third, they offer cleanup support, through a website — with free removal tools and a forum — and

COUNTRY	INITIATIVE
Australia	Internet Industry Code of Practice (iCode)
Germany	German Anti-Botnet Initiative (BotFrei)
Ireland	Irish Anti-Botnet Initiative
Japan	Cyber Clean Center / ACTIVE
Korea	KrCERT/CC Anti-Botnet Initiative
Netherlands	Dutch Anti-Botnet Initiative (Abuse-Hub)

Table 1: List of countries with anti-botnet initiatives [27]

[1] Microsoft also set a $250,000 bounty for information leading to arrests.

[2] It has now been replaced by a wider initiative involving all main providers and covering the bulk of the broadband market.

Welcome to botfrei.de!

Figure 2: The German Anti-Botnet Advisory Center website - botfrei.de

a call center [17]. The center covers a wide range of malware, including Conficker. We should mention that eco staff told us that much of the German Conficker response took place before the center was launched. In their own evaluations, the center reports successes in terms of the number of users visiting its website, the number of cleanup actions performed, and overall reductions in malware rates in Germany. Interestingly enough, a large number of users visit botfrei.de directly, without being prompted by their ISP. This highlights the impact of media attention, as well as the demand for proactive steps among part of the user population.

We only highlight Germany's botfrei program as an example. In short, one would expect that countries running similar anti-botnet initiatives to have higher cleanup rates of Conficker bots. This, we shall evaluate.

2.3 Related Work

Similar to other botnets, much of the work on the Conficker worm has focused predominantly on technical analysis, e.g., [29]. Other research has studied the worm's outbreak and modeled its infection patterns, e.g., [42], [16], [33] and [41]. There have also been a few studies looking into the functioning of the Working Group, e.g., [31]. None of this work looks specifically at the issue of remediation. Although [33] uses the same dataset as this paper to model the spread of the worm, their results are skewed by the fact that they ignore DHCP churn, which is known to cause errors in infection rates of up to one order of magnitude for some countries [37].

This paper also connects to the literature on botnet mitigation, specifically to cleanup efforts. This includes the industry guidelines we discussed earlier, e.g., [1], [27], [10] and [22]; as well as academic work that tries to model different mitigation strategies, e.g., [6], [18] and [13]. We contribute to this discussion by bringing longitudinal data to bear on the problem and empirically evaluating one of the key proposals to emanate from this literature. This expands some of our earlier work.

In a broader context, a large body of research focuses on other forms of botnet mitigation, e.g., [14, 37, 26, 30], modeling worm infections, e.g. [35, 44, 43, 28], and challenges in longitudinal cybersecurity studies. For the sake of brevity we will not cite more works in these areas here (— except for works used in other sections).

3 Methodology

Answering the central research question requires a number of steps. First, we set out to derive reliable estimates of the number of Conficker bots in each country over time. This involves processing and cleaning the noisy sinkhole data, as well as handling several measurement issues. Later, we use the estimates to compare infection trends in various countries, identify patterns and specifically see if countries with anti-botnet initiatives have done any better. We do this by by fitting a descriptive model to each country's time-series of infection rates. This provides us with a specific set of parameters, namely the growth rate, the peak infection level, and the decay rate. We explore a few alternative models and opt for a two-piece model that accurately captures these characteristics. Lastly, to answer the central question, we explore the relationship between the estimated parameters and a set of explanatory variables.

3.1 The Conficker Dataset

The Conficker dataset has four characteristics that make it uniquely suited for studying large-scale cleanup efforts. First, it contains the complete record of one sinkholed botnet, making it less convoluted than for example spam data, and with far fewer false positives. Second, it logs most of the population on a daily basis, avoiding limitations from seeing only a sample of the botnet. Third, the dataset is longitudinal and tracks a period of almost six years. Many sinkholes used in scientific research typically cover weeks rather than months, let alone six years. Fourth, most infection data reflects a mix of attacker and defender behavior, as well as different levels (global & local). This makes it hard to determine what drives a trend – is it the result of attacker behavior, defender innovation, or just randomness? Conficker, however, was neutralized early on, with the attackers losing control and abandoning the botnet. Most other global defensive actions (e.g., patching and sinkholing) were also done in early 2009. Hence, the infection levels in our dataset predominantly reflect cleanup efforts. These combined attributes make the Conficker dataset excellent for studying the policy effects we are interested in.

Raw Data

Our raw data comes from the Conficker sinkhole logs. As explained in the background section, Conficker bots used an innovative centralized command and control infrastructure. The bots seek to connect to a number of pseudo-random domains every day, and ask for updated instructions or binaries from their masters. The algorithm that generates this domain list was reverse engineered early on, and various teams, including the Conficker Working Group, seized legal control of these domains. The domains were then 'sinkholed': servers were set up to listen and log every attempt to access the domains. The resulting logs include the IP address of each machine making such an attempt, timestamps, and a few other bits of information.

Processing Sinkhole Logs

The raw logs were originally stored in plain text, before adoption of the *nmsg* binary format in late 2010. The logs are huge; a typical hour of logs in January 2013 is around half a gigabyte, which adds up to tens of terabytes per year. From the raw logs we extract the IP address, which in the majority of cases will be a Conficker A, B, or C bot (the sinkholed domains were not typically used for other purposes). Then, using the MaxMind GeoIP database [23] and an IP-to-ASN database based on Routeviews BGP data [4], we determine the country and Autonomous System that this IP address belonged to at that moment in time. We lastly count the number of unique IP addresses in each region per hour.

With some exceptions, we capture most Conficker bots worldwide. The limitations are due to sinkholes downtime; logs for some sinkholed domains not being handed over to the working group [7]; and bots being behind an egress firewall, blocking their access to the sinkhole. None of these issues however creates a systematic bias, so we may treat them as noise.

After processing the logs we have a dataset spanning from February 2009 to September 2014, covering 241 ISO country codes and 34,000 autonomous systems. The dataset contains approximately 178 million unique IP addresses per year. In this paper we focus on bots located in 62 countries, which were selected as follows. We started with the 34 members of the Organization for Economic Cooperation and Development (OECD), and 7 additional members of the European Union which are not part of the OECD. These countries have a common development baseline, and good data is available on their policies, making comparison easier. We add to this list 23 countries that rank high in terms of Conficker or spam bots — cumulatively covering 80 percent of all such bots worldwide. These countries are interesting from a cybersecurity perspective. Finally, two countries were removed due to severe measurement issues affecting their bot counts, which we will describe later. The full list of countries can be seen in figure 8 or in the appendix.

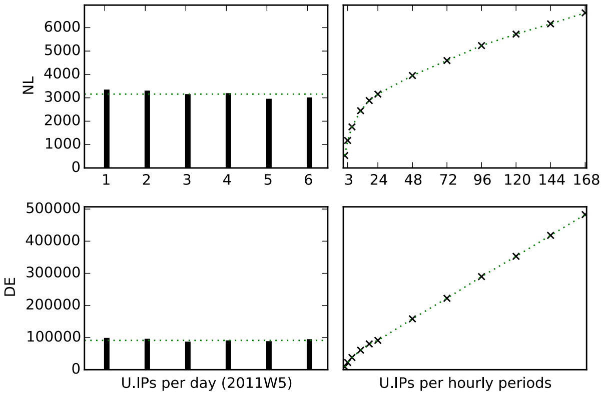

Figure 3: Unique IP counts over various time-periods

3.2 Counting bots from IP addresses

The Conficker dataset suffers from a limitation that is common among most sinkhole data and other data on infected machines, such as spam traps, firewall logs, and passive DNS records: one has to use IP addresses as a proxy for infected machines. Earlier research has established that IP addresses are coarse unique identifiers and they can be off by one order of magnitude in a matter of days [37], because of differences in the dynamic IP address allocation policies of providers (so-called *DHCP churn*). Simply put, because of dynamic addresses, the same infected machine can appear in the logs under multiple IP addresses. The higher the churn rate, the more over-counting.

Figure 3 visualizes this problem. It shows the count of unique Conficker IP addresses in February 2011 over various time periods — 3 hours, 12 hours, one day, up to a week. We see an interesting growth curve, non-linear at the start, then linear. Not all computers are powered on at every point in time, so it makes sense to see more IP addresses in the sinkhole over longer time periods. However, between the 6th and 7th day, we have most likely seen most infected machines already. The new IP addresses are unlikely to be new infections, as the daily count is stable over the period. The difference is thus driven by infected machines reappearing with a new IP address.

The figure shows IP address counts for the Netherlands and Germany. From qualitative reports we know that IP churn is relatively low in the Netherlands — an Internet subscriber can retain the same IP address for months — while in Germany the address typically changes every 24 hours. This is reflected in the figure: the slope for Germany is much steeper. Should one ignore the differences in churn rates among countries, and simply count unique IP addresses over a week, then a severe bias will be introduced against countries such as Germany. Using shorter time periods, though leading to under-counting, decreases this bias.[3] We settle for this simple solution: counting the average number of unique IPs *per hour*, thereby eliminating the churn factor. This hourly count will be a fraction of the total bot count, but that is not a problem when we make comparisons based on scale-invariant measures, such as cleanup rates.

Network Address Translation (NAT) and the use of HTTP proxies can also cause under-counting. This is particularly problematic if it happens at the ISP level, leading to large biases when comparing cleanup policies. After comparing subscriber numbers with IP address space size in our selection of countries, we concluded that ISP-level NAT is widely practiced in India. As we have no clear way of correcting such cases, we chose to exclude India from our analysis.

3.3 Missing measurements

The Conficker dataset has another problem that is also common: missing measurements. Looking back at figure 1, we see several sudden drops in bot counts, which we highlighted with dotted lines. These drops are primarily caused by sinkhole infrastructure downtime — typically for a few hours, but at one point even several weeks. These measurement errors are a serious issue, as they only occur in one direction and may skew our analysis. We considered several approaches to dealing with them. One approach is to model the measurement process explicitly. Another approach is to try and minimize the impact of aberrant observations by using robust curve-fitting methods. This approach adds unnecessary complexity and is not very intuitive. A third option is to pre-process the data using curve smoothing techniques; for instance by taking the exponentially weighted rolling average or applying the Hodrick-Prescott filter. Although not necessarily wrong, this also adds its own new biases as it changes data. The fourth approach, and the one that we use, is to detect and remove the outliers heuristically.

For this purpose, we calculate the distance between each weekly value in the global graph with the rolling median of its surrounding two months, and throw out the top 10%. This works because most bots log in about once a day, so the IP counts of adjacent periods are not independent. The IP count may increase, decrease, or slightly fluctuate, but a sudden decrease in infected machines followed by a sudden return of infections to the previous level is highly unlikely. The interested reader is referred to the appendix to see the individual graphs for all the countries with the outliers removed.[4]

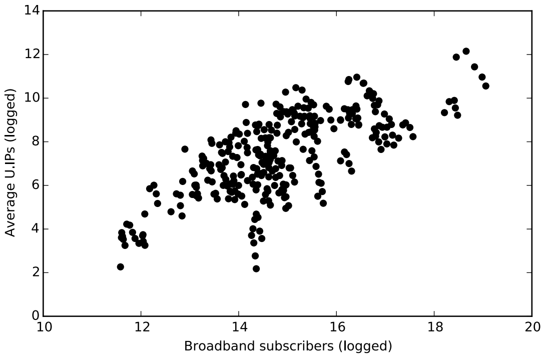

Figure 4: Conficker bots versus broadband subscribers

3.4 Normalizing bot counts by country size

Countries with more Internet users are likely to have more Conficker bots, regardless of remediation efforts. Figure 4 illustrates this. It thus makes sense to normalize the unique IP counts by a measure of country size; in particular if one is to compare peak infection rates. One such measure is the size of a country's IP space, but IP address usage practices vary considerably between countries. A more appropriate denominator and the one we use is the number of Internet broadband subscribers. This is available from a number of sources, including the Worldbank Development Indicators.

4 Modeling Infections

4.1 Descriptive Analysis

Figure 5 shows the Conficker infection trends for Germany, United States, France, and Russia. The x-axis is time; the y-axis is the average number of unique IP addresses seen per day in the sinkhole logs, corrected for churn. We observe a similar pattern: a period of rapid growth; a plateau period, where the number of infected machines peaks and remains somewhat stable for a short or longer amount of time; and finally, a period of gradual decline.

What explains these similar trends among countries, and in particular, the points in time where the changes

[3] Ideally, we would calculate a churn rate — the average number of IPs per bot per day — and use that to generate a good estimate of the actual number of bots. That is not an easy task, and requires making quite a number of assumptions.

[4] An extreme case was Malaysia, where the length of the drops and fluctuations spanned several months. This most likely indicates country-level egress filtering, prompting us to also exclude Malaysia from the analysis.

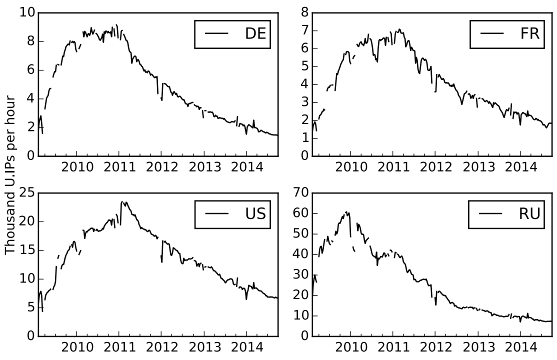

Figure 5: Conficker trends for four countries

occur on the graphs? At first glance, one might think that the decline is set off by some event — for instance, the arrest of the bot-masters, or a release of a patch. But this is not the case. As previously explained, all patches for Conficker were released by early 2009, while the worm continued spreading after that. This is because most computers that get infected with Conficker are "unprotected" — that is, they are either unpatched or without security software, in case the worm spreads via weak passwords on networks shares, USB drives, or domain controllers. The peak in 2010 – 2011 is thus the worm reaching some form of saturation where all vulnerable computers are infected. In the case of business networks, administrators may have finally gotten the worm's reinfection mechanisms under control [24].

Like the growth phase and the peak, the decline can also not be directly explained by external attacker behavior. Arrests related to Conficker occurred mid 2011, while the decline started earlier. In addition, most of the botnet was already out of the control of the attackers. What we are seeing appears to be a 'natural' process of the botnet. Infections may have spread faster in some countries, and cleanups may have been faster in others, but the overall patterns are similar across all countries.

4.2 Epidemic Models

It is often proposed in the security literature to model malware infections similarly as epidemics of infectious diseases, e.g. [28, 44]. The analog is that vulnerable hosts get infected, and start infecting other hosts in their vicinity; at some later point they are recovered or removed (cleaned, patched, upgraded or replaced).

This leads to multiple phases, similar to what we see for Conficker: in the beginning, each new infection increases the pressure on vulnerable hosts, leading to an explosive growth. Over time, fewer and fewer vulnerable hosts remain to be infected. This leads to a phase where the force of new infections and the force of recovery are locked in dynamic equilibrium. The size of the infected population reaches a plateau. In the final phase, the force of recovery takes over, and slowly the number of infections declines towards zero.

Early on in our modeling efforts we experimented with a number of epidemic models, but eventually decided against them. Epidemic models involve a set of latent compartments and a set of differential equations that govern the transitions between them — see [12] for an extensive overview. Most models make a number of assumptions about the underlying structure of the population and the propagation mechanism of the disease.

The basic models for instance assume constant transition rates over time. Such assumptions might hold to an acceptable degree in short time spans, but not over six years. The early works applying these models to the Code Red and Slammer worms [44, 43] used data spanning just a few weeks. One can still use the models even when the assumptions are not met, but the parameters cannot be then easily interpreted. To illustrate: the basic Kermack-McKendrick SIR model fits our data to a reasonable degree. However, we know that this model assumes no reinfections, while Conficker reinfections were a major problem for some companies [24].

More complex models reduce assumptions by adding additional latent variables. This creates a new problem: often when solved numerically, different combinations of the parameters fit the data equally well. We observed this for some countries with even the basic SIR model. Such estimates are not a problem when the aim is to predict an outbreak. But they are showstoppers when the aim is to compare and interpret the parameters and make inferences about policies.

4.3 Our model

For the outlined reasons, we opted for a simple descriptive model. The model follows the characteristic trend of infection rates, provides just enough flexibility to capture the differences between countries, and makes no assumptions about the underlying behavior of Conficker. It merely describes the observed trends in a small set of parameters.

The model consists of two parts: a logistic growth that ends in a plateau; followed by an exponential decay. Logistic growth is a basic model of self-limiting population growth, where first the rate of growth is proportional to the size of the existing population, and then declines as the natural limit is approached (— the seminal work of Staniford, et al. [35] also used logistic growth). In our case, this natural limit is the number of vulnerable hosts.

Exponential decay corresponds to a daily decrease of the number of Conficker bots by a fixed percentage. Figure 6 shows the number of infections per subscriber over

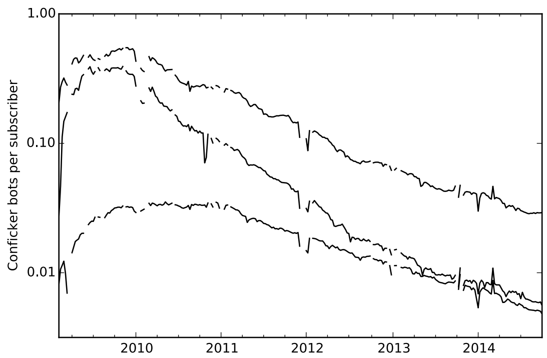

Figure 6: Conficker bots per subscriber on logarithm scale for (from top to bottom) Russia, Belarus, Germany.

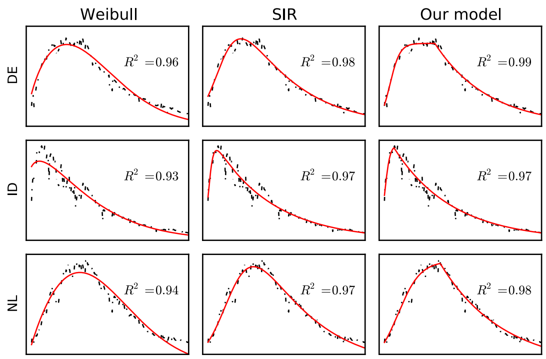

Figure 7: Comparison of alternative models

time for three countries on a logarithm scale. We see a downward-sloping straight line in the last phase that corresponds to an exponential decay: the botnet shrank by a more or less a constant percentage each day. We do not claim that the assumptions underpinning the logistic growth and the exponential decay models are fully satisfied, but in the absence of knowledge of the exact dynamics, their simplicity seems the most reasonable approach.

The model allows us to reduce the time series data for each country to these parameters: (1) the infection rate in the growth phase, (2) the peak number of infections, (3) the time at which this peak occurred, and (4) the exponential decay rate in the declining phase. We will fit our model on the time series for all countries, and then compare the estimates of these parameters.

Mathematically, our model is formulated as follows:

$$\text{bots}(t) = \begin{cases} \dfrac{K}{1+e^{-r(t-t_0)}}, & \text{if } t < t_P \\ \\ He^{-\gamma(t-t_P)}, & \text{if } t \geq t_P \end{cases} \tag{1}$$

where $\text{bots}(t)$ is the number of bots at time t, t_P is the time of the peak (where the logistic growth transitions to exponential decay), and H the height of the peak. The logistic growth phase has growth rate r, asymptote K, and midpoint t_0. The parameter γ is the exponential decay rate. The height of the peak is identified by the other parameters:

$$H = \frac{K}{1+e^{-r(t_P-t_0)}}.$$

4.4 Inspection of Model Fit

We fit the curves using the Levenberg-Marquardt least squares algorithm with the aid of the *lmfit* Python module. The results are point estimates; standard errors were computed by *lmfit* by approximating the Hessian matrix at the point estimates. With these standard errors we computed Wald-type confidence intervals (point estimate ± 2 s.e.) for all parameters. These intervals have no exact interpretation in this case, but provide some idea of the precision of the point estimates.

The reader can find plots of the fitted curves for all 62 countries in the appendix. The fits are good, with R^2 values all between 0.95 and 1. Our model is especially effective for countries with sharp peaks, that is, the abrupt transitions from growth to decay that can be seen in Hungary and South Africa, for example. For some countries, such as Pakistan and Ukraine, we have very little data on the growth phase, as they reached their peak infection rate around the time sinkholing started. For these countries we will ignore the growth estimates in further analysis. By virtue of our two-phase model, the estimates of the decay rates are unaffected by this issue.

We note that our model is deterministic rather than stochastic; that is, it does not account for one-time shocks in cleanup that lead to a lasting drop in infection rates. Nevertheless, we see that the data follows the fitted exponential decay curves quite closely, which indicates that bots get cleaned up at a constant rate and non-simultaneously.[5]

Alternative models: We tried fitting models from epidemiology (e.g. the SIR model) and reliability engineering (e.g. the Weibull curve), but they did not do well in such cases, and adjusted R^2 values were lower for almost all countries. Additionally, for a number of countries, the parameter estimates were unstable. Figure 7 illustrates why: our model's distinct phases captures the height of peak and exponential decay more accurately.

[5] The exception is China: near the end of 2010 we see a massive drop in Conficker infections. After some investigation, we found clues that this drop might be associated by a sudden spur in the adoption of IPv6 addresses, which are not directly observable to the sinkhole.

5 Findings

5.1 Country Parameter Estimates

Figure 8 shows the parameter estimates and their precision for each of the 62 countries: the growth rate, peak height, time of the peak, and the decay rate.

The variance in the peak number of infections is striking: between as little as 0.01% to over 1% of Internet broadband subscribers. The median is .1%. It appears that countries with high peaks tend to also have high growth rates, though we have to keep in mind that the growth rate estimates are less precise, because the data does not fully cover that phase. Looking at the peak height, it seems that this is not associated with low cleanup rates. For example, Belarus (BY) has the highest decay rate, but a peak height well above the median.

The timing of the peaks is distributed around the last weeks of 2010. Countries with earlier peaks are mostly countries with higher growth rates. This suggests that the time of the peak is simply a matter of when Conficker ran out of vulnerable machines to infect; a faster growth means this happens sooner. Hence, it seems unlikely that early peaks indicate successful remediation.

The median decay rate estimate is .009, which corresponds to a 37% decline per year ($100 \cdot (1 - e^{-.009 \cdot 52})$). In countries with low decay rates (around .005), the botnet shrank by 23% per year, versus over 50% per year on the high end.

5.2 National Anti-Botnet Initiatives

We are now in a position to address the paper's central question and to explore the effects of the leading national anti-botnet initiatives (ABIs). In figure 8, we have highlighted the countries with such initiatives as crosses. One would expect that these countries have slower botnet growth, a lower peak height, and especially a faster cleanup rate. There is no clear evidence for any of this; the countries with ABIs are all over the place. We do see some clustering on the lower end of the peak height graphs; however, this position is shared with a number of other countries that are institutionally similar (in terms of wealth for example) but not running such initiatives.

We can formally test if the population median is equal for the two groups using the Wilcoxon ranksum test. The *p*-value of the test when comparing the Conficker decay rate among the two sets of countries is 0.54, which is too large to conclude that the ABIs had a meaningful effect. It is somewhat surprising, and disappointing, to see no evidence for the impact of the leading remediation efforts on bot cleanup.

We briefly look at three possible explanations. The first one is that country trends might be driven by infections in other networks than those of the ISPs, as we know that the ABIs focus mostly on ISPs. This explanation fails, however, as can be seen in figure 2. The majority of the Conficker bots were located in the networks of the retail ISPs in these countries, compared to educational, corporate or governmental networks. This pattern held in 2010, the year of peak infections, and 2013, the decay phase, with one minor deviation: in the Netherlands, cleanup in ISP networks was faster than in other networks.

Country	ISP % 2010	ISP % 2013
AU	77%	74%
DE	89%	82%
FI	73%	69%
IE	72%	74%
JP	64%	67%
KR	83%	87%
NL	72%	**37%**
Others	81%	75%

Table 2: Conficker bots located in retail ISPs

A second explanation might be that the ABIs did not include Conficker in their notification and cleanup efforts. In two countries, Germany and the Netherlands, we were able to contact participants of the ABI. They claimed that Conficker sinkhole feeds were included and sent to the ISPs. Perhaps the ISPs did not act on the data — or at least not at a scale that would impact the decay rate; they might have judged Conficker infections to be of low risk, since the botnet had been neutralized. This explanation might be correct, but it also reinforces our earlier conclusion that the ABIs did not have a significant impact. After all, this explanation implies that the ABIs have failed to get the ISPs and their customers to undertake cleanup at a larger scale.

Given that cleanup incurs cost for the ISP, one could understand that they might decide to ignore sinkholed and neutralized botnets. On closer inspection, this decision seems misguided, however. If a machine is infected with Conficker, it means it is in a vulnerable — and perhaps infected — state for other malware as well. Since we had access to the global logs of the sinkhole for GameoverZeus — a more recent and serious threat — we ran a cross comparison of the two botnet populations. We found that based on common IP addresses, a surprising 15% of all GameoverZeus bots are also infected with Conficker. During six weeks at the end of 2014, the GameoverZeus sinkhole saw close to 1.9 million unique IP addresses; the Conficker sinkhole saw 12 million unique IP addresses; around 284 thousand addresses appear in both lists. Given that both malware types only infected a small percentage of the total pop-

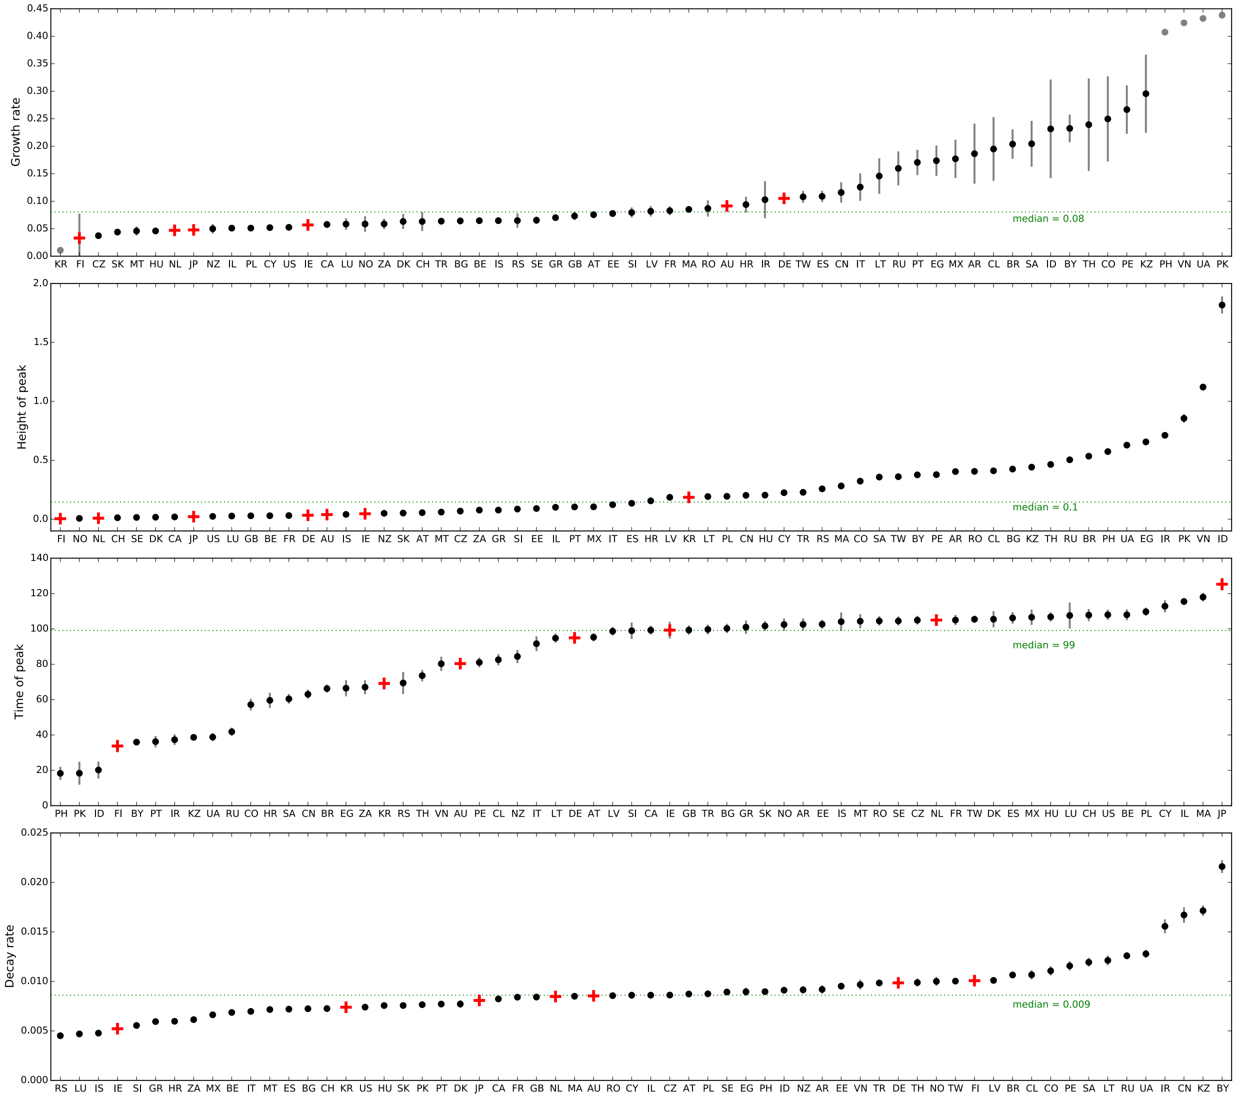

Figure 8: Parameter estimates and confidence intervals

ulation of broadband subscribers, this overlap is surprisingly large.[6] It stands in stark contrast to the findings of a recent study that systematically determined the overlap among 85 blacklists and found that most entries were unique to one list, and that overlap between independent lists was typically less than one percent [34]. In other words, Conficker bots should be considered worthwhile targets for cleanup.

5.3 Institutional Factors

Given that anti-botnet initiatives cannot explain the variation among the country parameters shown in figure 8, we turn our attention to several institutional factors that are often attributed with malware infection rates (e.g., see [40]). These are broadband access, unlicensed software use, and ICT development on a national level. In addition, given the spreading mechanism of Conficker, we also look at Operating System market shares, as well as PC upgrade cycles. We correlate these factors with the relevant parameters.

[6] The calculated overlap in terms of bots might be inflated as a result of both NAT and DHCP churn. Churn can in this case have both an over-counting and under-counting effect. Under-counting will occur if one bot appears in the two sinkholes with different IP addresses, as a result of different connection times to the sinkholes. Doing the IP comparisons at a daily level yields a 6% overlap, which is still considerable.

Correlating Growth Rate

Broadband access is often mentioned as a technological enabler of malware; in particular, since Conficker was a worm that spread initially by scanning for hosts to infect, one could expect its growth in countries with higher broadband speeds to be faster. Holding other factors constant, most epidemiological models would also predict this faster growth with increased network speeds. This turns out not to be the case. The Spearman correlation coefficient between average national broadband speeds, as reported by the International Telecommunication Union [15], and Conficker growth rate is in fact negative: -0.30. This is most probably due to other factors confounding with higher broadband speeds, e.g. national wealth. In any case, the effects of broadband access and speeds are negligible compared to other factors, and we will not pursue this further.

Correlating Height of Peak

As we saw, there is a wide dispersion between countries in the peak number of Conficker bots. What explains the large differences in peak infection rates?

Operating system market shares: Since Conficker only infects machines running Windows 2000, XP, Vista, or Server 2003/2008, some variation in peak height may be explained by differences in use of these operating systems (versus Windows 7 or non-Windows systems). We use data from StatCounter Global Stats [36], which is based on page view analytics of some three million websites. Figure 9 shows the peak height against the combined Windows XP and Vista market shares in January 2010 (other vulnerable OS versions were negligible). We see a strong correlation — with a Pearson correlation coefficient of 0.55. This in itself is perhaps not surprising.

Dividing the peak heights by the XP/Vista market shares gives us estimates of the *peak number of infections per vulnerable user*; we shall call this metric $\widetilde{\text{hp}}$. This metric allows for fairer comparisons between countries, as one would expect countries with higher market shares of vulnerable OS's to harbor more infections regardless of other factors. Interestingly, there is still considerable variation in this metric – the coefficient of variance is 1.2. We investigate two institutional factors that may explain this variation.

ICT development index is an index published by the ITU based on a number of well-established ICT indicators. It allows for benchmarking and measuring the digital divide and ICT development among countries (based on ICT readiness and infrastructure, ICT intensity and use, ICT skills and literacy [15]). This is obviously a broad indicator, and can indicate the ability to manage cybersecurity risks, including botnet cleanups, among both citizens and firms. Figure 10 shows this metric against $\widetilde{\text{hp}}$, and interestingly enough we see a strong correlation.

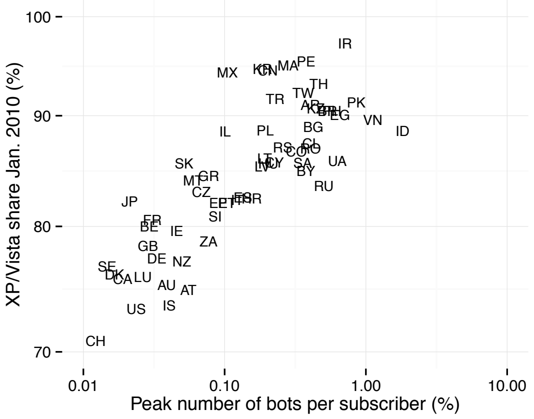

Figure 9: Bots versus XP & Vista use

Unlicensed software use or piracy rates are another oft mentioned factor influencing malware infection rates. In addition to the fact that pirated software might include malware itself, users running pirated OS's often turn off automatic updates, for fear of updates disabling their unlicensed software — even though Microsoft consistently states that it will also ship security updates to unlicensed versions of Windows [38]. Disabling automatic updates leaves a machine open to vulnerabilities, and stops automated cleanups. We use the unlicensed software rates calculated by the Business Software Alliance [5]. This factor also turns out to be strongly correlated with $\widetilde{\text{hp}}$, as shown in figure 10.

Since ICT development and piracy rates are themselves correlated, we use the following simple linear regression to explore thier joint association with peak Conficker infection rates:

$$\log(\widetilde{\text{hp}}) = \alpha + \beta_1 \cdot \text{ict-dev} + \beta_2 \cdot \text{piracy} + \varepsilon$$

where both regressors were standardized by subtracting the mean and dividing by two standard devia-

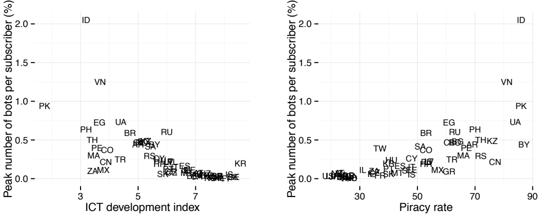

Figure 10: $\widetilde{\text{hp}}$ versus ICT development & piracy

tions. We use the logarithm of $\widetilde{hp}$ as it is a proportion. The least squares estimates (standard errors) are $\hat{\beta}_1 = -0.78(0.27)$, $p < 0.01$, and $\hat{\beta}_2 = 1.7(0.27)$, $p < 0.001$. These coefficients can be interpreted as follows: everything else kept equal, countries with low (one sd below the mean) ICT development have $e^{0.78} = 2.2$ times more Conficker bots per XP/Vista user at the peak than countries with high ICT development (one sd above the mean), and, similarly, countries with high piracy rates (one sd above the mean) have an $e^{1.7} = 5.5$ times higher peak than countries with low piracy rates (one sd below the mean). The R^2 of this regression is 0.78, which indicates that ICT development and piracy rates explain most of the variation in Conficker peak height.

Correlating Decay Rate

Although decay rates are less dispersed than peak heights, there are still noticeable differences among countries. Given the rather slow cleanup rates — the median of 0.009 translates to a 37% decrease in the number of bots after one year — one hypothesis that comes to mind is that perhaps some of the cleanup is being driven by users upgrading their OS's (to say Windows 7), or buying a new computer and disposing of the old fully.

For each country we estimated the **decay rate of the market share of Windows XP and Vista** from January 2011 to June 2013 using the StatCounter GlobalStats data. Figure 11 shows these decay rates versus Conficker decay rates. There is a weak correlation among the two, with a Spearman correlation coefficient of 0.26.

But more interesting and somewhat surprising is that in many countries, the Conficker botnet shrank at a slower pace than the market share of Windows XP / Vista (all countries below and to the right of the dashed line). Basically this means that the users infected with Conficker are less likely to upgrade their computers then the average consumer.[7]

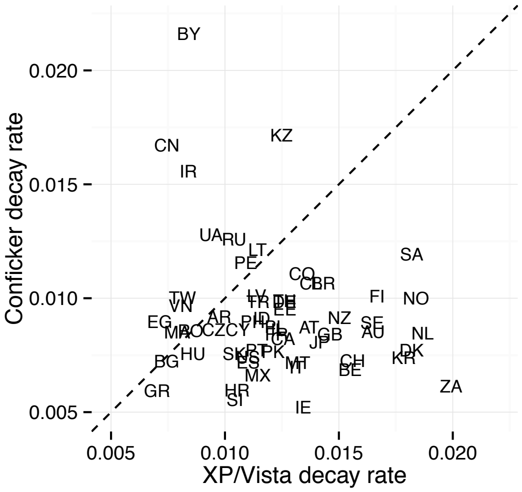

Figure 11: Conficker decay vs. XP/Vista decay

6 Discussion

We found that the large scale national anti-botnet initiatives had no observable impact on the growth, peak height, or decay of the Conficker botnet. This is surprising and unfortunate, as one would expect Conficker bots to be among those targeted for cleanup by such initiatives. We checked that the majority of bots were indeed located among the networks of ISPs, and also observed that some of these machines have multiple infections. Turning away from the initiatives and to institutional factors that could explain the differences among countries, we observed that the ICT development index and piracy rates can explain 78% of the variation in peak height, even after correcting for OS market shares. We also found that the Conficker cleanup rate is less than the average PC upgrade rate.

Perhaps not all security experts are surprised by these findings. They are nevertheless important in forming effective anti-botnet policies. We presented the research to an audience of industry practitioners active in botnet cleanup. Two North American ISPs commented that they informed their customers about Conficker infections — as part of the ISP's own policy, not a country-level initiative. They stated that some customers repeatedly ignored notifications, while others got re-infected soon after cleanup. Another difficulty was licensing issues requiring ISPs to point users to a variety of cleanup tool websites (e.g., on microsoft.com) instead of directly distributing a tool, which complicates the process for some users. Interestingly enough both ISPs ranked well with regards to Conficker peak, showing that their efforts did have a positive impact. Their challenges suggests areas for improvement.

Future work in this area can be taken in several directions. One is to test the various parameters against other independent variables — e.g., the number of CERTs, privacy regulation, and other governance indicators. A second avenue is to explore Conficker infection rates at the ISP level versus the country level. A random effects regression could reveal to what extent ISPs in the same country follow similar patterns. We might see whether particular ISPs differ widely from their country baseline, which would be interesting from an anti-botnet perspective. Third, it might be fruitful to contact a number of

[7] This difference between users who remain infected with Conficker and the average user might be more extreme in countries with a higher level of ICT development. This can be observed in the graph.

users still infected with Conficker in a qualitative survey, to see why they remain unaware or unworried about running infected machines. This can help develop new mitigation strategies for the most vulnerable part of the population. Perhaps some infections are forgotten embedded systems, not end users. Forth and more broadly is to conduct research on the challenges identified by the ISPs: notification mechanisms and simplifying cleanup.

7 Conclusion and Policy Implications

In this paper, we tackled the often ignored side of botnet mitigation: large-scale cleanup efforts. We explored the impact of the emerging best practice of setting up national anti-botnet initiatives with ISPs. Did these initiatives accelerate cleanup?

The longitudinal data from the Conficker botnet provided us with a unique opportunity to explore this question. We proposed a systematic approach to transform noisy sinkhole data into comparative infection metrics and normalized estimates of cleanup rates. After removing outliers, and by using the hourly Conficker IP address count per subscriber to compensate for a variety of known measurement issues, we modeled the infection trends using a two-part model. We thereby condensed the dataset to three key parameters for each country, and compared the growth, peak, and decay of Conficker, which we compared across countries.

The main findings were that institutional factors such as ICT development and unlicensed software use have influenced the spread and cleanup of Conficker more than the leading large scale anti-botnet initiatives. Cleanup seems even slower than the replacement of machines running Windows XP, and thus infected users appear outside the reach of remediation practices. At first glance, these findings seem rather gloomy. The Conficker Working Group, a collective effort against botnets, had noted remediation to be their largest failure [7]. We have now found that the most promising emerging practice to overcome that failure suffers similar problems.

So what can be done? Our findings lead us to identify several implications. First of all, the fact that peak infection levels strongly correlate with ICT development and software piracy, suggests that botnet mitigation can go hand in hand with economic development and capacity building. Helping countries develop their ICT capabilities can lower the global impact of infections over the long run. In addition, the strong correlation with software piracy suggests that automatic updates and unattended cleanups are some of the strongest tools in our arsenal. It support policies to enable security updates to install by default, and delivering them to all machines, including those running unlicensed copies [3]. Some of these points were also echoed by the ISPs mentioned in section 6.

Second, the fact that long-living bots appear in a reliable dataset — that is, one with few false positives — suggests that future anti-botnet initiatives need to commit ISPs to take action on such data sources, even if the sinkholed botnet is no longer a direct threat. These machines are vulnerable and likely to harbor other threats as well. Tracking these infections will be an important way to measure ISP compliance with these commitments, as well as incentivize cleanup for those users outside the reach of automated cleanup tools.

Third, given that cleanup is a long term effort, future anti-botnet initiatives should support, and perhaps fund, the long-term sustainability of sinkholes. This is a necessity if we want ISPs to act on this data.

A long term view is rare in the area of cybersecurity, which tends to focus on the most recent advances and threats. In contrast to C&C takedown, bot remediation needs the mindset of a marathon runner, not a sprinter. To conclude on a more optimistic note, Finland has been in the marathon for a longer time than basically all other countries. It pays off: they have been enjoying consistently low infection rates for years now. In other words, a long term view is not only needed, but possible.

Acknowledgment

The authors would like to explicitly thank Chris Lee, Paul Vixie and Eric Ziegast for providing us with access to the Conficker sinkhole and supporting our research.

We also thank Ning An, Ben Edwards, Dina Hadziosmanovic, Stephanie Forest, Jan Philip Koenders, Rene Mahieu, Hooshang Motarjem, Piet van Mieghem, Julie Ryan, as well as the participants of Microsoft DCC 2015 and USENIX reviewers for contributing ideas and providing feedback at various stages of this paper.

Appendix - Individual Country Graphs

In this appendix we provide the model fit for all the 62 countries used in the paper. The graphs show the relative number of Conficker bots in each country - as measured by average unique Conficker IP addresses per hour in the sinkholes, divided by broadband subscriber counts for each country. (Please refer to the methodology section for the rationale). In each graph, the solid line (in blue) indicates the measurement; the dotted line (in gray) is removed outliers; and the smooth-solid line (in red) indicates the fitted model. The model has four parameters: growth and decay rates — given on the graph — and height and time of peak infections — deducible from the axes. The R^2 is also given for each country.

Abstract

Mobile money, also known as branchless banking, brings much-needed financial services to the unbanked in the developing world. Leveraging ubiquitous cellular networks, these services are now being deployed as smart phone apps, providing an electronic payment infrastructure where alternatives such as credit cards generally do not exist. Although widely marketed as a more secure option to cash, these applications are often not subject to the traditional regulations applied in the financial sector, leaving doubt as to the veracity of such claims. In this paper, we evaluate these claims and perform the first in-depth measurement analysis of branchless banking applications. We first perform an automated analysis of all 46 known Android mobile money apps across the 246 known mobile money providers and demonstrate that automated analysis fails to provide reliable insights. We subsequently perform comprehensive manual teardown of the registration, login, and transaction procedures of a diverse 15% of these apps. We uncover pervasive and systemic vulnerabilities spanning botched certification validation, do-it-yourself cryptography, and myriad other forms of information leakage that allow an attacker to impersonate legitimate users, modify transactions in flight, and steal financial records. These findings confirm that the majority of these apps fail to provide the protections needed by financial services. Finally, through inspection of providers' terms of service, we also discover that liability for these problems unfairly rests on the shoulders of the customer, threatening to erode trust in branchless banking and hinder efforts for global financial inclusion.

1 Introduction

The majority of modern commerce relies on cashless payment systems. Developed economies depend on the near instantaneous movement of money, often across great distances, in order to fuel the engines of industry. These rapid, regular, and massive exchanges have created significant opportunities for employment and progress, propelling forward growth and prosperity in participating countries. Unfortunately, not all economies have access to the benefits of such systems and throughout much of the developing world, physical currency remains the de facto means of exchange.

Mobile money, also known as branchless banking, applications attempt to fill this void. Generally deployed by companies outside of the traditional financial services sector (e.g., telecommunications providers), branchless banking systems rely on the near ubiquitous deployment of cellular networks and mobile devices around the world. Customers can not only deposit their physical currency through a range of independent vendors, but can also perform direct peer-to-peer payments and convert credits from such transactions back into cash. Over the past decade, these systems have helped to raise the standard of living and have revolutionized the way in which money is used in developing economies. Over 30% of the GDP in many such nations can now be attributed to branchless banking applications [39], many of which now perform more transactions per month than traditional payment processors, including PayPal [36].

One of the biggest perceived advantages of these applications is security. Whereas carrying large amounts of currency long distances can be dangerous to physical security, branchless banking applications can allow for commercial transactions to occur without the risk of theft. Accordingly, these systems are marketed as a secure new means of enabling commerce. Unfortunately, the strength of such claims from a *technical* perspective has not been publicly investigated or verified. Such an analysis is therefore critical to the continued growth of branchless banking systems.

In this paper, we perform the first comprehensive analysis of branchless banking applications. Through these efforts, we make the following contributions:

- **Analysis of Branchless Banking Applications:** We perform the first comprehensive security analysis of branchless banking applications. First, we use a well-known automated analysis tool on all 46 known Android mobile money apps across all 246 known mobile money systems. We then methodically select seven Android-based branchless banking applications from Brazil, India, Indonesia, Thailand, and the Phillipines with a combined user base of millions. We then develop and execute a comprehensive, reproducible methodology for analyzing the entire application communication flow. In so doing, we create the first snapshot of the global state of security for such applications.

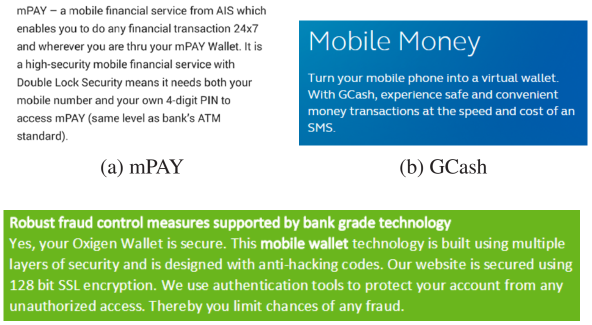
- **Identifications of Systemic Vulnerabilities:** Our analysis discovers pervasive weaknesses and shows that six of the seven applications broadly fail to preserve the integrity of their transactions. We then compare our results to those provided through automated analysis and show that current tools do not reliably indicate severe, systemic security faults. Accordingly, neither users nor providers can reason about the veracity of requests by the majority of these systems.

- **Analysis of Liability:** We combine our technical findings with the assignment of liability described within every application's terms of service, and determine that users of these applications have no recourse for fraudulent activity. Therefore, it is our belief that these applications create significant financial dangers for their users.

The remainder of this paper is organized as follows: Section 2 provides background information on branchless banking and describes how these applications compare to other mobile payment systems; Section 3 details our methodology and analysis architecture; Section 4 presents our findings and categorizes them in terms of the CWE classification system; Section 5 delivers discussion and recommendations for technical remediation; Section 6 offers an analysis of the Terms of Service and the assignment of liability; Section 7 discusses relevant related work; and Section 8 provides concluding remarks.

2 Mobile Money in the Developing World

The lack of access to basic financial services is a contributing factor to poverty throughout the world [17]. Millions live without access to basic banking services, such as value storage and electronic payments, simply because they live hours or days away from the nearest bank branch. Lacking this access makes it more difficult for the poor to save for future goals or prepare for future setbacks, conduct commerce remotely, or protect money against loss or theft. Accordingly, providing banking through mobile phone networks offers the promise of dramatically improving the lives of the world's poor.



mPAY – a mobile financial service from AIS which enables you to do any financial transaction 24x7 and wherever you are thru your mPAY Wallet. It is a high-security mobile financial service with Double Lock Security means it needs both your mobile number and your own 4-digit PIN to access mPAY (same level as bank's ATM standard).

(a) mPAY

Mobile Money

Turn your mobile phone into a virtual wallet. With GCash, experience safe and convenient money transactions at the speed and cost of an SMS.

(b) GCash

Robust fraud control measures supported by bank grade technology

Yes, your Oxigen Wallet is secure. This **mobile wallet** technology is built using multiple layers of security and is designed with anti-hacking codes. Our website is secured using 128 bit SSL encryption. We use authentication tools to protect your account from any unauthorized access. Thereby you limit chances of any fraud.

(c) Oxigen Wallet

Figure 1: Mobile money apps are heavily marketed as being safe to use. These screenshots from providers' marketing materials show the extent of these claims.

The M-Pesa system in Kenya [21] pioneered the *mobile money* service model, in which agents (typically local shopkeepers) act as intermediaries for deposits, withdrawals, and sometimes registration. Both agents and users interact with the mobile money system using SMS or a special application menu enabled by code on a SIM card, enabling users to send money, make bill payments, top up airtime, and check account balances. The key feature of M-Pesa and other systems is that their use does not require having a previously established relationship with a bank. In effect, mobile money systems are bootstrapping an alternative banking infrastructure in areas where traditional banking is impractical, uneconomic due to minimum balances, or simply non-existent. M-Pesa has not yet released a mobile app, but is arguably the most impactful mobile money system and highlights the promise of branchless banking for developing economies.

Mobile money has become ubiquitous and essential. M-Pesa boasts more than 18.2 million registrations in a country of 43.2 million [37]. In Kenya and eight other countries, there are more mobile money accounts than bank accounts. As of August 2014, there were a total of 246 mobile money services in 88 countries serving a total of over 203 million registered accounts, continuing a trend [49] up from 219 services in December 2013. Note that these numbers explicitly exclude services that are simply a mobile interface for existing banking systems. Financial security, and trust in branchless banking systems, depends on the assurances that these systems are secure against fraud and attack. Several of the apps that we study offer strong assurances of security in their promotional materials. Figure 1 provides examples

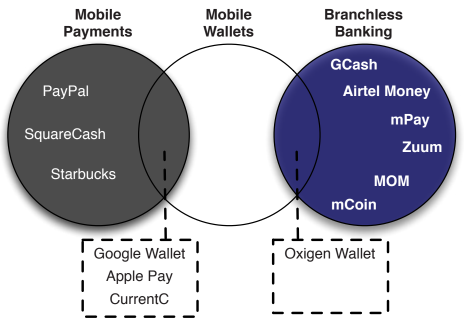


Figure 2: While Mobile Money (Branchless Banking) and Mobile Payments share significant overlapping functionality, the key differences are the communications methods the systems use and that mobile money systems do not rely on existing banking infrastructure.

of these promises. This promise of financial security is even reflected in the M-Pesa advertising slogan "Relax, you have got M-Pesa." [52]. However, the veracity of these claims is unknown.

2.1 Comparison to Other Services

Mobile money is closely related to other technologies. Figure 2 presents a Venn diagram indicating how representative mobile apps fall into the categories of mobile payments, mobile wallets, and branchless banking systems. Most mobile finance systems share the ability to make payments to other individuals or merchants. In our study, the mobile apps for these finance systems are distinguished as follows:

- **Mobile Payment** describes systems that allow a mobile device to make a payment to an individual or merchant using *traditional banking infrastructure*. Example systems include PayPal, Google Wallet, Apple Pay, Softpay (formerly ISIS), CurrentC, and Square Cash. These systems acting as an intermediary for an existing credit card or bank account.

- **Mobile Wallets** store multiple payment credentials for either mobile money or mobile payment systems and/or facilitate promotional offers, discounts, or loyalty programs. Many mobile money systems (like Oxigen Wallet, analyzed in this paper) and mobile payment systems (like Google Wallet and Apple Pay) are also mobile wallets.

- **Branchless Banking** is designed around policies that facilitate easy inclusion. Enrollment often simply requires just a phone number or national ID number be entered into the mobile money system. These systems have no minimum balances and low transaction fees, and feature reduced "Know Your Customer"[1] regulations [51]. Another key feature of branchless banking systems is that in many cases they do not rely on Internet (IP) connectivity exclusively, but also use SMS, Unstructured Supplementary Service Data (USSD), or cellular voice (via Interactive Voice Response, or IVR) to conduct transactions. While methods for protecting data confidentiality and integrity over IP are well established, the channel cryptography used for USSD and SMS has been known to be vulnerable for quite some time [56].

3 App Selection and Analysis

In this section, we discuss how apps were chosen for analysis and how the analysis was conducted.

3.1 Mallodroid Analysis

Using data from the GSMA Mobile Money Tracker [6], we identified a total of 47 Android mobile money apps across 28 countries. We first ran an automated analysis on all 47 of these apps using Mallodroid [28], a static analysis tool for detecting SSL/TLS vulnerabilities, in order to establish a baseline. Table 3 in the appendix provides a comprehensive list of the known Android mobile money applications and their static analysis results. Mallodroid detects vulnerabilities in 24 apps, but its analysis only provides a basic indicator of problematic code; it does not, as we show, exclude dead code or detect major flaws in design. For example, it cannot guarantee that sensitive flows *actually use* SSL/TLS. It similarly cannot detect ecosystem vulnerabilities, including the use of deprecated, vulnerable, or incorrect SSL/TLS configurations on remote servers. Finally, the absence of SSL/TLS does not necessarily condemn an application, as applications can still operate securely using other protocols. Accordingly, such automated analysis provides an incomplete picture at best, and at worst an incorrect one. This is a limitation of all automatic approaches, not just Mallodroid.

In the original Mallodroid paper, its authors performed a manual analysis on 100 of the 1,074 (9.3%) apps their tool detected to verify its findings; however, only 41% of those apps were vulnerable to SSL/TLS man-in-the-middle attacks. It is therefore imperative to further verify the findings of this tool to remove false positives and false negatives.

[1] "Know Your Customer" (KYC), "Anti-Money Laundering" (AML), and "Combating Financing of Terrorism" policies are regulations used throughout the world to frustrate financial crime activity.

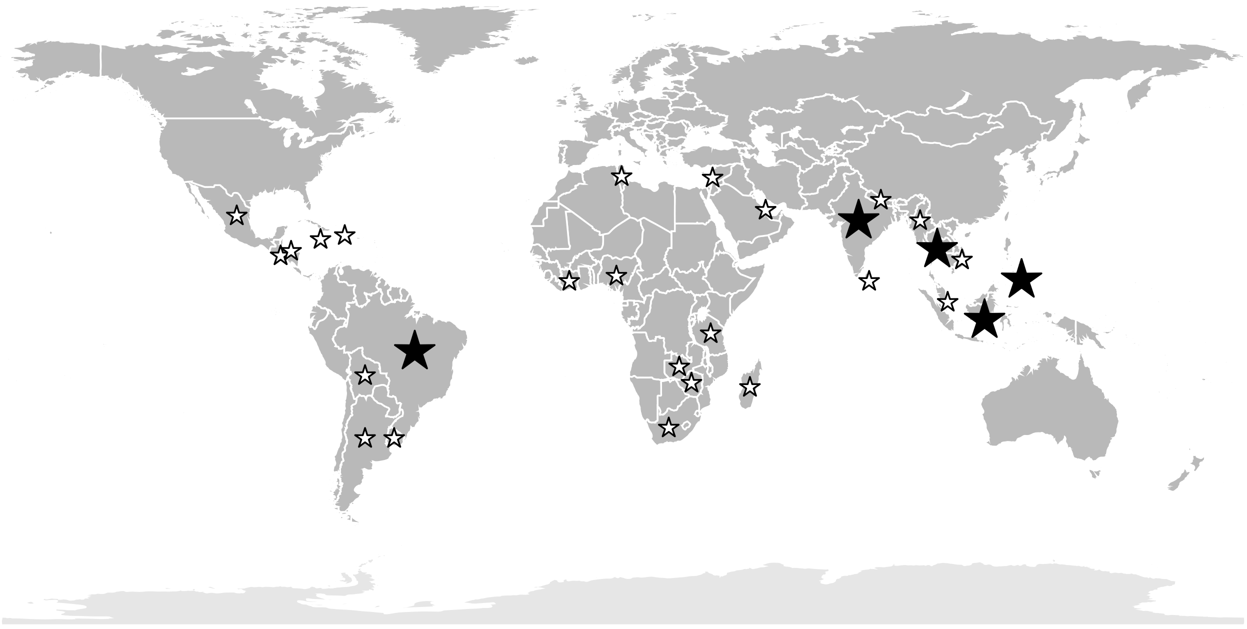

Figure 3: The mobile money applications we analyzed were developed for a diverse range of countries. In total, we performed an initial analysis on applications from 28 countries representing up to approximately 1.2 million users based on market download counts. From this, we selected 7 applications to fully analyze from 5 countries. Each black star represents these countries, and the white stars represent the remainder of the mobile money systems.

3.2 App Selection

Given the above observations, we selected seven mobile money apps for more extensive analysis. These seven apps represent 15% of the total applications and were selected to reflect diversity across markets, providers, features, download counts, and static analysis results. Collectively, these apps serve millions of users. Figure 3 shows the geographic diversity across all of the mobile money apps we observed and those we selected for manual analysis.

We focus on Android applications in this paper because Android has the largest market share worldwide [43], and far more mobile money applications are available for Android than iOS. However, while we cannot make claims about iOS apps that we did not analyze, we do note that all errors disclosed in Section 4 are possible in iOS and are not specific to Android.

3.3 Manual Analysis Process

Our analysis is the first of its kind to perform an in-depth analysis of the protocols used by these applications as well as inspect *both ends* of the SSL/TLS sessions they may use. Each layer of the communication builds on the last; any error in implementation potentially affects the security guarantees of all others. This holistic view of the entire app communication protocol at multiple layers offers a deep view of the fragility of these systems.

In order to accomplish this, our analysis consisted of two phases. The first phase provided an overview of the functionality provided by the app; this included analyzing the application's code and manifest and testing the quality of any SSL/TLS implementations on remote servers. Where possible, we obtained an in-country phone number and created an account for the mobile money system. The overview phase was followed by a reverse engineering phase involving manual analysis of the code. For those apps that we possessed accounts, we also executed the app and verified any findings we found in the code.

Our main interest is in verifying the integrity of these sensitive financial apps. While privacy issues like IMEI or location leakage are concerning [26], we focus on communications between the app and the IP or SMS backend systems, where an adversary can observe, modify, and/or generate transactions.

Phase 1: Inspection

In the inspection phase, we determined the basic functionality and structure of the app in order to guide later analysis. Figure 4 shows the overall toolchain for analyzing the apps along with each respective output.

The first step of the analysis was to obtain the application manifest using `apktool` [2]. We then used an simple script to generate a report identifying each app component (i.e., activities, services, content providers, and

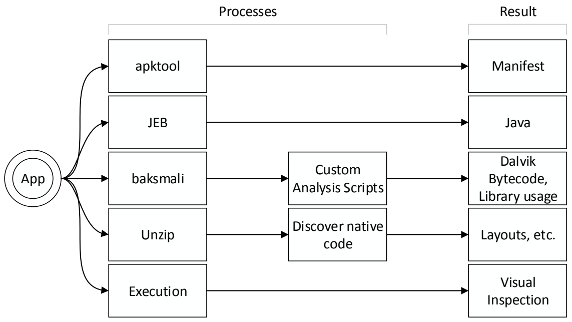

Figure 4: A visualization of the tools used for analyzing the mobile money apps.

broadcast receivers) as well as the permissions declared and defined by the app. This acted as a high-level proxy for understanding the capabilities of the app. With this report, we could note interesting or dangerous permissions (e.g., WRITE_EXTERNAL_STORAGE can leak sensitive information) and which activities are exported to other apps (which can be used to bypass authentication).

The second step of this phase was an automated review of the Dalvik bytecode. We used the `Baksmali` [10] tool to disassemble the application `dex` file. While disassembly provides the Dalvik bytecode, this alone does not assist in reasoning about the protocols, data flows, and behavior of an application. Further inspection is still required to understand the semantic context and interactions of classes and functions.

After obtaining the Dalvik bytecode, we used a script to identify classes that use interesting libraries; these included networking libraries, cryptography libraries (including `java.security` and `javax.crypto` and Bouncy Castle [11]), well-known advertising libraries (as identified by Chen et al. [18]), and libraries that can be used to evade security analysis (like Java ClassLoaders). References to these libraries are found directly in the Dalvik assembly with regular expressions. The third step of the overview was to manually take note of all packages included in the app (external libraries like social media libraries, user interface code, HTTP libraries, etc.).

While analyzing the application's code can provide deep insight into the application's behavior and client/server protocols, it does not provide any indication of the security of the connection as it is negotiated by the server. For example, SSL/TLS servers can offer vulnerable versions of the protocol, weak signature algorithms, and/or expired or invalid certificates. Therefore, the final step of the analysis was to check each application's SSL endpoints using the Qualys SSL Server Test [50].[2] This test provides a comprehensive, non-invasive view of the configuration and capabilities of a server's SSL/TLS implementation.

Phase 2: Reverse Engineering

In order to complete our holistic view of both the application protocols and the client/server SSL/TLS negotiation, we reverse engineered each app in the second phase. For this step, we used the commercial interactive JEB Decompiler [4] to provide Java syntax for most classes. While we primarily used the decompiled output for analysis, we also reviewed the Dalvik assembly to find vulnerabilities. Where we were able to obtain accounts for mobile money accounts, we also confirmed each vulnerability with our accounts when doing so would not negatively impact the service or other users.

Rather than start by identifying interesting methods and classes, we began analysis by following the application lifecycle as the Android framework does, starting with the `Application.onCreate()` method and moving on to the first Activity to execute. From there, we constructed the possible control paths a user can take from the beginning through account registration, login, and money transfer. This approach ensures that our findings are actually present in live code, and accordingly leads to conservative claims about vulnerabilities.[3] After tracing control paths through the `Activity` user interface code, we also analyze other components that appear to have sensitive functionality.

As stated previously, our main interest is in verifying the integrity of these financial applications. In the course of analysis, we look for security errors in the following actions:

- Registration and login
- User authentication after login
- Money transfers

These errors can be classified as:

- Improper authentication procedures
- Message confidentiality and integrity failures (including misuse of cryptography)
- Highly sensitive information leakage (including financial information or authentication credentials)
- Practices that discourage good security hygiene, such as permitting insecure passwords

We discuss our specific findings in Section 4.

3.3.1 Vulnerability Disclosure

As of the publication deadline of this paper we have notified all services of the vulnerabilities. We also included basic details of accepted mitigating practices for each

[2] For security reasons, Qualys does not test application endpoints on non-standard ports or without registered domain names.

[3] In the course of analysis, we found several vulnerabilities in what is apparently dead code. While we disclosed those findings to developers for completeness, we omit them from this paper.

ID	Common Weakness Enumeration	Airtel Money	mPAY	Oxigen Wallet	GCash	Zuum	MOM	mCoin
SSL/TLS & Certificate Verification								
CWE-295	Improper Certificate Validation	✗	✗		✗			✗
Non-standard Cryptography								
CWE-330	Use of Insufficiently Random Values	✗		✗	✗			
CWE-322	Key Exchange without Entity Authentication			✗			✗	
Access Control								
CWE-88	Argument Injection or Modification		✗					
CWE-302	Authentication Bypass by Assumed-Immutable Data			✗	✗			
CWE-521	Weak Password Requirements				✗			
CWE-522	Insufficiently Protected Credentials						✗	
CWE-603	Use of Client-Side Authentication						✗	
CWE-640	Weak Password Recovery Mechanism for Forgotten Password			✗				
Information Leakage								
CWE-200	Information Exposure			✗			✗	✗
CWE-532	Information Exposure Through Log Files		✗		✗		✗	
CWE-312	Cleartext Storage of Sensitive Information		✗		✗			✗
CWE-319	Cleartext Transmission of Sensitive Information			✗	✗		✗	

Table 1: Weaknesses in Mobile Money Applications, indexed to corresponding Common Weakness Enumeration (CWE) records. The CWE database is a comprehensive taxonomy of software vulnerabilities developed by MITRE [55] and provide a common language for software errors.

finding. Most have not sent any response to our disclosures. We have chosen to publicly disclose these vulnerabilities in this paper out of an obligation to inform users of the risks they face in using these insecure services.

4 Results

This section details the results of analyzing the mobile money applications. Overall, we find 28 significant vulnerabilities across seven applications. Table 1 shows these vulnerabilities indexed by CWE and broad categories (apps are ordered by download count). All but one application (Zuum) presents at least one major vulnerability that harmed the confidentiality of user financial information or the integrity of transactions, and most applications have difficulty with the proper use of cryptography in some form.

4.1 Automated Analysis

Our results for SSL/TLS vulnerabilities should mirror the output of an SSL/TLS vulnerability scanner such as Mallodroid. Though two applications were unable to be analyzed by Mallodroid, it detects at least one critical vulnerability in over 50% of the applications it successfully completed.

Mallodroid produces a false positive when it detects an SSL/TLS vulnerability in Zuum, an application that, through manual analysis, we verified was correctly performing certificate validation. The Zuum application *does contain* disabled certificate validation routines, but these are correctly enclosed in logic that checks for development modes.

Conversely, in the case of MoneyOnMobile, Mallodroid produces a false negative. MoneyOnMobile contains no SSL/TLS vulnerability because it does not employ SSL/TLS. While this can be considered correct operation of Mallodroid, it also does not capture the severe information exposure vulnerability in the app.

Overall, we find that Mallodroid, an extremely popular analysis tool for Android apps, does not detect the *correct* use of SSL/TLS in an application. It produces an alert for the most secure app we analyzed and did not for the least. In both cases, manual analysis reveals stark differences between the Mallodroid results and the real security of an app. A comprehensive, correct analysis must include a review of the application's validation and actual use of SSL/TLS sessions as well as *where* these are used in the application (e.g., used for all sensitive communications). Additionally, it is critical to understand whether the remote server enforces secure protocol versions, ciphers, and hashing algorithms. Only a manual analysis provides this holistic view of the communication between application and server so that a complete security evaluation can be made.

4.2 SSL/TLS

As we discussed above, problems with SSL/TLS certificate validation represented the most common vulnerability we found among apps we analyzed. Certificate validation methods inspect a received certificate to ensure that it matches the host in the URL, that it has a trust chain that terminates in a trusted certificate authority, and that it has not been revoked or expired. However, developers are able to disable this validation by creating a new class that implements the `X509TrustManager` interface using arbitrary validation methods, replacing the validation implemented in the parent library. In the applications that override the default code, the routines were empty; that is, they *do nothing* and do not throw excep-

Product	Qualys Score	Most Noteworthy Vulnerabilities
Airtel Money	A-	Weak signature algorithm (SHA1withRSA)
mPAY 1	F	SSL2 support, Insecure Client-Initiated Renegot.
mPAY 2	F	Vulnerable to POODLE attack
Oxigen Wallet	F	SSL2 support, MD5 cipher suite
Zuum	A-	Weak signature algorithm (SHA1withRSA)
GCash	C	Vulnerable to POODLE attack
mCoin	N/A	Uses expired, `localhost` self-signed certificate
MoneyOnMobile	N/A	App does not use SSL/TLS

Table 2: Qualys reports for domains associated with branchless banking apps. “Most Noteworthy Vulnerabilities” lists what Qualys considers to be the most dangerous elements of the server’s configuration. mPAY contacts two domains over SSL, both of which are separately tabulated below. Qualys would not scan mCoin because it connects to a specific IP address, not a domain.

tions on invalid certificates. This insecure practice was previously identified by Georgiev et al. [31] and is specifically targeted by Mallodroid.

Analyzing only the app does not provide complete visibility to the overall security state of an SSL/TLS session. Server misconfiguration can introduce additional vulnerabilities, even when the client application uses correctly implemented SSL/TLS. To account for this, we also ran the Qualys SSL Server Test [50] on each of the HTTPS endpoints we discovered while analyzing the apps. This service tests a number of properties of each server to identify configuration and implementation errors and provide a “grade” for the configuration. These results are presented in Table 2. Three of the endpoints we tested received failing scores due to insecure implementations of SSL/TLS. To underscore the severity of these misconfigurations, we have included the “Most Noteworthy Vulnerabilities” identified by Qualys.

mCoin. Coupling the manual analysis with the Qualys results, we found that in one case, the disabled validation routines were required for the application to function correctly. The mCoin API server provides a certificate that is issued to “localhost” (an invalid hostname for an external service), is expired, and is self-signed (has no trust chain). *No correct certificate validation routine would accept this certificate*. Therefore, without this routine, the mCoin application would be unable to establish a connection to its server. Although Mallodroid detected the disabled validation routines, only our full analysis can detect the relationship between the app’s behavior and the server’s configuration.

The implications of poor validation practices are severe, especially in these critical financial applications. Adversaries can intercept this traffic and sniff cleartext personal or financial information. Furthermore, without additional message integrity checking inside these weak SSL/TLS sessions, a man-in-the-middle adversary is free to manipulate the inside messages.

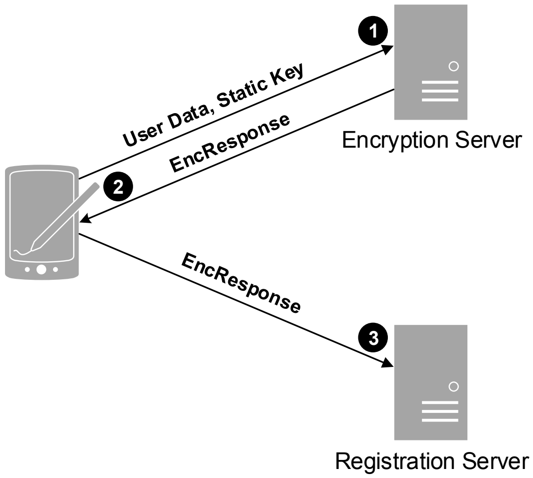

Figure 5: The user registration flow of MoneyOnMobile. All communication is over HTTP.

4.3 Non-Standard Cryptography

Despite the pervasive insecure implementations of SSL/TLS, the client/server protocols that these apps implement are similarly critical to their overall security. We found that four applications used their own custom cryptographic systems or had poor implementations of well-known systems in their protocols. Unfortunately, these practices are easily compromised and severely limit the integrity and privacy guarantees of the software, giving rise to the threat of forged transactions and loss of transaction privacy.

MoneyOnMobile. MoneyOnMobile does not use SSL/TLS. All API calls from the app use HTTP. In fact, we found only one use of cryptography in the application’s network calls. During the user registration process, the app first calls an encryption proxy web service, then sends the service’s response to a registration web service. The call to the encryption server includes both the user data and a fixed static key. A visualization of this protocol is shown in Figure 5.

The encryption server is accessed over the Internet via HTTP, exposing both the user and key data. Because this data is exposed during the initial call, its subsequent encryption and delivery to the registration service provides no security. We found no other uses of this or any other encryption in the MoneyOnMobile app; all other API calls are provided unobfuscated user data as input.

Oxigen Wallet. Like MoneyOnMobile, Oxigen Wallet does not use SSL/TLS. Oxigen Wallet’s registration messages are instead encrypted using the Blowfish algorithm, a strong block cipher. However, a long, random key is not generated for input into Blowfish. Instead, only 17 bits of the key are random. The remaining bits are filled by the mobile phone number, the date, and padding with 0s. The random bits are generated by the Random [34] random number generator. The standard Java documentation [44] *explicitly warns* in its documentation that Random is not sufficiently random for cryptographic key generation.[4] As a result, any attacker can read, modify, or spoof messages. These messages contain demographic information including first and last name, email address, date of birth, and mobile phone number, which constitutes a privacy concern for Oxigen Wallet's users.

After key generation, Oxigen Wallet transmits the key in plaintext along with the message to the server. In other words, every encrypted registration message *includes the key in plaintext*. Naturally, this voids every guarantee of the block cipher. In fact, any attacker who can listen to messages can decrypt and modify them with only a few lines of code.

The remainder of client-server interactions use an RSA public key to send messages to the server. To establish an RSA key for the server, Oxigen Wallet sends a simple HTTP request to receive an RSA key from the Oxigen Wallet server. This message is unauthenticated, which prevents the application from knowing that the received key is from Oxigen Wallet and not from an attacker. Thus, an attacker can pretend to be Oxigen Wallet and send an alternate key to the app. This would allow the attacker to read all messages sent by the client (including those containing passwords) and forward the messages to Oxigen Wallet (with or without modifications) if desired. This RSA man-in-the-middle attack is severe and puts all transactions by a user at risk. At the very least, this will allow an attacker to steal the password from messages. The password can later be used to conduct illicit transactions from the victim's account.

Finally, responses from the Oxigen Wallet servers are not encrypted. This means that any sensitive information that might be contained in a response (e.g., the name of a transaction recipient) can be read by any eavesdropper. This is both a privacy and integrity concern because an attacker could read and modify responses.

GCash. Unlike Oxigen Wallet, GCash uses a static key for encrypting communcations with the remote server. The GCash application package includes a file "enc.key," which contains a symmetric key. During the GCash login process, the user's PIN and session ID are encrypted using this key before being sent to the GCash servers. This key is posted publicly because it is included with every download of GCash. An attacker with this key can decrypt the user's PIN and session ID if the encrypted data is captured. This can subsequently give the attacker the ability to impersonate the user.

The session ID described above is generated during the login process and passed to the server to provide session authentication in subsequent messages. We did not find any other authenticator passed in the message body to the GCash servers after login. The session ID is created using a combination of the device ID, e.g., International Mobile Station Equipment Identity (IMEI), and the device's current date and time. Android will provide this device ID to any application with the READ_PHONE_STATE permission, and device IDs can be spoofed on rooted phones. Additionally, IMEI is frequently abused by mobile apps for persistent tracking of users [25], and is thus also stored in the databases of hundreds of products.

Although the session ID is not a cryptographic construct, the randomness properties required by a strong session ID match those needed by a strong cryptographic key. This lack of randomness results in predictable session IDs can then be used to perform any task as the session's associated user.

Airtel Money. Airtel Money performs a similar mistake while authenticating the user. When launching the application, the client first sends the device's phone number to check if there is an existing Airtel Money account. If so, the server sends back the user's account number in its response. Although this response is transmitted via HTTPS, the app does not validate certificates, creating a compound vulnerability where this information can be discovered by an attacker.

Sensitive operations are secured by the user's 4-digit PIN. The PIN is encrypted in transit using a weakly-constructed key that concatenates the device's phone number and account number in the following format:

$$Key_{enc} = \texttt{j7zgy1yv} \,\|\, phone\# \,\|\, account\# \qquad (1)$$

The prefixed text in the key is immutable and included with the application. Due to the weak SSL/TLS implementation during the initial messages, an adversary can obtain the user's account number and decrypt the PIN. The lack of randomness in this key again produces a vulnerability that can lead to user impersonation.

4.4 Access Control

A number of the applications that we analyzed used access control mechanisms that were poorly implemented or relied on incorrect or unverifiable assumptions that the user's device and its cellular communications channels are uncompromised. Multiple applications relied on SMS communications, but this channel is subject to a number of points of interception [56]. For example, another application on the device with the RECEIVE_SMS

[4] Although the Android offers a SecureRandom class for cryptographically-secure generation, it does not mention its necessity in the documentation.

permission could read the incoming SMS messages of the mobile money application. This functionality is outside the control of the mobile money application. Additionally, an attacker could have physical access to an unlocked phone, where messages can be inspected directly by a person. This channel does not, therefore, provide strong confidentiality or integrity guarantees.

MoneyOnMobile. The MoneyOnMobile app presents the most severe lack of access control we found among the apps we analyzed. The service uses two different PINs, the MPIN and TPIN, to authenticate the user for general functionality and transactions. However, we found that these PINs only prevent the user from moving between Android activities. In fact, the user's PINs are not required to execute any sensitive functionality via the backend APIs. All sensitive API calls (e.g., balance inquiry, mobile recharge, bill pay, etc.) except PIN changes can be executed with *only knowledge of the user's mobile phone number and two API calls.* MoneyOnMobile deploys no session identifiers, cookies, or other stateful tracking mechanisms during the app's execution; therefore, none of these are required to exploit the service.

The first required API call takes the mobile number as input and outputs various parameters of the account (e.g., Customer ID). These parameters identify the account as input in the subsequent API call. Due to the lack of any authentication on these sensitive functions, an adversary with no knowledge of the user's account can execute transactions on the user's behalf. Since the initial call provides information about a user account, this call allows an adversary to brute force phone numbers in order to find MoneyOnMobile users. This call also provides the remainder of the information needed to perform transactions on the account, severely compromising the security of the service.

mPAY. While the MoneyOnMobile servers do not require authentication before performing server tasks, we found the opposite is true with mPAY. The mPAY app accepts and performs unauthenticated commands from its server. The mPAY app uses a web/native app hybrid that allows the server to send commands to the app through the use of a URL parameter "method." These methods instruct the app to perform many actions, including starting the camera, opening the browser to an arbitrary URL, or starting an arbitrary app. If the control flow of the web application from the server side is secure, and the HTTP channel between client and server is free from injection or tampering, it is unlikely that these methods could be harmful. However, if an attacker can modify server code or redirect the URL, this functionality could be used to attack mobile users. Potential attacks include tricking users into downloading malware, providing information to a phishing website, or falling victim to a cross-site request forgery (CSRF) attack. As we discussed in the previous results, mPAY does not correctly validate the certificates used for its SSL/TLS sessions, and so these scenarios are unsettlingly plausible.

GCash. Although GCash implements authentication, it relies on easily-spoofable identity information to secure its accounts. During GCash's user registration process, the user selects a PIN for future authentication. The selected PIN is sent in plaintext over SMS along with the user's name and address. GCash then identifies the user with the phone number used to send the SMS message. This ties the user's account to their phone's SIM card. Unfortunately, SMS spoofing services are common, and these services provide the ability for an unskilled adversary to send messages appearing to be from an arbitrary number [27]. SIM cards can be damaged, lost, or stolen, and since the wallet balance is tied to this SIM, it may be difficult for a user to reclaim their funds.

Additionally, GCash requires the user to select a 4-digit PIN to register an account. As previously mentioned, this PIN is used to authenticate the user to the service. This allows only 10,000 possible combinations of PINs, which is quickly brute-forceable, though more intelligent guessing can be performed using data on the frequency of PIN selection [16]. We were not able to create an account with GCash to determine if the service locks accounts after a number of incorrect login attempts, which is a partial mitigation for this problem.

Oxigen Wallet. Like GCash, Oxigen Wallet also allows users to perform several sensitive actions via SMS. The most severe of these is requesting a new password. As a result, any attacker or application with access to a mobile phone's SMS subsystem can reset the password. That password can be used to login to the app or to send SMS messages to Oxigen Wallet for illicit transactions.

4.5 Information Leakage

Several of the analyzed applications exposed personally-identifying user information and/or data critical to the transactional integrity through various methods, including logging and preference storage.

4.5.1 Logging

The Android logging facility provides developers the ability to write messages to understand the state of their application at various points of its execution. These messages are written to the device's internal storage so they can be viewed at a future time. If the log messages were visible only to developers, this would not present the opportunity for a vulnerability. However, prior to Android 4.1, any application can declare the READ_LOGS permission and read the log files of any other application. That is, any arbitrary application (including malicious ones) may read the logs. According to statistics from Google [32], 20.7% of devices run a version of Android that allows other apps to read logs.

mPAY. mPAY logs include user credentials, personal identifiers, and card numbers.

GCash. GCash writes the plaintext PIN using the verbose logging facility. The Android developer documentation states that verbose logging should not be compiled into production applications [33]. Although GCash has a specific `devLog` function that only writes this data when a debug flag is enabled, there are still statements without this check. Additionally, the session ID is also logged using the native Android logging facility without checking for a developer debug flag. An attacker with GCash log access can identify the user's PIN and the device ID, which could be used to impersonate the user.

MoneyOnMobile. These logs include server responses and account balances.

4.5.2 Preference Storage

Android provides a separate mechanism for storing preferences. This system has the capability of writing the stored preferences to the device's local storage, where they can be recovered by inspecting the contents of the preferences file. Often, developers store preferences data in order to access it across application launches or from different sections of the code without needing to explicitly pass it. While the shared preferences are normally protected from the user and other apps, if the device is rooted (either by the user or a malicious application) the shared preferences file can be read.

GCash. GCash stores the user's PIN in this system. The application clears these preferences in several locations in the code (e.g., logout, expired sessions), however if the application terminates unexpectedly, these routines may not be called, leaving this sensitive information on the device.

mPAY. Similarly, mPAY stores the mobile phone number and customer ID in its preferences.

mCoin. Additionally, mCoin stores the user's name, birthday, and certain financial information such as the user's balance. We also found that mCoin exposes this data in transmission. Debugging code in the mCoin application is also configured to forward the user's mCoin shared preferences to the server with a debug report. As noted above, this may contain the user's personal information. This communication is performed over HTTP and sent in plaintext, providing no confidentiality for the user's data in transmission.

4.5.3 Other Leakage

Oxigen Wallet. We discussed in Section 4.3 that requests from the Oxigen Wallet client are encrypted (insecurely) with either RSA or Blowfish. Oxigen Wallet also discloses mobile numbers of account holders. On sign up, Oxigen Wallet sends a `GetProfile` request to a server to determine if the mobile number requesting a new account is already associated with an email address. The client sends an email address, and the server sends a full mobile number back to the client. The application does appear to understand the security need for this data as only the last few digits of the mobile number are shown on the screen (the remaining digits are replaced by `X`s). However, it appears that the full mobile number is provided in the network message. This means that if an attacker could somehow read the full message, he could learn the mobile number associated with the email address.

Unfortunately, the `GetProfile` request can be sent using the Blowfish encryption method previously described, meaning that an attacker could write his own code to poll the Oxigen Wallet servers to get mobile numbers associated with known email addresses. This enumeration could be used against a few targets or it may be done in bulk as a precursor to SMS spam, SMS phishing, or voice phishing. This bulk enumeration may also tax the Oxigen Wallet servers and degrade service for legitimate users. This attack would not be difficult for an attacker with even rudimentary programming ability.

4.6 Zuum

Zuum is a Brazilian mobile money application built by Mobile Financial Services, a partnership between Telefonica and MasterCard. While many of the other apps we analyzed were developed solely by cellular network providers or third-party development companies, MasterCard is an established company with experience building these types of applications.

This app is particularly notable because we did not find in Zuum the major vulnerabilities present in the other apps. In particular, the application uses SSL/TLS sessions with certificate validation enabled and includes a public key and performs standard cryptographic operations to protect transactions inside the session. Mallodroid detects Zuum's disabled certificate validation routines, but our manual analysis determines that these routines would not run. We discuss MasterCard's involvment in the Payment Card Industry standards, the app's terms of service, and the ramifications of compromise in Section 5.

4.7 Verification

We obtained accounts for MoneyOnMobile, Oxigen Wallet, and Airtel Money in India. For each app, we configured an Android emulator instance to forward its traffic through a man-in-the-middle proxy. In order to remain as passive as possible, we did not attempt to verify any transaction functionality (e.g., adding money to the account, sending or receiving money, paying bills, etc.). We were able to successfully verify every vulnerability that we identified for these apps.

5 Discussion

In this discussion section, we make observations about authentication practices and our SSL/TLS findings, regulations governing these apps, and whether smartphone applications are in fact safer than the legacy apps they replace.

Why do these apps use weak authentication? Numeric PINs were the authentication method of choice for the majority of the apps studied — only three apps allow use of a traditional password. This reliance on PINs is likely a holdover from earlier mobile money systems developed for feature phones. While such PINs are known to be weak against brute force attacks, they are chosen for SMS or USSD systems for two usability reasons. First, they are easily input on limited phone interfaces. Second, short numeric PINs remain usable for users who may have limited literacy (especially in Latin alphabets). Such users are far more common in developing countries, and prior research on secure passwords has assumed user literacy [54]. Creating a distinct strong password for the app may be confusing and limit user acceptability of new apps, despite the clear security benefits.

Beyond static PINs, Airtel Money and Oxigen Wallet (both based in India) use SMS-provided one-time passwords to authenticate users. While effective at preventing remote brute-force attacks, this step provides no defense against the other attacks we describe in the previous section.

Why do these apps fail to validate certificates? While this work and prior works have shown that many Android apps fail to properly validate SSL/TLS certificates [28], the high number of branchless banking apps that fail to validate certificates is still surprising, especially given the mission of these apps. Georgiev et al. found that many applications improperly validate certificates, yet identify the root cause as poorly designed APIs that make it easy to make a validation mistake [31]. One possible explanation is that certificate validation was disabled for a test environment which had no valid certificate. When the app was deployed, developers did not test for improper validation and did not remove the test code that disabled host name validation. Fahl et al. found this explanation to be common in developer interviews [29], and they also further explore other reasons for SSL/TLS vulnerabilities, including developer misunderstandings about the purpose of certificate validation.

In the absence of improved certificate management practices at the application layer, one possible defense is to enforce sane SSL/TLS configurations at the operating system layer. This capability is demonstrated by Fahl et al. for Android [29], while Bates et al. present a mechanism for Linux that simultaneously facilitates the use of SSL trust enhancements [15]. In the event that the system trusts compromised root certificates, a solution like DVCert [23] could be used to protect against man in the middle attacks.

Are legacy systems more secure? In Section 7, we noted that prior work had found that legacy systems are fundamentally insecure as they rely principally on insecure GSM bearer channels. Those systems rely on bearer channel security because of the practical difficulties of developing and deploying secure applications to a plethora of feature phone platforms with widely varying designs and computational capabilities. In contrast, we look at apps developed for relatively homogenous, well-resourced smartphones. One would expect that the advanced capabilities available on the Android platform would increase the security of branchless banking apps. However, given the vulnerabilities we disclose, the branchless banking apps we studied for Android put users at a *greater* risk than legacy systems. Attacking cellular network protocols, while shown to be practical [56], still has a significant barrier to entry in terms of equipment and expertise. In contrast, the attacks we disclose in this paper require only a laptop, common attack tools, and some basic security experience to discover and exploit. Effectively, these attacks are easier to exploit than the previously disclosed attacks against SMS and USSD interfaces.

Does regulation help? In the United States, the PCI Security Standards Council releases a Data Security Standard (PCI DSS) [48], which govern the security requirements for entities that handle cardholder data (e.g., card numbers and expiration dates). The council is a consortium of card issuers including Visa, MasterCard, and others that cooperatively develop this standard. Merchants that accept credit card payments from these issuers are generally required to adhere to the PCI DSS and are subject to auditing.

The DSS document includes requirements, testing procedures, and guidance for securing devices and networks that handle cardholder data. These are not, however, specific enough to include detailed implementation instructions. The effectiveness of these standards is not our main focus; we note that the PCI DSS can be used as a checklist-style document for ensuring well-rounded security implementations.

In 2008, the Reserve Bank of India (RBI) issued guidelines for mobile payment systems [13]. (By their definition, the apps we study would be included in these guidelines). In 12 short pages, they touch on aspects as broad as currencies allowed, KYC/AML policies, interbank settlement policies, corporate governance approval, legal jurisdiction, consumer protection, and technology and security standards for a myriad of delivery channels. The security standards give implementers wide leeway to use their best judgement about specific security practices. MoneyOnMobile, which had the most severe security issues among all of the apps we manually analyzed, prominently displays its RBI authorization on its web site.

Some prescriptions stand out from the rest: an objective to have "digital certificate based inquiry/transaction capabilities," a recommendation to have a mobile PIN that is encrypted on the wire and never stored in cleartext, and use of the mobile phone number as the chief identifier. These recommendations may be responsible for certain design decisions of Airtel Money and Oxigen Wallet (both based in India). For example, the digital certificate recommendation may have driven Oxigen Wallet developers to develop their (very flawed) public key encryption architecture. These recommendations also explain why Airtel Money elected to further encrypt the PIN (and only the PIN) in messages that are encapsulated by TLS. Further, the lack of guidance on what "strong encryption" entails may be partially responsible for the security failures of Airtel Money and Oxigen Wallet. Finally, we note that we believe that Airtel Money, while still vulnerable, was within the letter of the recommendations.

To our knowledge, other mobile money systems studied in this paper are not subject to such industry or government regulation. While a high-quality, auditable industry standard may lead to improved branchless banking security, it is not clear that guidelines like RBI's currently make much of a difference.

6 Terms of Service & Consumer Liability

After uncovering technical vulnerabilities for branchless banking, we investigated their potential implications for fraud liability. In the United States, the consumer is not held liable for fraudulent transactions beyond a small amount. This model recognizes that users are vulnerable to fraud that they are powerless to prevent, combat, or detect prior to incurring losses.

To determine the model used for the branchless banking apps we studied, we surveyed the Terms of Service (ToS) for each of the seven analyzed apps analyzed. The Airtel Money [1], GCash [3], mCoin [5], Oxigen Wallet [9], MoneyOnMobile [7], and Zuum [12] terms all hold the customer solely responsible for most forms of fraudulent activity. Each of these services hold the customer responsible for the safety and security of their password. GCash, mCoin, and Oxigen Wallet also hold the customer responsible for protecting their SIM (i.e., mobile phone). GCash provides a complaint system, provided that the customer notifies GCash in writing within 15 days of the disputed transaction. However, they also make it clear that erroneous transactions are not grounds for dispute. mPAY's terms [8] are less clear on the subject of liability; they provide a dispute resolution system, but do not detail the circumstances for which the customer is responsible. Across the body of these terms of service, it is overwhelmingly clear that the customer is responsible for all transactions conducted with their PIN/password on their mobile device.

The presumption of customer fault for transactions is at odds with the findings of this work. The basis for these arguments appear to be that, if a customer protects their PIN and protects their physical device, there is no way for a third party to initiate a fraudulent transaction. We have demonstrated that this is not the case. Passwords can be easily recovered by an attacker. Six of the seven apps we manually analyzed transmits authentication data over insecure connections, allowing them to be recovered in transit. Additionally, with only brief access to a customer's phone, an attacker could read GCash PINs out of the phone logs or trigger the Oxigen Wallet password recovery mechanism. Even when the mobile device and SIM card are fully under customer control, unauthorized transactions can still occur, due to the pervasive vulnerabilities found in these six apps. By launching a man-in-the-middle attack, an adversary would be able to tamper with transactions while in transit, misleading the provider into believing that a fraudulent transaction originated from a legitimate user. *These attacks are all highly plausible.* Exploits of the identified vulnerabilities are not probabilistic, but would be 100% effective. With only minimal technical capability, an adversary could launch these attacks given the ability to control a local wireless access point. This litany of vulnerabilities comes only from an analysis of client-side code. Table 2 hints that there may be further server side configuration issues, to say nothing of the security of custom server software, system software, or the operating systems used.

Similar to past findings for the "Chip & Pin" credit card system [40], it is possible that these apps are already being exploited in the wild, leaving consumers with no recourse to dispute fraudulent transactions. Based on the discovery of rampant vulnerabilities in these applications, we feel that the liability model for branchless banking applications must be revisited. Providers must not marry such vulnerable systems with a liability model that refuses to take responsibility for the technical flaws, and these realities could prevent sustained growth of branchless banking systems due to the high likelihood of fraud.

7 Related Work

Banking has been a motivation for computer security since the origins of the field. The original Data Encryption Standard was designed to meet the needs of banking and commerce, and Anderson's classic paper "Why Cryptosystems Fail" looked specifically at banking security [14]. Accordingly, mobile money systems have been scrutinized by computer security practitioners. Current research on mobile money systems to-date has focused on the challenges of authentication, channel security, and transaction verification in legacy systems designed for feature phones. Some prior work has provided threat modeling and discussion of broader system-wide security issues. To our knowledge, we are the first to examine the security of smartphone applications used by mobile money systems.

Mobile money systems rely on the network to provide identity services; in essence, identity is the telephone number (MS-ISDN) of the subscriber. To address physical access granting attackers access to accounts, researchers have investigated the use of a small one-time pads as authenticators in place of PINs. Panjwani et al. [47] present a new scheme that avoids vulnerabilities with using one-time passwords with PINs and SMS. Sharma et al. propose using scratch-off one-time authenticators for access with supplemental recorded voice confirmations [53]. These schemes add complexity to the system while only masking the PIN from an adversary who can see a message. These schemes do not provide any guarantees against an adversary who can modify messages or who recovers a message and a pad.

SMS-based systems, in particular, are vulnerable to eavesdropping or message tampering [42], and so have seen several projects to bring additional cryptographic mechanisms to mobile money systems [20, 41, 22]. Systems that use USSD, rather than SMS, as their bearer channel can also use code executing on the SIM card to cryptographically protect messages. However, it is unknown how these protocols are implemented or what guarantees they provide [45].

Finally, several authors have written papers investigating the holistic security of mobile money systems designed exclusively for "dumbphones." Paik et al. [45] note concerns about reliance on GSM traffic channel cryptographic guarantees, including the ability to intercept, replay, and spoof the source of SMS messages. Panjwani fulfills the goals laid out by Paik et al. by providing a brief threat model and a design to protect against the threats they identify [46]. While those papers focus on technical analysis, de Almeida [38] and Harris et al. [35] note the policy implications of the insecurity of mobile money.

While focused strictly on mobile money platforms, this paper also contributes to the literature of Android application security measurement. The pioneering work in this space was TaintDroid [25, 25], a dynamic analysis system that detected private information leakages. Shortly after, Felt et al. found that one-third of apps studied held privileges they did not need [30], while Chin et al. found that 60% of apps manually examined were vulnerable to attacks involving Android Intents [19]. More recently, Fahl et al. [28] and Egele et al. [24] use automated static analysis investigated cryptographic API use in Android, finding respectively that 8% of apps studied were vulnerable to man-in-the-middle attacks and that 88% of apps make some mistake with regards to cryptographic libraries [24]. Our work confirms these results apply to mobile money applications. This project is most similar to the work of Enck et al. [26], who automatically and manually analyzed 1,100 applications for a broad range of security concerns.

However, prior work does not investigate the security guarantees and the severe consequences of smart phone application compromise in branchless banking systems. Our work specifically investigates this open area of research and provides the world's first detailed security analysis of mobile money apps. In doing so, we demonstrate the risk to users who rely on these systems for financial security.

8 Conclusions

Branchless banking applications have and continue to hold the promise to improve the standard of living for many in the developing world. By enabling access to a cashless payment infrastructure, these systems allow residents of such countries to reap the benefits afforded to modern economies and decrease the physical security risks associated with cash transactions. However, the security of the applications providing these services has not previously been vetted in a comprehensive or public fashion. In this paper, we perform precisely such an analysis on seven branchless banking applications, balancing both popularity with geographic representation. Our analysis targets the registration, login, and transaction portions of the representative applications, and codifies discovered vulnerabilities using the CWE classification system. We find significant vulnerabilities in six of the seven applications, which prevent both users and providers from reasoning about the integrity of transactions. We then pair these technical findings with the discovery of fraud liability models that explicitly hold the end user culpable for all fraud. Given the systemic problems we identify, we argue that dramatic improvements to the security of branchless banking applications are imperative to protect the mission of these systems.

Acknowledgments

The authors are grateful to Saili Sahasrabudde for her assistance with this work. We would also like to thank the members of the SENSEI Center at the University of Florida for their help in preparing this work, as well as our anonymous reviewers for their helpful comments.

Measuring the Longitudinal Evolution of the Online Anonymous Marketplace Ecosystem

Kyle Soska and Nicolas Christin
Carnegie Mellon University
{ksoska, nicolasc}@cmu.edu

Abstract

February 2011 saw the emergence of Silk Road, the first successful online anonymous marketplace, in which buyers and sellers could transact with anonymity properties far superior to those available in alternative online or offline means of commerce. Business on Silk Road, primarily involving narcotics trafficking, rapidly boomed, and competitors emerged. At the same time, law enforcement did not sit idle, and eventually managed to shut down Silk Road in October 2013 and arrest its operator. Far from causing the demise of this novel form of commerce, the Silk Road take-down spawned an entire, dynamic, online anonymous marketplace ecosystem, which has continued to evolve to this day. This paper presents a long-term measurement analysis of a large portion of this online anonymous marketplace ecosystem, including 16 different marketplaces, over more than two years (2013–2015). By using long-term measurements, and combining our own data collection with publicly available previous efforts, we offer a detailed understanding of the growth of the online anonymous marketplace ecosystem. We are able to document the evolution of the types of goods being sold, and assess the effect (or lack thereof) of adversarial events, such as law enforcement operations or large-scale frauds, on the overall size of the economy. We also provide insights into how vendors are diversifying and replicating across marketplaces, and how vendor security practices (e.g., PGP adoption) are evolving. These different aspects help us understand how traditional, physical-world criminal activities are developing an online presence, in the same manner traditional commerce diversified online in the 1990s.

1 Introduction

In February 2011, a new Tor hidden service [16], called "Silk Road," opened its doors. Silk Road portrayed itself as an online anonymous marketplace, where buyers and sellers could meet and conduct electronic commerce transactions in a manner similar to the Amazon Marketplace, or the fixed price listings of eBay. The key innovation in Silk Road was to guarantee stronger anonymity properties to its participants than any other online marketplace. The anonymity properties were achieved by combining the network anonymity properties of Tor hidden services—which make the IP addresses of both the client and the server unknown to each other and to outside observers—with the use of the pseudonymous, decentralized Bitcoin electronic payment system [33]. Silk Road itself did not sell any product, but provided a feedback system to rate vendors and buyers, as well as escrow services (to ensure that transactions were completed to everybody's satisfaction) and optional hedging services (to buffer fluctuations in the value of the bitcoin).

Embolden by the anonymity properties Silk Road provided, sellers and buyers on Silk Road mostly traded in contraband and narcotics. While Silk Road was not the first venue to allow people to purchase such goods online—older forums such at the Open Vendor Database, or smaller web stores such as the Farmer's Market predated it—it was by far the most successful one to date at the time due to its (perceived) superior anonymity guarantees [13]. The Silk Road operator famously declared in August 2013 in an interview with Forbes, that the "War on Drugs" had been won by Silk Road and its patrons [18]. While this was an overstatement, the business model of Silk Road had proven viable enough that competitors, such as Black Market Reloaded, Atlantis, or the Sheep Marketplace had emerged.

Then, in early October 2013, Silk Road was shut down, its operator arrested, and all the money held in escrow on the site confiscated by law enforcement. Within the next couple of weeks, reports of Silk Road sellers and buyers moving to Silk Road's ex-competitors (chiefly, Sheep Marketplace and Black Market Reloaded) or starting their own anonymous marketplaces started to surface. By early November 2013, a novel incarnation of Silk Road, dubbed "Silk Road 2.0" was online—set up by former administrators and vendors of the original Silk Road.[1] Within a few months, numerous marketplaces following the same model of offering an online anonymous rendez-vous point for sellers and buyers appeared. These different marketplaces offered various levels of sophistication, durability and specialization (drugs, weapons, counterfeits, financial accounts, ...). At the same time, marketplaces would often disappear, sometimes due to arrests (e.g., as was the case with Utopia [19]), sometimes voluntarily (e.g., Sheep Marketplace [34]). In other words, the anonymous online marketplace ecosystem had evolved significantly compared to the early days when Silk Road was nearly a monopoly.

In this paper, we present our measurements and analysis of the anonymous marketplace ecosystem over a period of two and a half years between 2013 and 2015. Previous studies either focused on a specific marketplace (e.g., Silk Road [13]), or on simply describing high-level characteristics of certain marketplaces, such as the number of posted listings at a given point in time [15].

By using long-term measurements, combining our own data collection with publicly available previous efforts, and validating the completeness of our dataset using capture and recapture estimation, we offer a much more detailed understanding of the evolution of the online anonymous marketplace ecosystem. In particular, we are able to measure the effect of the Silk Road takedown on the overall sales volume; how reported "scams" in some marketplaces dented consumer confidence; how vendors are diversifying and replicating across marketplaces; and how security practices (e.g., PGP adoption) are evolving. These different aspects paint what we believe is an accurate picture of how traditional, physical-world criminal activities are developing an online presence, in the same manner traditional commerce diversified online in the 1990s.

We discover several interesting properties. Our analysis of the sales volumes demonstrates that as a whole the online anonymous marketplace ecosystem appears to be resilient, on the long term, to adverse events such as law enforcement take-downs or "exit scams" in which the operators abscond with the money. We also evidence stability over time in the types of products being sold and purchased: cannabis-, ecstasy- and cocaine-related products consistently account for about 70% of all sales. Analyzing vendor characteristics shows a mix of highly specialized vendors, who focus on a single product, and sellers who sell a large number of different products. We also discover that vendor population has long-tail characteristics: while a few vendors are (or were) highly successful, the vast majority of vendors grossed less than $10,000 over our entire study interval. This further substantiates the notion that online anonymous marketplaces are primarily competing with street dealers, in the retail space, rather than with established criminal organizations which focus on bulk sales.

The rest of this paper is structured as follows. Section 2 provides a brief overview of how the various online marketplaces we study operate. Section 3 describes our measurement methodology and infrastructure. Section 4 presents our measurement analysis. We discuss limitations of our approach and resulting open questions in Section 5, before introducing the related work in Section 6 and finally concluding in Section 7.

2 Online Anonymous Marketplaces

The sale of contraband and illicit products on the Internet can probably be traced back to the origins of the Internet itself, with a number of forums and bulletin board systems where buyers and sellers could interact.

However, online markets have met with considerable developments in sophistication and scale, over the past six years or so, going from relatively confidential "classifieds"-type of listings such as on the Open Vendor Database, to large online anonymous marketplaces. Following the Silk Road blueprint, modern online anonymous markets run as Tor hidden services, which gives participants (marketplace operators and participants such as buyers and sellers) communication anonymity properties far superior to those available from alternative solutions (e.g., anonymous hosting); and use pseudonymous online currencies as payment systems (e.g., Bitcoin [33]) to make it possible to exchange money electronically without the immediate traceability that conventional payment systems (wire transfers, or credit card payments) provide.

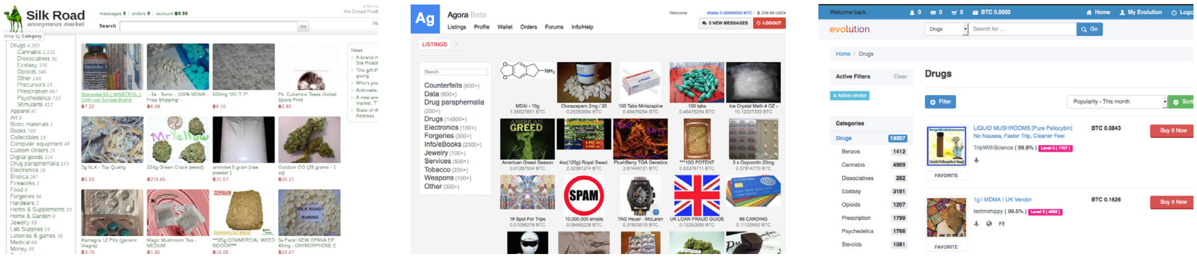
The common point between all these marketplaces is that they actually are not themselves selling contraband. Instead, they are risk management platforms for participants in (mostly illegal) transactions. Risk is mitigated on several levels. First, by abolishing physical interactions between transacting parties, these marketplaces claim to reduce (or indeed, eliminate) the potential for physical violence during the transaction.

Second, by providing superior anonymity guarantees compared to the alternatives, online anonymous marketplaces shield – to some degree[2] – transaction participants from law enforcement intervention.

Third, online anonymous marketplaces provide an escrow system to prevent financial risk. These systems are very similar in spirit to those developed by electronic

[1] Including, ironically, undercover law enforcement agents [7].

[2] Physical items still need to be delivered, which is a potential intervention point for law enforcement as shown in documented arrests [4].



(a) Silk Road (b) Agora (c) Evolution

Figure 1: **Example of marketplaces.** Most marketplaces use very similar interfaces, following the original Silk Road design.

commerce platforms such as eBay or the Amazon Marketplace. Suppose Alice wants to purchase an item from Bob. Instead of directly paying Bob, she pays the marketplace operator, Oscar. Oscar then instructs Bob that he has received the payment, and that the item should be shipped. After Alice confirms receipt of the item, Oscar releases the money held in escrow to Bob. This allows the marketplace to adjudicate any dispute that could arise if Bob claims the item has been shipped, but Alice claims not to have received it. Some marketplaces claim to support Bitcoin's recently standardized "multisig" feature which allows a transaction to be redeemed if, e.g., two out of three parties agree on its validity. For instance, Alice and Bob could agree the funds be transferred without Oscar's explicit blessing, which prevents the escrow funds from being lost if the marketplace is seized or Oscar is incapacitated.[3]

Fourth, and most importantly for our measurements, online anonymous marketplaces provide a feedback system to enforce quality control of the goods being sold. In marketplaces where feedback is mandatory, feedback is a good proxy to derive sales volumes [13]. We will adopt a similar technique to estimate sales volumes.

At the time of this writing the Darknet Stats service [1] lists 28 active marketplaces. As illustrated in Fig. 1 for the Evolution and Agora marketplaces, marketplaces tend to have very similar interfaces, often loosely based on the original Silk Road user interface. Product categories (on the right in each screen capture) are typically self-selected by vendors. We discovered that categories are sometimes incorrectly chosen, which led us to build our own tools to properly categorize items. Feedback data (not shown in the figure) comes in various flavors. Some marketplaces provide individual feedback per product and per transaction. This makes computation of sales volumes relatively easy as long as one can determine with good precision the time at which each piece of feedback was issued. Others provide feedback per vendor; if we can then link vendor feedback to specific items, we can again obtain a good estimate for sales volumes, but if not, we may not be able to derive any meaningful numbers. Last, in some marketplaces, feedback is either not mandatory, or only given as aggregates (e.g., "top 5% vendor"), which does not allow for detailed volume analysis.

3 Measurement methodology

Our measurement methodology consists of 1) crawling online anonymous marketplaces, and 2) parsing them. Table 1 lists all the anonymous marketplaces for which we have data. We scraped 35 different marketplaces a total of 1,908 times yielding a dataset of 3.2 TB in size. The total number of pages obtained from each scrape ranged from 27 to 331,691 pages and performing each scrape took anywhere from minutes up to five days.

The sheer size of the data corpus we are considering, as well as other challenging factors (e.g., hidden service latency and poor marketplace availability) led us to devise a custom web scraping framework built on top of Scrapy [3] and Tor [16], which we discuss first. We then highlight how we decide to parse (or ignore) marketplaces, before touching on validation techniques we use to ensure soundness of our analysis.

3.1 Scraping marketplaces

We designed and implemented the scraping framework with a few simple goals in mind. First, we want our scraping to be carried out in a *stealthy* manner. We do not want to alert a potential marketplace administrator to our presence lest our page requests be censored, by either modifying the content in an attempt to deceive us or denying the request altogether.

[3] The Evolution marketplace claimed to support multisig. However, Evolution's operators absconded with escrow money on March 17th, 2015 [9]; it turns out that their multisig implementation did not function as intended, and was rarely used. Almost none of the stolen funds have been recovered so far.

[4] The November 2011–July 2012 Silk Road data comes from a previously reported collection effort, with publicly available data [13].

Table 1: **Markets crawled.** The table describes which markets were crawled, the time the measurements spanned, and the number of snapshots that were taken. * denote market sites seized by the police, † voluntary shutdowns, and ‡ (suspected) fraudulent closures (owners absconding with escrow money).

Second, we want the scrapes to be *complete*, *instantaneous*, and *frequent*. Scrapes that are instantaneous and complete convey a coherent picture about what is taking place on the marketplace without doubts about possible unobserved actions or the inconsistency that may be introduced by time delay. Scraping very often ensures that we have high precision in dating when actions occurred, and reduces the chances of missing vendor actions, such as listing and rapidly de-listing a given item.

Third we want our scraper to be *reliable* even when the marketplace that we are measuring is not. Even when a marketplace is unavailable for hours, the scraper should hold state and retry to avoid an incomplete capture.

Fourth, the scraper should be capable of handling *client-side state* normally kept by the users browser such as cookies, and be *robust* enough to avoid any detection schemes that might be devised to thwart the scraper. We attempt to address these design objectives as follows.

Avoiding censorship Before we add a site to the scraping regimen, we first manually inspect it and identify its layout. We build and use as input to the scraper a configuration including regular expressions on the URLs for that particular marketplace. This allows us to avoid following links that may cause undesirable actions to be performed such as adding items to a cart, sending messages or logging out. We also provide as input to the scraper a session cookie that we obtain by manually logging into the marketplace and solving a CAPTCHA; and parameters such as the maximum desired scraping rate.

In addition to being careful about what to request from a marketplace, we obfuscate how we request content. For each page request, the scraper randomly selects a Tor circuit out of 20 pre-built circuits. This strategy ensures that the requests are being distributed over several rendezvous points in the Tor network. This helps prevent triggering anti-DDoS heuristics certain marketplaces use.[5] This strategy also provides redundancy in the event that one of the circuits being used becomes unreliable and speeds up the time it takes to observe the entire site.

Completeness, soundness, and instantaneousness The goal of the data collection is to make an observation of the entire marketplace at an instantaneous point in time, which yields information such as item listings, pricing information, feedback, and user pages. Instantaneous observations are of course impossible, and can only be approximated by scraping the marketplace as quickly as possible. Scraping a site aggressively however limits the stealth of the scraper; We manually identified sites that prohibit aggressive scraping (e.g., Agora) and imposed appropriate rate limits.

Scrape completeness is also crucial. A partial scrape of a site may lead to underestimating the activities taking place. Fortunately, since marketplaces leverage feedback to build vendor reputation, old feedback is rarely deleted. This means that it is sufficient for an item listing and its feedback to be eventually observed in order to know that the transaction took place. Over time, the price of an item may fluctuate however, and information about when the transaction occurred often becomes less precise, so it is much more desirable to observe feedback as soon as possible after it is left. We generally attempted a scrape for each marketplace once every two to three days unless the marketplace was either unavailable or the previous scrape had not yet completed; having collected most of the data we were interested in by that time, we scraped considerably less often toward the end of our data collection interval (February through May 2015).

Many marketplaces that we observed have quite poor reliability, with 70% uptime or lower. It is very difficult

[5] However some marketplaces, e.g., Agora, use session cookies to bind requests coming from different circuits, and require additional attention.

to extract entire scrapes from marketplaces suffering frequent outages. This is particularly true for large sites, where a complete scrape can take several days. As a workaround, we designed the scraping infrastructure to keep state and retry pages using an increasing back-off interval for up to 24 hours. Using such a system allowed the scraper to function despite brief outages in marketplace availability. Retrying the site after 24 hours would be futile as in most cases, the session cookie would have expired and the scrape would require a manual login, and thus a manual restart.

Most marketplaces require the user to log in before they are able to view item listings and other sensitive information. Fortunately, creating an account on these marketplaces is free. However, one typically needs to solve a CAPTCHA when logging in; this was done manually. The process of performing a scrape begins with manually logging into the marketplace, extracting the session cookie, and using it as input to the scrape to continue scraping under that session. In many cases the site will fail to respond to requests properly unless multiple cookies are managed or unless the user agent of the scraper matches the user agent of the browser that generated the cookie. We managed to emulate typical browser behavior in all but one case (BlueSky). We were unable to collect meaningful data on BlueSky, as an anti-scraping measure on the server side was to annihilate any session after approximately 100 page requests, and get the user to log in again.

3.2 Parsing marketplaces

The raw page data collected by the scraper needs to be parsed to extract information useful for analysis. The parser first identifies which marketplace a particular page was scraped from; it then determines which type of page is being analyzed (item listing, user page, feedback page, or any combination of those).

Each page is then parsed using a set of heuristics we manually devised for each marketplace. We treat the information extracted as a single *observation* and record it into a database. Information that does not exist or cannot be parsed is assigned default values.

The heuristics for parsing can often become quite complicated as many marketplaces observed over long periods of time went through several iterations of page formats. This justified our conscious decision to decouple scraping from parsing so that we could minimize data loss. Because of the high manual effort associated with creating and debugging new parsers for marketplaces, we only generated parsers for marketplaces that we perceived to be of significance. While observing the scrapes of several marketplaces, it became apparent that their volume was either extremely small (<\$1,000) or was not measurable by observing the website (e.g., because feedback is not mandatory). These marketplaces were omitted without greatly affecting the overall picture; their analysis is left for future work.

3.3 Internally validating data analysis

To ensure that the analysis we performed was not biased, and as a safety against egregious errors, both authors of this paper concurrently and independently developed multiple implementations of the analysis we present in the next section. During that stage of the work, the two authors relied on the same data sources, but used *different* analysis code and tools and did not communicate with each other until all results were produced.

We then internally confirmed that the independent estimations of total market volumes varied by less than 10% at any single point in time, and less than 5% on average, well within expected margin of errors for data indirectly estimated from potentially noisy sources (user feedback).[6] The independent reproducibility of the analysis is important since, as we will show, estimating market volumes presents many pitfalls, such as the risk of double-counting observations or using a holding price as the true value of an item.

3.4 Validating data completeness

The poor availability of certain marketplaces (e.g., Agora), combined with the large amount of time needed to fully scrape very large marketplaces raises concerns about data completeness. We attempt to estimate the amount of data that might be missing through a process known as marking and recapturing.

The basic idea is as follows. Consider that a given site scrape at time t contains a number M of feedback. Since we do not know whether the scrape is complete, we can only assert that M is a lower bound on the total number of feedback F actually present on the site at time t. Now, consider a second scrape (presumably taken after time t), which contains n pieces of feedback left at or before time t. The number n is another lower bound of F. We then estimate F as $\hat{F} = nM/m$, where m is the number of feedback captured in the first scrape that we *also* observe in the second scrape ($m \leq M$).

The Schnabel estimator [36] extends the above technique to estimate the size of a population to multiple samples, and is thus well-suited to our measurements. For n samples, if we denote by C_t the number of feedback in sample t, by M_t the total number of unique previously observed feedback in sample $(t-1)$, and by R_t the

[6] These minor discrepancies can be attributed to slightly different filtering heuristics, which we discuss later.

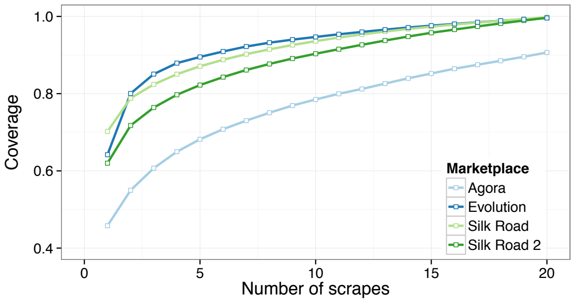

Figure 2: **Coverage of Agora, Silk Road 1, Silk Road 2, and Evolution.** This plot estimates the fraction of all feedback we obtain for a given time, as a function of the number of scrapes we collect.

number of previously observed feedback during sample t, we estimate the total number of feedback at time t as:

$$\hat{F} = \frac{\sum_{t=1}^{n} C_t M_t}{\sum_{t=1}^{n} R_t}\ .$$

The Schnabel estimator implicitly assumes that the distribution is time-invariant and that samples are drawn uniformly. To help ensure time invariance, the estimator begins with a sample at time t. Pieces of feedback with timestamps greater than t are omitted from all samples taken in the future ($t+\tau$). It is also important not to consider samples from too far into the future since items are occasionally de-listed and the corresponding feedback destroyed. To help minimize the impact of feedback deleted in the future, we only use samples within 60 days of t in our estimate.

We illustrate this estimate in Figure 2 for Agora, Silk Road 1, Silk Road 2, and Evolution after multiple observations have been made. Agora has relatively poor reliability and, on average, a single scrape will not manage to capture even half of the feedback present at that time on the site. On other marketplaces it is typical on the first visit to see as much as 60% of the entire population, or higher. After ten or more independent scrapes, we can expect to obtain a dataset that approaches 90% coverage or higher.

Figure 3 further illustrates our point, by comparing the number of pieces of feedback observed on Agora to its estimate. For most of the observed lifetime of Agora, the data that we have is very close to what we estimate the total to be. This is because information about a marketplace at a particular (past) point in time benefits from subsequent observations. Most recent observations do not have this benefit and therefore suffer from poor coverage, leading to significant divergence from their estimate. This results in potentially large underestimations towards the very end of our dataset, which will require us to censor some of this data when estimating volumes.

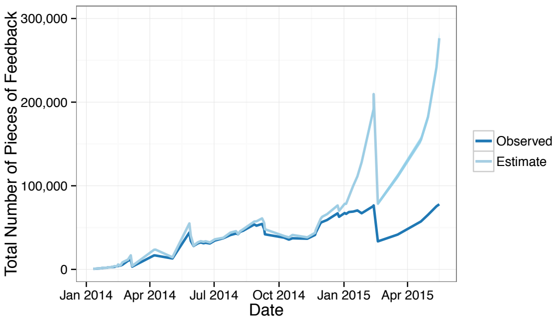

Figure 3: **Observed and estimated number of feedback present on Agora over time.** The lower and upper bounds for the estimate are nearly indistinguishable from the estimate itself.

4 Analysis

We next turn to data analysis. We first estimate the overall evolution of the sales volumes in the entire ecosystem over the past couple of years. We then move to an assessment of the types of products being sold over time. Last, we discuss findings about vendor activity and techniques.

4.1 Sales volumes

The first important question that our analysis answers is how much product in terms of money is being bought and sold on online anonymous marketplaces. While we cannot directly measure the money being transacted from buyers to sellers, or packages being shipped from vendors to customers, we do make frequent observations of product feedback left for particular item listings on the marketplaces. Similar to prior work [13], we use these observations of feedback as a proxy to estimate a lower bound for sales.

Caveats In many marketplaces (e.g., Silk Road, Silk Road 2.0, Agora, Evolution among others) customers are required to leave feedback for a vendor whenever they receive their order of one of the vendor's items. An order for an item may be of varying quantity, so a customer that purchases a single quantity of a product, and a customer that purchases multiple quantities of a product will both leave a single feedback. In an effort to be conservative, we make the assumption that for every feedback observed, only a single quantity was purchased.

Our prudent strategy of estimating sales volume from confirmed observations of feedback diverges from other, simpler approaches, such as counting the number of item listings offered (see, e.g., [15]). For instance, over the observed lifetime of Evolution, a few of the most successful item listings had feedback entries that indicated over 1 million dollars had been spent on each of them. The presence of these highly influential item listings suggests that simply counting the total number of listings on a site is a very poor indicator of sales volume. This claim is compounded by the observation that the average sales per item listing per day on Evolution in early July of 2014 was \$85.14; but by September 2014, after new vendors and item listings had entered, the sales per item listing had declined to \$19.42. Such volatile behavior is particularly common in marketplaces that are small or are going through periods of rapid growth.

Estimation We derived the estimates for the total amount of money transacted in three steps. We first took the set of all feedback observations that had been collected and removed any duplicates. For example, on two consecutive scrapes of a particular marketplace, the same item listing and its entire feedback history were observed and recorded twice. It would be incorrect to count two different observations of the same feedback twice. We thus developed a criterion for uniqueness for each marketplace—typically enforcing uniqueness of fields such as feedback message body, the vendor for which the feedback was left, the title of the item listing and the approximate date the feedback was left. Two pieces of feedback are considered different if and only if they differ in at least one of these categories.

The second step was to identify the the point in time at which the feedback was left. This time is an upper bound on when the transaction occurred. We obtained this estimate by noting the time of the observation and utilizing any information available about the age of the feedback. Different marketplaces have varying precision information about feedback timestamps. In the most precise instances, the time that the feedback was left is specified within the hour; in the most ambiguous cases, we can only infer the month in which feedback was deposited. Fortunately, due to our rather high sampling rate of the marketplaces, in most instances we have roughly a 24-hour accuracy on feedback time.

The third and final step is to identify the value of the transaction that each feedback represents. This involves pairing each feedback observation with a single observation of an item listing and its advertised price. Careful attention must be paid here as a few caveats exist, namely that the advertised price of an item listing varies with time, and that, in some rare cases, the corresponding item is never observed, leaving us unable to identify the value of the transaction.

Item prices change for two different reasons. The first and most common reason is that the vendors responsible for selling items are subject to standard free market pressures and may raise or lower their prices in response to competition, supply, demand, or other factors. The second reason is that when a vendor temporarily wishes to halt sales of an item with the expectation of selling it again in the future, instead of de-listing the item and losing all of the reviews and ratings that have accumulated over time, the vendor instead raises the price to something prohibitively high in order to discourage any sales. This is what we call a *holding price*. Holding prices are particularly dangerous for our analysis, because they can be in excess of millions of dollars. So, mistaking a holding price for an actual price just once could have dramatic consequences on the overall analysis.

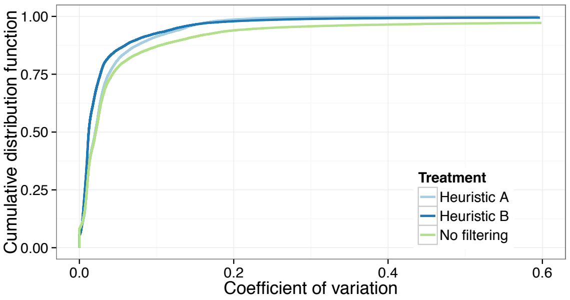

Figure 4: **C.d.f. of Coefficient of Variation for sets of observations of item listings** Both heuristics perform very similarly.

Dealing with holding prices Given a particular feedback and a set of observations of the corresponding product listing, the objective becomes to determine which observation yields the most accurate price for that feedback. Independent analysis (see Section 3.3) yielded two different heuristics for solving this problem. In the first heuristic (Heuristic A), we dismissed observations of the listing where the price was greater than \$10,000 USD as well as observations that showed prices of zero (free). We then dismissed observations that were greater than 5 times the median of the remaining samples as well as observations that were less than 25% the value of the median. We manually observed thousands of product listings and identified that only in some very rare cases were the assumptions violated.

The second heuristic (Heuristic B) proceeded by removing observations with a price >\$10,000 USD, as well as the upper quartile and any observations that were more than 100 times greater than the observation corresponding to the cheapest, non-zero price. To understand the effect that these heuristics had on observations, we calculated the coefficient of variation defined as $c_v = \sigma/\mu$ (standard deviation over mean) for the set

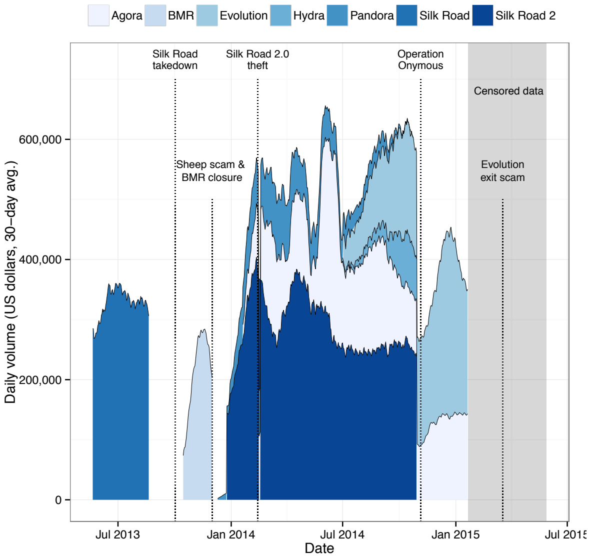

Figure 5: **Sales volumes in the entire ecosystem.** This stacked plot shows how sales volume vary over time for the marketplaces we study.

of observations for each item listing and plotted its cumulative distribution function.

Figure 4 shows that without any filtering, about 5% of all item listings were at some point sampled with highly variable prices, which suggests that a holding price was observed for this listing. Both heuristics produce relatively similar filtering; we ended up using Heuristic A in the rest of the analysis.

After applying the filter, there is still some smaller variation in the pricing of many listings which is consistent with the fluctuation in prices due to typical market pressures but it is clear that no listings with extremely high variations remain. 79,512 total unique item listings were identified, 1,003 (1.26%) of which had no valid observations remaining after filtering, meaning that the output of the heuristic was the empty set, the remaining 78,509 item listings returned at least one acceptable observation.

After filtering the listing observations, we pair each feedback with one of the remaining listing samples. To minimize the difference in estimated price of the feedback from the true price, we select the listing observation that is closest to the feedback in time. At this point we have a set of unique pieces of feedback, each mapped to a price at some point in time; from there, we can construct an estimate for the sales volumes.

Results We present our results in Figure 5 where we show the total volume, per marketplace we study, over time. The plot is stacked, which means that the top line corresponds to the total volume cleared by all marketplaces under study. In early 2013, we only have results for Silk Road, which at that point grossed around $300,000/day, far more than previously estimated for 2012 [13]. This number would project to over $100M in a year; combined by the previous $15M estimate [13] for early 2012, and "filling in" gaps for data we do not have in late 2012, appears consistent with the (revised) US Government calculations of $189M of total grossed income by Silk Road over its lifetime, based on Bitcoin transaction logs.

We then have a data collection gap, roughly corresponding to the time Silk Road was taken down. (We do not show volumes for Atlantis, which are negligible, in the order of $2,000–3,000/day.) Shortly after the Silk Road take-down we started measuring Black Market Reloaded, and realized that it has already made up for a vast portion of the volumes previously seen on Silk Road. We do not have sales data for Sheep Marketplace due to incomplete parses, but we do believe that the combination of both markets made up for the loss of Silk Road. Then, both Sheep and Black Market Reloaded closed – in the case of Sheep, apparently fraudulently. There was then quite a bit of turmoil with various markets starting and failing quickly. Only around late November 2013 did the ecosystem find a bit more stability, as Silk Road 2.0 had been launched and was rapidly growing. In parallel Pandora, Agora, and Evolution were also launched. By late January 2014, volumes far exceeded what was seen prior to the Silk Road take-down. At that point, though, a massive scam on Silk Road 2.0 caused dramatic loss of user confidence, which is evidenced by the rapid decrease until April 2014, before it starts recovering. Competitors however were not affected. (Agora does show spikes due to very imprecise feedback timing at a couple of points.) Eventually, in the Fall of 2014, the anonymous online marketplace ecosystem reached unprecedented highs. We started collecting data from Evolution in July, so it is possible that we miss quite a bit in the early part of 2014, but the overall take-away is unchanged. Finally, in November 2014, Operation Onymous [38] resulted in the take-down of Silk Road 2 and a number of less marketplaces. This did significantly affect total sales, but we immediately see a rebound by people going to Evolution and Agora. We censor the data we obtained from February 2015: at that point we only have results for Agora and Evolution, but coverage is poor, and as explained in Section 3, is likely to underestimate volumes significantly. We did note a short volume decrease prior to the Evolution "exit scam" of March 2015. We have not analyzed data for other smaller marketplaces (e.g., Black Bank, Middle Earth, or Nucleus) but suspect the volumes are much smaller. Finally, more recent marketplaces such as AlphaBay seem to have grown rapidly after the Evolution exit scam, but feedback on AlphaBay is not mandatory, and thus cannot be used to reliably estimate sales volumes.

In short, the entire ecosystem shows resilience to scams – Sheep, but also Pandora, which, as we can see started off very well before losing ground due to a loss in customer confidence, before shutting down. The effect of law enforcement take-downs (Silk Road 1&2, Operation Onymous) is mixed at best: the ecosystem relatively quickly recovered from the Silk Road shutdown, and appears to have withstood Operation Onymous quite well, since aggregate volumes were back within weeks to more than half what they were prior to Operation Onymous. We however caution that one would need longer term data to fully assess the impact of Operation Onymous.

4.2 Product categories

In addition to estimating the value of the products that are being sold, we strived to develop an understanding of what is being sold. Several marketplaces such as Agora and Evolution include information on item listing pages that describe the nature of the listing as provided by the vendor that posted it. Unfortunately these descriptions are often too specific, conflict across marketplaces, and in the case of some sites, are not even available at all.

For our analysis, we need a consistent and coherent labeling for all items, so that we could categorize them into broad mutually exclusive categories. We thus implemented a machine learning classifier that was trained and tested on samples from Agora and Evolution, where ground truth was available via labeling. We then took this classifier and applied it to item listings on all marketplaces to answer the question of what is being sold.

We took 1,941,538 unique samples from Evolution and Agora, where a sample is the concatenation of an item listing's title and all descriptive information about it that was parsed from the page. We tokenized each sample under the assumption that the sample is written in English, resulting in a total of 162,198 unique words observed. We then computed a *tf-idf* value for each of the 162,198 words in the support for each sample, and used these values as inputs to an L2-Penalized SVM under L2-Loss implemented using Python and *scikit-learn*.

We evaluated our classifier using 10-fold cross validation. The overall precision and recall were both (roughly) 0.98. We also evaluated the classifier on Agora data when trained with samples from Evolution and vice-versa to ensure that the classifier was not biased to only perform well on the distributions it was trained on. The confusion matrix in Figure 6 shows that classification performance is very strong for all categories. Only "Misc" is occasionally confused with Digital Goods and Prescriptions are occasionally confused with Benzos (which in fact is not necessarily surprising). We believe that these errors are most likely caused by mislabeled test samples. Although we drew our samples from Evolution and Agora which provide a specific label for each listing, the label is selected by the vendor and may be erroneous, particularly for listings that are hard to place. Manual inspection revealed that several of the errors came from item listings that offered US $100 Bills in exchange for Bitcoin.

Figure 6: **Classifier confusion matrix.** BNZ: Benzos, DG: Digital Goods, DIS: Dissociatives, ELEC: Electronics, MISC: Miscellaneous, OP: Opioids, PAR: Drug Paraphernalia, PSY: Psychedelics, RX: Prescription drugs, SL: Sildenafil, STI: Stimulants, STR: Steroids, THC: Cannabis, TOB: Tobacco, WPN: Weapons, X: Ecstasy.

We then applied the classifier to the aggregate analysis performed earlier. In addition to placing a particular feedback in time, and pairing it with an item listing observation to derive the price, we predicted the class label of that listing and aggregated the price by class label. Figure 7 shows the normalized market aggregate by category. Drug paraphernalia, weapons, electronics, tobacco, sildenafil, and steroids were collapsed into a category called 'Other' for clarity.

Over time the fraction of market share that belongs to each category is relatively stable. However, around October of 2013, December 2013, March 2014, and January 2015, cannabis spikes up to as much as half of the market share. These spikes correspond to the earlier mentioned 1) take-down of Silk Road, 2) closure of Black Market Reloaded and Sheep scam, 3) Silk Road 2.0 theft [5],

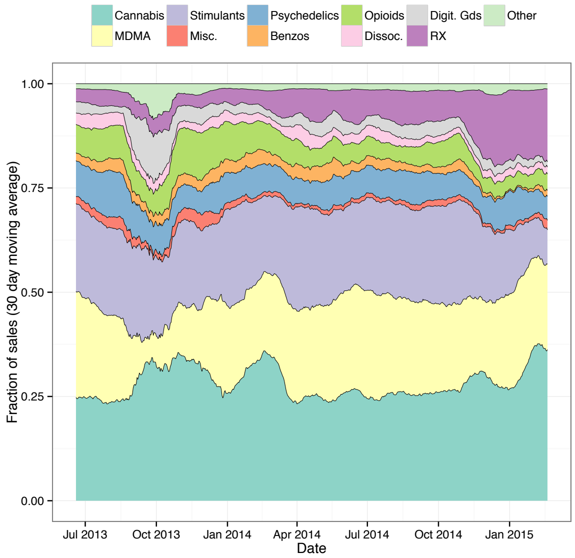

Figure 7: **Fractions of sales per item category.**

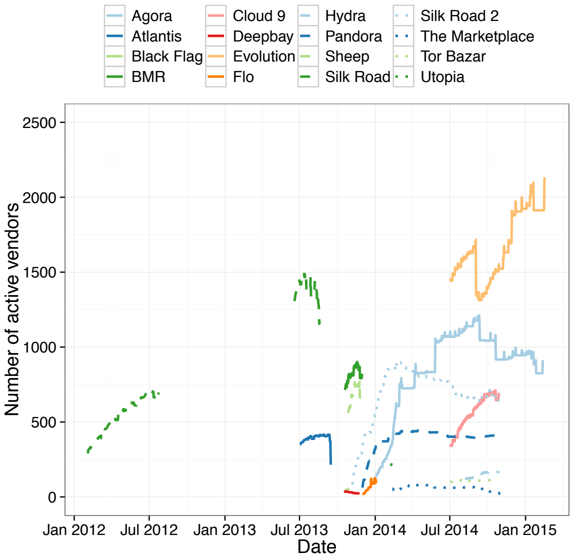

Figure 8: **Evolution of the number of active sellers over time.** Each "seller" here corresponds to a unique marketplace-vendor name pair. Certain sellers participate in several marketplaces and are thus counted multiple times here.

and 4) Operation Onymous respectively. These are all events that generated substantial doubts in both vendors and consumers regarding the safety and security of operating on these marketplaces. At these times the perceived risk of operation was higher, which may have exerted pressure towards buying and selling cannabis as opposed to other products for which the punishment if caught is much more severe. We can also see that digital goods take an unusually high market share in times of uncertainty, which is most obvious around October 2013: this is not surprising as digital goods are often a good way to quickly accumulate large numbers of listings on a new marketplace.

Figure 7 shows that after an event such as a take-down or large scale scam occurs, it takes about 2–3 months before consumer and vendor confidence is restored and the markets converge back to equilibrium. At equilibrium, cannabis and MDMA (ecstasy) are about 25% of market demand each with stimulants closely behind at about 20%. Psychedelics, opioids, and prescription drugs are a little less than 10% of market demand each, although starting in November 2014, prescription drugs have gained significant traction—perhaps making anonymous marketplaces a viable alternative to unlicensed online pharmacies.

4.3 Vendors

Online anonymous marketplaces are only successful when they manage to attract a large enough vendor population to provide a critical mass of offerings. At the same time, vendors are not bound to a specific marketplace. Anecdotal evidence shows that certain sellers list products on several marketplaces at once; likewise, certain sellers "move" from marketplace to marketplace in response to law enforcement take-down or other marketplace failures. Here, we try to provide a good picture of the vendor dynamics across the entire ecosystem.

Number of sellers Figure 8 shows, over time, the evolution of the number of active sellers on all the marketplaces we considered. For each marketplace, a seller is defined as active at time T is we observed her having at least one active listing at time $t \leq T$, and at least one active listing (potentially the same) at a time $t \geq T$. This is a slightly different definition from that used in Christin [13] which required an active listing at time t to count a seller as active. For us, active sellers include sellers that may be on vacation but will come back, whereas Christin did not include such sellers. As a result, our results for Silk Road are very slightly higher than his.

The main takeaway from Figure 8 is that the number of sellers overall has considerably increased since the days of Silk Road. By the time Silk Road stopped activities in 2013, it featured around 1,400 sellers; its leading competitors, Atlantis and Black Market Reloaded (BMR) were much smaller. After the Silk Road take-down (October 2013) and Atlantis closure, we observe that both BMR and the Sheep marketplace rapidly pick up a large influx of sellers. In parallel, Silk Road 2.0 also grows at

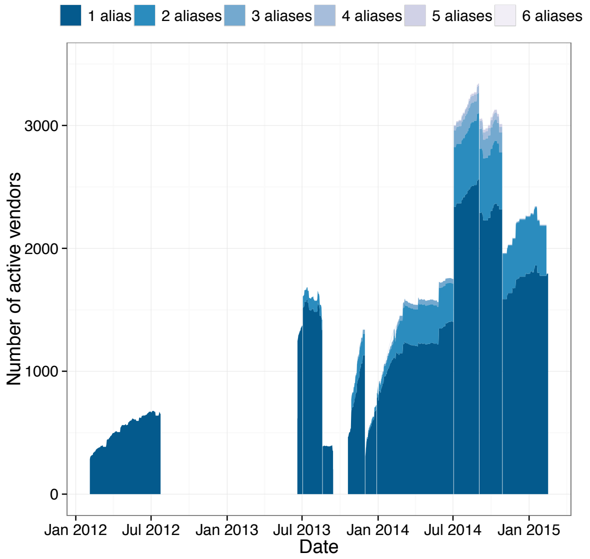

Figure 9: **Number of aliases per seller.** This plot shows the evolution of the number of aliases per seller across all marketplaces, over time. The contour of the curve denotes the total number of sellers overall.

a very rapid pace. Successful newcomers like Pandora, Agora, and Evolution also see quick rises in the number of sellers. After a certain amount of time, however, per-marketplace population tends to stabilize, even in the most popular marketplaces. On the other hand, we also observe that some marketplaces never took off: The Marketplace, Hydra, Deepbay, and Tor Bazaar, for instance, consistently have a small number of vendors. In other words, we see very strong network effects: Either marketplaces manage to get initial traction and then rapidly flourish, or they never manage to take off.

Sellers and aliases After Silk Road was taken down, a number of sellers reportedly moved to Black Market Reloaded or the Sheep Marketplace. More generally, nothing prevents a vendor from opening shop on multiple marketplaces; in fact, it is probably a desirable strategy to hedge against marketplace take-downs or failures. As a result, a given seller, Sally, may have multiple vendor accounts on several marketplaces: Sally may sell on Silk Road 2 as "Sally," on Agora as "sally" and on Evolution as "Easy Sally;" she may even have a second Evolution account ("The Real Easy Sally").

We formally define an *alias* as a unique (*vendor nickname*, *marketplace*) pair, and link different aliases to the same vendor using the combination of the following three heuristics. We first consider vendor nicknames on different marketplaces with only case differences as belonging to the same person (e.g., "Sally" and "sally"). We then use the InfoDesk feature of the Grams "DarkNet Markets" search engine [2] to further link various vendor nicknames.[7] We filter out vendor nicknames consisting only of a common substring (e.g., "weed," "dealer," "Amsterdam," ...) used by many vendors prior to conducting the search. Finally, we link all vendor accounts that claim to be using the same PGP key. Clearly, our linking strategy is very conservative – in the sense that minor variations like "Sally" and "Sally!" will not be linked absent a common PGP key.

Using this set of heuristics, from a total of 29,258 unique aliases observed across our entire measurement interval, we obtain a list of 9,386 sellers. In Figure 9, we show, over time, the number of vendors that have one, two or up to six aliases active at any given time T (where we use the same definition of "active" as earlier, i.e., the alias has at least one listing available before and after T). The plot is by definition incomplete since we can only take into account, for each time t, the marketplaces that we have crawled (and parsed) at time t.

For instance, the earlier part of the data show a complete monopoly: this is not surprising since we only have data for Silk Road at that time, even though Black Market Reloaded was also active at the same time. We observe in the summer of 2013 that a few vendors sell simultaneously on Silk Road and Atlantis, but the practice of having multiple vendor accounts on several sites seems to only really take hold in 2014, after many marketplaces failed in the Fall of 2013 (including Silk Road, and many of its short-lived successors). The second jump in July 2014 corresponds to our starting to collect data for the very large Evolution marketplace. Finally, the decrease observed in late 2014 is due to Operation Onymous [38], which – besides Silk Road 2.0 – took down a relatively large number of secondary marketplaces, such as Cloud 9.

Besides the relatively robust rise is the number of sellers to take-downs and scams, the main takeaway from this plot is that the majority of sellers appear to only use one alias – but this may be a bit misleading, as (as we will see later) a large number of vendors sell extremely limited quantities of products. An interesting extension would be to check whether "top" vendors diversify across marketplaces or not.

We complement this analysis by looking into the "survivability" functions of aliases and sellers, which we report in Figure 10. Here the survival function is defined as the probability $p(\tau)$ that a given seller (resp. alias) observed at time t be still active at time $t+\tau$. The figure shows the survival function, derived from a Kaplan-Meier estimator [24] to account for the fact that we have finite measurement intervals, along with 95% confidence

[7] It is not clear how the Grams search engine is implemented; we suspect the vendor directory is primarily based on manual curation.

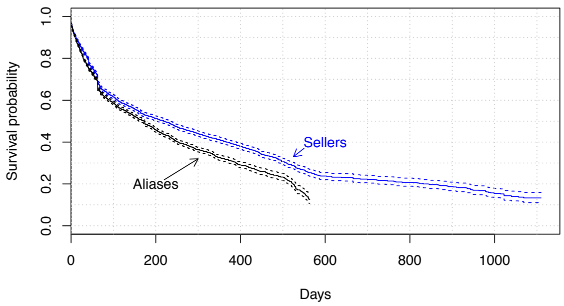

Figure 10: **Seller survivability analysis.** The plot describes the probability a given alias is still active after a certain number of days; and the probability a given seller (regardless of which alias it is using) is still active after a certain number of days. On average, sellers are active for 220 days, while aliases remain active for 172 days.

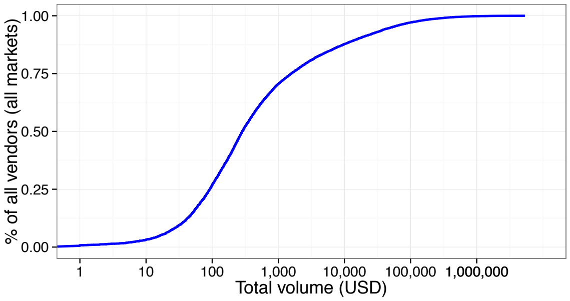

Figure 11: **Seller volumes.** A very small fraction of sellers generate significant profit. On average, a typical seller only makes a couple of hundreds dollars.

intervals. The key findings here are that half of the sellers are only present for 220 days or less; half of the aliases only exist for 172 days or less. More interesting is the "long-tail" phenomenon we observe: a number (more than 10%) of sellers have been active *throughout the entire measurement interval*. More generally approximately 25% of all sellers are "in it for the long run," and remain active (with various aliases on various marketplaces) for years.

Volumes per vendor In an effort to obtain a more clear understanding of how vendors operate, we aggregated unique feedback left for products by vendor. We used this to calculate the total value of the transactions for items sold by each vendor and then grouped these vendor aliases to yield the total value of transactions for each seller. Figure 11 plots the CDF of sellers by the total value of their transactions. About 70% of all sellers never managed to sell more than $1,000 worth of products. Another 18% of sellers were observed to sell between $1,000 and $10,000 but only about 2% of vendors managed to sell more than $100,000. In fact, 35 sellers were observed selling over $1,000,000 worth of product and the top 1% most successful vendors were responsible for 51.5% of all the volume transacted. Some of these sellers, like "SuperTrips" (or to a lesser extent, "Nod") from Silk Road, have been arrested, and numbers released in connection with these arrests are consistent with our findings [4, 6].

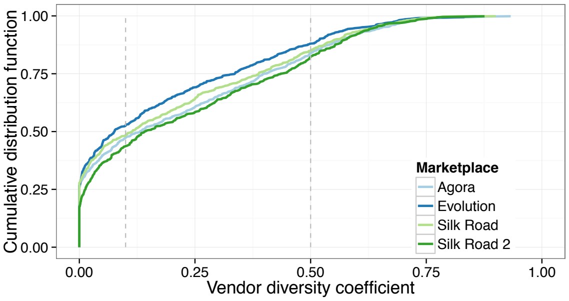

Figure 12: **Vendor diversity**

There is a clear discrepancy between sellers that experiment in the marketplaces and those who manage to leverage it to operate a successful business. Going forward, we define any seller that we have observed selling in excess of $10,000 to be successful. This allows us to draw conclusions only about vendors that have had a meaningful impact on the marketplace ecosystem. Now that we know how much sellers are selling, we wish to understand *what* they are selling. Once again we group feedback by vendor but this time we also use the classifier to categorize the items that were being sold and aggregate by category. Let $\mathscr{C}$ be the set of normalized item categories for each seller and $\mathscr{S}$ be the set of all sellers across all marketplaces. So, $|\mathscr{C}| = 16$, and $|\mathscr{S}| = 9,386$. Define $\mathscr{C}_i(s_j)$ as the normalized value of the i-th category for seller j such that $\forall s_j \in S,\ \sum_{i=1}^{|\mathscr{C}|} \mathscr{C}_i(s_j) = 1$. Then, we define the coefficient of diversity for a seller s_j as:

$$c_d = \left(1 - \max_i \left(\mathscr{C}_i(s_j)\right)\right) \frac{|\mathscr{C}|}{|\mathscr{C}| - 1} \ .$$

Intuitively, the coefficient of diversity is measuring how invested a seller is into their most popular category, normalized so that $c_d \in [0, 1]$. When evaluating the categories that different sellers are invested in, it only makes sense to consider successful sellers as less significant sellers are volatile and greatly influenced by an individual sale in some category.

Figure 12 plots the CDF of the coefficient of diversity for sellers from Evolution, Silk Road, Silk Road 2 and Agora that sold more than $10,000 total. From Figure 12 we argue that there are roughly three types of sellers. The first type of seller with a coefficient of diversity between 0 and 0.1 is highly specialized, and sells exactly one type of product. About half of all sellers are highly specialized and indicates that the seller has access to a steady long-term supply of some type of product. About one third of all vendors who specialize sell cannabis, another third sell digital goods, and the last third sell in the various other categories. While digital goods is a relatively small share of the total marketplace ecosystem, it tends to attract vendors that specialize. This is likely due to the domain expertise required for actions such as manufacturing fake IDs or stealing credit cards. The second type of seller has a diversity coefficient of between 0.1 and 0.5 and generally specializes in two or three types of products. The most common two categories to simultaneously specialize in are ecstasy and psychedelics – i.e., primarily recreational and club drugs. The third type of vendor has a diversity coefficient greater than 0.5 and has no specialty but rather sells a variety of items. These types of sellers may be networks of users with access to many different sources, or may be involved in arbitrage between markets.

PGP deployment We conclude our discussion of vendor behavior by looking in more detail at their security practices. While we cannot easily assess their overall operational security, we consider a very simple proxy for security behavior: the availability of a valid PGP key. From our data set, we extracted 7,717 PGP keys. Most vendors use keys of appropriate length, even though we did observe a couple of oddities (e.g., a 2,047-bit key!) that might indicate an incorrect use of the software. Inspired by Heninger et al. [20] and Lenstra et al. [25] we checked all pairs of keys to determine whether or not they had common primes. We did not find any, which either suggests that GPG software was always properly used and with a good random number generator, or, more likely, that our dataset is too small to contain evidence of weak keys.

We then plot in Figure 13 the fraction of vendors, over time, that have (at least) one usable PGP key. We take an extremely inclusive view of PGP deployment here: as long as a vendor has advertised a valid PGP key for one or her active aliases, we consider they are using PGP. As vendors deal with highly sensitive information such as postal delivery addresses of their customers, we would expect close to 100% deployment. We see that, despite improvements, this is not the case. In the original Silk Road, only approximately 2/3 to 3/4 of vendors had a valid PGP key listed. During the upheaval of the 2013 Fall, with many marketplaces opening and shutting down quickly, we see that PGP deployment is very low. When the situation stabilizes in January 2014, we observe an increase in PGP adoption; interestingly, *after* Operation Onymous, adoption seems even higher, which can be construed as an evolutionary argument: marketplaces that support and encourage PGP use by their sellers (such as Evolution and Agora) might have been also more secure in other respects, and more resilient against takedowns. Shortly before the Evolution shutdown, PGP deployment on Agora and Evolution was close to 90%.

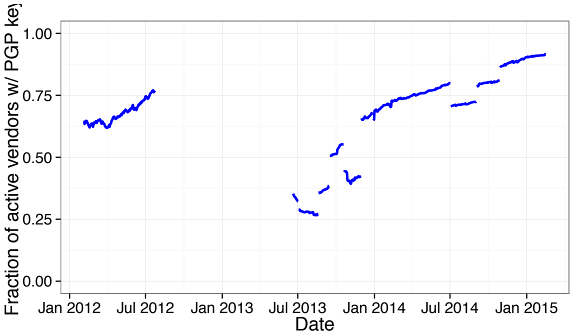

Figure 13: **PGP deployment over time.**

5 Discussion

A study of this kind brings up a number of important discussion points. We focus here on what we consider are the most salient ones: validation, ethics, and potential public policy take-aways.

5.1 Validation

Scientific measurements should be amenable to validation. Unfortunately, here, ground truth is rarely available, which in turn makes validation extremely difficult. Marketplace operators indeed generally do not publish metrics such as seller numbers or traffic volumes. However, in certain cases, we have limited information that we can use for spot-checking estimates.

Ross Ulbricht trial evidence (Silk Road) In October 2013, a San Francisco man by the name of Ross Ulbricht was arrested and charged as being the operator of Silk Road [8]. A large amount of data was subsequently entered into evidence used during his trial, which took place in January 2015. In particular, evidence contained relatively detailed accounting entries found on Mr. Ulbricht's laptop, and claimed to pertain to Silk Road. Chat transcripts (evidence GX226A, GX227C) place weekly volumes at $475,000/week in late March 2012 for instance: this is consistent with the data previously reported [13] and which we use for documenting Silk Road 1. Evidence GX250 contains a personal ledger which apparently faithfully documents Silk Road sales commissions. Projecting the data listed during the time of the previous study [13] ($680,279) over a year yields a yearly projection of about $1.2M; Christin's estimates were of $1.1M [13]. This hints that the technique of using feedback as a sales proxy, which we reuse here, produces reliable estimates.

Blake Benthall criminal complaint (Silk Road 2) In November 2014, another San Francisco man by the name of Blake Benthall was arrested and charged with being "Defcon," the Silk Road 2.0 administrator. The criminal complaint against Mr. Benthall [7] reports that in September 2014, the administrator, talking to an undercover agent actually working on Silk Road 2's staff, reports around $6M of monthly sales; and later amends this number to $8M. This corresponds to a daily sales volume of $200,000–$250,000 which is very close to what we report in Figure 5 for Silk Road 2 at that given time.

Leaked Agora seller page In December 2014, it was revealed that an Agora vendor page had been scraped and leaked on Pastebin [21]. This vendor page in particular contains a subset of all the vendor's transactions; one can estimate precisely the amount for that specific vendor on June 5, 2014 to $3,460. Checking in our database, our instantaneous estimate credits that seller with $3,408 on the day – which, considering Bitcoin exchange fluctuations is pretty much identical to the ground truth.

5.2 Ethics of data collection

We share much of the ethical concerns and views documented in previous work [13]. Our data collection, in particular, is massive, and could potentially put some strain on the Tor network, not to mention marketplace servers themselves. However, even though it is hard to assess we believe that our measurements represent a small fraction of all traffic that is going to online anonymous marketplaces. As discussed in Section 3 we are attempting to balance accuracy of the data collection with a light-weight enough crawling strategy to avoid detection – or worse, impacting the very operations we are trying to measure. In addition, we are contributing Tor relays with long uptimes on very fast networks to "compensate" for our own massive use of the network. Our work takes a number of steps to remain neutral. We certainly do not want to facilitate vendor or marketplace operator arrests. This is not just an ethical question, but is also a scientific one: our measurements, to be sound, should not impact the subject(s) being measured [23].

5.3 Public-policy take-aways

The main outcome of this work, we hope, is a critical evaluation of meaningful public policy toward online anonymous marketplaces. While members of Congress have routinely called for the take down of "brazen" online marketplaces, it is unclear that this is the most pragmatic use of taxpayer money.

In fact, our measurements suggest that the ecosystem appears quite resilient to law enforcement take-downs. We see this without ambiguity in response to the (original) Silk Road take-down; and while it is too early to tell the long-lasting impacts of Operation Onymous, its main effect so far seems to have been to consolidate transactions in the two dominant marketplaces at the time of the take-down. More generally, economics tell us that because user demand for drugs online is present (and quite massive), enterprising individuals will seemingly always be interested in accommodating this demand.

A natural question is whether the cat-and-mouse game between law enforcement and marketplace operators could end with the complete demise of online anonymous marketplaces. Our results suggest it is unlikely. Thus, considering the expenses incurred in very lengthy investigations and the level of international coordination needed in operations like Operation Onymous, the time may be ripe to investigate alternative solutions.

Reducing demand through prevention is certainly an alternative worth exploring on a global public policy level, but, from a law enforcement perspective, even active intervention could be much more targeted, e.g., toward seizing highly dangerous products while in transit. A number of documented successes in using traditional police work against sellers of hazardous substances (e.g., [35]) or large-scale dealers (e.g., [4, 6] among many others) show that law enforcement is not powerless to address the issue in the physical world.

6 Related work

The past decade has seen a large number of detailed research efforts aiming at gathering actual measurements from various online criminal ecosystems in order to devise meaningful defenses; see, e.g., [13, 14, 22, 26, 27, 28, 29, 32, 40, 41]. Anderson et al. [11] and Thomas et al. [37] provide a very good overview of the field. Closest among these papers to our work, McCoy et al. obtained detailed measurements of online pharmaceutical affiliates, showing that individual networks grossed between USD 12.8 million/year to USD 67.7 million/year. In comparison, the long-term rough average we see here is in the order of $150–180M/year for the entire online anonymous marketplace ecosystem. In other words, online marketplaces have seemingly surpassed more "traditional" ways of delivering illicit narcotics.

With respect to specific measurements of online anonymous marketplaces, the present paper builds up on our previous work [13]. Surprisingly few other efforts exist attempting to quantitatively characterize the economics of online anonymous marketplaces. Of note, Aldridge and Décary-Hétu [10] complement our original volume estimates by showing revised numbers of around $90M/year for Silk Road in 2013 right before its take-down. This is roughly in line with our own measurements, albeit slightly more conservative (Figure 5 shows about $300K/day for Silk Road in summer 2013.) More recent work by Dolliver [17] tries to assess the volumes on Silk Road 2.0. While she does not report volumes, her seller numbers are far smaller than ours, and we suspect her scrapes might have been incomplete. Looking at the problem from a different angle, Meiklejohn et al. [31] provide a detailed analysis of transaction traceability in the Bitcoin network, and show which addresses are related to Silk Road, which in turn could be a useful way of assessing the total volumes of that marketplace. A follow up paper [30] shows that purported Bitcoin "anonymity" (i.e., unlinkability) is greatly overstated, even when using newer mixing primitives.

On the customer side, Barratt et al. [12] provide an insightful survey of Silk Road patrons, showing that a lot of them associate with the "party culture," which is corroborated by our results showing that cannabis and ecstasy correspond to roughly half of the sales; likewise Van Hout and Bingham provide valuable insights into individual participants [39]. Our research complements these efforts by providing a macro-level view of the ecosystem.

7 Conclusions

Even though anonymous online marketplaces are a relatively recent development in the overall online crime ecosystem, our longitudinal measurements show that in the short four years since the development of the original Silk Road, total volumes have reached up to $700,000 daily (averaged over 30-day windows) and are generally stable around $300,000-$500,000 a day, far exceeding what had been previously reported. More remarkably, anonymous marketplaces are extremely resilient to take-downs and scams – highlighting the simple fact that economics (demand) plays a dominant role. In light of our findings, we suggest a re-evaluation of intervention policies against anonymous marketplaces. Given the high demand for the products being sold, it is not clear that take-downs will be effective; at least we have found no evidence they were. Even if one went to the impractical extreme of banning anonymous networks, demand would probably simply move to other channels, while some of the benefits associated with these markets (e.g., reduction in risks of violence at the retail level) would be lost. Instead, a focus on reducing consumer demand, e.g., through prevention, might be worth considering; likewise, it would be well-worth investigating whether more targeted interventions (e.g., at the seller level) have had measurable effects on the overall ecosystem. While our paper does not answer these questions, we believe that the data collection methodology we described, as well as some of the data we have collected, may enable further research in the field.

Acknowledgments

Under-Constrained Symbolic Execution: Correctness Checking for Real Code

Stanford University

Abstract

Software bugs are a well-known source of security vulnerabilities. One technique for finding bugs, symbolic execution, considers all possible inputs to a program but suffers from scalability limitations. This paper uses a variant, *under-constrained* symbolic execution, that improves scalability by directly checking individual functions, rather than whole programs. We present UC-KLEE, a novel, scalable framework for checking C/C++ systems code, along with two use cases. First, we use UC-KLEE to check whether patches introduce crashes. We check over 800 patches from BIND and OpenSSL and find 12 bugs, including two OpenSSL denial-of-service vulnerabilities. We also verify (with caveats) that 115 patches do not introduce crashes. Second, we use UC-KLEE as a generalized checking framework and implement checkers to find memory leaks, uninitialized data, and unsafe user input. We evaluate the checkers on over 20,000 functions from BIND, OpenSSL, and the Linux kernel, find 67 bugs, and verify that hundreds of functions are leak free and that thousands of functions do not access uninitialized data.

1 Introduction

Software bugs pervade every level of the modern software stack, degrading both stability and security. Current practice attempts to address this challenge through a variety of techniques, including code reviews, higher-level programming languages, testing, and static analysis. While these practices prevent many bugs from being released to the public, significant gaps remain.

One technique, testing, is a useful sanity check for code correctness, but it typically exercises only a small number of execution paths, each with a single set of input values. Consequently, it misses bugs that are only triggered by other inputs.

Another broad technique, static analysis, is effective at discovering many classes of bugs. However, static analysis generally uses abstraction to improve scalability and cannot reason precisely about program values and pointer relationships. Consequently, static tools often miss deep bugs that depend on specific input values.

One promising technique that addresses the limitations of both testing and static analysis is symbolic execution [4, 5, 40]. A symbolic execution tool conceptually explores all possible execution paths through a program in a bit-precise manner and considers all possible input values. Along each path, the tool determines whether any combination of inputs could cause the program to crash. If so, it reports an error to the developer, along with a concrete set of inputs that will trigger the bug.

Unfortunately, symbolic execution suffers from the well-known *path explosion* problem since the number of distinct execution paths through a program is often exponential in the number of if-statements or, in the worst case, infinite. Consequently, while symbolic execution often examines orders of magnitude more paths than traditional testing, it typically fails to exhaust all interesting paths. In particular, it often fails to reach code deep within a program due to complexities earlier in the program. Even when the tool succeeds in reaching deep code, it considers only the input values satisfying the few paths that manage to reach this code.

An alternative to whole-program symbolic execution is *under-constrained* symbolic execution [18, 42, 43], which directly executes an arbitrary function within the program, effectively *skipping* the costly path prefix from `main` to this function. This approach reduces the number and length of execution paths that must be explored. In addition, it allows library and OS kernel code without a `main` function to be checked easily and thoroughly.

This paper presents UC-KLEE, a scalable framework implementing under-constrained symbolic execution for C/C++ systems code without requiring a manual specification or even a single testcase. We apply this framework to two important use cases. First, we use it to check whether patches to a function introduce new bugs, which may or may not pose security vulnerabilities. Ironically, patches intended to fix bugs or eliminate security vulnerabilities are a frequent source of them. In many cases, UC-KLEE can *verify* (up to a given input bound and with standard caveats) that a patch does not introduce new crashes to a function, a guarantee not possible with existing techniques.

Second, we use UC-KLEE as a general code checking framework upon which specific checkers can be implemented. We describe three example checkers we implemented to find memory leaks, uses of uninitialized data, and unsanitized uses of user input, all of which *may* pose security vulnerabilities. Additional checkers may be added to our framework to detect a wide variety of bugs along symbolic, bit-precise execution paths through functions deep within a program. If UC-KLEE exhaustively checks all execution paths through a function, then it has effectively verified (with caveats) that the function passes the check (e.g., no leaks).

We evaluated these use cases on large, mature, and security-critical code. We validated over 800 patches from BIND [3] and OpenSSL [36] and found 12 bugs, including two OpenSSL denial-of-service vulnerabilities [12, 16]. UC-KLEE verified that 115 patches did not introduce new crashes, and it checked thousands of paths and achieved high coverage even on patches for which it did not exhaust all execution paths.

We applied our three built-in checkers to over 20,000 functions from BIND, OpenSSL, and the Linux kernel and discovered 67 new bugs, several of which appear to be remotely exploitable. Many of these were latent bugs that had been missed by years of debugging effort. UC-KLEE also exhaustively verified (with caveats) that 771 functions from BIND and OpenSSL that allocate heap memory do not cause memory leaks, and that 4,088 functions do not access uninitialized data.

The remainder of this paper is structured as follows: § 2 presents an overview of under-constrained symbolic execution; § 3 and § 4 discuss using UC-KLEE for validating patches and generalized checking, respectively; § 5 describes implementation tricks; § 6 discusses related work; and § 7 concludes.

2 Overview

This paper builds upon our earlier work on UC-KLEE [43], an extension to the KLEE symbolic virtual machine [5] designed to support equivalence verification and under-constrained symbolic inputs. Our tool checks C/C++ code compiled as *bitcode* (intermediate representation) by the LLVM compiler [29]. As in KLEE, it performs bit-accurate symbolic execution of the LLVM bitcode, and it executes any functions called by the code. Unlike KLEE, UC-KLEE begins executing code at an arbitrary function chosen by the user, rather than `main`.

With caveats (described in § 2.2), UC-KLEE provides verification guarantees on a per-path basis. If it exhausts all execution paths, then it has verified that a function has the checked property (e.g. that a patch does not introduce any crashes or that the function does not leak memory) up to the given input size.

Directly invoking functions within a program presents new challenges. Traditional symbolic execution tools generate input values that represent external input sources (e.g., command-line arguments, files, etc.). In most cases, a correct program should reject invalid external inputs rather than crash. By contrast, individual functions typically have *preconditions* imposed on their inputs. For example, a function may require that pointer arguments be non-null. Because UC-KLEE directly executes functions without requiring their preconditions to be specified by the user, the inputs it considers may be a superset (over-approximation) of the legal values handled by the function. Consequently, we denote UC-KLEE's symbolic inputs as *under-constrained* to reflect that they are missing preconditions (constraints).

While this technique allows previously-unreachable code to be deeply checked, the missing preconditions may cause *false positives* (spurious errors) to be reported to the user. UC-KLEE provides both automated heuristics and an interface for users to manually silence these errors by lazily specifying input preconditions using simple C code. In our experience, even simple annotations may silence a large number of spurious errors (see § 3.2.5) and this effort is orders of magnitude less work than eagerly providing a full specification for each function.

2.1 Lazy initialization

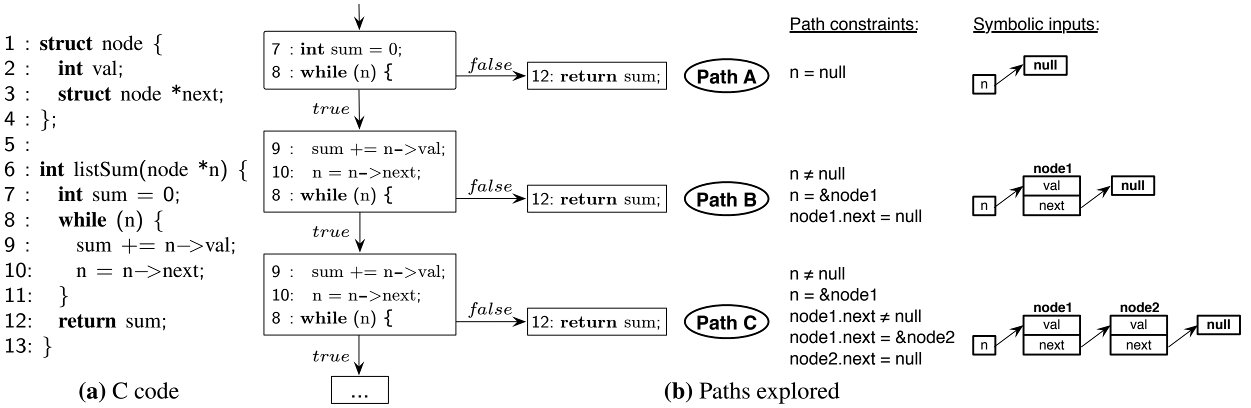
UC-KLEE automatically generates a function's symbolic inputs using lazy initialization [26, 46], which avoids the need for users to manually construct inputs, even for complex, pointer-rich data structures. We illustrate lazy initialization by explaining how UC-KLEE executes the example function `listSum` in Figure 1(a), which sums the entries in a linked list. Figure 1(b) summarizes the three execution paths we explore. For clarity, we elide error checks that UC-KLEE normally performs at memory accesses, division/remainder operations, and assertions.

UC-KLEE first creates an under-constrained symbolic value to represent the sole argument `n`. Although `n` is a pointer, it begins in the *unbound* state, not yet pointing to any object. UC-KLEE then passes this symbolic argument to `listSum` and executes as follows:

Line 7 The local variable `sum` is assigned a concrete value; no special action is taken.

Line 8 The code checks whether the symbolic variable `n` is non-null. At this point, UC-KLEE forks execution and considers both cases. We first consider the false path where $n = null$, (Path A). We then return to the true path where $n \neq null$ (Path B). On Path A, UC-KLEE adds $n = null$ as a path constraint and skips the loop.

Line 12 Path A returns `0` and terminates.



```
1 : struct node {
2 :   int val;
3 :   struct node *next;
4 : };
5 :
6 : int listSum(node *n) {
7 :   int sum = 0;
8 :   while (n) {
9 :     sum += n->val;
10:     n = n->next;
11:   }
12:   return sum;
13: }
```

(a) C code

(b) Paths explored

Figure 1: Example code fragment analyzed by UC-KLEE.

We now consider Path B.

Line 8 UC-KLEE adds the constraint $n \neq null$ and enters the loop.

Line 9 The code dereferences the pointer `n` for the first time on Path B. Because `n` is *unbound*, UC-KLEE allocates a new block of memory, denoted $node1$, to satisfy the dereference and adds the constraint $n = \&node1$ to *bind* the pointer `n` to this object. At this point, `n` is no longer unbound, so subsequent dereferences of that pointer will resolve to $node1$ rather than trigger additional allocations. The (symbolic) contents of $node1$ are marked as unbound, allowing future dereferences of pointers in this object to trigger allocations. This recursive process is the key to lazy initialization. Next, `sum` is incremented by the symbolic value $node1.val$.

Line 10 `n` is set to the value $node1.next$. Path B then returns to the loop header.

Line 8 The code tests whether `n` (set to $node1.next$) is non-null. UC-KLEE forks execution and considers both cases. We first consider $node1.next = null$, which we still refer to as Path B. We will then return to the true path where $node1.next \neq null$ (Path C). On Path B, $node1.next = null$ is added as a path constraint and execution exits the loop.

Line 12 Path B returns $node1.val$ and terminates.

We now consider Path C.

Line 8 UC-KLEE adds $node1.next \neq null$ as a path constraint, and Path C enters the loop.

Line 9 Path C dereferences the unbound symbolic pointer $node1.next$, which triggers allocation of a new object $node2$. This step illustrates the unbounded nature of many loops. To prevent UC-KLEE from allocating an unbounded number of objects as input, the tool accepts a command-line option to limit the depth of an input-derived data structure (*k*-bounding [17]). When a path attempts to exceed this limit, our tool silently terminates it. For this example, assume a depth limit of two, which causes UC-KLEE to terminate Path D (not shown) at line 9 during the next loop iteration.

Line 10 `n` is set to the value $node2.next$.

Line 8 UC-KLEE forks execution and adds the path constraint $node2.next = null$ to Path C.

Line 12 Path C returns $node1.val + node2.val$ and exits.

This example illustrates a simple but powerful recursive technique to automatically synthesize data structures from under-constrained symbolic input. Figure 2 shows an actual data structure our tool generated as input for one of the BIND bugs we discovered (Figure 5). The edges between each object are labeled with the field names contained in the function's debug information and included in UC-KLEE's error report.

2.2 Limitations

Because we build on our earlier version of UC-KLEE, we inherit its limitations [43]. The more important examples are as follows. The tool tests compiled code on a specific platform and does not consider other build configurations. It does not handle assembly (see § 4 for how we skip inline assembly), nor symbolic floating point operations. In addition, there is an explicit assumption that input-derived pointers reference unique objects (no aliasing, and no cyclical data structures), and the tool assigns distinct concrete addresses to allocated objects.

When checking whether patches introduce bugs, UC-KLEE aims to detect crashing bugs and does not look for performance bugs, differences in system call arguments, or concurrency errors. We can only check patches that do not add, remove, or reorder fields in data structures or change the type signatures of patched functions. We plan to extend UC-KLEE to support such patches by implementing a type map that supplies identical inputs to each version of a function in a "field aware" manner. How-

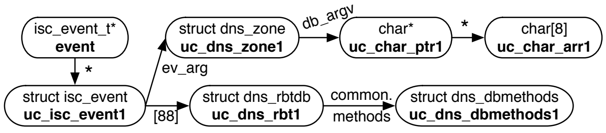


Figure 2: BIND data structure allocated by UC-KLEE.

ever, our current system does not support this, and we excluded such patches from our experiments.

3 Patch checking

To check whether a patch introduces new crashing bugs, UC-KLEE symbolically executes two compiled versions of a function: P, the unpatched version, and P', the patched version. If it finds any execution paths along which P' crashes but P does not (when given the same symbolic inputs), it reports a potential bug in the patch.

Recall that due to missing input preconditions, we cannot simply assume that all crashes are bugs. Instead, UC-KLEE looks for paths that exhibit *differing* crash behavior between P and P', which usually share an identical set of preconditions. Even if UC-KLEE does not know these preconditions, in practice, real code tends to show *error equivalence* [43], meaning that P and P' both crash (or neither crashes) on illegal inputs. For example, if a precondition requires a pointer to be non-null and both versions dereference the pointer, then P and P' will both crash when fed a null pointer as an argument.

In prior work, UC-KLEE [43] verified the equivalence of small library routines, both in terms of crashes and outputs. While detecting differences in functionality may point to interesting bugs, these discrepancies are typically meaningful only to developers of the checked code. Because this paper evaluates our framework on large, complex systems developed by third parties, we limit our discussion to crashes, which objectively point to bugs.

To check patches, UC-KLEE automatically generates a *test harness* that sets up the under-constrained inputs and invokes P and P'. Figure 3 shows a representative test harness. Lines 2–3 create an under-constrained input `n`. Line 4 calls `fooB` (P'). Note that UC-KLEE invokes P' before P to facilitate path pruning (§ 3.1). Line 5 discards any writes performed by `fooB` but preserves the path constraints so that `fooA` (P) will see the same initial memory contents and follow the corresponding path. Line 6 invokes `fooA`.

```
1 : int main() {
2 :    node *n;
3 :    ucklee_make_uc(&n);
4 :    fooB(n); /* run P' */
5 :    ucklee_reset_address_space();
6 :    fooA(n); /* run P */
7 :    return 0;
8 : }
```

Figure 3: Test harness.

If a path through `fooB` crashes, UC-KLEE unwinds the stack and resumes execution at line 5. If `fooA` also crashes on this path, then the two functions are crash equivalent and no error is reported. However, if `fooA` returns from line 6 *without* crashing, we report an error to the user as a possible bug in `fooB`. For this use case, we do not report errors in which `fooA` (P) crashes but `fooB` (P') does not, which suggest bugs *fixed* by a patch.

3.1 Path pruning

UC-KLEE employs several path pruning techniques to target errors and avoid uninteresting paths. The underlying UC-KLEE system includes a *static cross-checker* that walks over the LLVM [29] control flow graph, conservatively marking regions of basic blocks that differ between the original function P and the patched function P'. This algorithm is fairly straightforward, and we elide details for brevity. UC-KLEE soundly prunes paths that:

1. have never executed a "differing" basic block, and
2. cannot reach a differing basic block from their current program counter and call stack.

The second condition uses an inter-procedural reachability analysis from the baseline UC-KLEE system. Paths meeting both of these criteria are safe to prune because they will execute identical instruction sequences.

In addition, UC-KLEE introduces pruning techniques aimed specifically at detecting errors introduced by a patch. As our system executes P' (`fooB` in Figure 3), it prunes paths that either:

1. return from P' without triggering an error, or
2. trigger an error without reaching differing blocks.

In the first case, we are only concerned with errors *introduced* by the patch. In the second case, P and P' would both trigger the error.

Error uniquing. Our system aggressively uniques errors by associating each path executing P with the program counter (PC) of the error that occurred in P'. Once our system executes a non-error path that returns from P (and reports the error in P'), it prunes all current and future paths that hit the same error (PC and type) in P'. In practice, this enabled our system to prune thousands of redundant error paths.

3.2 Evaluation

We evaluated UC-KLEE on hundreds of patches from BIND and OpenSSL, two widely-used, security critical systems. Each codebase contains about 400,000 lines of C code, making them reasonable measures of UC-KLEE's scalability and robustness. For this experiment, we used a maximum symbolic object size of 25,000 bytes and a maximum symbolic data structure depth of 9 objects.

3.2.1 Patch selection and code modifications

We tried to avoid selection bias by using two complete sets of patches from the `git` repositories for recent stable branches: BIND 9.9 from 1/2013 to 3/2014 and OpenSSL 1.0.1 from 1/2012 to 4/2014. Many of the patches we encountered modified more than one function; this section uses *patch* to refer to changes to a single function, and *commit* to refer to a complete changeset.

We excluded all patches that: only changed copyright information, had build errors, modified build infrastructure only, removed dead functions only, applied only to disabled features (e.g., win32), patched only BIND `contrib` features, only touched regression/unit tests, or used variadic functions. We also eliminated all patches

Codebase	Function	Type	Cause	New	Vulnerability
BIND	`receive_secure_db`	assert fail	double lock acquisition	✓	
BIND	`save_nsec3param`	assert fail	uninitialized struct	✓	
BIND	`configure_zone_acl`	assert fail	inconsistent null argument handling	✓	
BIND	`isc_lex_gettoken`	assert fail	input parsing logic	✓	
OpenSSL	`PKCS5_PBKDF2_HMAC`	uninitialized pointer dereference	uninitialized struct		
OpenSSL	`dtls1_process_record`	assert fail	inconsistent null check		
OpenSSL	`tls1_final_finish_mac`	null pointer dereference	unchecked return value	✓	
OpenSSL	`do_ssl3_write`	null pointer dereference	callee side effect after null check	✓	CVE-2014-0198
OpenSSL	`PKCS7_dataDecode`	null pointer dereference	unchecked return value	✓	
OpenSSL	`EVP_DecodeUpdate`	out-of-bounds array access	negative count passed to memcpy	✓	CVE-2015-0292
OpenSSL	`dtls1_buffer_record`	use-after-free	improper error handling	✓	
OpenSSL	`pkey_ctrl_gost`	uninitialized pointer dereference	improper error handling	✓	

Figure 4: Summary of bugs UC-KLEE reported while checking patches. *New* indicates that the bug was previously unknown.

that yielded identical code after compiler optimizations. Because of tool limitations, we excluded patches that changed input datatypes (§ 2.2). Finally, to avoid inflating our verification numbers, we excluded three BIND commits that patched 200-300 functions each by changing a pervasive linked-list macro and/or replacing all uses of `memcpy` with `memmove`. Neither of these changes introduced any errors and, given their near-trivial modifications, shed little additional light on our tool's effectiveness. This yielded 487 patches from BIND and 324 patches from OpenSSL, both from 177 distinct commits to BIND and OpenSSL (purely by coincidence).

We compiled *patched* and *unpatched* versions of the codebase for each revision using an LLVM 2.7 toolchain. We then ran UC-KLEE over each patch for one hour. Each run was allocated a single Intel Xeon E5645 2.4GHz core and 4GB of memory on a compute cluster running 64-bit Fedora Linux 14. For these runs, we configured UC-KLEE to target crashes only in patched routines or routines they call. While this approach allows UC-KLEE to focus on the most likely source of errors, it does not detect bugs caused by the outputs of a function, which may trigger crashes elsewhere in the system (e.g., if the function unexpectedly returns null). UC-KLEE can report such differences, but we elide that feature in this paper.

Code modifications. In BIND and OpenSSL, we canonicalized several macros that introduced spurious code differences such as the `__LINE__`, `VERSION`, `SRCID`, `DATE`, and `OPENSSL_VERSION_NUMBER` macros. To support function-call annotations (§ 3.2.5) in BIND, we converted four preprocessor macros to function calls.

For BIND, we disabled expensive assertion-logging code and much of its debug `malloc` functionality, which UC-KLEE already provided. For OpenSSL, we added a new build target that disabled reference counting and address alignment. The reference counting caused many false positives; UC-KLEE reported double free errors due to unknown preconditions on an object's reference count.

3.2.2 Bugs found

From the patches we tested, UC-KLEE uncovered three previously unknown bugs in BIND and eight bugs in OpenSSL, six of which were previously unknown. These bugs are summarized in Figure 4.

```
1 :  LOCK_ZONE(zone);
2 :  if (DNS_ZONE_FLAG(zone, DNS_ZONEFLG_EXITING)
3 :      || !inline_secure(zone)) {
4 :    result = ISC_R_SHUTTINGDOWN;
5 :    goto unlock;
6 :  }
7 :  . . .
8 :  if (result != ISC_R_SUCCESS)
9 :    goto failure; /* ← bypasses UNLOCK_ZONE */
10:  . . .
11: unlock:
12:  UNLOCK_ZONE(zone);
13: failure:
14:  dns_zone_idetach(&zone);
```

Figure 5: BIND locking bug found in `receive_secure_db`.

Figure 5 shows a representative double-lock bug in BIND found by cross-checking. The patch moved the `LOCK_ZONE` earlier in the function (line 1), causing existing error handling code that jumped to `failure` (line 9) to bypass the `UNLOCK_ZONE` (line 12). In this case, the subsequent call to `dns_zone_idetach` (line 14) reacquires the already-held lock, which triggers an assertion failure. This bug was one of several we found that involved infrequently-executed error handling code. Worse, BIND often hides `goto failure` statements inside a `CHECK` macro, which was responsible for a bug we discovered in the `save_nsec3param` function (not shown). We reported the bugs to the BIND developers, who promptly confirmed and fixed them. These examples demonstrate a key benefit of UC-KLEE: it explores non-obvious execution paths that would likely be missed by a human developer, either because the code is obfuscated or an error condition is overlooked.

UC-KLEE is not limited to finding new bugs introduced by the patches; it can also find old bugs in patched code. We added a new mode where UC-KLEE flags errors that occur in both P and P' if the error *must* occur for all input values following that execution path (*must-fail* error described in § 3.2.5). This approach allowed us to find one new bug in BIND and four in OpenSSL. It also re-confirmed a number of bugs found by cross-checking above. This mode could be used to find bugs in functions that have not been patched, but we did not use it for that purpose in this paper.

Figure 6 shows a representative must-fail bug, a previously unknown null pointer dereference (denial-of-service) vulnerability we discovered in OpenSSL's

```
1 : if (wb−>buf == NULL) /* ← null pointer check */
2 :     if (!ssl3_setup_write_buffer(s))
3 :         return −1;
4 : . . .
5 : /* If we have an alert to send, lets send it */
6 : if (s−>s3−>alert_dispatch) {
7 :     /* call sets wb→buf to NULL */
8 :     i=s−>method−>ssl_dispatch_alert(s);
9 :     if (i <= 0)
10:         return(i);
11:     /* if it went, fall through and send more stuff */
12: }
13: . . .
14: unsigned char *p = wb−>buf; /* ← p = NULL */
15: *(p++)=type&0xff; /* ← null pointer dereference */
```

Figure 6: OpenSSL null pointer bug in `do_ssl3_write`.

`do_ssl3_write` function that led to security advisory CVE-2014-0198 [12] being issued. In this case, a developer attempted to prevent this bug by explicitly checking whether `wb->buf` is null (line 1). If the pointer is null, `ssl3_setup_write_buffers` allocates a new buffer (line 2). On line 6, the code then handles any pending alerts [20] by calling `ssl_dispatch_alert` (line 8). This call has the subtle side effect of freeing the write buffer when the common `SSL_MODE_RELEASE_BUFFERS` flag is set. After freeing the buffer, `wb->buf` is set to null (not shown), triggering a null pointer dereference on line 15.

This bug would be hard to find with other approaches. The write buffer is freed by a chain of function calls that includes a recursive call to `do_ssl3_write`, which one maintainer described as “sneaky” [44]. In contrast to static techniques that could not reason precisely about the recursion, UC-KLEE proved that under the circumstances when both an alert is pending and the release flag is set, a null pointer dereference *will* occur. This example also illustrates the weaknesses of regression testing. While a developer may write tests to make sure this function works correctly when an alert is pending *or* when the release flag is set, it is unlikely that a test would exercise these conditions simultaneously. Perhaps as a direct consequence, this vulnerability was nearly six years old.

3.2.3 Patches verified

In addition to finding new bugs, UC-KLEE exhaustively verified all execution paths for 67 (13.8%) of the patches in BIND, and 48 (14.8%) of the patches in OpenSSL. Our system effectively verified that, up to the given input bound and with the usual caveats, these patches did not introduce any new crashes. This strong result is not possible with imprecise static analysis or testing.

The median instruction coverage (§ 3.2.4) for the exhaustively verified patches was 90.6% for BIND and 100% for OpenSSL, suggesting that these patches were thoroughly tested. Only six of the patches in BIND and one in OpenSSL achieved very low (0-2%) coverage. We determined that UC-KLEE achieved low coverage on these patches due to dead code (2 patches); an insufficient symbolic input bound (2 patches); comparisons between input pointers (we assume no aliasing, 1 patch); symbolic `malloc` size (1 patch); and a trivial stub function that was optimized away (1 patch).

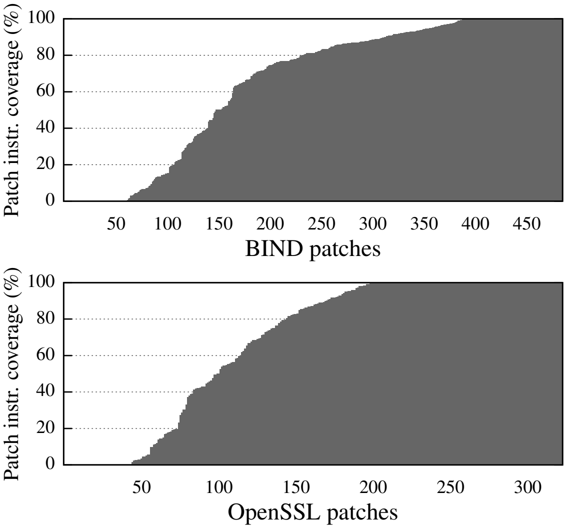

Figure 7: Coverage of patched instructions: 100% coverage for 98 BIND patches (20.1%) and 124 OpenSSL patches (38.3%). Median was 81.1% for BIND, 86.9% for OpenSSL.

3.2.4 Patches partially verified

This section measures how thoroughly we check non-terminating patches using two metrics: (1) instruction coverage, and (2) number of execution paths completed.

We conservatively measure instruction coverage by counting the number of instructions that differ in P' from P and then computing the percentage of these instructions that UC-KLEE executes at least once. Figure 7 plots the instruction coverage. The median coverage was 81.1% for BIND and 86.9% for OpenSSL, suggesting that UC-KLEE thoroughly exercised the patched code, even when it did not exhaust all paths.

Figure 8 plots the number of completed execution paths for each patch we did not exhaustively verify (§ 3.2.3) that hit at least one patched instruction. These graphs exclude 31 patches for BIND and 32 patches for OpenSSL for which our system crashed during the one hour execution window. The crashes were primarily due to bugs in our tool and memory exhaustion/blowup caused by symbolically executing cryptographic ciphers.

For the remaining patches, UC-KLEE completed a median of 5,828 distinct paths per patch for BIND and 1,412 for OpenSSL. At the upper end, 154 patches for BIND (39.6%) and 79 for OpenSSL (32.4%) completed over 10,000 distinct execution paths. At the bottom end, 58 patches for BIND (14.9%) and 46 for OpenSSL (18.9%) completed zero execution paths. In many cases, UC-KLEE achieved high coverage on these patches but neither detected errors nor ran the non-error paths to com-

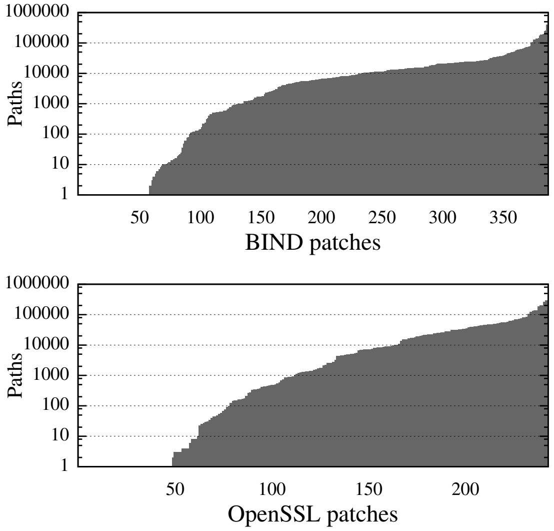

Figure 8: Completed execution paths (log scale). Median was 5,828 paths per patch for BIND and 1,412 for OpenSSL. Top quartile was 17,557 paths for BIND and 21,859 for OpenSSL.

pletion. A few reasons we observed for paths not running to completion included query timeouts, unspecified symbolic function pointers, or ineffective search heuristics.

These numbers should only be viewed as a crude approximation of thoroughness; they do not measure the independence between the paths explored (greater is preferable). On the other hand, they grossly undercount the number of distinct concrete values each symbolic path reasons about simultaneously. One would generally expect that exercising 1,000 or more paths through a patch, where each path simultaneously tests all feasible values, represents a dramatic step beyond the current standard practice of running the patch on a few tests.

3.2.5 False positives

This section describes our experience in separating true bugs from *false positives*, which were due to missing input preconditions. The false positives we encountered were largely due to three types of missing preconditions:

1. Data structure invariants, which apply to all instances of a data structure (e.g., a parent node in a binary search tree has a greater value than its left child).
2. State machine invariants, which determine the sequence of allowed values and the variable assignments that may exist simultaneously (e.g., a counter increases monotonically).
3. API invariants, which determine the legal inputs to API entry points (e.g., a caller must not pass a null pointer as an argument).

Figure 9 illustrates a representative example of a false positive from BIND, which was caused by a missing data structure invariant. The `isc_region_t` type consists of a buffer and a length, but UC-KLEE has no knowledge that the two are related. The code selects a valid buffer length at line 14, the shorter of the two buffers. At line 17, the code calls `memcmp` and supplies this length. Inside `memcmp`, UC-KLEE reported hundreds of false positives involving out-of-bounds memory reads. These errors occurred on false paths where the buffer pointed to by the `base` field was smaller than the associated `length` field.

```
1 : typedef struct isc_region {
2 :     unsigned char * base;
3 :     unsigned int    length;
4 : } isc_region_t;
5 :
6 : int isc_region_compare(isc_region_t *r1, isc_region_t *r2) {
7 :   unsigned int l;
8 :   int result;
9 :
10:   REQUIRE(r1 != NULL);
11:   REQUIRE(r2 != NULL);
12:
13:   /* chooses min. buffer length */
14:   l = (r1−>length < r2−>length) ? r1−>length : r2−>length;
15:
16:   /* memcmp reads out-of-bounds */
17:   if ((result = memcmp(r1−>base, r2−>base, l)) != 0)
18:     return ((result < 0) ? −1 : 1);
19:   else
20:     return ((r1−>length == r2−>length) ? 0 :
21:       (r1−>length < r2−>length) ? −1 : 1);
22: }
```

Figure 9: Example false positive in BIND. UC-KLEE does not associate `length` field with buffer pointed to by `base` field. Consequently, UC-KLEE falsely reports that `memcmp` (line 17) reads out-of-bounds from `base`.

UC-KLEE manages false positives using two approaches: manual annotations and automated heuristics.

Manual annotations. UC-KLEE supports two types of manual annotations: (1) data type annotations, and (2) function call annotations. Both are written in C and compiled with LLVM. UC-KLEE invokes data type annotations at the end of a path, prior to emitting an error. These are associated with named data types and specify invariants on symbolic inputs of that type (inferred from debug information when available). For the example above, we added the following simple annotation for the `isc_region_t` data type:

```
INVARIANT(r−>length <= OBJECT_SIZE(r−>base));
```

The `INVARIANT` macro requires that the condition hold. If it is infeasible (cannot be true) on the current path, UC-KLEE emits an error report with a flag indicating that the annotations have been violated. We use this flag to filter out uninteresting error reports. This one simple annotation allowed us to filter 623 errors, which represented about 7.5% of all the errors UC-KLEE reported for BIND.

Function call annotations are used to run specific code immediately prior to calling a function. For example, we wrote a function call annotation for BIND that runs before each call to `isc_mutex_lock`, with the same arguments:

```
void annot_isc_mutex_lock(isc_mutex_t *mp) {
  EXPECT(*mp == 0);
}
```

Figure 10: Effects of heuristics on false positives. *Tot.* indicates the total number of reports, of which *Bugs* are true errors; *Patches* indicates the number of patches that reported at least one error. P' *only* refers to errors that occurred only in function P'; *P and* P' occurred in both versions. Indent indicates successive heuristics; * indicates that we reviewed all the reports manually.

Macro	**Description**
`INVARIANT(condition)`	Add `condition` as a path constraint; kill path if infeasible.
`EXPECT(condition)`	Add `condition` as a path constraint if feasible; otherwise, ignore.
`IMPLIES(a, b)`	Logical implication: $a \rightarrow b$.
`HOLDS(a)`	Returns true if condition `a` *must* hold.
`MAY_HOLD(a)`	Returns true if condition `a` *may* hold.
`SINK(e)`	Forces `e` to be evaluated; prevents compiler from optimizing it away.
`VALID_POINTER(ptr)`	Returns true if `ptr` is valid; false otherwise.
`OBJECT_SIZE(ptr)`	Returns the size of the object pointed to by `ptr`; kills path if pointer is invalid.

Figure 11: C annotation macros.

The `EXPECT` macro adds the specified path constraint only if the condition is feasible on the current path and elides it otherwise. In this example, we avoid considering cases where the mutex is already locked. However, this annotation has no effect if the condition is *not* feasible (i.e., the lock has definitely been acquired along this path). This annotation allows UC-KLEE to detect errors in lock usage while suppressing false positives under the assumption that if a function attempts to acquire a lock supplied as input, then a likely input precondition is that the lock is not already held. This annotation did not prevent us from finding the BIND locking bug in `receive_secure_db` shown in Figure 5.

Figure 11 summarizes the convenience macros we provided for expressing annotations using C code. While annotations may be written using arbitrary C code, these macros provide a simple interface to functionality not expressible with C itself (e.g., determining the size of a heap object using `OBJECT_SIZE`). The `HOLDS` and `MAY_HOLD` macros allow code to check the feasibility of a Boolean expression without causing UC-KLEE to fork execution and trigger path explosion.

For BIND, we wrote 13 function call annotations and 31 data type annotations (about 400 lines of C). For OpenSSL, we wrote six data type annotations and no function call annotations (60 lines). We applied a single set of annotations for each codebase to all the patches we tested. In our experience, most of these annotations were simple to specify and often suppressed many false positives. We felt the level of effort required was reasonable compared to the sizes of the codebases we checked. We added annotations lazily, in response to false positives.

Figure 10 illustrates the effects of the annotations and heuristics on the error reports for BIND and OpenSSL. The P' *only* column describes errors that only occurred in the patched function, while *P and* P' describes errors that occurred in both versions. In this experiment, we are primarily concerned with bugs introduced by a patch, so our discussion describes P' *only* unless otherwise noted.

The manual annotations suppressed 42% of the reports for BIND but only 9.6% for OpenSSL. We attribute this difference to the greater effort we expended writing manual annotations for BIND, for which the automated heuristics were less effective without the annotations.

Automated heuristics. We tried numerous heuristics to reduce false reports. UC-KLEE augments each error report with a list of the heuristics that apply. The **must-fail** heuristic identifies errors that *must* occur for all input values following that execution path, since these are often true errors [18]. For example, assertion failures are must-fail when the condition must be false.

A variation on the must-fail heuristic is the **belief-fail** heuristic, which uses a form of belief analysis [19]. The intuition behind this heuristic is that if a function *contradicts* itself, it likely has a bug. For example, if the code checks that a pointer is null and then dereferences the pointer, it has a bug, regardless of any input preconditions. On the other hand, a function is generally agnostic to the assumptions made by the functions it calls. For example, if `strcmp` checks whether two strings have the same address, the caller does not acquire this belief, even if the path constraints now indicate that the two addresses match. Following this intuition, the belief-fail heuristic identifies errors that occur for all input values satisfying the *belief set*, which is the set of constraints (i.e., branch conditions) added within the current function or inherited from its caller, but not its callees. We track belief sets for each stack frame.

A second variation on must-fail is **concrete-fail**, which indicates that an assertion failure or memory error was triggered by a concrete (non-symbolic) condition or pointer, respectively. In practice, this heuristic and belief-fail were the most effective.

These heuristics reduced the total number of reports to a small enough number that we were able to inspect them all manually. While only 8.6% of the belief-fail errors for BIND and 20% of those for OpenSSL were true bugs, the total number of these errors (60) was manageable relative to the number of patches we tested (811). In total, the annotations and belief-fail heuristic eliminated 98.6% of false positives for BIND and 98.2% for OpenSSL.

A subset of the belief-fail errors were caused by reading past the end of an input buffer, and none of these were true bugs. Instead, they were due to paths reaching the input bound we specified. In many cases, our system would emit these errors for any input bound because they involved unbounded loops (e.g., `strlen`). The *excluding inputs* row in Figure 10 describes the subset of belief-fail errors not related to input buffers. This additional filter produced a small enough set of *P and P′* errors for OpenSSL that we were able to manually inspect them, discovering a number of additional bugs. We note that the *true errors* listed in Figure 10 constitute 12 distinct bugs; some bugs showed up in multiple error reports.

4 Generalized checking

In addition to checking patches, UC-KLEE provides an interface for rule-based checkers to be invoked during symbolic path exploration. These checkers are similar to tools built using dynamic instrumentation systems such as Valgrind [34] or Pin [30]. Unlike these frameworks, however, UC-KLEE applies its checkers to all possible paths through a function, not to a single execution path through a program. In addition, UC-KLEE considers all possible input values along each path, allowing it to discover bugs that might be missed when checking a single set of concrete inputs.

Conceptually, our framework is similar to WOODPECKER [8], a KLEE-based tool that allows system-specific checkers to run on top of (whole program) symbolic execution. In this paper, however, we focus on generic checkers we implemented for rules that apply to many systems, and we directly invoked these checkers on individual functions deep within each codebase.

UC-KLEE provides a simple interface for implementing checkers by deriving from a provided C++ base class. This interface provides hooks for a checker to intercept memory accesses, arithmetic operations, branches, and several types of errors UC-KLEE detects.

A user invoking UC-KLEE provides a compiled LLVM module and the name of a function to check. We refer to this function as the *top-level* function. Generally, the module has been linked to include all functions that might be called by the top-level function. When UC-KLEE encounters a function call, it executes the called function. When UC-KLEE encounters a call to a function missing from the LLVM module, however, it may optionally skip over the function call rather than terminate the path with an error message. When UC-KLEE skips a function call, it creates a new under-constrained value to represent the function's return value, but it leaves the function's arguments unchanged. This approach *under-approximates* the behaviors that the missing function might perform (e.g., writing to its arguments or globals). Consequently, UC-KLEE may miss bugs and cannot provide verification guarantees when functions are missing.

We briefly experimented with an alternative approach in which we overwrote the skipped function's arguments with new under-constrained values, but this over-approximation caused significant path explosion, mostly involving paths that could not arise in practice.

In addition to missing functions due to scalability limitations, we also encountered inline assembly (Linux kernel only) and unresolved symbolic function pointers. We skipped these two cases in the same manner as missing functions. For all three cases, UC-KLEE provides a hook to allow a checker to detect when a call is being skipped and to take appropriate actions for that checker.

In the remainder of this section, we describe each checker, followed by our experimental results in § 4.4.

4.1 Leak checker

Memory leaks can lead to memory exhaustion and pose a serious problem for long-running servers. Frequently, they are exploitable as denial-of-service vulnerabilities [10, 13, 14]. To detect memory leaks (which may or may not be remotely exploitable, depending on their location within a program), we implemented a leak checker on top of UC-KLEE. The leak checker considers a heap object to be leaked if, after returning from the top-level function, the object is not reachable from a *root set* of pointers. The root set consists of a function's (symbolic) arguments, its return value, and all global variables. This checker is similar to the leak detection in Purify [23] or Valgrind's memcheck [34] tool, but it thoroughly checks all paths through a specific function, rather than a single concrete path through a whole program.

When UC-KLEE encounters a missing function, the leak checker finds the set of heap objects that are reachable from each of the function call's arguments using a precise approach based on pointer referents [42, 43]. It then marks these objects as *possibly escaping*, since the missing function could capture pointers to these objects and prevent them from becoming unreachable. At the end of each execution path, the leak checker removes any possibly escaping objects from the set of leaked objects.

Doing so allows it to report only true memory leaks, at the cost of possibly omitting leaks when functions are missing. However, UC-KLEE may still report false leaks along invalid execution paths due to missing input preconditions. Consider the following code fragment:

```
1 : char* leaker() {
2 :     char *a = (char*) malloc(10); /* not leaked */
3 :     char *b = (char*) malloc(10); /* maybe leaked */
4 :     char *c = (char*) malloc(10); /* leaked! */
5 :
6 :     bar(b); /* skipped call to bar */
7 :     return a;
8 : }
```

When UC-KLEE returns from the function `leaker`, it inspects the heap and finds three allocated objects: `a`, `b`, and `c`. It then examines the root set of objects. In this example, there are no global variables and `leaker` has no arguments, so the root set consists only of `leaker`'s return value. UC-KLEE examines this return value and finds that the pointer `a` is live (and therefore not leaked). However, neither `b` nor `c` is reachable. It then looks at its list of *possibly escaping* pointers due to the skipped call to `bar` on line 6, which includes `b`. UC-KLEE subtracts `b` from the set of leaked objects and reports back to the user that `c` has been leaked. While this example is trivial, UC-KLEE discovered 37 non-trivial memory leak bugs in BIND, OpenSSL, and the Linux kernel (§ 4.4).

4.2 Uninitialized data checker

Functions that access uninitialized data from the stack or heap exhibit undefined or non-deterministic behavior and are particularly difficult to debug. Additionally, the prior contents of the stack or heap may hold sensitive information, so code that operates on these values may be vulnerable to a loss of confidentiality.

UC-KLEE includes a checker that detects accesses to uninitialized data. When a function allocates stack or heap memory, the checker fills it with special *garbage* values. The checker then intercepts all loads, binary operations, branches, and pointer dereferences to check whether any of the operands (or the result of a load) contain garbage values. If so, it reports an error to the user.

In practice, loads of uninitialized data are often intentional; they frequently arise within calls to `memcpy` or when code manipulates bit fields within a C `struct`. Our evaluation in § 4.4 therefore focuses on branches and dereferences of uninitialized pointers.

When a call to a missing function is skipped, the uninitialized data checker *sanitizes* the function's arguments to avoid reporting spurious errors in cases where missing functions write to their arguments.

4.3 User input checker

Code that handles untrusted user input is particularly prone to bugs that lead to security vulnerabilities since an attacker can supply any possible input value to exploit the code. Generally, UC-KLEE treats inputs to a function as *under-constrained* because they may have unknown preconditions. For cases where inputs originate from untrusted sources such as network packets or user-space data passed to the kernel, however, the inputs can be considered *fully-constrained*. This term indicates that the set of legal input values is known to UC-KLEE; in this case, any possible input value may be supplied. If any value triggers an error in the code, then the error is likely to be exploitable by an attacker, assuming that the execution path is feasible (does not violate other preconditions).

UC-KLEE maintains *shadow memory* (metadata) associated with each symbolic input that tracks whether each symbolic byte is under-constrained or fully-constrained. UC-KLEE provides an interface for system-specific C annotations to mark untrusted inputs as fully-constrained by calling the function `ucklee_clear_uc_byte`. This function sets the shadow memory for each byte to the *fully-constrained* state.

UC-KLEE includes a system-configurable user input checker that intercepts all errors and adds an `UNSAFE_INPUT` flag to errors caused by fully-constrained inputs. For memory access errors, the checker examines the pointer to see if it contains fully-constrained symbolic values. For assertion failures, it examines the assertion condition. For division-by-zero errors, it examines the divisor.

In all cases, the checker inspects the fully-constrained inputs responsible for an error and determines whether any path constraints compare the inputs to under-constrained data (originating elsewhere in the program). If so, the checker assumes that the constraints *may* properly sanitize the input, and it suppresses the error. Otherwise, it emits the error. This approach avoids reporting spurious errors to the user, at the cost of missing errors when inputs are partially (but insufficiently) sanitized.

We designed this checker primarily to find security vulnerabilities similar to the OpenSSL "Heartbleed" vulnerability [1, 11] from 2014, which passed an untrusted and unsanitized length argument to `memcpy`, triggering a severe loss of confidentiality. In that case, the code never attempted to sanitize the length argument. To test this checker, we ran UC-KLEE on an old version of OpenSSL without the fix for this bug and confirmed that our checker reports the error.

4.4 Evaluation

We evaluated UC-KLEE's checkers on over 20,000 functions from BIND, OpenSSL, and the Linux kernel. For BIND and OpenSSL, we used UC-KLEE to check all functions except those in the codebases' `test` directories. We used the same minor code modifications described in § 3.2.1, and we again used a maximum input

	Leak Checker				Uninitialized Data Checker					User Input Checker			
	Funcs.	Bugs	Reports	False	Funcs.	Bugs	Pointer Reports	Pointer False	Branch Reports	Funcs.	Bugs	Reports	False
BIND	6239	9	138	2.2%	6239	3	0	-	244*	6239	0	67	100%
OpenSSL	6579	5	$272^{\dagger}$	90.1%	6579	6	197	92.90%	564*	6579	0	5	100%
Linux kernel	5812	23	127	76.4%	7185	10	72	83.30%	494*	1857	11	145	80.0%

Figure 12: Summary of results from running UC-KLEE checkers on *Funcs* functions from each codebase. *Bugs* shows the number of distinct true bugs found (67 total). *Reports* shows the total number of errors reported by UC-KLEE in each category (multiple errors may point to a single bug). *False* reports the percentage of errors reported that did not appear to be true bugs (i.e., false positives). †excludes reports for obfuscated ASN.1 code. *denotes that we inspected only a handful of errors for that category.

```
1 : int gssp_accept_sec_context_upcall(struct net *net,
2 :                                     struct gssp_upcall_data *data) {
3 :   ...
4 :   ret = gssp_alloc_receive_pages(&arg);
5 :   ...
6 :   gssp_free_receive_pages(&arg);
7 :   ...
8 : }
9 : int gssp_alloc_receive_pages(struct gssx_arg_accept_sec_context *arg) {
10:   arg−>pages = kzalloc(...);
11:   ...
12:   return 0;
13: }
14: void gssp_free_receive_pages(struct gssx_arg_accept_sec_context *arg) {
15:   for (i = 0; i < arg−>npages && arg−>pages[i]; i++)
16:     __free_page(arg−>pages[i]);
17:   /* missing: kfree(arg−>pages); */
18: }
```

Figure 13: Linux kernel memory leak in RPCSEC_GSS protocol implementation used by NFS server-side AUTH_GSS.

size of 25,000 bytes and a depth bound of 9 objects.

For the Linux kernel, we included functions relevant to each checker, as described below. Unlike our evaluation in § 3.2, we did not use any manual annotations to suppress false positives. We ran UC-KLEE for up to five minutes on each function from BIND and the Linux kernel, and up to ten minutes on each OpenSSL function. We used the same machines as in § 3.2.

For BIND, we checked version 9.10.1-P1 (12/2014). For OpenSSL, we checked version 1.0.2 (1/2015). For the Linux kernel, we checked version 3.16.3 (9/2014).

Figure 12 summarizes the results. UC-KLEE discovered a total of 67 previously-unknown bugs[1]: 12 in BIND, 11 in OpenSSL, and 44 in the Linux kernel. Figure 14 lists the number of functions that UC-KLEE exhaustively verified (up to the given input bound and with caveats) as having each property. We omit verification results from the Linux kernel because UC-KLEE skipped many function calls and inline assembly, causing it to under-approximate the set of possible execution paths and preventing it from making any verification guarantees. We did link each Linux kernel function with other modules from the same directory, however, as well as the `mm/vmalloc.c` module.

	No leaks	No `malloc`	No uninitialized data
BIND	388	1776	2045
OpenSSL	383	1648	2043

Figure 14: Functions verified (with caveats) by UC-KLEE.

4.4.1 Leak checker

The leak checker was the most effective. It reported the greatest number of bugs (37 total) and the lowest false positive rate. Interestingly, only three of the 138 leak reports for BIND were spurious errors, a false positive rate of only 2.2%. For OpenSSL, we excluded 269 additional reports involving the library's obfuscated ASN.1 [25] parsing code, which we could not understand. Of the remaining 272 reports, the checker found five bugs but had a high false positive rate of 90.1%.

For the Linux kernel, we wrote simple C annotations (about 60 lines) to intercept calls to `kmalloc`, `vmalloc`, `kfree`, `vfree`, and several similar functions, and to forward these to UC-KLEE's built-in `malloc` and `free` functions. Doing so allowed us to track memory management without the overhead of symbolically executing the kernel's internal allocators. We then ran UC-KLEE on all functions that directly call these allocation functions.

Our system discovered 23 memory leaks in the Linux kernel. One particularly interesting example (Figure 13) involved the SunRPC layer's server-side implementation of `AUTH_GSS` authentication for NFS. Each connection triggering an upcall causes 512 bytes allocated at line 10 to be leaked due to a missing `kfree` that should be present around line 17. Since this leak may be triggered by remote connections, it poses a potential denial-of-service (memory exhaustion) vulnerability. The NFS maintainers accepted our patch to fix the bug.

UC-KLEE found that at least 2909 functions in BIND and at least 3700 functions in OpenSSL (or functions they call) allocate heap memory. As shown in Figure 14, UC-KLEE verified (with caveats) that 388 functions in BIND and 383 in OpenSSL allocate heap memory but do not leak it. Our system also verified that 1776 functions in BIND and 1648 functions in OpenSSL do not allocate heap memory, making them trivially leak-free.

4.4.2 Uninitialized data checker

The uninitialized data checker reported a total of 19 new bugs. One illustrative example, shown in Figure 15, in-

[1] A complete list of the bugs we discovered is available at: `http://cs.stanford.edu/~daramos/usenix-sec-2015`

```
1 :   points = OPENSSL_malloc(sizeof (EC_POINT*)*(num + 1));
2 :   ...
3 :   for (i = 0; i < num; i++) {
4 :     if ((points[i] = EC_POINT_new(group)) == NULL)
5 :       goto err; /* leaves 'points' only partially initialized */
6 :   }
7 :   ...
8 : err:
9 :   ...
10:   if (points) {
11:     EC_POINT **p;
12:     for (p = points; *p != NULL; p++)
13:       EC_POINT_free(*p); /* dereference/free of uninitialized pointer */
14:     OPENSSL_free(points);
15:   }
```

Figure 15: OpenSSL dereference/`free` of uninitialized pointer in `ec_wNAF_precompute_mult` function.

volves OpenSSL's elliptic curve cryptography. If the call to `EC_POINT_new` on line 4 fails, the code jumps to line 8, leaving the `points` array partially uninitialized. Line 13 then passes uninitialized pointers from the array to `EC_POINT_free`, which dereferences the pointers and passes them to `free`, potentially corrupting the heap. This is one of many bugs that we found involving infrequently executed error-handling code, a common source of security bugs.

UC-KLEE discovered an interesting bug (Figure 16) in BIND's UDP port randomization fix for Kaminsky's cache poisoning attack [9]. To prevent spoofed DNS replies, BIND must use unpredictable source port numbers. The `dispatch_createudp` function calls the `get_udpsocket` function at line 9, which selects a pseudorandom number generator (PRNG) at line 18 based on whether we are using a UDP or TCP connection. However, the `socktype` field isn't initialized in `dispatch_createudp` until line 12, meaning that the PRNG selection is based on uninitialized data. While it appears that the resulting port numbers are sufficiently unpredictable despite this bug, this example illustrates UC-KLEE's ability to find errors with potentially serious security implications.

For the Linux kernel, we checked the union of the functions we used for the leak checker and the user input checker (discussed below) and found 10 bugs.

Due to time limitations, we exhaustively inspected only the most serious category of errors: uninitialized pointers. The checker reported too many uninitialized branches for us to examine completely, but we did inspect a few dozen of these errors in an ad-hoc manner. All three of the bugs from BIND and one bug from the Linux kernel fell into this category. The remaining bugs were uninitialized pointer errors. We did not inspect the error reports for binary operations or load values.

Finally, our system verified (with caveats) that about a third of the functions from BIND (2045) and OpenSSL (2043) do not access uninitialized data. We believe that providing this level of guarantee on such a high percentage of functions with almost no manual effort is a strong result not possible with existing tools.

```
1 : #define DISP_ARC4CTX(disp) \
2 :   ((disp)->socktype == isc_sockettype_udp) \
3 :   ? (&(disp)->arc4ctx) : (&(disp)->mgr->arc4ctx)
4 : static isc_result_t dispatch_createudp(..., unsigned int attributes, ...) {
5 :   ...
6 :   result = dispatch_allocate(mgr, maxrequests, &disp);
7 :   ...
8 :   if ((attributes & DNS_DISPATCHATTR_EXCLUSIVE) == 0) {
9 :     result = get_udpsocket(mgr, disp, ...);
10:     ...
11:   }
12:   disp->socktype = isc_sockettype_udp; /* late initialization */
13:   ...
14: }
15: static isc_result_t get_udpsocket(..., dns_dispatch_t *disp, ...) {
16:   ...
17:   /* PRNG selected based on uninitialized 'socktype' field */
18:   prt = ports[dispatch_uniformrandom(DISP_ARC4CTX(disp), nports)];
19:   ...
20: }
```

Figure 16: BIND non-deterministic PRNG selection bug.

4.4.3 User input checker

The user input checker required us to identify data originating from untrusted sources. Chou [6] observed that data swapped from network byte order to host byte order is generally untrusted. We applied this observation to OpenSSL and used simple annotations (about 40 lines of C) to intercept calls to `n2s`, `n2l`, `n2l3`, `n2l6`, `c2l`, and `c2ln`, and mark the results fully-symbolic. We also applied a simple patch to OpenSSL to replace byte-swapping macros with function calls so that UC-KLEE could use our annotations. We hope to explore automated ways of identifying untrusted data in future work.

For BIND, we annotated (about 50 lines) the byte-swapping functions `ntohs` and `ntohl`, along with `isc_buffer_getuint8` and three other functions that generally read from untrusted buffers.

For the Linux kernel, we found that many network protocols store internal state in network byte order, leading to spurious errors if we consider these to be untrusted. Instead, we annotated (about 40 lines) the `copy_from_user` function and `get_user` macro (which we converted to a function call). In addition, we used an option in UC-KLEE to mark all arguments to the system call handlers `sys_*` as untrusted. Finally, we used UC-KLEE to check the 1502 functions that directly invoke `copy_from_user` and `get_user`, along with the 355 system call handlers in our build.

Reassuringly, this checker did not discover any bugs in the latest versions of BIND or OpenSSL. We attribute this both to the limited amount of data we marked as untrusted and to our policy of suppressing errors involving *possibly* sanitized data (see § 4.3). However, we were able to detect the 2014 "Heartbleed" vulnerability [1, 11] when we ran our system on an old version of OpenSSL.

Interestingly, we did discover 11 new bugs in the Linux kernel. Seven of these bugs were division- or

```
1 : static int dg_dispatch_as_host(..., struct vmci_datagram *dg) {
2 :   /* read length field from userspace datagram */
3 :   dg_size = VMCI_DG_SIZE(dg);
4 :   ...
5 :   dg_info = kmalloc(sizeof(*dg_info) +
6 :           (size_t) dg−>payload_size, GFP_ATOMIC);
7 :   ...
8 :   /* unchecked memcpy length; read overrun */
9 :   memcpy(&dg_info−>msg, dg, dg_size);
10:   ...
11: }
```

Figure 17: Linux kernel VMware Communication Interface driver unchecked `memcpy` length (buffer overread) bug.

remainder-by-zero operations that would trigger floating-point exceptions and crash the kernel. The remaining four bugs are out-of-bounds dereferences.

Figure 17 shows a buffer overread bug we discovered in the kernel driver for the VMware Communication Interface (VMCI) that follows a pattern nearly identical to "Heartbleed." The userspace datagram `dg` is read using `copy_from_user`. The code then allocates a destination buffer on line 5 and invokes `memcpy` on line 9 without sanitizing the `dg_size` field read from the datagram. An attacker could potentially use this bug to copy up to 69,632 bytes of private kernel heap memory and send it from the host OS to the guest OS. Fortunately, this vulnerability is only exploitable by code running locally on the host OS. The maintainers quickly patched this bug.

Figure 18 shows an unsanitized remainder-by-zero bug we found in the kernel driver for the CEPH distributed filesystem. The check at line 6 aims to prevent this bug with a 64-bit comparison, but the divisor at line 8 uses only the low 32 bits of the untrusted `stripe_unit` field (read from userspace using `copy_from_user`). A value such as `0xffffffff00000000` would pass the check but result in a remainder-by-zero error. An unprivileged local attacker could potentially issue an `ioctl` system call to crash the machine. We notified the developers, who promptly fixed the bug.

Because of the ad-hoc nature of this checker, we did not use it to exhaustively verify any properties about the functions we checked.

5 Implementation

This section details optimizations and techniques we implemented to scale our framework and address problems we encountered while applying it to large systems.

5.1 Object sizing

Recall that when an unbound symbolic pointer is dereferenced, UC-KLEE must allocate memory and bind the pointer to it. One challenge in implementing this functionality is picking a useful object size to allocate. If the size is too small, later accesses to this object may trigger out-of-bounds memory errors. On the other hand, a size that is too large can hide legitimate errors. We handled this tradeoff using two approaches.

```
1 : static long _validate_layout(..., struct ceph_ioctl_layout *l) {
2 :   ...
3 :   /* validate striping parameters */
4 :   if ((l−>object_size & ˜PAGE_MASK) ||
5 :        (l−>stripe_unit & ˜PAGE_MASK) ||
6 :        (l−>stripe_unit != 0 && /* ← 64-bit check */
7 :                                   /* 32-bit divisor: */
8 :         ((unsigned)l−>object_size % (unsigned)l−>stripe_unit)))
9 :           return −EINVAL;
10:   ...
11: }
```

Figure 18: Linux kernel CEPH distributed filesystem driver remainder-by-zero bug in `ioctl` handler.

The first approach, which we used for our experiment in § 3.2, implemented a form of *backtracking*. At each unbound pointer dereference, UC-KLEE *checkpoints* the execution state and chooses an initial allocation size using a heuristic that examines any available type information [42]. If the path later reads out-of-bounds from this object, UC-KLEE (1) emits the error to the user, and (2) restores the checkpoint and uses an allocation size large enough to satisfy the most recent memory access. UC-KLEE records the sequence of branches taken after each checkpoint, and it forces the path to *replay* the sequence of branches after increasing the allocation size. In practice, replaying branches exposed many sources of non-determinism in the baseline KLEE tool and its system modeling code, which we were able to eliminate through significant development effort.

An alternative approach that we recently incorporated into UC-KLEE is to use symbolically-sized objects, rather than selecting a single concrete size. Doing so avoids the need for backtracking in most cases by simultaneously considering many possible object sizes. At each memory access, UC-KLEE determines whether the offset could exceed the object's symbolic size. If so, it emits an error to the user. It also considers a path on which the offset does not exceed this bound and adds a path constraint that sets a lower bound on the object's size. We used this approach for our evaluation in § 4.4.

5.2 Error reporting

With whole program symbolic execution, symbolic inputs typically represent unstructured strings or byte arrays from command line arguments or file contents. In this case, an error report typically contains a single set of concrete inputs that trigger the error, along with a backtrace. With under-constrained symbolic execution, however, the inputs are often complex, pointer-rich data structures since UC-KLEE directly executes individual functions within a program. In this case, a single set of concrete values is not easily understood by a user, nor can it be used to trivially reproduce the error outside of UC-KLEE because pointer inputs expect memory objects (i.e., stack, heap, and globals) to be located at specific addresses.

To provide more comprehensible error reports, UC-

KLEE emits a *path summary* for each error. The path summary provides a complete listing of the source code executed along the path, along with the path constraints added by each line of source. The path constraints are expressed in a C-like notation and use the available LLVM debug information to determine the types and names of each field. Below we list example constraints that UC-KLEE included with error reports for BIND (§ 3.2):

```
Code:        REQUIRE(VALID_RBTDB(rbtdb));
Constraint:  uc_dns_rbtdb1.common.impmagic == 1380074548

Code:        if (source->is_file)
Constraint:  uc_inputsource1.is_file == 0

Code:        if (c == EOF)
Constraint:  uc_var2[uc_var1.current + 1] == 255
```

5.3 General KLEE optimizations

We added several scalability improvements to UC-KLEE that apply more broadly to symbolic execution tools. To reduce path explosion in library functions such as `strlen`, we implemented special versions that avoid forking paths by using symbolic if-then-else constructs. We also introduced scores of rules to simplify symbolic expressions [42]. We elide further details due to space.

5.3.1 Lazy constraints

During our experiments, we faced query timeouts and low coverage for several benchmarks that we traced to symbolic division and remainder operations. The worst cases occurred when an unsigned remainder operation had a symbolic value in the denominator. To address this challenge, we implemented a solution we refer to as *lazy constraints*. Here, we defer evaluation of expensive queries until we find an error. In the common case where an error does not occur or two functions exhibit crash equivalence along a path, our tool avoids ever issuing potentially expensive queries. When an error is detected, the tool re-checks that the error path is feasible (otherwise the error is invalid).

Figure 19(a) shows a simple example. With *eager constraints* (the standard approach), the if-statement at line 2 triggers an SMT query involving the symbolic integer division operation `y / z`. This query may be expensive, depending on the other path constraints imposed on `y` and `z`. To avoid a potential query timeout, UC-KLEE introduces a lazy constraint (Figure 19(b)). On line 1, it replaces the result of the integer division operation with a new, unconstrained symbolic value `lazy_x` and adds the lazy constraint `lazy_x = y / z` to the current path. At line 2, the resulting SMT query is the trivial expression `lazy_x > 10`. Because `lazy_x` is unconstrained, UC-KLEE will take both the *true* and *false* branches following the if-statement. One of these branches may violate the constraints imposed on `y` and `z`, so UC-KLEE must check that the lazy constraints are consistent with the full set of path constraints prior to emitting any errors to the user (i.e., if the path later crashes).

```
1 : int x = y / z;
2 : if (x > 10) /* query: y / z > 10 */
3 :    ...
```

(a) Eager constraints (standard)

```
1 : int x = lazy_x; /* adds lazy constraint: lazy_x = y / z */
2 : if (x > 10) /* query: lazy_x > 10 */
3 :    ...
```

(b) Lazy constraints

Figure 19: Lazy constraint used for integer division operation.

In many cases, the delayed queries are more efficient than their eager counterparts because additional path constraints added after the division operation have narrowed the solution space considered by the SMT solver. If our tool determines that the path is infeasible, it silently terminates the path. Otherwise, it reports the error to the user.

5.4 Function pointers

Systems such as the Linux kernel, BIND, and OpenSSL frequently use function pointers within `struct` types to emulate object-oriented methods. For example, different function addresses may be assigned depending on the version negotiated for an SSL/TLS connection [20]. This design poses a challenge for our technique because symbolic inputs contain symbolic function pointers. When our tool encounters an indirect call through one of these pointers, it is unclear how to proceed.

We currently require that users specify concrete function pointers to associate with each type of object (as the need arises). When our tool encounters an indirect call through a symbolic pointer, it looks at the object's debug type information. If the user has defined function pointers for that type of object, our tool executes the specified function. Otherwise, it reports an error to the user and terminates the path. The user can leverage these errors to specify function pointers only when necessary. For BIND, we found that most of these errors could be eliminated by specifying function pointers for only six types: three for memory allocation, and three for internal databases. For OpenSSL, we specified function pointers for only three objects: two related to support for multiple SSL/TLS versions, and one related to I/O.

When running UC-KLEE's checkers, we optionally allow the tool to skip unresolved function pointers, which allows it to check more code but prevents verification guarantees for the affected functions (see § 4).

6 Related work

This paper builds on prior work in symbolic execution [4], particularly KLEE [5] and our early work on UC-KLEE [43]. Unlike our previous work, which targeted small library routines, this paper targets large systems and supports generalized checking.

Other recent work has used symbolic execution to check patches. DiSE [39] performs whole program symbolic execution but prunes paths unaffected by a patch. Differential Symbolic Execution (DSE) [38] and regression verification [21] use abstraction to achieve scalability but may report false differences. By contrast, our approach soundly executes complete paths through each patched function, eliminating this source of false positives. Impact Summaries [2] complement our approach by soundly pruning paths and ignoring constraints unaffected by a patch.

SymDiff [27] provides a scalable solution to check the equivalence of two programs with fixed loop unrolling but relies on imprecise, uninterpreted functions. Differential assertion checking (DAC) [28] is the closest to our work and applies SymDiff to the problem of detecting whether properties that hold in P also hold in P', a generalization of crash equivalence. However, DAC suffers from the imprecisions of SymDiff and reports false differences when function calls are reordered by a patch. Abstract semantic differencing [37] achieves scalability through clever abstraction but, as with SymDiff, suffers additional false positives due to over-approximation.

Recent work has used symbolic execution to generate regression tests exercising the code changed by a patch [41, 31, 32]. While they can achieve high coverage, these approaches use existing regression tests as a starting point and greedily redirect symbolic branch decisions toward a patch, exploring only a small set of execution paths. By contrast, our technique considers all possible intermediate program values as input (with caveats).

Dynamic instrumentation frameworks such as Valgrind [34] and PIN [30] provide a flexible interface for checkers to examine a program's execution at runtime and flag errors. However, these tools instrument a single execution path running with concrete inputs, making them only as effective as the test that supplies the inputs.

Similar to our use of generalized checking in UC-KLEE is WOODPECKER [8], which uses symbolic execution to check system-specific rules. Unlike UC-KLEE, WOODPECKER applies to whole programs, so we expect it would not scale well to large systems. However, WOODPECKER aggressively prunes execution paths that are redundant with respect to individual checkers, a technique that would be useful in UC-KLEE.

Prior work in memory leak detection has used static analysis [45], dynamic profiling [24], and binary rewriting [23]. Dynamic tools such as Purify [23] and Valgrind [34] detect a variety of memory errors at runtime, including uses of uninitialized data. CCured [33] uses a combination of static analysis and runtime checks to detect pointer errors. Our user input checker relates to prior work in dynamic taint analysis, including TaintCheck [35] and Dytan [7].

7 Conclusions and future work

We have presented UC-KLEE, a novel framework for validating patches and applying checkers to individual C/C++ functions using under-constrained symbolic execution. We evaluated our tool on large-scale systems code from BIND, OpenSSL, and the Linux kernel, and we found a total of 79 bugs, including two OpenSSL denial-of-service vulnerabilities.

One avenue for future work is to employ UC-KLEE as a tool for finding general bugs (e.g., out-of-bounds memory accesses) in a single version of a function, rather than cross-checking two functions or using specialized checkers. Our preliminary experiments have shown that this use case results in a much higher rate of false positives, but we did find a number of interesting bugs, including the OpenSSL denial-of-service attack for which advisory CVE-2015-0291 [15, 22, 42] was issued.

In addition, we hope to further mitigate false positives by using ranking schemes to prioritize error reports, and by inferring invariants to reduce the need for manual annotations. In fact, many of the missing input preconditions can be thought of as consequences of a weak type system in C. We may target higher-level languages in the future, allowing our framework to assume many built-in invariants (e.g., that a length field corresponds to the size of an associated buffer).

TaintPipe: Pipelined Symbolic Taint Analysis

Jiang Ming, Dinghao Wu, Gaoyao Xiao, Jun Wang, and Peng Liu

Abstract

Taint analysis has a wide variety of compelling applications in security tasks, from software attack detection to data lifetime analysis. Static taint analysis propagates taint values following all possible paths with no need for concrete execution, but is generally less accurate than dynamic analysis. Unfortunately, the high performance penalty incurred by dynamic taint analyses makes its deployment impractical in production systems. To ameliorate this performance bottleneck, recent research efforts aim to decouple data flow tracking logic from program execution. We continue this line of research in this paper and propose *pipelined symbolic taint analysis*, a novel technique for parallelizing and pipelining taint analysis to take advantage of ubiquitous multi-core platforms. We have developed a prototype system called TaintPipe. TaintPipe performs very lightweight runtime logging to produce compact control flow profiles, and spawns multiple threads as different stages of a pipeline to carry out symbolic taint analysis in parallel. Our experiments show that TaintPipe imposes low overhead on application runtime performance and accelerates taint analysis significantly. Compared to a state-of-the-art inlined dynamic data flow tracking tool, TaintPipe achieves 2.38 times speedup for taint analysis on SPEC 2006 and 2.43 times for a set of common utilities, respectively. In addition, we demonstrate the strength of TaintPipe such as natural support of multi-tag taint analysis with several security applications.

1 Introduction

Taint analysis is a kind of program analysis that tracks some selected data of interest (taint seeds), e.g., data originated from untrusted sources, propagates them along program execution paths according to a customized policy (taint propagation policy), and then checks the taint status at certain critical location (taint sinks). It has been shown to be effective in dealing with a wide range of security problems, including software attack prevention [25, 40], information flow control [45, 34], data leak detection [49], and malware analysis [43], to name a few.

Static taint analysis [1, 36, 28] (STA) is performed prior to execution and therefore it has no impact on runtime performance. STA has the advantage of considering multiple execution paths, but at the cost of potential imprecision. For example, STA may result in either under-tainting or over-tainting [32] when merging results at control flow confluence points. Dynamic taint analysis (DTA) [25, 13, 27], in contrast, propagates taint as a program executes, which is more accurate than static taint analysis since it only considers the actual path taken at run time. However, the high runtime overhead imposed by dynamic taint propagation has severely limited its adoption in production systems. The slowdown incurred by conventional dynamic taint analysis tools [25, 13] can easily go beyond 30X times. Even with the state-of-the-art DTA tool based on Pin [20], typically it still introduces more than 6X slowdown.

The crux of the performance penalty comes from the strict coupling of program execution and data flow tracking logic. The original program instructions mingle with the taint tracking instructions, and usually it takes 6–8 extra instructions to propagate a taint tag in shadow memory [11]. In addition, the frequent "context switches" between the original program execution and its corresponding taint propagation lead to register spilling and data cache pollution, which add further pressure to runtime performance. The proliferation of multi-core systems has inspired researchers to decouple taint tracking logic onto spare cores in order to improve performance [24, 31, 26, 15, 17, 9]. Previous work can be classified into two categories. The first category is hardware-assisted approaches. For example, Speck [26] needs OS level support for speculative execution and rollback. Ruwase et al. [31] employ a customized hardware for logging a program trace and delivering it to other idle cores for inspection. Nagarajan et al. [24] utilize a hardware first-in first-out buffer to speed up communication between cores. Although they can achieve an appealing performance, the requirement of special hardware prevents them from being adopted using commodity hardware.

The second category is software-only methods that work with binary executables on commodity multi-core hardware [15, 17, 9]. These software-only solutions rely on dynamic binary instrumentation (DBI) to decouple dynamic taint analysis from program execution. The program execution and parallelized taint analysis have to be properly synchronized to transfer the runtime values that are necessary for taint analysis. Although these approaches look promising, they fail to achieve expected performance gains due to the large amounts of communication data and frequent synchronizations between the original program execution thread (or process) and its corresponding taint analysis thread (or process). Recent work ShadowReplica [17] creates a secondary shadow thread from primary application thread to run DTA in parallel. ShadowReplica conducts an offline optimization to generate optimized DTA logic code, which reduces the amount of information that needs to be communicated, and thus dramatically improves the performance. However, as we will show later, the performance improvement achieved by this “primary & secondary” thread model is fixed and cannot be improved further when more cores are available. Furthermore, in many security related tasks (e.g., binary de-obfuscation and malware analysis), precise static analysis for the offline optimization needed by ShadowReplica may not be feasible.

In this paper, we exploit another style of parallelism, namely pipelining. We propose a novel technique, called TaintPipe, for parallel data flow tracking using *pipelined symbolic taint analysis*. In principle, TaintPipe falls within the second category of taint decoupling work classified above. Essentially, in TaintPipe, threads form multiple pipeline stages, working in parallel. The execution thread of an instrumented application acts as the source of pipeline, which records information needed for taint pipelining, including the control flow data and the concrete execution states when the taint seeds are first introduced. To further reduce the online logging overhead, we adopt a compact profile format and an N-way buffering thread pool. The application thread continues executing and filling in free buffers, while multiple worker threads consume full buffers asynchronously. When each logged data buffer becomes full, an inlined call-back function will be invoked to initialize a taint analysis engine, which conducts taint analysis on a segment of straight-line code concurrently with other worker threads. Symbolic memory access addresses are determined by resolving indirect control transfer targets and approximating the ranges of the symbolic memory indices.

To overcome the challenge of propagating taint tags in a segment without knowing the incoming taint state, TaintPipe performs *segmented symbolic taint analysis*. That is, the taint analysis engine assigned to each segment calculates taint states symbolically. When a concrete taint state arrives, TaintPipe then updates the related taint states by replacing the relevant symbolic taint tags with their correct values. We call this *symbolic taint state resolution*. According to the segment order, TaintPipe sequentially computes the final taint state for every segment, communicates to the next segment, and performs the actual taint checks. Optimizations such as function summary and taint basic block cache offer enhanced performance improvements. Moreover, different from previous DTA tools, supporting bit-level and multi-tag taint analysis are straightforward for TaintPipe. TaintPipe does not require redesign of the structure of shadow memory; instead, each taint tag can be naturally represented as a symbolic variable and propagated with negligible additional overhead.

We have developed a prototype of TaintPipe, a pipelined taint analysis tool that decouples program execution and taint logic, and parallelizes taint analysis on straight-line code segments. Our implementation is built on top of Pin [23], for the pipelining framework, and BAP [5], for symbolic taint analysis. We have evaluated TaintPipe with a variety of applications such as the SPEC CINT2006 benchmarks, a set of common utilities, a list of recent real-life software vulnerabilities, malware, and cryptography functions. The experiments show that TaintPipe imposes low overhead on application runtime performance. Compared with a state-of-the-art inlined dynamic taint analysis tool, TaintPipe achieves overall 2.38 times speedup on SPEC CINT2006, and 2.43 times on a set of common utility programs, respectively. The efficacy experiments indicate that TaintPipe is effective in detecting a wide range of real-life software vulnerabilities, analyzing malicious programs, and speeding up cryptography function detection with multi-tag propagation. Such experimental evidence demonstrates that TaintPipe has potential to be employed by various applications in production systems. The contributions of this paper are summarized as follows:

- We propose a novel approach, TaintPipe, to efficiently decouple conventional inlined dynamic taint analysis by pipelining symbolic taint analysis on segments of straight-line code.
- Unlike previous taint decoupling work, which suffers from frequent communication and synchronization, we demonstrate that with very lightweight runtime value logging, TaintPipe rivals conventional inlined dynamic taint analysis in precision.

- Our approach does not require any specific hardware support or offline preprocessing, so TaintPipe is able to work on commodity hardware instantly.
- TaintPipe is naturally a multi-tag taint analysis method. We demonstrate this capability by detecting cryptography functions in binary with little additional overhead.

The remainder of the paper is organized as follows. Section 2 provides background information and an overview of our approach. Section 3 and Section 4 describe the details of the system design, online logging, and pipelined segmented symbolic taint analysis. We present the evaluation and application of our approach in Section 5. We discuss a few limitations in Section 6. We then present related work in Section 7 and conclude our paper in Section 8.

2 Background

In this section, we discuss the background and context information of the problem that TaintPipe seeks to solve. We start by comparing TaintPipe with the conventional inlined taint analysis approaches, and we then present the differences between the previous "primary & secondary" taint decoupling model and the pipelined decoupling style in TaintPipe.

2.1 Inlined Analysis vs. TaintPipe

Figure 1 ("Inlined DTA") illustrates a typical dynamic taint analysis mechanism based on dynamic binary instrumentation (DBI), in which the original program code and taint tracking logic code are tightly coupled. Especially, when dynamic taint analysis runs on the same core, they compete for the CPU cycles, registers, and cache space, leading to significant performance slowdown. For example, "context switch" happens frequently between the original program instructions and taint tracking instructions due to the starvation of CPU registers. This means there will be a couple of instructions, mostly inserted per program instruction, to save and restore those register values to and from memory. At the same time, taint tracking instructions themselves (e.g., shadow memory mapping) are already complicated enough. One taint shadow memory lookup operation normally needs 6–8 extra instructions [11].

Our approach, analogous to the hardware pipelining, decouples taint logic code to multiple spare cores. Figure 1 ("TaintPipe") depicts TaintPipe's framework, which consists of two concurrently running parts: 1) the instrumented application thread performing lightweight online logging and acting as the source of the pipeline; 2) multiple worker threads as different stages of the pipeline to perform symbolic taint analysis. Each horizontal bar with gray color indicates a working thread. We start online logging when the predefined taint seeds are introduced to the application. The collected profile is passed to a worker thread. Each worker thread constructs a straight-line code segment and then performs taint analysis in parallel. In principle, fully parallelizing dynamic taint analysis is challenging because there are strong serial data dependencies between the taint logic code and application code [31]. To address this problem, we propose *segmented symbolic taint analysis* inside each worker thread whenever the explicit taint information is not available, in which the taint state is symbolically calculated. The symbolic taint state will be updated later when the concrete data arrive. In addition to the control flow profile, the explicit execution state when the taint seeds are introduced is recorded as well. The purpose is to reduce the number of fresh symbolic taint variables.

We use a motivating example to introduce the idea of segmented symbolic taint analysis. Figure 2 shows an example for symbolic taint analysis on a *straight-line code segment*, which is a simplified code snippet of the `libtiff` buffer overflow vulnerability (CVE-2013-4231). Assume when a worker thread starts taint analysis on this code segment (Figure 2(a)), no taint state for the input data ("size" and "num" in our case) is defined. Instead of waiting for the explicit information, we treat the unknown values as taint symbols (`symbol1` for "size" and `symbol2` for "num", respectively) and summarize the net effect of taint propagation in the segment. The symbolic taint states are shown in Figure 2(b). When the explicit taint states are available, we resolve the symbolic taint states by replacing the taint symbols with their real taint tags or concrete values (Figure 2(c)). After that, we continue to perform concrete taint analysis like conventional DTA. Note that here we show pseudo-code for ease of understanding, while TaintPipe works on binary code.

Compared with inlined DTA, the application thread under TaintPipe is mainly instrumented with control flow profile logging code, which is quite lightweight. Therefore, TaintPipe results in much lower application runtime overhead. On the other hand, the execution of taint logic code is decoupled to multiple pipeline stages running in parallel. The accumulated effect of TaintPipe's pipeline leads to a substantial speedup on taint analysis.

2.2 "Primary & Secondary" Model

Some recent work [15, 17, 9] offloads taint logic code from the application (primary) thread to another shadow (secondary) thread and runs them on separate cores. At the same time, the primary thread communicates with

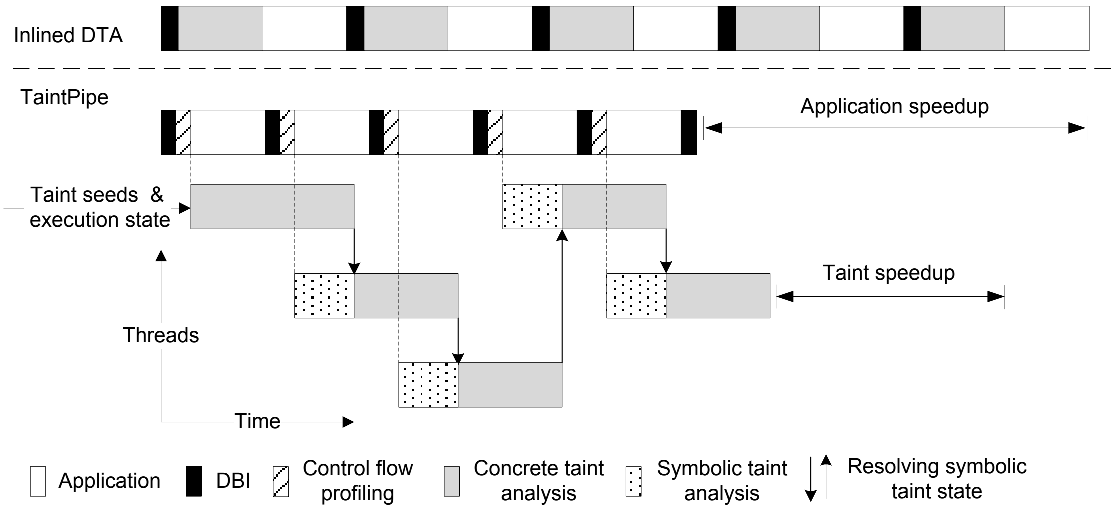

Figure 1: Inlined dynamic taint analysis vs. TaintPipe.

```
size = getc(infile);
A = -1;
B = size + 1;
C = (1 << size) - 1;
D = num & C;
```

(a) Code segment

Output	Taint state
A	0
B	symbol1 + 1
C	(1 << symbol1) − 1
D	symbol2 & ((1 << symbol1) − 1)

(b) Symbolic taint state

Output	Taint state
A	0
B	tag1 + 1
C	(1 << tag1) − 1
D	(1 << tag1) − 1

(c) Resolving symbolic taint state

Figure 2: An example of symbolic taint analysis on a code segment: (a) code segment; (b) symbolic taint states, the input value `size` and `num` are labeled as `symbol1` and `symbol2`, respectively; (c) resolving symbolic taint states when `size` is tainted as `tag1` and `num` is a constant value (num = 0xffffffff).

the secondary thread to convey the necessary information (e.g., the addresses of memory operations and control transfer targets) for performing taint analysis. However, this model suffers from frequent communication between the primary and secondary thread. In principle, every memory address that is loaded or stored has to be logged and transferred. Due to the frequent synchronization with the primary thread and the extra instructions to access shadow memory, taint logic execution in the secondary thread is typically slower than the application execution. As a result, the delay for each taint operation could be accumulated, leading to an delay proportional to the original execution. ShadowReplica [17] partially addresses this drawback by performing advanced offline static optimizations on the taint logic code to reduce the runtime overhead. However, in many security analysis scenarios, precise static analysis and optimizations over taint logic code are not feasible, e.g., reverse engineering and malware forensics. In such cases, program static features such as control flow graphs are possibly obfuscated.

In TaintPipe, we record compact control flow information to reconstruct *straight-line* code, in which all the targets of direct and indirect jumps have been resolved. However, we do not record or transfer the addresses of memory operations. Our key observation is that most addresses of memory operations can be inferred from the straight-line code. For example, if a basic block is ended with an indirect jump instruction `jmp eax`, we can quickly know the value of `eax` from the straight-line code. In this way, all the other memory indirect access calculated through `eax` (before it is updated) can be determined. For instance, we can infer the memory load address for the instruction: `mov ebx, [4*eax + 16]`. Even when the index of a memory lookup is a symbol, with the taint states and path predicates of the straight-line code, we can often narrow down the symbolic memory addresses to a small range in most cases.

Since TaintPipe's data communication is lightweight, TaintPipe can achieve nearly constant delay given enough number of worker threads. The upper limit number of worker threads is also bounded, which equals roughly the ratio of the taint analysis execution time over the application thread execution time for each segment.

Due to TaintPipe's pipelining design, it is possible that TaintPipe may detect an attack some time after the real attack has happened. However, this trade-off does not prevent TaintPipe from practically supporting a broad variety of security applications, such as attack forensic investigation and post-fact intrusion detection, which do not require strict runtime security enforcement. It is worth noting that different from ShadowReplica, TaintPipe does not depend on extensive static analysis to reduce data communication. Therefore, TaintPipe has a wider range of applications in speeding up analyzing obfuscated binaries, as static analysis of obfuscated binaries is of great challenge.

3 Design

3.1 Architecture

Figure 3 illustrates the architecture of TaintPipe. We have built the pipelining framework on top of a dynamic binary instrumentation tool, enabling TaintPipe to work with unmodified program binaries. The steps followed by TaintPipe for pipelining taint analysis are:

1. TaintPipe takes in a binary along with the taint seeds as input. The instrumented application thread starts execution with lightweight online logging for control flow and other information (Section 4.1.1).

2. Then the instrumented program is executed together with a multithreaded logging tool to efficiently deliver the logged data to memory (Section 4.1.2).

3. When the profile buffer becomes full, a taint analysis engine will be invoked for online pipelined taint analysis (Section 4.2.1).

4. The generated log data are then used to construct straight-line code, which helps to solve many precision loss problems in static taint analysis. In this stage, we generate a segment of executed code blocks for each logged data buffer. The memory addresses that are accessed through indirect jump targets are also resolved (Section 4.2.2).

5. The taint analysis engine will further translate straight-line code to taint operations, which avoid precision loss and support both multi-tag and bit-level taint analysis (Section 4.2.3).

6. With the constructed taint operations, TaintPipe performs pipelined symbolic taint analysis. When a thread finishes taint analysis with an explicit taint state, it synchronizes with its following thread to resolve the symbolic taint state (Section 4.2.4).

3.2 Segmented Symbolic Taint Analysis

In this section, we analyze symbolic taint analysis from a theoretical point of view to justify the correctness of our pipelining scheme. In order to formalize *segmented symbolic taint analysis*, we use the following notations:

1. Let σ denote a taint state, which maps variables to their taint tags.

2. Let $\mathscr{A}(\sigma,S)$ denote a symbolic taint analysis $\mathscr{A}$ on a straight-line code segment S, with an initial taint state σ. We use $\mathscr{A}_\sigma(S)$ for convenience.

Note that the straight-line code segment S has no control transfer statement. Conceptually, S only contains one type of statements, namely assignment statements. Of course, from the implementation point of view, there may be other types of statements, but they can all be regarded as assignment statements. For example, as we will show in Section 4.2.3, our taint operations contain assignment operations, laundering operations, and arithmetic operations. The latter two operations can be derived from taint assignment operations.

Based on the semantics of assignment statements, we define symbolic taint analysis for an assignment statement as follows:

$$\mathscr{A}_\sigma(x := e) = \sigma[x \mapsto e^t] \tag{1}$$

where e^t denotes the taint tag of e, and $[\cdot]$ is the taint state update operator. If x is a new variable, the taint state σ is extended with a new mapping from x to its taint. If x occurs in the taint state σ, for the variables in the domain of σ whose symbolic taint expressions depend on x, their symbolic taint expressions will be updated or recomputed with the new taint value of x.

Assume $\sigma_1 = \mathscr{A}_\sigma(i_1)$ for a statement i, then the symbolic taint analysis for two sequential statements $i_1;i_2$ is:

$$\mathscr{A}_\sigma(i_1;i_2) = \mathscr{A}_{\sigma_1}(i_2) \tag{2}$$

Assume straight-line code segment $S_1 = (i_1;S_1')$. We can then deduce the symbolic taint analysis on two sequential segments $S_1;S_2$ as follows:

$$\begin{aligned} &\mathscr{A}_\sigma(S_1;S_2)\\ =&\mathscr{A}_\sigma((i_1;S_1');S_2)\\ =&\mathscr{A}_\sigma(i_1;(S_1';S_2))\\ =&\cdots\\ =&\mathscr{A}_{\mathscr{A}_\sigma(S_1)}(S_2)\end{aligned} \tag{3}$$

That is, given $\mathscr{A}_\sigma(S_1) = \sigma_1$ and $\mathscr{A}_\varepsilon(S_2) = \sigma_2$, where ε is an empty taint state, Eq. 3 leads to:

$$\mathscr{A}_\sigma(S_1;S_2) = \sigma_2[\sigma_1] \tag{4}$$

Logged Control Flow
Straight-line Code Construciton
Pipelined Symbolic Taint Analysis

Figure 3: Architecture.

Here, we misuse the taint state update operator $[\cdot]$ and apply it to a taint state map, instead of a single taint variable update. With Eq. 4, we can perform segmented taint analysis in parallel or in a pipeline style. For two segments $S_1;S_2$, assume the starting taint state is σ_0. We start two threads, one compute $\mathscr{A}_{\sigma_0}(S_1)$ and the other computes $\mathscr{A}_{\varepsilon}(S_2)$, where ε is an empty taint state. Assume the result of the first thread analysis is σ_1 and the result of the second is σ_2. The symbolic taint analysis of $S_1;S_2$ is $\sigma_2[\sigma_1]$, that is, the right hand side of Eq. 4. Eq. 4 forms the foundation of our segmented taint analysis in a pipeline style.

4 Implementation

To demonstrate the efficacy of TaintPipe, we have developed a prototype on top of the dynamic binary instrumentation framework Pin [23] (version 2.12) and the binary analysis platform BAP [5] (version 0.8). The online logging and pipelining framework are implemented as Pin tools, using about 3,100 lines of C/C++ code. The taint operation constructors are built on BAP IL (intermediate language). TaintPipe's taint analysis engine is based on BAP's symbolic execution module, using about 4,400 lines of Ocaml and running concurrently with Pin tools. We utilize Ocaml's functor polymorphism so that taint states can be instantiated in either concrete or symbolic style. All of the functionality implemented in taint analysis engine are wrapped as function calls. To support communication between Pin tools and taint analysis engine, we develop a lightweight RPC interface so that each worker thread can directly call Ocaml code. The saving and loading of the taint cache lookup table is implemented using the Ocaml Marshal API, which encodes IL expressions as sequences of compact bytes and then stores them in a disk file.

Dynamic binary instrumentation tools tend to inline compact and branch-less code to the final translated code. For the code with conditional branches, DBI emits a function call instead, which introduces additional overhead. Therefore, we carefully design our instrumentation code to favor DBI's code inlining. To fully reduce online logging overhead, we also utilize Pin-specific optimizations. We leverage Pin's fast buffering APIs for efficient data buffering. For example, the inlined `INS_InsertFillBuffer()` writes the control flow profile directly to the given buffer; the callback function registered in `PIN_DefineTraceBuffer()` processes the buffer when it becomes full or thread exits. Besides, we force Pin to use the fastcall x86 calling convention to avoid emitting stack-based parameter loading instructions (i.e., push and pop). Currently Pin-tools do not support the Pthreads library. Thus we employ Pin Thread API to spawn multiple worker threads. We also implement a counting semaphore based on Pin's locking primitives to assist thread synchronization. Additionally, TaintPipe can be extended to support multithreaded applications with no difficulty by assigning one taint pipeline for each application thread.

4.1 Logging

TaintPipe's pipeline stages consist of multiple threads. The thread of instrumented application (producer) serves as the source of pipeline, and a number of Pin internal threads act as worker threads to perform symbolic taint analysis on the data collected from the application thread. Note that unlike application threads, worker threads are not JITed and therefore execute natively. One of the major drawbacks of previous dynamic taint analysis decoupling approaches is the large amount of information collected in the application thread and the high overhead of communication between the application thread and analysis thread. To address these challenges, TaintPipe performs lightweight online logging to record information required for pipelined taint analysis. The logged data comprise control flow profile and the concrete execution state when taint seeds are first introduced, which is the starting point of our pipelined taint analysis. The initial execution state, consisting of concrete context of registers and memory, (e.g., CR0∼CR4, EFLAGS and addresses of initial taint seeds), is used to reduce the number of fresh symbolic taint variables.

We take major two steps to reduce the application thread slowdown: First, we adopt a compact profile structure so that the profile buffer contains logged data as much as possible, and it is quite simple to recover the entry address of each basic block as well. Second, we apply the "one producer, multiple consumers" model and N-way buffering scheme to process full buffers asynchronously, which allows application to continue execution while pipelined taint analysis works in parallel. We will discuss each step in the following sub-sections.

4.1.1 Lightweight Online Logging

Besides the initial execution state when the taint seeds are introduced, TaintPipe collects control flow information, which is represented as a sequence of basic blocks executed. Conceptually, we can use a single bit to record the direction of conditional jump [29], which leads to a much more compact profile. However, reconstruction straight-line code from 1 bit profile is more complicated to make it fit for offline analysis. Zhao et al. [47] proposed *Detailed Execution Profile* (DEP), a 2-byte profile structure to represent 4-byte basic block address on x86-32 machine. In DEP, a 4-byte address is divided into two parts: *H-tag* for the 2 high bytes and *L-tag* for 2 low bytes. If two successive basic blocks have the same H-tag, only L-tag of each basic block enters the profile buffer; otherwise a special tag 0x0000 followed by the new H-tag will be logged into the buffer.

We extend DEP's scheme to support REP-prefix instructions. A number of x86 instructions related to string operations (e.g., MOVS, LODS) with REP-prefix are executed repeatedly until the counter register (ecx) counts down to 0. Dynamic binary instrumentation tools [23, 4] normally treat a REP-prefixed instruction as an implicit loop and generate a single instruction basic block in each iteration. In our evaluation, there are several cases that unrolling such REP-prefix instructions would be a performance bottleneck. We address this problem by adding additional escape tags to represent such implicit loops. Figure 4 presents an example of the control flow profile we adopted. The left part shows a segment of straight-line code containing 1028 basic blocks, and 1024 out of them are due to REP-prefixed instruction repetitions. Our profile (the right side of Figure 4) encodes such case with two consecutive escape tags (0xffff), followed by the number of iterations (0x0400).

We note that it is usually unnecessary to turn on the logging all the time. For example, when application starts executing, many functions are only used during loading. At that time, no sensitive taint seed is introduced. Therefore we perform on-demand logging to record control flow profile when necessary. As application starts running, we only instrument limited functions to inspect the various input channels that taint could be introduced into the application (taint seeds). Such taint seeds include standard input, files and network I/O. Besides, users can customize other values as taint seeds, such as function return values or parameters. When the pre-defined taint seeds are triggered, we turn on the control flow profile logging. At the same time, we save the current execution state to be used in the pipelined taint analysis. Many well-known library functions have explicit semantics, which facilitates us to selectively turn off logging inside these functions and propagate taint correspondingly at function level. We will discuss this issue further in Section 4.2.3.

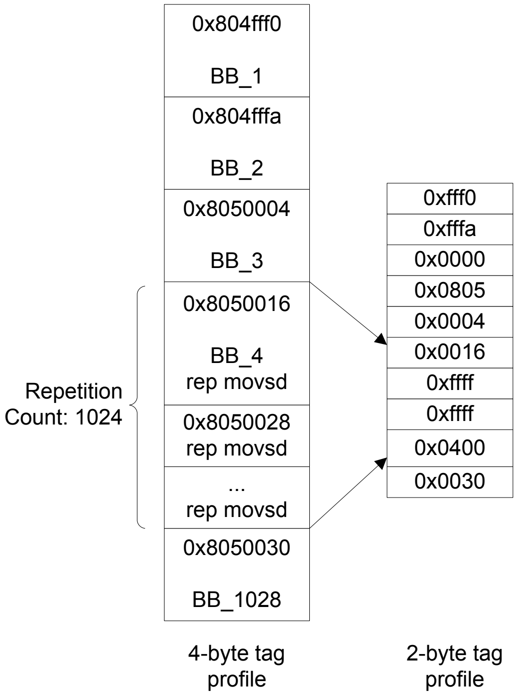

Figure 4: An example of 2-byte tag profile.

4.1.2 N-way Buffering Scheme

Since TaintPipe's online logging is lightweight, application (producer) thread's execution speed is typically faster than the processing speed of worker threads. To mitigate this bottleneck, we employed "one producer, multiple consumers" model and *N-way buffering scheme* [46]. At the center of our design is a thread pool, which is subdivided into n linked buffers, and the producer thread and multiple worker threads work on different buffers simultaneously. More specifically, when the instrumented application thread starts running, we first allocate n linked empty buffers ($n > 1$). At the same time, n Pin internal threads (worker threads) are spawned. Each worker thread is bound to one buffer and communicates with the application thread via semaphores. When a buffer becomes full, the application thread will release the full buffer to its corresponding worker thread and then continue to fill in the next available empty buffer. Given a full profile buffers, a worker thread will send it to a taint analysis engine to perform concrete/symbolic taint analysis in parallel. After that, the worker thread will release the profile buffer back to the application thread and wait for processing the next full buffer.

It is apparent that the availability of unused worker threads and the size of profile buffer will affect overall performance of TaintPipe (both application execution time and pipelined taint analysis) significantly. In Section 5.1, we will conduct a series of experiments to find the optimal values for these two factors.

4.2 Symbolic Taint Analysis

4.2.1 Taint Analysis Engine

When the application thread releases a full profile buffer, a worker thread is waked up to capture the profile buffer and then communicates with a taint analysis engine for pipelined taint analysis. The taint analysis engine will first convert the control flow profile to a segment of straight-line intermediate language (IL) code and then translates the IL code to even simpler taint logic operations. The translations are cached for efficiency at taint basic block level. The key components of taint analysis engine are illustrated in Figure 5.

The core of TaintPipe's taint analysis engine is an abstract taint analysis processor, which simulates a segment of taint operations and updates the taint states accordingly. The taint state structure contains two contexts: virtual registers keeping track of symbolic taint tags for register, and taint symbolic memory for symbolic taint tags in memory. The taint symbolic memory design is like the two-level page table structure and each page of memory consists of symbolic taint formulas rather than concrete values. After the initialization of the symbolic taint inputs, the engines perform taint analysis either concretely or symbolically in a pipeline style.

4.2.2 Straight-line Code Construction

Given the control flow profiles, recovering each basic block's H-tag and L-tag is quite straightforward. A basic block's entry address is the concatenation of its corresponding H-tag and L-tag [47]. The taint analysis engine should only execute the instructions required for taint propagation. Otherwise, the work thread may run much slower than the application thread. On the other side, due to the cumbersome x86 ISA, precisely propagating taint for the complex x86 instructions is an arduous work, especially for some instructions with side effect of conditional taint (e.g., `CMOV`). To achieve these two goals, we first extract the x86 instructions sequence from the application binary and then lift them to BIL [5], a RISC-like intermediate language. Since we know exactly the execution sequence, the sequence is a straight-line code. We have removed all the direct and indirect control transfer instructions and substituted them with control transfer target assertion statements.

After resolving an indirect control transfer, we go one step further to determine all the memory operation addresses which depend on this indirect control transfer target. For example, after we know the target of `jmp eax`, we continue to trace the use-def chain of `eax` for each memory load or store operation whose address is calculated through this `eax`. With the initial execution state (containing addresses of taint seeds) and indirect control transfer target resolving, we are able to decide most of the memory operation addresses.

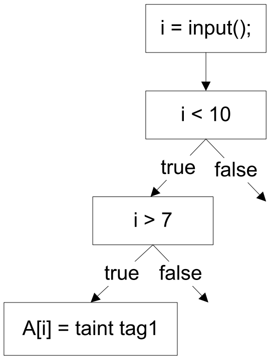

Figure 6: A path predicate constrains symbolic memory access within the boundary of $7 < i < 10$.

For some applications such as word processing, a symbolic taint input may be used as a memory lookup index. Without any constraint, a symbolic memory index could point to any memory cell. Inspired by the index-based memory model proposed by Cha et al. [8], we attempt to narrow down the symbolic memory accesses to a small range with symbolic taint states and path predicates. We first leverage value set analysis [2] to limit the range of a symbolic memory access and then refine the range by querying a constraint solver. The path predicate along the straight-line code usually limits the scope of symbolic memory access. Figure 6 shows such an example where the path predicate restricts the symbolic memory index i within a range such that $7 < i < 10$. When propagating a taint tag to the memory cell referenced by i, we conservatively taint all the possible memory slots, that is, `A[8]` and `A[9]` in Figure 6 will be tainted as `tag1`. In Section 5.3, we will demonstrate that our symbolic memory index solution only introduces marginal side effects.

4.2.3 Taint Operation Generation

Based on BIL statements, we construct taint operations. Taint operations inside a basic block are formed as "taint basic block" [37], which are cached for efficiency. To make the best of cache effect, we merge the basic blocks with only one predecessor and one successor. Since BIL explicitly reveals the side effect of intricate x86 instructions, it is easy to perform intra-block optimizations to get rid of redundant taint operations. Therefore, our taint

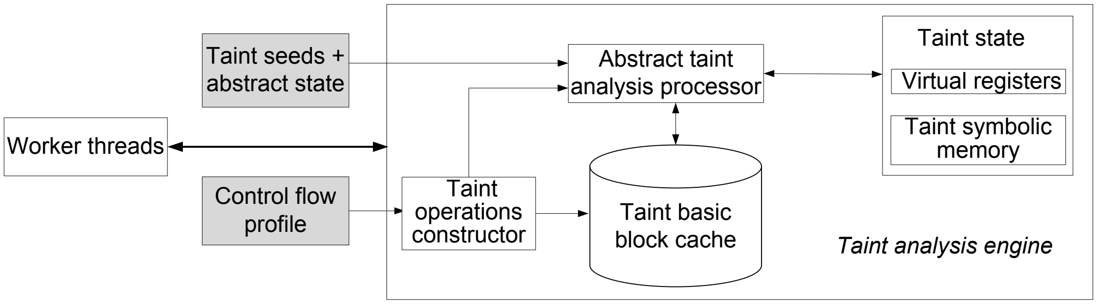

Figure 5: The structure of taint analysis engine.

operations are simple and accurate. Currently our taint operations mainly consist of three types of operations for tracking taint data:

1. Assignment operations: The operations in this category are involved in copying values between registers and registers/memory. We simply assign the taint tag of source operand to the destination operand.

2. Laundering operations: The operations are used to clean the taint tag of the destination operand. For example, `xor eax,eax` will clean the taint result of `eax`. We identify all laundering operations in taint basic blocks and substitute them with assignment operations.

3. Arithmetic and logic operations: This category of operations are the most difficult to handle. We emulate arithmetic and logic operations on the taint tags to capture their real semantics.

Figure 7 presents an example of taint operations for a basic block. TaintPipe's symbolic taint operations outperform conventional DTA approaches in three ways. First and foremost, multi-tag taint analysis is straightforward for TaintPipe. Each symbolic variable can naturally represent a taint tag (see Line 1 and Line 2 in Figure 7). Second, previous DTA tools mostly adopted a "short circuiting" method to handle arithmetic operations, that is, the destination is tainted if at least one of the source operands is tainted regardless of the real semantics. However, in many scenarios, it will lead to precision loss. Check the code at Line 4 and 5 in Figure 7, value *d* will always be zero since *b* is the negation of *a*. Unfortunately, some previous work may label *d* as tainted incorrectly [41]. Third, different from related work [20, 17], TaintPipe supports bit-level taint for EFLAGS register, representing whether a bit of the EFLAGS is tainted or not due to side effects. Recent work has demonstrated the value of bit-level taint in binary code de-obfuscation [42].

```
int a, b, c, d;
1: a = read ();          1: Taint (a) = tag1;
2: c = read ();          2: Taint (c) = tag2;
3: c = c xor c;          3: Taint (c) = 0;
4: b = ~ a;              4: Taint (b) = ~ tag1;
5: d = a & b;            5: Taint (d) = 0;
```

(a) a basic block (b) a taint basic block

Figure 7: Example: taint operations.

Table 1: Function summary.

Category	Function
No tainting	strcmp, strncmp, memcmp, strlen, strchr, strstr, strpbrk, strcspn, qsort, rand, time, clock, ctime
Function level	strcat, strncat, strcpy, strncpy, memcpy, memmove, strtok, atoi, itoa, abs tolower, toupper

Another major optimization we adopt is so called "function summary". As many well-known library functions have explicit semantics (e.g., atoi, strlen), we generate a summary of each function and propagate taint correspondingly at function level. Table 1 lists two types of function summary TaintPipe supports: 1) Functions within "no tainting" category do not have any side effect on taint state. We can safely turn off logging when executing them. 2) Some functions do propagate taint from an input parameter to output. We still turn off logging and update taint state correspondingly when these functions return.

4.2.4 Symbolic Taint State Resolution

In TaintPipe's pipeline framework, a worker thread may perform taint analysis concretely or symbolically in parallel. When a worker thread completes taint analysis with concrete taint tags, the final taint state it maintains is deterministic. Then it synchronizes with the subsequent worker thread to resolve the symbolic taint state maintained by the latter. Taint states are allocated in a shared memory area so that multiple threads can access them easily. Basically, given the concrete taint state at the beginning of a code segment, we replace a symbolic taint tag with the appropriate starting value (either a taint tag or a concrete value). We further update all the symbolic formula containing that symbolic taint tag. For example, the logic AND formula in Figure 2(b) will be simplified to a single taint tag. After that, the subsequent thread switches to the concrete taint analysis and continue processing the left segment code.

In this order, the taint states of each segment will be resolved and updated one by one. The defined taint policy (e.g., a function return value should not be tainted) is checked along the concrete taint analysis as well. A tainted sink is identified if it contains a symbolic formula; multiple tags are determined by counting the number of different symbols in the formula. Note that a previous hardware-assisted approach [31] utilized a separate "master" processor to update each segment's taint status sequentially. However, as pointed out by the paper, when there are more than a few "worker" processors, the master processor will become the bottleneck. Our approach amortizes the workload of the master processor to each worker thread.

5 Experimental Evaluation

We conducted experiments with several goals in mind. First, we wanted to choose optimal values for two factors that may affect TaintPipe's performance, namely control flow profile buffer size and the number of worker threads. Then we studied overall runtime overhead when running TaintPipe on the SPEC2006 int benchmarks and a number of common utilities. We also compared TaintPipe with a highly optimized inline dynamic taint analysis tool. At the same time, we wanted to make sure TaintPipe is effective in speeding up various security analysis tasks and can compete with conventional inlined dynamic taint analysis in precision. To this end, we demonstrated three compelling applications: 1) detecting software attacks; 2) tracking information flow in obfuscated malicious programs; and 3) identifying cryptography functions with multi-tag propagation.

5.1 Experiment Setup

Our experiment platform contains two Intel Xeon E5-2690 processors, 128GB of memory and a 250GB solid state drive, running Ubuntu12.04. Each processor is equipped with 8 2.9GHz cores, 16 hyper threads and 20MB L3 cache. The performance data reported in this section are all mean values with 5 repetitions.

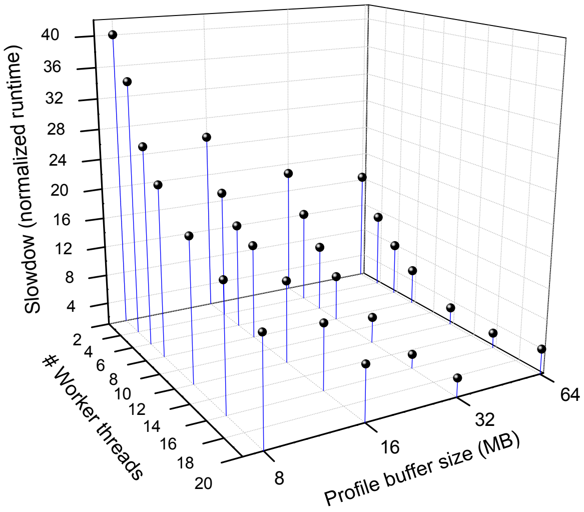

Figure 8: Optimal buffer size and number of worker threads.

TaintPipe's performance is affected by the size of the profile buffers and the number of worker threads. Generally, the more worker threads and larger profile buffers, the less possibility that an application is suspended to wait for a free buffer. On the other hand, our taint analysis engine has to take longer time to process larger segment code. We conducted a series of tests with the SPEC CPU2006 int benchmarks, under different settings of these two variables. We dynamically adjust the number of worker threads from 2 to 20 (2, 4, 6, 8, 12, 16 and 20), and profile size from 8MB to 64MB (8MB, 16MB, 32MB and 64MB). Figure 8 displays the experimental results. Roughly, as number of worker threads and buffer size increase, the application slowdown reduces. That is mainly because large buffer sizes allow application thread continue to fill up and worker threads spend less time on synchronization. After a certain point (buffer size $\geq$ 32MB and number of worker threads $>$ 16), overhead increases slightly. Two factors prevent TaintPipe from achieving more speedup. First, taint analysis engine slows down when processing large code segment. Second, more worker threads introduce larger communication latency when resolving symbolic taint states. According to the results, we set the two factors as their optimal values (32MB buffer size and 16 worker threads), which will be used in the following experiments.

5.2 Performance

To evaluate the performance gains achieved by pipelining taint logic, we compared TaintPipe with a state-of-the-art tool, libdft [20], which performs inlined dynamic taint analysis based on Pin ("libdft" bar). In addition, we developed a simple tool to measure the slowdown im-

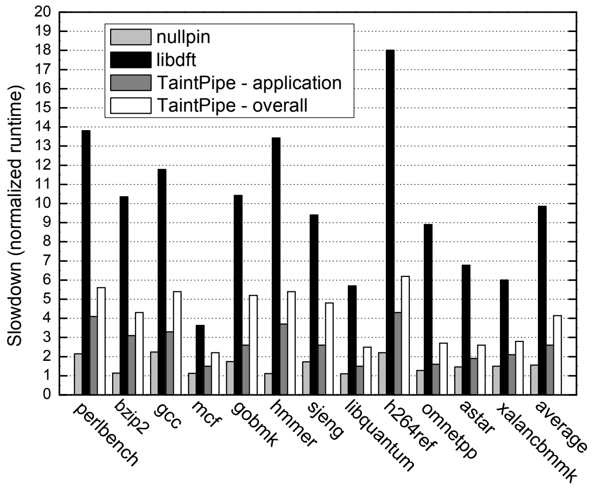

Figure 9: Slowdown on SPEC CPU2006.

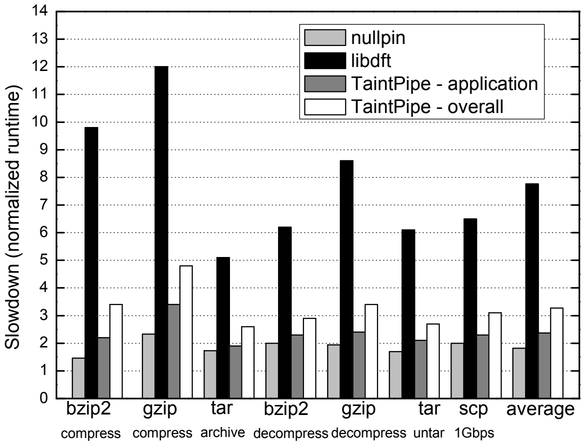

Figure 10: Slowdown on common Linux utilities.

posed exclusively by TaintPipe. It runs a program under Pin without any form of analysis ("nullpin" bar). The "TaintPipe - application" bar represents the running time of instrumented application thread alone, and "TaintPipe - overall" corresponds to the overall overhead when both the application thread and pipelined worker threads are running. The major reason we reported "TaintPipe - application" and "TaintPipe - overall" time separately is to show the two improvements, namely "Application speedup" and "Taint speedup" (see Figure 1). Since the application thread typically runs faster than the worker threads, the "TaintPipe - overall" time is actually dominated by the worker threads. Therefore, usually the "TaintPipe - overall" time represents the relative time spent by worker threads as well. The times reported in this section are all normalized to native execution, that is, application running time without dynamic binary instrumentation.

SPEC CPU2006. Figure 9 shows the normalized execution times when running the SPEC CPU2006 int benchmark suite under TaintPipe. On average, the instrumented application thread enforces a 2.60X slowdown to native execution, while the overall slowdown of TaintPipe is 4.14X. If we take Pin's environment runtime overhead ("nullpin" bar) as the baseline, we can see TaintPipe imposes 2.67X slowdown ("TaintPipe - overall" / "nullpin") and libdft introduces 6.4X slowdown—this number is coincident to the observation that propagating a taint tag normally requires extra 6–8 instructions [30, 11]. In summary, TaintPipe outperforms inlined dynamic taint analysis drastically: 2.38X faster than the inlined dynamic taint analysis, and 3.79X faster in terms of application execution. In the best case (*h264ref*), the application speedup under TaintPipe exceeds 4.18X.

Utilities. We also evaluated TaintPipe on four common Linux utilities, which were not chosen randomly. These four utilities represent three kinds of workloads: I/O bounded (`tar`), CPU bounded (`bzip2` and `gzip`), and the case in-between (`scp`). We applied `tar` to archive and extract the GNU Core utilities package (version 8.13) (∼50MB), then we employed `bzip2` and `gzip` to compress and decompress the archive file. Finally we utilized `scp` to copy the archive file over a 1Gbps link. As shown in Figure 10, TaintPipe reduced slowdown of dynamic taint analysis from 7.88X to 3.24X, by a factor of 2.43 on average.

Effects of Optimizations. In this experiment, we quantify the effects of taint logic optimizations we presented in Section 4.2, which are paramount for optimized TaintPipe performance. Figure 11 shows the impact of these optimizations when applied cumulatively on SPEC CPU2006 and the set of common utilities. The "unopt" bar approximates an un-optimized TaintPipe, which does not adopt any optimization method. The "O1" bar indicates the optimization of function summary, reducing application slowdown notably by 26.6% for SPEC CPU2006 and 25.0% for the common utilities. The "O2" bar captures the effect of taint basic block cache, leading to a further reduction by 19.0% and 22.9% for SPEC and utilities, respectively. Intra-block optimizations, denoted by "O3", offer further improvement, 12.0% with SPEC and 11.6% with the utilities).

Table 2: Tested software vulnerabilities.

Program	Vulnerability	CVE ID	# Taint Bytes		
			libdft	Temu	TaintPipe
Nginx	Validation Bypass	CVE-2013-4547	45	45	45
Micro_httpd	Validation Bypass	CVE-2014-4927	80	85	80
Tiny Server	Validation Bypass	CVE-2012-1783	125	126	125

Keitan	Backdoor	618	482	✓
Fireback	Backdoor	1038	620	✓

5.3 Security Applications

Software Attack Detection. One important application of taint analysis is to define taint policies, and ensure they are not violated during taint propagation. We tested TaintPipe with 12 recent software exploits listed in Table 2, which covers a wide range of real-life software vulnerabilities. For example, the vulnerabilities in `nginx`, `micro_httpd`, and `tiny server` allow remote attackers to bypass input validation and crash the program. The `libtiff` buffer overflow vulnerability leads to an out of bounds loop limit via a malformed gif image. Both `boa` and `thttpd` write data to a log file without sanitizing non-printable characters, which may be exploited to execute arbitrary commands. Since we have detailed vulnerability reports, we can easily mark the locations of taint sinks in the straight-line code and set corresponding taint policies.

In our evaluation, TaintPipe did not generate any false positives and successfully identified taint policy violations while incurring only small overhead. At the same time, we evaluated the accuracy of TaintPipe. To this end, we counted the total number of tainted bytes in the taint state when taint analysis hit the taint sinks. Column 4 $\sim$ 6 of Table 2 show the number of taint bytes when running libdft, Temu [44] and TaintPipe, respectively. Compared with the inlined dynamic taint analysis tools (libdft and Temu), TaintPipe's symbolic taint analysis achieves almost the same results in 8 cases and introduces only a few additional taint bytes in the other 4 cases. We attribute this to our conservative approach to handling of symbolic memory indices. The evaluation data show that TaintPipe does not result in over-tainting [32] and rivals the inlined dynamic taint analysis at the same level of precision.

Table 4: Cryptographic function detection time.

Algorithm	TaintPipe (s)	Temu (s)
TEA	3.8 (<1.1X)	15.2 (2.2X)
AES-CBC	12.3 (1.2X)	125.6 (3.8X)
Blowfish	4.5 (<1.1X)	21.4 (2.5X)
MD5	7.4 (<1.1X)	35.1 (2.6X)
SHA-1	8.8 (1.1X)	40.2 (3.3X)

Generating Taint Graphs for Malware. We ran 8 malware samples collected from `VX Heavens`[1] with TaintPipe.[2] Similar to Panorama [43], we tracked information flow and generated a *taint graph* for each sample. In a taint graph, nodes represent taint seeds or instructions operating on taint data, and a directed edge indicates an explicit data flow dependency between two nodes. Taint graph faithfully describes intrinsic malicious intents, which can be used as malware specification to detect suspicious samples [12]. The statistics of our testing results are presented in Table 3. It is worth noting that 6 out of 8 malware samples are applied with various control flow obfuscation methods (the fifth column), such as opaque predicates, control flow flattening, obfuscated control transfer targets, and call stack tampering. As a result, the control flow graphs are heavily cluttered. For example, malware samples `Keitan` and `Fireback` have a relatively high ratio of indirect jumps (e.g., `jmp eax`). Typically it is hard to precisely infer the destination of an indirect jump statically. Thus, the taint logic optimization methods that rely on accurate control flow graph [17, 18] will fail. In contrast, our approach does not rely on control flow graph and therefore we analyzed these obfuscated malware samples smoothly.

Cryptography Function Detection. Malware authors often use cryptography algorithms to encrypt malicious code, sensitive data, and communication. Detecting cryptography functions facilitates malware analysis and forensics. Recent work explored the *avalanche effect* to quickly identify possible cryptography functions by observing the input-output dependency with multi-tag taint analysis. That is, each byte in the encrypted message is dependent on almost all bytes of input data or key [7, 21, 48]. However, multi-tag dynamic taint analysis normally has to sacrifice more shadow memory and imposes much higher runtime overhead than single-tag dynamic taint analysis. Recall that multi-tag propagation is handled transparently in TaintPipe. In this experiment, we applied TaintPipe to detect such avalanche effects in binary code. We utilized the test case suite of Crypto++ library[3] and tested 5 cryptography algorithms. Each byte of the plain messages was labeled as a different taint tag. We compared TaintPipe with Temu [44], which supports multiple byte-to-byte taint propagation as well.[4] The detection time is shown in Table 4. We also reported the ratio of multi-tag's running time to single-tag's. The results show that TaintPipe is able to detect cryptographic functions with little additional overhead (less than 1.1X on average), while Temu's multi-tag propagation imposes a significant slowdown (2.9X to single-tag propagation on average).

6 Discussions and Limitations

Since TaintPipe's pipelining design leads to an asynchronous taint check, TaintPipe may detect a violation of taint policy after the real attack happens. One possible solution is to provide *synchronous* policy enforcement at critical points (e.g., indirect jump and system call sites). In that case, we can explicitly suspend the application thread, and wait for the worker threads to complete. Our current design spawns worker threads in the same process of running both Pin and the application. In the future, we plan to replace the worker threads with different processes to increase isolation.

As TaintPipe may perform symbolic taint analysis when explicit taint states are not available, TaintPipe exhibits similar limitations as symbolic execution of binaries. Recent work MAYHEM [8] proposes an advanced index-based memory model to deal with symbolic memory index. We plan to extend our symbolic memory index handling in the future. TaintPipe recovers the straight-line code by logging basic block entry address. However, with malicious self-modifying code, the entry address may not uniquely identify a code block. To address this issue, we can augment TaintPipe by logging the real executed instructions at the expense of runtime performance overhead.

Our focus is to demonstrate the feasibility of pipelined symbolic taint analysis. We have not fully optimized the symbolic taint analysis part which we believe can be greatly improved in terms of performance based on our current prototype. As our taint analysis engine simulates the semantics of taint operations, the speed of taint analysis is slow. One future direction is to execute concrete taint analysis natively like micro execution [16] and switch to the interpretation-style when performing symbolic taint analysis. Currently TaintPipe requires large share memory to reduce communication overhead between different pipeline stages. Therefore, our approach is more suitable for large servers with sufficient memory.

[1] http://vxheaven.org

[2] All these 8 samples are not packed. To analyze packed binaries, we can start TaintPipe when the unpacking procedure arrives at the original entry point.

[3] http://www.cryptopp.com/

[4] libdft does not support multi-tag taint analysis.

7 Related Work

In this section we first present previous work on static and dynamic taint analysis. Our work is a hybrid of these two analyses. Then we introduce previous efforts on taint logic code optimization, which benefits our taint operation generation. Finally, we describe recent work on decoupling taint tracking logic from original program execution, which is the closest to TaintPipe's method.

Static and Dynamic Taint Analysis. Since static taint analysis (STA) is performed prior to execution by considering all possible execution paths, it does not affect application runtime performance. STA has been applied to data lifetime analysis for Android applications [1], exploit code detection [36], and binary vulnerability testing [28]. Dynamic taint analysis (DTA) is more precise than static taint analysis as it only propagates taint following the real path taken at run time. DTA has been widely used in various security applications, including data flow policy enforcement [25, 40, 27], reversing protocol data structures [33, 38, 6], malware analysis [39] and Android security [14]. However, an intrinsic limitation of DTA is its significant performance slowdown. Schwartz et al. [32] formally defined the operational semantics for DTA and forward symbolic execution (FSE). Our approach is in fact a hybrid of these techniques. Worker thread conducts concrete taint analysis (like DTA) whenever explicit taint information is available; otherwise symbolic taint analysis (like STA and FSE) is performed.

Taint Logic Optimization. Taint logic code, deciding whether and how to propagate taint, require additional instructions and "context switches". Frequently executing taint logic code incurs substantial overhead. Minemu [3] achieved a decent runtime performance at the cost of sacrificing memory space to speed up shadow memory access. Moreover, Minemu utilized spare SSE registers to alleviate the pressure of general register spilling. As a result, Minemu only worked on 32-bit program. TaintEraser [49] developed function summaries for Windows programs to propagate taint at function level. Libdft [20] introduced two guidelines to facilitate DBI's code inlining: 1) tag propagation code should have no branch; 2) shadow memory updates should be accomplished with a single assignment. Ruwase et al. [30] applied compiler optimization techniques to eliminate redundant taint logic code in hot paths. Jee et al. [19] proposed *Taint Flow Algebra* to summarize the semantics of taint logic for basic blocks. All these efforts to generate optimized taint logic code are orthogonal and complementary to TaintPipe.

Decoupling Dynamic Taint Analysis. A number of researchers have considered the high performance penalty imposed by inlined dynamic taint analysis. They proposed various solutions to decouple taint tracking logic from application under examination [24, 31, 26, 15, 17, 9], which are close in spirit to our proposed approach. Speck [26] forked multiple taint analysis processes from application execution to spare cores by means of speculative execution, and utilized record/replay to synchronize taint analysis processes. Speck required OS level support for speculative execution and rollback. Speck's approach sacrifices processing power to achieve acceleration. Similar to TaintPipe's segmented symbolic taint analysis, Ruwase et al. [31] proposed *symbolic inheritance tracking* to parallelize dynamic taint analysis. TaintPipe differs from Ruwase et al.'s approach in three ways: 1) Their approach was built on top of a log-based architecture [10] for efficient communication with idle cores, while TaintPipe works on commodity multi-core hardware directly. 2) To achieve better parallelization, they adopted a relaxed taint propagation policy to set a binary operation as untainted, while TaintPipe performs full-fledged taint propagation so that we provide stronger security guarantees. 3) They used a separate "master" processor to update each segment's taint status sequentially, while TaintPipe resolves symbolic taint states between two consecutive segments. Our approach could achieve better performance when there are more than a few "worker" processors.

Software-only approaches [15, 17, 9] are the most related to TaintPipe. They decouple dynamic taint analysis to a shadow thread by logging the runtime values that are needed for taint analysis. However, as we have pointed out, these methods [15, 9] may suffer from high overhead of frequent communication between the application thread and shadow thread. Recent work ShadowReplica [17] ameliorates this drawback by adopting fine-grained offline optimizations to remove redundant taint logic code. In principle, it is possible to remove redundant taint logic by means of static offline optimizations. Unfortunately, even static disassembly of stripped binaries is still a challenge [22, 35]. Therefore, the assumption by ShadowReplica that an accurate control flow graph can be constructed may not be feasible in certain scenarios, such as analyzing control flow obfuscated software. We take a different angle to address this issue with lightweight runtime information logging and segmented symbolic taint analysis. We demonstrate the capability of TaintPipe in speeding up obfuscated binary analysis, which ShadowReplica may not be able to handle. Furthermore, ShadowReplica does not support bit-level and multi-tag taint analysis, while TaintPipe handles them naturally.

8 Conclusion

We have presented TaintPipe, a novel tool for pipelining dynamic taint analysis with segmented symbolic taint analysis. Different from previous parallelization work on taint analysis, TaintPipe uses a pipeline style that relies on straight-line code with very few runtime values, enabling lightweight online logging and much lower runtime overhead. We have evaluated TaintPipe on a number of benign and malicious programs. The results show that TaintPipe rivals conventional inlined dynamic taint analysis in precision, but with a much lower online execution slowdown. The performance experiments indicate that TaintPipe can speed up dynamic taint analysis by 2.43 times on a set of common utilities and 2.38 times on SPEC2006, respectively. Such experimental evidence demonstrates that TaintPipe is both efficient and effective to be applied in real production environments.

Type Casting Verification: Stopping an Emerging Attack Vector

Abstract

Many applications such as the Chrome and Firefox browsers are largely implemented in C++ for its performance and modularity. Type casting, which converts one type of an object to another, plays an essential role in enabling polymorphism in C++ because it allows a program to utilize certain general or specific implementations in the class hierarchies. However, if not correctly used, it may return unsafe and incorrectly casted values, leading to so-called *bad-casting* or *type-confusion* vulnerabilities. Since a bad-casted pointer violates a programmer's intended pointer semantics and enables an attacker to corrupt memory, bad-casting has critical security implications similar to those of other memory corruption vulnerabilities. Despite the increasing number of bad-casting vulnerabilities, the bad-casting detection problem has not been addressed by the security community.

In this paper, we present CAVER, a runtime bad-casting detection tool. It performs program instrumentation at compile time and uses a new runtime type tracing mechanism—the type hierarchy table—to overcome the limitation of existing approaches and efficiently verify type casting dynamically. In particular, CAVER can be easily and automatically adopted to target applications, achieves broader detection coverage, and incurs reasonable runtime overhead. We have applied CAVER to large-scale software including Chrome and Firefox browsers, and discovered 11 previously unknown security vulnerabilities: nine in GNU `libstdc++` and two in Firefox, all of which have been confirmed and subsequently fixed by vendors. Our evaluation showed that CAVER imposes up to 7.6% and 64.6% overhead for performance-intensive benchmarks on the Chromium and Firefox browsers, respectively.

1 Introduction

The programming paradigm popularly known as object-oriented programming (OOP) is widely used for developing large and complex applications because it encapsulates the implementation details of data structures and algorithms into objects; this in turn facilitates cleaner software design, better code reuse, and easier software maintenance. Although there are many programming languages that support OOP, C++ has been the most popular, in particular when runtime performance is a key objective. For example, all major web browsers—Internet Explorer, Chrome, Firefox, and Safari are implemented in C++.

An important OOP feature is type casting that converts one object type to another. Type conversions play an important role in polymorphism. It allows a program to treat objects of one type as another so that the code can utilize certain general or specific features within the class hierarchy. Unlike other OOP languages—such as `Java`—that always verify the safety of a type conversion using runtime type information (RTTI), C++ offers two kinds of type conversions: `static_cast`, which verifies the correctness of conversion at *compile time*, and `dynamic_cast`, which verifies type safety at *runtime* using RTTI. `static_cast` is much more efficient because runtime type checking by `dynamic_cast` is an expensive operation (e.g., 90 times slower than `static_cast` on average). For this reason, many performance critical applications like web browsers, Chrome and Firefox in particular, prohibit `dynamic_cast` in their code and libraries, and strictly use `static_cast`.

However, the performance benefit of `static_cast` comes with a security risk because information at compile time is by no means sufficient to fully verify the safety of type conversions. In particular, upcasting (casting a derived class to its parent class) is always safe, but downcasting (casting a parent class to one of its derived classes) may not be safe because the derived class may not be a subobject of a truly allocated object in downcasting. Unsafe downcasting is better known as *bad-casting* or *type-confusion*.

Bad-casting has critical security implications. First, bad-casting is *undefined behavior* as specified in the C++ standard (5.2.9/11 [26]). Thus, compilers cannot guarantee the correctness of a program execution after bad-casting occurs (more detailed security implication analysis on undefined behavior is provided in §2). In addition to undefined behavior, bad-casting is similar to memory corruption vulnerabilities like stack/heap overflows and use-after-free. A bad-casted pointer violates a programmer's intended pointer semantics, and allows an attacker to corrupt memory beyond the true boundary of an object. For example, a bad-casting vulnerability in Chrome (CVE-2013-0912) was used to win the Pwn2Own 2013 competition by leaking and corrupting a security sensitive memory region [31]. More alarmingly, bad-casting is not only security-critical but is also common in applications. For example, 91 bad-casting vulnerabilities have been reported over the last four years in Chrome. Moreover, over 90% of these bad-casting bugs were rated as *security-high*, meaning that the bug can be directly exploited or indirectly used to mount arbitrary code execution attacks.

To avoid bad-casting issues, several C++ projects employ custom RTTI, which embeds code to manually keep type information at runtime and verify the type conversion safety of `static_cast`. However, only a few C++ programs are designed with custom RTTI, and supporting custom RTTI in existing programs requires heavy manual code modifications.

Another approach, as recently implemented by Google in the Undefined Behavior Sanitizer (UBSAN) [42], optimizes the performance of `dynamic_cast` and replaces all `static_cast` with `dynamic_cast`. However, this approach is limited because `dynamic_cast` only supports polymorphic classes, whereas `static_cast` is used for both polymorphic and non-polymorphic classes. Thus, this simple replacement approach changes the program semantics and results in runtime crashes when `dynamic_cast` is applied to non-polymorphic classes. It is difficult to identify whether a `static_cast` operation will be used for polymorphic or non-polymorphic classes without runtime information. For this reason, tools following this direction have to rely on manual *blacklists* (i.e., opt-out and do not check all non-polymorphic classes) to avoid runtime crashes. For example, UBSAN has to blacklist 250 classes, ten functions, and eight whole source files used for the Chromium browser [9], which is manually created by repeated trial-and-error processes. Considering the amount of code in popular C++ projects, creating such a blacklist would require massive manual engineering efforts.

In this paper, we present CAVER, a runtime bad-casting detection tool that can be seamlessly integrated with large-scale applications such as commodity browsers. It takes a program's source code as input and automatically instruments the program to verify type castings at runtime. We designed a new metadata, the Type Hierarchy Table (`THTable`) to efficiently keep track of rich type information. Unlike RTTI, `THTable` uses a disjoint metadata scheme (i.e., the reference to an object's `THTable` is stored outside the object). This allows CAVER to overcome all limitations of previous bad-casting detection techniques: it not only supports both polymorphic classes and non-polymorphic classes, but also preserves the C++ ABI and works seamlessly with legacy code. More specifically, CAVER achieves three goals:

- **Easy-to-deploy.** CAVER can be easily adopted to existing C++ programs without any manual effort. Unlike current state-of-the-art tools like UBSAN, it does not rely on manual blacklists, which are required to avoid program corruption. To demonstrate, we have integrated CAVER into two popular web browsers, Chromium and Firefox, by only modifying its build configurations.
- **Coverage.** CAVER can protect all type castings of both polymorphic and non-polymorphic classes. Compared to UBSAN, CAVER covers 241% and 199% more classes and their castings, respectively.
- **Performance.** CAVER also employs optimization techniques to further reduce runtime overheads (e.g., type-based casting analysis). Our evaluation shows that CAVER imposes up to 7.6% and 64.6% overheads for performance-intensive benchmarks on the Chromium and Firefox browsers, respectively. On the contrary, UBSAN is 13.8% slower than CAVER on the Chromium browser, and it cannot run the Firefox browser due to a runtime crash.

To summarize, we make three major contribution as follows:

- **Security analysis of bad-casting.** We analyzed the bad-casting problem and its security implications in detail, thus providing security researchers and practitioners a better understanding of this emerging attack vector.
- **Bad-casting detection tool.** We designed and implemented CAVER, a general, automated, and easy-to-deploy tool that can be applied to any C++ application to detect (and mitigate) bad-casting vulnerabilities. We have shared CAVER with the Firefox team [1] and made our source code publicly available.
- **New vulnerabilities.** While evaluating CAVER, we discovered *eleven* previously unknown bad-casting vulnerabilities in two mature and widely-used open source projects, GNU `libstdc++` and Firefox. All vulnerabilities have been reported and fixed in these projects' latest releases. We expect that integration with unit tests and fuzzing infrastructure will allow CAVER to discover more bad-casting vulnerabilities in the future.

This paper is organized as follows. §2 explains bad-casting issues and their security implications. §3 illustrates high-level ideas and usages of CAVER, §4 describes the design of CAVER. §5 describes the implementation details of CAVER, §6 evaluates various aspects of

[1] The Firefox team at Mozilla asked us to share CAVER for regression testing on bad-casting vulnerabilities.

CaVer. §7 further discusses applications and limitations of CaVer, §8 describes related work. Finally, §9 concludes the paper.

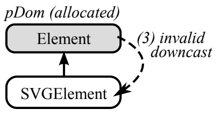
2 C++ Bad-casting Demystified

Type castings in C++. Type casting in C++ allows an object of one type to be converted to another so that the program can use different features of the class hierarchy. C++ provides four explicit casting operations: `static`, `dynamic`, `const`, and `reinterpret`. In this paper, we focus on the first two types — `static_cast` and `dynamic_cast` (5.2.9 and 5.2.7 in ISO/IEC N3690 [26]) — because they can perform downcasting and result in bad-casting. `static_cast` and `dynamic_cast` have a variety of different usages and subtle issues, but for the purpose of this paper, the following two distinctive properties are the most important: (1) time of verification: as the name of each casting operation implies, the correctness of a type conversion is checked (statically) at compile time for `static_cast`, and (dynamically) at runtime for `dynamic_cast`; (2) runtime support (RTTI): to verify type checking at runtime, `dynamic_cast` requires runtime support, called RTTI, that provides type information of the polymorphic objects.

Example 1 illustrates typical usage of both casting operations and their correctness and safety: (1) casting from a derived class (`pCanvas` of `SVGElement`) to a parent class (`pEle` of `Element`) is valid *upcasting*; (2) casting from the parent class (`pEle` of `Element`) to the original allocated class (`pCanvasAgain` of `SVGElement`) is valid *downcasting*; (3) on the other hand, the casting from an object allocated as a base class (`pDom` of `Element`) to a derived class (`p` of `SVGElement`) is invalid *downcasting* (i.e., a bad-casting); (4) memory access via the invalid pointer (`p->m_className`) can cause memory corruption, and more critically, compilers cannot guarantee any correctness of program execution after this incorrect conversion, resulting in *undefined behavior*; and (5) by using `dynamic_cast`, programmers can check the correctness of type casting at runtime, that is, since an object allocated as a base class (`pDom` of `Element`) cannot be converted to its derived class (`SVGElement`), `dynamic_cast` will return a `NULL` pointer and the error-checking code (line 18) can catch this bug, thus avoiding memory corruption.

Type castings in practice. Although `dynamic_cast` can guarantee the correctness of type casting, it is an expensive operation because parsing RTTI involves recursive data structure traversal and linear string comparison. From our preliminary evaluation, `dynamic_cast` is, on average, 90 times slower than `static_cast` on average. For large applications such as the Chrome browser, such performance overhead is not acceptable: simply launching Chrome incurs over 150,000 casts. Therefore, despite its security benefit, the use of `dynamic_cast` is strictly forbidden in Chrome development.

```
1  class SVGElement: public Element { ... };
2
3  Element *pDom = new Element();
4  SVGElement *pCanvas = new SVGElement();
5
6  // (1) valid upcast from pCanvas to pEle
7  Element *pEle = static_cast<Element*>(pCanvas);
8  // (2) valid downcast from pEle to pCanvasAgain (== pCanvas)
9  SVGElement *pCanvasAgain = static_cast<SVGElement*>(pEle);
10
11 // (3) invalid downcast (-> undefined behavior)
12 SVGElement *p = static_cast<SVGElement*>(pDom);
13 // (4) leads to memory corruption
14 p->m_className = "my-canvas";
15
16 // (5) invalid downcast with dynamic_cast, but no corruption
17 SVGElement *p = dynamic_cast<SVGElement*>(pDom);
18 if (p) {
19     p->m_className = "my-canvas";
20  }
```



Example 1: Code example using `static_cast` to convert types of object pointers (e.g., `Element` ↔ `SVGElement` classes). (1) is valid *upcast* and (2) is valid *downcast*. (3) is an invalid *downcast*. (4) Memory access via the invalid pointer result in memory corruption; more critically, compilers cannot guarantee the correctness of program execution after this incorrect conversion, resulting in *undefined behavior*. (5) Using `dynamic_cast`, on the other hand, the program can check the correctness of *downcast* by checking the returned pointer.

A typical workaround is to implement custom RTTI support. For example, most classes in WebKit-based browsers have an `isType()` method (e.g., `isSVGElement()`), which indicates the true allocated type of an object. Having this support, programmers can decouple a `dynamic_cast` into an explicit type check, followed by `static_cast`. For example, to prevent the bad-casting (line 12) in Example 1, the program could invoke the `isSVGElement()` method to check the validity of casting. However, this sort of type tracking and verification has to be manually implemented, and thus supporting custom RTTI in existing complex programs is a challenging problem. Moreover, due to the error-prone nature of manual modifications (e.g., incorrectly marking the object identity flag, forgetting to check the identity using `isType()` function, etc.), bad-casting bugs still occur despite custom RTTI [41].

Security implications of bad-casting. The C++ standard (5.2.9/11 [26]) clearly specifies that the behavior of an application becomes *undefined* after an incorrect `static_cast`. Because undefined behavior is an enigmatic issue, understanding the security implications and exploitability of bad-casting requires deep knowledge of common compiler implementations.

Generally, bad-casting vulnerabilities can be exploited via several means. An incorrectly casted pointer will either have wider code-wise visibility (e.g., allowing out-of-bound memory accesses), or become incorrectly adjusted (e.g., corrupting memory semantics because of misalignment). For example, when bad-casting occurs in proximity to a virtual function table pointer (vptr), an attacker can directly control input to the member variable (e.g., by employing abusive memory allocation techniques such as heap-spray techniques [16, 38]), overwrite the vptr and hijack the control flow. Similarly, an attacker can also exploit bad-casting vulnerabilities to launch non-control-data attacks [7].

The exploitability of a bad-casting bug depends on whether it allows attackers to perform out-of-bound memory access or manipulate memory semantics. This in turn relies on the details of object data layout as specified by the C++ application binary interface (ABI). Because the C++ ABI varies depending on the platform (e.g., Itanium C++ ABI [12] for Linux-based platforms and Microsoft C++ ABI [11] for Windows platforms), security implications for the same bad-casting bug can be different. For example, bad-casting may not crash, corrupt, or alter the behavior of an application built against the Itanium C++ ABI because the base pointer of both the base class and derived class always point to the same location of the object under this ABI. However, the same bad-casting bug can have severe security implications for other ABI implementations that locate a base pointer of a derived class differently from that of a base class, such as HP and legacy g++ C++ ABI [13]. In short, given the number of different compilers and the various architectures supported today, we want to highlight that bad-casting should be considered as a serious security issue. This argument is also validated from recent correspondence with the Firefox security team: after we reported two new bad-casting vulnerabilities in Firefox [4], they also pointed out the C++ ABI compatibility issue and rated the vulnerability as security-high.

Running example: CVE-2013-0912. Our illustrative Example 1 is extracted from a real-world bad-casting vulnerability—CVE-2013-0912, which was used to exploit the Chrome web browser in the Pwn2Own 2013 competition. However, the complete vulnerability is more complicated as it involves a multitude of castings (between siblings and parents).

In HTML5, an SVG image can be embedded directly into an HTML page using the <svg> tag. This tag is implemented using the SVGElement class, which inherits from the Element class. At the same time, if a web page happens to contain unknown tags (any tags other than standard), an object of the HTMLUnknownElement class will be created to represent this unknown tag. Since both tags are valid HTML elements, objects of these types can be safely casted to the Element class. Bad-casting occurs when the browser needs to render an SVG image. Given an Element object, it tries to downcast the object to SVGElement so the caller function can invoke member functions of the SVGElement class. Unfortunately, since not all Element objects are initially allocated as SVGElement objects, this

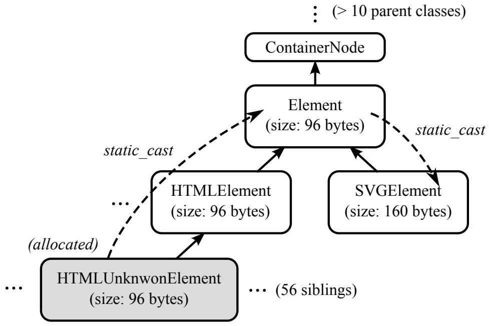


Figure 1: Inheritance hierarchy of classes involved in the CVE-2013-0912 vulnerability. MWR Labs exploited this vulnerability to hijack the Chrome browser in the Pwn2Own 2013 competition [31]. The object is allocated as HTMLUnknownElement and eventually converted (static_cast) to SVGElement. After this incorrect type casting, accessing member variables via this object pointer will cause memory corruption.

static_cast is not always valid. In the exploit demonstrated in the Pwn2Own 2013 competition [31], attackers used an object allocated as HTMLUnknownElement. As the size of an SVGElement object (160 bytes) is much larger than an HTMLUnknownElement object (96 bytes), this incorrectly casted object pointer allowed the attackers to access memory beyond the real boundary of the allocated HTMLUnknownElement object. They then used this capability to corrupt the vtable pointer of the object adjacent to the HTMLUnknownElement object, ultimately leading to a control-flow hijack of the Chrome browser. This example also demonstrates why identifying bad-casting vulnerabilities is not trivial for real-world applications. As shown in Figure 1, the HTMLUnknownElement class has more than 56 siblings and the Element class has more than 10 parent classes in WebKit. Furthermore, allocation and casting locations are far apart within the source code. Such complicated class hierarchies and disconnections between allocation and casting sites make it difficult for developers and static analysis techniques to reason about the true allocation types (i.e., alias analysis).

3 CAVER Overview

In this paper, we focus on the correctness and effectiveness of CAVER against bad-casting bugs, and our main application scenario is as a back-end testing tool for detecting bad-casting bugs. CAVER's workflow (Figure 2) is as simple as compiling a program with one extra compile and link flag (i.e., -fcaver for both). The produced binary becomes capable of verifying the correctness of every type conversion at runtime. When CAVER detects an incorrect type cast, it provides detailed information of the bad-cast: the source class, the destination class, the truly allocated class, and call stacks at the time the bad-cast is captured. Figure 3 shows a snippet of the actual report of CVE-2013-0912. Our bug report experience showed that the report generated by CAVER helped upstream main-

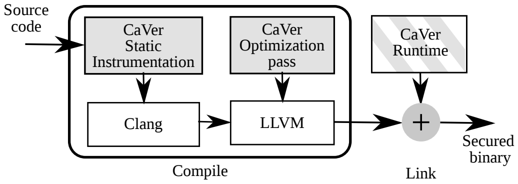

Figure 2: Overview of CAVER's design and workflow. Given the source code of a program, CAVER instruments possible castings at compile time, and injects CAVER's runtime to verify castings when they are performed.

tainers easily understand, confirm, and fix eleven newly discovered vulnerabilities without further examination.

4 Design

In this section, we introduce the design of CAVER. We first describe how the THTable is designed to generally represent the type information for both polymorphic and non-polymorphic classes (§4.1), and then explain how CAVER associates the THTable with runtime objects (§4.2). Next, we describe how CAVER verifies the correctness of type castings (§4.3). At the end of this section, we present optimization techniques used to reduce the runtime overhead of CAVER (§4.4).

4.1 Type Hierarchy Table

To keep track of the type information required for validating type casting, CAVER incorporates a new metadata structure, called the *Type Hierarchy Table* (THTable). Given a pointer to an object allocated as type T, the THTable contains the set of all possible types to which T can be casted. In C++, these possible types are a product of two kinds of class relationships: *is-a* and *has-a*. The *is-a* relationship between two objects is implemented as class inheritance, the *has-a* relationship is implemented as class composition (i.e., having a member variable in a class). Thus, for each class in a C++ program, CAVER creates a corresponding THTable that includes information about both relationships.

To represent class inheritance, the THTable employs two unique design decisions. First, information on inherited classes (i.e., base classes) is unrolled and serialized. This allows CAVER to efficiently scan through a set of base classes at runtime while standard RTTI requires recursive traversal. Second, unlike RTTI, which stores a mangled class name, the THTable stores the hash value of a class name. This allows CAVER to avoid expensive string equality comparisons. Note, since all class names are available to CAVER at compile time, all possible hash collisions can be detected and resolved to avoid false negatives during runtime. Moreover, because casting is only allowed between classes within the same inheritance chain, we only need to guarantee the uniqueness of hash values within a set of those classes, as opposed to guaranteeing global uniqueness.

The THTable also includes information of whether a base class is a phantom class, which cannot be represented based on RTTI and causes many false alarms in RTTI-based type verification solutions [9]. We say a class P is a phantom class of a class Q if two conditions are met: (1) Q is directly or indirectly derived from P; and (2) compared to P, Q does not have additional member variables or different virtual functions. In other words, they have the same data layout. Strictly speaking, allocating an object as P and downcasting it to Q is considered bad-casting as Q is not a base class of P. However, such bad-castings are harmless from a security standpoint, as the pointer semantic after downcasting is the same. More importantly, phantom classes are often used in practice to implement object relationships with empty inheritances. For these reasons, CAVER deliberately allows bad-castings caused by phantom classes. This is done by reserving a one bit space in the THTable for each base class, and marking if the base class is a phantom class. We will describe more details on how the phantom class information is actually leveraged in §4.3.

In addition, the THTable contains information on composited class(es) to generally represent the type information for both polymorphic and non-polymorphic classes and overcome the limitation of RTTI-based type verification solutions. RTTI-based solutions locate a RTTI reference via the virtual function table (VTable). However, since only polymorphic classes have VTable, these solutions can cause runtime crashes when they try to locate the VTable for non-polymorphic classes. Unlike RTTI, CAVER binds THTable references to the allocated object with external metadata (refer §4.2 for details). Therefore, CAVER not only supports non-polymorphic objects, but it also does not break the C++ ABI. However, composited class(es) now share the same THTable with their container class. Since a composited class can also have its own inheritances and compositions, we do not unroll information about composited class(es); instead, CAVER provides a reference to the composited class's THTable. The THTable also stores the layout information (offset and size) of each composited class to determine whether the given pointer points to a certain composited class.

Other than inheritance and composition information as described above, the THTable contains basic information on the corresponding type itself: a type size to represent object ranges; and a type name to generate user-friendly bad-casting reports.

4.2 Object Type Binding

To verify the correctness of type casting, CAVER needs to know the actual allocated type of the object to be casted. In CAVER, we encoded this type information in the THTable. In this subsection, we describe how CAVER binds the THTable to each allocated object. To overcome the limitations of RTTI-based solutions, CAVER uses a disjoint metadata scheme (i.e., the reference to an object's THTable is stored outside the object). With this unique metadata management scheme, CAVER not only supports both polymorphic classes and non-polymorphic classes, but also preserves the C++ ABI and works seamlessly with legacy code. Overall, type binding is done in two steps. First, CAVER instruments each allocation site of an application to pass the allocation metadata to its runtime library. Second, CAVER's runtime library maintains the allocation metadata and supports efficient lookup operations.

Instrumentation. The goal of the instrumentation is to pass all information of an allocated object to the runtime library. To bind a THTable to an object, the runtime library needs two pieces of information: a reference to the THTable and the base address of the allocated object.

In C++, objects can be allocated in three ways: in heap, on stack, or as global objects. In all three cases, the type information of the allocated object can be determined statically at compile time. This is possible because C++ requires programmers to specify the object's type at its allocation site, so the corresponding constructor can be invoked to initialize memory. For global and stack objects, types are specified before variable names; and for heap objects, types are specified after the new operator. Therefore, CAVER can obtain type information by statically inspecting the allocation site at compile time. Specifically, CAVER generates the THTable (or reuses the corresponding THTable if already generated) and passes the reference of the THTable to the runtime library. An example on how CAVER instruments a program is shown in Example 2.

For heap objects, CAVER inserts one extra function invocation (trace_heap() in Example 2) to the runtime library after each new operator, and passes the information of the object allocated by new; a reference to the THTable and the base address of an object. A special case for the new operator is an array allocation, where a set of objects of the same type are allocated. To handle this case, we add an extra parameter to inform the runtime library on how many objects are allocated together at the base address.

Unlike heap objects, stack objects are implicitly allocated and freed. To soundly trace them, CAVER inserts two function calls for each stack object at the function prologue and epilogue (trace_stack_begin() and trace_stack_end() in Example 2), and passes the same information of the object as is done for heap objects. A particular challenge is that, besides function returns, a stack unwinding can also happen due to exceptions and setjmp/longjmp. To handle these cases, CAVER leverages existing compiler functionality (e.g., EHScopeStack::Cleanup in clang) to guarantee that the runtime library is always invoked once the execution context leaves the given function scope.

```
  // Heap objects (dynamically allocated)
  void func_heap_ex() {
    C *p_heap_var = new C;
    C *p_heap_array = new C[num_heap_array];
+   trace_heap(&THTable(C), p_heap_var, 1);
+   trace_heap(&THTable(C), p_heap_array, num_heap_array);
    ...
  }

  // Stack objects
  void func_stack_ex() {
    C stack_var;
+   trace_stack_begin(&THTable(C), &stack_var, 1);
    ...
+   trace_stack_end(&stack_var);
  }

  // Global objects
  C global_var;

  // @.ctors: (invoked at the program's initialization)
  //   trace_global_helper_1() and trace_global_helper_2()
+ void trace_global_helper_1() {
+   trace_global(&THTable(C), &global_var, 1);
+ }

   // Verifying the correctness of a static casting
  void func_verify_ex() {
    B *afterAddr = static_cast<A>(beforeAddr);
+   verify_cast(beforeAddr, afterAddr, type_hash(A));
  }
```

Example 2: An example of how CAVER instruments a program. Lines marked with + represent code introduced by CAVER, and &THTable(T) denotes the reference to the THTable of class T. In this example, we assume that the THTable of each allocated class has already been generated by CAVER.

To pass information of global objects to the runtime library, we leverage existing program initialization procedures. In ELF file format files [46], there is a special section called .ctors, which holds constructors that must be invoked during an early initialization of a program. Thus, for each global object, CAVER creates a helper function (trace_global_helper_1() in Example 2) that invokes the runtime library with static metadata (the reference to the THTable) and dynamic metadata (the base address and the number of array elements). Then, CAVER adds the pointer to this helper function to the .ctors section so that the metadata can be conveyed to the runtime library[2].

[2] Although the design detail involving .ctors section is platform dependent, the idea of registering the helper function into the initialization

Runtime library. The runtime library of CAVER maintains all the metadata (`THTable` and base address of an object) passed from tracing functions during the course of an application execution. Overall, we consider two primary requirements when organizing the metadata. First, the data structure must support range queries (i.e., given a pointer pointing to an address within an object ([base, base+size)) CAVER should be able to find the corresponding `THTable` of the object). This is necessary because the object pointer does not always point to the allocation base. For example, the pointer to be casted can point to a composited object. In case of multi-inheritance, the pointer can also point to one of the parent classes. Second, the data structure must support efficient store and retrieve operations. CAVER needs to store the metadata for every allocation and retrieve the metadata for each casting verification. As the number of object allocations and type conversions can be huge (see §6), these operations can easily become the performance bottleneck.

We tackle these challenges using a hybrid solution (see Appendix 2 for the algorithm on runtime library functions). We use red-black trees to trace global and stack objects and an alignment-based direct mapping scheme to trace heap objects[3].

We chose red-black trees for stack and global objects for two reasons. First, tree-like data structures are well known for supporting efficient range queries. Unlike hash-table-based data structures, tree-based data structures arrange nodes according to the order of their keys, whose values can be numerical ranges. Since nodes are already sorted, a balanced tree structure can guarantee $O(logN)$ complexity for range queries while hash-table-based data structure requires $O(N)$ complexity. Second, we specifically chose red-black trees because there are significantly more search operations than update operations (i.e., more type conversion operations than allocations, see §6), thus red-black trees can excel in performance due to self-balancing.

In CAVER, each node of a red-black tree holds the following metadata: the base address and the allocation size as the key of the node, and the `THTable` reference as the value of the node.

For global object allocations, metadata is inserted into the global red-black tree when the object is allocated at runtime, with the key as the base address and the allocation size[4], and the value as the address of the `THTable`. We maintain a per-process global red-black tree without locking mechanisms because there are no data races on the global red-black tree in CAVER. All updates on the global red-black tree occur during early process start-up (i.e., before executing any user-written code) and update orders are well serialized as listed in the .ctors section.

For stack object allocations, metadata is inserted to the stack red-black tree similar to the global object case. Unlike a global object, we maintain a *per-thread* red-black tree for stack objects to avoid data races in multi-threaded applications. Because a stack region (and all operations onto this region) are exclusive to the corresponding thread's execution context, this per-thread data structure is sufficient to avoid data races without locks.

For heap objects, we found that red-black trees are not a good design choice, especially for multi-threaded programs. Different threads in the target programs can update the tree simultaneously, and using locks to avoid data races resulted in high performance overhead, as data contention occured too frequently. Per-thread red-black trees used for stack objects are not appropriate either, because heap objects can be shared by multiple threads. Therefore, we chose to use a custom memory allocator that can support alignment-based direct mapping schemes [3, 22]. In this scheme, the metadata can be maintained for a particular object, and can be retrieved with $O(1)$ complexity on the pointer pointing to anywhere within the object's range.

4.3 Casting Safety Verification

This subsection describes how CAVER uses traced information to verify the safety of type casting. We first describe how the instrumentation is done at compile time, and then describe how the runtime library eventually verifies castings during runtime.

Instrumentation. CAVER instruments `static_cast` to invoke a runtime library function, `verify_cast()`, to verify the casting. Here, CAVER analyzes a type hierarchy involving source and destination types in `static_cast` and only instruments for downcast cases. When invoking `verify_cast()`, CAVER passes the following three pieces of information: `beforeAddr`, the pointer address before the casting; `afterAddr`, the pointer address after the casting; and `TargetTypeHash`, the hash value of the destination class to be casted to (denoted as `type_hash(A)` in Example 2).

Runtime library. The casting verification (Appendix 1) is done in two steps: (1) locating the corresponding `THTable` associated with the object pointed to by `beforeAddr`; and (2) verifying the casting operation by checking whether `TargetTypeHash` is a valid type where `afterAddr` points.

To locate the corresponding `THTable`, we first check the data storage membership because we do not know how the object `beforeAddr` points to is allocated. Checks

function list can be generalized for other platforms as others also support .ctors-like features

[3] The alignment-based direct mapping scheme can be applied for global and stack objects as well, but this is not implemented in the current version. More details can be found in §7.

[4] The allocation size is computed by multiplying the type size represented in `THTable` and the number of array elements passed during runtime.

are ordered by their expense, and the order is critical for good performance. First, a stack object membership is checked by determinig whether the beforeAddr is in the range between the stack top and bottom; then, a heap object membership is checked by whether the beforeAddr is in the range of pre-mapped address spaces reserved for the custom allocator; finally a global object membership is checked with a bit vector array for each loaded binary module. After identifying the data storage membership, CAVER retrieves the metadata containing the allocation base and the reference to the THTable. For stack and global objects, the corresponding red-black tree is searched. For heap objects, the metadata is retrieved from the custom heap.

Next, CAVER verifies the casting operation. Because the THTable includes all possible types that the given object can be casted to (i.e., all types from both inheritances and compositions), CAVER exhaustively matches whether TargetTypeHash is a valid type where afterAddr points. To be more precise, the afterAddr value is adjusted for each matching type. Moreover, to avoid false positives due to a phantom class, CAVER tries to match all phantom classes of the class to be casted to.

4.4 Optimization

Since performance overhead is an important factor for adoption, CAVER applies several optimization techniques. These techniques are applied in two stages, as shown in Figure 2. First, offline optimizations are applied to remove redundant instrumentations. After that, additional runtime optimizations are applied to further reduce the performance overhead.

Safe-allocations. Clearly, not all allocated objects will be involved in type casting. This implicates that CAVER does not need to trace type information for objects that would never be casted. In general, soundly and accurately determining whether objects allocated at a given allocation site will be casted is a challenging problem because it requires sophisticated static points-to analysis. Instead, CAVER takes a simple, yet effective, optimization approach inspired from C type safety checks in CCured [33]. The key idea is that the following two properties always hold for downcasting operations: (1) bad-casting may happen only if an object is allocated as a child of the source type or the source type itself; and (2) bad-casting never happens if an object is allocated as the destination type itself or a child of the destination type. This is because static_cast guarantees that the corresponding object must be a derived type of the source type. Since CAVER can observe all allocation sites and downcasting operations during compilation, it can recursively apply the above properties to identify *safe-allocation* sites, i.e., the allocated objects will never cause bad-casting.

Caching verification results. Because casting verification involves loops (over the number of compositions and the number of bases) and recursive checks (in a composition case), it can be a performance bottleneck. A key observation here is that the verification result is always the same for the same allocation type and the same target type (i.e., when the type of object pointed by afterAddr and TargetTypeHash are the same). Thus, in order to alleviate this potential bottleneck, we maintain a cache for verification results, which is inspired by UBSAN [42]. First, a verification result is represented as a concatenation of the address of a corresponding THTable, the offset of the afterAddr within the object, and the hash value of target type to be casted into (i.e., &THTable || offset || TargetTypeHash). Next, this concatenated value is checked for existence in the cache before verify_cast() actually performs verification. If it does, verify_cast() can conclude that this casting is correct. Otherwise, verify_cast() performs actual verification using the THTable, and updates the cache only if the casting is verified to be correct.

5 Implementation

We implemented CAVER based on the LLVM Compiler project [43] (revision 212782, version 3.5.0). The static instrumentation module is implemented in Clang's CodeGen module and LLVM's Instrumentation module. The runtime library is implemented using the compiler-rt module based on LLVM's Sanitizer code base. In total, CAVER is implemented in 3,540 lines of C++ code (excluding empty lines and comments).

CAVER is currently implemented for the Linux x86 platform, and there are a few platform-dependent mechanisms. For example, the type and tracing functions for global objects are placed in the .ctors section of ELF. As these platform-dependent features can also be found in other platforms, we believe CAVER can be ported to other platforms as well. CAVER interposes threading functions to maintain thread contexts and hold a per-thread red-black tree for stack objects. CAVER also maintains the top and bottom addresses of stack segments to efficiently check pointer membership on the stack. We also modified the front-end drivers of Clang so that users of CAVER can easily build and secure their target applications with one extra compilation flag and linker flag, respectively.

6 Evaluation

We evaluated CAVER with two popular web browsers, Chromium [40] (revision 295873) and Firefox [44] (revision 213433), and two benchmarks from SPEC CPU2006 [39][5]. Our evaluation aims to answer the following questions:

[5] Although CAVER was able to correctly run all C++ benchmarks in SPEC CPU2006, only 483.xalancbmk and 450.soplex have downcast operations.

- How easy is it to deploy CAVER to applications? (§6.1)
- What are the new vulnerabilities CAVER found? (§6.2)
- How precise is CAVER's approach in detecting bad-casting vulnerabilities? (§6.3)
- How good is CAVER's protection coverage? (§6.4)
- What are the instrumentation overheads that CAVER imposes and how many type castings are verified by CAVER? (§6.5)
- What are the runtime performance overheads that CAVER imposes? (§6.6)

Comparison methods. We used UBSAN, the state-of-art tool for detecting bad-casting bugs, as our comparison target of CAVER. Also, We used CAVER-NAIVE, which disabled the two optimization techniques described in §4.4, to show their effectiveness on runtime performance optimization.

Experimental setup. All experiments were run on Ubuntu 13.10 (Linux Kernel 3.11) with a quad-core 3.40 GHz CPU (Intel Xeon E3-1245), 16 GB RAM, and 1 TB SSD-based storage.

6.1 Deployments

As the main design goal for CAVER is automatic deployments, we describe our experience of applying CAVER to tested programs including SPEC CPU 2006 benchmarks, the Chromium browser, and the Firefox browser. CAVER was able to successfully build and run these programs without any program-specific understanding of the code base. In particular, we added one line to the build configuration file to build SPEC CPU 2006, 21 lines to the `.gyp` build configuration to build the Chromium browser, and 10 lines to the `.mozconfig` build configuration file to build the Firefox browser. Most of these build configuration changes were related to replacing `gcc` with `clang`.

On the contrary, UBSAN crashed while running xalancbmk in SPEC CPU 2006 and while running the Firefox browser due to checks on non-polymorphic classes. UBSAN also crashed the Chromium browser without blacklists, but was able to run once we applied the blacklists provided by the Chromium project [9]. In particular, to run Chromium, the blacklist has 32 different rules that account for 250 classes, ten functions, and eight whole source files. Moreover, this blacklist has to be maintained constantly as newly introduced code causes new crashes in UBSAN [10]. This is a practical obstacle for adopting UBSAN in other C++ projects—although UBSAN has been open sourced for some time, Chromium remains the only major project that uses UBSAN, because there is a dedicated team to maintain its blacklist.

6.2 Newly Discovered Bad-casting Vulnerabilities

To evaluate CAVER's capability of detecting bad-casting bugs, we ran CAVER-hardened Chromium and Firefox with their regression tests (mostly checking functional correctness). During this evaluation, CAVER found eleven previously unknown bad-casting vulnerabilities in GNU `libstdc++` while evaluating Chromium and Firefox. Table 1 summarizes these vulnerabilities including related class information: allocated type, source, and destination types in each bad-casting. In addition, we further analyzed their security impacts: potential compatibility problems due to the C++ ABI (see §2) or direct memory corruption, along with security ratings provided by Mozilla for Firefox.

CAVER found two vulnerabilities in the Firefox browser. The Firefox team at Mozilla confirmed and fixed these, and rated both as *security-high*, meaning that the vulnerability can be abused to trigger memory corruption issues. These two bugs were casting the pointer into a class which is not a base class of the originally allocated type. More alarmingly, there were type semantic mismatches after the bad-castings—subsequent code could dereference the incorrectly casted pointer. Thus the C++ ABI and Memory columns are checked for these two cases.

CAVER also found nine bugs in GNU `libstdc++` while running the Chromium browser. We reported these bugs to the upstream maintainers, and they have been confirmed and fixed. Most of these bugs were triggered when `libstdc++` converted the type of an object pointing to its composite objects (e.g., `Base_Ptr` in `libstdc++`) into a more derived class (`Rb_Tree_node` in `libstdc++`), but these derived classes were not base classes of what was originally allocated (e.g., `EncodedDescriptorDatabase` in Chromium). Since these are generic bugs, meaning that benign C++ applications will encounter these issues even if they correctly use `libstdc++` or related libraries, it is difficult to directly evaluate their security impacts without further evaluating the applications themselves.

These vulnerabilities were identified with legitimate functional test cases. Thus, we believe CAVER has great potential to find more vulnerabilities once it is utilized for more applications and test cases, as well as integrated with fuzzing infrastructures like ClusterFuzz [2] for Chromium.

6.3 Effectiveness of Bad-casting Detection

To evaluate the correctness of detecting bad-casting vulnerabilities, we tested five bad-casting exploits of Chromium on the CAVER-hardened Chromium binary (see Table 2). We backported five bad-casting vulnerabilities as unit tests while preserving important features that may affect CAVER's detection algorithm, such as class inheritances and their compositions, and allocation

Product	Bug ID	Vulnerable	Types	Security Implication		
		Function	Allocation / Source / Destination	ABI	Mem	Rating
Firefox	1074280 [4]	PaintLayer()	BasicThebesLayer / Layer / BasicContainerLayer	✓	✓	High (CVE-2014-1594)
Firefox	1089438 [5]	EvictContent()	PRCListStr / PRCList / nsSHistory	✓	✓	High

`libstdc++`	63345 [30]	end() const	Importer / Link_type / Rb_Tree_node	✓	-	†

Table 1: A list of vulnerabilities newly discovered by CaVer. All security vulnerabilities listed here are confirmed, and already fixed by the corresponding development teams. Columns under Types represent classes causing bad-castings: allocation, source and destination classes. Columns under Security Implication represents the security impacts of each vulnerability: whether the vulnerability has C++ ABI incompatibility issues (ABI); whether the vulnerability triggers memory corruption (Mem); and the actual security assessment ratings assigned by the vendor (Rating). †: The GNU `libstdc++` members did not provide security ratings.

size. This backporting was due to the limited support for the `LLVM/clang` compiler by older Chromium (other than CVE-2013-0912). Table 2 shows our testing results on these five known bad-casting vulnerabilities. CaVer successfully detected all vulnerabilities.

In addition to real vulnerabilities, we thoroughly evaluated CaVer with test cases that we designed based on all possible combinations of bad-casting vulnerabilities: (1) whether an object is polymorphic or non-polymorphic; and (2) the three object types: allocation, source, and destination.

$$|\{\text{Poly, non-Poly}\}|^{|\{\text{Alloc, From, To}\}|} = 8$$

Eight different unit tests were developed and evaluated as shown in Table 3. Since CaVer's design generally handles both polymorphic and non-polymorphic classes, CaVer successfully detected all cases. For comparison, UBSan failed six cases mainly due to its dependency on RTTI. More severely, among the failed cases, UBSan crashed for two cases when it tried to parse RTTI non-polymorphic class objects, showing it is difficult to use without manual blacklists. Considering Firefox contains greater than 60,000 downcasts, (see Table 4), creating such a blacklist for Firefox would require massive manual engineering efforts.

6.4 Protection Coverage

Table 4 summarizes our evaluation of CaVer's protection coverage during instrumentation, including the number of protected types/classes (the left half), and the number of protected type castings (the right half). In our evaluation with C++ applications in SPEC CPU 2006, Firefox, and Chromium, CaVer covers 241% more types than UBSan; and protects 199% more type castings.

6.5 Instrumentation Overheads

There are several sources that increase a program's binary size (see Table 5), including (1) the inserted functions for tracing objects' type and verifying type castings, (2) the `THTable` of each class, and (3) CaVer's runtime library. Although CaVer did not perform much instrumentation for most SPEC CPU 2006 applications, the file size increase still was noticeable. This increase was caused by the statically linked runtime library (245 KB). The CaVer-hardened Chromium requires 6× more storage compared to Firefox because the Chromium code bases contains more classes than Firefox. The additional `THTable` overhead is the dominant source of file size increases. (see Table 4). For comparison, UBSan increased the file size by 64% and 49% for Chromium and Firefox, respectively; which indicates that `THTable` is an efficient representation of type information compared to RTTI.

Name	# of tables		# of verified cast	
	RTTI	`THTable`	UBSan	CaVer
483.xalancbmk	881	3,402	1,378	1,967
450.soplex	39	227	0	2
Chromium	24,929	94,386	11,531	15,611
Firefox	9,907	30,303	11,596	71,930

Table 4: Comparisons of protection coverage between UBSan and CaVer. In the # of tables column, `VTable` shows the number of virtual function tables and `THTable` shows the number of type hierarchy tables, each of which is generated to build the program. # of verified cast shows the number `static_cast` instrumented in UBSan and CaVer, respectively. Overall, CaVer covers 241% and 199% more classes and their castings, respectively, compared to UBSan.

Name	File Size (KB)				
	Orig.	UBSan		CaVer	
483.xalancbmk	6,111	6,674	9%	7,169	17%
450.soplex	466	817	75%	861	84%
Chromium	249,790	612,321	145%	453,449	81%
Firefox	242,704	395,311	62%	274,254	13%

Table 5: The file size increase of instrumented binaries: CaVer incurs 64% and 49% less storage overheads in Chromium and Firefox browsers, compared to UBSan.

CVE #	Bug ID	Type Names			Security Rating	Mitigated
		Allocation	Source	Destination		by CaVer
CVE-2013-0912	180763	HTMLUnknownElement	Element	SVGElement	High	✓
CVE-2013-2931	302810	MessageEvent	Event	LocatedEvent	High	✓
CVE-2014-1731	349903	RenderListBox	RenderBlockFlow	RenderMeter	High	✓
CVE-2014-3175	387016	SpeechSynthesis	EventTarget	SpeechSynthesisUtterance	High	✓
CVE-2014-3175	387371	ThrobAnimation	Animation	MultiAnimation	Medium	✓

Table 2: Security evaluations of CaVer with known vulnerabilities of the Chromium browser. We first picked five known bad-casting bugs and wrote test cases for each vulnerability, retaining features that may affect CaVer's detection algorithm, including class hierarchy and their compositions, and related classes including allocation, source, and destination types). CaVer correctly detected all vulnerabilities.

(a) CaVer, P Alloc

From \ To	P	Non-P
P	✓	✓
Non-P	✓	✓

(b) CaVer, Non-P Alloc

From \ To	P	Non-P
P	✓	✓
Non-P	✓	✓

(c) UBSan, P Alloc

From \ To	P	Non-P
P	✓	X
Non-P	✓	X

(d) UBSan, Non-P Alloc

From \ To	P	Non-P
P	Crash	X
Non-P	Crash	X

Table 3: Evaluation of protection coverage against all possible combinations of bad-castings. P and Non-P mean polymorphic and non-polymorphic classes, respectively. In each cell, ✓marks a successful detection, X marks a failure, and Crash marks the program crashed. (a) and (b) show the results of CaVer with polymorphic class allocations and non-polymorphic class allocations, respectively, and (c) and (d) show the cases of UBSan. CaVer correctly detected all cases, while UBSan failed for 6 cases including 2 crashes.

6.6 Runtime Performance Overheads

In this subsection, we measured the runtime overheads of CaVer by using SPEC CPU 2006's C++ benchmarks and various browser benchmarks for Chromium and Firefox. For comparison, we measured runtime overheads of the original, non-instrumented version (compiled with `clang`), and the UBSan-hardened version.

Microbenchmarks. To understand the performance characteristics of CaVer-hardened applications, we first profiled micro-scaled runtime behaviors related to CaVer's operations (Table 6). For workloads, we used the built-in input for the two C++ applications of SPEC CPU 2006, and loaded the default start page of the Chromium and Firefox browsers. Overall, CaVer traced considerable number of objects, especially for the browsers: 783k in Chromium, and 15,506k in Firefox.

We counted the number of *verified castings* (see Table 6), and the kinds of allocations (i.e., global, stack, or heap). In our experiment, Firefox performed 710% more castings than Chromium, which implies that the total number of verified castings and the corresponding performance overheads highly depends on the way the application is written and its usage patterns.

SPEC CPU 2006. With these application characteristics in mind, we first measured runtime performance impacts of CaVer on two SPEC CPU 2006 programs, xalancbmk and soplex. CaVer slowed down the execution of xalancbmk and soplex by 29.6% and 20.0%, respectively. CaVer-naive (before applying the optimization techniques described in §4.4) slowed down xalancbmk and soplex by 32.7% and 20.8% respectively.

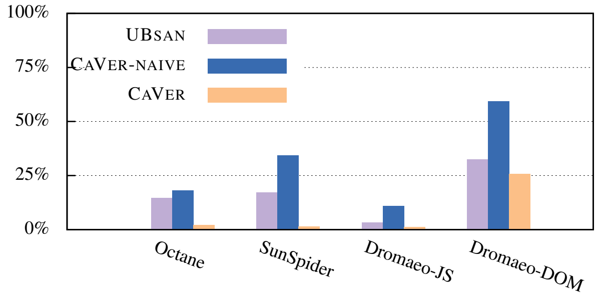

Figure 4: Browser benchmark results for the Chromium browser. On average, while CaVer-naive incurs 30.7% overhead, CaVer showed 7.6% runtime overhead after the optimization. UBSan exhibits 16.9% overhead on average.

For UBSan, xalancbmk crashed because of RTTI limitations in handling non-polymorphic types, and soplex becomes 21.1% slower. Note, the runtime overheads of CaVer is highly dependent on the application characteristics (e.g., the number of downcasts performed in runtime). Thus, we measured overhead with more realistic workloads on two popular browsers, Chromium and Firefox.

Browser benchmarks (Chromium). To understand the end-to-end performance of CaVer, we measured the performance overhead of web benchmarks. We tested four browser benchmarks: Octane [21], SunSpider [47], Dromaeo-JS [29], and Dromaeo-DOM [29], each of which evaluate either the performance of the JavaScript engine or page rendering.

Figure 4 shows the benchmark results of the Chromium browser. On average, CaVer showed 7.6% overhead while CaVer-naive showed 30.7%, which implies the

Name	Object Tracing					Verified Castings			
	Global	Stack		Heap		Global	Stack	Heap	Total
	Total	Peak	Total	Peak	Total				
483.xalancbmk	165	32	190k	8k	88k	0	104	24k	24k
450.soplex	36	1	364	141	658	0	0	0	0
Chromium	3k	274	350k	79k	453k	963	338	150k	151k
Firefox	24k	38k	14,821k	213k	685k	41k	524k	511k	1,077k

Table 6: The number of traced objects and type castings verified by CAVER in our benchmarks. Under the *Object Tracing* column, *Peak* and *Total* denote the maximum number of traced objects during program execution, and the total number of traced objects until its termination, respectively. *Global*, *Stack*, and *Heap* under the *Verified Casts* represent object's original types (allocation) involved in castings. Note that Firefox heavily allocates objects on stack, compared to Chromium. Firefox allocated 4,134% more stack objects, and performs 1,550% more type castings than Chromium.

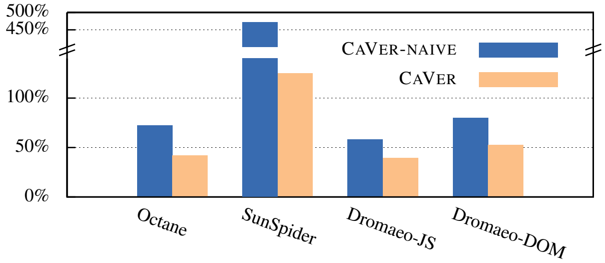

Figure 5: Browser benchmark results for the Firefox browser. On average, CAVER and CAVER-NAIVE showed 64.6% and 170.3% overhead, respectively.

Name	Original		UBSAN		CAVER	
	Peak	Avg	Peak	Avg	Peak	Avg
483.xalancbmk	9	8	crash	crash	14	12
450.soplex	2	2	2	2	5	5
Chromium	376	311	952	804	878	738
Firefox	165	121	crash	crash	208	157

Table 7: Runtime memory impacts (in KB) while running target programs. UBSAN crashed while running xalancbmk and Firefox due to the non-polymorhpic typed classes. *Peak* and *Avg* columns denote the maximum and average memory usages, respectively, while running the program. CAVER used 137% more memory on Chromium, and 23% more memory on Firefox. UBSAN used 158% more memory on Chromium.

optimization techniques in §4.4 provided a 23.1% performance improvement. This performance improvement is mostly due to the safe-allocation optimization, which identified 76,381 safe-allocation types (81% of all types used for Chromium) and opted-out to instrument allocation sites on such types. Compared to UBSAN, CAVER is 13.8% faster even though it offers more wide detection coverage on type casting. Thus, we believe this result shows that CAVER's THTable design and optimization techniques are efficient in terms of runtime performances.

Browser benchmarks (Firefox). We applied CAVER to the Firefox browser and measured the performance overhead for the web benchmarks used in evaluating the Chromium browser. On average, CAVER imposed 64.6% overhead while CAVER-NAIVE imposed 170.3% overhead (Figure 5). Similar to the Chromium case, most of performance improvements are from safe-allocation optimization, which identified 21,829 safe-allocation types (72% of all used types for Firefox). UBSAN was unable to run Firefox because it crashed due to the inability of its RTTI to handle non-polymorphic types, so we do not present the comparison number. Compared to CAVER's results on Chromium, the CAVER-enhanced Firefox showed worse performance, mainly due to the enormous amount of stack objects allocated by Firefox (Table 6). In order words, the potential performance impacts rely on the usage pattern of target applications, rather than the inherent overheads of CAVER's approaches.

Memory overheads. UBSAN and CAVER achieve fast lookup of the metadata of a given object by using a custom memory allocator that is highly optimized for this purpose, at the cost of unnecessary memory fragmentation. In our benchmark (Table 7), UBSAN used 2.5× more memory at peak and average; and CAVER used 2.3× more memory at peak and average, which is an 8% improvement over UBSAN. Considering CAVER's main purpose is a diagnosis tool and the amount of required memory is not large (< 1 GB), we believe that these memory overheads are acceptable cost in practice for the protection gained.

7 Discussion

Integration with fuzzing tools. During our evaluations, we relied on the built-in test inputs distributed with the target programs, and did not specifically attempt to improve code coverage. Yet CAVER is capable of discovering dozens of previously unknown bad-casting bugs. In the future, we plan to integrate CAVER with fuzzing tools like the ClusterFuzz [2] infrastructure for Chromium to improve code coverage. By doing so, we expect to discover more bad-casting vulnerabilities.

Optimization. In this paper, we focused on the correctness, effectiveness, and usability of CAVER. Although we developed several techniques to improve performance, optimization is not our main focus. With more powerful optimization techniques, we believe CAVER can also be used for runtime bad-casting mitigation.

For example, one direction we are pursuing is to use static analysis to prove whether a type casting is always safe. By doing so, we can remove redundant cast verification.

Another direction is to apply alignment-based direct mapping scheme for global and stack objects as well. Please recall that red-black trees used for global and stack objects show $O(logN)$ complexity, while alignment-based direct mapping scheme guarantees $O(1)$ complexity. In order to apply alignment-based direct mapping scheme for global and stack objects together, there has to be radical semantic changes in allocating stack and global objects. This is because alignment-based direct mapping scheme requires that all objects have to be strictly aligned. This may not be difficult for global objects, but designing and implementing for stack objects would be non-trivial for the following reasons: (1) essentially this may involve a knapsack problem (i.e., given different sized stack objects in each stack frame, what are the optimal packing strategies to reduce memory uses while keeping a certain alignment rule); (2) an alignment base address for each stack frame has to be independently maintained during runtime; (3) supporting variable length arrays (allowed in ISO C99 [18]) in stack would be problematic as the packing strategy can be only determined at runtime in this case.

Furthermore, it is also possible to try even more extreme approaches to apply alignment-based direct mapping scheme—simply migrating all stack objects to be allocated in heap. However, this may result in another potential side effects in overhead.

8 Related work

Bad-casting detection. The virtual function table checking in Undefined Behavior Sanitizer (UBSAN-vptr) [42] is the closest related work to CAVER. Similar to CAVER, UBSAN instruments `static_cast` at compile time, and verifies the casting at runtime. The primary difference is that UBSan relies on RTTI to retrieve the type information of an object. Thus, as we have described in §4, UBSAN suffers from several limitations of RTTI . (1) Coverage: UBSAN cannot handle non-polymorphic classes as there is no RTTI for these classes; (2) Ease-of-deployments: hardening large scale software products with UBSAN is non-trivial due to the coverage problem and phantom classes. As a result, UBSAN has to rely on blacklisting [9] to avoid crashes.

RTTI alternatives. Noticing the difficulties in handling complex C++ class hierarchies in large-scale software, several open source projects use a custom form of RTTI. For example, the LLVM project devised a custom RTTI [27]. LLVM-style RTTI requires all classes to mark its identity once it is created (i.e., in C++ constructors) and further implement a static member function to retrieve its identity. Then, all type conversions can be done with templates that leverage this static member function implemented in every class. Because the static member function can tell the true identity of an object, theoretically, all type conversions are always correct and have no bad-casting issues. Compared to CAVER, the drawback of this approach is that it requires manual source code modification. Thus, it would be non-trivial to modify large projects like browsers to switch to this style. More alarmingly, since it relies on developers' manual modification, if developers make mistakes in implementations, bad-casting can still happen [41].

Runtime type tracing. Tracing runtime type information offers several benefits, especially for debugging and profiling. [37] used RTTI to avoid complicated parsing supports in profiling parallel and scientific C++ applications. Instead of relying on RTTI, [15, 28] instruments memory allocation functions to measure complete heap memory profiles. CAVER is inspired by these runtime type tracing techniques, but it introduced the `THTable`, a unique data structure to support efficient verification of complicated type conversion.

Memory corruption prevention. As described in §2, bad-casting can provide attackers access to memory beyond the boundary of the casted object. In this case, there will be a particular violation (e.g., memory corruptions) once it is abused to mount an attack. Such violations can be detected with existing software hardening techniques, which prevents memory corruption attacks and thus potentially stop attacks abusing bad-casting. In particular, Memcheck (Valgrind) [34] and Purify [23] are popularly used solutions to detect memory errors. AddressSanitizer [36] is another popular tool developed recently by optimizing the way to represent and probe the status of allocated memory. However, it cannot detect if the attacker accesses beyond red-zones or stressing memory allocators to abuse a quarantine zone [8]. Another direction is to enforce spatial memory safety [14, 25, 32, 33, 48], but this has drawbacks when handling bad-casting issues. For example, Cyclone [25] requires extensive code modifications; CCured [33] modifies the memory allocation model; and SVA [14] depends on a new virtual execution environment. More fundamentally, most only support C programs.

Overall, compared to these solutions, we believe CAVER makes a valuable contribution because it detects the root cause of one important vulnerability type: bad-casting. CAVER can provide detailed information on how a bad-casting happens. More importantly, depending on certain test cases or workloads, many tools cannot detect bad-casting if a bad-casted pointer is not actually used to violate memory safety. However, CAVER can immediately detect such latent cases if any bad-casting occurs.

Control Flow Integrity (CFI). Similar to memory corruption prevention techniques, supporting CFI [1, 49–51] may prevent attacks abusing bad-casting as many exploits hijack control flows to mount an attack. Furthermore, specific to C++ domain, SafeDispatch [24] and VTV [45] guarantee the integrity of virtual function calls to prevent hijacks over virtual function calls. First of all, soundly implementing CFI itself is challenging. Recent research papers identified security holes in most of CFI implementations [6, 17, 19, 20]. More importantly, all of these solutions are designed to only protect control-data, and thus it cannot detect any non-control data attacks [7]. For example, the recent vulnerability exploit against `glibc` [35] was able to completely subvert the victim's system by merely overwriting non-control data—`EXIM`'s runtime configuration. However, because CAVER is not relying on such post-behaviors originating from bad-casting, it is agnostic to specific exploit methods.

9 Conclusion

The bad-casting problem in C++ programs, which occurs when the type of an object pointer is converted to another that is incorrect and unsafe, has serious security implications. We have developed CAVER, a runtime bad-casting detection tool. It uses a new runtime type tracing mechanism, the Type Hierarchy Table, to efficiently verify type casting dynamically. CAVER provides broader coverage than existing approaches with smaller or comparable performance overhead. We have implemented CAVER and have applied it to large-scale software including the Chromium and Firefox browsers. To date, CAVER has found eleven previously unknown vulnerabilities, which have been reported and subsequently fixed by the corresponding open-source communities.

Acknowledgment

Abstract

We present new biases in RC4, break the Wi-Fi Protected Access Temporal Key Integrity Protocol (WPA-TKIP), and design a practical plaintext recovery attack against the Transport Layer Security (TLS) protocol. To empirically find new biases in the RC4 keystream we use statistical hypothesis tests. This reveals many new biases in the initial keystream bytes, as well as several new long-term biases. Our fixed-plaintext recovery algorithms are capable of using multiple types of biases, and return a list of plaintext candidates in decreasing likelihood.

To break WPA-TKIP we introduce a method to generate a large number of identical packets. This packet is decrypted by generating its plaintext candidate list, and using redundant packet structure to prune bad candidates. From the decrypted packet we derive the TKIP MIC key, which can be used to inject and decrypt packets. In practice the attack can be executed within an hour. We also attack TLS as used by HTTPS, where we show how to decrypt a secure cookie with a success rate of 94% using $9 \cdot 2^{27}$ ciphertexts. This is done by injecting known data around the cookie, abusing this using Mantin's *ABSAB* bias, and brute-forcing the cookie by traversing the plaintext candidates. Using our traffic generation technique, we are able to execute the attack in merely 75 hours.

1 Introduction

RC4 is (still) one of the most widely used stream ciphers. Arguably its most well known usage is in SSL and WEP, and in their successors TLS [8] and WPA-TKIP [19]. In particular it was heavily used after attacks against CBC-mode encryption schemes in TLS were published, such as BEAST [9], Lucky 13 [1], and the padding oracle attack [7]. As a mitigation RC4 was recommended. Hence, at one point around 50% of all TLS connections were using RC4 [2], with the current estimate around 30% [18]. This motivated the search for new attacks, relevant examples being [2, 20, 31, 15, 30]. Of special interest is the attack proposed by AlFardan et al., where roughly $13 \cdot 2^{30}$ ciphertexts are required to decrypt a cookie sent over HTTPS [2]. This corresponds to about 2000 hours of data in their setup, hence the attack is considered close to being practical. Our goal is to see how far these attacks can be pushed by exploring three areas. First, we search for new biases in the keystream. Second, we improve fixed-plaintext recovery algorithms. Third, we demonstrate techniques to perform our attacks in practice.

First we empirically search for biases in the keystream. This is done by generating a large amount of keystream, and storing statistics about them in several datasets. The resulting datasets are then analysed using statistical hypothesis tests. Our null hypothesis is that a keystream byte is uniformly distributed, or that two bytes are independent. Rejecting the null hypothesis is equivalent to detecting a bias. Compared to manually inspecting graphs, this allows for a more large-scale analysis. With this approach we found many new biases in the initial keystream bytes, as well as several new long-term biases.

We break WPA-TKIP by decrypting a complete packet using RC4 biases and deriving the TKIP MIC key. This key can be used to inject and decrypt packets [48]. In particular we modify the plaintext recovery attack of Paterson et al. [31, 30] to return a list of candidates in decreasing likelihood. Bad candidates are detected and pruned based on the (decrypted) CRC of the packet. This increases the success rate of simultaneously decrypting all unknown bytes. We achieve practicality using a novel method to rapidly inject identical packets into a network. In practice the attack can be executed within an hour.

We also attack RC4 as used in TLS and HTTPS, where we decrypt a secure cookie in realistic conditions. This is done by combining the *ABSAB* and Fluhrer-McGrew biases using variants of the of Isobe et al. and AlFardan et al. attack [20, 2]. Our technique can easily be extended to include other biases as well. To abuse Mantin's *ABSAB* bias we inject known plaintext around the cookie, and exploit this to calculate Bayesian plaintext likelihoods over the unknown cookie. We then generate a list of (cookie) candidates in decreasing likelihood, and use this to brute-force the cookie in negligible time. The algorithm to generate candidates differs from the WPA-TKIP one due to the reliance on double-byte instead of single-byte likelihoods. All combined, we need $9 \cdot 2^{27}$ encryptions of a cookie to decrypt it with a success rate of 94%. Finally we show how to make a victim generate this amount within only 75 hours, and execute the attack in practice.

To summarize, our main contributions are:

- We use statistical tests to empirically detect biases in the keystream, revealing large sets of new biases.
- We design plaintext recovery algorithms capable of using multiple types of biases, which return a list of plaintext candidates in decreasing likelihood.
- We demonstrate practical exploitation techniques to break RC4 in both WPA-TKIP and TLS.

The remainder of this paper is organized as follows. Section 2 gives a background on RC4, TKIP, and TLS. In Sect. 3 we introduce hypothesis tests and report new biases. Plaintext recovery techniques are given in Sect. 4. Practical attacks on TKIP and TLS are presented in Sect. 5 and Sect. 6, respectively. Finally, we summarize related work in Sect. 7 and conclude in Sect. 8.

2 Background

We introduce RC4 and its usage in TLS and WPA-TKIP.

2.1 The RC4 Algorithm

The RC4 algorithm is intriguingly short and known to be very fast in software. It consists of a Key Scheduling Algorithm (KSA) and a Pseudo Random Generation Algorithm (PRGA), which are both shown in Fig. 1. The state consists of a permutation $\mathcal{S}$ of the set $\{0,\ldots,255\}$, a public counter i, and a private index j. The KSA takes as input a variable-length key and initializes $\mathcal{S}$. At each round $r = 1,2,\ldots$ of the PRGA, the yield statement outputs a keystream byte Z_r. All additions are performed modulo 256. A plaintext byte P_r is encrypted to ciphertext byte C_r using $C_r = P_r \oplus Z_r$.

2.1.1 Short-Term Biases

Several biases have been found in the initial RC4 keystream bytes. We call these short-term biases. The most significant one was found by Mantin and Shamir. They showed that the second keystream byte is twice as likely to be zero compared to uniform [25]. Or more formally that $\Pr[Z_2 = 0] \approx 2 \cdot 2^{-8}$, where the probability is over the random choice of the key. Because zero occurs more often than expected, we call this a positive bias. Similarly, a value occurring less often than expected is called a negative bias. This result was extended by Maitra et al. [23] and further refined by Sen Gupta et al. [38] to show that there is a bias towards zero for most initial keystream bytes. Sen Gupta et al. also found key-length dependent biases: if ℓ is the key length, keystream byte Z_ℓ has a positive bias towards $256-\ell$ [38]. AlFardan et al. showed that all initial 256 keystream bytes are biased by empirically estimating their probabilities when 16-byte keys are used [2]. While doing this they found additional strong biases, an example being the bias towards value r for all positions $1 \leq r \leq 256$. This bias was also independently discovered by Isobe et al. [20].

Listing (1) RC4 Key Scheduling (KSA).

```
j, S = 0, range(256)
for i in range(256):
  j += S[i] + key[i % len(key)]
  swap(S[i], S[j])
return S
```

Listing (2) RC4 Keystream Generation (PRGA).

```
S, i, j = KSA(key), 0, 0
while True:
  i += 1
  j += S[i]
  swap(S[i], S[j])
  yield S[S[i] + S[j]]
```

Figure 1: Implementation of RC4 in Python-like pseudo-code. All additions are performed modulo 256.

The bias $\Pr[Z_1 = Z_2] = 2^{-8}(1-2^{-8})$ was found by Paul and Preneel [33]. Isobe et al. refined this result for the value zero to $\Pr[Z_1 = Z_2 = 0] \approx 3 \cdot 2^{-16}$ [20]. In [20] the authors searched for biases of similar strength between initial bytes, but did not find additional ones. However, we did manage to find new ones (see Sect. 3.3).

2.1.2 Long-Term Biases

In contrast to short-term biases, which occur only in the initial keystream bytes, there are also biases that keep occurring throughout the whole keystream. We call these long-term biases. For example, Fluhrer and McGrew (FM) found that the probability of certain digraphs, i.e., consecutive keystream bytes (Z_r, Z_{r+1}), deviate from uniform throughout the whole keystream [13]. These biases depend on the public counter i of the PRGA, and are listed in Table 1 (ignoring the condition on r for now). In their analysis, Fluhrer and McGrew assumed that the internal state of the RC4 algorithm was uniformly random.

Digraph	Condition	Probability
(0,0)	$i = 1$	$2^{-16}(1+2^{-7})$
(0,0)	$i \neq 1, 255$	$2^{-16}(1+2^{-8})$
(0,1)	$i \neq 0, 1$	$2^{-16}(1+2^{-8})$
(0,$i+1$)	$i \neq 0, 255$	$2^{-16}(1-2^{-8})$
($i+1$,255)	$i \neq 254 \wedge r \neq 1$	$2^{-16}(1+2^{-8})$
(129,129)	$i = 2, r \neq 2$	$2^{-16}(1+2^{-8})$
(255,$i+1$)	$i \neq 1, 254$	$2^{-16}(1+2^{-8})$
(255,$i+2$)	$i \in [1, 252] \wedge r \neq 2$	$2^{-16}(1+2^{-8})$
(255,0)	$i = 254$	$2^{-16}(1+2^{-8})$
(255,1)	$i = 255$	$2^{-16}(1+2^{-8})$
(255,2)	$i = 0, 1$	$2^{-16}(1+2^{-8})$
(255,255)	$i \neq 254 \wedge r \neq 5$	$2^{-16}(1-2^{-8})$

Table 1: Generalized Fluhrer-McGrew (FM) biases. Here i is the public counter in the PRGA and r the position of the first byte of the digraph. Probabilities for long-term biases are shown (for short-term biases see Fig. 4).

This assumption is only true after a few rounds of the PRGA [13, 26, 38]. Consequently these biases were generally not expected to be present in the initial keystream bytes. However, in Sect. 3.3.1 we show that most of these biases do occur in the initial keystream bytes, albeit with different probabilities than their long-term variants.

Another long-term bias was found by Mantin [24]. He discovered a bias towards the pattern $ABSAB$, where A and B represent byte values, and $\mathcal{S}$ a short sequence of bytes called the gap. With the length of the gap $\mathcal{S}$ denoted by g, the bias can be written as:

$$\Pr[(Z_r, Z_{r+1}) = (Z_{r+g+2}, Z_{r+g+3})] = 2^{-16}(1+2^{-8}e^{\frac{-4-8g}{256}}) \tag{1}$$

Hence the bigger the gap, the weaker the bias. Finally, Sen Gupta et al. found the long-term bias [38]

$$\Pr[(Z_{w256}, Z_{w256+2}) = (0,0)] = 2^{-16}(1+2^{-8})$$

where $w \geq 1$. We discovered that a bias towards $(128, 0)$ is also present at these positions (see Sect. 3.4).

2.2 TKIP Cryptographic Encapsulation

The design goal of WPA-TKIP was for it to be a temporary replacement of WEP [19, §11.4.2]. While it is being phased out by the WiFi Alliance, a recent study shows its usage is still widespread [48]. Out of 6803 networks, they found that 71% of protected networks still allow TKIP, with 19% exclusively supporting TKIP.

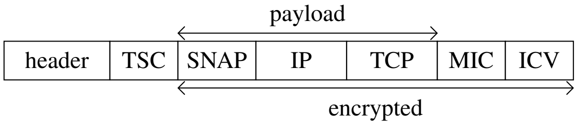

Figure 2: Simplified TKIP frame with a TCP payload.

Our attack on TKIP relies on two elements of the protocol: its weak Message Integrity Check (MIC) [44, 48], and its faulty per-packet key construction [2, 15, 31, 30]. We briefly introduce both aspects, assuming a 512-bit Pairwise Transient Key (PTK) has already been negotiated between the Access Point (AP) and client. From this PTK a 128-bit temporal encryption key (TK) and two 64-bit Message Integrity Check (MIC) keys are derived. The first MIC key is used for AP-to-client communication, and the second for the reverse direction. Some works claim that the PTK, and its derived keys, are renewed after a user-defined interval, commonly set to 1 hour [44, 48]. However, we found that generally only the Groupwise Transient Key (GTK) is periodically renewed. Interestingly, our attack can be executed within an hour, so even networks which renew the PTK every hour can be attacked.

When the client wants to transmit a payload, it first calculates a MIC value using the appropriate MIC key and the Micheal algorithm (see Fig. Figure 2). Unfortunately Micheal is straightforward to invert: given plaintext data and its MIC value, we can efficiently derive the MIC key [44]. After appending the MIC value, a CRC checksum called the Integrity Check Value (ICV) is also appended. The resulting packet, including MAC header and example TCP payload, is shown in Figure 2. The payload, MIC, and ICV are encrypted using RC4 with a per-packet key. This key is calculated by a mixing function that takes as input the TK, the TKIP sequence counter (TSC), and the transmitter MAC address (TA). We write this as $\mathrm{K} = \mathrm{KM}(\mathrm{TA}, \mathrm{TK}, \mathrm{TSC})$. The TSC is a 6-byte counter that is incremented after transmitting a packet, and is included unencrypted in the MAC header. In practice the output of KM can be modelled as uniformly random [2, 31]. In an attempt to avoid weak-key attacks that broke WEP [12], the first three bytes of K are set to [19, §11.4.2.1.1]:

$$\mathrm{K}_0 = \mathrm{TSC}_1 \quad \mathrm{K}_1 = (\mathrm{TSC}_1 \mid 0\mathrm{x}20) \,\&\, 0\mathrm{x}7\mathrm{f} \quad \mathrm{K}_2 = \mathrm{TSC}_0$$

Here, TSC_0 and TSC_1 are the two least significant bytes of the TSC. Since the TSC is public, so are the first three bytes of K. Both formally and using simulations, it has been shown this actually weakens security [2, 15, 31, 30].

2.3 The TLS Record Protocol

We focus on the TLS record protocol when RC4 is selected as the symmetric cipher [8]. In particular we assume the handshake phase is completed, and a 48-byte TLS master secret has been negotiated.

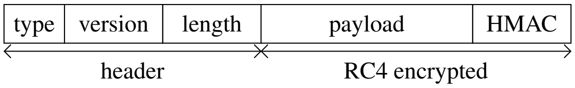

Figure 3: TLS Record structure when using RC4.

To send an encrypted payload, a TLS record of type application data is created. It contains the protocol version, length of the encrypted content, the payload itself, and finally an HMAC. The resulting layout is shown in Fig. 3. The HMAC is computed over the header, a sequence number incremented for each transmitted record, and the plaintext payload. Both the payload and HMAC are encrypted. At the start of a connection, RC4 is initialized with a key derived from the TLS master secret. This key can be modelled as being uniformly random [2]. None of the initial keystream bytes are discarded.

In the context of HTTPS, one TLS connection can be used to handle multiple HTTP requests. This is called a persistent connection. Slightly simplified, a server indicates support for this by setting the HTTP `Connection` header to `keep-alive`. This implies RC4 is initialized only once to send all HTTP requests, allowing the usage of long-term biases in attacks. Finally, cookies can be marked as being `secure`, assuring they are transmitted only over a TLS connection.

3 Empirically Finding New Biases

In this section we explain how to empirically yet soundly detect biases. While we discovered many biases, we will not use them in our attacks. This simplifies the description of the attacks. And, while using the new biases may improve our attacks, using existing ones already sufficed to significantly improve upon existing attacks. Hence our focus will mainly be on the most intriguing new biases.

3.1 Soundly Detecting Biases

In order to empirically detect new biases, we rely on hypothesis tests. That is, we generate keystream statistics over random RC4 keys, and use statistical tests to uncover deviations from uniform. This allows for a large-scale and automated analysis. To detect single-byte biases, our null hypothesis is that the keystream byte values are uniformly distributed. To detect biases between two bytes, one may be tempted to use as null hypothesis that the pair is uniformly distributed. However, this falls short if there are already single-byte biases present. In this case single-byte biases imply that the pair is also biased, while both bytes may in fact be independent. Hence, to detect double-byte biases, our null hypothesis is that they are independent. With this test, we even detected pairs that are actually more uniform than expected. Rejecting the null hypothesis is now the same as detecting a bias.

To test whether values are uniformly distributed, we use a chi-squared goodness-of-fit test. A naive approach to test whether two bytes are independent, is using a chi-squared independence test. Although this would work, it is not ideal when only a few biases (outliers) are present. Moreover, based on previous work we expect that only a few values between keystream bytes show a clear dependency on each other [13, 24, 20, 38, 4]. Taking the Fluhrer-McGrew biases as an example, at any position at most 8 out of a total 65536 value pairs show a clear bias [13]. When expecting only a few outliers, the M-test of Fuchs and Kenett can be asymptotically more powerful than the chi-squared test [14]. Hence we used the M-test to detect dependencies between keystream bytes. To determine which values are biased between dependent bytes, we perform proportion tests over all value pairs.

We reject the null hypothesis only if the p-value is lower than 10^{-4}. Holm's method is used to control the family-wise error rate when performing multiple hypothesis tests. This controls the probability of even a single false positive over all hypothesis tests. We always use the two-sided variant of an hypothesis test, since a bias can be either positive or negative.

Simply giving or plotting the probability of two dependent bytes is not ideal. After all, this probability includes the single-byte biases, while we only want to report the strength of the dependency between both bytes. To solve this, we report the absolute relative bias compared to the expected single-byte based probability. More precisely, say that by multiplying the two single-byte probabilities of a pair, we would expect it to occur with probability p. Given that this pair actually occurs with probability s, we then plot the value $|q|$ from the formula $s = p \cdot (1+q)$. In a sense the relative bias indicates how much information is gained by not just considering the single-byte biases, but using the real byte-pair probability.

3.2 Generating Datasets

In order to generate detailed statistics of keystream bytes, we created a distributed setup. We used roughly 80 standard desktop computers and three powerful servers as workers. The generation of the statistics is done in C. Python was used to manage the generated datasets and control all workers. On start-up each worker generates a cryptographically random AES key. Random 128-bit RC4 keys are derived from this key using AES in counter mode. Finally, we used R for all statistical analysis [34].

Our main results are based on two datasets, called `first16` and `consec512`. The `first16` dataset estimates $\Pr[Z_a = x \wedge Z_b = y]$ for $1 \leq a \leq 16$, $1 \leq b \leq 256$, and $0 \leq x, y < 256$ using 2^{44} keys. Its generation took

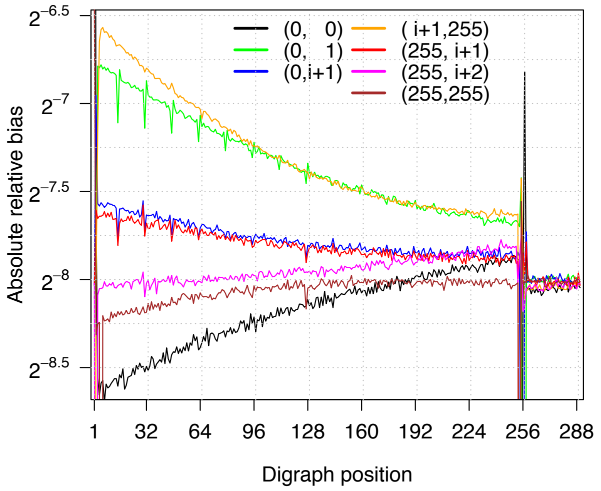

Figure 4: Absolute relative bias of several Fluhrer-McGrew digraphs in the initial keystream bytes, compared to their expected single-byte based probability.

roughly 9 CPU years. This allows detecting biases between the first 16 bytes and the other initial 256 bytes. The `consec512` dataset estimates $\Pr[Z_r = x \wedge Z_{r+1} = y]$ for $1 \leq r \leq 512$ and $0 \leq x, y < 256$ using 2^{45} keys, which took 16 CPU years to generate. It allows a detailed study of consecutive keystream bytes up to position 512.

We optimized the generation of both datasets. The first optimization is that one run of a worker generates at most 2^{30} keystreams. This allows usage of 16-bit integers for all counters collecting the statistics, even in the presence of significant biases. Only when combining the results of workers are larger integers required. This lowers memory usage, reducing cache misses. To further reduce cache misses we generate several keystreams before updating the counters. In independent work, Paterson et al. used similar optimizations [30]. For the `first16` dataset we used an additional optimization. Here we first generate several keystreams, and then update the counters in a sorted manner based on the value of Z_a. This optimization caused the most significant speed-up for the `first16` dataset.

3.3 New Short-Term Biases

By analysing the generated datasets we discovered many new short-term biases. We classify them into several sets.

3.3.1 Biases in (Non-)Consecutive Bytes

By analysing the `consec512` dataset we discovered numerous biases between consecutive keystream bytes. Our first observation is that the Fluhrer-McGrew biases are also present in the initial keystream bytes. Exceptions occur at positions 1, 2 and 5, and are listed in Table 1 (note the extra conditions on the position r). This is surprising, as the Fluhrer-McGrew biases were generally not expected to be present in the initial keystream bytes [13]. However, these biases are present, albeit with different probabilities. Figure 4 shows the absolute relative bias of most Fluhrer-McGrew digraphs, compared to their expected single-byte based probability (recall Sect. 3.1). For all digraphs, the sign of the relative bias q is the same as its long-term variant as listed in Table 1. We observe that the relative biases converge to their long-term values, especially after position 257. The vertical lines around position 1 and 256 are caused by digraphs which do not hold (or hold more strongly) around these positions.

First byte	Second byte	Probability
Consecutive biases:		
$Z_{15} = 240$	$Z_{16} = 240$	$2^{-15.94786}(1 - 2^{-4.894})$
$Z_{31} = 224$	$Z_{32} = 224$	$2^{-15.96486}(1 - 2^{-5.427})$
$Z_{47} = 208$	$Z_{48} = 208$	$2^{-15.97595}(1 - 2^{-5.963})$
$Z_{63} = 192$	$Z_{64} = 192$	$2^{-15.98363}(1 - 2^{-6.469})$
$Z_{79} = 176$	$Z_{80} = 176$	$2^{-15.99020}(1 - 2^{-7.150})$
$Z_{95} = 160$	$Z_{96} = 160$	$2^{-15.99405}(1 - 2^{-7.740})$
$Z_{111} = 144$	$Z_{112} = 144$	$2^{-15.99668}(1 - 2^{-8.331})$
Non-consecutive biases:		
$Z_3 = 4$	$Z_5 = 4$	$2^{-16.00243}(1 + 2^{-7.912})$
$Z_3 = 131$	$Z_{131} = 3$	$2^{-15.99543}(1 + 2^{-8.700})$
$Z_3 = 131$	$Z_{131} = 131$	$2^{-15.99347}(1 - 2^{-9.511})$
$Z_4 = 5$	$Z_6 = 255$	$2^{-15.99918}(1 + 2^{-8.208})$
$Z_{14} = 0$	$Z_{16} = 14$	$2^{-15.99349}(1 + 2^{-9.941})$
$Z_{15} = 47$	$Z_{17} = 16$	$2^{-16.00191}(1 + 2^{-11.279})$
$Z_{15} = 112$	$Z_{32} = 224$	$2^{-15.96637}(1 - 2^{-10.904})$
$Z_{15} = 159$	$Z_{32} = 224$	$2^{-15.96574}(1 + 2^{-9.493})$
$Z_{16} = 240$	$Z_{31} = 63$	$2^{-15.95021}(1 + 2^{-8.996})$
$Z_{16} = 240$	$Z_{32} = 16$	$2^{-15.94976}(1 + 2^{-9.261})$
$Z_{16} = 240$	$Z_{33} = 16$	$2^{-15.94960}(1 + 2^{-10.516})$
$Z_{16} = 240$	$Z_{40} = 32$	$2^{-15.94976}(1 + 2^{-10.933})$
$Z_{16} = 240$	$Z_{48} = 16$	$2^{-15.94989}(1 + 2^{-10.832})$
$Z_{16} = 240$	$Z_{48} = 208$	$2^{-15.92619}(1 - 2^{-10.965})$
$Z_{16} = 240$	$Z_{64} = 192$	$2^{-15.93357}(1 - 2^{-11.229})$

Table 2: Biases between (non-consecutive) bytes.

A second set of strong biases have the form:

$$\Pr[Z_{w16-1} = Z_{w16} = 256 - w16] \qquad (2)$$

with $1 \leq w \leq 7$. In Table 2 we list their probabilities. Since 16 equals our key length, these are likely key-length dependent biases.

Another set of biases have the form $\Pr[Z_r = Z_{r+1} = x]$. Depending on the value x, these biases are either negative or positive. Hence summing over all x and calculating $\Pr[Z_r = Z_{r+1}]$ would lose some statistical informa-

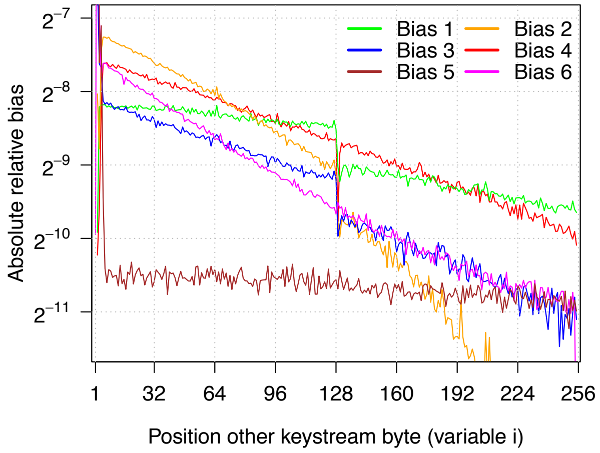

Figure 5: Biases induced by the first two bytes. The number of the biases correspond to those in Sect. 3.3.2.

tion. In principle, these biases also include the Fluhrer-McGrew pairs $(0,0)$ and $(255,255)$. However, as the bias for both these pairs is much higher than for other values, we don't include them here. Our new bias, in the form of $\Pr[Z_r = Z_{r+1}]$, was detected up to position 512.

We also detected biases between non-consecutive bytes that do not fall in any obvious categories. An overview of these is given in Table 2. We remark that the biases induced by $Z_{16} = 240$ generally have a position, or value, that is a multiple of 16. This is an indication that these are likely key-length dependent biases.

3.3.2 Influence of Z_1 and Z_2

Arguably our most intriguing finding is the amount of information the first two keystream bytes leak. In particular, Z_1 and Z_2 influence all initial 256 keystream bytes. We detected the following six sets of biases:

1) $Z_1 = 257 - i \wedge Z_i = 0$ 4) $Z_1 = i - 1 \wedge Z_i = 1$
2) $Z_1 = 257 - i \wedge Z_i = i$ 5) $Z_2 = 0 \wedge Z_i = 0$
3) $Z_1 = 257 - i \wedge Z_i = 257 - i$ 6) $Z_2 = 0 \wedge Z_i = i$

Their absolute relative bias, compared to the single-byte biases, is shown in Fig. 5. The relative bias of pairs 5 and 6, i.e., those involving Z_2, are generally negative. Pairs involving Z_1 are generally positive, except pair 3, which always has a negative relative bias. We also detected dependencies between Z_1 and Z_2 other than the $\Pr[Z_1 = Z_2]$ bias of Paul and Preneel [33]. That is, the following pairs are strongly biased:

A) $Z_1 = 0 \wedge Z_2 = x$ C) $Z_1 = x \wedge Z_2 = 0$
B) $Z_1 = x \wedge Z_2 = 258 - x$ D) $Z_1 = x \wedge Z_2 = 1$

Bias A and C are negative for all $x \neq 0$, and both appear to be mainly caused by the strong positive bias

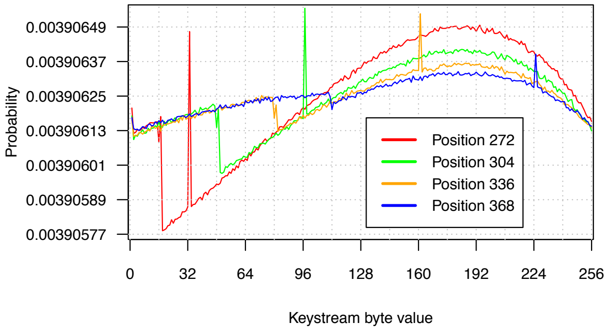

Figure 6: Single-byte biases beyond position 256.

$\Pr[Z_1 = Z_2 = 0]$ found by Isobe et al. Bias B and D are positive. We also discovered the following three biases:

$$\Pr[Z_1 = Z_3] = 2^{-8}(1 - 2^{-9.617}) \tag{3}$$
$$\Pr[Z_1 = Z_4] = 2^{-8}(1 + 2^{-8.590}) \tag{4}$$
$$\Pr[Z_2 = Z_4] = 2^{-8}(1 - 2^{-9.622}) \tag{5}$$

Note that all either involve an equality with Z_1 or Z_2.

3.3.3 Single-Byte Biases

We analysed single-byte biases by aggregating the `consec512` dataset, and by generating additional statistics specifically from single-byte probabilities. The aggregation corresponds to calculating

$$\Pr[Z_r = k] = \sum_{y=0}^{255} \Pr[Z_r = k \wedge Z_{r+1} = y] \tag{6}$$

We ended up with 2^{47} keys used to estimate single-byte probabilities. For all initial 513 bytes we could reject the hypothesis that they are uniformly distributed. In other words, all initial 513 bytes are biased. Figure 6 shows the probability distribution for some positions. Manual inspection of the distributions revealed a significant bias towards $Z_{256+k \cdot 16} = k \cdot 32$ for $1 \leq k \leq 7$. These are likely key-length dependent biases. Following [26] we conjecture there are single-byte biases even beyond these positions, albeit less strong.

3.4 New Long-Term Biases

To search for new long-term biases we created a variant of the `first16` dataset. It estimates

$$\Pr[Z_{256w+a} = x \wedge Z_{256w+b} = y] \tag{7}$$

for $0 \leq a \leq 16$, $0 \leq b < 256$, $0 \leq x, y < 256$, and $w \geq 4$. It is generated using 2^{12} RC4 keys, where each key was used to generate 2^{40} keystream bytes. This took roughly 8 CPU years. The condition on w means we always dropped the initial 1023 keystream bytes. Using this dataset we can detect biases whose periodicity is a proper divisor of 256 (e.g., it detected all Fluhrer-McGrew biases). Our new short-term biases were not present in this dataset, indicating they indeed only occur in the initial keystream bytes, at least with the probabilities we listed. We did find the new long-term bias

$$\Pr[(Z_{w256}, Z_{w256+2}) = (128, 0)] = 2^{-16}(1 + 2^{-8}) \quad (8)$$

for $w \geq 1$. Surprisingly this was not discovered earlier, since a bias towards $(0,0)$ at these positions was already known [38]. We also specifically searched for biases of the form $\Pr[Z_r = Z_{r'}]$ by aggregating our dataset. This revealed that many bytes are dependent on each other. That is, we detected several long-term biases of the form

$$\Pr[Z_{256w+a} = Z_{256w+b}] \approx 2^{-8}(2 \pm 2^{-16}) \quad (9)$$

Due to the small relative bias of 2^{-16}, these are difficult to reliably detect. That is, the pattern where these biases occur, and when their relative bias is positive or negative, is not yet clear. We consider it an interesting future research direction to (precisely and reliably) detect all keystream bytes which are dependent in this manner.

4 Plaintext Recovery

We will design plaintext recovery techniques for usage in two areas: decrypting TKIP packets and HTTPS cookies. In other scenarios, variants of our methods can be used.

4.1 Calculating Likelihood Estimates

Our goal is to convert a sequence of ciphertexts $\mathcal{C}$ into predictions about the plaintext. This is done by exploiting biases in the keystream distributions $p_k = \Pr[Z_r = k]$. These can be obtained by following the steps in Sect. 3.2. All biases in p_k are used to calculate the likelihood that a plaintext byte equals a certain value μ. To accomplish this, we rely on the likelihood calculations of AlFardan et al. [2]. Their idea is to calculate, for each plaintext value μ, the (induced) keystream distributions required to witness the captured ciphertexts. The closer this matches the real keystream distributions p_k, the more likely we have the correct plaintext byte. Assuming a fixed position r for simplicity, the induced keystream distributions are defined by the vector $N^\mu = (N_0^\mu, \ldots, N_{255}^\mu)$. Each N_k^μ represents the number of times the keystream byte was equal to k, assuming the plaintext byte was μ:

$$N_k^\mu = |\{C \in \mathcal{C} \mid C = k \oplus \mu\}| \quad (10)$$

Note that the vectors N^μ and $N^{\mu'}$ are permutations of each other. Based on the real keystream probabilities p_k we calculate the likelihood that this induced distribution would occur in practice. This is modelled using a multinomial distribution with the number of trails equal to $|\mathcal{C}|$, and the categories being the 256 possible keystream byte values. Since we want the probability of this *sequence* of keystream bytes we get [30]:

$$\Pr[\mathcal{C} \mid P = \mu] = \prod_{k \in \{0,\ldots,255\}} (p_k)^{N_k^\mu} \quad (11)$$

Using Bayes' theorem we can convert this into the likelihood λ_μ that the plaintext byte is μ:

$$\lambda_\mu = \Pr[P = \mu \mid \mathcal{C}] \sim \Pr[\mathcal{C} \mid P = \mu] \quad (12)$$

For our purposes we can treat this as an equality [2]. The most likely plaintext byte μ is the one that maximises λ_μ. This was extended to a pair of dependent keystream bytes in the obvious way:

$$\lambda_{\mu_1,\mu_2} = \prod_{k_1,k_2 \in \{0,\ldots,255\}} (p_{k_1,k_2})^{N_{k_1,k_2}^{\mu_1,\mu_2}} \quad (13)$$

We found this formula can be optimized if most keystream values k_1 and k_2 are independent and uniform. More precisely, let us assume that all keystream value pairs in the set $\mathcal{I}$ are independent and uniform:

$$\forall (k_1,k_2) \in \mathcal{I} \colon\ p_{k_1,k_2} = p_{k_1} \cdot p_{k_2} = u \quad (14)$$

where u represents the probability of an unbiased double-byte keystream value. Then we rewrite formula 13 to:

$$\lambda_{\mu_1,\mu_2} = (u)^{M^{\mu_1,\mu_2}} \cdot \prod_{k_1,k_2 \in \mathcal{I}^c} (p_{k_1,k_2})^{N_{k_1,k_2}^{\mu_1,\mu_2}} \quad (15)$$

where

$$M^{\mu_1,\mu_2} = \sum_{k_1,k_2 \in \mathcal{I}} N_{k_1,k_2}^{\mu_1,\mu_2} = |\mathcal{C}| - \sum_{k_1,k_2 \in \mathcal{I}^c} N_{k_1,k_2}^{\mu_1,\mu_2} \quad (16)$$

and with $\mathcal{I}^c$ the set of dependent keystream values. If the set $\mathcal{I}^c$ is small, this results in a lower time-complexity. For example, when applied to the long-term keystream setting over Fluhrer-McGrew biases, roughly 2^{19} operations are required to calculate all likelihood estimates, instead of 2^{32}. A similar (though less drastic) optimization can also be made when single-byte biases are present.

4.2 Likelihoods From Mantin's Bias

We now show how to compute a double-byte plaintext likelihood using Mantin's *ABSAB* bias. More formally, we want to compute the likelihood λ_{μ_1,μ_2} that the plaintext bytes at fixed positions r and $r+1$ are μ_1 and μ_2, respectively. To accomplish this we abuse surrounding known plaintext. Our main idea is to first calculate the likelihood of the *differential* between the known and unknown plaintext. We define the differential $\widehat{Z}_r^g$ as:

$$\widehat{Z}_r^g = (Z_r \oplus Z_{r+2+g}, Z_{r+1} \oplus Z_{r+3+g}) \tag{17}$$

Similarly we use $\widehat{C}_r^g$ and $\widehat{P}_r^g$ to denote the differential over ciphertext and plaintext bytes, respectively. The *ABSAB* bias can then be written as:

$$\Pr[\widehat{Z}_r^g = (0,0)] = 2^{-16}(1 + 2^{-8} \mathrm{e}^{\frac{-4-8g}{256}}) = \alpha(g) \tag{18}$$

When XORing both sides of $\widehat{Z}_r^g = (0,0)$ with $\widehat{P}_r^g$ we get

$$\Pr[\widehat{C}_r^g = \widehat{P}_r^g] = \alpha(g) \tag{19}$$

Hence Mantin's bias implies that the ciphertext differential is biased towards the plaintext differential. We use this to calculate the likelihood $\lambda_{\widehat{\mu}}$ of a differential $\widehat{\mu}$. For ease of notation we assume a fixed position r and a fixed *ABSAB* gap of g. Let $\widehat{\mathcal{C}}$ be the sequence of captured ciphertext differentials, and μ_1' and μ_2' the known plaintext bytes at positions $r+2+g$ and $r+3+g$, respectively. Similar to our previous likelihood estimates, we calculate the probability of witnessing the ciphertext differentials $\widehat{\mathcal{C}}$ assuming the plaintext differential is $\widehat{\mu}$:

$$\Pr[\widehat{\mathcal{C}} \mid \widehat{P} = \widehat{\mu}] = \prod_{\widehat{k} \in \{0,\ldots,255\}^2} \Pr[\widehat{Z} = \widehat{k}]^{N_{\widehat{k}}^{\widehat{\mu}}} \tag{20}$$

where

$$N_{\widehat{k}}^{\widehat{\mu}} = \left| \left\{ \widehat{C} \in \widehat{\mathcal{C}} \mid \widehat{C} = \widehat{k} \oplus \widehat{\mu} \right\} \right| \tag{21}$$

Using this notation we see that this is indeed identical to an ordinary likelihood estimation. Using Bayes' theorem we get $\lambda_{\widehat{\mu}} = \Pr[\widehat{\mathcal{C}} \mid \widehat{P} = \widehat{\mu}]$. Since only one differential pair is biased, we can apply and simplify formula 15:

$$\lambda_{\widehat{\mu}} = (1 - \alpha(g))^{|\mathcal{C}| - |\widehat{\mu}|} \cdot \alpha(g)^{|\widehat{\mu}|} \tag{22}$$

where we slightly abuse notation by defining $|\widehat{\mu}|$ as

$$|\widehat{\mu}| = \left| \left\{ \widehat{C} \in \widehat{\mathcal{C}} \mid \widehat{C} = \widehat{\mu} \right\} \right| \tag{23}$$

Finally we apply our knowledge of the known plaintext bytes to get our desired likelihood estimate:

$$\lambda_{\mu_1,\mu_2} = \lambda_{\widehat{\mu} \oplus (\mu_1', \mu_2')} \tag{24}$$

To estimate at which gap size the *ABSAB* bias is still detectable, we generated 2^{48} blocks of 512 keystream bytes. Based on this we empirically confirmed Mantin's *ABSAB* bias up to gap sizes of at least 135 bytes. The theoretical estimate in formula 1 slightly underestimates the true empirical bias. In our attacks we use a maximum gap size of 128.

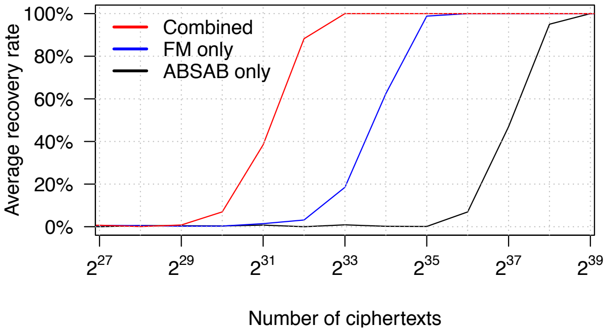

Figure 7: Average success rate of decrypting two bytes using: (1) one *ABSAB* bias; (2) Fluhrer-McGrew (FM) biases; and (3) combination of FM biases with 258 *ABSAB* biases. Results based on 2048 simulations each.

4.3 Combining Likelihood Estimates

Our goal is to combine multiple types of biases in a likelihood calculation. Unfortunately, if the biases cover overlapping positions, it quickly becomes infeasible to perform a single likelihood estimation over all bytes. In the worst case, the calculation cannot be optimized by relying on independent biases. Hence, a likelihood estimate over n keystream positions would have a time complexity of $\mathcal{O}(2^{2 \cdot 8 \cdot n})$. To overcome this problem, we perform and combine multiple separate likelihood estimates.

We will combine multiple types of biases by multiplying their individual likelihood estimates. For example, let λ'_{μ_1,μ_2} be the likelihood of plaintext bytes μ_1 and μ_2 based on the Fluhrer-McGrew biases. Similarly, let λ'_{g,μ_1,μ_2} be likelihoods derived from *ABSAB* biases of gap g. Then their combination is straightforward:

$$\lambda_{\mu_1,\mu_2} = \lambda'_{\mu_1,\mu_2} \cdot \prod_g \lambda'_{g,\mu_1,\mu_2} \tag{25}$$

While this method may not be optimal when combining likelihoods of dependent bytes, it does appear to be a general and powerful method. An open problem is determining which biases can be combined under a single likelihood calculation, while keeping computational requirements acceptable. Likelihoods based on other biases, e.g., Sen Gupta's and our new long-term biases, can be added as another factor (though some care is needed so positions properly overlap).

To verify the effectiveness of this approach, we performed simulations where we attempt to decrypt two bytes using one double-byte likelihood estimate. First this is done using only the Fluhrer-McGrew biases, and using only one *ABSAB* bias. Then we combine $2 \cdot 129$ *ABSAB* biases and the Fluhrer-McGrew biases, where we use the method from Sect. 4.2 to derive likelihoods from *ABSAB* biases. We assume the unknown bytes are surrounded at both sides by known plaintext, and use a maximum *ABSAB* gap of 128 bytes. Figure 7 shows the results of this experiment. Notice that a single *ABSAB* bias is weaker than using all Fluhrer-McGrew biases at a specific position. However, combining several *ABSAB* biases clearly results in a major improvement. We conclude that our approach to combine biases significantly reduces the required number of ciphertexts.

4.4 List of Plaintext Candidates

In practice it is useful to have a list of plaintext candidates in decreasing likelihood. For example, by traversing this list we could attempt to brute-force keys, passwords, cookies, etc. (see Sect. 6). In other situations the plaintext may have a rigid structure allowing the removal of candidates (see Sect. 5). We will generate a list of plaintext candidates in decreasing likelihood, when given either single-byte or double-byte likelihood estimates.

First we show how to construct a candidate list when given single-byte plaintext likelihoods. While it is trivial to generate the two most likely candidates, beyond this point the computation becomes more tedious. Our solution is to incrementally compute the N most likely candidates based on their length. That is, we first compute the N most likely candidates of length 1, then of length 2, and so on. Algorithm 1 gives a high-level implementation of this idea. Variable $P_r[i]$ denotes the i-th most likely plaintext of length r, having a likelihood of $E_r[i]$. The two `min` operations are needed because in the initial loops we are not yet be able to generate N candidates, i.e., there only exist 256^r plaintexts of length r. Picking the μ' which maximizes $pr(\mu')$ can be done efficiently using a priority queue. In practice, only the latest two versions of lists E and P need to be stored. To better maintain numeric stability, and to make the computation more efficient, we perform calculations using the logarithm of the likelihoods. We implemented Algorithm 1 and report on its performance in Sect. 5, where we use it to attack a wireless network protected by WPA-TKIP.

To generate a list of candidates from double-byte likelihoods, we first show how to model the likelihoods as a hidden Markov model (HMM). This allows us to present a more intuitive version of our algorithm, and refer to the extensive research in this area if more efficient implementations are needed. The algorithm we present can be seen as a combination of the classical Viterbi algorithm, and Algorithm 1. Even though it is not the most optimal one, it still proved sufficient to significantly improve plaintext recovery (see Sect. 6). For an introduction to HMMs we refer the reader to [35]. Essentially an HMM models a system where the internal states are not observable, and after each state transition, output is (probabilistically) produced dependent on its new state.

Algorithm 1: Generate plaintext candidates in decreasing likelihood using single-byte estimates.

```
Input: $L$ : Length of the unknown plaintext
       $\lambda_{1 \leq r \leq L,\, 0 \leq \mu \leq 255}$: single-byte likelihoods
       $N$: Number of candidates to generate
Returns: List of candidates in decreasing likelihood
$P_0[1] \leftarrow \varepsilon$
$E_0[1] \leftarrow 0$
for $r = 1$ to $L$ do
    for $\mu = 0$ to $255$ do
        $pos(\mu) \leftarrow 1$
        $pr(\mu) \leftarrow E_{r-1}[1] + \log(\lambda_{r,\mu})$
    for $i = 1$ to $\min(N, 256^r)$ do
        $\mu \leftarrow \mu'$ which maximizes $pr(\mu')$
        $P_r[i] \leftarrow P_{r-1}[pos(\mu)] \parallel \mu$
        $E_r[i] \leftarrow E_{r-1}[pos(\mu)] + \log(\lambda_{r,\mu})$
        $pos(\mu) \leftarrow pos(\mu) + 1$
        $pr(\mu) \leftarrow E_{r-1}[pos(\mu)] + \log(\lambda_{r,\mu})$
        if $pos(\mu) > \min(N, 256^{r-1})$ then
            $pr(\mu) \leftarrow -\infty$
return $P_N$
```

We model the plaintext likelihood estimates as a first-order time-inhomogeneous HMM. The state space S of the HMM is defined by the set of possible plaintext values $\{0, \ldots, 255\}$. The byte positions are modelled using the time-dependent (i.e., inhomogeneous) state transition probabilities. Intuitively, the "current time" in the HMM corresponds to the current plaintext position. This means the transition probabilities for moving from one state to another, which normally depend on the current time, will now depend on the position of the byte. More formally:

$$\Pr[S_{t+1} = \mu_2 \mid S_t = \mu_1] \sim \lambda_{t,\mu_1,\mu_2} \qquad (26)$$

where t represents the time. For our purposes we can treat this as an equality. In an HMM it is assumed that its current state is not observable. This corresponds to the fact that we do not know the value of any plaintext bytes. In an HMM there is also some form of output which depends on the current state. In our setting a particular plaintext value leaks no observable (side-channel) information. This is modelled by always letting every state produce the same null output with probability one.

Using the above HMM model, finding the most likely plaintext reduces to finding the most likely state sequence. This is solved using the well-known Viterbi algorithm. Indeed, the algorithm presented by AlFardan et al. closely resembles the Viterbi algorithm [2]. Similarly, finding the N most likely plaintexts is the same as finding the N most likely state sequences. Hence any N-best variant of the Viterbi algorithm (also called list Viterbi

Algorithm 2: Generate plaintext candidates in decreasing likelihood using double-byte estimates.

```
Input: $L$ : Length of the unknown plaintext plus two
       $m_1$ and $m_L$: known first and last byte
       $\lambda_{1 \leq r < L,\, 0 \leq \mu_1, \mu_2 \leq 255}$: double-byte likelihoods
       $N$: Number of candidates to generate
Returns: List of candidates in decreasing likelihood

for $\mu_2 = 0$ to 255 do
    $E_2[\mu_2, 1] \leftarrow \log(\lambda_{1,m_1,\mu_2})$
    $P_2[\mu_2, 1] \leftarrow m_1 \parallel \mu_2$

for $r = 3$ to $L$ do
    for $\mu_2 = 0$ to 255 do
        for $\mu_1 = 0$ to 255 do
            $pos(\mu_1) \leftarrow 1$
            $pr(\mu_1) \leftarrow E_{r-1}[\mu_1, 1] + \log(\lambda_{r,\mu_1,\mu_2})$

        for $i = 1$ to $\min(N, 256^{r-1})$ do
            $\mu_1 \leftarrow \mu$ which maximizes $pr(\mu)$
            $P_r[\mu_2, i] \leftarrow P_{r-1}[\mu_1, pos(\mu_1)] \parallel \mu_2$
            $E_r[\mu_2, i] \leftarrow E_{r-1}[\mu_1, pos(\mu_1)] + \log(\lambda_{r,\mu_1,\mu_2})$

            $pos(\mu_1) \leftarrow pos(\mu_1) + 1$
            $pr(\mu_1) \leftarrow E_{r-1}[\mu_1, pos(\mu_1)] + \log(\lambda_{r,\mu_1,\mu_2})$

            if $pos(\mu_1) > \min(N, 256^{r-2})$ then
                $pr(\mu_1) \leftarrow -\infty$

return $P_N[m_L, :]$
```

algorithm) can be used, examples being [42, 36, 40, 28]. The simplest form of such an algorithm keeps track of the N best candidates ending in a particular value μ, and is shown in Algorithm 2. Similar to [2, 30] we assume the first byte m_1 and last byte m_L of the plaintext are known. During the last round of the outer for-loop, the loop over μ_2 has to be executed only for the value m_L. In Sect. 6 we use this algorithm to generate a list of cookies.

Algorithm 2 uses considerably more memory than Algorithm 1. This is because it has to store the N most likely candidates for each possible ending value μ. We remind the reader that our goal is not to present the most optimal algorithm. Instead, by showing how to model the problem as an HMM, we can rely on related work in this area for more efficient algorithms [42, 36, 40, 28]. Since an HMM can be modelled as a graph, all k-shortest path algorithms are also applicable [10]. Finally, we remark that even our simple variant sufficed to significantly improve plaintext recovery rates (see Sect. 6).

5 Attacking WPA-TKIP

We use our plaintext recovery techniques to decrypt a full packet. From this decrypted packet the MIC key can be derived, allowing an attacker to inject and decrypt packets. The attack takes only an hour to execute in practice.

5.1 Calculating Plaintext Likelihoods

We rely on the attack of Paterson et al. to compute plaintext likelihood estimates [31, 30]. They noticed that the first three bytes of the per-packet RC4 key are public. As explained in Sect. 2.2, the first three bytes are fully determined by the TKIP Sequence Counter (TSC). It was observed that this dependency causes strong TSC-dependent biases in the keystream [31, 15, 30], which can be used to improve the plaintext likelihood estimates. For each TSC value they calculated plaintext likelihoods based on empirical, per-TSC, keystream distributions. The resulting 256^2 likelihoods are combined by multiplying them over all TSC pairs. In a sense this is similar to combining multiple types of biases as done in Sect. 4.3, though here the different types of biases are known to be independent. We use the single-byte variant of the attack [30, §4.1] to obtain likelihoods $\lambda_{r,\mu}$ for every unknown byte r.

The downside of this attack is that it requires detailed per-TSC keystream statistics. Paterson at al. generated statistics for the first 512 bytes, which took 30 CPU years [30]. However, in our attack we only need these statistics for the first few keystream bytes. We used 2^{32} keys per TSC value to estimate the keystream distribution for the first 128 bytes. Using our distributed setup the generation of these statistics took 10 CPU years.

With our per-TSC keystream distributions we obtained similar results to that of Paterson et al. [31, 30]. By running simulations we confirmed that the odd byte positions [30], instead of the even ones [31], can be recovered with a higher probability than others. Similarly, the bytes at positions 49-51 and 63-67 are generally recovered with higher probability as well. Both observations will be used to optimize the attack in practice.

5.2 Injecting Identical Packets

We show how to fulfil the first requirement of a successful attack: the generation of identical packets. If the IP of the victim is know, and incoming connections towards it are not blocked, we can simply send identical packets to the victim. Otherwise we induce the victim into opening a TCP connection to an attacker-controlled server. This connection is then used to transmit identical packets to the victim. A straightforward way to accomplish this is by social engineering the victim into visiting a website hosted by the attacker. The browser will open a TCP connection with the server in order to load the website. However, we can also employ more sophisticated methods that have a broader target range. One such method is abusing the inclusion of (insecure) third-party resources on popular websites [27]. For example, an attacker can register a mistyped domain, accidentally used in a resource address (e.g., an image URL) on a popular website. Whenever the victim visits this website and loads the resource, a TCP connection is made to the server of the attacker. In [27] these types of vulnerabilities were found to be present on several popular websites. Additionally, any type of web vulnerability that can be abused to make a victim execute JavaScript can be utilised. In this sense, our requirements are more relaxed than those of the recent attacks on SSL and TLS, which *require* the ability to run JavaScript code in the victim's browser [9, 1, 2]. Another method is to hijack an existing TCP connection of the victim, which under certain conditions is possible without a man-in-the-middle position [17]. We conclude that, while there is no universal method to accomplish this, we can assume control over a TCP connection with the victim. Using this connection we inject identical packets by repeatedly retransmitting identical TCP packets, even if the victim is behind a firewall. Since retransmissions are valid TCP behaviour, this will work even if the victim is behind a firewall.

We now determine the optimal structure of the injected packet. A naive approach would be to use the shortest possible packet, meaning no TCP payload is included. Since the total size of the LLC/SNAP, IP, and TCP header is 48 bytes, the MIC and ICV would be located at position 49 up to and including 60 (see Fig. 2). At these locations 7 bytes are strongly biased. In contrast, if we use a TCP payload of 7 bytes, the MIC and ICV are located at position 56 up to and including 60. In this range 8 bytes are strongly biased, resulting in better plaintext likelihood estimates. Through simulations we confirmed that using a 7 byte payload increases the probability of successfully decrypting the MIC and ICV. In practice, adding 7 bytes of payload also makes the length of our injected packet unique. As a result we can easily identify and capture such packets. Given both these advantages, we use a TCP data packet containing 7 bytes of payload.

5.3 Decrypting a Complete Packet

Our goal is to decrypt the injected TCP packet, including its MIC and ICV fields. Note that all these TCP packets will be encrypted with a different RC4 key. For now we assume all fields in the IP and TCP packet are known, and will later show why we can safely make this assumption. Hence, only the 8-byte MIC and 4-byte ICV of the packet remain unknown. We use the per-TSC keystream statistics to compute single-byte plaintext likelihoods for all 12 bytes. However, this alone would give a very low success probability of simultaneously (correctly) decrypting all bytes. We solve this by realising that the TKIP ICV is a simple CRC checksum which we can easily verify ourselves. Hence we can detect bad candidates by inspecting their CRC checksum. We now generate a plaintext candidate list, and traverse it until we find a packet having a correct CRC. This drastically improves the probability of simultaneously decrypting all bytes. From the decrypted packet we can derive the TKIP MIC key [44], which can then be used to inject and decrypt arbitrary packets [48].

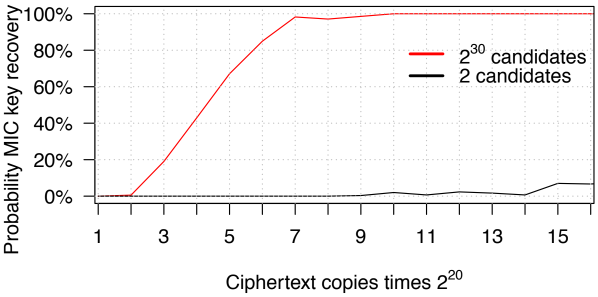

Figure 8: Success rate of obtaining the TKIP MIC key using nearly 2^{30} candidates, and using only the two best candidates. Results are based on 256 simulations each.

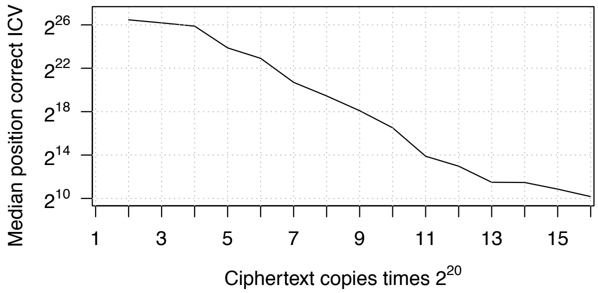

Figure 9: Median position of a candidate with a correct ICV with nearly 2^{30} candidates. Results are based on 256 simulations each.

Figure 8 shows the success rate of finding a packet with a good ICV and deriving the correct MIC key. For comparison, it also includes the success rates had we only used the two most likely candidates. Figure 9 shows the median position of the first candidate with a correct ICV. We plot the median instead of average to lower influence of outliers, i.e., at times the correct candidate was unexpectedly far (or early) in the candidate list.

The question that remains how to determine the contents of the unknown fields in the IP and TCP packet. More precisely, the unknown fields are the internal IP and port of the client, and the IP time-to-live (TTL) field. One observation makes this clear: both the IP and TCP header contain checksums. Therefore, we can apply exactly the same technique (i.e., candidate generation and pruning) to derive the values of these fields with high success rates. This can be done independently of each other, and independently of decrypting the MIC and ICV.

Another method to obtain the internal IP is to rely on HTML5 features. If the initial TCP connection is created by a browser, we can first send JavaScript code to obtain the internal IP of the victim using WebRTC [37]. We also noticed that our NAT gateway generally did not modify the source port used by the victim. Consequently we can simply read this value at the server. The TTL field can also be determined without relying on the IP checksum. Using a `traceroute` command we count the number of hops between the server and the client, allowing us to derive the TTL value at the victim.

5.4 Empirical Evaluation

To test the plaintext recovery phase of our attack we created a tool that parses a raw `pcap` file containing the captured Wi-Fi packets. It searches for the injected packets, extracts the ciphertext statistics, calculates plaintext likelihoods, and searches for a candidate with a correct ICV. From this candidate, i.e., decrypted injected packet, we derive the MIC key.

For the ciphertext generation phase we used an OpenVZ VPS as malicious server. The incoming TCP connection from the victim is handled using a custom tool written in Scapy. It relies on a patched version of Tcpreplay to rapidly inject the identical TCP packets. The victim machine is a Latitude E6500 and is connected to an Asus RT-N10 router running Tomato 1.28. The victim opens a TCP connection to the malicious server by visiting a website hosted on it. For the attacker we used a Compaq 8510p with an AWUS036nha to capture the wireless traffic. Under this setup we were able to generate roughly 2500 packets per second. This number was reached even when the victim was actively browsing YouTube videos. Thanks to the 7-byte payload, we uniquely detected the injected packet in all experiments without any false positives.

We ran several test where we generated and captured traffic for (slightly more) than one hour. This amounted to, on average, capturing $9.5 \cdot 2^{20}$ different encryptions of the packet being injected. Retransmissions were filtered based on the TSC of the packet. In nearly all cases we successfully decrypted the packet and derived the MIC key. Recall from Sect. 2.2 that this MIC key is valid as long as the victim does not renew its PTK, and that it can be used to inject and decrypt packets from the AP to the victim. For one capture our tool found a packet with a correct ICV, but this candidate did not correspond to the actual plaintext. While our current evaluation is limited in the number of captures performed, it shows the attack is practically feasible, with overall success probabilities appearing to agree with the simulated results of Fig. 8.

Listing 3: Manipulated HTTP request, with known plaintext surrounding the cookie at both sides.

```
GET / HTTP/1.1
Host: site.com
User-Agent: Mozilla/5.0 (X11; Linux i686; rv:32.0)
     Gecko/20100101 Firefox/32.0
Accept: text/html,application/xhtml+xml,application/
     xml;q=0.9,*/*;q=0.8
Accept-Language: en-US,en;q=0.5
Accept-Encoding: gzip, deflate
Cookie: auth=XXXXXXXXXXXXXXXX; injected1=known1;
     injected2=knownplaintext2; ...
```

6 Decrypting HTTPS Cookies

We inject known data around a cookie, enabling use of the *ABSAB* biases. We then show that a HTTPS cookie can be brute-forced using only 75 hours of ciphertext.

6.1 Injecting Known Plaintext

We want to be able to predict the position of the targeted cookie in the encrypted HTTP requests, and surround it with known plaintext. To fix ideas, we do this for the secure `auth` cookie sent to `https://site.com`. Similar to previous attacks on SSL and TLS, we assume the attacker is able to execute JavaScript code in the victim's browser [9, 1, 2]. In our case, this means an active man-in-the-middle (MiTM) position is used, where plaintext HTTP channels can be manipulated. Our first realisation is that an attacker can predict the length and content of HTTP headers preceding the `Cookie` field. By monitoring plaintext HTTP requests, these headers can be sniffed. If the targeted `auth` cookie is the first value in the `Cookie` header, this implies we know its position in the HTTP request. Hence, our goal is to have a layout as shown in Listing 3. Here the targeted cookie is the first value in the `Cookie` header, preceded by known headers, and followed by attacker injected cookies.

To obtain the layout in Listing 3 we use our MiTM position to redirect the victim to `http://site.com`, i.e., to the target website over an insecure HTTP channel. If the target website uses HTTP Strict Transport Security (HSTS), but does not use the `includeSubDomains` attribute, this is still possible by redirecting the victim to a (fake) subdomain [6]. Since few websites use HSTS, and even fewer use it properly [47], this redirection will likely succeed. Against old browsers HSTS can even be bypassed completely [6, 5, 41]. Since secure cookies guarantee only confidentiality but not integrity, the insecure HTTP channel can be used to overwrite, remove, or inject secure cookies [3, 4.1.2.5]. This allows us to remove all cookies except the `auth` cookie, pushing it to the front of the list. After this we can inject cookies that will be included after the `auth` cookie. An example of a HTTP(S) request manipulated in this manner is shown in Listing 3. Here the secure `auth` cookie is surrounded by known plaintext at both sides. This allows us to use Mantin's *ABSAB* bias when calculating plaintext likelihoods.

6.2 Brute-Forcing The Cookie

In contrast to passwords, many websites do not protect against brute-forcing cookies. One reason for this is that the password of an average user has a much lower entropy than a random cookie. Hence it makes sense to brute-force a password, but not a cookie: the chance of successfully brute-forcing a (properly generated) cookie is close to zero. However, if RC4 can be used to connect to the web server, our candidate generation algorithm voids this assumption. We can traverse the plaintext candidate list in an attempt to brute-force the cookie.

Since we are targeting a cookie, we can exclude certain plaintext values. As RFC 6265 states, a cookie value can consists of at most 90 unique characters [3, §4.1.1]. A similar though less general observation was already made by AlFardan et al. [2]. Our observation allows us to give a tighter bound on the required number of ciphertexts to decrypt a cookie, even in the general case. In practice, executing the attack with a reduced character set is done by modifying Algorithm 2 so the for-loops over μ_1 and μ_2 only loop over allowed characters.

Figure 10 shows the success rate of brute-forcing a 16-character cookie using at most 2^{23} attempts. For comparison, we also include the probability of decrypting the cookie if only the most likely plaintext was used. This also allows for an easier comparison with the work for AlFardan et al. [2]. Note that they only use the Fluhrer-McGrew biases, whereas we combine serveral *ABSAB* biases together with the Fluhrer-McGrew biases. We conclude that our brute-force approach, as well as the inclusion of the *ABSAB* biases, significantly improves success rates. Even when using only 2^{23} brute-force attempts, success rates of more than 94% are obtained once $9 \cdot 2^{27}$ encryptions of the cookie have been captured. We conjecture that generating more candidates will further increase success rates.

6.3 Empirical Evaluation

The main requirement of our attack is being able to collect sufficiently many encryptions of the cookie, i.e., having many ciphertexts. We fulfil this requirement by forcing the victim to generate a large number of HTTPS requests. As in previous attacks on TLS [9, 1, 2], we accomplish this by assuming the attacker is able to execute JavaScript in the browser of the victim. For example, when performing a man-in-the-middle attack, we can inject JavaScript into any plaintext HTTP connection. We then use `XMLHttpRequest` objects to issue Cross-Origin Requests to the targeted website. The browser will automatically add the secure cookie to these (encrypted) requests. Due to the same-origin policy we cannot read the replies, but this poses no problem, we only require that the cookie is included in the request. The requests are sent inside HTML5 WebWorkers. Essentially this means our JavaScript code will run in the background of the browser, and any open page(s) stay responsive. We use GET requests, and carefully craft the values of our injected cookies so the targeted `auth` cookie is always at a fixed position in the keystream (modulo 256). Recall that this alignment is required to make optimal use of the Fluhrer-McGrew biases. An attacker can learn the required amount of padding by first letting the client make a request without padding. Since RC4 is a stream cipher, and no padding is added by the TLS protocol, an attack can easily observe the length of this request. Based on this information it is trivial to derive the required amount of padding.

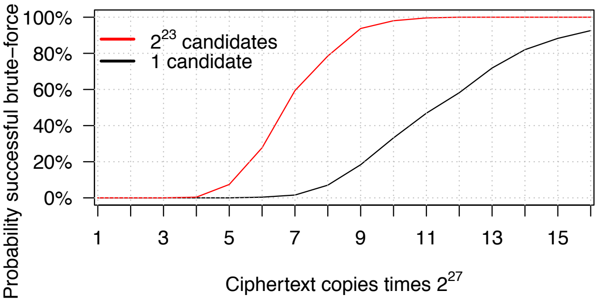

Figure 10: Success rate of brute-forcing a 16-byte cookie using roughly 2^{23} candidates, and only the most likely candidate, dependent on the number of collected ciphertexts. Results based on 256 simulations each.

To test our attack in practice we implemented a tool in C which monitors network traffic and collects the necessary ciphertext statistics. This requires reassembling the TCP and TLS streams, and then detecting the 512-byte (encrypted) HTTP requests. Similar to optimizing the generation of datasets as in Sect. 3.2, we cache several requests before updating the counters. We also created a tool to brute-force the cookie based on the generated candidate list. It uses persistent connections and HTTP pipelining [11, §6.3.2]. That is, it uses one connection to send multiple requests without waiting for each response.

In our experiments the victim uses a 3.1 GHz Intel Core i5-2400 CPU with 8 GB RAM running Windows 7. Internet Explorer 11 is used as the browser. For the server a 3.4 GHz Intel Core i7-3770 CPU with 8 GB RAM is used. We use nginx as the web server, and configured RC4-SHA1 with RSA as the only allowable cipher suite. This assures that RC4 is used in all tests. Both the server and client use an Intel 82579LM network card, with the link speed set to 100 Mbps. With an idle browser this setup resulted in an average of 4450 requests per second. When the victim was actively browsing YouTube videos this decreased to roughly 4100. To achieve such numbers, we found it's essential that the browser uses persistent connections to transmit the HTTP requests. Otherwise a new TCP and TLS handshake must be performed for every request, whose round-trip times would significantly slow down traffic generation. In practice this means the website must allow a `keep-alive` connection. While generating requests the browser remained responsive at all times. Finally, our custom tool was able to test more than 20000 cookies per second. To execute the attack with a success rate of 94% we need roughly $9 \cdot 2^{27}$ ciphertexts. With 4450 requests per seconds, this means we require 75 hours of data. Compared to the (more than) 2000 hours required by AlFardan et al. [2, §5.3.3] this is a significant improvement. We remark that, similar to the attack of AlFardan et al. [2], our attack also tolerates changes of the encryption keys. Hence, since cookies can have a long lifetime, the generation of this traffic can even be spread out over time. With 20000 brute-force attempts per second, all 2^{23} candidates for the cookie can be tested in less than 7 minutes.

We have executed the attack in practice, and successfully decrypted a 16-byte cookie. In our instance, capturing traffic for 52 hours already proved to be sufficient. At this point we collected $6.2 \cdot 2^{27}$ ciphertexts. After processing the ciphertexts, the cookie was found at position 46229 in the candidate list. This serves as a good example that, if the attacker has some luck, less ciphertexts are needed than our $9 \cdot 2^{27}$ estimate. These results push the attack from being on the verge of practicality, to feasible, though admittedly somewhat time-consuming.

7 Related Work

Due to its popularity, RC4 has undergone wide cryptanalysis. Particularly well known are the key recovery attacks that broke WEP [12, 50, 45, 44, 43]. Several other key-related biases and improvements of the original WEP attack have also been studied [21, 39, 32, 22].

We refer to Sect. 2.1 for an overview of various biases discovered in the keystream [25, 23, 38, 2, 20, 33, 13, 24, 38, 15, 31, 30]. In addition to these, the long-term bias $\Pr[Z_r = Z_{r+1} \mid 2 \cdot Z_r = i_r] = 2^{-8}(1+2^{-15})$ was discovered by Basu et al. [4]. While this resembles our new short-term bias $\Pr[Z_r = Z_{r+1}]$, in their analysis they assume the internal state $\mathcal{S}$ is a random permutation, which is true only after a few rounds of the PRGA. Isobe et al. searched for dependencies between initial keystream bytes by empirically estimating $\Pr[Z_r = y \wedge Z_{r-a} = x]$ for $0 \leq x, y \leq 255$, $2 \leq r \leq 256$, and $1 \leq a \leq 8$ [20]. They did not discover any new biases using their approach. Mironov modelled RC4 as a Markov chain and recommended to skip the initial $12 \cdot 256$ keystream bytes [26]. Paterson et al. generated keystream statistics over consecutive keystream bytes when using the TKIP key structure [30]. However, they did not report which (new) biases were present. Through empirical analysis, we show that biases between consecutive bytes are present even when using RC4 with random 128 bit keys.

The first practical attack on WPA-TKIP was found by Beck and Tews [44] and was later improved by other researchers [46, 16, 48, 49]. Recently several works studied the per-packet key construction both analytically [15] and through simulations [2, 31, 30]. For our attack we replicated part of the results of Paterson et al. [31, 30], and are the first to demonstrate this type of attack in practice. In [2] AlFardan et al. ran experiments where the two most likely plaintext candidates were generated using single-byte likelihoods [2]. However, they did not present an algorithm to return arbitrarily many candidates, nor extended this to double-byte likelihoods.

The SSL and TLS protocols have undergone wide scrutiny [9, 41, 7, 1, 2, 6]. Our work is based on the attack of AlFardan et al., who estimated that $13 \cdot 2^{30}$ ciphertexts are needed to recover a 16-byte cookie with high success rates [2]. We reduce this number to $9 \cdot 2^{27}$ using several techniques, the most prominent being usage of likelihoods based on Mantin's *ABSAB* bias [24]. Isobe et al. used Mantin's *ABSAB* bias, in combination with previously decrypted bytes, to decrypt bytes after position 257 [20]. However, they used a counting technique instead of Bayesian likelihoods. In [29] a guess-and-determine algorithm combines *ABSAB* and Fluhrer-McGrew biases, requiring roughly 2^{34} ciphertexts to decrypt an individual byte with high success rates.

8 Conclusion

While previous attacks against RC4 in TLS and WPA-TKIP were on the verge of practicality, our work pushes them towards being practical and feasible. After capturing $9 \cdot 2^{27}$ encryptions of a cookie sent over HTTPS, we can brute-force it with high success rates in negligible time. By running JavaScript code in the browser of the victim, we were able to execute the attack in practice within merely 52 hours. Additionally, by abusing RC4 biases, we successfully attacked a WPA-TKIP network within an hour. We consider it surprising this is possible using only known biases, and expect these types of attacks to further improve in the future. Based on these results, we strongly urge people to stop using RC4.

Abstract

Despite recent high-profile attacks on the RC4 algorithm in TLS, its usage is still running at about 30% of all TLS traffic. We provide new attacks against RC4 in TLS that are focussed on recovering user passwords, still the pre-eminent means of user authentication on the Internet today. Our new attacks use a generally applicable Bayesian inference approach to transform *a priori* information about passwords in combination with gathered ciphertexts into *a posteriori* likelihoods for passwords. We report on extensive simulations of the attacks. We also report on a "proof of concept" implementation of the attacks for a specific application layer protocol, namely BasicAuth. Our work validates the truism that attacks only get better with time: we obtain good success rates in recovering user passwords with 2^{26} encryptions, whereas the previous generation of attacks required around 2^{34} encryptions to recover an HTTP session cookie.

1 Introduction

TLS in all current versions allows RC4 to be used as its bulk encryption mechanism. Attacks on RC4 in TLS were first presented in 2013 in [2] (see also [13, 16]). Since then, usage of RC4 in TLS has declined, but it still accounted for around 30% of all TLS connections in March 2015.[1] Moreover, the majority of websites still support RC4[2] and a small proportion of websites *only* support RC4.[3]

We describe attacks recovering TLS-protected passwords whose ciphertext requirements are significantly reduced compared to those of [2]. Instead of the 2^{34} ciphertexts that were needed for recovering 16-byte, base64-encoded secure cookies in [2], our attacks now require around 2^{26} ciphertexts. We also describe a proof-of-concept implementation of these attacks against a specific application-layer protocol making use of passwords, namely BasicAuth.

1.1 Our Contributions

We obtain our improved attacks by revisiting the statistical methods of [2], refining, extending and applying them to the specific problem of recovering TLS-protected passwords. Passwords are a good target for our attacks because they are still very widely used on the Internet for providing user authentication in protocols like BasicAuth and IMAP, with TLS being used to prevent them being passively eavesdropped. To build effective attacks, we need to find and exploit systems in which users' passwords are automatically and repeatedly sent under the protection of TLS, so that sufficiently many ciphertexts can be gathered for our statistical analyses.

Bayesian analysis We present a formal Bayesian analysis that combines an *a priori* plaintext distribution with keystream distribution statistics to produce *a posteriori* plaintext likelihoods. This analysis formalises and extends the procedure followed in [2] for single-byte attacks. There, only keystream distribution statistics were used (specifically, biases in the individual bytes in the early portion of the RC4 keystream) and plaintexts were assumed to be uniformly distributed, while here we also exploit (partial) knowledge of the plaintext distribution to produce a more accurate estimate of the *a posteriori* likelihoods. This yields a procedure that is optimal (in the sense of yielding a maximum *a posteriori* estimate for the plaintext) if the plaintext distribution is known exactly.

[1] According to data obtained from the International Computer Science Institute (ICSI) Certificate Notary project, which collects statistics from live upstream SSL/TLS traffic in a passive manner; see http://notary.icsi.berkeley.edu.

[2] According to statistics obtained from SSL Pulse; see https://www.trustworthyinternet.org/ssl-pulse/.

[3] Amounting to 0.79% according to a January 2015 survey of about 400,000 of the Alexa top 1 million sites; see https://securitypitfalls.wordpress.com/2015/02/01/january-2015-scan-results/.

In the context of password recovery, an *estimate* for the *a priori* plaintext distribution can be empirically formed by using data from password breaches or by synthetically constructing password dictionaries. We will demonstrate, via simulations, that this Bayesian approach improves performance (measured in terms of success rate of plaintext recovery for a given number of ciphertexts) compared to the approach in [2].

Our Bayesian analysis concerns vectors of consecutive plaintext bytes, which is appropriate given passwords as the plaintext target. This, however, means that the keystream distribution statistics also need to be for vectors of consecutive keystream bytes. Such statistics do not exist in the prior literature on RC4, except for the Fluher-McGrew biases [10] (which supply the distributions for adjacent byte pairs far down the keystream). Fortunately, in the early bytes of the RC4 keystream, the single-byte biases are dominant enough that a simple product distribution can be used as a reasonable estimate for the distribution on vectors of keystream bytes. We also show how to build a more accurate approximation to the relevant keystream distributions using double-byte distributions. (Obtaining the double-byte distributions to a suitable degree of accuracy consumed roughly 4800 core-days of computation; for details see the full version [12].) This approximation is not only more accurate but also *necessary* when the target plaintext is located further down the stream, where the single-byte biases disappear and where double-byte biases become dominant. Indeed, our double-byte-based approximation to the keystream distribution on vectors can be used to smoothly interpolate between the region where single-byte biases dominate and where the double-byte biases come into play (which is exhibited as a fairly sharp transition around position 256 in the keystream).

In the end, what we obtain is a formal algorithm that estimates the likelihood of each password in a dictionary based on both the *a priori* password distribution and the observed ciphertexts. This formal algorithm is amenable to efficient implementation using either the single-byte based product distribution for keystreams or the double-byte-based approximation to the distribution on keystreams. The dominant terms in the running time for both of the resulting algorithms is $\mathcal{O}(nN)$ where n is the length of the target password and N is the size of the dictionary used in the attack.

An advantage of our new algorithms over the previous work in [2] is that they output a value for the likelihood of each password candidate, enabling these to be ranked and then tried in order of descending likelihood.

Note that our Bayesian approach is quite general and not limited to recovery of passwords, nor to RC4 – it can be applied whenever the plaintext distribution is approximately known, where the same plaintext is repeatedly encrypted, and where the stream cipher used for encryption has known biases in either single bytes or adjacent pairs of bytes.

Evaluation We evaluate and compare our password recovery algorithms through extensive simulations, exploring the relationships between the main parameters of our attack:

- The length n of the target password.
- The number S of available encryptions of the password.
- The starting position r of the password in the plaintext stream.
- The size N of the dictionary used in the attack, and the availability (or not) of an *a priori* password distribution for this dictionary.
- The number of attempts T made (meaning that our algorithm is considered successful if it ranks the correct password amongst the top T passwords, i.e. the T passwords with highest likelihoods as computed by the algorithm).
- Which of our two algorithms is used (the one computing the keystream statistics using the product distribution or the one using a double-byte-based approximation).
- Whether the passwords are Base64 encoded before being transmitted, or are sent as raw ASCII/Unicode.

Given the many possible parameter settings and the cost of performing simulations, we focus on comparing the performance with all but one or two parameters or variables being fixed in each instance.

Proofs of concept Our final contribution is to apply our attacks to specific and widely-deployed applications making use of passwords over TLS: BasicAuth and (in the full version [12]), IMAP. We introduce BasicAuth and describe a proof-of-concept implementation of our attacks against it, giving an indication of the practicality of our attacks. We do the same for IMAP in the full version [12].

For both applications, we have significant success rates with only $S = 2^{26}$ ciphertexts, in contrast to the roughly 2^{34} ciphertexts required in [2]. This is because we are able to force the target passwords into the first 256 bytes of plaintext, where the large single-byte biases in RC4 keystreams come into play. For example, with $S = 2^{26}$ ciphertexts, we would expect to recover a length 6 BasicAuth password with 44.5% success rate after $T = 5$ attempts; the rate rises to 64.4% if $T = 100$ attempts are made. In practice, many sites do not configure any limit on the number of BasicAuth attempts made by a client; moreover a study [5] showed that 84% of websites surveyed allowed for up to 100 password guesses (though these sites were not necessarily using BasicAuth as their authentication mechanism). As we will show, our result compares very favourably to the previous attacks and to random guessing of passwords without any reference to the ciphertexts.

However, there is a downside too: to make use of the early, single-byte biases in RC4 keystreams, we have to repeatedly cause TLS connections to be closed and new ones to be opened. Because of latency in the TLS Handshake Protocol, this leads to a significant slowdown in the wall clock running time of the attack; for $S = 2^{26}$, a latency of 100ms, and exploiting browsers' propensity to open multiple parallel connections, we estimate a running time of around 300 hours for the attack. This is still more than 6 times faster than the 2000 hours estimated in [2]. Furthermore, the attack's running time reduces proportionately to the latency of the TLS Handshake Protocol, so in environments where the client and server are close – for example in a LAN – the execution time could be a few tens of hours.

2 Further Background

2.1 The RC4 algorithm

Originally a proprietary stream cipher designed by Ron Rivest in 1987, RC4 is remarkably fast when implemented in software and has a very simple description. Details of the cipher were leaked in 1994 and the cipher has been subject to public analysis and study ever since.

RC4 allows for variable-length key sizes, anywhere from 40 to 256 bits, and consists of two algorithms, namely, a *key scheduling algorithm* (KSA) and a *pseudo-random generation algorithm* (PRGA). The KSA takes as input an l-byte key and produces the initial internal state $st_0 = (i, j, \mathscr{S})$ for the PRGA; $\mathscr{S}$ is the canonical representation of a permutation of the numbers from 0 to 255 where the permutation is a function of the l-byte key, and i and j are indices for $\mathscr{S}$. The KSA is specified in Algorithm 1 where K represents the l-byte key array and $\mathscr{S}$ the 256-byte state array. Given the internal state st_r, the PRGA will generate a keystream byte Z_{r+1} as specified in Algorithm 2.

2.2 Single-byte biases in the RC4 Keystream

RC4 has several cryptographic weaknesses, notably the existence of various biases in the RC4 keystream, see for example [2, 10, 14, 15, 19]. Large single-byte biases are prominent in the early postions of the RC4 keystream. Mantin and Shamir [15] observed the first of these biases, in Z_2 (the second byte of the RC4 keystream), and showed how to exploit it in what they called a *broadcast attack*, wherein the same plaintext is repeatedly encrypted under different keys. AlFardan *et al.* [2] performed large-scale computations to estimate these early biases, using 2^{45} keystreams to compute the single-byte keystream distributions in the first 256 output positions. They also provided a statistical approach to recovering plaintext bytes in the broadcast attack scenario, and explored its exploitation in TLS. Much of the new bias behaviour they observed was subsequently explained in [18]. Unfortunately, from an attacker's perspective, the single-byte biases die away very quickly beyond position 256 in the RC4 keystream. This means that they can only be used in attacks to extract plaintext bytes which are found close to the start of plaintext streams. This was a significant complicating factor in the attacks of [2], where, because of the behaviour of HTTP in modern browsers, the target HTTP secure cookies were not so located.

Algorithm 1: RC4 key scheduling (KSA)

```
input  : key $K$ of $l$ bytes
output : initial internal state $st_0$
begin
    for $i = 0$ to 255 do
        $\mathscr{S}[i] \leftarrow i$
    $j \leftarrow 0$
    for $i = 0$ to 255 do
        $j \leftarrow j + \mathscr{S}[i] + K[i \bmod l]$
        swap($\mathscr{S}[i], \mathscr{S}[j]$)
    $i, j \leftarrow 0$
    $st_0 \leftarrow (i, j, \mathscr{S})$
    return $st_0$
```

Algorithm 2: RC4 keystream generator (PRGA)

```
input  : internal state $st_r$
output : keystream byte $Z_{r+1}$
         updated internal state $st_{r+1}$
begin
    parse $(i, j, \mathscr{S}) \leftarrow st_r$
    $i \leftarrow i + 1$
    $j \leftarrow j + \mathscr{S}[i]$
    swap($\mathscr{S}[i], \mathscr{S}[j]$)
    $Z_{r+1} \leftarrow \mathscr{S}[\mathscr{S}[i] + \mathscr{S}[j]]$
    $st_{r+1} \leftarrow (i, j, \mathscr{S})$
    return $(Z_{r+1}, st_{r+1})$
```

2.3 Double-byte biases in the RC4 Keystream

Fluhrer and McGrew [10] showed that there are biases in adjacent bytes in RC4 keystreams, and that these so-called double-byte biases are persistent throughout the keystream. The presence of these long-term biases (and the absence of any other similarly-sized double-byte biases) was confirmed computationally in [2]. AlFardan *et al.* [2] also exploited these biases in their double-byte attack to recover HTTP secure cookies.

Because we wish to exploit double-byte biases in early portions of the RC4 keystream and because the analysis of [10] assumes the RC4 permutation $\mathscr{S}$ is uniformly random (which is not the case for early keystream bytes), we carried out extensive computations to estimate the initial double-byte keystream distributions: we used roughly 4800 core-days of computation to generate 2^{44} RC4 keystreams for random 128-bit RC4 keys (as used in TLS); we used these keystreams to estimate the double-byte keystream distributions for RC4 in the first 512 positions.

While the gross behaviour that we observed is dominated by products of the known single-byte biases in the first 256 positions and by the Fluhrer-McGrew biases in the later positions, we did observe some new and interesting double-byte biases. Since these are likely to be of independent interest to researchers working on RC4, we report in more detail on this aspect of our work in the full version [12].

2.4 RC4 and the TLS Record Protocol

We provide an overview of the TLS Record Protocol with RC4 selected as the method for encryption and direct the reader to [2, 6, 7, 8] for further details.

Application data to be protected by TLS, i.e, a sequence of bytes or a record R, is processed as follows: An 8-byte sequence number `SQN`, a 5-byte header `HDR` and R are concatenated to form the input to an HMAC function. We let T denote the resulting output of this function. In the case of RC4 encryption, the plaintext, $P = T||R$, is XORed byte-per-byte with the RC4 keystream. In other words,

$$C_r = P_r \oplus Z_r,$$

for the r^{th} bytes of the ciphertext, plaintext and RC4 keystream respectively (for $r = 1, 2, 3 \ldots$). The data that is transmitted has the form `HDR`$||C$, where C is the concatenation of the individual ciphertext bytes.

The RC4 algorithm is intialized in the standard way at the start of each TLS connection with a 128-bit encryption key. This key, K, is derived from the TLS master secret that is established during the TLS Handshake Protocol; K is either established via the the full TLS Handshake Protocol or TLS session resumption. The first few bytes to be protected by RC4 encryption is a `Finished` message of the TLS Handshake Protocol. We do not target this record in our attacks since this message is not constant over multiple sessions. The exact size of this message is important in dictating how far down the keystream our target plaintext will be located; in turn this determines whether or not it can be recovered using only single-byte biases. A common size is 36 bytes, but the exact size depends on the output size of the TLS PRF used in computing the `Finished` message and of the hash function used in the HMAC algorithm in the record protocol.

Decryption is the reverse of the process described above. As noted in [2], any error in decryption is treated as fatal – an error message is sent to the sender and all cryptographic material, including the RC4 key, is disposed of. This enables an active attacker to force the use of new encryption and MAC keys: the attacker can induce session termination, followed by a new session being established when the next message is sent over TLS, by simply modifying a TLS Record Protocol message. This could be used to ensure that the target plaintext in an attack is repeatedly sent under the protection of a fresh RC4 key. However, this approach is relatively expensive since it involves a rerun of the full TLS Handshake Protocol, involving multiple public key operations and, more importantly, the latency involved in an exchange of 4 messages (2 complete round-trips) on the wire. A better approach is to cause the TCP connection carrying the TLS traffic to close, either by injecting sequences of `FIN` and `ACK` messages in both directions, or by injecting a `RST` message in both directions. This causes the TLS *connection* to be terminated, but not the TLS *session* (assuming the session is marked as "resumable" which is typically the case). This behaviour is codified in [8, Section 7.2.1]. Now when the next message is sent over TLS, a TLS session resumption instance of the Handshake Protocol is executed to establish a fresh key for RC4. This avoids the expensive public key operations and reduces the TLS latency to 1 round-trip before application data can be sent. On large sites, session resumption is usually handled by making use of TLS session tickets [17] on the server-side.

2.5 Passwords

Text-based passwords are arguably the dominant mechanism for authenticating users to web-based services and computer systems. As is to be expected of user-selected secrets, passwords do not follow uniform distributions. Various password breaches of recent years, including the Adobe breach of 150 million records in 2013 and the RockYou leak of 32.6 million passwords in 2009, attest to this with passwords such as `123456` and `password` frequently being counted amongst the most popular.[4] For example, our own analysis of the RockYou password data set confirmed this: the number of unique passwords in the RockYou dataset is 14,344,391, meaning that (on average) each password was repeated 2.2 times, and we indeed found the most common password to be `123456` (accounting for about 0.9% of the entire data set). Our later simulations will make extensive use of the RockYou data set as an attack dictionary. A more-fine grained analysis of it can be found in [20]. We also make use of data from the Singles.org breach for generating our target passwords. Singles.org is a now-defunct Christian dating website that was breached in 2009; religiously-inspired passwords such as `jesus` and `angel` appear with high frequency in its 12,234 distinct entries, making its frequency distribution quite different from that of the RockYou set.

There is extensive literature regarding the reasons for poor password selection and usage, including [1, 9, 21, 22]. In [4], Bonneau formalised a number of different metrics for analysing password distributions and studied a corpus of 70M Yahoo! passwords (collected in a privacy-preserving manner). His work highlights the importance of careful validation of password guessing attacks, in particular, the problem of estimating attack complexities in the face of passwords that occur rarely – perhaps uniquely – in a data set, the so-called *hapax legomena* problem. The approach to validation that we adopt benefits from the analysis of [4], as explained further in Section 4.

3 Plaintext Recovery via Bayesian Analysis

In this section, we present a formal Bayesian analysis of plaintext recovery attacks in the broadcast setting for stream ciphers. We then apply this to the problem of extracting passwords, specialising the formal analysis and making it implementable in practice based only on the single-byte and double-byte keystream distributions.

3.1 Formal Bayesian Analysis

Suppose we have a candidate set of N plaintexts, denoted $\mathscr{X}$, with the *a priori* probability of an element $x \in \mathscr{X}$ being denoted p_x. We assume for simplicity that all the candidates consist of byte strings of the same length n. For example $\mathscr{X}$ might consist of all the passwords of a given length n from some breach data set, and then p_x can be computed as the relative frequency of x in the data set. If the frequency data is not available, then the uniform distribution on $\mathscr{X}$ can be assumed.

Next, suppose that a plaintext from $\mathscr{X}$ is encrypted S times, each time under independent, random keys using a stream cipher such as RC4. Suppose also that the first character of the plaintext always occurs in the same position r in the plaintext stream in each encryption. Let $c = (c_{ij})$ denote the $S \times n$ matrix of bytes in which row i, denoted $c^{(i)}$ for $0 \le i < S$, is a vector of n bytes corresponding to the values in positions $r, \ldots, r+n-1$ in ciphertext i. Let X be the random variable denoting the (unknown) value of the plaintext.

We wish to form a maximum a posteriori (MAP) estimate for X, given the observed data c and the *a priori* probability distribution p_x, that is, we wish to maximise $\Pr(X = x \mid C = c)$ where C is a random variable corresponding to the matrix of ciphertext bytes.

Using Bayes' theorem, we have

$$\Pr(X = x \mid C = c) = \Pr(C = c \mid X = x) \cdot \frac{\Pr(X = x)}{\Pr(C = c)}.$$

Here the term $\Pr(X = x)$ corresponds to the *a priori* distribution p_x on $\mathscr{X}$. The term $\Pr(C = c)$ is independent of the choice of x (as can be seen by writing $\Pr(C = c) = \sum_{x \in \mathscr{X}} \Pr(C = c \mid X = x) \cdot \Pr(X = x)$). Since we are only interested in maximising $\Pr(X = x \mid C = c)$, we ignore this term henceforth.

Now, since ciphertexts are formed by XORing keystreams z and plaintext x, we can write

$$\Pr(C = c \mid X = x) = \Pr(W = w)$$

where w is the $S \times n$ matrix formed by XORing each row of c with the vector x and W is a corresponding random variable. Then to maximise $\Pr(X = x \mid C = c)$, it suffices to maximise the value of

$$\Pr(X = x) \cdot \Pr(W = w)$$

over $x \in \mathscr{X}$. Let $w^{(i)}$ denote the i-th row of the matrix w, so $w^{(i)} = c^{(i)} \oplus x$. Then $w^{(i)}$ can be thought of as a vector of keystream bytes (coming from positions $r, \ldots, r+n-1$) induced by the candidate x, and we can write

$$\Pr(W = w) = \prod_{i=0}^{S-1} \Pr(Z = w^{(i)})$$

where, on the right-hand side of the above equation, Z denotes a random variable corresponding to a vector of bytes of length n starting from position r in the keystream. Writing $\mathscr{B} = \{\texttt{0x00}, \ldots, \texttt{0xFF}\}$ for the set of bytes, we can rewrite this as:

$$\Pr(W = w) = \prod_{z \in \mathscr{B}^n} \Pr(Z = z)^{N_{x,z}}$$

where the product is taken over all possible byte strings of length n and $N_{x,z}$ is defined as:

$$N_{x,z} = |\{i : z = c^{(i)} \oplus x\}_{0 \le i < S}|,$$

[4] A comprehensive list of data breaches, including password breaches, can be found at `http://www.informationisbeautiful.net/visualizations/worlds-biggest-data-breaches-hacks/`.

that is, $N_{x,z}$ counts the number of occurrences of vector z in the rows of the matrix formed by XORing each row of c with candidate x. Putting everything together, our objective is to compute for each candidate $x \in \mathscr{X}$ the value:

$$\Pr(X = x) \cdot \prod_{z \in \mathscr{B}^n} \Pr(Z = z)^{N_{x,z}}$$

and then to rank these values in order to determine the most likely candidate(s).

Notice that the expressions here involve terms $\Pr(Z = z)$ which are probabilities of occurrence for n consecutive bytes of keystream. Such estimates are not generally available in the literature, and for the values of n we are interested in (corresponding to putative password lengths), obtaining accurate estimates for them by sampling many keystreams would be computationally prohibitive. Moreover, the product $\prod_{z \in \mathscr{B}^n}$ involves 2^{8n} terms and is not amenable to calculation. Thus we must turn to approximate methods to make further progress.

Note also that taking $n = 1$ in the above analysis, we obtain exactly the same approach as was used in the single-byte attack in [2], except that we include the *a priori* probabilities $\Pr(X = x)$ whereas these were (implicitly) assumed to be uniform in [2].

3.2 Using a Product Distribution

Our task is to derive simplified ways of computing the expression

$$\Pr(X = x) \cdot \prod_{z \in \mathscr{B}^n} \Pr(Z = z)^{N_{x,z}}$$

and then apply these to produce efficient algorithms for computing (approximate) likelihoods of candidates $x \in \mathscr{X}$.

The simplest approach is to assume that the n bytes of the keystreams can be treated independently. For RC4, this is actually a very good approximation in the regime where single-byte biases dominate (that is, in the first 256 positions). Thus, writing $Z = (Z_r, \dots, Z_{r+n-1})$ and $z = (z_r, \dots, z_{r+n-1})$ (with the subscript r denoting the position of the first keystream byte of interest), we have:

$$\Pr(Z = z) \approx \prod_{j=0}^{n-1} \Pr(Z_{r+j} = z_{r+j}) = \prod_{j=0}^{n-1} p_{r+j,z}$$

where now the probabilities appearing on the right-hand side are single-byte keystream probabilities, as reported in [2] for example. Then writing $x = (x_0, \dots, x_{n-1})$ and rearranging terms, we obtain:

$$\prod_{z \in \mathscr{B}^n} \Pr(Z = z)^{N_{x,z}} \approx \prod_{j=0}^{n-1} \prod_{z \in \mathscr{B}} p_{r+j,z}^{N_{x_j,z,j}}$$

where $N_{y,z,j} = |\{i : z = c_{i,j} \oplus y\}_{0 \le i < S}|$ counts (now for single bytes instead of length n vectors of bytes) the number of occurrences of byte z in the column vector formed by XORing column j of c with a candidate byte y.

Notice that, as in [2], the counters $N_{y,z,j}$ for $y \in \mathscr{B}$ can all be computed efficiently by permuting the counters $N_{\texttt{0x00},z,j}$, these being simply counters for the number of occurrences of each byte value z in column j of the ciphertext matrix c.

In practice, it is more convenient to work with logarithms, converting products into sums, so that we evaluate for each candidate $x = (x_0, \dots, x_{n-1})$ an expression of the form

$$\gamma_x := \log(p_x) + \sum_{j=0}^{n-1} \sum_{z \in \mathscr{B}} N_{x_j,z,j} \log(p_{r+j,z}).$$

Given a large set of candidates $\mathscr{X}$, we can streamline the computation by first computing the counters $N_{y,z,j}$, then, for each possible byte value y, the value of the inner sum $\sum_{z \in \mathscr{B}} N_{y,z,j} \log(p_{r+j,z})$, and then reusing these individual values across all the relevant candidates x for which $x_j = y$. This reduces the evaluation of γ_x for a single candidate x to $n+1$ additions of real numbers.

The above procedure, including the various optimizations, is specified as an attack in Algorithm 3. We refer to it as our single-byte attack because of its reliance on the single-byte keystream probabilities $p_{r+j,z}$. It outputs a collection of approximate log likelihoods $\{\gamma_x : x \in \mathscr{X}\}$ for each candidate $x \in \mathscr{X}$. These can be further processed to extract, for example, the candidate with the highest score, or the top T candidates.

3.3 Double-byte-based Approximation

We continue to write $Z = (Z_r, \dots, Z_{r+n-1})$ and $z = (z_r, \dots, z_{r+n-1})$ and aim to find an approximation for $\Pr(Z = z)$ which lends itself to efficient computation of approximate log likelihoods as in our first algorithm. Now we rely on the double-byte keystream distribution, writing

$$p_{s,z_1,z_2} := \Pr((Z_s, Z_{s+1}) = (z_1, z_2)), \quad s \ge 1, k_1, k_2 \in \mathscr{B}$$

for the probabilities of observing bytes (z_1, z_2) in the RC4 keystream in positions $(s, s+1)$. We estimated these probabilities for r in the range $1 \le r \le 511$ using 2^{44} RC4 keystreams – for details, see the full version; for larger r, these are well approximated by the Fluhrer-McGrew biases [10] (as was verified in [2]).

We now make the Markovian assumption that, for each j,

$$\begin{aligned} &\Pr(Z_j = z_j \mid Z_{j-1} = z_{j-1} \wedge \dots \wedge Z_0 = z_0) \\ &\qquad \approx \Pr(Z_j = z_j \mid Z_{j-1} = z_{j-1}), \end{aligned}$$

```
Algorithm 3: Single-byte attack
input  : $c_{i,j} : 0 \le i < S, 0 \le j < n$ – array formed from $S$ independent encryptions of fixed $n$-byte candidate $X$
         $r$ – starting position of $X$ in plaintext stream
         $\mathcal{X}$ – collection of $N$ candidates
         $p_x$ – a priori probability of candidates $x \in \mathcal{X}$
         $p_{r+j,z}$ $(0 \le j < n, z \in \mathcal{B})$ – single-byte keystream distribution
output : $\{\gamma_x : x \in \mathcal{X}\}$ – set of (approximate) log likelihoods for candidates in $\mathcal{X}$
begin
    for $j = 0$ to $n-1$ do
        for $z =$ 0x00 to 0xFF do
            $N'_{z,j} \leftarrow 0$
    for $j = 0$ to $n-1$ do
        for $i = 0$ to $S-1$ do
            $N'_{c_{i,j},j} \leftarrow N'_{c_{i,j},j} + 1$
    for $j = 0$ to $n-1$ do
        for $y =$ 0x00 to 0xFF do
            for $z =$ 0x00 to 0xFF do
                $N_{y,z,j} \leftarrow N'_{z\oplus y,j}$
            $L_{y,j} = \sum_{z\in\mathcal{B}} N_{y,z,j}\log(p_{r+j,z})$,
    for $x = (x_0,\ldots,x_{n-1}) \in \mathcal{X}$ do
        $\gamma_x \leftarrow \log(p_x) + \sum_{j=0}^{n-1} L_{x_j,j}$
    return $\{\gamma_x : x \in \mathcal{X}\}$
```

meaning that byte j in the keystream can be modelled as depending only on the preceding byte and not on earlier bytes. We can write

$$\Pr(Z_j = z_j \mid Z_{j-1} = z_{j-1}) = \frac{\Pr(Z_j = z_j \wedge Z_{j-1} = z_{j-1})}{\Pr(Z_{j-1} = z_{j-1})}$$

where the numerator can then be replaced by p_{j-1,z_{j-1},z_j} and the denominator by $p_{j-1,z_{j-1}}$, a single-byte keystream probability. Then using an inductive argument and our assumption, we easily obtain:

$$\Pr(Z = z) \approx \frac{\prod_{j=0}^{n-2} p_{r+j,z_j,z_{j+1}}}{\prod_{j=1}^{n-2} p_{r+j,z_j}}$$

giving an approximate expression for our desired probability in terms of single-byte and double-byte probabilities. Notice that if we assume that the adjacent byte pairs are independent, then we have $p_{r+j,z_j,z_{j+1}} = p_{r+j,z_j} \cdot p_{r+j+1,z_{j+1}}$ and the above expression collapses down to the one we derived in the previous subsection.

For candidate x, we again write $x = (x_0,\ldots,x_{n-1})$ and rearranging terms, we obtain:

$$\prod_{z\in\mathcal{B}^n} \Pr(Z = z)^{N_{x,z}} \approx \frac{\prod_{j=0}^{n-2}\prod_{z_1\in\mathcal{B}}\prod_{z_2\in\mathcal{B}} p_{r+j,z_1,z_2}^{N_{x_j,x_{j+1},z_1,z_2,j}}}{\prod_{j=1}^{n-2}\prod_{z\in\mathcal{B}} p_{r+j,z}^{N_{x_j,z,r+j}}}$$

where $N_{y_1,y_1,z_1,z_2,j} = |\{i : z_1 = c_{i,j} \oplus y_1 \wedge z_2 = c_{i,j+1} \oplus y_2\}_{0\le i<S}|$ counts (now for consecutive pairs of bytes) the number of occurrences of bytes (z_1,z_2) in the pair of column vectors formed by XORing columns $(j, j+1)$ of c with candidate bytes (y_1,y_2) (and where $N_{x_j,z,r+j}$ is as in our previous algorithm).

Again, the counters $N_{y_1,y_2,z_1,z_2,j}$ for $y_1,y_2 \in \mathcal{B}$ can all be computed efficiently by permuting the counters $N_{\texttt{0x00},\texttt{0x00},z_1,z_2,j}$, these being simply counters for the number of occurrences of pairs of byte values (z_1,z_2) in column j and $j+1$ of the ciphertext matrix c. As before, we work with logarithms, so that we evaluate for each candidate $x = (x_0,\ldots,x_{n-1})$ an expression of the form

$$\gamma_x := \log(p_x) + \sum_{j=0}^{n-2}\sum_{z_1\in\mathcal{B}}\sum_{z_2\in\mathcal{B}} N_{x_j,x_{j+1},z_1,z_2,j}\log(p_{r+j,z_1,z_2}) - \sum_{j=1}^{n-2}\sum_{z\in\mathcal{B}} N_{x_j,z,r+j}\log(p_{r+j,z}).$$

With appropriate pre-computation of the terms $N_{y_1,y_2,z_1,z_2,j}\log(p_{r+j,z_1,z_2})$ and $N_{y,z,r+j}\log(p_{r+j,z})$ for all y_1,y_2 and all y, the computation for each candidate $x \in \mathcal{X}$ can be reduced to roughly $2n$ floating point additions. The pre-computation can be further reduced by computing the terms for only those pairs (y_1,y_2) actually arising in candidates in $\mathcal{X}$ in positions $(j, j+1)$. We use this further optimisation in our implementation.

The above procedure is specified as an attack in Algorithm 4. We refer to it as our double-byte attack because of its reliance on the double-byte keystream probabilities p_{s,z_1,z_2}. It again outputs a collection of approximate log likelihoods $\{\gamma_x : x \in \mathscr{X}\}$ for each candidate $x \in \mathscr{X}$, suitable for further processing. Note that for simplicity of presentation, it involves a quintuply-nested loop to compute the values $N_{y_1,y_2,z_1,z_2,j}$; these values should of course be directly computed from the $(n-1)\cdot 2^{16}$ pre-computed counters $N'_{c_{i,j},c_{i,j+1},j}$ in an in-line fashion using the formula $N_{y_1,y_2,z_1,z_2,j} = N'_{z_1\oplus y_1,z_2\oplus y_2,,j}$.

4 Simulation Results

4.1 Methodology

We performed extensive simulations of both of our attacks, varying the different parameters to evaluate their effects on success rates. We focus on the problem of password recovery, using the RockYou data set as an attack dictionary and the Singles.org data set as the set of target passwords. Except where noted, in each simulation, we performed 256 independent runs of the relevant attack. In each attack in a simulation, we select a password of some fixed length n from the Singles.org password data set according to the known *a priori* probability distribution for that data set, encrypt it S times in different starting positions r using random 128-bit keys for RC4, and then attempt to recover the password from the ciphertexts using the set of all passwords of length n from the entire RockYou data set (14 million passwords) as our candidate set $\mathscr{X}$. We declare success if the target password is found within the top T passwords suggested by the algorithm (according to the approximate likelihood measures γ_x). Our default settings, unless otherwise stated, are $n = 6$ and $T = 5$. Six is the most common password length in the data sets we encountered; $T = 5$ is an arbitrary choice, and we examine the effect of varying T in detail below. We try all values for r between 1 and $256-n+1$, where the single-byte biases dominate the behaviour of the RC4 keystreams. Typical values of S are 2^s where $s \in \{20,22,24,26,28\}$.

Using different data sets for the attack dictionary and the target set from which encrypted passwords are chosen is more realistic than using a single dictionary for both purposes, not least because in a real attack, the exact content and *a priori* distribution of the target set would not be known. This approach also avoids the problem of *hapax legomena* highlighted in [4]. However, this has the effect of limiting the success rates of our attacks to less than 100%, since there are highly likely passwords in the target set (such as `jesus`) that do not occur at all, or only have very low *a priori* probabilities in the attack dictionary, and conversely. Figure 1 compares the use of the RockYou password distribution to attack Singles.org passwords with the less realistic use of the RockYou password distribution to attack RockYou itself. It can be seen that, for the particular choice of attack parameters ($S = 2^{24}$, $n = 6$, $T = 5$, double-byte attack), the effect on success rate is not particularly large. However, for other attack parameters, as we will see below, we observe a maximum success rate of around 80% for our attacks, whereas we would achieve 100% success rates if we used RockYou against itself. The observed maximum success rate could be increased by augmenting the attack dictionary with synthetically generated, site-specific passwords and by removing RockYou-specific passwords from the attack dictionary. We leave the development and evaluation of these improvements to future work.

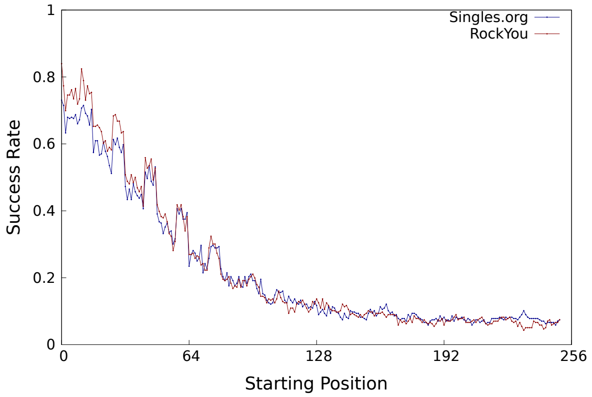

Figure 1: Recovery rate for Singles.org passwords using RockYou data set as dictionary, compared to recovery rate for RockYou passwords using RockYou data set as dictionary ($S = 2^{24}$, $n = 6$, $T = 5$, $1 \leq r \leq 251$, double-byte attack).

Many data sets are available from password breaches. We settled on using RockYou for the attack dictionary because it was one of the biggest data sets in which all passwords and their associated frequencies were available, and because the distribution of passwords, while certainly skewed, was less skewed than for other data sets. We used Singles.org for the target set because the Singles.org breach occurred later than the RockYou breach, so that the former could reasonably used as an attack dictionary for the latter. Moreover, the Singles.org distribution being quite different from that for RockYou makes password recovery against Singles.org using RockYou as a dictionary more challenging for our attacks. A detailed evaluation of the extent to which the success rates of our attacks depend on the choice of attack dictionary and target set is beyond the scope of this current work.

A limitation of our approach as described is that we assume the password length n to be already known. Sev-

Algorithm 4: Double-byte attack

```
input : $c_{i,j} : 0 \leq i < S, 0 \leq j < n$ – array formed from $S$ independent encryptions of fixed $n$-byte candidate $X$

                    for $z_2 = \texttt{0x00}$ to $\texttt{0xFF}$ do
                        $N_{y_1,y_2,z_1,z_2,j} \leftarrow N'_{z_1 \oplus y_1, z_2 \oplus y_2,,j}$
                $L_{y_1,y_2,j} = \sum_{z_1 \in \mathscr{B}} \sum_{z_2 \in \mathscr{B}} N_{y_1,y_2,z_1,z_2,j} \log(p_{r+j,z_1,z_2})$,
    for $x = (x_0, \ldots, x_{n-1}) \in \mathscr{X}$ do
        $\gamma_x \leftarrow \log(p_x) + \sum_{j=0}^{n-2} L_{x_j,x_{j+1},j} - \sum_{j=1}^{n-2} L_{x_j,j}$
    return $\{\gamma_x : x \in \mathscr{X}\}$
```

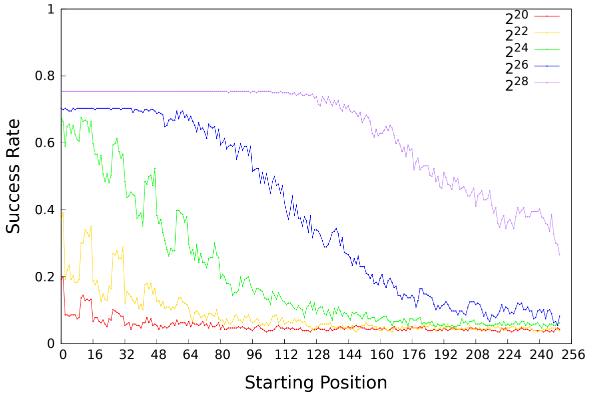

Figure 2: Recovery rates for single-byte algorithm for $S = 2^{20}, \dots, 2^{28}$ ($n = 6$, $T = 5$, $1 \le r \le 251$).

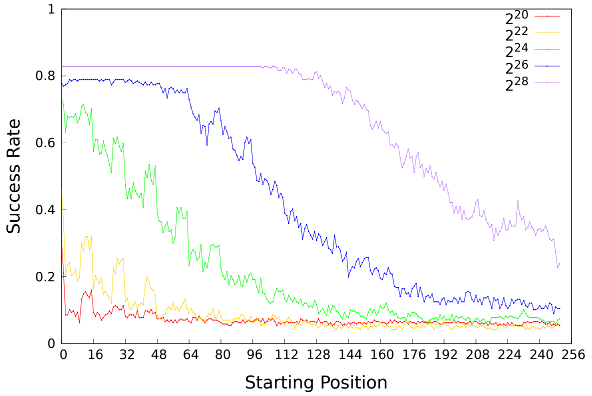

Figure 3: Recovery rates for double-byte algorithm for $S = 2^{20}, \dots, 2^{28}$ ($n = 6$, $T = 5$, $1 \le r \le 251$).

eral solutions to this problem are described in the full version [12].

4.2 Results

Single-Byte Attack We ran the attack described in Algorithm 3 with our default parameters ($n = 6$, $T = 5$, $1 \le r \le 251$) for $S = 2^s$ with $s \in \{20, 22, 24, 26, 28\}$ and evaluated the attack's success rate. We used our default of 256 independent runs per parameter set. The results are shown in Figure 2. We observe that:

- The performance of the attack improves markedly as S, the number of ciphertexts, increases, but the success rate is bounded by 75%. We attribute this to the use of one dictionary (RockYou) to recover passwords from another (Singles.org) – for the same attack parameters, we achieved 100% success rates when using RockYou against RockYou, for example.
- For 2^{24} ciphertexts we see a success rate of greater than 60% for small values of r, the assumed position of the password in the RC4 keystream. We see a drop to below 50% for starting positions greater than 32. We note the effect of the key-length-dependent biases on password recovery; passwords encrypted at starting positions $16\ell - n, 16\ell - n + 1, \dots, 16\ell - 1, 16\ell$, where $\ell = 1, 2, \dots, 6$, have a higher probability of being recovered in comparison to neighbouring starting positions.
- For 2^{28} ciphertexts we observe a success rate of more than 75% for $1 \le r \le 120$.

Double-Byte Attack Analogously, we ran the attack of Algorithm 4 for $S = 2^s$ with $s \in \{20, 22, 24, 26, 28\}$ and our defaults of $n = 6$, $T = 5$. The results for these simulations are shown in Figure 3. Note that:

- Again, at 2^{24} ciphertexts the effect of key-length-dependent biases is visible.
- For 2^{26} ciphertexts we observe a success rate that is greater than 78% for $r \le 48$.

Comparing the Single-Byte Attack with a Naive Algorithm Figure 4 provides a comparison between our single-byte algorithm with $T = 1$ and a naive password recovery attack based on the methods of [2], in which the password bytes are recovered one at a time by selecting the highest likelihood byte value in each position and declaring success if all bytes of the password are recovered correctly. Significant improvement over the naive attack can be observed, particularly for high values of r. For example with $S = 2^{24}$, the naive algorithm essentially has a success rate of zero for every r, whereas our single-byte algorithm has a success rate that exceeds 20% for $1 \le r \le 63$. By way of comparison, an attacker knowing the password length and using the obvious guessing strategy would succeed with probability 4.2% with a single guess, this being the *a priori* probability of the password 123456 amongst all length 6 passwords in the Singles.org dataset (and 123456 being the highest ranked password in the RockYou dictionary, so the first one that an attacker using this strategy with the RockYou dictionary would try). As another example, with $S = 2^{28}$ ciphertexts, a viable recovery rate is observed all the way up to $r = 251$ for our single-byte algorithm, whereas the naive algorithm fails badly beyond $r = 160$ for even this large value of S. Note however that the naive attack can achieve a success rate of 100% for sufficiently large S, whereas our attack cannot. This is because the naive attack directly

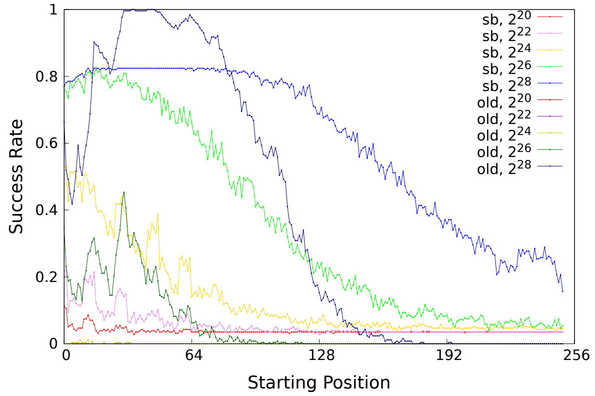

Figure 4: Performance of our single-byte algorithm versus a naive single-byte attack based on the methods of AlFardan *et al.* (labelled "old") ($n = 6$, $T = 1$, $1 \le r \le 251$).

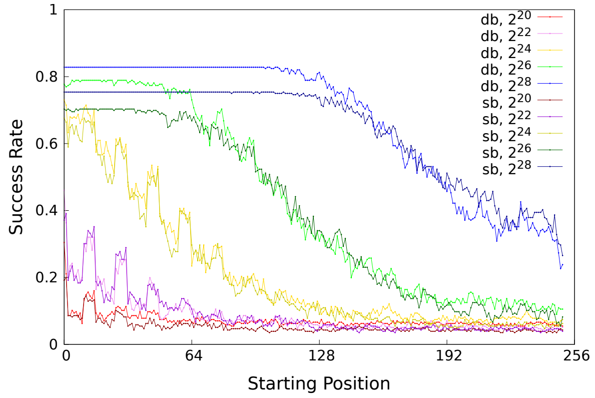

Figure 5: Recovery rate of single-byte versus double-byte algorithm for $S = 2^{20}, \dots, 2^{28}$ ($n = 6$, $T = 5$, $1 \le r \le 251$).

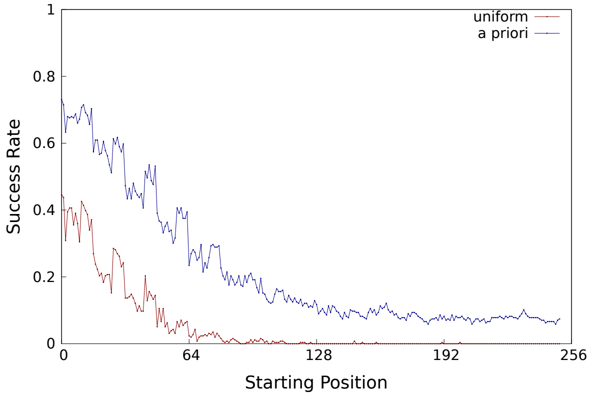

Figure 6: Recovery rate for uniformly distributed passwords versus known *a priori* distribution ($S = 2^{24}$, $n = 6$, $T = 5$, $1 \le r \le 251$, double-byte algorithm).

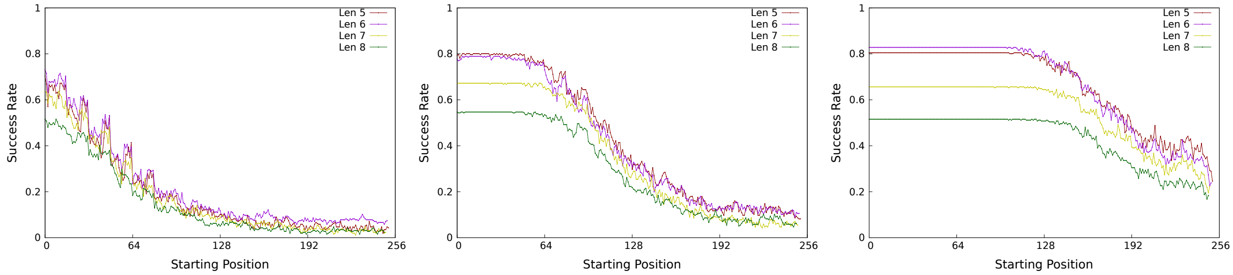
computes a password candidate rather than evaluating the likelihood of candidates from a list which may not contain the target password. On the other hand, our attack trivially supports larger values of T, whereas the naive attack is not so easily modified to enable this feature.

Comparing the Single-Byte and Double-Byte Attacks Figure 5 provides a comparison of our single-byte and double-byte attacks. With all other parameters equal, the success rates are very similar for the initial 256 positions. The reason for this is the absence of many strong double-byte biases that do not arise from the known single-byte biases in the early positions of the RC4 keystream.

Effect of the *a priori* Distribution As a means of testing the extent to which our success rates are influenced by knowledge of the *a priori* probabilities of the candidate passwords, we ran simulations in which we tried to recover passwords sampled correctly from the Singles.org dataset but using a uniform *a priori* distribution for the RockYou-based dictionary used in the attack. Figure 6 shows the results ($S = 2^{24}$, $n = 6$, $T = 5$, double-byte attack) of these simulations, compared to the results we obtain by exploiting the *a priori* probabilities in the attack. It can be seen that a significant gain is made by using the *a priori* probabilities, with the uniform attack's success rate rapidly dropping to zero at around $r = 128$.

Effect of Password Length Figure 7 shows the effect of increasing n, the password length, on recovery rates, with the sub-figures showing the performance of our double-byte attack for different numbers of ciphertexts ($S = 2^s$ with $s \in \{24, 26, 28\}$). Other parameters are set to their default values. As intuition suggests, password recovery becomes more difficult as the length increases. Also notable is that the ceiling on success rate of our attack decreases with increasing n, dropping from more than 80% for $n = 5$ to around 50% for $n = 8$. This is due to the fact that only 48% of the length 8 passwords in the Singles.org data set actually occur in the RockYou attack dictionary: our attack is doing as well as it can in this case, and we would expect stronger performance with an attack dictionary that is better matched to the target site.

Effect of Increasing Try Limit T Recall that the parameter T defines the number of password trials our attacks make. The number of permitted attempts for specific protocols like BasicAuth and IMAP is server-dependent and not mandated in the relevant specifications. Whilst not specific to our chosen protocols, a 2010 study [5] showed that 84% of websites surveyed allowed at least $T = 100$ attempts; many websites appear to actually al-



(a) 2^{24} ciphertexts

(b) 2^{26} ciphertexts

(c) 2^{28} ciphertexts

Figure 7: Effect of password length on recovery rate ($T = 5$, $1 \leq r \leq 251$, double-byte algorithm).

low $T = \infty$. Figure 8 shows the effect of varying T in our double-byte algorithm for different numbers of ciphertexts ($S = 2^s$ with $s \in \{24, 26, 28\}$). Other parameters are set to their default values. It is clear that allowing large values of T boosts the success rate of the attacks.

Note however that a careful comparison must be made between our attack with parameter T and the success rate of the obvious password guessing attack given T attempts. Such a guessing attack does not require any ciphertexts but instead uses the *a priori* distribution on passwords in the attack dictionary (RockYou) to make guesses for the target password in descending order of probability, the success rate being determined by the *a priori* probabilities of the guessed passwords in the target set (Singles.org). Clearly, our attacks are only of value if they significantly out-perform this ciphertext-less attack.

Figure 9 shows the results of plotting $\log_2(T)$ against success rate α for $S = 2^s$ with $s \in \{14, 16, \ldots, 28\}$. The figure then illustrates the value of T necessary in our attack to achieve a given password recovery rate α for different values of S. This measure is related to the α-work-factor metric explored in [4] (though with the added novelty of representing a work factor when one set of passwords is used to recover passwords from a different set). To generate this figure, we used 1024 independent runs rather than the usual 256, but using a fixed set of 1024 passwords sampled according to the *a priori* distribution for Singles.org. This was in an attempt to improve the stability of the results (with small numbers of ciphertexts S, the success rate becomes heavily dependent on the particular set of passwords selected and their *a priori* probabilities, while we wished to have comparability across different values of S).

The success rates shown in Figure 9 are for our double-byte attack with $n = 6$ and $r = 133$, this specific choice of r being motivated by it being the location of passwords for our BasicAuth attack proof-of-concept when the Chrome browser is used (similar results are obtained for other values of r). The graph also shows the corresponding work factor T as a function of α for the guessing attack (labeled “optimal guessing” in the figure).

Figure 9 shows that our attack far outperforms the guessing attack for larger values of S, with a significant advantage accruing for $S = 2^{24}$ and above. However, the advantage over the guessing attack for smaller values of S, namely 2^{20} and below, is not significant. This can be attributed to our attack simply not being able to compute stable enough statistics for these small numbers of ciphertexts. In turn, this is because the expected random fluctuations in the keystream distributions overwhelm the small biases; in short, the signal does not sufficiently exceed the noise for these low values of S.

Effect of Base64 Encoding We investigated the effect of Base64 encoding of passwords on recovery rates, since many application layer protocols use such an encoding. The encoding increases the password length, making recovery harder, but also introduces redundancy, potentially helping the recovery process to succeed. Figure 10 shows our simulation results comparing the performance of our double-byte algorithm acting on 6-character passwords and on Base64 encoded versions of them. It is apparent from the figure that the overall effect of the Base64 encoding is to help our attack to succeed. In practice, the start of the target password may not be well-aligned with the Base64 encoding process (for example, part of the last character of the username and/or a delimiter such as “:” may be jointly encoded with part of the first character of the password). This can be handled by building a special-purpose set of candidates $\mathscr{X}$ for each possibility. Handling this requires some care when mounting a real attack against a specific protocol; a detailed analysis is deferred to future work.

Shifting Attack In certain application protocols and attack environments (such as HTTPS) it is possible for the adversary to incrementally pad the plaintext messages so that the unknown bytes are always aligned with positions having large keystream biases. Our algorithm descriptions

and code are both easily modified to handle this situation, and we have conducted simulations with the resulting shift attack. We report on these simulations in the full version, [12].

5 Practical Validation

In this section we describe proof-of-concept implementations of our attacks against a specific application-layer protocol running over TLS, namely BasicAuth. In the full version [12], we additionally consider the IMAP protocol as a target.

5.1 Introducing BasicAuth

Defined as part of the HTTP/1.0 specification [3] and extended in [11], the Basic Access Authentication scheme (BasicAuth) provides a simple means for controlling access to webpages and other protected resources. In view of its simplicity, the scheme is still very widely used in the enterprise application space. The protocol essentially involves the client sending the server a username and password in Base64 encoded form, and as such, requires the use of a lower-layer secure protocol like TLS to mitigate trivial eavesdropping attacks. Certain web browsers display a login dialog when an initiating challenge message is received from the server and many browsers present users with the option of storing their user credentials in the browser, with the credentials thereafter being automatically presented on behalf of the user.

The client response to the challenge is of the form
`Authorization: Basic Base64(userid:password)`
where `Base64`(·) denotes the Base64 encoding function (which maps 3 characters at a time onto 4 characters of output).

5.2 Attacking BasicAuth

To obtain a working attack against BasicAuth, we need to ensure that two conditions are met:

- The Base64-encoded password included in the BasicAuth client response can be located sufficiently early in the plaintext stream.

- There is a method for forcing a browser to repeatedly send the BasicAuth client response.

We have observed that the first condition is met for particular browsers, including Google Chrome. For example, we inspected HTTPS traffic sent from Chrome to an iChair server.[5] We observed the user's Base64-encoded password being sent with every HTTP(S) request in the same position in the stream, namely position $r = 133$ (this includes 16 bytes consumed by the client's `Finished` message as well as the 20-bytes consumed by the TLS Record Protocol tag). For Mozilla Firefox, the value of r was the less useful 349.

[5] iChair is a popular system for conference reviewing, widely used in the cryptography research community and available from `http://www.baigneres.net/ichair`. It uses BasicAuth as its user authentication mechanism.

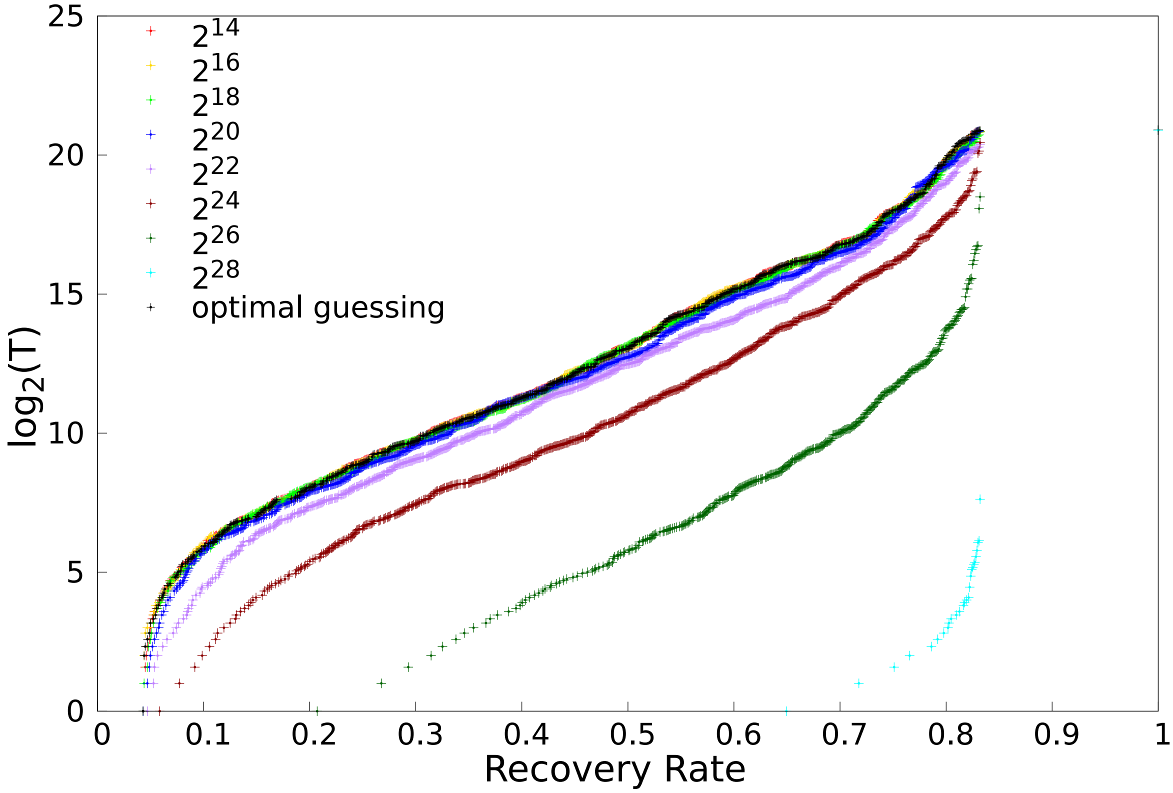

Figure 9: Value of T required to achieve a given password recovery rate α for $S = 2^s$ with $s \in \{14, 16, \ldots, 28\}$ ($n = 6$, $r = 133$, double-byte algorithm).

For the second condition, we adopt the methods used in the BEAST, CRIME and Lucky 13 attacks on TLS, and also used in attacking RC4 in [2]: we assume that the user visits a site `www.evil.com` which loads JavaScript into the user's browser; the JavaScript makes GET or POST requests to the target website at `https://www.good.com` by using `XMLHttpRequest` objects (this is permitted under Cross Origin Resource Sharing (CORS), a mechanism developed to allow JavaScript to make requests to a domain other than the one from which the script originates). The Base64-encoded BasicAuth password is automatically included in each such request. To force the password to be repeatedly encrypted at an early position in the RC4 keystream, we use a MITM attacker to break the TLS connection (by injecting sequences of TCP `FIN` and `ACK` messages into the connection). This requires some careful timing on the part of the JavaScript and the MITM attacker.

We built a proof-of-concept demonstration of these components to illustrate the principles. We set up a virtual network with three virtual machines each running Ubuntu 14.04, kernel version 3.13.0-32. On the first machine, we installed iChair. We configured the iChair web server to use RC4 as its default TLS cipher. The second machine was running the Chrome 38 browser and acted as the client in our attack. We installed the required JavaScript directly on this machine rather than downloading from another site. The third machine acted as the MITM attacker, required to intercept the TLS-protected traffic and to tear-down the TLS connections. We used the Python tool Scapy[6] to run an ARP poisoning attack on the client and server from the MITM so as to be able to intercept packets; with the connection hijacked we were able to force a graceful shutdown of the connection between the client and the server after the password-bearing record had been observed and recorded. We observed that forcing a graceful shutdown of each subsequent connection did allow for TLS resumption (rather than leading to the need for a full TLS Handshake run).

With this setup, the JavaScript running in the client browser sent successive HTTPS GET requests to the

[6] Available at `http://www.secdev.org/projects/scapy/`.

iChair server every 80ms. Our choice of 80ms was motivated by the fact that for our particular configuration, we observed a total time of around 80ms for TLS resumption, delivery of the password-bearing record and the induced shutdown of the TCP connection. This choice enabled us to capture 2^{16} encrypted password-bearing records in 1.6 hours (the somewhat greater than expected time here being due to anomalies in network behaviour). Running at this speed, the attack was stable over a period of hours.

We note that the latency involved in our setup is much lower than would be found in a real network in which the server may be many hops away from the client: between 500ms and 1000ms is typical for establishing an initial TLS connection to a remote site, with the latency being roughly half that for session resumptions. Notably, the cost of public key operations is not the issue, but rather the network latency involved in the round-trips required for TCP connection establishment and then running the TLS Handshake. However, browsers also open up multiple TLS connections in parallel when fetching multiple resources from a site, as a means of reducing the latency perceived by users; the maximum number of concurrent connections per server is 6 for both the Chrome and Firefox browsers (though, we only ever saw roughly half this number in practice, even with low inter-request times). This means that, assuming a TLS resumption latency (including the client's TCP `SYN`, delivery of the password-bearing record and the final, induced TCP `ACK`) of 250ms and the JavaScript is running fast enough to induce the browser to maintain 6 connections in parallel, the amount of time needed to mount an attack with $S = 2^{26}$ would be on the order of 776 hours. If the latency was further reduced to 100ms (because of proximity of the server to the client), the attack execution time would be reduced to 312 hours.

Again setting $n = 6$, $T = 100$, $r = 133$ and using the simulation results displayed in Figure 10, we would expect a success rate of 64.4% for this setup (with $S = 2^{26}$). For $T = 5$, the corresponding success rate would be 44.5%.

We emphasise that we have not executed a complete attack on these scales, but merely demonstrated the feasibility of the attack in our laboratory setup.

6 Conclusion and Open Problems

We have presented plaintext recovery attacks that derive from a formal Bayesian analysis of the problem of estimating plaintext likelihoods given an *a priori* plaintext distribution, suitable keystream distribution information, and a large number of encryptions of a fixed plaintext under independent keys. We applied these ideas to the specific problem of recovering passwords encrypted by the RC4 algorithm with 128-bit keys as used in TLS, though they are of course more generally applicable – to uses of RC4 other than in TLS, and to stream ciphers with non-uniform keystream distributions in general. Using large-scale simulations, we have investigated the performance of these attacks under different settings for the main parameters.

We then studied the applicability of these attacks for a specific application layer protocol, BasicAuth. For certain browsers and clients, the passwords were located at a favourable point in the plaintext stream and we could induce the password to be repeatedly encrypted under fresh, random keys. We built a proof-of-concept implementation of the attack. It was difficult to arrange for the rate of generation of encryptions to be as high as desired for a speedy attack. This was mainly due to the latency associated with TLS connection establishment (even with session resumption) rather than any fundamental barrier.

Good-to-excellent password recovery success rates can be achieved using 2^{24} – 2^{28} ciphertexts in our attacks. We also demonstrated that our single-byte attack for password recovery significantly outperforms a naive password recovery attack based on the ideas of [2]. We observed an improvement over a guessing strategy even for low numbers (2^{22} or 2^{24}) of ciphertexts. By contrast to these numbers, the preferred double-byte attack of [2] required on the order of 2^{34} encryptions to recover a 16-byte cookie, though without incurring the time overheads arising from TLS session resumption that our approach incurs.

Our research has led to the identification of a number of areas for further work:

- Our Bayesian approach can also be applied to the situation where we model the plaintext as a word from a language described as a Markov model with memory. It would be interesting to investigate the extent to which this approach can be applied to either password recovery or more general analysis of, say, typical HTTP traffic.

- We have focussed on the use of the single-byte biases described in [2] and the double-byte biases of Fluhrer and McGrew (and from our own extensive computations for the first 512 keystream positions). Other biases in RC4 keystreams are known, for example [14]. It is a challenge to integrate these in our Bayesian framework, with the aim being to further improve our attacks.

- We identified new double-byte biases early in the RC4 keystream which deserve a theoretical explanation.

- It would be an interesting challenge to develop algorithms for constructing synthetic, site-specific dictionaries along with *a priori* probability distributions. Existing work in this direction includes Marx's WordHound tool.[7]

- We identified several open questions in the discussion of our simulation results, including the effect of the choice of password data sets on success rates, and the evaluation of different methods for recovering the target password's length.

Acknowledgements

We would like to thank Google, Dan Kaminsky at White Ops and Ingo von Maurich at Ruhr Universität Bochum for their generous donation of computing resources. Dan gave us free rein on a 512-core system for the 4800 core-days necessary to perform our double-byte keystream distribution estimates, while resources from Google and Ruhr Universität Bochum were used to conduct our attack simulations. We would also like to thank Alexei Melnikov for acting as our IMAP oracle.

Eclipse Attacks on Bitcoin's Peer-to-Peer Network

Ethan Heilman[*] *Alison Kendler*[*] *Aviv Zohar*[†] *Sharon Goldberg*[*]
[*]*Boston University* [†]*Hebrew University/MSR Israel*

Abstract

We present eclipse attacks on bitcoin's peer-to-peer network. Our attack allows an adversary controlling a sufficient number of IP addresses to monopolize all connections to and from a victim bitcoin node. The attacker can then exploit the victim for attacks on bitcoin's mining and consensus system, including N-confirmation double spending, selfish mining, and adversarial forks in the blockchain. We take a detailed look at bitcoin's peer-to-peer network, and quantify the resources involved in our attack via probabilistic analysis, Monte Carlo simulations, measurements and experiments with live bitcoin nodes. Finally, we present countermeasures, inspired by botnet architectures, that are designed to raise the bar for eclipse attacks while preserving the openness and decentralization of bitcoin's current network architecture.

1 Introduction

While cryptocurrency has been studied since the 1980s [22, 25, 28], bitcoin is the first to see widespread adoption.A key reason for bitcoin's success is its baked-in decentralization. Instead of using a central bank to regulate currency, bitcoin uses a decentralized network of nodes that use computational proofs-of-work to reach consensus on a distributed public ledger of transactions, *aka.,* the *blockchain*. Satoshi Nakamoto [52] argues that bitcoin is secure against attackers that seek to shift the blockchain to an inconsistent/incorrect state, as long as these attackers control less than half of the computational power in the network. But underlying this security analysis is the crucial assumption of *perfect information*; namely, that all members of the bitcoin ecosystem can observe the proofs-of-work done by their peers.

While the last few years have seen extensive research into the security of bitcoin's computational proof-of-work protocol *e.g.,* [14, 29, 36, 37, 45, 49, 50, 52, 58, 60], less attention has been paid to the peer-to-peer network used to broadcast information between bitcoin nodes (see Section 8). The bitcoin peer-to-peer network, which is bundled into the core bitcoind implementation, *aka.,* the Satoshi client, is designed to be open, decentralized, and independent of a public-key infrastructure. As such, cryptographic authentication between peers is not used, and nodes are identified by their IP addresses (Section 2). Each node uses a randomized protocol to select eight peers with which it forms long-lived *outgoing connections*, and to propagate and store addresses of other potential peers in the network. Nodes with public IPs also accept up to 117 *unsolicited incoming connections* from any IP address. Nodes exchange views of the state of the blockchain with their incoming and outgoing peers.

Eclipse attacks. This openness, however, also makes it possible for adversarial nodes to join and attack the peer-to-peer network. In this paper, we present and quantify the resources required for *eclipse attacks* on nodes with public IPs running bitcoind version 0.9.3. In an eclipse attack [27, 61, 62], the attacker monopolizes all of the victim's incoming and outgoing connections, thus isolating the victim from the rest of its peers in the network. The attacker can then filter the victim's view of the blockchain, force the victim to waste compute power on obsolete views of the blockchain, or coopt the victim's compute power for its own nefarious purposes (Section 1.1). We present *off-path* attacks, where the attacker controls endhosts, but not key network infrastructure between the victim and the rest of the bitcoin network. Our attack involves rapidly and repeatedly forming unsolicited incoming connections to the victim from a set of endhosts at attacker-controlled IP addresses, sending bogus network information, and waiting until the victim restarts (Section 3). With high probability, the victim then forms all eight of its outgoing connections to attacker-controlled addresses, and the attacker also monopolizes the victim's 117 incoming connections.

Our eclipse attack uses extremely low-rate TCP connections, so the main challenge for the attacker is to obtain a sufficient number of IP addresses (Section 4). We consider two attack types: (1) infrastructure attacks, modeling the threat of an ISP, company, or nation-state that holds several *contiguous* IP address blocks and seeks to subvert bitcoin by attacking its peer-to-peer network, and (2) botnet attacks, launched by bots with addresses in *diverse* IP address ranges. We use probabilistic analysis, (Section 4) measurements (Section 5), and experiments on our own live bitcoin nodes (Section 6) to find that while botnet attacks require far fewer IP addresses, there are hundreds of organizations that have sufficient IP resources to launch eclipse attacks (Section 4.2.1). For example, we show how an infrastructure attacker with 32 distinct /24 IP address blocks (8192 address total), or a botnet of 4600 bots, can always eclipse a victim with at least 85% probability; this is independent of the number of nodes in the network. Moreover, 400 bots sufficed in tests on our live bitcoin nodes. To put this in context, if 8192 attack nodes joined today's network (containing $\approx$ 7200 public-IP nodes [4]) and honestly followed the peer-to-peer protocol, they could eclipse a target with probability about $(\frac{8192}{7200+8192})^8 = 0.6\%$.

Our attack is only for nodes with public IPs; nodes with private IPs may be affected if all of their outgoing connections are to eclipsed public-IP nodes.

Countermeasures. Large miners, merchant clients and online wallets have been known to modify bitcoin's networking code to reduce the risk of network-based attacks. Two countermeasures are typically recommended [3]: (1) disabling incoming connections, and (2) choosing 'specific' outgoing connections to well-connected peers or known miners (*i.e.,* use whitelists). However, there are several problems with scaling this to the full bitcoin network. First, if incoming connections are banned, how do new nodes join the network? Second, how does one decide which 'specific' peers to connect to? Should bitcoin nodes form a private network? If so, how do they ensure compute power is sufficiently decentralized to prevent mining attacks?

Indeed, if bitcoin is to live up to its promise as an open and decentralized cryptocurrency, we believe its peer-to-peer network should be open and decentralized as well. Thus, our next contribution is a set of countermeasures that preserve openness by allowing unsolicited incoming connections, while raising the bar for eclipse attacks (Section 7). Today, an attacker with enough addresses can eclipse *any* victim that accepts incoming connections and then restarts. Our countermeasures ensure that, with high probability, if a victim stores enough legitimate addresses that accept incoming connections, then the victim be cannot eclipsed *regardless of the number of IP addresses the attacker controls.* Our countermeasures 1, 2, and 6 have been deployed in bitcoind v0.10.1; we also developed a patch [40] with Countermeasures 3,4.

1.1 Implications of eclipse attacks

Apart from disrupting the bitcoin network or selectively filtering a victim's view of the blockchain, eclipse attacks are a useful building block for other attacks.

Engineering block races. A block race occurs when two miners discover blocks at the same time; one block will become part of the blockchain, while the other "orphan block" will be ignored, yielding no mining rewards for the miner that discovered it. An attacker that eclipses many miners can engineer block races by hording blocks discovered by eclipsed miners, and releasing blocks to both the eclipsed and non-eclipsed miners once a competing block has been found. Thus, the eclipsed miners waste effort on orphan blocks.

Splitting mining power. Eclipsing an x-fraction of miners eliminates their mining power from the rest of the network, making it easier to launch mining attacks (*e.g.,* the 51% attack [52]). To hide the change in mining power under natural variations [19], miners could be eclipsed gradually or intermittently.

Selfish mining. With selfish mining [14,29,37,60], the attacker strategically withholds blocks to win more than its fair share of mining rewards. The attack's success is parameterized by two values: α, the ratio of mining power controlled by the attacker, and γ, the ratio of honest mining power that will mine on the attacker's blocks during a block race. If γ is large, then α can be small. By eclipsing miners, the attacker increases γ, and thus decreases α so that selfish mining is easier. To do this, the attacker drops any blocks discovered by eclipsed miners that compete with the blocks discovered by the selfish miners. Next, the attacker increases γ by feeding only the selfish miner's view of the blockchain to the eclipsed miner; this coopts the eclipsed miner's compute power, using it to mine on the selfish-miner's blockchain.

Attacks on miners can harm the entire bitcoin ecosystem; mining pools are also vulnerable if their gateways to the public bitcoin network can be eclipsed. Eclipsing can also be used for double-spend attacks on non-miners, where the attacker spends some bitcoins multiple times:

0-confirmation double spend. In a 0-confirmation transaction, a customer pays a transaction to a merchant who releases goods to the customer *before* seeing a block confirmation *i.e.,* seeing the transaction in the blockchain [18]. These transactions are used when it is inappropriate to wait the 5-10 minutes typically needed to for a block confirmation [20], *e.g.,* in retail point-of-sale systems like BitPay [5], or online gambling sites like Betcoin [57]. To launch a double-spend attack against the merchant [46], the attacker eclipses the merchant's bitcoin node, sends the merchant a transaction T for goods, and sends transaction T' double-spending those bitcoins to the rest of the network. The merchant releases the goods to the attacker, but since the attacker controls all of the merchant's connections, the merchant cannot tell the rest of the network about T, which meanwhile confirms T'. The attacker thus obtains the goods without paying. 0-confirmation double-spends have occurred in the wild [57]. This attack is as effective as a Finney attack [39], but uses eclipsing instead of mining power.

N-confirmation double spend. If the attacker has eclipsed an x-fraction of miners, it can also launch N-confirmation double-spending attacks on an eclipsed merchant. In an N-confirmation transaction, a merchant releases goods only after the transaction is confirmed in a block of depth $N-1$ in the blockchain [18]. The attacker sends its transaction to the eclipsed miners, who incorporate it into their (obsolete) view of the blockchain. The attacker then shows this view of blockchain to the eclipsed merchant, receives the goods, and sends both the merchant and eclipsed miners the (non-obsolete) view of blockchain from the non-eclipsed miners. The eclipsed miners' blockchain is orphaned, and the attacker obtains goods without paying. This is similar to an attack launched by a mining pool [10], but our attacker eclipses miners instead of using his own mining power.

Other attacks exist, *e.g.,* a transaction hiding attack on nodes running in SPV mode [16].

2 Bitcoin's Peer-to-Peer Network

We now describe bitcoin's peer-to-peer network, based on bitcoind version 0.9.3, the most current release from 9/27/2014 to 2/16/2015, whose networking code was largely unchanged since 2013. This client was originally written by Satoshi Nakamoto, and has near universal market share for public-IP nodes (97% of public-IP nodes according to Bitnode.io on 2/11/2015 [4]).

Peers in the bitcoin network are identified by their IP addresses. A node with a public IP can initiate up to *eight outgoing connections* with other bitcoin nodes, and accept up to 117 *incoming connections*.[1] A node with a private IP only initiates eight outgoing connections. Connections are over TCP. Nodes only propagate and store public IPs; a node can determine if its peer has a public IP by comparing the IP packet header with the bitcoin VERSION message. A node can also connect via Tor; we do not study this, see [16, 17] instead. We now describe how nodes propagate and store network information, and how they select outgoing connections.

2.1 Propagating network information

Network information propagates through the bitcoin network via DNS seeders and ADDR messages.

DNS seeders. A DNS seeder is a server that responds to DNS queries from bitcoin nodes with a (not cryptographically-authenticated) list of IP addresses for bitcoin nodes. The seeder obtains these addresses by periodically crawling the bitcoin network. The bitcoin network has six seeders which are queried in two cases only. The first when a new node joins the network for the first time; it tries to connect to the seeders to get a list of active IPs, and otherwise fails over to a hardcoded list of about 600 IP addresses. The second is when an existing node restarts and reconnects to new peers; here, the seeder is queried only if 11 seconds have elapsed since the node began attempting to establish connections and the node has less than two outgoing connections.

ADDR messages. ADDR messages, containing up to 1000 IP address and their timestamps, are used to obtain network information from peers. Nodes accept unsolicited ADDR messages. An ADDR message is solicited *only* upon establishing a outgoing connection with a peer; the peer responds with up to three ADDR message each containing up to 1000 addresses randomly selected from its tables. Nodes push ADDR messages to peers in two cases. Each day, a node sends its own IP address in a ADDR message to each peer. Also, when a node receives an ADDR message with no more than 10 addresses, it forwards the ADDR message to two randomly-selected connected peers.

2.2 Storing network information

Public IPs are stored in a node's tried and new tables. Tables are stored on disk and persist when a node restarts.

The tried table. The tried table consists of 64 *buckets*, each of which can store up to 64 unique addresses for peers to whom the node has successfully established an incoming or outgoing connection. Along with each stored peer's address, the node keeps the timestamp for the most recent successful connection to this peer.

Each peer's address is mapped to a bucket in tried by taking the hash of the peer's (a) IP address and (b) *group*, where the group defined is the /16 IPv4 prefix containing the peer's IP address.A bucket is selected as follows:

```
SK = random value chosen when node is born.
IP = the peer's IP address and port number.
Group = the peer's group

i = Hash( SK, IP ) % 4
Bucket = Hash( SK, Group, i ) % 64
return Bucket
```

Thus, every IP address maps to a single bucket in tried, and each group maps to up to four buckets.

[1] This is a configurable. Our analysis only assumes that nodes have 8 outgoing connections, which was confirmed by [51]'s measurements.

When a node successfully connects to a peer, the peer's address is inserted into the appropriate `tried` bucket. If the bucket is full (*i.e.,* contains 64 addresses), then *bitcoin eviction* is used: four addresses are randomly selected from the bucket, and the oldest is (1) replaced by the new peer's address in `tried`, and then (2) inserted into the `new` table. If the peer's address is already present in the bucket, the timestamp associated with the peer's address is updated. The timestamp is also updated when an actively connected peer sends a `VERSION`, `ADDR`, `INVENTORY`, `GETDATA` or `PING` message and more than 20 minutes elapsed since the last update.

The `new` table. The `new` table consists of 256 buckets, each of which can hold up 64 addresses for peers to whom the node has not yet initiated a successful connection. A node populates the `new` table with information learned from the DNS seeders, or from `ADDR` messages.

Every address a inserted in `new` belongs to (1) a *group*, defined in our description of the `tried` table, and (2) a *source group*, the group the contains the IP address of the connected peer or DNS seeder from which the node learned address a. The bucket is selected as follows:

```
SK = random value chosen when node is born.
Group     = /16 containing IP to be inserted.
Src_Group = /16 containing IP of peer sending IP.

i = Hash( SK, Src_Group, Group ) % 32
Bucket = Hash( SK, Src_Group, i) % 256
return Bucket
```

Each (*group*, *source group*) pair hashes to a single `new` bucket, while each *group* selects up to 32 buckets in `new`. Each bucket holds unique addresses. If a bucket is full, then a function called `isTerrible` is run over all 64 addresses in the bucket; if any one of the addresses is terrible, in that it is (a) more than 30 days old, or (b) has had too many failed connection attempts, then the terrible address is evicted in favor of the new address; otherwise, *bitcoin eviction* is used with the small change that the evicted address is discarded.

2.3 Selecting peers

New outgoing connections are selected if a node restarts or if an outgoing connection is dropped by the network. A bitcoin node never deliberately drops a connection, except when a blacklisting condition is met (*e.g.,* the peer sends `ADDR` messages that are too large).

A node with $\omega \in [0,7]$ outgoing connections selects the $\omega + 1^{th}$ connection as follows:

(1) Decide whether to select from `tried` or `new`, where

$$\Pr[\text{Select from } \texttt{tried}] = \frac{\sqrt{\rho}(9-\omega)}{(\omega+1)+\sqrt{\rho}(9-\omega)} \qquad (1)$$

and ρ is the ratio between the number of addresses stored in `tried` and the number of addresses stored in `new`.

(2) Select a random address from the table, with a bias towards addresses with fresher timestamps: (i) Choose a random non-empty bucket in the table. (ii) Choose a random position in that bucket. (ii) If there is an address at that position, return the address with probability

$$p(r,\tau) = \min(1, \tfrac{1.2^r}{1+\tau}) \qquad (2)$$

else, reject the address and return to (i). The acceptance probability $p(r,\tau)$ is a function of r, the number of addresses that have been rejected so far, and τ, the difference between the address's timestamp and the current time in measured in ten minute increments.[2]

(3) Connect to the address. If connection fails, go to (1).

3 The Eclipse Attack

Our attack is for a victim with a public IP. Our attacker (1) populates the `tried` table with addresses for its attack nodes, and (2) overwrites addresses in the `new` table with "trash" IP addresses that are not part of the bitcoin network. The "trash" addresses are unallocated (*e.g.,* listed as "available" by [56]) or as "reserved for future use" by [43] (*e.g.,* 252.0.0.0/8). We fill `new` with "trash" because, unlike attacker addresses, "trash" is not a scarce resource. The attack continues until (3) the victim node restarts and chooses new outgoing connections from the `tried` and `new` tables in its persistant storage (Section 2.3). With high probability, the victim establishes all eight outgoing connections to attacker addresses; all eight addresses will be from `tried`, since the victim cannot connect to the "trash" in `new`. Finally, the attacker (5) occupies the victim's remaining 117 incoming connections. We now detail each step of our attack.

3.1 Populating `tried` and `new`

The attacker exploits the following to fill `tried` and `new`:

1. Addresses from unsolicited incoming connections are stored in the `tried` table; thus, the attacker can insert an address into the victim's `tried` table simply by connecting to the victim from that address. Moreover, the *bitcoin eviction* discipline means that the attacker's fresher addresses are likely to evict any older legitimate addresses stored in the `tried` table (Section 2.2).

2. A node accepts unsolicited `ADDR` messages; these addresses are inserted directly into the `new` table without testing their connectivity (Section 2.2). Thus, when our attacker connects to the victim from an adversarial address, it can also send `ADDR` messages with 1000 "trash"

[2] The algorithm also considers the number of failed connections to this address; we omit this because it does not affect our analysis.

addresses. Eventually, the trash overwrites all legitimate addresses in new. We use "trash" because we do not want to waste our IP address resources on overwriting new.

3. Nodes only rarely solicit network information from peers and DNS seeders (Section 2.1). Thus, while the attacker overwrites the victim's tried and new tables, the victim almost never counteracts the flood of adversarial information by querying legitimate peers or seeders.

3.2 Restarting the victim

Our attack requires the victim to restart so it can connect to adversarial addresses. There are several reasons why a bitcoin node could restart, including ISP outages, power failures, and upgrades, failures or attacks on the host OS; indeed, [16] found that a node with a public IP has a 25% chance of going offline after 10 hours. Another predictable reason to restart is a software update; on 1/10/2014, for example, bitnodes.io saw 942 nodes running Satoshi client version 0.9.3, and by 29/12/2014, that number had risen to 3018 nodes, corresponding to over 2000 restarts. Since updating is often *not* optional, especially when it corresponds to critical security issues; 2013 saw three such bitcoin upgrades, and the heartbleed bug [53] caused one in 2014. Also, since the community needs to be notified about an upgrade in advance, the attacker could watch for notifications and then commence its attack [2]. Restarts can also be deliberately elicited via DDoS [47, 65], memory exhaustion [16], or packets-of-death (which have been found for bitcoind [6,7]). The bottom line is that the security of the peer-to-peer network should not rely on 100% node uptime.

3.3 Selecting outgoing connections

Our attack succeeds if, upon restart, the victim makes all its outgoing connections to attacker addresses. To do this, we exploit the bias towards selecting addresses with fresh timestamps from tried; by investing extra time into the attack, our attacker ensures its addresses are fresh, while all legitimate addresses become increasingly stale. We analyze this with few simple assumptions:

1. An f-fraction of the addresses in the victim's tried table are controlled by the adversary and the remaining $1-f$-fraction are legitimate. (Section 4 analyzes how many addresses the adversary therefore must control.)

2. *All* addresses in new are "trash"; all connections to addresses in new fail, and the victim is forced to connect to addresses from tried (Section 2.3).

3. The attack proceeds in *rounds*, and repeats each round until the moment that the victim restarts. During a single round, the attacker connects to the victim from each of its adversarial IP addresses. A round takes time τ_a, so all adversarial addresses in tried are younger than τ_a.

4. An f'-fraction addresses in tried are actively connected to the victim before the victim restarts. The timestamps on these legitimate addresses are updated every 20 minute or more (Section 2.2). We assume these timestamps are fresh (*i.e.,* $\tau = 0$) when the victim restarts; this is the worst case for the attacker.

5. The *time invested in the attack* τ_ℓ is the time elapsed from the moment the adversary starts the attack, until the victim restarts. If the victim did not obtain new legitimate network information during of the attack, then, excluding the f'-fraction described above, the legitimate addresses in tried are older than τ_ℓ.

Success probability. If the adversary owns an f-fraction of the addresses in tried, the probability that an adversarial address is accepted on the first try is $p(1,\tau_a)\cdot f$ where $p(1,\tau_a)$ is as in equation (2); here we use the fact that the adversary's addresses are no older than τ_a, the length of the round. If $r-1$ addresses were rejected during this attempt to select an address from tried, then the probability that an adversarial address is accepted on the r^{th} try is bounded by

$$p(r,\tau_a)\cdot f\prod_{i=1}^{r-1} g(i,f,f',\tau_a,\tau_\ell)$$

where

$$\begin{aligned} g(i,f,f',\tau_a,\tau_\ell) = {} & (1-p(i,\tau_a))\cdot f + (1-p(i,0))\cdot f' \\ & + (1-p(i,\tau_\ell))\cdot(1-f-f') \end{aligned}$$

is the probability that an address was rejected on the i^{th} try given that it was also rejected on the $i-1^{th}$ try. An adversarial address is thus accepted with probability

$$q(f,f',\tau_a,\tau_\ell) = \sum_{r=1}^{\infty} p(r,\tau_a)\cdot f\prod_{i=1}^{r-1} g(i,f,f',\tau_a,\tau_\ell) \tag{3}$$

and the victim is eclipsed if all eight outgoing connections are to adversarial addresses, which happens with probability $q(f,f',\tau_a,\tau_\ell)^8$. Figure 1 plots $q(f,f',\tau_a,\tau_\ell)^8$ vs f for $\tau_a = 27$ minutes and different choices of τ_ℓ; we assume that $f' = \frac{8}{64\times 64}$, which corresponds to a full tried table containing eight addresses that are actively connected before the victim restarts.

Random selection. Figure 1 also shows success probability if addresses were just selected uniformly at random from each table. We do this by plotting f^8 vs f. Without random selection, the adversary has a 90% success probability even if it only fills $f = 72\%$ of tried, as long as it attacks for $\tau_\ell = 48$ hours with $\tau_a = 27$ minute rounds. With random selection, 90% success probability requires $f = 98.7\%$ of tried to be attacker addresses.

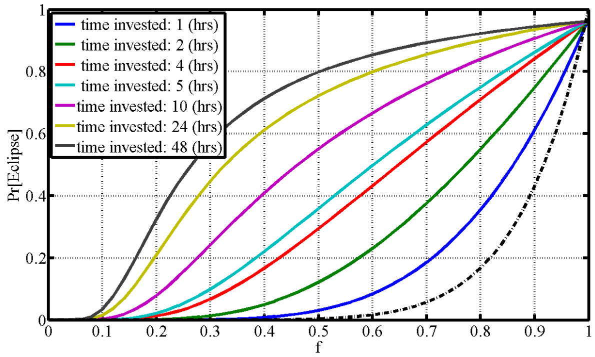

Figure 1: Probability of eclipsing a node $q(f, f', \tau_a, \tau_\ell)^8$ (equation (3)) vs f the fraction of adversarial addresses in tried, for different values of time invested in the attack τ_ℓ. Round length is $\tau_a = 27$ minutes, and $f' = \frac{8}{64\times 64}$. The dotted line shows the probability of eclipsing a node if random selection is used instead.

3.4 Monopolizing the eclipsed victim

Figure 1 assumes that the victim has exactly eight *outgoing connections*; all we require in terms of *incoming connections* is that the victim has a few open slots to accept incoming TCP connections from the attacker.

While it is often assumed that the number of TCP connections a computer can make is limited by the OS or the number of source ports, this applies only when OS-provided TCP sockets are used; a dedicated attacker can open an arbitrary number of TCP connections using a custom TCP stack. A custom TCP stack (see *e.g.,* zmap [35]) requires minimal CPU and memory, and is typically bottlenecked only by bandwidth, and the bandwidth cost of our attack is minimal:

Attack connections. To fill the tried table, our attacker repeatedly connects to the victim from each of its addresses. Each connection consists of a TCP handshake, bitcoin VERSION message, and then disconnection via TCP RST; this costs 371 bytes upstream and 377 bytes downstream. Some attack connections also send one ADDR message containing 1000 addresses; these ADDR messages cost 120087 bytes upstream and 437 bytes downstream including TCP ACKs.

Monopolizing connections. If that attack succeeds, the victim has eight outgoing connections to the attack nodes, and the attacker must occupy the victim's remaining incoming connections. To prevent others from connecting to the victim, these TCP connections could be maintained for 30 days, at which point the victim's address is terrible and forgotten by the network. While bitcoin supports block inventory requests and the sending of blocks and transactions, this consumes significant bandwidth; our attacker thus does not to respond to inventory requests. As such, setting up each TCP connection costs 377 bytes upstream and 377 bytes downstream, and is maintained by ping-pong packets and TCP ACKs consuming 164 bytes every 80 minutes.

We experimentally confirmed that a bitcoin node will accept all incoming connections from the same IP address. (We presume this is done to allow multiple nodes behind a NAT to connect to the same node.) Maintaining the default 117 incoming TCP connections costs $\frac{164\times 117}{80\times 60} \approx 4$ bytes per second, easily allowing one computer to monopolize multiple victims at the same time. As an aside, this also allows for *connection starvation attacks* [32], where an attacker monopolizes all the incoming connections in the peer-to-peer network, making it impossible for new nodes to connect to new peers.

4 How Many Attack Addresses?

Section 3.3 showed that the success of our attack depends heavily on τ_ℓ, the time invested in the attack, and f, the fraction of attacker addresses in the victim's tried table. We now use probabilistic analysis to determine how many addresses the attacker must control for a given value of f; it's important to remember, however, that even if f is small, our attacker can still succeed by increasing τ_ℓ. Recall from Section 2.2 that bitcoin is careful to ensure that a node does not store too many IP addresses from the same *group* (*i.e.,* /16 IPv4 address block). We therefore consider two attack variants:

Botnet attack (Section 4.1). The attacker holds several IP addresses, each in a *distinct* group. This models attacks by a botnet of hosts scattered in diverse IP address blocks. Section 4.1.1 explains why many botnets have enough IP address diversity for this attack.

Infrastructure attack (Section 4.2). The attacker controls several IP address blocks, and can intercept bitcoin traffic sent to any IP address in the block, *i.e.,* the attacker holds multiple sets of addresses in the same *group*. This models a company or nation-state that seeks to undermine bitcoin by attacking its network. Section 4.2.1 discusses organizations that can launch this attack.

We focus here on tried; Appendix B considers how to send "trash"-filled ADDR messages that overwrite new.

4.1 Botnet attack

The botnet attacker holds t addresses in distinct groups. We model each address as hashing to a uniformly-random bucket in tried, so the number of addresses hashing to each bucket is binomally distributed[3] as $B(t, \frac{1}{64})$. How many of the 64×64 entries in tried

[3] $B(n, p)$ is a binomial distribution counting successes in a sequence of n independent yes/no trials, each yielding 'yes' with probability p.

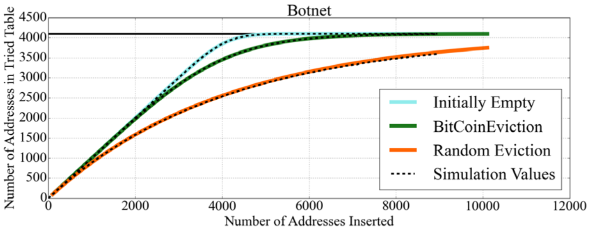

Figure 2: Botnet attack: the expected number of addresses stored in `tried` for different scenarios vs the number of addresses (bots) t. Values were computed from equations (4), (7) and (8), and confirmed by Monte Carlo simulations (with 100 trials/data point).

can the attacker occupy? We model various scenarios, and plot results in Figure 2.

1. Initially empty. In the best case for the attacker, all 64 buckets are initially empty and the expected number of adversarial addresses stored in the `tried` table is

$$64E[\min(64, B(t, \tfrac{1}{64}))] \qquad (4)$$

2. Bitcoin eviction. Now consider the worst case for the attacker, where each bucket i is full of 64 legitimate addresses. These addresses, however, will be *older* than all A_i distinct adversarial addresses that the adversary attempts to insert into to bucket i. Since the bitcoin eviction discipline requires each newly inserted address to select four random addresses stored in the bucket and to evict the oldest, if one of the four selected addresses is a legitimate address (which will be older than all of the adversary's addresses), the legitimate address will be overwritten by the adversarial addresses.

For $a = 0....A_i$, let Y_a be the number of adversarial addresses actually stored in bucket i, given that the adversary inserted a unique addresses into bucket i. Let $X_a = 1$ if the a^{th} inserted address successfully overwrites a legitimate address, and $X_a = 0$ otherwise. Then,

$$E[X_a|Y_{a-1}] = 1 - (\tfrac{Y_{a-1}}{64})^4$$

and it follows that

$$E[Y_a|Y_{a-1}] = Y_{a-1} + 1 - (\tfrac{Y_{a-1}}{64})^4 \qquad (5)$$

$$E[Y_1] = 1 \qquad (6)$$

where (6) follows because the bucket is initially full of legitimate addresses. We now have a recurrence relation for $E[Y_a]$, which we can solve numerically. The expected number of adversarial addresses in all buckets is thus

$$64 \sum_{a=1}^{t} E[Y_a] \Pr[B(t, \tfrac{1}{64}) = a] \qquad (7)$$

3. Random eviction. We again consider the attacker's worst case, where each bucket is full of legitimate addresses, but now we assume that each inserted address evicts a randomly-selected address. (This is not what bitcoin does, but we analyze it for comparison.) Applying Lemma A.1 (Appendix A) we find the expected number of adversarial addresses in all buckets is

$$4096(1 - (\tfrac{4095}{4096})^t) \qquad (8)$$

4. Exploiting multiple rounds. Our eclipse attack proceeds in *rounds*; in each round the attacker repeatedly inserts each of his t addresses into the `tried` table. While each address always maps to the same bucket in `tried` in each round, bitcoin eviction maps each address to a *different slot* in that bucket in every round. Thus, an adversarial address that is not stored into its `tried` bucket at the end of one round, might still be successfully stored into that bucket in a future round. Thus far, this section has only considered a single round. But, more addresses can be stored in `tried` by repeating the attack for multiple rounds. After sufficient rounds, the expected number of addresses is given by equation (4), *i.e.,* the attack performs as in the best-case for the attacker!

4.1.1 Who can launch a botnet attack?

The 'initially empty' line in Figure 2 indicates that a botnet exploiting multiple rounds can completely fill `tried` with ≈ 6000 addresses. While such an attack cannot easily be launched from a legitimate cloud service (which typically allocates < 20 addresses per tenant [1, 8, 9]), botnets of this size and larger than this have attacked bitcoin [45, 47, 65]; the Miner botnet, for example, had 29,000 hosts with public IPs [54]. While some botnet infestations concentrate in a few IP address ranges [63], it is important to remember that our botnet attack requires no more than ≈ 6000 groups; many botnets are orders of magnitude larger [59]. For example, the Walowdac botnet was mostly in ranges 58.x-100.x and 188.x-233.x [63], which creates $42 \times 2^8 + 55 \times 2^8 = 24832$ groups. Randomly sampling from the list of hosts in the Carna botnet [26] 5000 times, we find that 1250 bots gives on average 402 distinct groups, enough to attack our live bitcoin nodes (Section 6). Furthermore, we soon show in Figure 3 that an infrastructure attack with $s > 200$ groups easily fills every bucket in `tried`; thus, with $s > 400$ groups, the attack performs as in Figure 2, even if many bots are in the same group. .

4.2 Infrastructure attack

The attacker holds addresses in s distinct *groups*. We determine how much of `tried` can be filled by an attacker controlling s groups s containing t IP addresses/group.

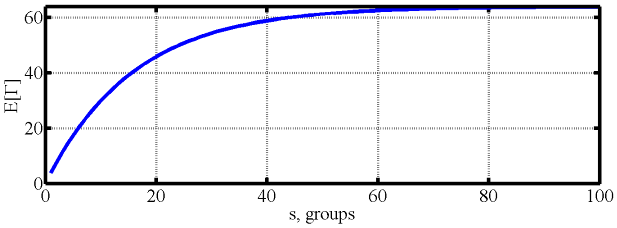

Figure 3: Infrastructure attack. $E[\Gamma]$ (expected number of non-empty buckets) in `tried` vs s (number of groups).

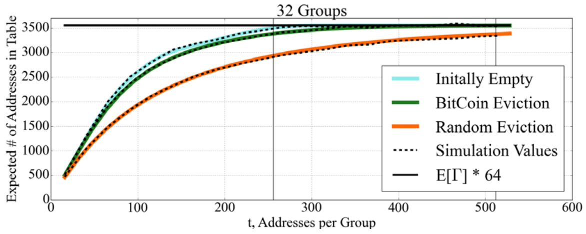

Figure 4: Infrastructure attack with $s = 32$ groups: the expected number of addresses stored in `tried` for different scenarios vs the number of addresses per group t. Results obtained by taking the product of equation (9) and equations from the full version [41], and confirmed by Monte Carlo simulations (100 trials/data point). The horizontal line assumes all $E[\Gamma]$ buckets per (9) are full.

How many groups? We model the process of populating `tried` (per Section 2.2) by supposing that four independent hash functions map each of the s groups to one of 64 buckets in `tried`. Thus, if $\Gamma \in [0,64]$ counts the number of non-empty buckets in `tried`, we use Lemma A.1 to find that

$$E[\Gamma] = 64\left(1-\left(\tfrac{63}{64}\right)^{4s}\right) \approx \left(1-e^{-\frac{4s}{64}}\right) \qquad (9)$$

Figure 3 plots $E[\Gamma]$; we expect to fill 55.5 of 64 buckets with $s = 32$, and all but one bucket with $s > 67$ groups.

How full is the `tried` table? The full version [41] determines the expected number of addresses stored per bucket for the first three scenarios described in Section 4.1; the expected fraction $E[f]$ of `tried` filled by adversarial addresses is plotted in in Figure 4. The horizontal line in Figure 4 show what happens if each of $E[\Gamma]$ buckets per equation (9) is full of attack addresses.

The adversary's task is easiest when all buckets are initially empty, or when a sufficient number of rounds are used; a single /24 address block of 256 addresses suffices to fill each bucket when $s = 32$ grouips is used. Moreover, as in Section 4.1, an attack that exploits multiple rounds performs as in the 'initially empty' scenario. Concretely, with 32 groups of 256 addresses each (8192 addresses in total) an adversary can expect to fill about $f = 86\%$ of the `tried` table after a sufficient number of rounds. The attacker is almost as effective in the bitcoin-eviction scenario with only one round; meanwhile, one round is much less effective with random eviction.

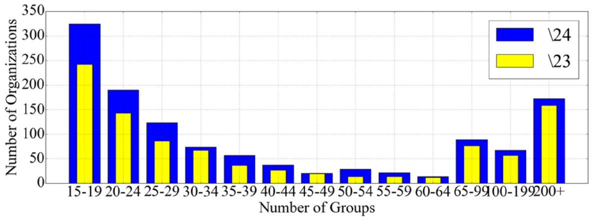

Figure 5: Histogram of the number of organizations with s groups. For the /24 data, we require $t = 256$ addresses per group; for /23, we require $t = 512$.

4.2.1 Who can launch an infrastructure attack?

Which organizations have enough IP address resources to launch infrastructure attacks? We compiled data mapping IPv4 address allocation to organizations, using CAIDA's AS to organization dataset [23] and AS to prefix dataset [24] from July 2014, supplementing our data with information from the RIPE database [55]. We determined how many groups (*i.e.,* addresses in the same /16 IPv4 address block) and addresses per group are allocated to each organization; see Figure 5. There are 448 organizations with over $s = 32$ groups and at least $t = 256$ addresses per group; if these organizations invest $\tau_\ell = 5$ hours into an attack with a $\tau_a = 27$-minute round, then they eclipse the victim with probability greater than 80%.

National ISPs in various countries hold a sufficient number of groups ($s \geq 32$) for this purpose; for example, in Sudan (Sudanese Mobile), Columbia (ETB), UAE (Etisalat), Guatemala (Telgua), Tunisia (Tunisia Telecom), Saudi Arabia (Saudi Telecom Company) and Dominica (Cable and Wireless). The United States Department of the Interior has enough groups ($s = 35$), as does the S. Korean Ministry of Information and Communication ($s = 41$), as do hundreds of others.

4.3 Summary: infrastructure or botnet?

Figures 4, 2 show that the botnet attack is far superior to the infrastructure attack. Filling $f = 98\%$ of the victim's `tried` table requires a 4600 node botnet (attacking for a sufficient number of rounds, per equation (4)). By contrast, an infrastructure attacker needs 16,000 addresses, consisting of $s = 63$ groups (equation (9)) with $t = 256$ addresses per group. However, per Section 3.3, if our attacker increases the time invested in the attack τ_ℓ, it can be far less aggressive about filling `tried`. For example, per Figure 1, attacking for $\tau_\ell = 24$ hours with $\tau_a = 27$ minute rounds, our success probability exceeds

oldest	#		Age of addresses (in days)				
addr	addr	% live	<1	$1-5$	$5-10$	$10-30$	>30
38 d*	243	28%	36	71	28	79	29
41 d*	162	28%	23	29	27	44	39
42 d*	244	19%	25	45	29	95	50
42 d*	195	23%	23	40	23	64	45
43 d*	219	20%	66	57	23	50	23
103 d	4096	8%	722	645	236	819	1674
127 d	4096	8%	90	290	328	897	2491
271 d	4096	8%	750	693	356	809	1488
240 d	4096	6%	419	445	32	79	3121
373 d	4096	5%	9	14	1	216	3856

Table 1: Age and churn of addresses in `tried` for our nodes (marked with *) and donated peers files.

85% with just $f = 72\%$; in the worst case for the attacker, this requires only 3000 bots, or an infrastructure attack of $s = 20$ groups and $t = 256$ addresses per group (5120 addresses). The same attack ($f = 72\%$, $\tau_a = 27$ minutes) running for just 4 hours still has $> 55\%$ success probability. To put this in context, if 3000 bots joined today's network (with < 7200 public-IP nodes [4]) and honestly followed the peer-to-peer protocol, they could eclipse a victim with probability $\approx (\frac{3000}{7200+3000})^8 = 0.006\%$.

5 Measuring Live Bitcoin Nodes

We briefly consider how parameters affecting the success of our eclipse attacks look on "typical" bitcoin nodes. We thus instrumented five bitcoin nodes with public IPs that we ran (continuously, without restarting) for 43 days from 12/23/2014 to 2/4/2015. We also analyze several peers files that others donated to us on 2/15/2015. Note that there is evidence of wide variations in metrics for nodes of different ages and in different regions [46]; as such, our analysis (Section 3-4) and some of our experiments (Section 6) focus on the attacker's worst-case scenario, where tables are initially full of fresh addresses.

Number of connections. Our attack requires the victim to have available slots for incoming connections. Figure 6 shows the number of connections over time for one of our bitcoin nodes, broken out by connections to public or private IPs. There are plenty of available slots; while our node can accommodate 125 connections, we never see more than 60 at a time. Similar measurements in [17] indicate that 80% of bitcoin peers allow at least 40 incoming connections. Our node saw, on average, 9.9 connections to public IPs over the course of its lifetime; of these, 8 correspond to *outgoing* connections, which means we rarely see incoming connections from public IPs. Results for our other nodes are similar.

Connection length. Because public bitcoin nodes rarely drop outgoing connections to their peers (except upon restart, network failure, or due to blacklisting, see Section 2.3), many connections are fairly long lived. When we sampled our nodes on 2/4/2015, across all of our nodes, 17% of connections had lasted more than 15 days, and of these, 65.6% were to public IPs. On the other hand, many bitcoin nodes restart frequently; we saw that 43% of connections lasted less than two days and of these, 97% were to nodes with private IPs. This may explain why we see so few incoming connections from public IPs; many public-IP nodes stick to their mature long-term peers, rather than our young-ish nodes.

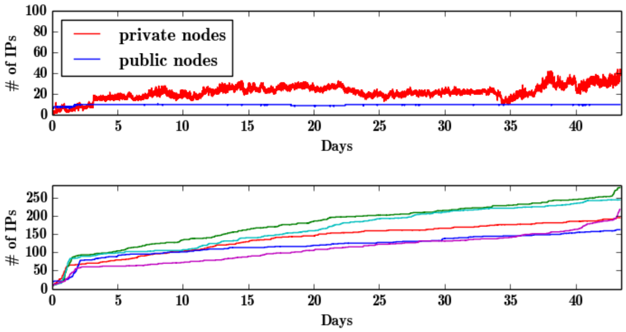

Figure 6: (Top) Incoming + outgoing connections vs time for one of our nodes. (Bottom) Number of addresses in `tried` vs time for all our nodes.

Size of `tried` and `new` tables. In our worst case attack, we supposed that the `tried` and `new` tables were completely full of fresh addresses. While our Bitcoin nodes' `new` tables filled up quite quickly (99% within 48 hours), Table 1 reveals that their `tried` tables were far from full of fresh addresses. Even after 43 days, the `tried` tables for our nodes were no more than $300/4096 \approx 8\%$ full. This likely follows because our nodes had very few incoming connections from public IPs; thus, most addresses in `tried` result from successful outgoing connections to public IPs (infrequently) drawn from `new`.

Freshness of `tried`. Even those few addresses in `tried` are not especially fresh. Table 1 shows the age distribution of the addresses in `tried` for our nodes and from donated peers files. For our nodes, 17% of addresses were more than 30 days old, and 48% were more than 10 days old; these addresses will therefore be less preferred than the adversarial ones inserted during an eclipse attack, even if the adversary does not invest much time τ_ℓ in attacking the victim.

Churn. Table 1 also shows that a small fraction of addresses in `tried` were online when we tried connecting to them on 2/17/2015.[4] This suggests further vulnerability to eclipse attacks, because if most legitimate addresses in `tried` are offline when a victim resets, the victim is likely to connect to an adversarial address.

[4] For consistency with the rest of this section, we tested our nodes tables from 2/4/2015. We also repeated this test for tables taken from our nodes on 2/17/2015, and the results did not deviate more than 6% from those of Table 1.

	Attacker resources					Experiment							Predicted

Table 2: Summary of our experiments.

6 Experiments

We now validate our analysis with experiments.

Methodology. In each of our experiments, the victim (bitcoind) node is on a virtual machine on the attacking machine; we also instrument the victim's code. The victim node runs on the public bitcoin network (*aka,* mainnet). The attacking machine can read all the victim's packets to/from the public bitcoin network, and can therefore forge TCP connections from arbitrary IP addresses. To launch the attack, the attacking machine forges TCP connections from each of its attacker addresses, making an incoming connection to the victim, sending a `VERSION` message and sometimes also an `ADDR` message (per Appendix B) and then disconnecting; the attack connections, which are launched at regular intervals, rarely occupy all of the victim's available slots for incoming connections. To avoid harming the public bitcoin network, (1) we use "reserved for future use" [43] IPs in 240.0.0.0/8-249.0.0.0/8 as attack addresses, and 252.0.0.0/8 as "trash" sent in `ADDR` messages, and (2) we drop any `ADDR` messages the (polluted) victim attempts to send to the public network.

At the end of the attack, we repeatedly restart the victim and see what outgoing connections it makes, dropping connections to the "trash" addresses and forging connections for the attacker addresses. If all 8 outgoing connections are to attacker addresses, the attack succeeds, and otherwise it fails. Each experiment restarts the victim 50 times, and reports the fraction of successes. At each restart, we revert the victim's tables to their state at the end of the attack, and rewind the victim's system time to the moment the attack ended (to avoid dating timestamps in `tried` and `new`). We restart the victim 50 times to measure the success rate of our (probabilistic) attack; in a real attack, the victim would only restart once.

Initial conditions. We try various initial conditions:

1. Worst case. In the attacker's worst-case scenario, the victim initially has `tried` and `new` tables that are completely full of legitimate addresses with fresh timestamps. To set up the initial condition, we run our attack for no longer than one hour on a freshly-born victim node, filling `tried` and `new` with IP addresses from 251.0.0.0/8, 253.0.0.0/8 and 254.0.0.0/8, which we designate as "legitimate addresses"; these addresses are no older than one hour when the attack starts. We then restart the victim and commence attacking it.

2. Transplant case. In our transplant experiments, we copied the `tried` and `new` tables from one of our five live bitcoin nodes on 8/2/2015, installed them in a fresh victim with a different public IP address, restarted the victim, waited for it to establish eight outgoing connections, and then commenced attacking. This allowed us to try various attacks with a consistent initial condition.

3. Live case. Finally, on 2/17/2015 and 2/18/2015 we attacked our live bitcoin nodes while they were connected to the public bitcoin network; at this point our nodes had been online for 52 or 53 days.

Results (Table 2). Results are in Table 2. The first five columns summarize attacker resources (the number of groups s, addresses per group t, time invested in the attack τ_ℓ, and length of a round τ_a per Sections 3-4). The next two columns present the initial condition: the number of addresses in `tried` and `new` prior to the attack. The following four columns give the size of `tried` and `new`, and the number of attacker addresses they store, at the end of the attack (when the victim first restarts). The *wins* columns counts the fraction of times our attack succeeds after restarting the victim 50 times.

The final three columns give predictions from Sections 3.3, 4. The *attack addrs* columns give the expected number of addresses in `new` (Appendix B) and `tried`. For `tried`, we assume that the attacker runs his attack for enough rounds so that the expected number of addresses in `tried` is governed by equation (4) for the botnet, and the 'initially empty' curve of Figure 4 for the infrastructure attack. The final column predicts success per Section 3.3 using *experimental values* of τ_a, τ_ℓ, f, f'.

Observations. Our results indicate the following:

1. Success in worst case. Our experiments confirm that an infrastructure attack with 32 groups of size /24 (8192 attack addresses total) succeeds in the worst case with very high probability. We also confirm that botnets are superior to infrastructure attacks; 4600 bots had 100% success even with a worst-case initial condition.

2. Accuracy of predictions. Almost all of our attacks had an experimental success rate that was *higher* than the predicted success rate. To explain this, recall that our predictions from Section 3.3 assume that legitimate addresses are exactly τ_ℓ old (where τ_ℓ is the time invested in the attack); in practice, legitimate addresses are likely to be even older, especially when we work with `tried` tables of real nodes (Table 1). Thus, Section 3.3's predictions are a lower bound on the success rate.

Our experimental botnet attacks were dramatically more successful than their predictions (*e.g.,* 88% actual vs. 34% predicted), most likely because the addresses initially in `tried` were already very stale prior to the attack (Table 1). Our infrastructure attacks were also more successful then their predictions, but here the difference was much less dramatic. To explain this, we look to the `new` table. While our success-rate predictions assume that `new` is completely overwritten, our infrastructure attacks failed to completely overwrite the `new` table;[5] thus, we have some extra failures because the victim made outgoing connections to addresses in `new`.

3. Success in a 'typical' case. Our attacks are successful with even fewer addresses when we test them on our live nodes, or on tables taken from those live nodes. Most strikingly, a small botnet of 400 bots succeeds with very high probability; while this botnet completely overwrites `new`, it fills only $400/650 = 62\%$ of `tried`, and still manages to win with more than 80% probability.

7 Countermeasures

We have shown how an attacker with enough IP addresses and time can eclipse any target victim, regardless of the state of the victim's `tried` and `new` tables. We now present countermeasures that make eclipse attacks more difficult. Our countermeasures are inspired by botnet architectures (Section 8), and designed to be faithful to bitcoin's network architecture.

The following five countermeasures ensure that: (1) If the victim has h legitimate addresses in `tried` before the attack, and a p-fraction of them accept incoming connections during the attack when the victim restarts, then even an attacker *with an unbounded number of addresses* cannot eclipse the victim with probability exceeding equation (10). (2) If the victim's oldest outgoing connection is to a legitimate peer before the attack, then the eclipse attack *fails* if that peer accepts incoming connections when the victim restarts.

1. Deterministic random eviction. Replace bitcoin eviction as follows: just as each address deterministically hashes to a single bucket in `tried` and `new` (Section 2.2), an address also deterministically hashes to a single slot in that bucket. This way, an attacker cannot increase the number of addresses stored by repeatedly inserting the same address in multiple rounds (Section 4.1). Instead, addresses stored in `tried` are given by the 'random eviction' curves in Figures 2, 4, reducing the attack addresses stored in `tried`.

2. Random selection. Our attacks also exploit the heavy bias towards forming outgoing connections to addresses with fresh timestamps, so that an attacker that owns only a small fraction $f = 30\%$ of the victim's `tried` table can increase its success probability (to say 50%) by increasing τ_ℓ, the time it invests in the attack (Section 3.3). We can eliminate this advantage for the attacker if addresses are selected at random from `tried` and `new`; this way, a success rate of 50% always requires the adversary to fill $\sqrt[8]{0.5} = 91.7\%$ of `tried`, which requires 40 groups in an infrastructure attack, or about 3680 peers in a botnet attack. Combining this with deterministic random eviction, the figure jumps to 10194 bots for 50% success probability.

These countermeasures harden the network, but still allow an attacker with enough addresses to overwrite all of `tried`. The next countermeasure remedies this:

3. Test before evict. Before storing an address in its (deterministically-chosen) slot in a bucket in `tried`, first check if there is an older address stored in that slot. If so, briefly attempt to connect to the older address, and if connection is successful, then the older address is *not* evicted from the `tried` table; the new address is stored in `tried` only if the connection fails.

We analyze these three countermeasures. Suppose that there are h legitimate addresses in the `tried` table prior to the attack, and model network churn by supposing that each of the h legitimate addresses in `tried` is live (*i.e.,* accepts incoming connections) independently with probability p. With test-before-evict, the adversary cannot evict $p \times h$ legitimate addresses (in expectation) from `tried`, regardless of the number of distinct addresses it controls. Thus, even if the rest of `tried` is full of adversarial addresses, the probability of eclipsing the victim is bounded to about

$$\Pr[\text{eclipse}] = f^8 < \left(1 - \tfrac{p \times h}{64 \times 64}\right)^8 \tag{10}$$

This is in stark contrast to today's protocol, where attackers with enough addresses have *unbounded* success probability even if `tried` is *full* of legitimate addresses.

[5] The `new` table holds 16384 addresses and from 6^{th} last column of Table 2 we see the `new` is not full for our infrastructure attacks. Indeed, we predict this in Appendix B.

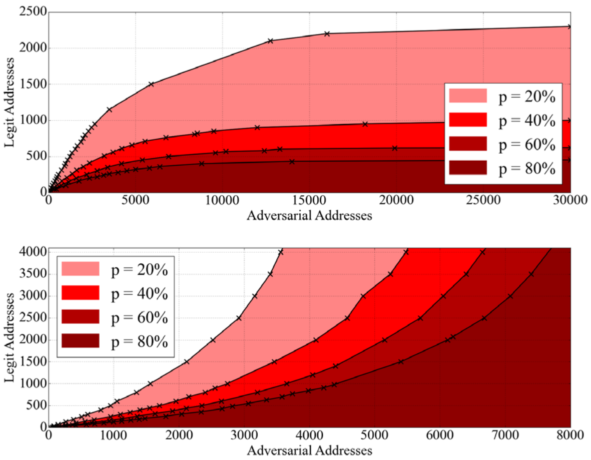

Figure 7: The area below each curve corresponds to a number of bots a that can eclipse a victim with probability at least 50%, given that the victim initially has h legitimate addresses in tried. We show one curve per churn rate p. (Top) With test before evict. (Bottom) Without.

We perform Monte-Carlo simulations assuming churn p, h legitimate addresses initially stored in tried, and a botnet inserting a addresses into tried via unsolicited incoming connections. The area below each curve in Figure 7 is the number of bots a that can eclipse a victim with probability at least 50%, given that there are initially h legitimate addresses in tried. With test-before-evict, the curves plateau horizontally at $h = 4096(1-\sqrt[8]{0.5})/p$; as long as h is greater than this quantity, even a botnet *with an infinite number of addresses* has success probability bounded by 50%. Importantly, the plateau is absent without test-before-evict; a botnet with enough addresses can eclipse a victim *regardless* of the number of legitimate addresses h initially in tried.

There is one problem, however. Our bitcoin nodes saw high churn rates (Table 1). With a $p = 28\%$ churn rate, for example, bounding the adversary's success probability to 10% requires about $h = 3700$ addresses in tried; our nodes had $h < 400$. Our next countermeasure thus adds more legitimate addresses to tried:

4. Feeler Connections. Add an outgoing connection that establish short-lived test connections to randomly-selected addresses in new. If connection succeeds, the address is evicted from new and inserted into tried; otherwise, the address is evicted from new.

Feeler connections clean trash out of new while increasing the number of fresh address in tried that are likely to be online when a node restarts. Our fifth countermeasure is orthogonal to those above:

5. Anchor connections. Inspired by Tor entry guard rotation rates [33], we add two connections that persist between restarts. Thus, we add an anchor table, recording addresses of current outgoing connections and the time of first connection to each address. Upon restart, the node dedicates two extra outgoing connections to the oldest anchor addresses that accept incoming connections. Now, in addition to defeating our other countermeasures, a successful attacker must also disrupt anchor connections; eclipse attacks fail if the victim connects to an anchor address not controlled by the attacker.

Apart from these five countermeasures, a few other ideas can raise the bar for eclipse attacks:

6. More buckets. Among the most obvious countermeasure is to increase the size of the tried and new tables. Suppose we doubled the number of buckets in the tried table. If we consider the infrastructure attack, the buckets filled by s groups jumps from $(1-e^{-\frac{4s}{64}})$ (per equation (9) to $(1-e^{-\frac{4s}{128}})$. Thus, an infrastructure attacker needs double the number of groups in order to expect to fill the same fraction of tried. Similarly, a botnet needs to double the number of bots. Importantly, however, this countermeasure is helpful only when tried already contains many legitimate addresses, so that attacker owns a smaller fraction of the addresses in tried. However, if tried is mostly empty (or contains mostly stale addresses for nodes that are no longer online), the attacker will still own a large fraction of the addresses in tried, even though the number of tried buckets has increased. Thus, this countermeasure should also be accompanied by another countermeasure (*e.g.,* feeler connections) that increases the number of legitimate addresses stored in tried.

7. More outgoing connections. Figure 6 indicates our test bitcoin nodes had at least 65 connections slots available, and [17] indicates that 80% of bitcoin peers allow at least 40 incoming connections. Thus, we can require nodes to make a few additional outgoing connections without risking that the network will run out of connection capacity. Indeed, recent measurements [51] indicate that certain nodes (*e.g.,* mining-pool gateways) do this already. For example, using twelve outgoing connections instead of eight (in addition to the feeler connection and two anchor connections), decreases the attack's success probability from f^8 to f^{12}; to achieve 50% success probability the infrastructure attacker now needs 46 groups, and the botnet needs 11796 bots.

8. Ban unsolicited ADDR messages. A node could choose not to accept large unsolicited ADDR messages (with > 10 addresses) from incoming peers, and only solicit ADDR messages from outgoing connections when its new table is too empty. This prevents adversarial incoming connections from flooding a victim's new table with trash addresses. We argue that this change is not harmful, since even in the current network, there is no shortage of address in the new table (Section 5). To make this more concrete, note that a node request ADDR messages upon establishing an outgoing connection. The peer responds with n randomly selected addresses from its tried and new tables, where n is a random number between x and 2500 and x is 23% of the addresses the peer has stored. If each peer sends, say, about $n = 1700$ addresses, then new is already $8n/16384 = 83\%$ full the moment that the bitcoin node finishing establishing outgoing connections.

9. Diversify incoming connections. Today, a bitcoin node can have all of its incoming connections come from the same IP address, making it far too easy for a single computer to monopolize a victim's incoming connections during an eclipse attack or connection-starvation attack [32]. We suggest a node accept only a limited number of connections from the same IP address.

10. Anomaly detection. Our attack has several specific "signatures" that make it detectable including: (1) a flurry of short-lived incoming TCP connections from diverse IP addresses, that send (2) large ADDR messages (3) containing "trash" IP addresses. An attacker that suddenly connects a large number of nodes to the bitcoin network could also be detected, as could one that uses eclipsing per Section 1.1 to dramatically decrease the network's mining power. Thus, monitoring and anomaly detection systems that look for this behavior are also be useful; at the very least, they would force an eclipse attacker to attack at low rate, or to waste resources on overwriting new (instead of using "trash" IP addresses).

Status of our countermeasures. We disclosed our results to the bitcoin core developers in 02/2015. They deployed Countermeasures 1, 2, and 6 in the bitcoind v0.10.1 release, which now uses deterministic random eviction, random selection, and scales up the number of buckets in tried and new by a factor of four. To illustrate the efficacy of this, consider the worst-case scenario for the attacker where tried is completely full of legitimate addresses. We use Lemma A.1 to estimate the success rate of a botnet with t IP addresses as

$$\Pr[\text{Eclipse}] \approx \left(1 - (\tfrac{16383}{16384})^t\right)^8 \qquad (11)$$

Plotting (11) in Figure 8, we see that this botnet requires 163K addresses for a 50% success rate, and 284K address for a 90% success rate. This is good news, but we caution that ensuring that tried is full of legitimate address is still a challenge (Section 5), especially since there may be fewer than 16384 public-IP nodes in the bitcoin network at a given time. Countermeasures 3 and 4 are designed to deal with this, and so we have also developed a patch with these two countermeasures; see [40] for our implementation and its documentation.

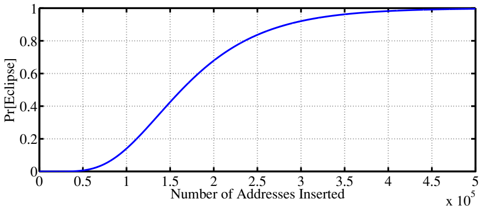

Figure 8: Probability of eclipsing a node vs the number of addresses (bots) t for bitcoind v0.10.1 (with Countermeasures 1,2 and 6) when tried is initially full of legitimate addresses per equation (11).

8 Related Work

The bitcoin peer-to-peer (p2p) network. Recent work considers how bitcoin's network can delay or prevent block propagation [31] or be used to deanonymize bitcoin users [16, 17, 48]. These works discuss aspects of bitcoin's networking protocol, with [16] providing an excellent description of ADDR message propagation; we focus instead on the structure of the tried and new tables, timestamps and their impact on address selection (Section 2). [17] shows that nodes connecting over Tor can be eclipsed by a Tor exit node that manipulates both bitcoin and Tor. Other work has mapped bitcoin peers to autonomous systems [38], geolocated peers and measured churn [34], and used side channels to learn the bitcoin network topology [16, 51].

p2p and botnet architectures. There has been extensive research on eclipse attacks [27, 61, 62] in structured p2p networks built upon distributed hash tables (DHTs); see [64] for a survey. Many proposals defend against eclipse attacks by adding more structure; [61] constrains peer degree, while others use constraints based on distance metrics like latency [42] or DHT identifiers [13]. Bitcoin, by contrast, uses an unstructured network. While we have focused on exploiting specific quirks in bitcoin's existing network, other works *e.g.,* [11, 15, 21, 44] design new unstructured networks that are robust to Byzantine attacks. [44] blacklists misbehaving peers. Puppetcast's [15] centralized solution is based on public-key infrastructure [15], which is not appropriate for bitcoin. Brahms [21] is fully decentralized, and instead constrains the rate at which peers exchange network information—a useful idea that is a significant departure from bitcoin's current approach. Meanwhile, our goals are also more modest than those in these works; rather than requiring that each node is *equally likely* to be sampled by an honest node, we just want to limit eclipse attacks on initially well-connected nodes. Thus, our countermeasures are inspired by botnet architectures, which share this same goal. Rossow *et al.* [59] finds that many botnets, like bitcoin, use unstructured peer-to-peer networks and gossip (*i.e.,* ADDR messages), and describes how botnets defend against attacks that flood local address tables with bogus information. The Sality botnet refuses to evict "high-reputation" addresses; our anchor countermeasure is similar (Section 7). Storm uses test-before-evict [30], which we have also recommended for bitcoin. Zeus [12] disallows connections from multiple IP in the same /20, and regularly clean tables by testing if peers are online; our feeler connections are similar.

9 Conclusion

We presented an eclipse attack on bitcoin's peer-to-peer network that undermines bitcoin's core security guarantees, allowing attacks on the mining and consensus system, including *N*-confirmation double spending and adversarial forks in the blockchain. Our attack is for nodes with public IPs. We developed mathematical models of our attack, and validated them with Monte Carlo simulations, measurements and experiments. We demonstrated the practically of our attack by performing it on our own live bitcoin nodes, finding that an attacker with 32 distinct /24 IP address blocks, or a 4600-node botnet, can eclipse a victim with over 85% probability in the attacker's *worst case*. Moreover, even a 400-node botnet sufficed to attack our own live bitcoin nodes. Finally, we proposed countermeasures that make eclipse attacks more difficult while still preserving bitcoin's openness and decentralization; several of these were incorporated in a recent bitcoin software upgrade.

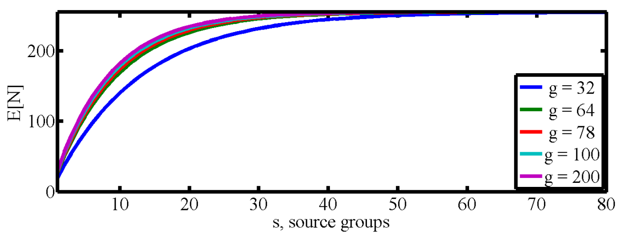

Figure 9: $E[N]$ vs s (the number of source groups) for different choices of g (number of groups per source group) when overwriting the new table per equation (13).

A A Useful Lemma

Lemma A.1. *If k items are randomly and independently inserted into n buckets, and X is a random variable counting the number of non-empty buckets, then*

$$E[X] = n\left(1 - (\tfrac{n-1}{n})^k\right) \approx n(1 - e^{-\frac{k}{n}}) \qquad (12)$$

Proof. Let $X_i = 1$ if bucket i is non-empty, and $X_i = 0$ otherwise. The probability that the bucket i is empty after the first item is inserted is $(\frac{n-1}{n})$. After inserting k items

$$\Pr[X_i = 1] = 1 - \left(\tfrac{n-1}{n}\right)^k$$

It follows that

$$E[X] = \sum_{i=1}^{n} E[X_i] = \sum_{i=1}^{n} \Pr[X_i = 1] = n(1 - (\tfrac{n-1}{n})^k)$$

(12) follows since $(\frac{n-1}{n}) \approx e^{-1/n}$ for $n \gg 1$. □

B Overwriting the New Table

How should the attacker send ADDR messages that overwrite the new table with "trash" IP addresses? Our "trash" is from the unallocated Class A IPv4 address block 252.0.0.0/8, designated by IANA as "reserved for future use" [43]; any connections these addresses will fail, forcing the victim to choose an address from tried. Next, recall (Section 2.2) that the pair *(group, source group)* determines the bucket in which an address in an ADDR message is stored. Thus, if the attacker controls nodes in s different groups, then s is the number of *source groups*. We suppose that nodes in each source group can push ADDR messages containing addresses from g distinct groups; the "trash" 252.0.0.0/8 address block give an upper bound on g of $2^8 = 256$. Each group contains a distinct addresses. How large should s, g, and a be so that the new table is overwritten by "trash" addresses?

B.1 Infrastructure strategy

In an infrastructure attack, the number of source groups s is constrained, and the number of groups g is essentially unconstrained. By Lemma A.1, the expected number of buckets filled by a s source groups is

$$E[N] = 256(1 - (\tfrac{255}{256})^{32s}) \qquad (13)$$

We expect to fill ≈ 251 of 256 new buckets with $s = 32$.

Each (group, source group) pair maps to a unique bucket in new, and each bucket in new can hold 64 addresses. Bitcoin eviction is used, and we suppose each new bucket is completely full of legitimate addresses that are older than all the addresses inserted by the adversary via ADDR messages. Since all a addresses in a particular (group, source group) pair map to a single bucket, it follows that the number of addresses that actually stored in that bucket is given by $E[Y_a]$ in the recurrence relation of equations of (5)-(6). With $a = 125$ addresses, the adversary expects to overwrite $E[Y_a] = 63.8$ of the 64 legitimate addresses in the bucket. We thus require each source group to have 32 peers, and each peer to send ADDR messages with 8 distinct groups of $a = 125$ addresses. Thus, there are $g = 32 \times 8 = 256$ groups per source group, which is exactly the maximum number of groups available in our trash IP address block. Each peer sends exactly one ADDR message with $8 \times 125 = 1000$ address, for a total of $256 \times 125 \times s$ *distinct* addresses sent by all peers. (There are 2^{24} addresses in the 252.0.0.0/8 block, so all these addresses are distinct if $s < 524$.)

B.2 Botnet strategy

In a botnet attack, each of the attacker's t nodes is in a distinct source group. For $s = t > 200$, which is the case for all our botnet attacks, equation (13) shows that the number of source groups $s = t$ is essentially unconstrained. We thus require each peer to send a single ADDR message containing 1000 addresses with 250 distinct groups of four addresses each. Since $s = t$ is so large, we can model this by assuming that each (group, source group) pair selects a bucket in new uniformly at random, and inserts 4 addresses into that bucket; thus, the expected number of addresses inserted per bucket will be tightly concentrated around

$$4 \times E[B(250t, \tfrac{1}{256}] = 3.9t$$

For $t > 200$, we expect at least 780 address to be inserted into each bucket. From equations (5) and (6), we find $E[Y_{780}] \approx 64$, so that each new bucket is likely to be full.

Compiler-instrumented, Dynamic Secret-Redaction of Legacy Processes for Attacker Deception

Frederico Araujo and Kevin W. Hamlen
The University of Texas at Dallas
{frederico.araujo, hamlen}@utdallas.edu

Abstract

An enhanced dynamic taint-tracking semantics is presented and implemented, facilitating fast and precise runtime secret redaction from legacy processes, such as those compiled from C/C++. The enhanced semantics reduce the annotation burden imposed upon developers seeking to add secret-redaction capabilities to legacy code, while curtailing over-tainting and label creep.

An implementation for LLVM's DataFlow Sanitizer automatically instruments taint-tracking and secret-redaction support into annotated C/C++ programs at compile-time, yielding programs that can self-censor their address spaces in response to emerging cyber-attacks. The technology is applied to produce the first information flow-based honey-patching architecture for the Apache web server. Rather than merely blocking intrusions, the modified server deceptively diverts attacker connections to secret-sanitized process clones that monitor attacker activities and disinform adversaries with honey-data.

1 Introduction

Redaction of sensitive information from documents has been used since ancient times as a means of concealing and removing secrets from texts intended for public release. As early as the 13th century B.C., Pharaoh Horemheb, in an effort to conceal the acts of his predecessors from future generations, so thoroughly located and erased their names from all monument inscriptions that their identities weren't rediscovered until the 19th century A.D. [22]. In the modern era of digitally manipulated data, *dynamic taint analysis* (cf., [40]) has become an important tool for automatically tracking the flow of secrets (*tainted data*) through computer programs as they execute. Taint analysis has myriad applications, including program vulnerability detection [5, 6, 9, 25, 33, 34, 37, 45, 46], malware analysis [19, 20, 36, 48], test set generation [3, 42], and information leak detection [4, 14, 21, 23, 24, 49].

Our research introduces and examines the associated challenge of secret redaction from program process images. Safe, efficient redaction of secrets from program address spaces has numerous potential applications, including the safe release of program memory dumps to software developers for debugging purposes, mitigation of cyber-attacks via runtime self-censoring in response to intrusions, and attacker deception through honey-potting.

A recent instantiation of the latter is *honey-patching* [2], which proposes crafting software security patches in such a way that future attempted exploits of the patched vulnerabilities appear successful to attackers. This frustrates attacker vulnerability probing, and affords defenders opportunities to disinform attackers by divulging "fake" secrets in response to attempted intrusions. In order for such deceptions to succeed, honey-patched programs must be imbued with the ability to impersonate unpatched software with all secrets replaced by honey-data. That is, they require a technology for rapidly and thoroughly redacting all secrets from the victim program's address space at runtime, yielding a vulnerable process that the attacker may further penetrate without risk of secret disclosure.

Realizing such runtime process secret redaction in practice educes at least two significant research challenges. First, the redaction step must yield a runnable program process. Non-secrets must therefore not be conservatively redacted, lest data critical for continuing the program's execution be deleted. Secret redaction for running processes is hence especially sensitive to *label creep* and *over-tainting* failures. Second, many real-world programs targeted by cyber-attacks were not originally designed with information flow tracking support, and are often expressed in low-level, type-unsafe languages, such as C/C++. A suitable solution must be amenable to retrofitting such low-level, legacy software with annotations sufficient to distinguish non-secrets from secrets, and with efficient flow-tracking logic that does not impair performance.

Our approach builds upon the LLVM compiler's [31] DataFlow Sanatizer (DFSan) infrastructure [18], which adds byte-granularity taint-tracking support to C/C++ programs at compile-time. At the source level, DFSan's taint-tracking capabilities are purveyed as runtime data-classification, data-declassification, and taint-checking operations, which programmers add to their programs to identify secrets and curtail their flow at runtime. Unfortunately, straightforward use of this interface for redaction of large, complex legacy codes can lead to severe over-tainting, or requires an unreasonably detailed retooling of the code with copious classification operations. This is unsafe, since missing even one of these classification points during retooling risks disclosing secrets to adversaries.

To overcome these deficiencies, we augment DFSan with a declarative, type annotation-based secret-labeling mechanism for easier secret identification; and we introduce a new label propagation semantics, called *Pointer Conditional-Combine Semantics* (PC^{2}S), that efficiently distinguishes secret data within C-style graph data structures from the non-secret structure that houses the data. This partitioning of the bytes greatly reduces over-tainting and the programmer's annotation burden, and proves critical for precisely redacting secret process data whilst preserving process operation after redaction.

Our innovations are showcased through the development of a taint tracking-based honey-patching framework for three production web servers, including the popular Apache HTTP server (∼2.2M SLOC). The modified servers respond to detected intrusions by transparently forking attacker sessions to unpatched process clones in confined decoy environments. Runtime redaction preserves attacker session data without preserving data owned by other users, yielding a deceptive process that continues servicing the attacker without divulging secrets. The decoy can then monitor attacker strategies, harvest attack data, and disinform the attacker with honey-data in the form of false files or process data.

Our contributions can be summarized as follows:

- We introduce a pointer tainting methodology through which secret sources are derived from statically annotated data structures, lifting the burden of identifying classification code-points in legacy C code.
- We propose and formalize taint propagation semantics that accurately track secrets while controlling taint spread. Our solution is implemented as a small extension to LLVM, allowing it to be applied to a large class of COTS applications.
- We implement a memory redactor for secure honey-patching. Evaluation shows that our implementation is both more efficient and more secure than previous pattern-matching based redaction approaches.
- Implementations and evaluations for three production web servers demonstrate that the approach is feasible for large-scale, performance-critical software with reasonable overheads.

Listing 1: Apache's URI parser function (excerpt)

```
1  /* first colon delimits username:password */
2  s1 = memchr(hostinfo, ':', s − hostinfo);
3  if (s1) {
4    uptr−>user = apr_pstrmemdup(p, hostinfo, s1 − hostinfo);
5    ++s1;
6    uptr−>password = apr_pstrmemdup(p, s1, s − s1);
7  }
```

2 Approach Overview

We first outline practical limitations of traditional dynamic taint-tracking for analyzing dataflows in server applications, motivating our research. We then overview our approach and its application to the problem of redacting secrets from runtime process memory images.

2.1 Dynamic Taint Analysis

Dynamic taint analyses enforce *taint policies*, which specify how data confidentiality and integrity classifications (*taints*) are introduced, propagated, and checked as a program executes. *Taint introduction* rules specify taint sources—typically a subset of program inputs. *Taint propagation* rules define how taints flow. For example, the result of summing tainted values might be a sum labeled with the union (or more generally, the *lattice join*) of the taints of the summands. *Taint checking* is the process of reading taints associated with data, usually to enforce an information security policy. Taints are usually checked at data usage or disclosure points, called *sinks*.

Extending taint-tracking to low-level, legacy code not designed with taint-tracking in mind is often difficult. For example, the standard approach of specifying taint introductions as annotated program inputs often proves too coarse for inputs comprising low-level, unstructured data streams, such as network sockets. Listing 1 exemplifies the problem using a code excerpt from the Apache web server [1]. The excerpt partitions a byte stream (stored in buffer `s1`) into a non-secret user name and a secret password, delimited by a colon character. Naïvely labeling input `s1` as secret to secure the password over-taints the user name (and the colon delimiter, and the rest of the stream), leading to excessive label creep—everything associated with the stream becomes secret, with the result that nothing can be safely divulged.

A correct solution must more precisely identify data field `uptr->password` (but not `uptr->user`) as secret after the unstructured data has been parsed. This is achieved in DFSan by manually inserting a runtime classification operation after line 6. However, on a larger scale this brute-force labeling strategy imposes a dangerously heavy annotation burden on developers, who must manually locate all such classification points. In C/C++ programs littered with pointer arithmetic, the correct classification points can often be obscure. Inadvertently omitting even one classification risks information leaks.

2.2 Sourcing & Tracking Secrets

To ease this burden, we introduce a mechanism whereby developers can identify secret-storing structures and fields *declaratively* rather than operationally. For example, to correctly label the password in Listing 1 as secret, users of our system may add type qualifier SECRET_STR to the password field's declaration in its abstract datatype definition. Our modified LLVM compiler responds to this static annotation by dynamically tainting all values assigned to the password field. Since datatypes typically have a single point of definition (in contrast to the many code points that access them), this greatly reduces the annotation burden imposed upon code maintainers.

In cases where the appropriate taint is not statically known (e.g., if each password requires a different, user-specific taint label), parameterized type-qualifier SECRET$\langle f \rangle$ identifies a user-implemented function f that computes the appropriate taint label at runtime.

Unlike traditional taint introduction semantics, which label program input values and sources with taints, recognizing structure fields as taint sources requires a new form of taint semantics that conceptually interprets dynamically identified *memory addresses* as taint sources. For example, a program that assigns address &(uptr->password) to pointer variable p, and then assigns a freshly allocated memory address to $*p$, must automatically identify the freshly allocated memory as a new taint source, and thereafter taint any values stored at $*p[i]$ (for all indexes i).

To achieve this, we leverage and extend DFSan's *pointer-combine semantics (PCS)* feature, which optionally combines (i.e., joins) the taints of pointers and pointees during pointer dereferences. Specifically, when *PCS on-load* is enabled, read-operation $*p$ yields a value tainted with the join of pointer p's taint and the taint of the value to which p points; and when *PCS on-store* is enabled, write-operation $*p := e$ taints the value stored into $*p$ with the join of p's and e's taints. Using PCS leads to a natural encoding of SECRET annotations as pointer taints. Continuing the previous example, PCS propagates uptr->password's taint to p, and subsequent dereferencing assignments propagate the two pointers' taints to secrets stored at their destinations.

PCS works well when secrets are always separated from the structures that house them by a level of pointer indirection, as in the example above (where uptr->password is a pointer to the secret rather than the secret itself). However, label creep difficulties arise when structures mix secret values with non-secret pointers. To illustrate, consider a simple linked list ℓ of secret integers, where each integer has a different taint. In order for PCS on-store to correctly classify values stored to ℓ->secret_int, pointer ℓ must have taint γ_1, where γ_1 is the desired taint of the first integer. But this causes stores to ℓ->next to incorrectly propagate taint γ_1 to the node's next-pointer, which propagates γ_1 to subsequent nodes when dereferenced. In the worst case, all nodes become labeled with all taints. Such issues have spotlighted effective pointer tainting as a significant challenge in the taint-tracking literature [17, 27, 40, 43].

Listing 2: Abbreviated Apache's session record struct

```
typedef struct {
    NONSECRET apr_pool_t *pool;
    NONSECRET apr_uuid_t *uuid;
    SECRET_STR const char *remote_user;
    apr_table_t *entries;
    ...
} SECRET session_rec;
```

To address this shortcoming, we introduce a new, generalized PC^{2}S semantics that augments PCS with pointer-combine *exemptions* conditional upon the static type of the pointee. In particular, a PC^{2}S taint-propagation policy may dictate that taint labels are not combined when the pointee has pointer type. Hence, ℓ->secret_int receives ℓ's taint because the assigned expression has integer type, whereas ℓ's taint is *not* propagated to ℓ->next because the latter's assigned expression has pointer type. We find that just a few strategically selected exemption rules expressed using this refined semantics suffices to vastly reduce label creep while correctly tracking all secrets in large legacy source codes.

In order to strike an acceptable balance between security and usability, our solution only automates tainting of C/C++ style structures whose non-pointer fields share a common taint. Non-pointer fields of mixed taintedness within a single struct are not supported automatically because C programs routinely use pointer arithmetic to reference multiple fields in a struct via a common pointer (imparting the pointer's taint to all the struct's non-pointer fields). Our work therefore targets the common case in which the taint policy is expressible at the granularity of structures, with exemptions for fields that point to other (differently tainted) structure instances. This corresponds to the usual scenario where a non-secret graph structure (e.g., a tree) stores secret data in its nodes.

Users of our system label structure datatypes as SECRET (implicitly introducing a taint to all fields within the structure), and additionally annotate pointer fields as NONSECRET to exempt their taints from pointer-combines during dereferences. Pointers to dynamic-length, null-terminated secrets get annotation SECRET_STR. For example, Listing 2 illustrates the annotation of session_req, used by Apache to store remote users' session data. Finer-granularity policies remain enforceable, but require manual instrumentation via DFSan's API, to precisely distinguish which of the code's pointer dereference operations propagate pointer taints. Our solution thus complements existing approaches.

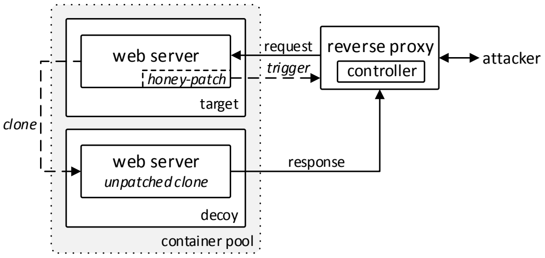

Figure 1: Architectural overview of honey-patching.

2.3 Application Study: Honey-Patching

Our discoveries are applied to realize practical, efficient honey-patching of legacy web servers for attacker deception. Typical software security patches fix newly discovered vulnerabilities at the price of advertising to attackers which systems have been patched. Cyber-criminals therefore easily probe today's Internet for vulnerable software, allowing them to focus their attacks on susceptible targets.

Honey-patching, depicted in Figure 1, is a recent strategy for frustrating such attacks. In response to malicious inputs, honey-patched applications clone the attacker session onto a confined, ephemeral, decoy environment, which behaves henceforth as an unpatched, vulnerable version of the software. This potentially augments the server with an embedded honeypot that waylays, monitors, and disinforms criminals.

Highly efficient cloning is critical for such architectures, since response delays risk alerting attackers to the deception. The cloning process must therefore rapidly locate and redact all secrets from the process address space, yielding a runnable process with only the attacker's session data preserved. Moreover, redaction must not be overly conservative. If redaction crashes the clone with high probability, or redacts obvious non-secrets, this too alerts the attacker. To our knowledge, no prior taint-tracking approach satisfies all of these demanding performance, precision, and legacy-maintainability requirements. We therefore select honey-patching of Apache as our flagship case-study.

3 Formal Semantics

For explanatory precision, we formally define our new taint-tracking semantics in terms of the simple, typed intermediate language (IL) in Figure 2, inspired by prior work [40]. The simplified IL abstracts irrelevant details of LLVM's IR language, capturing only those features needed to formalize our analysis.

3.1 Language Syntax

Programs $\mathcal{P}$ are lists of commands, denoted $\overline{c}$. Commands consist of variable assignments, pointer-dereferencing assignments (stores), conditional branches, function invocations, and function returns. Expressions evaluate to value-taint pairs $\langle u, \gamma \rangle$, where u ranges over typical value representations, and γ is the taint label associated with u. Labels denote sets of taints; they therefore comprise a lattice ordered by subset ($\sqsubseteq$), with the empty set $\bot$ at the bottom (denoting public data), and the universe $\top$ of all taints at the top (denoting maximally secret data). Join operation $\sqcup$ denotes least upper bound.

$$\begin{array}{ll}
\textit{programs} & \mathcal{P} ::= \overline{c} \\
\textit{commands} & c ::= v{:=}e \mid \texttt{store}(\tau, e_1, e_2) \mid \texttt{ret}(\tau,\ e) \\
 & \quad \mid \texttt{call}(\tau, e, \overline{args}) \mid \texttt{br}(e, e_1, e_0) \\
\textit{expressions} & e ::= v \mid \langle u, \gamma \rangle \mid \Diamond_b(\tau, e_1, e_2) \mid \texttt{load}(\tau, e) \\
\textit{binary ops} & \Diamond_b ::= \text{typical binary operators} \\
\textit{variables} & v \\
\textit{values} & u ::= \text{values of underlying IR language} \\
\textit{types} & \tau ::= \mathit{ptr}\ \tau \mid \tau\ \overline{\tau} \mid \text{primitive types} \\
\textit{taint labels} & \gamma \in (\Gamma, \sqsubseteq) \quad \text{(label lattice)} \\
 & \\
\textit{locations} & \ell ::= \text{memory addresses} \\
\textit{environment} & \Delta : v \rightharpoonup u \\
\textit{prog counter} & pc \\
\textit{stores} & \sigma : (\ell \rightharpoonup u) \cup (v \rightharpoonup \ell) \\
\textit{functions} & f \\
\textit{function table} & \phi : f \rightharpoonup \ell \\
\textit{taint contexts} & \lambda : (\ell \cup v) \rightharpoonup \gamma \\
\textit{propagation} & \rho : \overline{\gamma} \to \gamma \\
\textit{prop contexts} & \mathcal{A} : f \to \rho \\
\textit{call stack} & \Xi ::= \mathit{nil} \mid \langle f,\ pc,\ \Delta,\ \overline{\gamma} \rangle :: \Xi
\end{array}$$

Figure 2: Intermediate representation syntax.

Variable names range over identifiers and function names, and the type system supports pointer types, function types, and typical primitive types. Since DFSan's taint-tracking is dynamic, we here omit a formal static semantics and assume that programs are well-typed.

Execution contexts are comprised of a store σ relating locations to values and variables to locations, an environment Δ mapping variables to values, and a tainting context λ mapping locations and variables to taint labels. Additionally, to express the semantics of label propagation for external function calls (e.g., runtime library API calls), we include a function table ϕ that maps external function names to their entry points, a propagation context $\mathcal{A}$ that dictates whether and how each external function propagates its argument labels to its return value label, and the call stack Ξ. Taint propagation policies returned by $\mathcal{A}$ are expressed as customizable mappings ρ from argument labels $\overline{\gamma}$ to return labels γ.

$$\frac{}{\sigma, \Delta, \lambda \vdash u \Downarrow \langle u, \bot \rangle}\;\textsc{Val} \qquad \frac{}{\sigma, \Delta, \lambda \vdash v \Downarrow \langle \Delta(v), \lambda(v) \rangle}\;\textsc{Var}$$

$$\frac{\sigma, \Delta, \lambda \vdash e_1 \Downarrow \langle u_1, \gamma_1 \rangle \quad \sigma, \Delta, \lambda \vdash e_2 \Downarrow \langle u_2, \gamma_2 \rangle}{\sigma, \Delta, \lambda \vdash \Diamond_b(\tau,\ e_1,\ e_2) \Downarrow \langle u_1 \Diamond_b u_2, \gamma_1 \sqcup \gamma_2 \rangle}\;\textsc{BinOp} \qquad \frac{\sigma, \Delta, \lambda \vdash e \Downarrow \langle u, \gamma \rangle}{\sigma, \Delta, \lambda \vdash \texttt{load}(\tau,\ e) \Downarrow \langle \sigma(u), \rho_{load}(\tau, \gamma, \lambda(u)) \rangle}\;\textsc{Load}$$

$$\frac{\sigma, \Delta, \lambda \vdash e \Downarrow \langle u, \gamma \rangle \quad \Delta' = \Delta[v \mapsto u] \quad \lambda' = \lambda[v \mapsto \gamma]}{\langle \sigma, \Delta, \lambda, \Xi, pc, v := e \rangle \to_1 \langle \sigma, \Delta', \lambda', \Xi, pc + 1, \mathcal{P}[pc + 1] \rangle}\;\textsc{Assign}$$

$$\frac{\sigma, \Delta, \lambda \vdash e_1 \Downarrow \langle u_1, \gamma_1 \rangle \quad \sigma, \Delta, \lambda \vdash e_2 \Downarrow \langle u_2, \gamma_2 \rangle \quad \sigma' = \sigma[u_1 \mapsto u_2] \quad \lambda' = \lambda[u_1 \mapsto \rho_{store}(\tau, \gamma_1, \gamma_2)]}{\langle \sigma, \Delta, \lambda, \Xi, pc, \texttt{store}(\tau, e_1, e_2) \rangle \to_1 \langle \sigma', \Delta, \lambda', \Xi, pc + 1, \mathcal{P}[pc + 1] \rangle}\;\textsc{Store}$$

$$\frac{\sigma, \Delta, \lambda \vdash e \Downarrow \langle u, \gamma \rangle \quad fr = \langle f, pc', \Delta', \overline{\gamma} \rangle \quad \lambda' = \lambda[v_{ret} \mapsto \mathcal{A}\, f\, \overline{\gamma}]}{\langle \sigma, \Delta, \lambda, fr :: \Xi, pc, \texttt{ret}(\tau, e) \rangle \to_1 \langle \sigma, \Delta'[v_{ret} \mapsto u], \lambda', \Xi, pc', \mathcal{P}[pc'] \rangle}\;\textsc{Ret}$$

Figure 3: Operational semantics of a generalized label propagation semantics.

3.2 Operational Semantics

Figure 3 presents an operational semantics defining how taint labels propagate in an instrumented program. Expression judgments are large-step ($\Downarrow$), while command judgments are small-step ($\to_1$). At the IL level, expressions are pure and programs are non-reflective.

Abstract machine configurations consist of tuples $\langle \sigma, \Delta, \lambda, \Xi, pc, \iota \rangle$, where pc is the program pointer and ι is the current instruction. Notation $\Delta[v \mapsto u]$ denotes function Δ with v remapped to u, and notation $\mathcal{P}[pc]$ refers to the program instruction at address pc. For brevity, we omit $\mathcal{P}$ from machine configurations, since it is fixed.

Rule Val expresses the typical convention that hard-coded program constants are initially untainted ($\bot$). Binary operations are eager, and label their outputs with the join ($\sqcup$) of their operand labels.

The semantics of $\texttt{load}(\tau, e)$ read the value stored in location e, where the label associated with the loaded value is obtained by propagation function ρ_{load}. Dually, $\texttt{store}(\tau, e_1, e_2)$ stores e_2 into location e_1, updating λ according to ρ_{store}. In C programs, these model pointer dereferences and dereferencing assignments, respectively. Parameterizing these rules in terms of abstract propagation functions ρ_{load} and ρ_{store} allows us to instantiate them with customized propagation policies at compile-time, as detailed in §3.3.

External function calls $\texttt{call}(\tau, f, \overline{e_1 \cdots e_n})$ evaluate arguments $\overline{e_1 \cdots e_n}$, create a new stack frame fr, and jump to the callee's entry point. Returns then consult propagation context $\mathcal{A}$ to appropriately label the value returned by the function based on the labels of its arguments. Context $\mathcal{A}$ can be customized by the user to specify how labels propagate through external libraries compiled without taint-tracking support.

NCS	$\rho_{\{load,store\}}(\tau, \gamma_1, \gamma_2) := \gamma_2$
PCS	$\rho_{\{load,store\}}(\tau, \gamma_1, \gamma_2) := \gamma_1 \sqcup \gamma_2$
PC^{2}S	$\rho_{\{load,store\}}(\tau, \gamma_1, \gamma_2) := (\tau \text{ is } ptr)\ ?\ \gamma_2 : (\gamma_1 \sqcup \gamma_2)$

Figure 4: Polymorphic functions modeling no-combine, pointer-combine, and PC^{2}S label propagation policies.

3.3 Label Propagation Semantics

The operational semantics are parameterized by propagation functions ρ that can be instantiated to a specific propagation policy at compile-time. This provides a base framework through which we can study different propagation policies and their differing characteristics.

Figure 4 presents three polymorphic functions that can be used to instantiate propagation policies. On-load propagation policies instantiate ρ_{load}, while on-store policies instantiate ρ_{store}. The instantiations in Figure 4 define no-combine semantics (DFSan's on-store default), PCS (DFSan's on-load default), and our PC^{2}S extensions:

No-combine. The no-combine semantics (NCS) model a traditional, pointer-transparent propagation policy. Pointer labels are ignored during loads and stores, causing loaded and stored data retain their labels irrespective of the labels of the pointers being dereferenced.

Pointer-Combine Semantics. In contrast, PCS joins pointer labels with loaded and stored data labels during loads and stores. Using this policy, a value is tainted on-load (resp., on-store) if its source memory location (resp., source operand) is tainted or the pointer value dereferenced during the operation is tainted. If both are tainted with different labels, the labels are joined to obtain a new label that denotes the union of the originals.

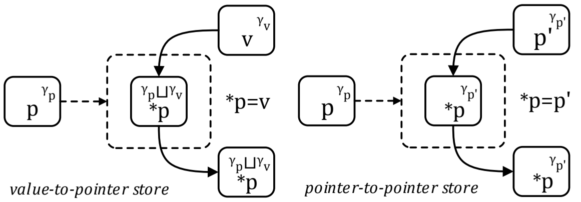

Figure 5: PC^{2}S propagation policy on store commands.

Pointer Conditional-Combine Semantics. PC^{2}S generalizes PCS by conditioning the label-join on the static type of the data operand. If the loaded/stored data has pointer type, it applies the NCS rule; otherwise, it applies the PCS rule. The resulting label propagation for stores is depicted in Figure 5.

This can be leveraged to obtain the best of both worlds. PC^{2}S pointer taints retain most of the advantages of PCS—they can identify and track aliases to birthplaces of secrets, such as data structures where secrets are stored immediately after parsing, and they automatically propagate their labels to data stored there. But PC^{2}S resists PCS's over-tainting and label creep problems by avoiding propagation of pointer labels through levels of pointer indirection, which usually encode relationships with other data whose labels must remain distinct and separately managed.

Condition (τ is ptr) in Figure 4 can be further generalized to any decidable proposition on static types τ. We use this feature to distinguish pointers that cross data ownership boundaries (e.g., pointers to other instances of the parent structure) from pointers that target value data (e.g., strings). The former receive NCS treatment by default to resist over-tainting, while the latter receive PCS treatment by default to capture secrets and keep the annotation burden low.

In addition, PC^{2}S is at least as efficient as PCS because propagation policy ρ is partially evaluated at compile-time. Thus, the choice of NCS or PCS semantics for each pointer operation is decided purely statically, conditional upon the static types of the operands. The appropriate specialized propagation implementation is then in-lined into the resulting object code during compilation.

Example. To illustrate how each semantics propagate taint, consider the IL pseudo-code in Listing 3, which revisits the linked-list example informally presented in §2.2. Input stream s includes a non-secret request identifier and a secret key of primitive type (e.g., unsigned long).

If one labels stream s secret, then the public $request\_id$ becomes over-tainted in all three semantics, which is undesirable because a redaction of $request\_id$ may crash the program (when $request\_id$ is later used as an array index). A better solution is to label pointer p secret and employ PCS, which correctly labels the key at the moment it is stored. However, PCS additionally taints the $next$-pointer, leading to over-tainting of all the nodes in the containing linked-list, some of which may contain keys owned by other users. PC^{2}S avoids this over-tainting by exempting the next pointer from the combine-semantics. This preserves the data structure while correctly labeling the secret data it contains.

Listing 3: IL pseudo-code for storing public ids and secret keys from an unstructured input stream into a linked list.

```
store(id, request_id, get(s, id_size));
store(key, p[request_id]->key, get (s, key_size));
store(ctx_t*, p[request_id]->next, queue_head);
```

4 Implementation

Figure 6 presents an architectural overview of our implementation, SignaC[1] (Secret Information Graph iNstrumentation for Annotated C). At a high level, the implementation consists of three components: (1) a source-to-source preprocessor, which (a) automatically propagates user-supplied, source-level type annotations to containing datatypes, and (b) in-lines taint introduction logic into dynamic memory allocation operations; (2) a modified LLVM compiler that instruments programs with PC^{2}S taint propagation logic during compilation; and (3) a runtime library that the instrumented code invokes during program execution to introduce taints and perform redaction. Each component is described below.

4.1 Source-Code Rewriting

Type attributes. Users first annotate data structures containing secrets with the type qualifier `SECRET`. This instructs the taint-tracker to treat all instantiations (e.g., dynamic allocations) of these structures as taint sources. Additionally, qualifier `NONSECRET` may be applied to pointer fields within these structures to exempt them from PCS. The instrumentation pass generates NCS logic instead for operations involving such members. Finally, qualifier `SECRET_STR` may be applied to pointer fields whose destinations are dynamic-length byte sequences bounded by a null terminator (strings).

To avoid augmenting the source language's grammar, these type qualifiers are defined using source-level attributes (specified with `_attribute_`) followed by a specifier. `SECRET` uses the `annotate` specifier, which defines a purely syntactic qualifier visible only at the compiler's front-end. In contrast, `NONSECRET` and `SECRET_STR` are required during the back-end instrumentation. To this end, we leverage Quala [39], which extends LLVM with an overlay type system. Quala's `type_annotate` specifier propagates the type qualifiers throughout the IL code.

[1] named after *pointillism* co-founder Paul Signac

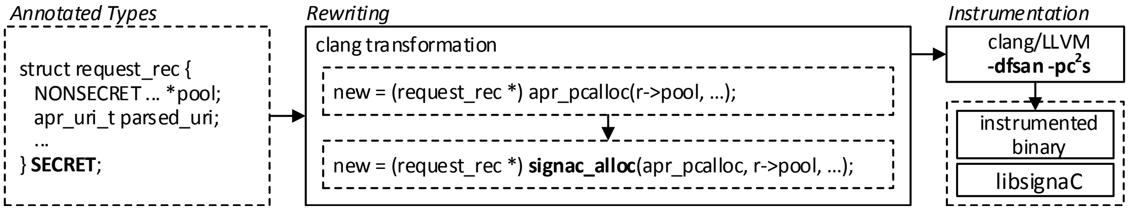

Figure 6: Architectural overview of SignaC illustrating its three-step, static instrumentation process: (1) annotation of security-relevant types, (2) source-code rewriting, and (3) compilation with the sanitizer's instrumentation pass.

Type attribute rewriting. In the preprocessing step, the target application undergoes a source-to-source transformation pass that rewrites all dynamic allocations of annotated data types with taint-introducing wrappers. Implementing this transformation at the source level allows us to utilize the full type information that is available at the compiler's front-end, including purely syntactic attributes such as `SECRET` annotations.

Our implementation leverages Clang's tooling API [12] to traverse and apply the desired transformations directly into the program's AST. At a high-level, the rewriting algorithm takes the following steps:

1. It first amasses a list of all *security-relevant datatypes*, which are defined as (a) all structs and unions annotated `SECRET`, (b) all types defined as aliases (e.g., via typedef) of security-relevant datatypes, and (c) all structs and unions containing secret-relevant datatypes not separated from the containing structure by a level of pointer indirection (e.g., nested struct definitions). This definition is recursive, so the list is computed iteratively from the transitive closure of the graph of datatype definition references.
2. It next finds all calls to memory allocation functions (e.g., malloc, calloc) whose return values are *explicitly* or *implicitly* cast to a security-relevant datatype. Such calls are wrapped in calls to SignaC's runtime library, which dynamically introduces an appropriate taint label to the newly allocated structure.

The task of identifying memory allocation functions is facilitated by a user-supplied list that specifies the memory allocation API. This allows the rewriter to handle programs that employ custom memory management. For example, Apache defines custom allocators in its Apache Portable Runtime (APR) memory management interface.

4.2 PC^{2}S Instrumentation

The instrumentation pass next introduces LLVM IR code during compilation that propagates taint labels during program execution. Our implementation extends DFSan with the PC^{2}S label propagation policy specified in §3.

Taint representation. To support a large number of taint labels, DFSan adopts a low-overhead representation of labels as 16-bit integers, with new labels allocated sequentially from a pool. Rather than reserving 2^n labels to represent the full power set of a set of n primitive taints, DFSan lazily reserves labels denoting non-singleton sets on-demand. When a label union operation is requested at a join point (e.g., during binary operations on tainted operands), the instrumentation first checks whether a new label is required. If a label denoting the union has already been reserved, or if one operand label subsumes the other, DFSan returns the already-reserved label; otherwise, it reserves a fresh union label from the label pool. The fresh label is defined by pointers to the two labels that were joined to form it. Union labels are thus organized as a dynamically growing binary DAG—the *union table*.

This strategy benefits applications whose label-joins are sparse, visiting only a small subset of the universe of possible labels. Our PC^{2}S semantics' curtailment of label creep thus synergizes with DFSan's lazy label allocation strategy, allowing us to realize taint-tracking for legacy code that otherwise exceeds the maximum label limit. This benefit is further evidenced in our evaluation (§5).

Table 1 shows the memory layout of an instrumented program. DFSan maps (without reserving) the lower 32 TB of the process address space for *shadow memory*, which stores the taint labels of the values stored at the corresponding application memory addresses. This layout allows for efficient lookup of shadow addresses by masking and shifting the application's addresses. Labels of values not stored in memory (e.g., those stored in machine registers or optimized away at compile-time) are tracked at the IL level in SSA registers, and compiled to suitable taint-tracking object code.

Function calls. Propagation context $\mathcal{A}$ defined in §3 models label propagation across external library function calls, expressed in DFSan as an Application Binary Interface (ABI). The ABI lists functions whose label-propagation

Table 1: Memory layout of an instrumented program.

Start	End	Memory Region
0x700000008000	0x800000000000	application memory
0x200000000000	0x200200000000	union table
0x000000010000	0x200000000000	shadow memory
0x000000000000	0x000000010000	reserved by kernel

behavior (if any) should be replaced with a fixed, user-defined propagation policy at call sites. For each such function, the ABI specifies how the labels of its arguments relate to the label of its return value.

DFSan natively supports three such semantics: (1) *discard*, which corresponds to propagation function $\rho_{\mathit{dis}}(\overline{\gamma}) := \bot$ (return value is unlabeled); (2) *functional*, corresponding to propagation function $\rho_{\mathit{fun}}(\overline{\gamma}) := \bigsqcup\overline{\gamma}$ (label of return value is the union of labels of the function arguments); and (3) *custom*, denoting a custom-defined label propagation wrapper function.

DFSan pre-defines an ABI list that covers glibc's interface. Users may extend this with the API functions of external libraries for which source code is not available or cannot be instrumented. For example, to instrument Apache with `mod_ssl`, we mapped OpenSSL's API functions to the ABI list. In addition, we extended the custom ABI wrappers of *memory transfer functions* (e.g., `strcpy`, `strdup`) and *input functions* (e.g., `read`, `pread`) to implement PC^{2}S. For instance, we modified the wrapper for `strcpy(`$dest$`,`src`)` to taint $dest$ with $\gamma_{src} \sqcup \gamma_{dest}$ when instrumenting code under PC^{2}S.

Static instrumentation. The instrumentation pass is placed at the end of LLVM's optimization pipeline. This ensures that only memory accesses surviving all compiler optimizations are instrumented, and that instrumentation takes place just before target code is generated. Like other LLVM *transform* passes, the program transformation operates on LLVM IR, traversing the entire program to insert label propagation code. At the front-end, compilation flags parametrize the label propagation policies for the store and load operations discussed in §3.3.

String handling. Strings in C are not first-class types; they are implemented as character pointers. C's type system does not track their lengths or enforce proper termination. This means that purely static typing information is insufficient for the instrumentation to reliably identify strings or propagate their taints to all constituent bytes on store. To overcome this problem, users must annotate secret-containing, string fields with `SECRET_STR`. This cues the runtime library to taint up to and including the pointee's null terminator when a string is assigned to such a field. For safety, our runtime library (see §4.3) zeros the first byte of all fresh memory allocations, so that uninitialized strings are always null-terminated.

Store instructions. Listing 4 summarizes the instrumentation procedure for stores in diff style. By default, DFSan instruments NCS on store instructions: it reads the shadow memory of the value operand (line 1) and copies it onto the shadow of the pointer operand (line 10). If PC^{2}S is enabled (lines 2 and 11), the instrumentation consults the static type of the value operand and checks whether it is a non-pointer or non-exempt pointer field (which also subsumes `SECRET_STR`) in lines 3–4. If so, the shadows of the pointer and value operands are joined (lines 5–6), and the resulting label is stored into the shadow of the pointer operand. If the instruction stores a string annotated with `SECRET_STR`, the instrumentation calls a runtime library function that copies the computed shadow to all bytes of the null-terminated string (lines 12–15).

Listing 4: Store instruction instrumentation

```
 1     Value* Shadow = DFSF.getShadow(SI.getValueOperand());
 2  +  if (Cl_PC2S_OnStore) {
 3  +    Type *t = SI.getValueOperand()->getType();
 4  +    if (!t->isPointerTy() || !isExemptPtr(&SI)) {
 5  +      Value *PtrShadow = DFSF.getShadow(SI.getPointerOperand());
 6  +      Shadow = DFSF.combineShadows(Shadow, PtrShadow, &SI);
 7  +    }
 8  +  }
 9     ...
10     DFSF.storeShadow(SI.getPointerOperand(), Size, Align, Shadow, &SI);
11  +  if (Cl_PC2S_OnStore) {
12  +    if (isSecretStr(&SI)) {
13  +      Value *Str = IRB.CreateBitCast(v, Type::getInt8PtrTy(Ctx));
14  +      IRB.CreateCall2(DFSF.DFS.DFSanSetLabelStrFn, Shadow, Str);
15  +    }
16  +  }
```

Listing 5: Load instruction instrumentation

```
1    Value *Shadow = DFSF.loadShadow(LI.getPointerOperand(), Size, ...);
2  + if (Cl_PC2S_OnLoad) {
3  +   if (!isExemptPtr(&LI)) {
4  +     Value *PtrShadow = DFSF.getShadow(LI.getPointerOperand());
5  +     Shadow = DFSF.combineShadows(Shadow, PtrShadow, &LI);
6  +   }
7  + }
8    ...
9    DFSF.setShadow(&LI, Shadow);
```

Load instructions. Listing 5 summarizes the analogous instrumentation for load instructions. First, the instrumentation loads the shadow of the value pointed by the pointer operand (line 1). If PC^{2}S is enabled (line 2), then the instrumentation checks whether the dereferenced pointer is tainted (line 3). If so, the shadow of the pointer operand is joined with the shadow of its value (lines 4–5), and the resulting label is saved to the shadow (line 9).

Memory transfer intrinsics. LLVM defines intrinsics for standard memory transfer operations, such as `memcpy` and `memmove`. These functions accept a source pointer src, a destination pointer dst, and the number of bytes len to be transferred. DFSan's default instrumentation destructively copies the shadow associated with src to the shadow of dst, which is not the intended propagation policy of PC^{2}S. We therefore instrument these functions as shown in Listing 6. The instrumentation reads the shadows of src and dst (lines 2–3), computes the union of the two shadows (line 4), and stores the combined shadows to the shadow of dst (line 5).

4.3 Runtime Library

Runtime support for the type annotation mechanism is encapsulated in a tiny C library, allowing for low coupling

Listing 6: Memory transfer intrinsics instrumentation

```
+ if (Cl_PC2S_OnStore && !isExemptPtr(&I)) {
+   Value *DestShadow = DFSF.getShadow(I.getDest());
+   Value *SrcShadow = DFSF.getShadow(I.getSource());
+   DestShadow = DFSF.combineShadows(SrcShadow, DestShadow, &I);
+   DFSF.storeShadow(I.getDest(), Size, Align, DestShadow, &I);
+ }
```

Listing 7: Taint-introducing memory allocations

```
1  #define signac_alloc(alloc, args...) ({ \
2    void *__p = alloc ( args ); \
3    signac_taint(&__p, sizeof(void*)); \
4    __p; })
```

between a target application and the sanitizer's logic. The source-to-source rewriter and instrumentation phases inline logic that calls this library at runtime to introduce taints, handle special taint-propagation cases (e.g., string support), and check taints at sinks (e.g., during redaction). The library exposes three API functions:

- `signac_init(`pl`)`: initialize a tainting context with a fresh label instantiation pl for the current principal.
- `signac_taint(`$addr$`,`$size$`)`: taint each address in interval $[addr, addr{+}size)$ with pl.
- `signac_alloc(`$alloc$`,...)`: wrap allocator $alloc$ and taint the address of its returned pointer with pl.

Function `signac_init` instantiates a fresh taint label and stores it in a thread-global context, which function f of annotation SECRET$\langle f \rangle$ may consult to identify the owning principal at taint-introduction points. In typical web server architectures, this function is strategically hooked at the start of a new connection's processing cycle. Function `signac_taint` sets the labels of each address in interval $[addr, addr{+}size)$ with the label pl retrieved from the session's context.

Listing 7 details `signac_alloc`, which wraps allocations of SECRET-annotated data structures. This variadic macro takes a memory allocation function *alloc* and its arguments, invokes it (line 2), and taints the address of the pointer returned by the allocator (line 3).

4.4 Apache Instrumentation

To instrument a particular server application, such as Apache, our approach requires two small, one-time developer interventions: First, add a call to `signac_init` at the start of a user session to initialize a new tainting context for the newly identified principal. Second, annotate the security-relevant data structures whose instances are to be tracked. For instance, in Apache, `signac_init` is called upon the acceptance of a new server connection, and annotated types include `request_rec`, `connection_rec`, `session_rec`, and `modssl_ctx_t`. These structures are where Apache stores URI parameters and request content information, private connection data such as remote IPs, key-value entries in user sessions, and encrypted connection information.

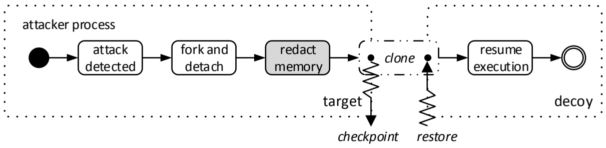

Figure 7: Honey-patch response to an intrusion attempt.

5 Evaluation

This section demonstrates the practical advantages and feasibility of our approach for retrofitting large legacy C codes with taint-tracking, through the development and evaluation of a honey-patching memory redaction architecture for three production web servers. All experiments were performed on a quad-core VM with 8 GB RAM running 64-bit Ubuntu 14.04. The host machine is an Intel Xeon E5645 workstation running 64-bit Windows 7.

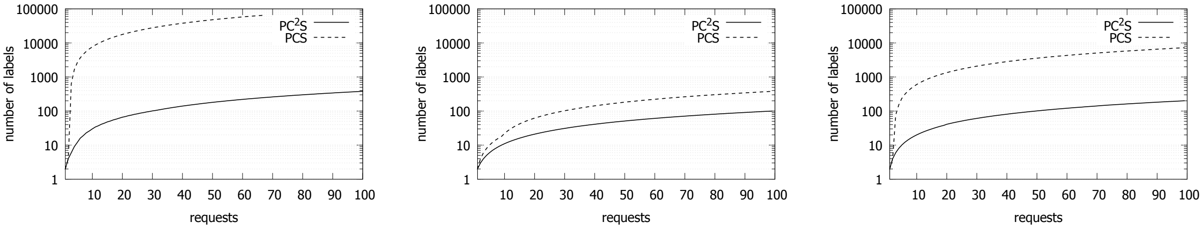
5.1 Honey-patching

Figure 7 illustrates how honey-patches respond to intrusions by cloning attacker sessions to decoys. Upon intrusion detection, the honey-patch forks a shallow, local clone of the victim process. The cloning step redacts all secrets from the clone's address space, optionally replacing them with honey-data. It then resumes execution in the decoy by emulating an unpatched implementation. This impersonates a successful intrusion, luring the attacker away from vulnerable victims, and offering defenders opportunities to monitor and disinform adversaries.

Prior honey-patches implement secret redaction as a brute-force memory sweep that identifies and replaces plaintext string secrets. This is both slow and unsafe; the sweep constitutes a majority of the response delay overhead during cloning [2], and it can miss binary data secrets difficult to express reliably as regular expressions. Using SignaC, we implemented an information flow-based redaction strategy for honey-patching that is faster and more reliable than prior approaches.

Our redaction scheme instruments the server with dynamic taint-tracking. At redaction time, it scans the resulting shadow memory for labels denoting secrets owned by user sessions other than the attacker's, and redacts such secrets. The shadow memory and taint-tracking libraries are then unloaded, leaving a decoy process that masquerades as undefended and vulnerable.

Evaluated software. We implemented taint tracking-based honey-patching for three production web servers: Apache, Nginx, and Lighttpd. Apache and Nginx are the top two servers of all active websites, with 50.1% and 14.8% market share, respectively [32]. Apache comprises 2.27M SLOC mostly in C [35]. Nginx and Lighttpd are smaller, having about 146K and 138K SLOC, respectively. All three are commercial-grade, feature-rich, open-source



(a) Apache

(b) Nginx

(c) Lighttpd

Figure 8: Experiment comparing label creeping behavior of PC^{2}S and PCS on Apache, Nginx, and Lighttpd.

software products without any built-in support for information flow tracking.

To augment these products with PC^{2}S-style taint-tracking support, we manually annotated secret-storing structures and pointer fields. Altogether, we added approximately 45, 30, and 25 such annotations to Apache, Nginx, and Lighttpd, respectively. For consistent evaluation comparisons, we only annotated Apache's core modules for serving static and dynamic content, encrypting connections, and storing session data; we omitted its optional modules. We also manually added about 20–30 SLOC to each server to initialize the taint-tracker. Considering the sizes and complexity of these products, we consider the PC^{2}S annotation burden exceptionally light relative to prior approaches.

5.2 Taint Spread

Over-tainting protection. To test our approach's resistance to taint explosions, we submitted a stream of (non keep-alive) requests to each instrumented web server, recording a cumulative tally of distinct labels instantiated during taint-tracking. Figure 8 plots the results, comparing traditional PCS to our PC^{2}S extensions. On Apache, traditional PCS is impractical, exceeding the maximum label limit in just 68 requests. In contrast, PC^{2}S instantiates vastly fewer labels (note that the y-axes are *logarithmic scale*). After extrapolation, we conclude that an average 16,384 requests are required to exceed the label limit under PC^{2}S—well above the standard 10K-request TTL limit for worker threads.

Taint spread control is equally critical for preserving program functionality after redaction. To demonstrate, we repeated the experiment with a simulated intrusion after $n \in [1, 100]$ legitimate requests. Figure 9 plots the cumulative tally of how many bytes received a taint during the history of the run on Apache. In all cases, redaction crashed PCS-instrumented processes cloned after just 2–3 legitimate requests (due to erasure of over-tainted bytes). In contrast, PC^{2}S-instrumented processes never crashed; their decoy clones continued running after redaction, impersonating vulnerable servers. This demonstrates our approach's facility to realize effective taint-tracking in legacy codes for which prior approaches fail.

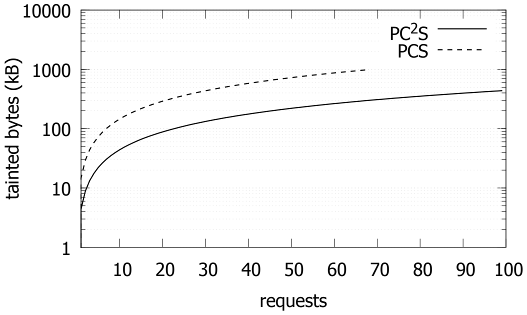


Figure 9: Cumulative tally of bytes tainted on Apache.

Table 2: Honey-patched security vulnerabilities

Software	Version	CVE-ID	Description
Bash[1]	4.3	CVE-2014-6271	Improper parsing of environment variables
OpenSSL[1]	1.0.1f	CVE-2014-0160	Buffer over-read in heartbeat protocol extension
Apache	2.2.21	CVE-2011-3368	Improper URL validation
Apache	2.2.9	CVE-2010-2791	Improper timeouts of keep-alive connections
Apache	2.2.15	CVE-2010-1452	Bad request handling
Apache	2.2.11	CVE-2009-1890	Request content length out of bounds
Apache	2.0.55	CVE-2005-3357	Bad SSL protocol check

[1] tested with Apache 2.4.6

Under-tainting protection. To double-check that PC^{2}S redaction was actually erasing all secrets, we created a workload of legitimate post requests with pre-seeded secrets to a web-form application. We then automated exploits of the honey-patched vulnerabilities listed in Table 2, including the famous Shellshock and Heartbleed vulnerabilities. For each exploit, we ran the legacy, brute-force memory sweep redactor after SignaC's redactor to confirm that the former finds no secrets missed by the latter. We also manually inspected memory dumps of each clone to confirm that none of the pre-seeded secrets

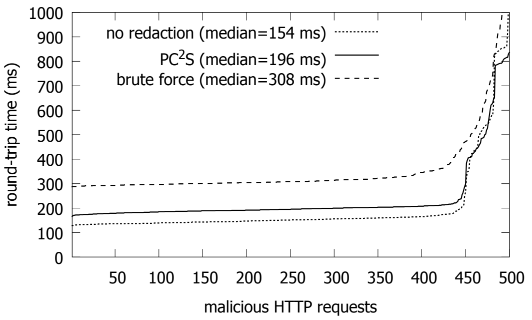

Figure 10: Request round-trip times for attacker session forking on honey-patched Apache.

survived. In all cases, the honey-patch responds to the exploits as a vulnerable decoy server devoid of secrets.

5.3 Performance

Redaction performance. To evaluate the performance overhead of redacting secrets, we benchmarked three honey-patched Apache deployments: (1) a baseline instance without memory redaction, (2) brute-force memory sweep redaction, and (3) our PC^{2}S redactor. We used Apache's server benchmarking tool (*ab*) to launch 500 malicious HTTP requests against each setup, each configured with a pool of 25 decoys.

Figure 10 shows request round-trip times for each deployment. PC^{2}S redaction is about $1.6\times$ faster than brute-force memory sweep redaction; the former's request times average 0.196s, while the latter's average 0.308s. This significant reduction in cloning delay considerably improves the technique's deceptiveness, making it more transparent to attackers. Nginx and Lighttpd also exhibit improved response times of 16% (0.165s down to 0.138s) and 21% (0.155s down to 0.122s), respectively.

Taint-tracking performance. To evaluate the performance overhead of the static instrumentation, three Apache setups were tested: a static-content HTML website ($\sim$20 KB page size), a CGI-based Bash application that returns the server's environment variables, and a dynamic PHP website displaying the server's configuration. For each web server setup, *ab* was executed with four concurrency levels c (i.e., the number of parallel threads). Each run comprises 500 concurrent requests, plotted in ascendant order of their round-trip times (RTT).

Figure 11 shows the results for $c = 1, 10, 50$, and 100, and the average overheads observed for each test profile are summarized in Table 3. Our measurements show overheads of $2.4\times$, $1.1\times$, and $0.3\times$ for the static-content, CGI, and PHP websites, respectively, which is consistent with dynamic taint-tracking overheads reported in the prior literature [41]. Since server computation accounts for only about 10% of overall web site response delay in practice [44], this corresponds to observable overheads of about 24%, 11%, and 3% (respectively).

Table 3: Average overhead of instrumentation

Benchmark	$c = 1$	$c = 10$	$c = 50$	$c = 100$
Static	2.50	2.34	2.56	2.32
CGI Bash	1.29	0.98	1.00	0.97
PHP	0.41	0.37	0.30	0.31

While such overhead characterizes feasibility, it is irrelevant to deception because unpatched, patched, and honey-patched vulnerabilities are all slowed equally by the taint-tracking instrumentation. The overhead therefore does not reveal which apparent vulnerabilities in a given server instance are genuine patching lapses and which are deceptions, and it does not distinguish honey-patched servers from servers that are slowed by any number of other factors (e.g., fewer computational resources). In addition, it is encouraging that high relative overheads were observed primarily for static websites that perform little or no significant computation. This suggests that the more modest 3% overhead for computationally heavier PHP sites is more representative of servers for which computational performance is an issue.

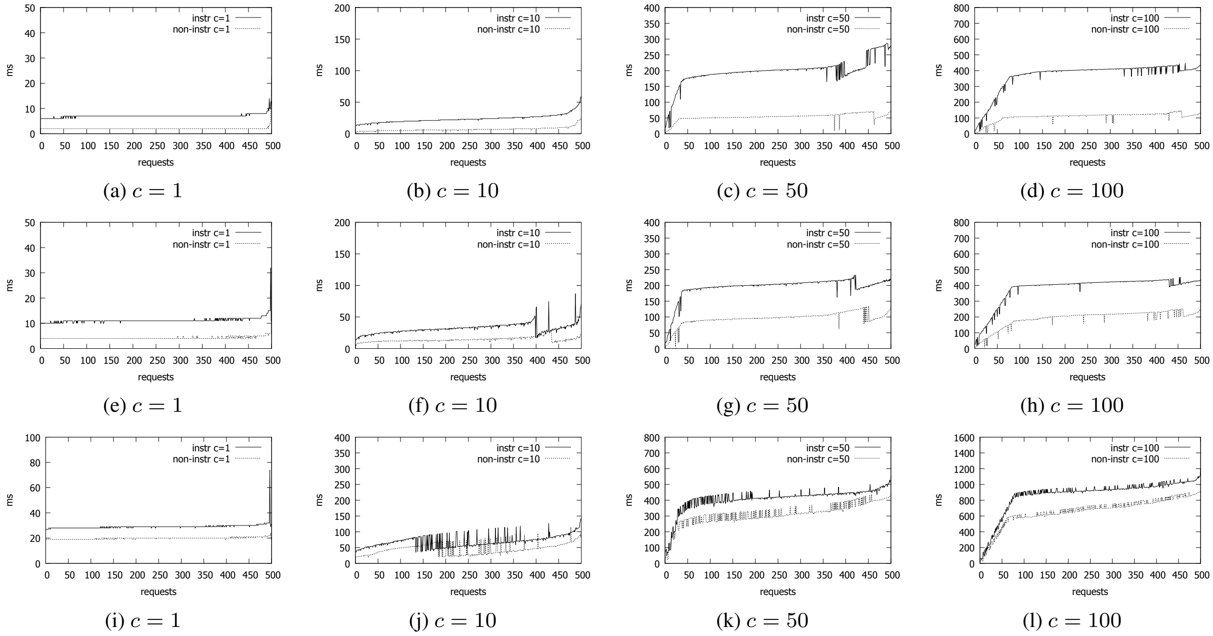
6 Discussion

6.1 Approach Limitations

Our research significantly eases the task of tracking secrets within standard, pointer-linked, graph data-structures as they are typically implemented in low-level languages, like C/C++. However, there are many non-standard, low-level programming paradigms that our approach does not fully support automatically. Such limitations are discussed below.

Pointer Pre-aliases. PC^{2}S fully tracks all pointer aliases via taint propagation starting from the point of taint-introduction (e.g., the code point where a secret is first assigned to an annotated structure field after parsing). However, if the taint-introduction policy misidentifies secret sources too late in the program flow, dynamic tracking cannot track pointer *pre-aliases*—aliases that predate the taint-introduction. For example, if a program first initializes string p_1, then aliases $p_2 := p_1$, and finally initializes secret-annotated field f via $f := p_1$, PC^{2}S automatically labels p_1 (and f) but not pre-alias p_2.

In most cases this mislabeling of pre-aliases can be mitigated by enabling PC^{2}S both on-load and on-store. This causes secrets stored via p_2 to receive the correct label on-load when they are later read via p_1 or f. Likewise, secrets read via p_2 retain the correct label if they were earlier stored via p_1 or f. Thus, only data stored *and* read purely using independent pre-alias p_2 remain untainted.



(a) $c = 1$ (b) $c = 10$ (c) $c = 50$ (d) $c = 100$

(e) $c = 1$ (f) $c = 10$ (g) $c = 50$ (h) $c = 100$

(i) $c = 1$ (j) $c = 10$ (k) $c = 50$ (l) $c = 100$

Figure 11: Dynamic taint-tracking performance (measured in request round-trip times) with varying concurrency c for a static web site (a–d), Bash CGI application (e–h), and PHP application (i–l).

This is a correct enforcement of the user's policy, since the policy identifies $f := p_1$ as the taint source, not p_2. If this treatment is not desired, the user must therefore specify a more precise policy that identifies the earlier origin of p_1 as the true taint source (e.g., by manually inserting a dynamic classification operation where p_1 is born), rather than identifying f as the taint source.

Structure granularity. Our automation of taint-tracking for graph data-structures implemented in low-level languages leads to taint annotations at the granularity of whole struct declarations, not individual value fields. Thus, all non-pointer fields within a secret-annotated C struct receive a common taint under our semantics. This coarse granularity is appropriate for C programs since such programs can (and often do) refer to multiple data fields within a given struct instance using a common pointer. For example, *marshalling* is typically implemented as a pointer-walk that reads a byte stream directly into all data fields (but not the pointer fields) of a struct instance byte-by-byte. All data fields therefore receive a common label after marshalling.

Reliable support for structs containing secrets of mixed taint therefore requires a finer-grained taint-introduction policy than is expressible by declarative annotations of C structure definitions. Such policies must be operationally specified in C through runtime classifications at secret-introducing code points. Our focus in this research is on automating the much more common case where each node of the graph structure holds secrets of uniform classification, toward lifting the user's annotation burden for this most common case.

Dynamic-length secrets. Our implementation provides built-in support for a particularly common form of dynamic-length secret—null-terminated strings. This can be extended to support other forms of dynamic-length secrets as needed. For example, strings with an explicit length count rather than a terminator, fat and bounded pointers [26], and other variable-length, dynamically allocated, data structures can be supported through the addition of an appropriate annotation type and a dynamic taint-propagating function that extends pointer taints to the entire pointee during assignments.

Implicit Flows. Our dynamic taint-tracking tracks explicit information flows, but not implicit flows that disclose information through control-flows rather than dataflows. Tracking implicit flows generally requires static information flow analysis to reason about disclosures through inaction (non-observed control-flows) rather than merely actions. Such analysis is often intractable (and generally undecidable) for low-level languages like C, whose control-flows include unstructured and dynamically computed transitions.

Likewise, dynamic taint-tracking does not monitor side-channels, such as resource consumption (e.g., memory or power consumption), runtimes, or program termination, which can also divulge information. For our problem domain (program process redaction), such channels are largely irrelevant, since attackers may only exfiltrate information after redaction, which leaves no secrets for the attacker to glean, directly or indirectly.

6.2 Process Memory Redaction

Our research introduces live process memory image sanitization as a new problem domain for information flow analysis. Process memory redaction raises unique challenges relative to prior information flow applications. It is exceptionally sensitive to over-tainting and label creep, since it must preserve process execution (e.g., for process debugging, continued service availability, or attacker deception); it demands exceptionally high performance; and its security applications prominently involve large, low-level, legacy codes, which are the most frequent victims of cyber-attacks. Future work should expand the search for solutions to this difficult problem to consider the suitability of other information flow technologies, such as static type-based analyses.

6.3 Language Compatibility

While our implementation targets one particularly ubiquitous source language (C/C++), our general approach is applicable to other similarly low-level languages, as well as scripting languages whose interpreters are implemented in C (e.g., PHP, Bash). Such languages are common choices for implementing web services, and targeting them is therefore a natural next step for the web security thrust of our research.

7 Related Work

Dynamic tracking of in-memory secrets. Dynamic taint-tracking lends itself as a natural technique for tracking secrets in software. It has been applied to study sensitive data lifetime (i.e., propagation and duration in memory) in commodity applications [10, 11], analyze spyware behavior [19, 48], and impede the propagation of secrets to unauthorized sinks [21, 23, 49].

TaintBochs [10] uses whole-system simulation to understand secret propagation patterns in several large, widely deployed applications, including Apache, and implements *secure deallocation* [11] to reduce the risk of exposure of in-memory secrets. Panorama [48] builds a system-level information-flow graph using process emulation to identify malicious software tampering with information that was not intended for their consumption. Egele et al. [19] also utilize whole-system dynamic tainting to analyze spyware behavior in web browser components. While valuable, the performance impact of whole-system analyses—often on the order of 2000% [10, 19, 48]—remains a significant obstacle, rendering such approaches impractical for most live, high-performance, production server applications.

More recently, there has been growing interest in runtime detection of information leaks [21, 49]. For instance, TaintDroid [21] extends Android's virtualized architecture with taint-tracking support to detect misuses of users' private information across mobile apps. TaintEraser [49] uses dynamic instrumentation to apply taint analysis on binaries for the purpose of identifying and blocking information leaking to restricted output channels. To achieve this, it monitors and rewrites sensitive bytes escaping to the network and the local file system. Our work adopts a different strategy to instrument secret-redaction support into programs, resulting in applications that can proactively respond to attacks by self-censoring their address spaces with minimal overhead.

Pointer taintedness. In security contexts, many categories of widely exploited, memory-overwrite vulnerabilities (e.g., format string, memory corruption, buffer overflow) have been recognized as detectable by dynamic taint-checking on pointer dereferences [7, 8, 15, 16, 28]. Hookfinder [47] employs data and pointer tainting semantics in a full-system emulation approach to identify malware hooking behaviors in victim systems. Other systems follow a similar technique to capture system-wide information-flow and detect privacy-breaching malware [19, 48].

With this high practical utility come numerous theoretical and practical challenges for effective pointer tainting [17, 27, 43]. On the theoretical side, there are varied views of how to interpret a pointer's label. (Does it express a property of the pointer value, the values it points to, values read or stored by dereferencing the pointer, or all three?) Different taint tracking application contexts solicit differing interpretations, and the differing interpretations lead to differing taint-tracking methodologies. Our contributions include a pointer tainting methodology that is conducive to tracking in-memory secrets.

On the practical side, imprudent pointer tainting often leads to taint explosion in the form of over-tainting or label-creep [40, 43]. This can impair the feasibility of the analysis and increase the likelihood of crashes in programs that implement data-rewriting policies [49]. To help overcome this, sophisticated strategies involving pointer injection (PI) analysis have been proposed [16, 28]. PI uses a taint bit to track the flow of legitimate pointers and another bit to track the flow of untrusted data, disallowing dereferences of tainted values that do not have a corresponding pointer tainted. Our approach uses static typing information in lieu of PI bits to achieve lower runtime overheads and broader compatibility with low-level legacy code.

Application-level instrumentation. Much of the prior work on dynamic taint analysis has employed dynamic binary instrumentation (DBI) frameworks [9,13,29,33,38,49] to enforce taint-tracking policies on software. These approaches do not require application recompilation, nor do they depend on source code information.

However, despite many optimization advances over the years, dynamic instrumentation still suffers from significant performance overheads, and therefore cannot support high-performance applications, such as the redaction speeds required for attacker-deceiving honey-patching of production server code. Our work benefits from research advances on static-instrumented, dynamic data flow analysis [6, 18, 30, 46] to achieve both high performance and high accuracy by leveraging LLVM's compilation infrastructure to instrument taint-propagating code into server code binaries.

8 Conclusion

PC^{2}S significantly improves the feasibility of dynamic taint-tracking for low-level legacy code that stores secrets in graph data structures. To ease the programmer's annotation burden and avoid taint explosions suffered by prior approaches, it introduces a novel pointer-combine semantics that resists taint over-propagation through graph edges. Our LLVM implementation extends C/C++ with declarative type qualifiers for secrets, and instruments programs with taint-tracking capabilities at compile-time.

The new infrastructure is applied to realize efficient, precise honey-patching of production web servers for attacker deception. The deceptive servers self-redact their address spaces in response to intrusions, affording defenders a new tool for attacker monitoring and disinformation.

Abstract

Control-Flow Integrity (CFI) is a defense which prevents control-flow hijacking attacks. While recent research has shown that coarse-grained CFI does not stop attacks, fine-grained CFI is believed to be secure.

We argue that assessing the effectiveness of practical CFI implementations is non-trivial and that common evaluation metrics fail to do so. We then evaluate fully-precise static CFI — the most restrictive CFI policy that does not break functionality — and reveal limitations in its security. Using a generalization of non-control-data attacks which we call Control-Flow Bending (CFB), we show how an attacker can leverage a memory corruption vulnerability to achieve Turing-complete computation on memory using just calls to the standard library. We use this attack technique to evaluate fully-precise static CFI on six real binaries and show that in five out of six cases, powerful attacks are still possible. Our results suggest that CFI may not be a reliable defense against memory corruption vulnerabilities.

We further evaluate shadow stacks in combination with CFI and find that their presence for security is necessary: deploying shadow stacks removes arbitrary code execution capabilities of attackers in three of six cases.

1 Introduction

Attacking software systems by exploiting memory-corruption vulnerabilities is one of the most common attack methods today according to the list of Common Vulnerabilities and Exposures. To counter these threats, several hardening techniques have been widely adopted, including ASLR [29], DEP [38], and stack canaries [10]. Each has limitations: stack canaries protect only against contiguous overwrites of the stack, DEP protects against code injection but not against code reuse, and ASLR does not protect against information leakage.

We classify defense mechanisms into two broad categories: *prevent-the-corruption* and *prevent-the-exploit*. Defenses that prevent the corruption stop the actual memory corruption before it can do any harm to the program (i.e., no attacker-controlled values are ever used out-of-context). Examples for prevent-the-corruption defenses are SoftBound [22], Data-Flow Integrity [6], or Code-Pointer Integrity [18]. In contrast, prevent-the-exploit defenses allow memory corruption to occur but protect the application from subsequent exploitation; they try to survive or tolerate adversarial corruption of memory. Examples for prevent-the-exploit defenses are DEP [38] or stack canaries [10].

Control-Flow Integrity (CFI) [1, 3, 12, 15, 27, 30, 31, 39, 41–44] is a promising stateless prevent-the-exploit defense mechanism that aims for complete protection against control-flow hijacking attacks under a threat model with a powerful attacker that can read and write into the process's address space. CFI ensures that program execution follows a valid path through the static Control-Flow Graph (CFG). Any deviation from the CFG is a CFI violation, terminating the application. CFI is not specific to any particular exploitation vector for control-flow hijacking. Rather, it enforces its policy on all indirect branch instructions. Therefore any attempt by an attacker to alter the control-flow in an invalid manner will be detected, regardless of *how* the attacker changes the target of the control-flow transfer instruction.

CFI is often coupled with a protected shadow stack, which ensures that each return statement matches the corresponding call and thereby prevents an attacker from tampering with return addresses. While the foundational work [1, 15] included a shadow stack as part of CFI, some more recent research has explored variants of CFI that omit the shadow stack for better performance [9]. Whereas conformance to the CFG is a stateless policy, shadow stacks are inherently dynamic and are more precise than any static policy can be with respect to returns.

Many prior attacks on CFI have focused on attacking a weak or suboptimal implementation of CFI. Our focus is on evaluating the effectiveness of CFI in its best achievable form, instead of artifacts of some (possibly weak) CFI implementation. We define *fully-precise static CFI* as the best achievable CFI policy as follows: a branch from one instruction to another is allowed if and only if some benign execution makes that same control-flow transfer. Such a policy could be imagined as taking any CFG over-approximation and removing edges until removing additional edges would break functionality.

Thus, fully-precise static CFI is the most restrictive stateless CFI policy that still allows the program to run as intended. Both coarse-grained and fine-grained CFI are less precise than fully-precise static CFI, because they both over-approximate the set of valid targets for each indirect transfer (though to a different degree). In contrast, fully-precise static CFI involves no approximation by definition. We acknowledge that fully-precise static CFI might be stricter than anything that can be practically implemented, but this makes any attacks all the more meaningful: our results help us understand fundamental limits on the effectiveness of the strongest possible CFI policy.

Through several methods of evaluation, we argue that fully-precise static CFI is neither completely broken (as most coarse-grained defenses are) nor totally secure. We explore what CFI can and cannot prevent, and hope that this will stimulate a broader discussion about ways to further strengthen CFI.

We evaluate the security of fully-precise static CFI both with and without shadow stacks. Recent research achieves better performance by omitting the shadow stack in favor of a static policy on return statements. We still call it fully-precise static CFI when we have added a shadow stack, because the shadow stack is orthogonal. This does not change the fact that the CFI policy is static.

CFI works by preventing an attacker from deviating from the control-flow graph. Our attacks do not involve breaking the CFI mechanism itself: we even assume the mechanism is implemented perfectly to its fullest extent. Rather, our analysis demonstrates that an attacker can still create exploits for most real applications, without causing execution to deviate from the control-flow graph.

This paper provides the following contributions:

1. formalization and evaluation of a space of different kinds of CFI schemes;
2. new attacks on fully-precise static CFI, which reveal fundamental limits on the effectiveness of CFI;
3. evidence that existing metrics for CFI security are ineffective;
4. evidence that CFI without a shadow stack is broken;
5. widely applicable Turing-complete attacks on CFI with shadow stacks; and,
6. practical case studies of the security of fully-precise static CFI for several existing applications.

2 Background and software attacks

Over the past few decades, one of the most common attack vectors has been exploitation of memory corruption within programs written in memory-unsafe languages.In response, operating systems and compilers have started to support countermeasures against specific exploitation vectors and vulnerability types, but current hardening techniques are still unable to stop all attacks. We briefly provide an overview of these attacks; more information may be found elsewhere [37].

2.1 Control-Flow Hijacking

One way to exploit a memory corruption bug involves hijacking control flow to execute attacker-supplied or already-existing code in an application's address space. These methods leverage the memory corruption bug to change the target of an indirect branch instruction (*ret*, *jmp* *, or *call* *). By doing so, an attacker can completely control the next instructions to execute.

2.2 Code-Reuse Attacks

Data Execution Prevention (DEP) prevents executing attacker-injected code. However, redirecting control-flow to already-existing executable code in memory remains feasible. One technique, return-to-libc [25, 36], reuses existing functions in the address space of the vulnerable process. Runtime libraries (such as libc) often provide powerful functions, e.g., wrapper functions for most system calls. One example is libc's `system()` function, which allows the attacker to execute shell commands. Code-reuse attacks are possible when attacker-needed code is already available in the address space of a vulnerable process.

2.3 Return Oriented Programming

Return Oriented Programming (ROP) [25, 36] is a more advanced form of code-reuse attack that lets the attacker perform arbitrary computation solely by reusing existing code. It relies upon short instruction sequences (called "gadgets") that end with an indirect branch instruction. This allows them to be chained, so the attacker can perform arbitrary computation by executing a carefully-chosen sequence of gadgets. ROP can be generalized to use indirect jump or call instructions instead of returns [4, 7].

2.4 Non-Control-Data Attacks

A non-control-data attack [8] is an attack where a memory corruption vulnerability is used to corrupt only data, but not any code pointer. (A *code pointer* is a pointer which refers to the code segment, for example, a return address or function pointer.) Depending on the circumstances, these attacks can be as effective as arbitrary code-execution attacks. For instance, corrupting the parameter to a sensitive function (e.g., libc's `execve()`) may allow an attacker to execute arbitrary programs. An attacker may also be able to overwrite security configuration values and disable security checks. Non-control-data attacks are realistic threats and hard to defend against, due to the fact that most defense mechanisms focus on the protection of code pointers.

2.5 Control-Flow Bending

We introduce a generalization of non-control-data attacks which we call *Control-Flow Bending* (CFB). While non-control-data attacks do not directly modify any control-flow data (e.g., return addresses, indirect branch targets), in control-flow bending we allow these modifications so long as the modified indirect branch target is still in the valid set of addresses as defined by the CFI policy (or any other enforced control-flow or code pointer integrity protection). CFB allows an attacker to bend the control-flow of the application (compared to hijacking it) but adheres to an imposed security policy.

We define a "data-only" attack as a non-control-data attack where the entire execution trace is identical to some feasible non-exploit execution trace. (An execution trace is the ordered sequence of instructions which execute, and does not include the effects those instructions have except with respect to control flow.) While data-only attacks may change the control flow of an application, the traces will still look legitimate, as the observed trace can also occur during valid execution. In contrast, CFB is more general: it refers to any attack where each control-flow transfer is within the valid CFG, but the execution trace is not necessarily required to match some valid non-exploit trace.

In general, defense mechanisms implement an abstract machine and can only observe security violations according to the restrictions of that machine, e.g., CFI enforces that control flow follows a finite state machine.

For example, an attacker who directly overwrites the arguments to `exec()` is performing a data-only attack: no control flow has been changed. An attacker who overwrites an `is_admin` flag half-way through processing a request is performing a non-control-data attack: the data that was overwritten is non-control-data, but it affects the control-flow of the program. An attacker who modifies a function pointer to point to a different (valid) call target is mounting a CFB attack.

3 Threat model and attacker goals

Threat model. For this paper we assume a powerful yet realistic threat model. We assume the attacker can write arbitrarily to memory at one point in time during the execution of the program. We assume the process is running with non-executable data and non-writeable code which is hardware enforced.

This threat model is a realistic generalization of memory corruption vulnerabilities: the vulnerability typically gives the attacker some control over memory. In practice there may be a set of specific constraints on what the attacker can write where; however, this is not something a defender can rely upon. To be a robust defense, CFI mechanisms must be able to cope with arbitrary memory corruptions, so in our threat model we allow the attacker full control over memory once.

Limiting the memory corruption to a single point in time does weaken the attacker. However, this makes our attacks all the more meaningful.

Attacker goals. There are three kinds of outcomes an attacker might seek, when exploiting a vulnerability:

1. *Arbitrary code execution:* The attacker can execute arbitrary code and can invoke arbitrary system calls with arbitrary parameters. In other words, the attacker can exercise all permissions that the application has. Code execution might involve injecting new code or re-using already-existing code; from the attacker's perspective, there is no difference as long as the effects are the same.

2. *Confined code execution:* The attacker can execute arbitrary code within the application's address space, but cannot invoke arbitrary system calls. The attacker might be able to invoke a limited set of system calls (e.g., the ones the program would usually execute, or just enough to send information back to the attacker) but cannot exercise all of the application's permissions. Reading and leaking arbitrary memory of the vulnerable program is still possible.

3. *Information leakage:* The attacker can read and leak arbitrary values from memory.

Ideally, a CFI defense would prevent all three attacker goals. The more it can prevent, the stronger the defense.

4 Definition of CFI flavors

Control-Flow Integrity (CFI) [1, 15] adds a stateless check before each indirect control-flow transfer (indirect jump/call, or function return) to ensure that the target location is in a static set defined by the control-flow graph.

4.1 Fully-Precise Static CFI

We define *Fully-Precise Static CFI* as follows: an indirect control-flow transfer along some edge is allowed only if there exists a non-malicious trace that follows that edge. (An execution is not malicious if it exercises only intended program behavior.) In other words, consider the most restrictive control-flow graph that still allows all feasible non-malicious executions, i.e., the CFG contains an edge if and only if that edge is used by some benign execution. Fully-precise static CFI then enforces that execution follows this CFG. Thus, fully-precise static CFI enforces the most precise (and most restrictive) policy possible that does not break functionality.

We know of no way to implement fully-precise static CFI: real implementations often use static analysis and over-approximate the CFG and thus are not fully precise. We do not design a better CFI scheme. The goal of our work is to evaluate the strongest form of CFI that could conceptually exist, and attempt to gain insight on its limitations. This notion of fully-precise static CFI allows us to transcend the recent arms race caused by defenders proposing forms of CFI [9, 28] and then attackers defeating them [5, 14, 16].

4.2 Practical CFI

Practical implementations of CFI are always limited by the precision of the CFG that can be obtained. Current CFI implementations face two sources of over-approximation. First, due to challenges in accurate static analysis, the set of allowed targets for each indirect call instruction typically depends only upon the function pointer type, and this set is often larger than necessary.

Second, most CFI mechanisms use a static points-to analysis to define the set of allowed targets for each indirect control transfer. Due to imprecisions and limitations of the analysis (e.g., aliasing in the case of points-to analysis) several sets may be merged, leading to an over-approximation of allowed targets for individual indirect control-flow transfers. The degree of over-approximation affects the precision and effectiveness of practical CFI mechanisms.

Previous work has classified practical CFI defenses into two categories: coarse-grained and fine-grained. Intuitively, a defense is fine-grained if it is a close approximation of fully-precise static CFI and coarse-grained if there are many unnecessary edges in the sets.

4.3 Stack integrity

The seminal work on CFI [1] combined two mechanisms: restricting indirect control transfers to the CFG, and a shadow call stack to restrict return instructions. The shadow stack keeps track of the current functions on the application call stack, storing the return instruction pointers in a separate region that the attacker cannot access. Each return instruction is then instrumented so that it can only return to the function that called it. For compatibility with exceptions, practical implementations often allow return instructions to return to any function on the shadow stack, not just the one on the top of the stack. As a result, when a protected shadow stack is in use, the attacker has very limited influence over return instructions: all the attacker can do is unwind stack frames. The attacker cannot cause return instructions to return to arbitrary other locations (e.g., other call-sites) in the code.

Unfortunately, a shadow stack does introduce performance overhead, so some modern schemes have proposed omitting the shadow stack [9]. We analyze both the security of CFI with a shadow stack and CFI without a shadow stack. We assume the shadow stack is protected somehow and cannot be overwritten; we do not consider attacks against the implementation of the shadow stack.

5 Evaluating practical CFI

While there has been considerable research on how to make CFI more fine-grained and efficient, most CFI publications still lack a thorough security evaluation. In fact, the security evaluation is often limited to coarse metrics such as Average Indirect target Reduction (AIR) or gadget reduction. Evaluating the security effectiveness of CFI this way does not answer how effective these policies are in preventing actual attacks.

In this section, we show that metrics such as AIR and gadget reduction are not good indicators for the effectiveness of a CFI policy, even for simple programs. We discuss CFI effectiveness and why it is difficult to measure with a single value and propose a simple test that indicates if a CFI policy is trivially broken.

5.1 AIR and gadget reduction

The AIR metric [44] measures the relative reduction in the average number of valid targets for all indirect branch instructions that a CFI scheme provides: without CFI, an indirect branch could target any instruction in the program; CFI limits this to a set of valid targets. The gadget reduction metric measures the relative reduction in the number of gadgets that can be found at locations that are valid targets for an indirect branch instruction.

These metrics measure how effectively a CFI implementation reduces the set of valid targets (or gadgets) for indirect branch instructions, *on average*. However, they fail to capture both (i) the target reduction of individual locations (e.g., a scheme can have high AIR even if one branch instruction has a large set of surplus targets, if the other locations are close to optimal) and (ii) the importance and risk of the allowed control transfers. Similarly, the gadget reduction metric does not weight targets according to their usefulness to an attacker: every code location or gadget is considered to be equally useful.

For example, consider an application with 10MB of executable memory and an AIR of 99%. An attacker would still have 1% of the executable memory at their disposal — 100,000 potential targets — to perform code-reuse attacks. A successful ROP attack requires only a handful of gadgets within these potential targets, and empirically, 100,000 targets is much more than is usually needed to find those gadgets [35]. As this illustrates, averages and metrics that are relative to the code size can be misleading. What is relevant is the absolute number of available gadgets and how useful they are to an attacker.

5.2 CFI security effectiveness

Unfortunately, it is not clear how to construct a single metric that accurately measures the effectiveness of CFI. Ideally, we would like to measure the ability of CFI to stop an attacker from mounting a control-flow hijack attack. More specifically, a CFI effectiveness metric should indicate whether control-flow hijacking and code-reuse attacks are still possible under a certain attacker model or not, and if so, how much harder it is for an attacker to perform a successful attack in the presence of CFI. However, what counts as successful exploitation of a software vulnerability depends on the goals of the attacker (see Section 3) and is not easily captured by a single number.

These observations suggest that assessing CFI effectiveness is hard, especially if no assumptions are made regarding what a successful attack is and what the binary image of the vulnerable program looks like.

5.3 Basic exploitation test

We propose a *Basic Exploitation Test* (BET): a simple test to quickly rule out some trivially broken implementations of CFI. Passing the BET is not a security guarantee, but failing the BET means that the CFI scheme is insecure.

In particular, the BET involves selecting a minimal program — a simple yet representative program that contains a realistic vulnerability — and then determining whether attacks are still possible if that minimal program is protected by the CFI scheme under evaluation. The minimal program should be chosen to use a subset of common run-time libraries normally found in real applications, and constructed so it contains a vulnerability that allows hijacking control flow in a way that is seen in real-life attacks. For instance, the minimal program might allow an attacker to overwrite a return address or the target of an indirect jump/call instruction.

The evaluator then applies the CFI scheme to the minimal program, selects an attacker goal from Section 3, and determines whether that goal is achievable on the protected program. If the attack is possible, the CFI scheme fails the BET. We argue that if a CFI scheme is unable to protect a minimal program it will also fail to protect larger real-life applications, as larger programs afford the attacker even more opportunities than are found in the minimal program.

5.4 BET for coarse-grained CFI

We apply the BET to a representative coarse-grained CFI policy. We show that the scheme is broken, even though its AIR and gadget reduction metrics are high. This demonstrates that AIR and gadget reduction numbers are not reliable indicators for the security effectiveness of a CFI scheme even for small programs. These results generalize the conclusion of recent work [5,14,16], by showing that coarse-grained CFI schemes are broken even for trivially small real-life applications.

Minimal program and attacker goals. Our minimal vulnerable program is shown in Figure 1. It is written in C, compiled with gcc version 4.6.3 under Ubuntu LTS 12.04 for x86 32-bit, and dynamically linked against `ld-linux` and `libc`. The program contains a stack-based buffer overflow. A vulnerability in `vulnFunc()` allows an attacker to hijack the return target of `vulnFunc()` and a memory leak in `memLeak()` allows the attacker to bypass stack canaries and ASLR.

Coarse-grained CFI policy. The coarse-grained CFI policy we analyze is a more precise version of several recently proposed static CFI schemes [43, 44]: each implementation is less accurate than our combined version. We use a similar combined static CFI policy as used in recent work [14, 16].

Our coarse-grained CFI policy has three equivalence classes, one for each indirect branch type. Returns and indirect jumps can target any instruction following a call instruction. Indirect calls can target any defined symbol, i.e., the potential start of any function. This policy is overly strict, especially for indirect jumps; attacking a stricter coarse-grained policy makes our results stronger.

Results. We see in Table 1 that our minimal program linked against its libraries achieves high AIR and gadget reduction numbers for our coarse-grained CFI policy. However, as we will show, all attacker goals from Section 3 can be achieved.

```
#include <stdio.h>
#include <string.h>
#define STDIN 0

void memLeak() {
    char buf[64];
    int nr, i;
    unsigned int *value;
    value = (unsigned int*)buf;
    scanf("%d", &nr);
    for (i = 0; i < nr; i++)
        printf("0x%08x␣", value[i]);
}

void vulnFunc() {
    char buf[1024];
    read(STDIN, buf, 2048);
}

int main(int argc, char* argv[]) {
    setbuf(stdout, NULL);
    printf("echo>␣");
    memLeak();
    printf("\nread>␣");
    vulnFunc();
    printf("\ndone.\n");
    return 0;
}
```

Figure 1: Our minimal vulnerable program that allows hijacking a return instruction target.

	AIR	Gadget red.	Targets	Gadgets
No CFI	0%	0%	1850580	128929
CFI	99.06%	98.86%	19611	1462

Table 1: Basic metrics for the minimal vulnerable program under no CFI and our coarse-grained CFI policy.

```
G1 # arbitrary load (1/2)
   f38ff:       pop    %edx
   f3900:       pop    %ecx
   f3901:       pop    %eax
   f3902:       ret

G2 # arbitrary load (2/2)
   412d2:       add    $0x20,%esp
   412d5:       xor    %eax,%eax
   412d7:       pop    %ebx
   412d8:       pop    %esi
   412d9:       pop    %edi
   412da:       ret

G3 # arbitrary read
   2ee25:       add    $0x1771cf,%ecx
   2ee2b:       mov    0x54(%ecx),%eax
   2ee31:       ret

G4 # arbitrary write
   3fb11:       pop    %ecx
   3fb12:       add    $0xa,%ecx
   3fb18:       mov    %ecx,(%edx)
   3fb1a:       ret

G5 # arbitrary call
   1b008:       mov    %esi,(%esp)
   1b00b:       call   *%edi
```

Figure 2: Our call-site gadgets within libc.

```
000b8d60 <execve>:
...
   b8d72:         call    ...
   b8d77:         add     $0xed27d,%ebx
   b8d7d:         mov     0xc(%esp),%edi
   b8d81:         xchg    %ebx,%edi
   b8d83:         mov     $0xb,%eax
   b8d88:         call    *%gs:0x10
```

Figure 3: Disassembly of libc's execve() function. There is an instruction (0xb8d77) that can be returned to by any return gadget under coarse-grained CFI.

We first identified all gadgets that can be reached without violating the given CFI policy. We found five gadgets that allow us to implement all attacker goals as defined in Section 3. All five gadgets were within libc and began immediately following a call instruction. Two gadgets can be used to load a set of general purpose registers from the attacker-controlled stack and then return. One gadget implements an arbitrary memory write ("write-what-where") and then returns. Another gadget implements an arbitrary memory read and then returns. Finally, we found a fifth gadget — a "call gadget" — that ends with an indirect call through one of the attacker-controlled registers, and thus can be used to perform arbitrary calls. The five gadgets are shown in Figure 2. By routing control-flow through the first four gadgets and then to the call gadget, the attacker can call any function.

The attacker can use these gadgets to execute arbitrary system calls by calling __kernel_vsyscall. In Linux systems (x86 32-bit), system calls are routed through a virtual dynamic shared object (linux-gate.so) mapped into user space by the kernel at a random address. The address is passed to the user space process. If the address is leaked, the attacker can execute arbitrary system calls by calling __kernel_vsyscall using a call gadget. Calls to __kernel_vsyscall are within the allowed call targets as libc itself calls __kernel_vsyscall.

Alternatively, the attacker could call libc's wrappers for each specific system call. For example, the attacker could call execve() within libc to execute the execve system call. Interestingly, if the wrapper functions contain calls, we can directly return to an instruction after such a call and before the system call is issued. For an example, see Figure 3: returning to 0xb8d77 allows us to directly issue the system call without using the call gadget (we simply direct one of the other gadgets to return there). There are some side effects on register ebx and edi but it is straightforward to take them into account.

Arbitrary code execution is also possible. In the absence of CFI, an attacker might write new code somewhere into memory, call mprotect() to make that memory region executable, and then jump to that location to execute the injected code. CFI will prevent this, as the location of the injected code will never be in one of the target sets. We bypass this protection by using `mprotect()` to make already-mapped code writeable. The attacker can overwrite these already-available code pages with malicious code and then transfer control to it using our call gadget. The result is that the attacker can inject and execute arbitrary code and invoke arbitrary system calls with arbitrary parameters. As an alternative `mmap()` could also be used to allocate readable and executable memory (if not prohibited).

The minimal program shown in Figure 1 contains a vulnerability that allows the attacker to overwrite a return address on the stack. We also analyzed other minimal programs that allow the attacker to hijack an indirect jump or indirect call instruction, with similar results. We omit the details of these analyses for brevity. A minimal vulnerable program for initial indirect jump or indirect call hijacking is found in Appendix A.

Based on these results we conclude that coarse-grained CFI policies are not effective in protecting even small and simple programs, such as our minimal vulnerable program example. Our analysis also shows that AIR and gadget reduction metrics fail to indicate whether a CFI scheme is effective at preventing attacks; if such attacks are possible on a small program, then attacks will be easier on larger programs where the absolute number of valid locations and gadgets is even higher.

6 Attacks on Fully-Precise Static CFI

We now turn to evaluating fully-precise static CFI. Recall from Section 2.5 that we define control-flow bending as a generalization of non-control-data attacks. We examine the potential for control-flow bending attacks on CFI schemes with and without a shadow stack.

6.1 Necessity of a shadow stack

To begin, we argue that CFI must have a shadow stack to be a strong defense. Without one, an attacker can easily traverse the CFG to reach almost any program location desired and thereby break the CFI scheme.

For a static, stateless policy like fully-precise static CFI without a shadow stack, the best possible policy for returns is to allow return instructions within a function F to target any instruction that follows a call to F. However, for functions that are called often, this set can be very large. For example, the number of possible targets for the return statements in `malloc()` is immense. Even though dynamically only one of these should be allowed at any given time, a stateless policy must allow all of these edges.

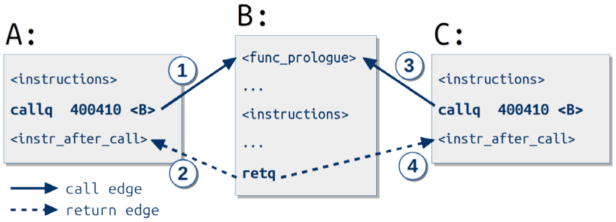

Figure 4: A control-flow graph where the lack of a shadow stack allows an attacker to mount a control-flow bending attack.

This is elaborated in Figure 4. Functions A and C both contain calls to function B. The return in function B must therefore be able to target the instruction following both of these calls. In normal execution, the program will execute edge 1 followed by edge 2, or edge 3 followed by edge 4. However, an attacker may be able to cause edge 3 to be followed by edge 2, or edge 1 to be followed by edge 4.

In practice this is even more problematic with tail-call optimizations, when signal handlers are used, or when the program calls `setjmp/longjmp`. We ignore these cases. This makes our job as an attacker more difficult, but we base our attacks on the fundamental properties of CFI instead of corner cases which might be handled separately.

6.1.1 Dispatcher functions

For an attacker to cause a function to return to a different location than it was called from, she must be able to overwrite the return address on the stack after the function is called yet before it returns. This is easy to arrange when the memory corruption vulnerability occurs within that specific function. However, often the vulnerability is found in uncommonly called (not well tested) functions.

To achieve more power, we make use of *dispatcher functions* (analogous to dispatcher gadgets for JOP [4]). A dispatcher function is one that can overwrite its own return address when given arguments supplied by an attacker. If we can find a dispatcher function that will be called later and use the vulnerability to control its arguments, we can make it overwrite its own return address. This lets us return to any location where this function was called.

Any function that contains a "write-what-where" primitive when the arguments are under the attacker's control can be used as a dispatcher function. Alternatively, a function that can write to only limited addresses can still work as long as the return address is within the limits. Not every function has this property, but a significant fraction of all functions do. For example, assume we control all of the arguments to `memcpy()`. We can

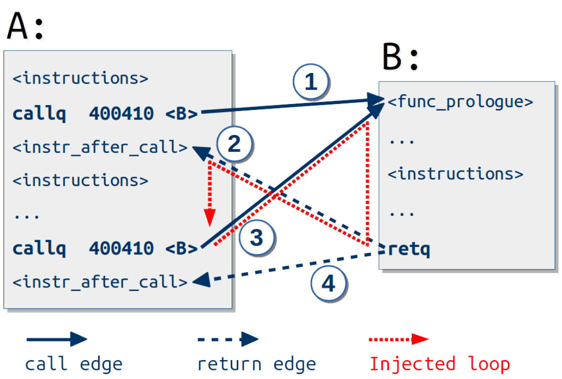

Figure 5: An example of loop injection. Execution follows call edge ③, then returns along edge ②.

point the source buffer to an attacker-controlled location, the target buffer to the address where `memcpy()`'s return address will be found, and set the length to the word size. Then, when `memcpy()` is invoked, `memcpy()` will overwrite its own return address and then return to some other location in the code chosen by the attacker. If this other location is in the valid CFG (i.e., it is an instruction following some call to `memcpy()`), then it is an allowed edge and CFI will allow the return. Thus, `memcpy()` is a simple example of a dispatcher function.

We found many dispatcher functions in `libc`, e.g.,

1. `memcpy()` — As described above.
2. `printf()` — Using the "%n" format specifier, the attacker can write an arbitrary value to an arbitrary location and thus cause `printf()` to overwrite its own return address.
3. `strcat()` — Similar to `memcpy()`. Only works if the address to return to does not contain null bytes.
4. `fputs()` — We rely on the fact that when `fputs()` is called, characters are first temporarily buffered to a location as specified in the `FILE` argument. An attacker can therefore specify a `FILE` where the temporary buffer is placed on top of the return address. Most functions that take a `FILE` struct as an argument can be used in a similar manner.

Similar functions also exist in Windows libraries. Application-specific dispatcher functions can be useful as well, as they may be called more often.

Any function that calls a dispatcher function is itself a dispatcher function: instead of having the callee overwrite its own address, it can be used to overwrite the return address of its caller (or higher on the call chain).

6.1.2 Loop injection

One further potential use of dispatcher functions is that they can be used to create loops in the control-flow graph when none were intended, a process which we call *loop injection*. We can use this to help us achieve Turing-complete computation if we require a loop.

Consider the case where there are two calls to the same dispatcher function, where the attacker controls the arguments to the second call and it is possible to reach the second call from the first through a valid CFG path. For example, it is common for programs to make multiple successive calls to `printf()`. If the second call to `printf()` allows an attacker to control the arguments, then this could cause a potential loop. This is achievable because the second call to `printf()` can return to the instruction following the first call to `printf()`. We can then reach the second call to `printf()` from there (by assumption) and we have completed the loop.

Figure 5 contains an example of this case. Under normal execution, function A would begin by executing the first call to function B on edge 1. Function B returns on edge 2, after which function A continues executing. The second call to function B is then executed, on edge 3. B this time returns on edge 4. Notice that the return instruction in function B has two valid outgoing edges.

An attacker can manipulate this to inject a loop when function B is a dispatcher function. The attacker allows the first call to B to proceed normally on edge 1, returning on edge 2. The attacker sets up memory so that when B is called the second time, the return will follow edge 2 instead of the usual edge 4. That is, even though the code was originally intended as straight-line execution, there exists a back-edge that will be allowed by any static, stateless CFI policy without a shadow stack. A shadow stack would block the transfer along edge 2.

6.2 Turing-complete computation

CFI ensures that the execution flow of a program stays within a predefined CFG. CFI implicitly assumes that the attacker *must* divert from this CFG for successful exploitation. We demonstrate that an attacker can achieve Turing-complete computation while following the CFG. This is not directly one of the attacker goals outlined in Section 3, however it is often a useful step in achieving attacks [14].

Specifically, we show that a single call to `printf()` allows an attacker to perform Turing-complete computation, even when protected with a shadow stack. We dub this printf-oriented programming. In our evaluation, we found it was possible to mount this kind of attack against all but one binary (which rewrote their own limited version of printf).

Our attack technique is not specific to `printf()`: we have constructed a similar attack using `fputs()` which is widely applicable but requires a loop obtained in the control-flow graph (via loop injection or otherwise) to be

Turing-complete. See Appendix C.

6.2.1 Printf-oriented programming

When we control the arguments to `printf()`, it is possible to obtain Turing-complete computation. We show this formally in Appendix B by giving calls to `printf()` which create logic gates. In this section, we give the intuition behind our attacks by showing how an attacker can conditionally write a value at a given location.

Assume address C contains a condition value, which is an integer that is promised to be either zero or one. If the value is one, then we wish to store the constant X at target address T. That is, we wish to perform the computation `*T = *C ? X : *T`. We show how this can be achieved using one call to `printf()`.

To do this, the attacker supplies the specially-crafted format string "`%s%hhnQ%*d%n`" and passes arguments $(C, S, X-2, 0, T)$, defined as follows:

1. C — the address of the condition. While the "`%s`" format specifier expects a string, we pass a pointer to the condition value, which is either the integer 0 or the integer 1. Because of the little-endian nature of x86, the integer 1 contains the byte 0x01 in the first (low) byte and 0x00 in the second byte. This means that when we print it as a string, if the condition value is 1 then exactly one byte will be written out whereas if it is 0 then nothing will be be printed.
2. S — the address of the Q in the format string (i.e., the address of the format string, plus 6). The "`%hhn`" specifier will write a single byte of output consisting of the number of characters printed so far, and will write it on top of the Q in the format string. If we write a 0, the null byte, then the format string will stop executing. If we write a 1, the format string will keep going. It is this action which creates the conditional.
3. $X-2$ — the constant we wish to store, minus two. This specifies the number of bytes to pad in the integer which will be printed. It is the value we wish to save minus two, because two bytes will have already been printed.
4. 0 — an integer to print. We do not care that we are actually printing a 0, only the padding matters.
5. T — the target save location. At this point in time, we have written exactly X bytes to the output, so "`%n`" will write that value at the target address.

Observe that in this example, we have made use of a *self-modifying* format string.

6.2.2 Practical printf-oriented programming

The previous section assumed that the attacker has control of the format string argument, which is usually not the case. We show using simple techniques it is possible to achieve the same results without this control.

We first define the *destination* of a `printf()` call according to its type. The destination of an `sprintf()` call is the address the first argument points to (the destination buffer). The destination of a `fprintf()` call is the address of the temporary buffer in the `FILE` struct. The destination of a plain `printf()` call is the destination buffer of `fprintf()` when called with `stdout`.

Our attack requires three conditions to hold:

- the attacker controls the destination buffer;
- the format string passed to the call to `printf()` already contains a "`%s`" specifier; and,
- the attacker controls the argument to the format specifier as well as a few of the words further down on the stack.

We mount our attack by pointing the destination buffer on top of the stack. We use the "`%s`" plus the controlled argument to overwrite the pointer to the format string (which is stored on the stack), replacing it with a pointer to an attacker-controlled format string. We then skip past any uncontrolled words on the stack with harmless ` ``%x'' ` specifiers. We can then use the remaining controlled words to pivot the `va_list` pointer.

If we do not control any buffer on the stack, we can obtain partial control of the stack by continuing our arbitrary write with the `%s` specifier to add arguments to `printf()`. Note that this does not allow us to use null bytes in arguments, which in 64-bit systems in particular makes exploitation difficult.

6.3 Implications

Our analysis of fully-precise static CFI, the strongest imaginable static CFI policy, shows that preventing attackers with partial control over memory from gaining Turing-complete computation is almost impossible. Run-time libraries and applications contain powerful functions that are part of the valid CFG and can be used by attackers to implement their malicious logic. Attackers can use dispatcher functions to bend control flow within the valid CFG to reach these powerful functions.

Furthermore, we see that if an attacker can find one of these functions and control arguments to it, the attacker will be able to both write to and read from arbitrary addresses at multiple points in time. Defenses which allow attackers to control arguments to these functions must be able to protect against this stronger threat model.

7 Fully-Precise Static CFI Case Studies

We now look at some practical case studies to examine how well fully-precise static CFI can defend against real-

	CFI without shadow stack				CFI with shadow stack			
Binary	Arbitrary write	Info. leakage	Confined code execution	Arbitrary code execution	Arbitrary write	Info. leakage	Confined code execution	Arbitrary code execution
nginx	yes	write	dispatcher	dispatcher	yes	write	no	no
apache	no	write	printf	dispatcher	no	write	write	write
smbclient	yes	printf	printf	printf	yes	printf	printf	printf
wireshark	yes	printf	printf	dispatcher	yes	printf	write	write
xpdf	?	dispatcher	printf	dispatcher	?	write	printf	no
mysql	?	dispatcher	printf	dispatcher	?	write	printf	no

Table 2: The results of our evaluation of the 6 binaries. The 2nd and 6th columns indicate whether the vulnerability we examined allows an attacker to control memory. The other columns indicate which attack goals would be achievable, assuming the attacker controls memory. A “no” indicates that we were not able to achieve that attack goal; anything else indicates it is achievable, and indicates the attack technique we used to achieve the goal. A “?” indicates we were not able to reproduce the exploit.

life exploits on vulnerable programs, both with and without a shadow stack. We split our evaluation into two parts. First, we show that attackers can indeed obtain arbitrary control over memory given actual vulnerabilities. Second, we show that given a program where the attacker controls memory at one point in time, it is possible to mount a control-flow bending attack. Our results are summarized in Table 2.

Our examples are all evaluated on a Debian 5 system running the binaries in x86 64-bit mode. We chose 64-bit mode because most modern systems are running as 64-bit, and attacks are more difficult on 64-bit due to the increased number of registers (data is loaded off of the stack less often).

We do not implement fully-precise static CFI. Instead, for each of our attacks, we manually verify that each indirect control-flow transfer is valid by checking that the edge taken occurs during normal program execution. Because of this, we do not need to handle dynamically linked libraries specially: we manually check those too.

7.1 Control over memory

The threat model we defined earlier allows the attacker to control memory at a single point in time. We argue that this level of control is achievable with most vulnerabilities, by analyzing four different binaries.

7.1.1 Nginx stack buffer overflow

We examined the vulnerability in CVE-2013-2028 [19]: a signedness bug in the chunked decoding component of nginx. We found it is possible to write arbitrary values to arbitrary locations, even when nginx is protected by fully-precise static CFI with a shadow stack, by modifying internal data structures to perform a control-flow bending attack.

The vulnerability occurs when an attacker supplies a large claimed buffer size, overflowing an integer and triggering a stack-based buffer overflow. An attacker can exploit this by redirecting control flow down a path that would never occur during normal execution. The Server Side Includes (SSI) module contains a call to `memcpy()` where all three arguments can be controlled by the attacker. We can arrange memory so after `memcpy()` completes, the process will not crash and will continue accepting requests. This allows us to send multiple requests and set memory to be exactly to the attacker’s choosing.

Under benign usage, this `memcpy()` method is called during the parsing of a SSI file. The stack overflow allows us to control the stack and overwrite the pointer to the request state (which is passed on the stack) to point to a forged request structure, constructed to contain a partially-completed SSI structure. This lets us re-direct control flow to this `memcpy()` call. We are able to control its source and length arguments easily because they point to data on the heap which we control. The destination buffer is not typically under our control: it is obtained by the result of a call to nginx’s memory allocator. However, we can cause the allocator to return a pointer to an arbitrary location by controlling the internal data structures of the memory allocator.

7.1.2 Apache off by one error

We examined an off-by-one vulnerability in Apache’s handling of URL parameters [11]. We found that it is no longer exploitable in practice, when Apache is protected with CFI.

The specific error overwrites a single extra word on the stack; however, this word is not under the attacker’s control. Instead, the word is a pointer to a string on the heap, and the string on the heap is under the attacker’s control. This is a very contrived exploit, and it was not exploitable on the majority of systems in the first place due to the word on the stack not containing any meaningful data. However, on some systems the overwritten word contained a pointer to a data structure which contains function pointers. Later, one of these function pointers would be invoked, allowing for a ROP attack.

When Apache is protected with CFI, the attacker is not able to meaningfully modify the function pointers, and therefore cannot actually gain anything. CFI is effective in this instance because the attacker never obtains control of the machine in the first place.

7.1.3 Smbclient printf vulnerability

We examined a format string vulnerability in smbclient [26]. Since we already fully control the format string of a `printf()` statement, we can trivially control all of memory with printf-oriented programming.

7.1.4 Wireshark stack buffer overflow

A vulnerability in Wireshark's parsing of mpeg files allows an attacker to supply a large packet and overflow a stack buffer. We identify a method of creating a repeatable arbitrary write given this vulnerability even in the presence of a shadow stack.

The vulnerability occurs in the `packet_list_dissect_and_cache_record` function where a fixed-size buffer is created on the stack. An attacker can use an integer overflow to create a buffer of an arbitrary size larger than the allocated space. This allows for a stack buffer overflow.

We achieve an arbitrary write even in the presence of a shadow stack by identifying an arbitrary write in the `packet_list_change_record` function. Normally, this would not be good enough, as this only writes a single memory location. However, an attacker can loop this write due to the fact that the GTK library method `gtk_tree_view_column_cell_set_cell_data`, which is on the call stack, already contains a loop that iterates an attacker-controllable number of times. These two taken together give full control over memory.

7.1.5 Xpdf & Mysql

For two of our six case studies, we were unable to reproduce the public exploit, and as such could not test if memory writes are possible from the vulnerability.

7.2 Exploitation assuming memory control

We now demonstrate that an attacker who can control memory at one point in time can achieve all three goals listed in Section 3, including the ability to issue attacker-desired system calls. (Our assumption is well-founded: in the prior section we showed this is possible.) Prior work has already shown that if arbitrary writes are possible (e.g., through a vulnerability) then data-only attacks are realistic [8]. We show that control-flow bending attacks that are not data-only attacks are also possible.

7.2.1 Evaluation of nginx

Assuming the attacker can perform arbitrary writes, we show that the attacker can read arbitrary files off of the server and relay them to the client, read arbitrary memory out of the server, and execute an arbitrary program with arbitrary arguments. The first two attack goals can be achieved even with a shadow stack; our third attack only works if there is no shadow stack. Nginx is the only binary which is not exploitable by printf-oriented programming, because nginx rewrote their own version of `printf()` and removed "`%n`".

An attacker can read any file that nginx has access to and cause their contents to be written to the output socket, using a purely non-control-data attack. For brevity, we do not describe this attack in detail: prior work has described that these types of exploits are possible.

Our second attack can be thought of as a more controlled version of the recent Heartbleed vulnerability [21], allowing the attacker to read from an *arbitrary* address and dump it to the attacker. The response handling in nginx has two main phases. First, it handles the header of the request and in the process initializes many structs. Then, it parses and handles the body of the request, using these structs. Since the vulnerability in nginx occurs during the parsing of the request body, we use our control over memory to create a forged struct that was not actually created during the initialization phase. In particular, we initialize the `postpone_filter` module data structure (which is not used under normal execution) with an internally-inconsistent state. This causes the module to read data from an arbitrary address of an arbitrary length and copy it to the response body.

Our final attack allows us to invoke `execve()` with arbitrary arguments, if fully-precise static CFI is used without a shadow stack. We use `memcpy()` as a dispatcher function to return into `ngx_sprintf()` and then again into `ngx_exec_new_binary()`, which later on calls `execve()`. By controlling its arguments, the attacker gets arbitrary code execution.

In contrast, when there is a shadow stack, we believe it is impossible for an attacker to trigger invocation of `execve()` due to privilege separation provided by fully-precise static CFI. The master process spawns children via `execve()`, but it is only ever called there — there is no code path that leads to `execve()` from any code point that is reachable within a child process. Thus, in this case CFI effectively provides a form of privilege separation for free, if used with a shadow stack.

7.2.2 Evaluation of apache

On Apache the attacker can invoke `execve()` with arbitrary arguments. Other attacks similar to those on nginx are possible; we omit them for brevity. When there is no shadow stack, we can run arbitrary code by using `strcat()` as a dispatcher gadget to return to a function which later invokes `execve()` under compilations which link the Windows `main` method. When there is a shadow stack, we found a loop that checks, for each module, if the module needs to be executed for the current request. By modifying the conditions on this loop we can cause `mod_cgi` to execute an arbitrary shell command under any compilation. Observe that this attack involves overwriting a function pointer, although to a valid target.

7.2.3 Evaluation of smbclient

Smbclient contains an interpreter that accepts commands from the user and sends them to a Samba fileserver. An attacker who controls memory can drive the interpreter to send any action she desired to the fileserver. This allows an attacker to perform any action on the Samba filesystem that the user could. This program is a demonstration that on some programs, CFI provides essentially no value due to the expressiveness of the original application.

This is one of the most difficult cases for CFI. The only value CFI adds to a binary is restricting it to its CFG: however, when the CFG is easy to traverse and gives powerful functions, CFI adds no more value than a system call filter.

7.2.4 Evaluation of wireshark

An attacker who controls memory can write to any file that the current user has access to. This gives power equivalent to arbitrary code execution by, for example, overwriting the `authorized_keys` file. This is possible because wireshark can save traces, and an attacker who controls memory can trivially overwrite the filename being written to with one the attacker picks.

If the attacker waits for the user to click save and simply overwrites the file argument, this would be a data-only attack under our definitions. It is also possible to use control-flow bending to invoke `file_save_as_cb()` directly, by returning into the GTK library and overwriting a code pointer with the file save method, which is within the CFG.

7.2.5 Evaluation of xpdf

Similar to wireshark, an attacker can use xpdf to write to arbitrary files using `memcpy()` as a dispatcher gadget when there is no shadow stack. When a shadow stack is present, we are limited to a printf-oriented programming attack and we can only write files with specific extensions, which does not obviously give us ability to run arbitrary code.

7.2.6 Evaluation of mysql

When no shadow stack is present, attacks are trivial. A dispatcher gadget lets us return into `do_system()`, `do_exec()`, or `do_perl()` from within the mysql client. (For this attack we assume a vulnerable client to connects to a malicious server controlled by the attacker.) When a shadow stack is present the attacker is more limited, but we still can use printf-oriented programming to obtain arbitrary computation on memory. We could not obtain arbitrary execution with a shadow stack.

7.3 Combining attacks

As these six case studies indicate, control-flow bending is a realistic attack technique. In the five cases where CFI does not immediately stop the exploit from occurring, as it does for Apache, an attacker can use the vulnerability to achieve arbitrary writes in memory. From here, it is possible to mount traditional data-only attacks (e.g., by modifying configuration data-structures). We showed that using control-flow bending techniques, more powerful attacks are possible. We believe this attack technique is general and can be applied to other applications and vulnerabilities.

8 Related work

Control-flow integrity. Control-flow integrity was originally proposed by Abadi et al. [1, 15] a decade ago. Classical CFI instruments indirect branch target locations with equivalence-class numbers (encoded as a label in a side-effect free instruction) that are checked at branch locations before taking the branch. Many other CFI schemes have been proposed since then.

The most coarse-grained policies (e.g., Native Client [40] or PittSFIeld [20]) align valid targets to the beginning of chunks. At branches, these CFI schemes ensure that control-flow is not transferred to unaligned addresses. Fine-grained approaches use static analysis of source code to construct more accurate CFGs (e.g., WIT [2] and HyperSafe [39]). Recent work by Niu et al. [27] added support for separate compilation and dynamic loading. Binary-only CFI implementations are generally more coarse-grained: MoCFI [13] and BinCFI [44] use static binary rewriting to instrument indirect branches with additional CFI checks.

CFI evaluation metrics. Others have attempted to create methods to evaluate practical CFI implementations. The Average Indirect target Reduction (AIR) [44] metric was proposed to measure how much on average the set of indirect valid targets is reduced for a program under CFI. We argue that this metric has limited utility, as even high AIR values of 99% are insecure, allowing an attacker to perform arbitrary computation and issue arbitrary system calls. The gadget reduction metric is another way to evaluate CFI effectiveness [27], by measuring how much the set of reachable gadgets is reduced overall. Gadget finder tools like ROPgadget [34] or ropper [33] can be used to estimate this metric.

CFI security evaluations. There has recently been a significant effort to analyze the security of specific CFI schemes, both static and dynamic. Göktaş et al. [16] analyzed the security of static coarse-grained CFI schemes and found that the specific policy of requiring returns to target call-preceded locations is insufficient. Following this work, prevent-the-exploit-style coarse-grained CFI schemes with dynamic components that rely on runtime heuristics were defeated [5, 14]. The attacks relied upon the fact that the attacks could hide themselves from the dynamic heuristics, and then reduced down to attacks on coarse-grained CFI. Our evaluation of minimal programs builds on these results by showing that coarse-grained CFI schemes which have an AIR value of 99% are still vulnerable to attacks on trivially small programs.

Non-control data attacks. Attacks that target only sensitive data structures were categorized as *pure data attacks* by Pincus and Baker [32]. Typically, these attacks would overwrite application-specific sensitive variables (such as the “is authenticated” boolean which exists within many applications). This was expanded by Chen et al. [8] who demonstrated that *non-control data attacks* are practical attacks on real programs. Our work generalizes these attacks to allow modifications of control-flow data, but only in a way that follows the CFI policy.

Data-flow integrity. Nearly as old of an idea as CFI, Data-Flow Integrity (DFI) provides guarantees for the integrity of the data within a program [6]. Although the original scheme used static analysis to compute an approximate data-flow graph — what we would now call a coarse-grained approach — more refined DFI may be able to protect against our attacks. We believe security evaluation of prevent-the-corruption style defenses such as DFI is an important future direction of research.

Type- and memory-safety. Other defenses have tried to bring type-safety and memory-safety to unsafe languages like C and C++. SoftBound [22] is a compile-time defense which enforces spatial safety in C, but at a 67% performance overhead. CETS [23] extends this work with a compile-time defense that enforces temporal safety in C, by protecting against memory management errors. CCured [24] adds type-safe guarantees to C by attempting to statically determine when errors cannot occur, and dynamically adding checks when nothing can be proven statically. Cyclone [17] takes a more radical approach and re-designs C to be type- and memory-safe. Code-Pointer Integrity (CPI) [18] reduces the overhead of SoftBound by only protecting code pointers. While CPI protects the integrity of all indirect control-flow transfers, limited control-flow bending attacks using conditional jumps may be possible by using non-control-data attacks. Evaluating control-flow bending attacks on CPI would be an interesting direction for future work.

9 Conclusion

Control-flow integrity has historically been considered a strong defense against control-flow hijacking attacks and ROP attacks, if implemented to its fullest extent. Our results indicate that this is not entirely the case, and that control-flow bending allows attackers to perform meaningful attacks even against systems protected by fully-precise static CFI. When no shadow stack is in place, dispatcher functions allow powerful attacks. Consequently, CFI without return instruction integrity is not secure. However, CFI with a shadow stack does still provide value as a defense, if implemented correctly. It can significantly raise the bar for writing exploits by forcing attackers to tailor their attacks to a particular application; it limits an attacker to issue only system calls available to the application; and it can make specific vulnerabilities unexploitable under some circumstances.

Our work has several implications for design and deployment of CFI schemes. First, shadow stacks appear to be essential for the security of CFI. We also call for adversarial analysis of new CFI schemes before they are deployed, as our work indicates that many published CFI schemes have significant security weaknesses. Finally, to make control-flow bending attacks harder, deployed systems that use CFI should consider combining CFI with other defenses, such as data integrity protection to ensure that data passed to powerful functions cannot be corrupted in the presence of a memory safety violation.

More broadly, our work raises the question: just how much security can prevent-the-exploit defenses (which allow the vulnerability to be triggered and then try to prevent exploitation) provide? In the case of CFI, we argue the answer to this question is that it still provides some, but not complete, security. Evaluating other prevent-the-exploit schemes is an important area of future research.

We hope that the analyses in this paper help establish a basis for better CFI security evaluations and defenses.

10 Acknowledgments

We would like to thank Jay Patel and Michael Theodorides for assisting us with three of the case studies. We would also like to thank Scott A. Carr, Per Larsen, and the anonymous reviewers for countless discussions, feedback, and suggestions on improving the paper. This work was supported by NSF grant CNS-1513783, by the AFOSR under MURI award FA9550-12-1-0040, and by Intel through the ISTC for Secure Computing.

A Minimal vulnerable program for indirect jump or call hijacking

The program in Figure 6 contains a bug that allows the attacker to reliably hijack an indirect jump or indirect call target. The function `overflow()` allows an attacker to overflow a struct allocated on the stack that contains two pointers used as the targets for an indirect jump or an indirect call, respectively. The attacker can use the indirect jump or call to divert control flow to a return gadget and continue with a classic ROP attack. Alternatively, an attacker may rely on JOP or COP techniques. We also examined variations of this minimal vulnerable program, e.g., putting the struct somewhere on the heap or requiring the attacker to first perform a stack pivot to ensure that the stack pointer points to attacker-controlled data.

```
#include <stdio.h>
#include <string.h>
#define STDIN 0

void jmptarget();
void calltarget();

struct data {
 char buf[1024];
 int arg1;
 int arg2;
 int arg3;
 void (*jmpPtr)();
 void (*callPtr)(int,int,int);
};

void overflow() {
 struct data our_data;
 our_data.jmpPtr = &&label;
 our_data.callPtr = &calltarget;
 printf("%x\n", (unsigned int)&our_data.buf);
 printf("\ndata>␣");
 read(STDIN, our_data.buf, 1044);
 printf("\n");
 asm("push␣%0;push␣%1;push␣%2;call␣*%3;add␣$12,%%esp;"
 : : "r"(our_data.arg3),
     "r"(our_data.arg2),
     "r"(our_data.arg1),
     "r"(our_data.callPtr));
 asm("jmp␣*%0" : : "r"(our_data.jmpPtr));
 printf("?\n");
label:
 printf("label␣reached\n");
}

void jmptarget() {
 printf("jmptarget()␣called\n");
}

void calltarget(int arg1, int arg2, int arg3) {
 printf("calltarget()␣called␣(args:␣%x,␣%x,␣%x)\n",
 arg1, arg2, arg3);
}

int main(int argc, char* argv[]) {
 setbuf(stdout, NULL);
 overflow();
 printf("\ndone.\n");
 return 0;
}
```

Figure 6: A minimal vulnerable program that allows hijack of an indirect jump or indirect call target.

B Printf is Turing-complete

The semantics of `printf()` allow for Turing-complete computation while following the minimal CFG.

At a high level, we achieve Turing-completeness by creating logic gates out of calls to `printf()`. We show how to expand a byte to its eight bits, and how to compact the eight bits back to a byte. We will compute on values by using them in their base-1 (unary) form and we will use string concatenation as our primary method of arithmetic. That is, we represent a true value as the byte sequence 0x01 0x00, and the false value by the byte sequence 0x00 0x00, so that when treated as strings their lengths are 1 and 0 respectively.

Figure 7 contains an implementation of an OR gate using only calls to `printf()`. In the first call to `printf()`, if either of the two inputs is non-zero, the output length will be non-zero, so the output will be set to a non-zero value. The second call to `printf()` normalizes the value so if it was any non-zero value it becomes a one. Figure 7 implements a NOT gate using the fact that adding 255 is the same as subtracting one, modulo 256.

In order to operate on bytes instead of bits in our contrived format, we implement a test gate which can test if a byte is equal to a specific value. By repeating this test gate for each of the 256 potential values, we can convert a 8-bit value to its "one-hot encoding" (a 256-bit value with a single bit set, corresponding to the original value). Splitting a byte into bits does not use a pointer to a byte, but a byte itself. This requires that the byte is on the stack. Moving it there takes some effort, but can still be done with `printf()`. The easiest way to achieve this would be to interweave calls to `memcpy()` and `printf()`, copying the bytes to the stack with `memcpy()` and then operating on them with

```
void or(int* in1, int* in2, int* out) {
  printf("%s%s%n", in1, in2, out);
  printf("%s%n", out, out);
}

void not(int* in, int* out) {
  printf("%*d%s%n", 255, in, out);
  printf("%s%n", out, out);
}

void test(int in, int const, int* out) {
  printf("%*d%*d%n", in, 0, 256-const, 0, out);
  printf("%s%n", out, out);
  printf("%*d%s%n", 255, out, out);
  printf("%s%n", out, out);
}

char* pad = memalign(257, 256);
memset(pad, 1, 256);
pad[256] = 0;
void single_not(int* in, int* out) {
  printf("%*d%s%n%hhn%s%s%n", 255, in, out,
         addr_of_argument, pad, out, out);
}
```

Figure 7: Gadgets for logic gates using printf.

printf(). However, this requires more of the program CFG, so we instead developed a technique to achieve the same goal without resorting to memcpy(). When printf() is invoked, the characters are not sent directly to the stdout stream. Instead, printf() will use the FILE struct corresponding to the stdout stream to buffer the data temporarily. Since the struct is stored in a writable memory location, the attacker can invoke printf() with the “%n” format specifier to point the buffer onto the stack. Then, by reading values out of memory with “%s” the attacker can move these values onto the stack. Finally, the buffer can be moved back to its original location.

It is possible to condense multiple calls to printf() to only one. Simply concatenating the format strings is not enough, because the length of the strings is important with the “%n” modifier. That is, after executing a NOT gate, the string length will either be 255 or 256. We cannot simply insert another NOT gate, as that would make the length be one of 510, 511, or 512. We fix this by inserting a *length-repairing sequence* of “%hhn%s”, which pads the length of the string to zero modulo 256. We use it to create a NOT gate in a single call to printf() in Figure 7. Using this technique, we can condense an arbitrary number of gates into a single call to printf(). This allows bounded Turing-complete computation.

To achieve full Turing-complete computation, we need a way to loop a format string. This is possible by overwriting the pointer inside printf() that tracks which character in the format string is currently being executed. The attacker is unlucky in that at the time the “%n” format specifier is used, this value is saved in a register on our 64-bit system. However, we identify one point in time in which the attacker can always mount the attack. The printf() function makes calls to puts() for the static components of the string. When this function call is made, all registers are saved to the stack. It turns out that an attacker can overwrite this pointer from within the puts() function. By doing this, the format string can be looped.

An attacker can cause puts() to overwrite the desired pointer. Prior to printf() calling puts(), the attacker uses “%n” format specifiers to overwrite the stdout FILE object so that the temporary buffer is placed directly on top of the stack where the index pointer will be saved. Then, we print the eight bytes corresponding to the new value we want the pointer to have. Finally, we use more “%n” format specifiers to move the buffer back to some other location so that more unintended data will not be overwritten.

C Fputs-oriented programming

These printf-style attacks are not unique to printf(): many other functions can be exploited in a similar manner. We give one further attack using fputs(). For brevity, we show how an attacker can achieve a conditional write, however other computation is possible.

The FILE struct contains three char* fields to temporarily buffer character data before it is written out: a base pointer, a current pointer, and an end pointer. fputs() works by storing bytes sequentially starting from the base pointer keeping track with the current pointer. When it exceeds the end pointer, the data is written out, and the current pointer is set back to the base. Programmatically, the way this works is that if the current pointer is larger than the end pointer, fputs() flushes the buffer and then sets the current pointer to the base pointer and continues writing.

This can be used to conditionally copy from source address S to target address T if the byte address C is nonzero. Using fputs(), the attacker copies the byte at C on top of each of the 8 bytes in the end pointer. Then, the attacker sets the current pointer to T and then calls fputs() with this FILE and argument S. If the byte at C is zero, the end pointer is the NULL pointer, and no data is written. Otherwise, the data is written.

This attack requires two calls to fputs(). We initialize memory with the constant pointers that are desired. The first call to fputs() moves the C byte over the end pointer. The second call is the conditional move. The two calls can be obtained by loop injection, or by identifying an actual loop in the CFG.

Automatic Generation of Data-Oriented Exploits

Abstract

As defense solutions against control-flow hijacking attacks gain wide deployment, control-oriented exploits from memory errors become difficult. As an alternative, attacks targeting non-control data do not require diverting the application's control flow during an attack. Although it is known that such data-oriented attacks can mount significant damage, no systematic methods to automatically construct them from memory errors have been developed. In this work, we develop a new technique called *data-flow stitching*, which systematically finds ways to join data flows in the program to generate data-oriented exploits. We build a prototype embodying our technique in a tool called FLOWSTITCH that works directly on Windows and Linux binaries. In our experiments, we find that FLOWSTITCH automatically constructs 16 previously unknown and three known data-oriented attacks from eight real-world vulnerable programs. All the automatically-crafted exploits respect fine-grained CFI and DEP constraints, and 10 out of the 19 exploits work with standard ASLR defenses enabled. The constructed exploits can cause significant damage, such as disclosure of sensitive information (e.g., passwords and encryption keys) and escalation of privilege.

1 Introduction

In a memory error exploit, attackers often seek to execute arbitrary malicious code, which gives them the ultimate freedom in perpetrating damage with the victim program's privileges. Such attacks typically hijack the program's control flow by exploiting memory errors. However, such control-oriented attacks, including code-injection and code-reuse attacks, can be thwarted by efficient defense mechanisms such as control-flow integrity (CFI) [10, 43, 44], data execution prevention (DEP) [12], and address space layout randomization (ASLR) [15, 33]. Recently, these defenses have become practical and are gaining universal adoption in commodity operating systems and compilers [8, 36], making control-oriented attacks increasingly difficult.

However, control-oriented attacks are not the only malicious consequence of memory error exploits. Memory errors also enable attacks through corrupting non-control data — a well-known result from Chen *et al.* [19]. We refer to the general class of non-control data attacks as *data-oriented attacks*, which allow attackers to tamper with the program's data or cause the program to disclose secret data inadvertently. Several recent high-profile vulnerabilities have highlighted the menace of these attacks. In a recent exploit on Internet Explorer (IE) 10, it has been shown that changing a single byte — specifically the *Safemode* flag — is sufficient to run arbitrary code in the IE process [6]. The Heartbleed vulnerability is another example wherein sensitive data in an SSL-enabled server could be leaked without hijacking the control-flow of the application [7].

If data-oriented attacks can be constructed such that the exploited program follows a legitimate control flow path, they offer a realistic attack mechanism to cause damage even in the presence of state-of-the-art control-flow defenses, such as DEP, CFI and ASLR. However, although data-oriented attacks are conceptually understood, most of the known attacks are straightforward corruption of non-control data. No systematic methods to identify and construct these exploits from memory errors have been developed yet to demonstrate the power of data-oriented attacks. In this work, we study systematic techniques for automatically constructing data-oriented exploits from given memory corruption flaws.

Based on a new concept called *data-flow stitching*, we develop a novel solution that enables us to systematize the understanding and construction of data-oriented attacks. The intuition behind this approach is that non-control data is often far more abundant than control data in a program's memory space; as a result, there exists an opportunity to reuse existing data-flow patterns in the program to do the attacker's bidding. The main idea of data-flow stitching is to "stitch" existing data-flow paths in the program to form new (unintended) data-flow paths via exploiting memory errors. Data-flow stitching can thus connect two or more data-flow paths that are disjoint in the benign execution of the program. Such a stitched execution, for instance, allows the attacker to write out a secret value (e.g., cryptographic keys) to the program's public output, which otherwise would only be used in private operations of the application.

Problem. Our goal is to check whether a program is exploitable via data-oriented attacks, and if so, to automatically generate working data-oriented exploits. We aim to develop an exploit generation toolkit that can be used in conjunction with a dynamic bug-finding tool. Specifically, from an input that triggers a memory corruption bug in the program, with the knowledge of the program, our toolkit constructs a data-oriented exploit.

Compared to control-oriented attacks, data-oriented attacks are more difficult to carry out, since attackers cannot run malicious code of their choice even after the attack. Though non-control data is abundant in a typical program's memory space, due to the large range of possibilities for memory corruption and their subtle influence on program memory states, identifying how to corrupt memory values for a successful exploit is difficult. The main challenge lies in searching through the large space of memory state configurations, such that the attack exhibits an unintended data consequence, such as information disclosure or privilege escalation. An additional practical challenge is that defenses such as ASLR randomize addresses, making it even harder since absolute address values cannot be used in exploit payloads.

Our Approach. In this work, we develop a novel solution to construct data-oriented exploits through data-flow stitching. Our approach consists of a variety of techniques that stitch data flows in a much more efficient manner compared to manual analysis or brute-force searching. We develop ways to prioritize the searching for data-flow stitches that require a single new edge or a small number of new edges in the new data-flow path. We also develop techniques to address the challenges caused by limited knowledge of memory layout. To further prune the search space, we model the path constraints along the new data-flow path using symbolic execution, and check its feasibility using SMT solvers. This can efficiently prune out memory corruptions that cause the attacker to lose control over the application's execution, like triggering exceptions, failing on compiler-inserted runtime checks, or causing the program to abort abruptly. By addressing these challenges, a data-oriented attack that causes unintended behavior can be constructed, without violating control-flow requirements in the victim program.

We build a tool called FLOWSTITCH embodying these techniques, which operates directly on x86 binaries. FLOWSTITCH takes as input a vulnerable program with a memory error, an input that exploits the memory error, as well as benign inputs to that program. It employs dynamic binary analysis to construct an information-flow graph, and efficiently searches for data flows to be stitched. FLOWSTITCH outputs a working data-oriented exploit that either leaks or tampers with sensitive data.

Results. We show that automatic data-oriented exploit generation is feasible. In our evaluation, we find that multiple data-flow exploits can often be constructed from a single vulnerability. We test FLOWSTITCH on eight real-world vulnerable applications, and FLOWSTITCH automatically constructs 19 data-oriented exploits from eight applications, 16 of which are previously unknown to be feasible from known memory errors. All constructed exploits violate memory safety, but completely respect fine-grained CFI constraints. That is, they create no new edges in the static control-flow graph. All the attacks work with the DEP protection turned on, and 10 exploits (out 19) work even when ASLR is enabled. The majority of known data-oriented attacks (c.f. Chen *et. al.* [19], Heartbleed [7], IE-Safemode [6]) are straightforward non-control data corruption attacks, requiring at most one data-flow edge. In contrast, seven exploits we have constructed are only feasible with the addition of multiple data-flow edges in the data-flow graph, showing the efficacy of our automatic construction techniques.

Contributions. This paper makes the following contributions:

- We conceptualize *data-flow stitching* and develop a new approach that systematizes the construction of data-oriented attacks, by composing the benign data flows in an application via a memory error.
- We build a prototype of our approach in an automatic data-oriented attack generation tool called FLOWSTITCH. FLOWSTITCH operates directly on Windows and Linux x86 binaries.
- We show that constructing data-oriented attacks from common memory errors is feasible, and offers a promising way to bypass many defense mechanisms to control-flow attacks. Specifically, we show that 16 previously unknown and three known data-oriented attacks are feasible from eight vulnerabilities. All our 19 constructed attacks bypass DEP and the CFI checks, and 10 of them bypass ASLR.

2 Problem Definition

2.1 Motivating Example

The following example shown in Code 1 is modeled after a web server. It loads the web site's private key from a

```
1  int server() {
2    char *userInput, *reqFile;
3    char *privKey, *result, output[BUFSIZE];
4    char fullPath[BUFSIZE] = "/path/to/root/";
5
6    privKey = loadPrivKey("/path/to/privKey");
7    /* HTTPS connection using privKey */
8    GetConnection(privKey, ...);
9    userInput = read_socket();
10   if (checkInput(userInput)) {
11     /* user input OK, parse request */
12     reqFile = getFileName(userInput);
13     /* stack buffer overflow */
14     strcat(fullPath, reqFile);
15     result = retrieve(fullPath);
16     sprintf(output,"%s:%s",reqFile,result);
17     sendOut(output);
18   }
19 }
```

Code 1: Vulnerable code snippet. String concatenation on line 14 introduces a stack buffer overflow vulnerability.

file, and uses it to establish an HTTPS connection with the client. After receiving the input — a file name, the code sanitizes the input by invoking `checkInput()` (on line 10). The code then retrieves the file content and sends the content and the file name back to the client. There is a stack buffer overflow vulnerability on line 14, through which the client can corrupt the stack memory immediately after the `fullPath` buffer.

However, there is no obvious security-sensitive non-control data [19] on the stack of the vulnerable function. To create a data-oriented attack, we analyze the data flow patterns in the program's execution under a benign input, which contains at least two data flows: the flow involving the sensitive private key pointed to by the pointer named `privKey`, and the flow involving the input file name pointed by the pointer named `reqFile`, which is written out to the program's public outputs. Note that in the benign run, these two data flows do not intersect — that is, they have no shared variables or direct data dependence between them, but we can corrupt memory in such a way that the secret private key gets written out to the public output. Specifically, the attacker crafts an attack exploiting the buffer overflow to corrupt the pointer `reqFile`, making it to point to the private key. This forces the program to copy the private key to the output buffer in the `sprintf` function on line 16, and then the program sends the output buffer to the client on line 17. Note that the attack alters no control data, and executes the same execution path as the benign run.

This example illustrates the idea of *data-flow stitching*, an exploit mechanism to manipulate the benign data flows in a program execution without changing its control flow. Though it is not difficult to manually analyze this simplified example to construct a data-oriented attack, real-world programs are much more complex and often available in binary-only form. Constructing data-oriented attacks for such programs is a challenging task we tackle in this work.

2.2 Objectives & Threat Model

In this paper, we aim to develop techniques to automatically construct data-oriented attacks by stitching data flows. The generated data-oriented attacks result in the following consequences:

G1: Information disclosure. The attacks leak sensitive data to attackers. Specifically, we target the following sources of security-sensitive data:

- **Passwords and private keys**. Leaking passwords and private keys help bypass authentication controls and break secure channels established by encryption techniques.
- **Randomized values**. Several memory protection defenses utilize randomized values generated by the program at runtime, such as stack canaries, CFI-enforcing tags, and randomized addresses. Disclosure of such information allows attackers bypass randomization-based defenses.

G2: Privilege escalation. The attacks grant attackers the access to privileged application resources. Specifically, we focus on the following kinds of program data:

- **System call parameters**. System calls are used for high-privilege operations, like `setuid()`. Corrupting system call parameters can lead to privilege escalation.
- **Configuration settings**. Program configuration data, especially for server programs (e.g., data loaded from `httpd.conf` for Apache servers) specifies critical information, such as the user's permission and the root directory of the web server. Corrupting such data directly escalates privilege.

Threat Model. We assume the execution environment has deployed defense mechanisms against control-flow hijacking attacks, such as fine-grained CFI [10,32], non-executable data [12] and state-of-the-art implementation of ASLR. Therefore attackers cannot mount control flow hijacking attacks. All non-deterministic system generated values, e.g., stack-canaries or CFI tags, are assumed to be secret and unknown to attackers.

2.3 Problem Definition

To systematically construct data-oriented exploits, we introduce a new abstraction called the *two-dimensional data-flow graph (2D-DFG)*, which represents the flows of data in a given program execution in two dimensions: memory addresses and execution time. Specifically, a

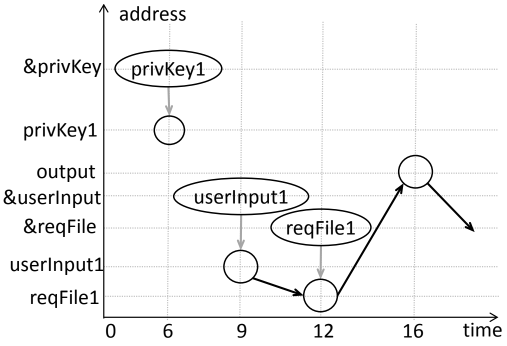

Figure 1: 2D-DFG of a concrete execution of Code 1. Black edges are data edges, while grey edges are address edges. For clarity, vertices do not strictly conform the order on address-axis (this applies to all figures). We use line number to represent the time. $var1$ means a particular value (constant) of the variable `var` in Code 1.

2D-DFG is a directed graph, represented as $G = \{V,E\}$, where V is the set of vertices, and E is the set of edges. A vertex in V is a variable instance, i.e., a point in the two dimensional address-time space, denoted as (a,t), where a is the address of the variable, and t is a representation of the execution time when the variable instance is created. The address includes both memory addresses and register names[1], and the execution time is represented as an instruction counter in the execution trace of the program. An edge (v', v) from vertex v' to vertex v denotes a data dependency created during the execution, i.e., the value of v or the address of v is derived from the value of v'. Therefore, the 2D-DFG also embodies the "points to" relation between pointer variables and pointed variables. Each vertex v has a `value` property, denoted as $v.value$.

A new vertex $v = (a,t)$ is created if an instruction writes to address a at the execution time t. A new data edge (v′, v) is created if an instruction takes v' as the source operand and takes v as a destination operand. A new address edge (v′, v) is created if an instruction takes v′ as the address of one operand v. Therefore, an instruction may create several vertices at a given point in execution if it changes more than one variables, for instance in the loop-prefixed instructions (e.g., `repmov`). Note that the 2D-DFG is a representation of the direct data dependencies created in a program execution under a concrete input, not the static data-flow graph often used in static analysis. Figure 1 shows a 2D-DFG of Code 1.

We define the core problem of *data-flow stitching* as follows. For a program with a memory error, we take the following parameters as the input: a 2D-DFG G from a benign execution of the program, a memory error influence I, and two vertices v_S (source) and v_T (target). In our example, v_S is the private key buffer, shown as (privKey1[2], 6) in Figure 1 and v_T is the public output buffer, shown as (output, 16) in Figure 1. Our goal is to generate an exploit input that exhibits a new 2D-DFG $G' = \{V',E'\}$, where V' and E' result from the memory error exploit, and that G' contains data-flow paths from v_S to v_T. Let $\overline{E} = E' - E$ be the edge-set difference and $\overline{V} = V' - V$ be the vertex-set difference. Then, $\overline{E}$ is the set of new edges we need to generate to get E' from E.

The memory error influence I is the set of memory locations which can be written to by the memory error, represented as a set of vertices. Therefore, we must select $\overline{V}$ to be a subset of vertices in I. To achieve **G1** we consider variables carrying program secrets as source vertices and variables written to public outputs as target vertices. In the development of attacks for **G2**, source vertices are attacker-controlled variables and target vertices are security-critical variables such as system call parameters. A successful data-oriented attack should additionally satisfy the following critical requirements:

- **R1.** The exploit input satisfies the program path constraints to reach the memory error, create new edges and continue the execution to reach the instruction creating v_T.
- **R2.** The instructions executed in the exploit must conform to the program's static control flow graph.

2.4 Key Technique & Challenges

The key idea in data-flow stitching is to efficiently search for the new data-flow edge set $\overline{E}$ to add in G' such that it creates new data-flow paths from v_S to v_T. For each edge $(x,y) \in \overline{E}$, x is data-dependent on v_S and v_T is data-dependent on y. We denote the sub-graph of G containing all the vertices that are data-dependent on v_S as the source flow. We also denote the sub-graph of G containing all the vertices that v_T is data-dependent on as the target flow. For each vertex pair (x, y), where x is in the source flow and y is in the target flow, we check whether (x, y) is a feasible edge of $\overline{E}$ resulting from the inclusion of vertices from I. The vertices x and y may either be contained in I directly, or be connected via a sequence of edges by corruption of their pointers which are in I. If we change the address to which x is written, or change the address from which y is read, the value of x will flow to y. If so, we call (x, y) the *stitch edge*, x the *stitch source*, and y the *stitch target*. For example, in Figure 2, we change the pointer (which is in I) of the file name from $reqFile1$ to $privKey1$. Then the flow of the private key and the flow of the file name are stitched, as we discuss in Section 2.1. In finding data-flow stitching in the 2D-DFG, we face the following challenges:

- **C1. Large search space for stitching.** A 2D-DFG from a real-world program has many data flows and a large number of vertices. For example, there are

[1] We treat the register name as a special memory address.

[2] privKey1 here means the key buffer address, a concrete value.

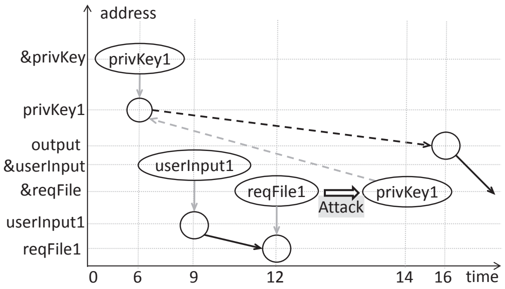

Figure 2: A data-oriented attack of Code 1. This attack connects flow of the private key and flow of the file name, with the new edges (dashed lines).

776 source vertices and 56 target vertices in one of SSHD attacks. Therefore, the search space to find a feasible path is large, for we often need heavy analysis to connect each pair of vertices.

- **C2. Limited knowledge of memory layout.** Most of the modern operating systems have enabled ASLR by default. The base addresses of data memory regions, like the stack and the heap, are randomized and thus are difficult to predict.

The 2D-DFG captures only the data dependencies in the execution, abstracting away control dependence and any conditional constraints the the program imposes along the execution path. To satisfy the requirements **R1** and **R2** completely, the following challenge must be addressed:

- **C3. Complex program path constraints.** A successful data-oriented attack causes the victim program execute to the memory error, create a stitch edge, and continue without crashing. This requires the input to satisfy all path constraints, respect the program's control flow integrity constraints, and avoid invalid memory accesses.

3 Data-flow Stitching

Data-oriented exploits can manipulate data-flow paths in a number of different ways to stitch the source and target vertices. The solution space can be categorized based on the number of new edges added by the exploit. The simplest case of data-oriented exploits is when the exploit adds a single new edge. More complex exploits that use a sequence of corrupted values can be crafted when a single-edge stitch is infeasible. We discuss these cases to solve challenge **C1** in Section 3.1 and 3.2. To overcome the challenge **C2**, we develop two methods to make data-oriented attacks work even when ASLR is deployed, discussed in Section 3.3. For each stitch candidate, we consider the path constraints and CFI requirement (**C3**) to generate input that trigger the stitch edge in Section 4.4.

```
1   struct passwd { uid_t pw_uid; ... } *pw;
2   ...
3   int uid = getuid();
4   pw->pw_uid = uid;
5   ...                  //format string error
6   void passive(void) { ...
7     seteuid(0);                 //set root uid
8     ...
9     seteuid(pw->pw_uid);  //set normal uid
10    ... }
```

Code 2: Code snippet of wu-ftpd, setting uid back to process user id.

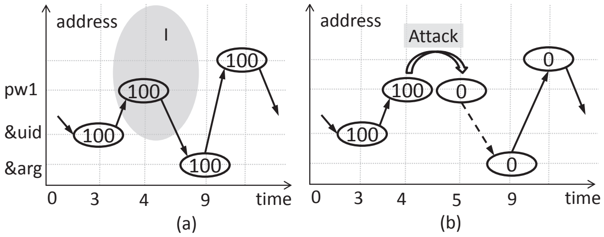

Figure 3: Target flow in the single-edge stitch of wu-ftpd. &arg is the stack address of setuid's argument. (a) is the original target flow, where the pw->pwd_uid has vale 100 and address $pw1$. Grey area stands for the memory influence I. With the stitching attack, the value at address $pw1$ is changed to 0 in (b).

3.1 Basic Stitching Technique

A basic data-oriented exploit adds one edge in the new edge set $\overline{E}$ to connect v_S with v_T. We call this case a *single-edge stitch*. For instance, attackers can create a single new vertex at the memory corruption point by overwriting a security-critical data value, causing escalation of privileges. Most of the previously known data-oriented attacks are cases of single-edge stitches, including attacks studied by Chen *et al.* [19] and the IE Safemode attack [6]. We use the example of a vulnerable web server wu-ftpd, shown in Code 2, which was used by Chen *et al.* to explain non-control data attacks [19]. In this exploit, the attackers utilizes a format string vulnerability (skipped on line 5) to overwrite the security-critical pw->pw_uid with root user's id. The subsequent setuid call on line 9, which is intended to drop the process privileges, instead makes the program retain its root user privileges. Figure 3 (a) and Figure 3 (b) show the 2D-DFG for the execution of the vulnerable code fragment under a benign and the exploit payload respectively. Numbers on time-axis are the line numbers in Code 2. The exploit aims to introduce a single edge to write a zero value from the network input to the memory allocated to the pw->pw_id. Note that the exploit is a valid path in the static control-flow graph.

Search for Single-Edge Stitch. Instead of brute-forcing all vertices in the target flow for a stitch edge, we propose a method that utilizes the influence set I of the mem-

StitchAlgo-1: Single-edge Stitch

```
Input: $G$: benign 2D-DFG,            $I$: memory influence,
       $v_T$: target vertex,          $cp$: memory error vertex,
       $X$: value to be in $V_T$.value (requirement for stitch edge)
Output: $\overline{E}$: stitch edge candidate set
$\overline{E} = \emptyset$
$TDFlow$ = dataSubgraph($G$, $v_T$)                    /* only data edges */
foreach $v \in V(TDFlow)$ do
    if $isRegister(v)$ then
        continue                                       /* Skip registers */
    if $\exists\ (v, v') \in E(TDFlow): \exists\ t : v.time < t < v'.time \wedge$
    $(v.address, t) \in I$ then
        $\overline{E} = \overline{E} \cup \{(cp, v)\}$           /* Stitch edge candidate */
```

ory error to prune the search space. The influence set I contains vertices that can be corrupted by the memory error, like the grey area shown in Figure 3. For vertices in the target flow, attackers can only affect those in the intersection of the target flow and the influence I. Other vertices do not yield a single-edge stitch and can be filtered out. Specifically, we utilize three observations here. First, register vertices can be ignored since memory error exploit cannot corrupt them. Second, the vertex must be defined (written) before the memory error and used (read) after the memory error. In Figure 3 (a), the code reads vertex (&uid, 3) before the memory error and writes vertices (&arg, 9) and the following one after the memory error. Therefore these three vertices are useless for single-edge stitches. Third, in the memory address dimension, the vertex address should belong to the memory region of the influence I. In our example, only vertex (pw1, 4) falls into the intersection of the target flow and the influence area and we select this vertex for stitch. StitchAlgo-1 shows the algorithm to identify single-edge stitch. From the given 2D-DFG, StitchAlgo-1 gets the target flow $TDFlow$ for the target vertex v_T, which only considers data edges. For each vertex v that satisfies the requirements, we add the edge from memory error vertex to v into $\overline{E}$ as one possible solution.

We consider the search space reduction due to our algorithm over a brute-force search for stitch edges. The naïve brute-force search would consider the Cartesian product of all vertices in the source flow and the target flow. In our algorithm, this search is reduced to the Cartesian product of only the live variables in the source flow at the time of corruption, and the vertices in the target flow as well as in I. In our experiments, we show that this reduction can be significant.

3.2 Advanced Stitching Technique

Single-edge stitch is a basic stitching method, creating one new edge. Advanced data-flow stitching techniques create paths with multiple edges in the new edge set $\overline{E}$. A *multi-edge stitch* can be synthesized through several ways. Attackers can use several single-edge stitches to create a multi-edge stitch. Another way is to perform *pointer stitch*, which corrupts a variable that is later used as a pointer to vertices in the source or target flow. Since the pointer determines the address of the stitch source or the stitch target, corrupting the pointer introduces two different edges: one edge for the new "points to" relationship and one edge for the changed data flow. We revisit the example of `wu-ftpd` shown earlier in Code 2, illustrating a multi-edge stitch exploit in it. Instead of directly modifying the field `pw_uid`, we change its base pointer `pw` to an address of a structure with a constant `0` at the offset corresponding to the `pw_uid`. The vulnerable code then reads `0` and uses it as the argument of `setuid`, creating a privilege escalation attack. Figure 4 shows the 2D-DFGs for the benign and attack executions. Changing the value of `pw` creates two new edges (dashed lines): the grey edge that connects the corrupted pointer to a new variable it points to, and the black edge that writes the new variable into `setuid` argument. As a result, we create a two-edge stitch.

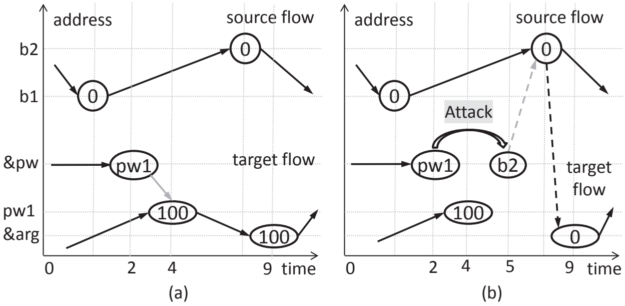

Figure 4: Two-edge stitch of `wu-ftpd`. The target flow is `pw->pw_uid`'s flow, and the source flow is the flow of a constant 0. With the attack, the variable `pw` at `&pw` is changed to $b2$. A later operation reads 0 from $b2$ and writes it to stack for `setuid`. Two edges are changed: one for pointer dereference and another for data movement.

Identifying Pointer Stitches. Our algorithm for finding multi-edge exploits using pointer stitching is shown in the StitchAlgo-2. The basic idea is to check each memory vertex in the source flow and the target flow. If it is pointed to by another vertex in the 2D-DFG, we select the pointer vertex to corrupt. The search for stitchable pointers on the target flow is different from that on the source flow. Specifically, for a vertex v in the target flow, we need to find an data edge (v', v) and a pointer vertex vp of v', and then change vp to point to a vertex vs in the source flow, so that a new edge (vs, v) will be created to stitch the data flows. For a vertex v in the source flow, we need to find an data edge (v, v') and a pointer vertex vp of v', and change vp to point to a vertex vt in the target flow, so that a new edge (v, vt) will be created to stitch the data flows. At the same time, we need to consider the liveness of the stitching vertices. For example, the source vertex

```
StitchAlgo-2: Pointer Stitch
Input: $G$: benign 2D-DFG,            $I$: memory influence,
       $v_S$: source vertex,          $v_T$: target vertex,
       $cp$: memory error vertex
Output: $\overline{E}$: stitch edge candidate set
$\overline{E} = \emptyset$
$SrcFlow$ = subgraph($G$, $v_S$)      /* both data and address edges. */
$TgtFlow$ = subgraph($G$, $v_T$)
$SDFlow$ = dataSubgraph($G$, $v_S$)        /* only data edges */
$TDFlow$ = dataSubgraph($G$, $v_T$)
foreach $v \in V(TDFlow)$ do
    if $isRegister(v)$ then continue
    if $\nexists\ (vi \in E(I) \wedge (v, v') \in TDFlow) : vi.time < v'.time$ then
    continue
    foreach $(vp, v) \in E(TgtFlow) - E(TDFlow)$ do
        /* Only consider address edges.                     */
        if $vp$ is used to write $v$ then continue
        /* Expect data flow from $v$                          */
        foreach $vs \in V(SDFlow)$ do
            if $\neg isRegister(vs) \wedge vs.isAliveAt(vp.time)$ then
                StitchAlgo-1($G$, $I$, $vp$, $cp$, $vs$.address)
foreach $v \in V(SDFlow)$ do
    if $isRegister(v)$ then continue
    if $\forall\ vi \in I: v.time < vi.time$ then continue
    foreach $(vp, v) \in E(SrcFlow) - E(SDFlow)$ do
        if $vp$ is used to read $v$ then continue
        /* Expect data flow into $v$                          */
        foreach $vt \in V(TDFlow)$ do
            if $\neg\ isRegister(vt) \wedge \exists (vt, v') \in TDFlow : vt.time$
            $< vp.time < v'.time$ then
                StitchAlgo-1($G$, $I$, $vp$, $cp$, $vt$.address)
```

should carry valid source data when it is used to write data out to the target vertex. Once we select the pointer vertex vp and its value (vt's or vs's address), the last step is to set the value into vp through the memory error exploit. StitchAlgo-2 invokes the basic stitching technique in StitchAlgo-1 to complete the last step.

Our technique uses vertex liveness and the memory error influence I to significantly reduce the search space. A naïve solution to finding pointer stitches would consider all pairs (vs, vt) where vs is in the source flow and vt is in the target flow. The search space will be the Cartesian product of the vertex set in the source flow (denoted as $V(SrcFlow)$) and the vertex set in the target flow (denoted as $V(TgtFlow)$). In contrast, in StitchAlgo-2, if the memory corruption occurs at time $t1$, the vertex used in the stitch edge from the source flow must be live at $t1$. Similarly, the vertex used in the stitch edge from the target flow should be created after $t1$. We illustrate it in Figure 5, where only the black vertices are candidates. Furthermore, we restrict our search to the set of vertices whose pointer vertices vp are inside the memory influence as well. We call the selected vertices from the source flow *R-set*. Similarly, we call the vertices selected from the target flow *W-set*. Our algorithm reduces the search space to the Cartesian product of the R-set and W-set instead.

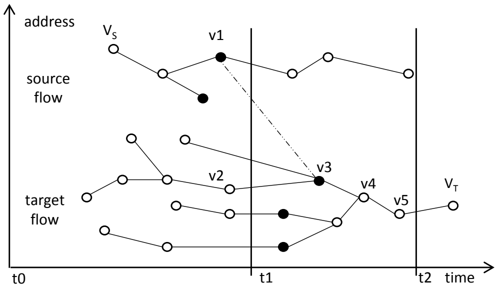

Figure 5: Stitch edge selection. The execution starts at time $t0$, and reaches memory error instructions at time $t1$. Target data is used at time $t2$, just before target vertex V_T. There are two stitch source candidates (black points in the source flow) and three stitch destination candidate (black points in the target flow). One of the stitch edge candidate is shown using the dotted line.

$$R\text{-}set = V(SrcFlow) \cap I, \quad W\text{-}set = V(TgtFlow) \cap I$$

$$|SS_{naive}| \;=\; |V(SrcFlow)| \times |V(TgtFlow)|$$

$$|SS_{pointer-stitch}| \;=\; |\ R\text{-}set\ | \times |\ W\text{-}set\ |$$

Pointer stitch constitutes a natural hierarchy of exploits, which can consist of multiple levels of dereferences of attacker-controlled pointers. For instance, in a *two-level pointer stitch* we can construct an exploit that corrupts a pointer vp_2 that points to the pointer vp. This can be achieved by treating vp as the target vertex, another pointer vp' holding the intended value (vt's or vs's address) as the source vertex and applying StitchAlgo-2 to change vp. In this case, StitchAlgo-2 is recursively used twice. Similarly, *N-level stitch* corrupts a pointer vp_N of the the pointer $vp_{(N-1)}$ to make an attack (and so on), by applying StitchAlgo-2 N times recursively. Note that for a N-level stitch to work, we need to make sure the source vertex vp'_N "aligns" with the target vertex vp_N at each level, such that the program dereferences vp_N N-1 times to get the vertex vp, and dereferences vp'_N N-1 time to get the intended value in the exploit.

Pointer stitch is one specific way to implement multi-edge stitches. In principle, it can be composed to create more powerful exploits, combining several other single-edge stitches in a "multi-step" stitch attack. In a multi-step stitch, several intermediate data flows are used to achieve data-flow stitching. Each step can be realized by pointer stitch or single-edge stitch. Multi-step stitch is useful when direct stitches of the source flow and the target flow are not feasible.

3.3 Challenges from ASLR

Address space layout randomization (ASLR) deployed by modern systems poses a strong challenge in mounting

Table 1: Deterministic memory region size of binaries on Ubuntu 12.04 x86 system. Position-independent executables have size 0. Two largest numbers are highlighted for each directory.

size (KB)	/bin	/sbin	/usr/bin	/usr/sbin	Total
0	21	22	73	18	134
1 - 8	10	**33**	**150**	**20**	**213**
8 - 16	12	17	113	11	153
16 - 32	**23**	17	**147**	14	**201**
32 - 64	**19**	**22**	103	**25**	169
64 - 128	15	8	66	8	97
128 - 256	7	2	35	4	48
256 - 512	3	2	32	3	40
> 512	2	2	32	2	38
Total	112	125	751	105	1093

successful data-oriented attacks since vertex addresses are highly unpredictable. We develop two methods in data-oriented attacks to address this challenge: stitching with deterministic addresses and stitching by address reuse. Note that attackers can use others methods developed for control flow attacks to bypass ASLR here, like disclosure of random addresses [14, 35].

3.3.1 Stitching With Deterministic Addresses

When security-critical data is stored in deterministic memory addresses, stitching data flows of such data is not affected by ASLR. Existing work [2, 34, 37] have shown that current ASLR implementations leave a large portion of program data in the deterministic memory region. For example, Linux binaries are often compiled without the "*-pie*" option, resulting in deterministic memory regions. We study deterministic memory size of Ubuntu 12.04 (x86) binaries under directories `/bin`, `/sbin`, `/usr/bin` and `/usr/sbin`, and show the results in Table 1. Among 1093 analyzed programs, more than 87.74% have deterministic memory regions. Two hundred and twenty-three programs have deterministic memory regions larger than 64KB. Inside such memory regions, there is many security-critical data, like randomized addresses in `.got.plt` and configuration structures in `.bss`. Hence we believe stitch with deterministic addresses in real-world programs is practical.

We build an information leakage attack against the `orzhttpd` web server [5] (details in Section 6.4.3) using the stitch with deterministic addresses. To respond to a page request, `orzhttpd` uses a pointer to retrieve the HTTP protocol version string. The pointer is stored in memory. If we replace the pointer value with the address of a secret data, the server will send that secret to the client. However this requires both the address of the pointer and the address of the secret to be predictable. In the `orzhttpd` example, we find that the address of the pointer is fixed (`0x8051164`) and choose the contents of the `.got.plt` section (allocated at a fixed address) as the secret to leak out. Figure 6 shows two 2D-DFGs for the benign execution and the attack, respectively. With this attack, the content of `.got.plt` is sent to the attacker, which leads to an memory address disclosure exploit useful for constructing second-stage control-hijacking attacks or stealing secret data in randomized memory region. Unlike a direct memory disclosure attack, here we use the corruption of deterministically-allocated data to leak randomized addresses.

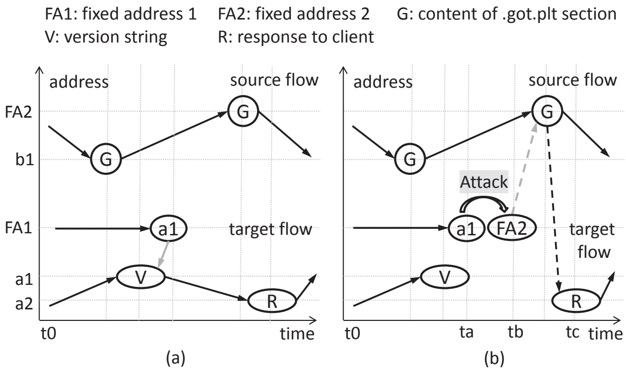

Figure 6: Stitch with deterministic memory addresses of the `orzhttpd` server. This attack is the similar to the one in Figure 4, except the address of the source vertex and the pointer's address of of the target vertex are fixed. This attack works with ASLR.

Identifying Stitch with Deterministic Addresses. We represent the deterministic memory region as a set *D*. Our algorithm considers the intersection of *D* for the vertices in the source flow and the target flow. The previously outlined stitching algorithms can then be used directly prioritizing the vertices in the intersection with *D*.

3.3.2 Stitching By Address Reuse

If the security-critical data only exists inside the randomized memory region, data-oriented attacks cannot use deterministic addresses. To bypass ASLR in such cases, we leverage the observation that a lot of randomized addresses are stored in memory. If we can reuse such real-time randomized addresses instead of providing concrete address in the exploit, the generated data-oriented attacks will be stable (agnostic to address randomization). There are two types of address reuse: partial address reuse and complete address reuse.

Partial Address Reuse. A variable's relative address, with respect to the module base address or with respect to another variable in the same module, is usually fixed. Attackers can easily calculate such relative addresses in advance. On the other hand, instructions commonly get a memory address with one base address and one relative offset (e.g., array access, switch table). If attackers control the offset variable, they can corrupt the offset with the pre-computed relative address from the selected vertex (source vertex or target vertex) and reuse the randomized base address. In this way attackers can access

```
1  struct user_details { uid_t uid; ... } ud;
2  ...                   //run with root uid
3  ud.uid = getuid();    //in get_user_info()
4  ...
5  vfprintf(...);        //in sudo_debug()
6  ...
7  setuid(ud.uid);       //in sudo_askpass()
8  ...
```

Code 3: Code snippet of sudo, setting uid to normal user id.

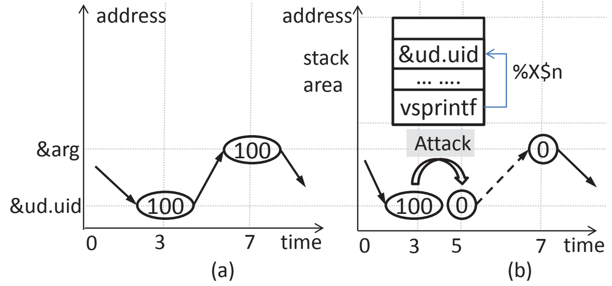

Figure 7: Stitch by complete memory address reuse of sudo. The dashed line is the new edge (single-edge stitch). An address of *ud.uid* exists on ancestor's stack frame, which is reused to overwrite *ud.uid*.

the intended data without knowing their randomized addresses. We show an example of a vulnerable instruction pattern, that allows the attacker partial ability to read a value from memory and write it out without knowing randomized addresses. If attackers control %eax, they can reuse the source base address %esi in the first instruction, and reuse the destination base address %edi in the second instruction. In fact, any memory access instruction with a corrupted offset can be used to mount partial address reuse attack.

```
//attackers control %eax
mov   (%esi,%eax,4), %ebx   //reuse %esi
mov   %ecx, (%edi,%eax,4)   //reuse %edi
```

Complete Address Reuse. We observe that a variable's address is frequently saved in memory due to the limitation of CPU registers. If the memory error allows retrieving such spilled memory address for reading or writing, attackers can reuse the randomized vertex address existing in memory to bypass ASLR. For example, in the following assembly code, if attacker controls %eax on line 1, it can load a randomized address into %ebx from memory. Then, attacker can access the target vertex pointed by %ebx without knowing the concrete randomized address. The attacker merely needs to know the right offset value to use in %eax on line 2, or may have a deterministic %esi value to gain arbitrary control over addresses loaded on line 2.

```
1  //attacker controls %eax
2  mov   (%esi, %eax, 4), %ebx
3  mov   %ecx, (%ebx) / mov (%ebx), %ecx
```

Let us consider a real example of the sudo program [9] that shows how to use such instruction patterns that permit complete address reuse meaningfully. Code 3 shows the related code of sudo, where a format string vulnerable exists in the sudo_debug function (line 5). At the time of executing vfprintf() on line 5, the address of the user identity variable (ud.uid) exists on the stack. The vfprintf() function with format string "%$X$$n" uses the Xth argument on stack for "%n". By specifying the value of X, vfprintf() can retrieve the address of ud.uid from its ancestor's stack frame and change the ud.uid to the root user ID without knowing the stack base address. Figure 7 shows the 2D-DFGs for the benign execution and the attack. This attack works even if the fine-grained ASLR is deployed.

Identifying Stitch by Address Reuse. Memory error instructions for address reuse stitch should match the patterns we discuss above. For partial address reuse, the memory error exploit corrupts variable offsets, while for complete address reuse, the memory error exploit can retrieve addresses from memory. Our approach intersects the memory error influence I with the source flow and the target flow. Then we search from the new source flow and the new target flow to identify matched instructions, from which we can build stitch by address reuse with methods discuss above.

4 The FlowStitch System

We design a system called FlowStitch to systematically generate data-oriented attacks using data-flow stitching. As shown in Figure 8, FlowStitch takes three inputs: a program with memory errors, an error-exhibiting input, and a benign input of the program. The two inputs should drive the program execution down the same execution path until the memory error instruction, with the error-exhibiting input causing a crash. FlowStitch builds data-oriented attacks using the memory errors in five steps. First, it generates the execution trace for the given program. We call the execution trace with the benign input the *benign trace*, and the execution trace with the error-exhibiting input the *error-exhibiting trace*. Second, FlowStitch identifies the influence of the memory errors from the error-exhibiting trace and generates constraints on the program input to reach memory errors. Third, FlowStitch performs data-flow analysis and security-sensitive data identification using the benign trace. Fourth, FlowStitch selects stitch candidates from the identified security-sensitive data flows with the methods discussed in Section 3. Finally, FlowStitch checks the feasibility of creating new edges with the memory errors and validates the exploit. It finally outputs the input to mount a data-oriented attack.

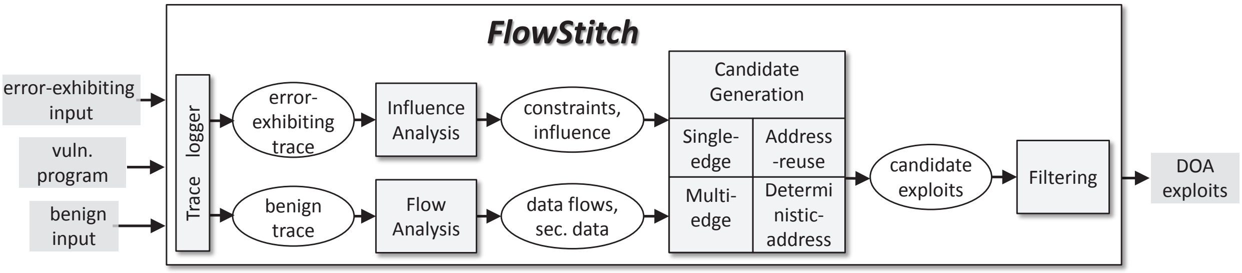

Figure 8: Overview of FLOWSTITCH. FLOWSTITCH takes a vulnerable program, an error-exhibiting input and a benign input of the program as inputs. It builds data-oriented attacks against the given program using data-flow stitching. Finally it outputs the data-oriented attack exploits.

FLOWSTITCH requires that the error-exhibiting input and the benign input make the program follow the same code path until memory error happens. Such pairs of inputs can be found by existing symbolic execution tools, like BAP [16] and SAGE [25], which explore multiple execution paths with various inputs. Before detecting one error-exhibiting execution, these tools usually have explored many matched benign executions.

4.1 Memory Error Influence Analysis

FLOWSTITCH analyzes the error-exhibiting trace to understand the influence I of the memory errors. It identifies two aspects of the memory error influence: the time when the memory errors happens during the execution (temporal influence) and the memory range that can be written to in the memory error (spatial influence). From the error-exhibiting trace, FLOWSTITCH detects instructions whose memory dereference addresses are derived from the error-exhibiting input. We call these instructions *memory error instructions*. Note that data flows ending before such instructions or starting after them cannot be affected by the memory error, therefore they are out of the temporal influence.

Attackers get access to unintended memory locations with memory error instructions. However, the program's logic limits the total memory range accessible to attackers. To identify the spatial influence of the memory error instruction, we employ dynamic symbolic execution techniques. We generate a symbolic formula from the error-exhibiting trace in which all the inputs are symbolic variables and all the path constraints are asserted true. Inputs that satisfy the formula imply that the execution to memory error instructions with an unintended address[3]. The set of addresses that satisfy these constraints and can be dereferenced at the memory error instruction constitute the spatial influence.

4.2 Security-Sensitive Data Identification

As we discuss in Section 2.3, FLOWSTITCH synthesizes flows of security-sensitive data. There are four types of data that are interesting for stitching: input data, output data, program secret and permission flags. To identify input data, FLOWSTITCH performs taint analysis at the time of trace generation, treating the given input as an external taint source. For output data, FLOWSTITCH identifies a set of program sinks that send out the program data, like `send()` and `printf()`. The parameters used in sinks are the output data. Further, we classify program secret and permission flags into two categories: the program-specific data and the generic data. FLOWSTITCH accepts user specification to find out program-specific data. For example, user can provide addresses of security flags. For the generic data, FLOWSTITCH uses the following methods to automatically infer it.

- **System call parameters.** FLOWSTITCH identifies all system calls from the trace, like `setuid`, `unlink`. Based on the system call convention, FLOWSTITCH collects the system call parameters.
- **Configuration data.** To identify configuration data, FLOWSTITCH treats the configuration file as a taint source and uses taint analysis to track the usage of the configuration data.
- **Randomized data.** FLOWSTITCH identifies stack canary based on the instructions that set and check the canary, and identifies randomized addresses if they are not inside the deterministic memory region.

Deterministic Memory Region Identification. FLOWSTITCH identifies the deterministic memory region for stitch with deterministic addresses (Section 3.3.1). It first checks the program binary to identify the memory regions that will not be randomized at runtime. If the program is not position-independent, all the data sections shown in the binary headers will be at deterministic addresses. FLOWSTITCH collects loadable sections and gets a deterministic memory set D. FLOWSTITCH further scans benign traces to find all the memory writing instructions that write data into the deterministic memory set to identify data stored in such region.

[3] This is true if the symbolic formula constructed is complete [26].

Note that based on the functionality of the security-sensitive data, we predefine goals of the attacks. For example, the attack of `setuid` parameter is to change it to the root user's id 0. For a web server's home directory string, the goal is to set it to system root directory.

4.3 Stitching Candidate Selection

For identified security-sensitive data, FLOWSTITCH generates its data flow from the 2D-DFG. FLOWSTITCH selects the source flow originated from the source vertex V_S and the target flow ended at the target vertex V_T. It then uses the stitching methods discussed in Section 3 to find stitching solutions. Although any combination of stitching methods can be used here, FLOWSTITCH uses the following policy in order to produce a successful stitching efficiently.

1. FLOWSTITCH tries the single-edge stitch technique before the multi-edge stitch technique. After the single-edge stitch's search space is exhausted, it moves to multi-edge stitch. FLOWSTITCH stops searching at four-edge stitch in our experiments.
2. FLOWSTITCH considers stitch with deterministic addresses before stitch by address reuse. After exhausting the search space of deterministic address and address reuse space, FLOWSTITCH continues searching stitches with concrete addresses shown in benign traces, for cases without ASLR.

4.4 Candidate Filtering

To overcome challenge **C3**, FLOWSTITCH checks the feasibility of each selected stitch edge candidate. We define the *stitchability constraint* to cover the following constraints.

- Path conditions to reach memory error instructions;
- Path conditions to continue to the target flow;
- Integrity of the control data;

FLOWSTITCH generates the stitchability constraint using symbolic execution tools. The constraint is sent to SMT solvers as an input. If the solver cannot find any input satisfying the constraint, FLOWSTITCH picks the next candidate stitch edge. If it exists, the input will be the witness input that is used to exercise the execution path in order to exhibit the data-oriented attack. Due to the concretization in symbolic constraint generation in the implementation, the constraints might not be complete [26], i.e., it may allow inputs that results in different paths. FLOWSTITCH concretely verifies the input generated by the SMT solver to check if it successfully mounts the data-oriented attack on the program.

5 Implementation

We prototype FLOWSTITCH on Ubuntu 12.04 32 bit system. Note that as the first step the trace generation tool can work on both Windows and Linux systems to generate traces. Although the following analysis steps are performed on Ubuntu, FLOWSTITCH works for both Windows and Linux binaries.

Trace Generation. Our trace generation is based on the Pintraces tool provided by BAP [16]. Pintraces is a Pin [28] tool that uses dynamic binary instrumentation to record the program execution status. It logs all the instructions executed by the program into the trace file, together with the operand information. In our evaluation, the traces also contain dynamic taint information to facilitate the extraction of data flows.

Data Flow Generation. For input data and configuration data, FLOWSTITCH uses the taint information to get the data flows. To generate the data flow of the security-sensitive data, FLOWSTITCH performs backward and forward slicing on the benign trace to locate all the related instructions. It is possible for one instruction to have multiple source operands. For example, in `add %eax, %ebx`, the destination operand `%ebx` is derived from `%eax` and `%ebx`. In this case, one vertex has multiple parent vertices. As a result, the generated data flow is a graph where each node may have multiple parents.

Constraint Generation and Solving. The generation of the stitchability constraint required in Section 4.4 is implemented in three parts: path constraints, influence constraints, and CFI constraints.The stitchability constraint is expressed as a logical conjunction of these three parts. We use BAP to generate formulas which capture the path conditions and influence constraints. For control flow integrity constraint, we implement a procedure to search the trace for all the indirect `jmp` or `ret` instruction. Memory locations holding the return addresses or indirect jump targets are recorded. The control flow integrity requires that at runtime, the memory location containing control data should not be corrupted by the memory errors. The stitchability constraint is checked for satisfiability using the Z3 SMT-solver [22], which produces a witness input when the constraint is satisfiable.

6 Evaluation

In this section, we evaluate the effectiveness of data-flow stitching using FLOWSTITCH, including single-edge stitch, multi-edge stitch, stitch with deterministic addresses and stitch by address reuse. We also measure the search space reduction using FLOWSTITCH and the performance of FLOWSTITCH.

6.1 Efficacy in Exploit Generation

Table 2 shows the programs used in our evaluation, as well as their running environments and vulnerabilities. The trace generation phase is performed on different

Table 2: Experiment environments and benchmarks. # of Data-Oriented Attacks gives the number of attacks generated by FlowStitch, including privilege escalation attacks and information leakage attacks. FlowStitch generates 19 data-oriented attacks from 8 vulnerable programs.

ID	Vul. Program	Vulnerability	Environment (32b)	# of Data-Oriented Attacks	
				Escalation	Leakage
CVE-2013-2028	nginx	stack buffer overflow	Ubuntu 12.04	1	1
CVE-2012-0809	sudo	format string	Ubuntu 12.04	1	0
CVE-2009-4769	httpdx	format string	Windows XP SP3	4	1
bugtraq ID: 41956	orzhttpd	format string	Ubuntu 9.10	1	1
CVE-2002-1496	null httpd	heap overflow	Ubuntu 9.10	2	0
CVE-2001-0820	ghttpd	stack buffer overflow	Ubuntu 12.04	1	0
CVE-2001-0144	SSHD	integer overflow	Ubuntu 9.10	2	1
CVE-2000-0573	wu-ftpd	format string	Ubuntu 9.10	2	1
Total	8 programs			14	5

Table 3: Evaluation of FlowStitch on generating data-oriented attacks. In the Attack Description column, L_i stands for information leakage attack, while M_i represents privilege escalation attack. The third column indicates whether the built attack can bypass ASLR or not. The "CP" column shows the number of memory error instructions. Trace size is the number of instructions inside the trace. The last four columns show the number of stitch sources and stitch targets before and after our selection. SrcFlow means source flow, while TgtFlow stands for target flow.

Vul. Apps	Attack Description	ASLR Bypass	CP	Error-exhibiting Trace Size	Benign Trace Size	# of nodes before		# of nodes after	
						SrcFlow	TgtFlow	SrcFlow	TgtFlow

systems according to the tested program. All generated traces are analyzed by FlowStitch on a 32-bit Ubuntu 12.04 system. The vulnerabilities used for the experiments come from four different categories to ensure that FlowStitch can handle different vulnerabilities. Seven of the 8 vulnerable programs are server programs, including HTTP and FTP servers, which are the common targets of remote attacks. The other one is the `sudo` program, which allows users to run command as another user on Unix-like system. The last four vulnerabilities were discussed in [19], where data-oriented attacks were manually built. We apply FlowStitch on these vulnerabilities to verify the efficacy of our method.

Results. Our result demonstrates that FlowStitch can effectively generate data-oriented attacks with different vulnerabilities on different platforms. The number of generated data-oriented attacks on each program is shown in Table 2 and their details are given in Table 3. FlowStitch generates a total of 19 data-oriented attacks for eight real-world vulnerable programs, more than two attacks per program on average. Among 19 data-oriented attacks, there are five information leakage attacks and 14 privilege escalation attacks. For the vulnerable `httpdx` server, FlowStitch generates five data-oriented attacks from a format string vulnerability.

Out of the 19 data-oriented attacks, 16 are previously unknown. The three known attacks are two `uid`-corruption attacks on `SSHD` and `wu-ftpd`, and a CGI directory corruption attack on `null httpd`, discussed in [19]. FlowStitch successfully reproduces known attacks and builds new data-oriented attacks with the same vulnerabilities. Note that FlowStitch produces a different `ghttpd` CGI directory corruption attack than the one described in [19]. Details of this attack are discussed in Section 6.4.2. The results show the efficacy of our systematic approach in identifying new data-oriented attacks.

From our experiments, seven out of 19 of the data-oriented attacks are generated using multi-edge stitch. The significant number of new data-oriented attacks generated by multi-edge stitch highlights the importance of a systematic approach in managing the complexity and identifying new data-oriented attacks. As a measurement of the efficacy of ASLR on data-oriented attacks, we report that 10 of 19 attacks work even with ASLR deployed. Among 10 attacks, two attacks reuse randomized addresses on the stack and eight attacks corrupt data in the deterministic memory region. We observe that security-sensitive data such as configuration option is usually represented as a global variable in C programs and reside in the `.bss` segment. This highlights the limitation of current ASLR implementations which randomize the stack and heap addresses but not the `.bss` segment.

For three of 19 attacks, FLOWSTITCH requires the user to specify the security-sensitive data, including the private key of `nginx`, the root password hash and the authenticated flag of `SSHD`. For others, FLOWSTITCH automatically infers the security-sensitive data using techniques discussed in Section 4.2. Once such data is identified, FLOWSTITCH automatically generates data-oriented exploits.

6.2 Reduction in Search Space

Data-flow stitching has a large search space due to the large number of vertices in the flows to be stitched. Manual checking through a large search space is difficult. For example, in the root password hash leakage attack against `SSHD` server, there are 776 vertices in source flow containing the hashed root passwords. In the target flow, there are 56 vertices leading to the output data. Without considering the influence of the memory errors, there are a total of 43,456 possible stitch edges. After applying the methods described in Section 3, we get the intersection of the memory error influence I with the stitch source set R-set and the stitch target set W-set. In this way, the number of candidate edges is reduced from 43,456 to 194, obtaining a reduction ratio of 224.

The last four columns in Table 3 give the detailed information of the search space for each attack. For most of the data-oriented attacks, there is a significant reduction in the number of possible stitches. `ghttpd`-M_0 achieves the highest reduction ratio of 21,474 while `SSHD`-M_1 achieves the lowest reduction ratio of two. The median reduction ratio is 183 achieved by `wu-ftpd`-M_1(multi-edge). Given the relatively large spatial influence of the memory error, most of the reduction is achieved by the temporal influence of I.

6.3 Performance

Table 4: Performance of trace and flow generation using FLOWSTITCH. The unit used in the table is second, so 1:07 means one minute and seven seconds.

Attacks		Trace Gen		Slicing		Total
		error	benign	error	benign	
nginx	L_0	0:08	0:22	0:06	2:41	3:17
	M_0		0:36		0:12	1:02
sudo	M_0	0:35	1:07	1:17	3:34	6:33
httpdx	L_0	0:08	0:45	0:12	5:56	7:01
	M_0		0:51		4:44	5:55
	M_1		0:50		4:52	6:02
	M_2		1:03		4:45	6:08
	M_3		0:53		4:47	6:00
orzhttpd	L_0	0:17	0:20	0:12	0:24	1:13
	M_0		0:20		1:04	1:53
null httpd	M_0	0:13	1:20	0:14	6:21	8:08
	M_1		0:52		2:29	3:48
ghttpd	M_0	0:09	0:18	0:12	0:09	0:48
SSHD	L_0	2:35	9:38	1:02	21:08	34:23
	M_0		5:30		1:22	10:29
	M_1		5:30		1:00	10:07
wu-ftpd	L_0	0:12	0:50	0:19	5:42	7:03
	M_0		0:31		0:27	1:29
	M_1		0:31		0:26	1:28
Average		0:32	1:41	0:26	3:47	6:27

We measure the time FLOWSTITCH uses to generate data-oriented attacks. Table 4 shows the results, including the time of trace generation and the time of data-flow collection (slicing). Note that the trace generation time includes the time to execute instructions that are not logged (e.g., `crypto` routines and `mpz` library for `SSHD`). As we can see from Table 4, FLOWSTITCH takes an average of six minutes and 27 seconds to generate the trace and flows. Most of them are generated within 10 minutes. The information leakage attack of `SSHD` server takes the longest time, 34 minutes and 23 seconds, since crypto routines execute a large number of instructions. From the performance results, we can see that the generation of data flows through trace slicing takes up most of the generation time, from 20 percent to 87 percent. Currently, our slicer works on BAP IL file. We plan to optimize the slicer using parallel tools in the future.

6.4 Case Studies

We present five case studies to demonstrate the effectiveness of stitching methods and interesting observations.

6.4.1 Sensitive Data Lifespan

A common defense employed to reduce the effectiveness of data-oriented attacks is to limit the lifespan of security-critical data [19, 20]. This case study highlights the difficulty of doing it correctly. In the implementation of `SSHD`, the program explicitly zeros out sensitive data, such as the RSA private keys, as soon as they are not in use. For password authentication on Linux, `getspnam()` provided by glibc is often used to obtain the password hash. Rather than using the password hash directly, `SSHD` makes a local copy of the password hash on stack for its use. Although the program makes no special effort is to clear the copy on the stack, the password on stack is eventually overwritten by subsequent function frames before it can be leaked. The developer explicitly deallocates the original hash value using `endspent()` [1] in the glibc internal data structures. However, glibc does not clear the deallocated memory after `endspent()` is called and this allows FLOWSTITCH to successfully leak the hash from the copy held by glibc. Hence, this case study highlights that sensitive information should not be kept by the program after usage, and that identifying all copies of sensitive data in memory is difficult at the source level.

6.4.2 Multi-edge Stitch – ghttpd CGI Directory

The `ghttpd` application is a light-weight web server supporting CGI. A stack buffer overflow vulnerability was reported in version 1.4.0 - 1.4.3, allowing remote attackers to smash the stack of the vulnerable `Log()` function. During the security-sensitive data identification, FLOWSTITCH detects `execv()` is used to run an executable file. One of `execv()`'s arguments is the address of the program path string. Controlling it allows attackers to run arbitrary commands. FLOWSTITCH is unable to find a new data dependency edge using single-edge stitching, since there is no security-sensitive data on the stack frame to corrupt. FLOWSTITCH then proceeds to search for a multi-edge stitch. For the program path parameter of `execv()`, FLOWSTITCH identifies its flow, which includes use of a series of stack frame-base pointers saved in memory. The temporal constraints of the memory error exploit only allow the saved `%ebp` of the `Log()` function to be corrupted. Once the `Log()` function returns, the saved `%ebp` is used as a pointer, referring to all the local variables and parameters of `Log()` caller's stack frame. FLOWSTITCH corrupts the saved `%ebp` to change the variable for the CGI directory used in `execv()` system call. This attack is a four-edge stitch by composing two pointer stitches.

Chen *et al.* [19] discussed a data-oriented attack with the same vulnerability, which was in fact a two-edge stitch. However, that attack no longer works in our experiment. The `ghttpd` program compiled on our Ubuntu 12.04 platform does not store the address of command string on the stack frame of `Log()`. Only the four-edge stitching can be used to attack our `ghttpd` binary.

6.4.3 Bypassing ASLR – orzhttpd Attacks

The `orzhttpd` web server has a format string vulnerability which the attacker can exploit to control almost the whole memory space of the vulnerable program. FLOWSTITCH identifies the deterministic memory region and the randomized address on stack under `fprintf()` frame. The first attack which bypasses ASLR is a privilege escalation attack. This attack corrupts the web root directory with single-edge stitching and memory address reuse. The root directory string is stored on the heap, which is allocated at runtime. FLOWSTITCH identifies the address of the heap string from the stack and reuses it to directly change the string to `/` based on the pre-defined goal (Section 4.2). The second attack is an information leakage attack, which leaks randomized addresses in the `.got.plt` section. FLOWSTITCH identifies the deterministic memory region from the binary and performs a multi-edge stitch. The stitch involves modifying the pointer of an HTTP protocol string stored in a deterministic memory region. FLOWSTITCH changes the pointer value to the address of `.got.plt` section and a subsequent call to send the HTTP protocol string leaks the randomized addresses to attackers.

6.4.4 Privilege Escalation – Nginx Root Directory

The `Nginx` HTTP server 1.3.9-1.4.0 has a buffer overflow vulnerability [4]. FLOWSTITCH checks the local variables on the vulnerable stack and identifies two data pointers that can be used to perform arbitrary memory corruption. The memory influence of the overwriting is limited by the program logic. FLOWSTITCH identifies the web root directory string from the configuration data. It tries single-edge stitching to corrupt the root directory setting. The root directory string is inside the memory influence of the arbitrary overwriting. FLOWSTITCH overwrites the value `0x002f` into the string location, thus changing the root directory into `/`. FLOWSTITCH verifies the attack by requesting `/etc/passwd` file. As a result, the server sends the file content back to the client.

6.4.5 Information Leakage – httpdx Password

The `httpdx` server has a format string vulnerability between version 1.4 to 1.5 [3]. The vulnerable `tolog()` function records FTP commands and HTTP requests into a server-side log file. Note that direct exploitation of this vulnerability does not leak information. Using the error-exhibiting trace, FLOWSTITCH identifies the memory error instruction and figures out that there is almost no limitation on the memory range affected by attackers. From the `httpdx` binary, FLOWSTITCH manages to find a total of 102MB of deterministic memory addresses. From the benign trace, FLOWSTITCH generates data flows of the root user passwords. This is the secret to be leaked out. The FLOWSTITCH generates the necessary data flow which reaches the `send()` system call automatically.

Starting from the memory error instruction, FLOWSTITCH searches backwards in the secret data flow and identifies vertices inside the deterministic memory region. FLOWSTITCH successfully finds two such memory locations containing the “admin” password: one is a buffer containing the whole configuration file, and another only contains the password. At the same time, FLOWSTITCH searches forwards in the output flow to find the vertices that affect the buffer argument of `send()`. Our tool identifies vertices within the deterministic memory region. The solver gives one possible input that will trigger the attack. FLOWSTITCH confirms this attack by providing the attack input to the server and receiving the "admin" user password.

7 Related Work

Data-Oriented Attack. Several work [21,32,36,38,41,43,44] has been done to improve the practicality of CFI, increasing the barrier to constructing control flow hijacking attacks. Instead, data-oriented attacks are serious alternatives. Data-oriented attacks have been conceptually known for a decade. Chen *et al.* constructed non-control-data exploits to show that data-oriented attack is a realistic threat [19]. However, no systematic method to develop data-oriented attacks is known yet. In our paper, we develop a systematic way to search for possible data-oriented attacks. This method searches attacks within the candidate space efficiently and effectively.

Automatic Exploit Generation. Brumley *et al.* [17] described an automatic exploit generation technique based on program patches. The idea is to identify the difference between the patched and the unpatched binaries, and generate an input to trigger the difference. Avgerinos *et al.* [13] discussed Automatic Exploit Generation(AEG) to generate real exploits resulting in a working shell. Felmetsger *et al.* [24] discussed automatic exploit generation for web applications. The previous work focused on generating control flow hijacking exploits. FLOWSTITCH on the other hand generates data-oriented attacks that do not violate the control flow integrity. To our knowledge, FLOWSTITCH is the first tool to systematically generate data-oriented attacks.

Defenses against Data-Oriented Attacks. Data-oriented attacks can be prevented by enforcing data-flow integrity (DFI). Existing work enforces DFI through dynamic information tracking [23, 39, 40] or by legitimate memory modification instruction analysis [18,42]. However, DFI defenses are not yet practical, requiring large overheads or manual declassification. An ultimate defense is to enforce the memory safety to prevent the attacks in their first steps. Cyclone [27] and CCured [31] introduce a safe type system to the type-unsafe C languages. SoftBound [29] with CETS [30] uses bound checking with fat-pointer to force a complete memory safety. Cling [11] enforces temporal memory safety through type-safe memory reuse. Data-oriented attack prevention requires a complete memory safety.

8 Conclusion

In this paper, we present a new concept called data-flow stitching, and develop a novel solution to systematically construct data-oriented attacks. We discuss novel stitching methods, including single-edge stitch, multi-edge stitch, stitch with deterministic addresses and stitch by address reuse. We build a prototype of data-flow stitching, called FLOWSTITCH. FLOWSTITCH generates 19 data-oriented attacks from eight vulnerable programs. Sixteen attacks are previously unknown attacks. All attacks bypass DEP and the CFI checks, and 10 bypass ASLR. The result shows that automatic generation of data-oriented exploits exhibiting significant damage is practical.

Protocol state fuzzing of TLS implementations

Abstract

We describe a largely automated and systematic analysis of TLS implementations by what we call 'protocol state fuzzing': we use state machine learning to infer state machines from protocol implementations, using only black-box testing, and then inspect the inferred state machines to look for spurious behaviour which might be an indication of flaws in the program logic. For detecting the presence of spurious behaviour the approach is almost fully automatic: we automatically obtain state machines and any spurious behaviour is then trivial to see. Detecting whether the spurious behaviour introduces exploitable security weaknesses does require manual investigation. Still, we take the point of view that any spurious functionality in a security protocol implementation is dangerous and should be removed.

We analysed both server- and client-side implementations with a test harness that supports several key exchange algorithms and the option of client certificate authentication. We show that this approach can catch an interesting class of implementation flaws that is apparently common in security protocol implementations: in three of the TLS implementations analysed new security flaws were found (in GnuTLS, the Java Secure Socket Extension, and OpenSSL). This shows that protocol state fuzzing is a useful technique to systematically analyse security protocol implementations. As our analysis of different TLS implementations resulted in different and unique state machines for each one, the technique can also be used for fingerprinting TLS implementations.

1 Introduction

TLS, short for Transport Layer Security, is widely used to secure network connections, for example in HTTPS. Being one of the most widely used security protocols, TLS has been the subject of a lot of research and many issues have been identified. These range from cryptographic attacks (such as problems when using RC4 [4]) to serious implementation bugs (such as Heartbleed [13]) and timing attacks (for example, Lucky Thirteen and variations of the Bleichenbacher attack [3, 30, 9]).

To describe TLS, or protocols in general, a state machine can be used to specify possible sequences of messages that can be sent and received. Using automated learning techniques, it is possible to automatically extract these state machines from protocol implementations, relying only on black-box testing. In essence, this involves fuzzing different sequences of messages, which is why we call this approach *protocol state fuzzing*. By analysing these state machines, logical flaws in the protocol flow can be discovered. An example of such a flaw is accepting and processing a message to perform some security-sensitive action *before* authentication takes place. The analysis of the state machines can be done by hand or using a model checker; for the analyses discussed in this paper we simply relied on manual analysis. Both approaches require knowledge of the protocol to interpret the results or specify the requirements. However, in security protocols, every superfluous state or transition is undesirable and a reason for closer inspection. The presence of such superfluous states or transitions is typically easy to spot visually.

1.1 Related work on TLS

Various formal methods have been used to analyse different parts and properties of the TLS protocol [33, 16, 22, 32, 20, 31, 26, 24, 28]. However, these analyses look at abstract descriptions of TLS, not actual implementations, and in practice many security problems with TLS have been due to mistakes in implementation [29]. To bridge the gap between the specification and implementation, formally verified TLS implementations have been proposed [7, 8].

Existing tools to analyse TLS implementations mainly focus on fuzzing of individual messages, in particular the certificates that are used. These certificates have been the source of numerous security problems in the past. An automated approach to test for vulnerabilities in the processing of certificates is using Frankencerts as proposed by Brubaker et al. [10] or using the tool x509test[1]. Fuzzing of individual messages is orthogonal to the technique we propose as it targets different parts or aspects of the code. However, the results of our analysis could be used to guide fuzzing of messages by indicating protocol states that might be interesting places to start fuzzing messages.

Another category of tools analyses implementations by looking at the particular configuration that is used. Examples of this are the SSL Server Test[2] and sslmap[3].

Finally, closely related research on the implementation of state machines for TLS was done by Beurdouche et al. [6]. We compare their work with ours in Section 5.

1.2 Related work on state machine learning

When learning state machines, we can distinguish between a passive and active approach. In passive learning, only existing data is used and based on this a model is constructed. For example, in [14] passive learning techniques are used on observed network traffic to infer a state machine of the protocol used by a botnet. This approach has been combined with the automated learning of message formats in [23], which then also used the model obtained as a basis for fuzz-testing.

When using active automated learning techniques, as done in this paper, an implementation is actively queried by the learning algorithm and based on the responses a model is constructed. We have used this approach before to analyse implementations of security protocols in EMV bank cards [1] and handheld readers for online banking [11], and colleagues have used it to analyse electronic passports [2]. These investigations did not reveal new security vulnerabilities, but they did provide interesting insights in the implementations analysed. In particular, it showed a lot of variation in implementations of bank cards [1] – even cards implementing the same MasterCard standard – and a known attack was confirmed for the online banking device and confirmed to be fixed in a new version [11].

1.3 Overview

We first discuss the TLS protocol in more detail in Section 2. Next we present our setup for the automated learning in Section 3. The results of our analysis of nine TLS implementations are subsequently discussed in Section 4, after which we conclude in Section 5.

2 The TLS protocol

The TLS protocol was originally known as SSL (Secure Socket Layer), which was developed at Netscape. SSL 1.0 was never released and version 2.0 contained numerous security flaws [37]. This lead to the development of SSL 3.0, on which all later versions are based. After SSL 3.0, the name was changed to TLS and currently three versions are published: 1.0, 1.1 and 1.2 [17, 18, 19]. The specifications for these versions are published in RFCs issued by the Internet Engineering Task Force (IETF).

To establish a secure connection, different subprotocols are used within TLS:

- The *Handshake* protocol is used to establish session keys and parameters and to optionally authenticate the server and/or client.
- The *ChangeCipherSpec* protocol – consisting of only one message – is used to indicate the start of the use of established session keys.
- To indicate errors or notifications, the *Alert* protocol is used to send the level of the alert (either warning or fatal) and a one byte description.

In Fig. 1 a normal flow for a TLS session is given. In the ClientHello message, the client indicates the desired TLS version, supported cipher suites and optional extensions. A cipher suite is a combination of algorithms used for the key exchange, encryption, and MAC computation. During the key exchange a premaster secret is established. This premaster secret is used in combination with random values from both the client and server to derive the master secret. This master secret is then used to derive the actual keys that are used for encryption and MAC computation. Different keys are used for messages from the client to the server and for messages in the opposite direction. Optionally, the key exchange can be followed by client verification where the client proves it knows the private key corresponding to the public key in the certificate it presents to the server. After the key exchange and optional client verification, a ChangeCipherSpec message is used to indicate that from that point on the agreed keys will be used to encrypt all messages and add a MAC to them. The Finished message is finally used to conclude the handshake phase. It contains a keyed hash, computed using the master secret, of all previously exchanged handshake messages. Since it is sent after the ChangeCipherSpec message it is the first message that is encrypted and MACed. After the handshake phase, application data can be exchanged over the established secure channel.

[2] `https://www.ssllabs.com/ssltest/`

[3] `https://www.thesprawl.org/projects/sslmap/`

To add additional functionality, TLS offers the possibility to add extensions to the protocol. One example of such an extension is the – due to Heartbleed [13] by now well-known – Heartbeat Extension, which can be used to keep a connection alive using HeartbeatRequest and HeartbeatResponse messages [36].

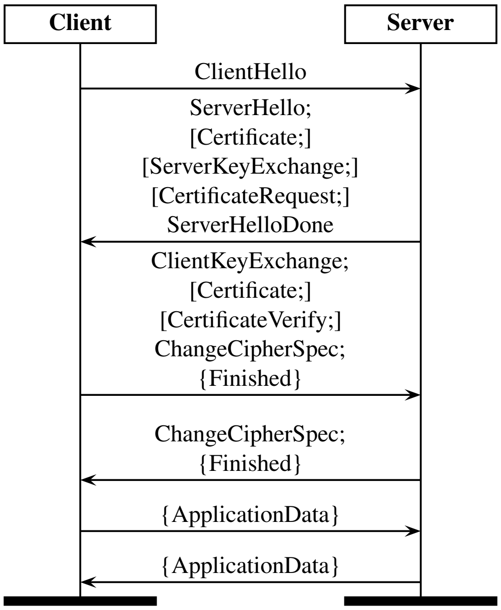

Figure 1: A regular TLS session. An encrypted message m is denoted as {m}. If message m is optional, this is indicated by [m].

3 State machine learning

To infer the state machines of implementations of the TLS protocol we used LearnLib [34], which uses a modified version of Angluin's L* algorithm [5]. An implementation that is analysed is referred to as the *System Under Test (SUT)* and is considered to be a black box. LearnLib has to be provided with a list of messages it can send to the SUT (also known as the *input alphabet*), and a command to reset the SUT to its initial state. A test harness is needed to translate abstract messages from the input alphabet to concrete messages that can be sent to the SUT. To be able to implement this test harness we need to know the messages that are used by the SUT. By sending sequences of messages and reset commands, LearnLib tries to come up with hypotheses for the state machine based on the responses it receives from the SUT. Such hypotheses are then checked for equivalence with the actual state machine. If the models are not equivalent, a counter-example is returned and LearnLib will use this to redefine its hypothesis.

As the actual state machine is not known, the equivalence check has to be approximated, with what is effectively a form of model-based testing. For this we use an improved version of Chow's W-method [12]. The W-method is guaranteed to be correct given an upper bound for the number of states. For LearnLib we can specify a depth for the equivalence checking: given a hypothesis for the state machine, the upper bound for the W-method is set to the number of found states plus the specified depth. The algorithm will only look for counterexample traces of which the lengths is at most the set upper bound, and if none can be found the current hypothesis for the state machine is assumed to be equivalent with the one implemented. This assumption is correct if the actual state machine does not have more states than the number of found states plus the specified depth. The W-method is very powerful but comes at a high cost in terms of performance. Therefore we improved the algorithm to take advantage of a property of the system we learn, namely that once a connection is closed, all outputs returned afterwards will be the same (namely *Connection closed*). So when looking for counterexamples, extending a trial trace that results in the connection being closed is pointless. The W-method, however, will still look for counterexamples by extending traces which result in a closed connection. We improved the W-method by adding a check to see if it makes sense to continue searching for counterexamples with a particular prefix, and for this we simply check if the connection has not been closed. This simple modification of the W-method greatly reduced the number of equivalence queries needed, as we will see in Section 4.

3.1 Test harness

To use LearnLib, we need to fix an input alphabet of messages that can be sent to the SUT. This alphabet is an abstraction of the actual messages sent. In our analyses we use different input alphabets depending on whether we test a client or server, and whether we perform a more limited or more extensive analysis. To test servers we support the following messages: ClientHello (RSA and DHE), Certificate (RSA and empty), ClientKeyExchange, ClientCertificateVerify, ChangeCipherSpec, Finished, ApplicationData (regular and empty), HeartbeatRequest and HeartbeatResponse. To test clients we support the following messages: ServerHello (RSA and DHE), Certificate (RSA and empty), CertificateRequest, ServerKeyExchange, ServerHelloDone, ChangeCipherSpec, Finished, ApplicationData (regular and empty), HeartbeatRequest and HeartbeatResponse.

We thus support all regular TLS messages as well as the messages for the Heartbeat Extension. The test harness supports both TLS version 1.2 and, in order to test older implementations, version 1.0. The input alphabet is not fixed, but can be configured per analysis as desired. For the output alphabet we use all the regular TLS messages as well as the messages from the Alert protocol that can be returned. This is extended with some special symbols that correspond with exceptions that can occur in the test harness:

- *Empty*, this is returned if no data is received from the SUT before a timeout occurs in the test harness.
- *Decryption failed*, this is returned if decryption fails in the test harness after a ChangeChipherSpec message was received. This could happen, for example, if not enough data is received, the padding is incorrect after decryption (e.g. because a different key was used for encryption) or the MAC verification fails.
- *Connection closed*, this is returned if a socket exception occurs or the socket is closed.

LearnLib uses these abstract inputs and outputs as labels on the transitions of the state machine. To interact with an actual TLS server or client we need a test harness that translates the abstract input messages to actual TLS packets and the responses back to abstract responses. As we make use of cryptographic operations in the protocol, we needed to introduce state in our test harness, for instance to keep track of the information used in the key exchange and the actual keys that result from this. Apart from this, the test harness also has to remember whether a ChangeCipherSpec was received or sent, as we have to encrypt and MAC all corresponding data after this message. Note that we only need a single test harness for TLS to then be able to analyse any implementation. Our test harness can be considered a 'stateless' TLS implementation.

When testing a server, the test harness is initialised by sending a ClientHello message to the SUT to retrieve the server's public key and preferred ciphersuite. When a reset command is received we set the internal variables to these values. This is done to prevent null pointer exceptions that could otherwise occur when messages are sent in the wrong order.

After sending a message the test harness waits to receive responses from the SUT. As the SUT will not always send a response, for example because it may be waiting for a next message, the test harness will generate a timeout after a fixed period. Some implementations require longer timeouts as they can be slower in responding. As the timeout has a significant impact on the total running time we varied this per implementation.

To test client implementations we need to launch a client for every test sequence. This is done automatically by the test harness upon receiving the *reset* command. The test harness then waits to receive the ClientHello message, after which the client is ready to receive a query. Because the first ClientHello is received before any query is issued, this message does not appear explicitly in the learned models.

4 Results

We analysed the nine different implementations listed in Table 1. We used demo client and server applications that came with the different implementations except with the Java Secure Socket Extension (JSSE). For JSSE we wrote simple server and client applications. For the implementations listed the models of the server-side were learned using our modified W-method for the following alphabet: ClientHello (RSA), Certificate (empty), ClientKeyExchange, ChangeCipherSpec, Finished, ApplicationData (regular and empty), HeartbeatRequest. For completeness we learned models for both TLS version 1.0 and 1.2, when available, but this always resulted in the same model.

Due to space limitations we cannot include the models for all nine implementations in this paper, but we do include the models in which we found security issues (for GnuTLS, Java Secure Socket Extension, and OpenSSL), and the model of RSA BSAFE for Java to illustrate how much simpler the state machine can be. The other models can be found in [15] as well as online, together with the code of our test harness.[4] We wrote a Python application to automatically simplify the models by combining transitions with the same responses and replacing the abstract input and output symbols with more readable names. Table 2 shows the times needed to obtain these state machines, which ranged from about 9 minutes to over 8 hours.

A comparison between our modified equivalence algorithm and the original W-method can be found in Table 3. This comparison is based on the analysis of GnuTLS 3.3.12 running a TLS server. It is clear that by taking advantage of the state of the socket our algorithm performs much better than the original W-method: the number of equivalence queries is over 15 times smaller for our method when learning a model for the server.

When analysing a model, we first manually look if there are more paths than expected that lead to a successful exchange of application data. Next we determine whether the model contains more states than necessary and identify unexpected or superfluous transitions. We also check for transitions that can indicate interesting behaviour such as, for example, a 'Bad record MAC' alert or a *Decryption failed* message. If we come across any

unexpected behaviour, we perform a more in-depth analysis to determine the cause and severity.

An obvious first observation is that all the models of server-side implementations are very different. For example, note the huge difference between the models learned for RSA BSAFE for Java in Fig. 6 and for OpenSSL in Fig. 7. Because all the models are different, they provide a unique fingerprint of each implementation, which could be used to remotely identify the implementation that a particular server is using.

Most demo applications close the connection after their first response to application data. In the models there is then only one ApplicationData transition where application data is exchanged instead of the expected cycle consisting of an ApplicationData transition that allows server and client to continue exchanging application data after a successful handshake.

In the subsections below we discuss the peculiarities of models we learned, and the flaws they revealed. Correct paths leading to an exchange of application data are indicated by thick green transitions in the models. If there is any additional path leading to the exchange of application data this is a security flaw and indicated by a dashed red transition.

4.1 GnuTLS

Fig. 2 shows the model that was learned for GnuTLS 3.3.8. In this model there are two paths leading to a successful exchange of application data: the regular one without client authentication and one where an empty client certificate is sent during the handshake. As we did not require client authentication, both are acceptable paths. What is immediately clear is that there are more states than expected. Closer inspection reveals that there is a ‘shadow’ path, which is entered by sending a HeartbeatRequest message during the handshake protocol. The handshake protocol then does proceed, but eventually results in a fatal alert (‘Internal error’) in response to the Finished message (from state *8*). From every state in the handshake protocol it is possible to go to a corresponding state in the ‘shadow’ path by sending the HeartbeatRequest message. This behaviour is introduced by a security bug, which we will discuss below. Additionally there is a redundant state *5*, which is reached from states *3* and *9* when a ClientHello message is sent. From state *5* a fatal alert is given to all subsequent messages that are sent. One would expect to already receive an error message in response to the ClientHello message itself.

Forgetting the buffer in a heartbeat As mentioned above, HeartbeatRequest messages are not just ignored in the handshake protocol but cause some side effect: sending a HeartbeatRequest during the handshake protocol will cause the implementation to return an alert message in response to the Finished message that terminates the handshake. Further inspection of the code revealed the cause: the implementation uses a buffer to collect all handshake messages in order to compute a hash over these messages when the handshake is completed, but this buffer is reset upon receiving the heartbeat message. The alert is then sent because the hashes computed by server and client no longer match.

Table 3: Analysis of the GnuTLS 3.3.12 server using different alphabets and equivalence algorithms

This bug can be exploited to effectively bypass the integrity check that relies on comparing the keyed hashes of the messages in the handshake: when also resetting this buffer on the client side (i.e. our test harness) at the same time we were able to successfully complete the handshake protocol, but then no integrity guarantee is provided on the previous handshake messages that were exchanged.

By learning the state machine of a GnuTLS client we confirmed that the same problem exists when using GnuTLS as a client.

This problem was reported to the developers of GnuTLS and is fixed in version 3.3.9. By learning models of newer versions, we could confirm the issue is no longer present, as can be seen in Fig. 3.

To exploit this problem both sides would need to reset the buffer at the same time. This might be hard to achieve as at any time either one of the two parties is computing a response, at which point it will not process any incoming message. If an attacker would successfully succeed to exploit this issue no integrity would be provided on any message sent before, meaning a fallback attack would be possible, for example to an older TLS version or weaker cipher suite.

4.2 mbed TLS

For mbed TLS, previously known as PolarSSL, we tested version 1.3.10. We saw several paths leading to a successful exchange of data. Instead of sending a regular ApplicationData message, it is possible to first send one empty ApplicationData message after which it is still possible to send the regular ApplicationData message. Sending two empty ApplicationData messages directly after each other will close the connection. However, if in between these message an unexpected handshake message is sent, the connection will not be closed and only a warning is returned. After this it is also still possible to send a regular ApplicationData message. While this is strange behaviour, it does not seem to be exploitable.

4.3 Java Secure Socket Extension

For Java Secure Socket Extension we analysed Java version 1.8.0_25. The model contains several paths leading to a successful exchange of application data and contains more states than expected (see Fig. 4). This is the result of a security issue which we will discuss below.

As long as no Finished message has been sent it is apparently possible to keep renegotiating. After sending a ClientKeyExchange, other ClientHello messages are accepted as long as they are eventually followed by another ClientKeyExchange message. If no ClientKeyExchange message was sent since the last ChangeCipherSpec, a ChangeCipherSpec message will result in an error (state *7*). Otherwise it either leads to an error state if sent directly after a ClientHello (state *8*) or a successful change of keys after a ClientKeyExchange.

Accepting plaintext data More interesting is that the model contains *two* paths leading to the exchange of application data. One of these is a regular TLS protocol run, but in the second path the ChangeCipherSpec message from the client is omitted. Despite the server not receiving a ChangeCipherSpec message it still responds with a ChangeCipherSpec message to a plaintext Finished message by the client. As a result the server will send its data encrypted, but it expects data from the client to be unencrypted. A similar problem occurs when trying to negotiate new keys. By skipping the ChangeCipherSpec message and just sending the Finished message the server will start to use the new keys, whereas the client needs to continue to use its old keys.

This bug invalidates any assumption of integrity or confidentiality of data sent to the server, as it can be tricked into accepting plaintext data. To exploit this issue it is, for example, possible to include this behaviour in a rogue library. As the attack is transparent to applications using the connection, both the client and server application would think they talk on a secure connection, where in reality anyone on the line could read the client's data and tamper with it. Fig. 5 shows a protocol run where this bug is triggered. The bug was report to Oracle and is identified by CVE-2014-6593. A fix was released in their Critical Security Update in January 2015. By analysing JSSE version 1.8.0_31 we are able to confirm the issue was indeed fixed.

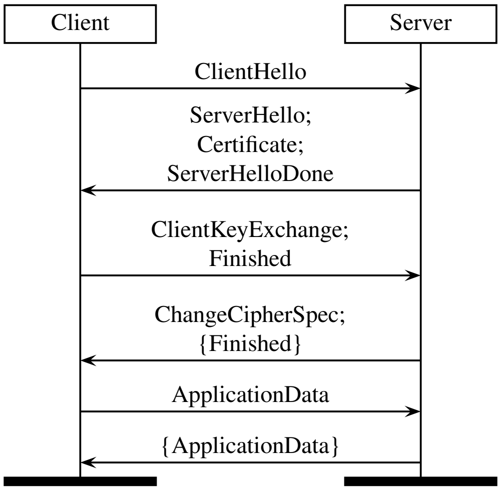

Figure 5: A protocol run triggering a bug in the JSSE, causing the server to accept plaintext application data.

This issue was identified in parallel by Beurdouche et al. [6], who also reported the same and a related issue for the client-side. By learning the client, we could confirm that the issue was also present there. Moreover, after receiving the ServerHello message, the client would accept the Finish message and start exchanging application data at any point during the handshake protocol. This makes it possible to completely circumvent both server authentication and the confidentiality and integrity of the data being exchanged.

4.4 miTLS

MiTLS is a formally verified TLS implementation written in F# [8]. For miTLS 0.1.3, initially our test harness had problems to successfully complete the handshake protocol and the responses seemed to be nondeterministic because sometimes a response was delayed and appeared to be received in return to the next message. To solve this, the timeout had to be increased considerably when waiting for incoming messages to not miss any message. This means that compared to the other implementations, miTLS was relatively slow in our setup. Additionally, miTLS requires the Secure Renegotiation extension to be enabled in the ClientHello message. The learned model looks very clean with only one path leading to an exchange of application data and does not contain more states than expected.

4.5 RSA BSAFE for C

The RSA BSAFE for C 4.0.4 library resulted in a model containing two paths leading to the exchange application data. The only difference between the paths is that an

empty ApplicationData is sent in the second path. However, the alerts that are sent are not very consistent as they differ depending on the state and message. For example, sending a ChangeCipherSpec message after an initial ClientHello results in a fatal alert with reason ‘Illegal parameter’, whereas application data results in a fatal alert with ‘Unexpected message’ as reason. More curious however is a fatal alert ‘Bad record MAC’ that is returned to certain messages after the server received the ChangeCipherSpec in a regular handshake. As this alert is only returned in response to certain messages, while other messages are answered with an ‘Unexpected message’ alert, the server is apparently able to successfully decrypt and check the MAC on messages. Still, an error is returned that it is not able to do this. This seems to be a non-compliant usage of alert messages.

At the end of the protocol the implementation does not close the connection. This means we cannot take any advantage from a closed connection in our modified W-method and the analysis therefore takes much longer than for the other implementations.

4.6 RSA BSAFE for Java

The model for RSA BSAFE for Java 6.1.1 library looks very clean, as can be seen in Fig. 6. The model again contains only one path leading to an exchange of application data and no more states than necessary. In general all received alerts are ‘Unexpected message’. The only exception is when a ClientHello is sent after a successful handshake, in which case a ‘Handshake failure’ is given. This makes sense as the ClientHello message is not correctly formatted for secure renegotiation, which is required in this case. This model is the simplest that we learned during our research.

4.7 Network Security Services

The model for NSS that was learned for version 3.17.4 looks pretty clean, although there is one more state than one would expect. There is only one path leading to a successful exchange of application data. In general all messages received in states where they are not expected are responded to with a fatal alert ('Unexpected message'). Exceptions to this are the Finished and Heartbeat messages: these are ignored and the connection is closed without any alert. Other exceptions are non-handshake messages sent before the first ClientHello: then the server goes into a state where the connection stays open but nothing happens anymore. Although the TLS specification does not explicitly specify what to do in this case, one would expect the connection to be closed, especially since it's not possible to recover from this. Because the connection is not actually closed in this case the analysis takes longer, as we have less advantage of our modification of the W-method to decide equivalence.

4.8 OpenSSL

Fig. 7 shows the model inferred for OpenSSL 1.01j. In the first run of the analysis it turned out that HeartbeatRequest message sent during the handshake phase were 'saved up' and only responded to after the handshake phase was finished. As this results in infinite models we had to remove the heartbeat messages from the input alphabet. This model obtained contains quite a few more states than expected, but does only contain one path to successfully exchange application data.

The model shows that it is possible to start by sending two ClientHello messages, but not more. After the second ClientHello message there is no path to a successful exchange of application data in the model. This is due to the fact that OpenSSL resets the buffer containing the handshake messages every time when sending a ClientHello, whereas our test harness does this only on initialisation of the connection. Therefore, the hash computed by our test harness at the end of the handshake is not accepted and the Finished message in state *9* is responded to with an alert. Which messages are included in the hash differs per implementation: for JSSE all handshake messages since the beginning of the connection are included.

Re-using keys In state *8* we see some unexpected behaviour. After successfully completing a handshake, it is possible to send an additional ChangeCipherSpec message after which all messages are responded to with a 'Bad record MAC' alert. This usually is an indication of wrong keys being used. Closer inspection revealed that at this point OpenSSL changes the keys that the client uses to encrypt and MAC messages to the server keys. This means that in both directions the same keys are used from this point.

We observed the following behaviour after the additional ChangeCipherSpec message. First, OpenSSL expects a ClientHello message (instead of a Finished message as one would expect). This ClientHello is responded to with the ServerHello, ChangeCipherSpec and Finished messages. OpenSSL does change the server keys then, but does not use the new randoms from the ClientHello and ServerHello to compute new keys. Instead the old keys are used and the cipher is thus basically reset (i.e. the original IVs are set and the MAC counter reset to 0). After receiving the ClientHello message, the server does expect the Finished message, which contains the keyed hash over the messages since the second ClientHello and does make use of the new client and server randoms. After this, application data can be send over the connection, where the same keys are used in both directions. The issue was reported to the OpenSSL team and was fixed in version 1.0.1k.

Figure 8: Learned state machine model for OpenSSL 1.0.1g, an older version of OpenSSL which had a known security flaw [27].

Early ChangeCipherSpec The state machine model of the older version OpenSSL 1.0.1g (Fig. 8) reveals a known vulnerability that was recently discovered [27], which makes it possible for an attacker to easily compute the session keys that are used in the versions up to 1.0.0l and 1.0.1g, as described below.

As soon as a ChangeCipherSpec message is received, the keys are computed. However, this also happened when no ClientKeyExchange was sent yet, in which case an empty master secret is used. This results in keys that are computed based on only public data. In version 1.0.1 it is possible to completely hijack a session by sending an early ChangeCipherSpec message to both the server and client, as in this version the empty master secret is also used in the computation of the hash in the Finished message. In the model of OpenSSL version 1.0.1g in Fig. 8 it is clear that if a ChangeCipherSpec message is received too early, the Finished message is still accepted as a ChangeCipherSpec is returned (see path *0, 1, 6, 9, 12* in the model). This is an indication of the bug and would be reason for closer inspection. The incoming messages after this path cannot be decrypted anymore however, because the corresponding keys are only computed by our test harness as soon as the ChangeCipherSpec message is received, which means that these keys are actually based on the ClientKeyExchange message. A simple modification of the test harness to change the point at which the keys are computed will even provide a successful exploitation of the bug.

An interesting observation regarding the evolution of the OpenSSL code is that for the four different versions that we analysed (1.0.1g, 1.0.1j, 1.0.1l and 1.0.2) the number of states reduces with every version. For version 1.0.2 there is still one state more than required, but this is an error state from which all messages result in a closed connection.

4.9 nqsb-TLS

A recent TLS implementation, nqsb-TLS, is intended to be both a specification and usable implementation written in OCaml [25]. For nsqb-TLS we analysed version 0.4.0. Our analysis revealed a bug in this implementation: alert messages are not encrypted even after a ChangeCipherSpec is received. This bug was reported to the nqsb-TLS developers and is fixed in a newer version. What is more interesting is a design decision with regard to the state machine: after the client sends a ChangeCipherSpec, the server immediately responds with a ChangeCipherSpec. This is different compared to all other implementations, that first wait for the client to also send a Finished message before sending a response. This is a clear example where the TLS specifications are not completely unambiguous and adding a state machine would remove room for interpretation.

5 Conclusion

We presented a thorough analysis of commonly used TLS implementations using the systematic approach we call protocol state fuzzing: we use state machine learning, which relies only on black box testing, to infer a state machine and then we perform a manual analysis of the state machines obtained. We demonstrated that this is a powerful and fast technique to reveal security flaws: in 3 out of 9 tested implementations we discovered new flaws. We applied the method on both server- and client-side implementations. By using our modified version of the W-method we are able to drastically reduce the number of equivalence queries used, which in turn results in a much lower running time of the analysis.

Our approach is able to find mistakes in the logic in the state machine of implementations. Deliberate backdoors, that are for example triggered by sending a particular message 100 times, would not be detected. Also mistakes in, for example, the parsing of messages or certificates would not be detected.

An overview of different approaches to prevent security bugs and more generally improve the security of software is given in [38] (using the Heartbleed bug as a basis). The method presented in this paper would not have detected the Heartbleed bug, but we believe it makes a useful addition to the approaches discussed in [38]. It is related to some of the approaches listed there; in particular, state machine learning involves a form of negative testing: the tests carried out during the state machine learning include many negative tests, namely those where messages are sent in unexpected orders, which one would expect to result in the closing of the connection (and which probably *should* result in closing of the connection, to be on the safe side). By sending messages in an unexpected order we get a high coverage of the code, which is different from for example full branch code coverage, as we trigger many different paths through the code.

In parallel with our research Beurdouche et al. [6] independently performed closely related research. They also analyse protocol state machines of TLS implementations and successfully find numerous security flaws. Both approaches have independently come up with the same fundamental idea, namely that protocol state machines are a great formalism to systematically analyse implementations of security protocols. Both approaches require the construction of a framework to send arbitrary TLS messages, and both approaches reveal that OpenSSL and JSSE have the most (over)complicated state machines.

The approach of Beurdouche et al. is different though: whereas we infer the state machines from the code without prior knowledge, they start with a manually constructed reference protocol state machine, and subsequently use this as a basis to test TLS implementations. Moreover, the testing they do here is not truly random, as the 'blind' learning by LearnLib is, but uses a set of test traces that is automatically generated using some heuristics.

The difference in the issues identified by Beurdouche et al. and us can partly be explained by the difference in functionality that is supported by the test frameworks used. For example, our framework supports the Heartbeat extension, whereas theirs supports Diffie-Hellman certificates and export cipher suites. Another reason is the fact that our approach has a higher coverage due to its 'blind' nature.

One advantage of our approach is that we don't have to construct a correct reference model by hand beforehand. But in the end, we do have to decide which behaviour is unwanted. Having a visual model helps here, as it is easy to see if there are states or transitions that seem redundant and don't occur in other models. Note that both approaches ultimately rely on a manual analysis to assess the security impact of any protocol behaviour that is deemed to be deviant or superfluous.

When it comes to implementing TLS, the specifications leave the developer quite some freedom as how to implement the protocol, especially in handling errors or exceptions. Indeed, many of the differences between models we infer are variations in error messages. These are not fixed in the specifications and can be freely chosen when implementing the protocol. Though this might be useful for debugging, the different error messages are probably not useful in production (especially since they differ per implementation).

This means that there is not a single 'correct' state machine for the TLS protocol and indeed every implementation we analysed resulted in a different model. However, there are some clearly wrong state machines. One would expect to see a state machine where there is clearly one correct path (or possibly more depending on the configuration) and all other paths going to one error state – preferably all with the same error code. We have seen one model that conforms to this, namely the one for RSA BSAFE for Java, shown in Fig. 6.

Of course, it would be interesting to apply the same technique we have used on TLS implementations here on implementations of other security protocols. The main effort in protocol state fuzzing is developing a test harness. But as only one test harness is needed to test all implementations for a given protocol, we believe that this is a worthwhile investment. In fact, one can argue that for any security protocol such a test harness should be provided to allow analysis of implementations.

The first manual analysis of the state machines we obtain is fairly straightforward: any superfluous strange behaviour is easy to spot visually. This step could even be automated as well by providing a correct reference state machine. A state machine that we consider to be correct would be the one that we learned for RSA BSAFE for Java.

Deciding whether any superfluous behaviour is exploitable is the hardest part of the manual analysis, but for security protocols it makes sense to simply require that there should not be any superfluous behaviour whatsoever.

The difference behaviour between the various implementations might be traced back to Postel's Law:

> 'Be conservative in what you send,
> be liberal in what you accept.'

As has been noted many times before, e.g. in [35], this is an unwanted and risky approach in security protocols: if there is any suspicion about inputs they should be discarded, connections should be closed, and no response should be given that could possibly aid an attacker. To quote [21]: 'It's time to deprecate Jon Postel's dictum and to be conservative in what you accept'.

Of course, ideally state machines would be included in the official specifications of protocols to begin with. This would provide a more fundamental solution to remove – or at least reduce – some of the implementation freedom. It would avoid each implementer having to come up with his or her own interpretation of English prose specifications, avoiding not only lots of work, but also the large variety of state machines in implementations that we observed, and the bugs that some of these introduce.

Princeton Univ.

Abstract

We have proved, with machine-checked proofs in Coq, that an OpenSSL implementation of HMAC with SHA-256 correctly implements its FIPS functional specification *and* that its functional specification guarantees the expected cryptographic properties. This is the first machine-checked cryptographic proof that combines a source-program implementation proof, a compiler-correctness proof, and a cryptographic-security proof, with no gaps at the specification interfaces.

The verification was done using three systems within the Coq proof assistant: the Foundational Cryptography Framework, to verify crypto properties of functional specs; the Verified Software Toolchain, to verify C programs w.r.t. functional specs; and CompCert, for verified compilation of C to assembly language.

1 Introduction

HMAC is a cryptographic authentication algorithm, the "Keyed-Hash Message Authentication Code," widely used in conjunction with the SHA-256 cryptographic hashing primitive. The sender and receiver of a message m share a secret session key k. The sender computes $s = \text{HMAC}(k,m)$ and appends s to m. The receiver computes $s' = \text{HMAC}(k,m)$ and verifies that $s' = s$. In principle, a third party will not know k and thus cannot compute s. Therefore, the receiver can infer that message m really originated with the sender.

What could go wrong?

Algorithmic/cryptographic problems. The compression function underlying SHA might fail to have the cryptographic property of being a pseudorandom function (PRF); the SHA algorithm might not be the right construction over its compression function; the HMAC algorithm might fail to have the cryptographic property of being a PRF; we might even be considering the wrong crypto properties.

Implementation problems. The SHA program (in C) might incorrectly implement the SHA algorithm; the HMAC program might incorrectly implement the HMAC algorithm; the programs might be correct but permit side channels such as power analysis, timing analysis, or fault injection.

Specification mismatch. The specification of HMAC or SHA used in the cryptographic-properties [15] proof might be subtly different from the one published as the specification of computer programs [28, 27]. The proofs about C programs might interpret the semantics of the C language differently from the C compiler.

Based on Bellare and Rogaway's probabilistic game framework [16] for cryptographic proofs, Halevi [30] advocates creating an "automated tool to help us with the mundane parts of writing and checking common arguments in [game-based] proofs." Barthe *et al.* [13] present such a tool in the form of CertiCrypt, a framework that "enables the machine-checked construction and verification" of proofs using the same game-based techniques, written in code. Barthe *et al.*'s more recent EasyCrypt system [12] is a more lightweight, user-friendly version (but not *foundational,* i.e., the implementation is not proved sound in any machine-checked general-purpose logic). In this paper we use the Foundational Cryptography Framework (FCF) of Petcher and Morrisett [38].

But the automated tools envisioned by Halevi—and built by Barthe *et al.* and Petcher—address only the "algorithmic/cryptographic problems." We also need machine-checked tools for functional correctness of C programs—not just static analysis tools that verify the absence of buffer overruns. And we need the functional-correctness tools to connect, with machine-checked proofs of equivalence, to the crypto-algorithm proofs. By 2015, proof systems for formally reasoning about crypto algorithms and C programs have come far enough that it is now possible to do this.

Figure 1: Architecture of our assurance case.

Here we present machine-checked proofs, in Coq, of many components, connected and checked at their specification interfaces so that we get a truly end-to-end result: *Version 0.9.1c of OpenSSL's HMAC and SHA-256 correctly implements the FIPS 198-1 and FIPS 180-4 standards, respectively; and that same FIPS 198-1 HMAC standard is a PRF, subject to certain standard (unproved) assumptions about the SHA-256 algorithm that we state formally and explicitly.*

Software is large, complex, and always under maintenance; if we "prove" something about a real program then the proof (and its correspondence to the syntactic program) had better be checked by machine. Fortunately, as Gödel showed, checking a proof is a simple calculation. Today, proof checkers can be simple trusted (and trustworthy) kernel programs [7].

A *proof assistant* comprises a proof-checking kernel with an untrusted proof-development system. The system is typically *interactive,* relying on the user to build the overall structure of the proof and supply the important invariants and induction hypotheses, with many of the details filled in by tactical proof automation or by decision procedures such as SMT or Omega.

Coq is an open-source proof assistant under development since 1984. In the 21st century it has been used for practical applications such as Leroy's correctness proof of an optimizing C compiler [34]. But note, that compiler was not itself written in C; the proof theory of C makes life harder, and only more recently have people done proofs of substantial C programs in proof assistants [32, 29].

Our entire proof (including the algorithmic/cryptographic proofs, the implementation proofs, and the specification matches) is done in Coq, so that we avoid misunderstandings at interfaces. To prove our main theorem, we took these steps (cf. Figure 1):

1. *Formalized.*[5] We use a Coq formalization of the FIPS 180-4 Secure Hash Standard [28] as a specification of SHA-256. (Henceforth, "formalized" or "proved" implies "in the Coq proof assistant.")

2. *Formalized.** We have formalized the FIPS 198-1 Keyed-Hash Message Authentication Code [27] as a specification of HMAC. (Henceforth, the * indicates new work first reported in this paper; otherwise we provide a citation to previous work.)

3. *Formalized.** We have formalized Bellare's functional characterization of the HMAC algorithm.

4. *Proved.** We have proved the equivalence of FIPS 198-1 with Bellare's functional characterization of HMAC.

5. *Formalized.*[6] We use *Verifiable C*, a program logic (embedded in Coq) for specifying and proving functional correctness of C programs.

6. *Formalized.*[35] Leroy has formalized the operational semantics of the C programming language.

7. *Proved.*[6] Verifiable C has been proved sound. That is, if you specify and prove any input-output property of your C program using Verifiable C, then that property actually holds in Leroy's operational semantics of the C language.

8. *Formalized.*[35] Leroy has formalized the operational semantics of the Intel x86 (and PowerPC and ARM) assembly language.

9. *Proved.*[35] If the CompCert optimizing C compiler translates a C program to assembly language, then input-output property of the C program is preserved in the assembly-language program.

10. *Formalized.*[5] We rely on a formalization (in Verifiable C) of the *API interface* of the OpenSSL header file for SHA-256, including its semantic connection to the formalization of the FIPS Secure Hash Standard.

11. *Proved.*[5] The C program implementing SHA-256, lightly adapted from the OpenSSL implementation, has the input-output (API) properties specified by the formalized API spec of SHA-256.

12. *Formalized.** We have formalized the API interface of the OpenSSL header file for HMAC, including its semantic connection to our FIPS 198-1 formalization.

13. *Proved.** Our C program implementing HMAC, lightly adapted from the OpenSSL implementation, has the input-output (API) properties specified by our formalization of FIPS 198-1.

14. *Formalized.** Bellare *et al.* proved properties of HMAC [15, 14] subject to certain assumptions about the underlying cryptographic compression function (typically SHA). We have formalized those assumptions.

15. *Formalized.** Bellare *et al.* proved that HMAC implements a pseudorandom function (PRF); we have formalized what exactly that means. (Bellare's work is "formal" in the sense of rigorous mathematics and LaTeX; we formalized our work in Coq so that proofs of these properties can be machine-checked.)

16. *Proved.** We prove that, subject to these formalized assumptions about SHA, Bellare's HMAC algorithm is a PRF; this is a mechanization of a variant of the 1996 proof [15] using some ideas from the 2006 proofs [14].

Theorem. *The assembly-language program, resulting from compiling OpenSSL 0.9.1c using CompCert, correctly implements the FIPS standards for HMAC and SHA, and implements a cryptographically secure PRF subject to the usual assumptions about SHA.*

Proof. Machine-checked, in Coq, by chaining together specifications and proofs 1–16. Available open-source at https://github.com/PrincetonUniversity/VST/, subdirectories sha, fcf, hmacfcf.

The *trusted code base* (TCB) of our system is quite small, comprising only items 1, 2, 8, 12, 14, 15. Items 4, 7, 9, 11, 13, 16 need not be trusted, because they are proofs checked by the kernel of Coq. Items 3, 5, 6, 10 need not be trusted, because they are specification interfaces checked on both sides by Coq, as Appel [5, §8] explains.

One needs to trust the Coq kernel and the software that compiles it; see Appel's discussion [5, §12].

We do not analyze timing channels or other side channels. But the programs we prove correct are standard C programs for which standard timing and side-channel analysis tools and techniques can be used.

The HMAC brawl. Bernstein [19] and Koblitz and Menezes [33] argue that the security guarantees proved by Bellare *et al.* are of little value in practice, because these guarantees do not properly account for the power of precomputation by the adversary. In effect, they argue that item 15 in our enumeration is the wrong specification for desired cryptographic properties of a symmetric-key authentication algorithm. This may well be true; here we use Bellare's specification in a demonstration of end-to-end machine-checked proof. As improved specifications and proofs are developed by the theorists, we can implement them using our tools. Our proofs are sufficiently modular that only items 15 and 16 would change.

Which version of OpenSSL. We verified HMAC/SHA from OpenSSL 0.9.1c, dated March 1999, which does not include the home-brew object system "engines" of more recent versions of OpenSSL. We further simplified the code by specializing OpenSSL's use of generic "envelopes" to the specific hash function SHA-256, thus obtaining a statically linked code. Verifiable C is capable of reasoning about function pointers and home-brew object systems [6, Chapter 29]—it is entirely plausible that a formal specification of "engines" and "envelopes" could be written down—but such proofs are more complex.

2 Formalizing functional specifications

(Items 1, 2 of the architecture.) The FIPS 180-4 specification of the SHA function can be formalized in Coq as this mathematical function:

```
Definition SHA_256 (str : list Z) : list Z :=
  intlist_to_Zlist (
    hash_blocks init_registers (generate_and_pad str)).
```

where hash_blocks, init_registers, and generate_and_pad are translations of the FIPS standard. Z is Coq's type for (mathematical) integers; the (list Z) is the contents of a string of bytes, considered as their integer values. SHA-256 works internally in 32-bit unsigned modular arithmetic; intlist_to_Zlist converts a sequence of 32-bit machine ints to the mathematical contents of a byte-sequence. See Appel [5] for complete details. The functional spec of SHA-256, including definitions of all these functions, comes to 169 lines of Coq, all of which is in the trusted base for the security/correctness proof.

In this paper we show the full functional spec for HMAC256, the HMAC construction applied to hash function SHA_256:

```
Definition mkKey (l:list Z):list Z :=
  zeropad (if |l| > 64 then SHA_256 l else l).
Definition KeyPreparation (k: list Z):list byte :=
  map Byte.repr (mkKey k).
Definition HASH l m := SHA_256 (l++m)
Definition HmacCore m k :=
  HASH (opad ⊕ k) (HASH (ipad ⊕ k) m)
Definition HMAC256 (m k : list Z) : list Z :=
  HmacCore m (KeyPreparation k)
```

where zeropad right-extends[1] its argument to length 64 (i.e. to SHA256's block size, in bytes), ipad and opad are the padding constants from FIPS198-1, ⊕ denotes byte-wise XOR, and ++ denotes list concatenation.

3 API specifications of C functions

(Items 10, 12 of the architecture.) Hoare logic [31], dating from 1969, is a method of proving correctness of imperative programs using preconditions, postconditions, and loop invariants. Hoare's original logic did not handle pointer data structures well. Separation logic, introduced in 2001 [37], is a variant of Hoare logic that encapsulates "local actions" on data structures.

Verifiable C [6] is a separation logic that applies to the real C language. Verifiable C's rules are complicated in some places, to capture C's warts and corner cases.

The FIPS 180 and FIPS 198 specifications—and our definitions of SHA_256 and HMAC256—do not explain how the "mathematical" sequences of bytes are laid out in the arrays and structs passed as parameters to (and used internally by) the C functions. For this we need an *API spec.* Using Verifiable C, one specifies the API behavior of each function: the data structures it operates on, its preconditions (what it assumes about the input data structures available in parameters and global variables), and the postcondition (what it guarantees about its return value and changes to data structures). Appel [5, §7] explains how to build such API specs and shows the API spec for the SHA_256 function.

Here we show the API spec for HMAC. First we define a Coq record type,

```
Record DATA := { LEN:Z; CONT: list Z }.
```

If *key* has type DATA, then LEN(*key*) is an integer and CONT(*key*) is "contents" of the key, a sequence of integers. We do not use Coq's dependent types *here* to enforce that LEN corresponds to the length of the CONT field, but see the *has_lengthK* constraint below.

To specify the API of a C-language function in Verifiable C, one writes

DECLARE f WITH $\vec{v}$
    PRE[*params*] *Pre*   POST [*ret*] *Post*.

where f is the name of the function, *params* are the formal parameters (of various C-language types), and *ret* is the C return type. The precondition *Pre* and postcondition *Post* have the form PROP P LOCAL Q SEP R, where P is a list of pure propositions (true independent of the current program state), Q is a list of local/global variable bindings, and R is a list of *sep*aration logic predicates that describe the contents of memory. The WITH clause describes *logical* variables $\vec{v}$, abstract mathematical values that can be referred to anywhere in the precondition and postcondition.

In our HMAC256_spec, shown below, the first "abstract mathematical value" listed in this WITH clause is the key-pointer *kp*, whose "mathematical" type is "C-language value',' or val. It represents an address in memory where the HMAC session key is passed. In the LOCAL part of the PREcondition, we say that the formal parameter _key actually contains the value *kp* on entry to the function, and in the SEP part we say that there's a data_block at location *kp* containing the actual *key* bytes. In the postcondition we refer to *kp* again, saying that the data_block at address *kp* is still there, unchanged by the HMAC function.

[1] The more recent RFC4868 mandates that when HMAC is used for authentication, *a fixed key length equal to the output length of the hash functions MUST be supported, and key lengths other than the output length of the associated hash function MUST NOT be supported.* Our specification clearly separates KeyPreparation from HmacCore, but at the top level follows the more permissive standards RFC2104/FIPS198-1 as well as the implementation reality of even contemporary snapshots of OpenSSL and its clones.

```
Definition HMAC256_spec :=
 DECLARE _HMAC
  WITH kp: val, key:DATA, KV:val,
        mp: val, msg:DATA, shmd: share, md: val
  PRE [ _key OF tptr tuchar, _key_len OF tint,
        _d OF tptr tuchar, _n OF tint,
        _md OF tptr tuchar ]
   PROP(writable_share shmd;
         has_lengthK (LEN key) (CONT key);
         has_lengthD 512 (LEN msg) (CONT msg))
   LOCAL(temp _md md; temp _key kp; temp _d mp;
          temp _key_len (Vint (Int.repr (LEN key)));
          temp _n (Vint (Int.repr (LEN msg)));
          gvar _K256 KV)
   SEP(`(data_block Tsh (CONT key) kp);
       `(data_block Tsh (CONT msg) mp);
       `(K_vector KV);
       `(memory_block shmd (Int.repr 32) md))
 POST [ tvoid ]
   PROP() LOCAL()
   SEP(`(K_vector KV);
       `(data_block shmd
          (HMAC256 (CONT msg) (CONT key)) md);
       `(data_block Tsh (CONT key) kp);
       `(data_block Tsh (CONT msg) mp)).
```

The next WITH value is *key*, a DATA value, that is, a mathematical sequence of byte values along with its (supposed) length. In the PROP clause of the precondition, we enforce this supposition with *has_lengthK* (LEN *key*) (CONT *key*).

The function Int.repr injects from the mathematical integers into 32-bit signed/unsigned numbers. So temp _n (Vint (Int.repr (LEN *msg*))) means, take the mathematical integer (LEN *msg*), smash it into a 32-bit signed number, inject that into the space of C values, and assert that the parameter _n contains this value on entry to the function. This makes reasonable sense if $0 \leq$ LEN $msg < 2^{32}$, which is elsewhere enforced by *has_lengthD*. Such 32-bit range constraints are part of C's "warts and all," which are rigorously accounted for in Verifiable C. Both *has_lengthK* and *has_lengthD* are user-defined predicates within the HMAC API spec.

The precondition contains an uninitialized 32-byte memory_block at address *md*, and the _md parameter of the C function contains the value *md*. In the postcondition, we find that at address *md* the memory block has become an initialized data block containing a representation of HMAC256 (CONT *msg*) (CONT *key*).

For stating and proving these specifications, the following characteristics of separation logic are crucial:

1. The SEP lists are interpreted using the *separating conjunction* $*$ which (in contrast to ordinary conjunction $\wedge$) enforces disjointness of the memory regions specified by each conjunct. Thus, the precondition requires—and the postcondition guarantees—that keys, messages, and digests do not overlap.

2. Implicit in the semantic interpretation of a separation logic judgment is a *safety guarantee* of the absence of memory violations and other runtime errors, apart from memory exhaustion. In particular, verified code is guaranteed to respect the specified *footprint*: it will neither read from, nor modify or free any memory outside the region specified by the SEP clause of PRE. Moreover, all heap that is locally allocated is either locally freed, or is accounted for in POST. Hence, memory leaks are ruled out.

3. As a consequence of these locality principles, separation logic specifications enjoy a *frame property*: a verified judgment remains valid whenever we add an arbitrary additional separating conjunct to *both* SEP-clauses. The corresponding proof rule, the *frame rule*, is crucial for modular verification, guaranteeing, for example, that when we call SHA-256, the HMAC data structure remains unmodified.

The HMAC API spec has the 25 lines shown here plus a few more for definitions of auxiliary predicates (has_lengthK 3 lines, has_lengthD 3 lines, etc.); *plus* the API spec for SHA-256, all in the trusted base.

Incremental hashing. OpenSSL's HMAC and SHA functions are incremental. One can initialize the hasher with a key, then incrementally append message-fragments (not necessarily block-aligned) to be hashed, then finalize to produce the message digest. We fully support this incremental API in our correctness proofs. For simplicity we did not present it here, but Appel [5] presents the incremental API for SHA-256. The API spec for fully incremental SHA-256 is 247 lines of Coq; the simple (nonincremental) version has a *much* smaller API spec, similar to the 25+6 lines shown here for the nonincremental HMAC.

Once every function is specified, we use Verifiable C to prove that each function's body satisfies its specification. See Section 6.

4 Cryptographic properties of HMAC

(Items 14, 15, 16 of the architecture.) This section describes a mechanization of a cryptographic proof of security of HMAC. The final result of this proof is similar to the result of Bellare et al. [15], though the structure of the proof and some of the definitions are influenced

by Bellare's later proof [14]. This proof uses a more abstract model of HMAC (compared to the functional spec in §2) in which keys are in $\{0,1\}^b$ (the set of bit vectors of length b), inputs are in $\{0,1\}^*$ (bit lists), and outputs are in $\{0,1\}^c$ for arbitrary b and c such that $c \leq b$. An implementation of HMAC would require that b and c are multiples of some word size, and the input is an array of words, but these issues are typically not considered in cryptographic proofs.

In the context of the larger proof described in this paper, we refer to this model of HMAC in which sizes are arbitrary as the *abstract specification* of HMAC. In order to use security results related to this specification, we must show that this specification is appropriately related to the specification provided in §2. We chose to prove the security of the abstract specification, rather than directly proving the security of a more concrete specification, because there is significant value in this organization. Primarily, this organization allows us to use the exact definitions and assumptions from the cryptography literature, and we therefore gain greater assurance that the definitions are correct and the assumptions are reasonable. Also, this approach demonstrates how an existing mechanized proof of cryptographic security can be used in a verification of the security of an implementation. This organization also helps decompose the proof, and it allows us to deal with issues related to the implementation in isolation from issues related to cryptographic security.

We address the "gap" between the abstract and concrete HMAC specifications by proving that they are equivalent. Section 5 outlines the proof and states the equivalence theorem.

4.1 The Foundational Cryptography Framework

This proof of security was completed using the Foundational Cryptography Framework (FCF), a Coq library for reasoning about the security of cryptographic schemes in the computational model [38]. FCF provides a probabilistic programming language for describing all cryptographic constructions, security definitions, and problems that are assumed to be hard. Probabilistic programs are described using Gallina, the purely functional programming language of Coq, extended with a computational monad that adds sampling uniformly random bit vectors. The type of probabilistic computations that return values of type A is Comp A. The code uses {0,1}^n to describe sampling a bit vector of length n. Arrows (<-$) denote sequencing (i.e. bind) in the monad.

Listing 1 contains an example program implementing a one-time pad on bit vectors of length c (for any natural number c). The program produces a random bit vector and stores it in p, then returns the *xor* (using the standard Coq function BVxor) of p and the argument x.

```
Definition OTP c (x : Bvector c) : Comp (Bvector c)
  := p <-$ {0, 1}^c; ret (BVxor c p x)
```

Listing 1: Example Program: One-Time Pad.

The language of FCF has a denotational semantics that relates programs to discrete, finite probability distributions. A distribution on type A is modeled as a function in $A \rightarrow \mathbb{Q}$ which should be interpreted as a probability mass function. FCF provides a theory of distributions, a program logic, and a library of tactics that can be used to complete proofs without appealing directly to the semantics. We can use FCF to prove that two distributions are equivalent, that the distance between the probabilities of two events is bounded by some value, or that the probability of some event is less than some value. Such claims enable cryptographic proofs in the "sequence of games" style [16].

In some cryptographic definitions and proofs, an adversary is allowed to interact with an "oracle" that maintains state while accepting queries and providing responses. In FCF, an oracle has type S → A → Comp (B ∗ S) for types S, A, and B, of state, input, and output, respectively. The OracleComp type is provided to allow an adversary to interact with an oracle without viewing or modifying its state. By combining an OracleComp with an oracle and a value for the initial state of the oracle, we obtain a computation returning a pair of values, where the first value is produced by the OracleComp at the end of its interaction with the oracle, and the second value is the final state of the oracle.

4.2 HMAC Security

We mechanized a proof of the following fact. If h is a compression function, and h^* is a Merkle-Damgård hash function constructed from h, then HMAC based on h^* is a pseudorandom function (PRF) assuming:

1. h is a PRF.
2. h^* is weakly collision-resistant (WCR).
3. The dual family of h (denoted $\bar{h}$) is a PRF against $\oplus$-related-key attacks.

The formal definition of a PRF is shown in Listing 2. In this definition, f is a function in K → D → R that should be a PRF. That is, for a key k : K, an adversary who does not know k cannot gain much *advantage* in distinguishing f k from a random function in D → R.

The adversary A is an OracleComp that interacts with either an oracle constructed from f or with randomFunc, a random function constructed by producing random values for outputs and memoizing them so they can be repeated the next time the same input is provided. The randomFunc oracle uses a list of pairs as its state, so an empty list is provided as its initial state. The value tt is the "unit" value, where unit is a placeholder type much like "void" in the C language. This definition uses alternative arrows (such as <-$2) to construct sequences in which the first computation produces a tuple, and a name is given to each value in the tuple. The size of the tuple is provided in the arrow in order to assist the parser.

```
Definition f_oracle (k : K) (x : unit) (d : D)
                : Comp (R × unit) :=
  ret (f k d, tt).

Definition PRF_G0 : Comp bool :=
  k <-$ RndKey;
  [b, _] <-$2 A (f_oracle k) tt; ret b.

Definition PRF_G1 : Comp bool :=
  [b, _] <-$2 A (randomFunc) nil; ret b.

Definition PRF_Advantage : Rat :=
  | Pr[PRF_G0] -Pr[PRF_G1] |.
```

Listing 2: Definition of a PRF. The f_oracle function wraps the function f (closed over key k) and turns it into an oracle. A is an adversary. Comp bool is the type of probabilistic computations that produce a bool. Rat is the type of (unary, nonnegative) rational numbers.

This security definition is provided in the form of a "game" in which the adversary tries to determine whether the oracle is f (in game 0) or a random function (in game 1). After interacting with the oracle, the adversary produces a bit, and the adversary "wins" if this bit is likely to be different in the games. We define the *advantage* of the adversary to be the difference between the probability that it produces "true" in game 0 and in game 1. We can conclude that f is a PRF if this advantage is sufficiently small.

```
Definition Adv_WCR_G : Comp bool :=
  k <-$ RndKey;
  [d1, d2, _] <-$3 A (f_oracle k) tt;
  ret ((d1 != d2) && ((f k d1) ?= (f k d2))).

Definition Adv_WCR : Rat := Pr[Adv_WCR_G].
```

Listing 3: Definition of Weak Collision-Resistance.

Listing 3 defines a weakly collision-resistant function. This definition uses a single game in which the adversary is allowed to interact with an oracle defined by a keyed function f. At the end of this interaction, the adversary attempts to produce a collision, or a pair of different input values that produce the same output. In this game, we use ?= and != to denote tests for equality and inequality, respectively. The advantage of the adversary is the probability with which it is able to locate a collision.

Finally, the security proof assumes that a certain keyed function is a PRF against ⊕-related-key attacks (RKA). This definition (Listing 4) is similar to the definition of a PRF, except the adversary is also allowed to provide a value that will be xored with the unknown key before the PRF is called. Note that this assumption is applied to the *dual family* of h, in which the roles of inputs and keys are reversed. So a single input value is chosen at random and fixed, and the adversary queries the oracle by providing values which are used as keys.

```
Definition RKA_F (k: Bvector b) (s: unit)
            (p: Bvector b × Bvector c)
        : (Bvector c × unit) :=
  ret (f ((fst p) xor k) (snd p), tt).

Definition RKA_R (k: Bvector b)
          (s : list (Bvector c × Bvector c))
          (p: Bvector b × Bvector c)
          : (Bvector c × list (Bvector c × Bvector c) :=
  randomFunc s ((fst p) xor k, (snd p))

Definition RKA_G0 : Comp bool :=
  k <-$ RndKey; [b, _] <-$2 A (RKA_F k) tt; ret b.

Definition RKA_G1 : Comp bool :=
  k <-$ RndKey; [b, _] <-$2 A (RKA_R k) nil; ret b.

Definition RKA_Advantage : Rat :=
  | Pr[RKA_G0] -Pr[RKA_G1] |.
```

Listing 4: Definition of Security against ⊕ Related-Key Attacks. b is the key length of the compression function, c is the input length of the compression function; Bvector b is the type of bit-vectors of length b.

The proof of security has the same basic structure (Figure 2) as Bellare's more recent HMAC proof [14], though we simplify the proof significantly by assuming h^* is WCR. The proof makes use of a nested MAC (NMAC) construction that is similar to HMAC, but it uses h^* in a way that is not typically possible in implementations of hash functions. The proof begins by showing that NMAC is a PRF given that h is a PRF and h^* is WCR. Then we show that NMAC and HMAC are "close" (that no adversary can effectively distinguish them) under the assumption that $\bar{h}$ is a ⊕-RKA-secure PRF. Finally, we combine these two results to derive that HMAC is a PRF.

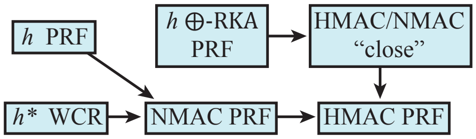

Figure 2: HMAC Security Proof Structure

We also mirror Bellare's proof by reasoning about slightly generalized forms of HMAC and NMAC (called GHMAC and GNMAC) that require the input to be a list of bit vectors of length b. The proof also makes use of a "two-key" version of HMAC that uses a bit vector of length $2b$ as the key. To simplify the development of this proof, we build HMAC on top of these intermediate constructions in the abstract specification (Listing 5).

```
Definition h_star k (m : list (Bvector b))
  := fold_left h m k.
Definition hash_words := h_star iv.

Definition GNMAC k m :=
  let (k_Out, k_In) := splitVector c c k in
  h k_Out (app_fpad (h_star k_In m)).

Definition GHMAC_2K k m :=
  let (k_Out, k_In) := splitVector b b k in
  let h_in := (hash_words (k_In :: m)) in
  hash_words (k_Out :: (app_fpad h_in) :: nil).

Definition HMAC_2K k (m : list bool) :=
  GHMAC_2K k (splitAndPad m).

Definition HMAC (k : Bvector b) :=
  HMAC_2K ((k xor opad) ++ (k xor ipad)).
```

Listing 5: HMAC Abstract Specification.

splitAndPad produces a list of bit-vectors from a list of bits (padding the last bit-vector as needed), and app_fpad is a padding function that produces a bit vector of length b from a bit vector of length c. In the HMAC function, we use constants opad and ipad to produce a key of length $2b$ from a key of length b.

The statement of security for HMAC is shown in Listing 6. We show that HMAC is a PRF by giving an expression that bounds the advantage of an arbitrary adversary A. This expression is the sum of three terms, where each term represents the advantage of some adversary against some other security definition.

The listing describes all the parameters to each of the security definitions. In all these definitions, the first parameter is the computation that produces random keys, and in PRF_Advantage and RKA_Advantage, the second parameter is the computation that produces random values in the range of the function. In all definitions, the penultimate parameter is the function of interest, and the final parameter is some constructed adversary. The descriptions of these adversaries are omitted for brevity, but only their computational complexity is relevant (e.g. all adversaries are in ZPP assuming adversary A is in ZPP).

```
Theorem HMAC_PRF:
  PRF_Advantage ({0, 1}^b) ({0, 1}^c) HMAC A <=
  PRF_Advantage ({0, 1}^c) ({0, 1}^c) h B1 +
  Adv_WCR ({0, 1}^c) h_star B2 +
  RKA_Advantage ({0, 1}^b) ({0, 1}^c)
    (BVxor b) (dual_f h) B3.
```

Listing 6: Statement of Security for HMAC.

We can view the result in Listing 6 in the asymptotic setting, in which there is a security parameter η, and parameters c and b are polynomial in η. In this setting, it is possible to conclude that the advantage of A against HMAC is negligible in η assuming that each of the other three terms is negligible in η. We can also view this result in the *concrete setting*, and use this expression to obtain *exact security* measures for HMAC when the values of b and c are fixed according the sizes used by the implementation. The latter interpretation is more informative, and probably more appropriate for reasoning about the cryptographic security of an implementation.

5 Equivalence of the two functional specs

(Item 4 of the architecture.) In §2 we described a bytes-and-words specification following FIPS198-1, suited for proving the C program; call that the *concrete specification*. In §4 we described a length-constrained bit-vector specification following Bellare *et al.*'s original papers; call that the *abstract specification*. Here we describe the proof that these two specifications are equivalent.

Proof outline. There are seven main differences between the concrete and abstract specs:

(0) The abstract spec, as its name suggests, leaves several variables as parameters to be instantiated. Thus, in order to compute with the abstract HMAC, one must pass it "converted" variables and "wrapped" functions from the concrete HMAC.

(1) The abstract spec operates on bits, whereas the concrete spec operates on bytes.

(2) The abstract spec uses the dependent type Bvector n, which is a length-constrained bit list of length n, whereas the concrete spec uses byte lists and int lists, whose lengths are unconstrained by definition.

(3) Due to its use of dependent types, the abstract spec must pad its input twice in an ad-hoc manner, whereas the concrete spec uses the SHA-256 padding function consistently.

(4) The concrete spec treats the hash function (SHA-256) as a black box, whereas the abstract spec exposes various parts of its functionality, such as its initialization vector, internal compression function, and manner of iteration. (It does this because the Bellare-style proofs rely on the Merkle-Damgård structure of the hash function.)

(5) The abstract spec pads the message and splits it into a list of blocks so that it can perform an explicit fold over the list of lists. However, the concrete spec leaves the message as a list of bytes and performs an implicit fold over the list, taking a new block at each iteration.

(6) The abstract spec defines HMAC via the HMAC_2K and GHMAC_2K structures, not directly.

Instantiating the abstract specification. The abstract HMAC spec leaves the following parameters abstract:

```
Variable c p : nat.

(* compression function *)
Variable h : Bvector c → Bvector b → Bvector c.

(* initialization vector *)
Variable iv : Bvector c.
Variable splitAndPad : Blist → list (Bvector b).
Variable fpad : Bvector c → Bvector p.
Variable opad ipad : Bvector b.
```

The abstract HMAC spec is also more general than the concrete spec, since it operates on bit vectors, not byte lists, and does not specify a block size or output size. After "replacing" the vectors with lists (see the explanation of difference (2)) and specializing $c = p = 256$ (resulting in $b = 512$), we may instantiate abstract parameters with concrete parameters or functions from SHA-256, wrapped in *bytesToBits* and/or *intlist_to_Zlist* conversion functions. For example, we instantiate the block size to 256 and the output size to 512, and define *iv* and *h* as:

```
Definition intsToBits := bytesToBits ∘ intlist_to_Zlist.
Definition sha_iv : Blist :=
  intsToBits SHA256.init_registers.
Definition sha_h (regs : Blist) (block : Blist) : Blist :=
  intsToBits (SHA256.hash_block (bitsToInts regs)
                                (bitsToInts block)).
```

The *intlist_to_Zlist* conversion function is necessary because portions of the SHA-256 spec operate on lists of *Integer*s, as specified in our bytes-and-words formalization of FIPS 180-4. (*Z* in Coq denotes arbitrary-precision mathematical integers. Our SHA-256 spec represents byte values as *Z*. An *Integer* is four byte-*Z*s packed big-endian into a 32-bit integer.)

We are essentially converting the types of the functions from functions on intlists (*intlist* → ... → *intlist*) to functions on Blists (*Blist* → ... → *Blist*) by converting their inputs and outputs.

Let us denote by HmacAbs256 the instantiation of function HMAC from Listing 5 to these parameters. Since Bellare's proof assumes that the given key is of the right length (the block size), our formal equivalence result relates HmacAbs256 to the function HmacCore from Section 2, i.e. to the part of HMAC256 that is applied after key length normalization. (Unlike Bellare, FIPS 198 includes steps to first truncate or pad the key if it is too long or short.)

Theorem. For key vector kv of type Bvector 256 and message m of type list bool satisfying $|l| \equiv 0 \ (mod\ 8)$,

$$\mathsf{HmacAbs256}\ kv\ m \approx \mathsf{HmacCore}\ \overline{m}\ (\mathsf{map\ Bytes.repr}\ \overline{kv}).$$

where $\overline{(\cdot)}$ denotes bitsToBytes conversion, and $\approx$ is equality modulo conversion between lists and vectors.

Reconciling other differences. The last difference (6) is easily resolved by unfolding the definitions of HMAC_2K and GHMAC_2K. We solve the other six problems by changing definitions and massaging the two specs toward each other, proving equality or equivalence each time.

Bridging (5) is basically the proof of correctness of a *deforestation* transformation. Consider a message m as a list of bits b_i. First, split it into 512-bit blocks B_i, then "fold" (the "reduce" operation in map-reduce) the hash operation H over it, starting with the initialization vector iv: $H(H(H(iv, B_0), B_1), \ldots, B_{n-1})$. Alternatively, express this as a recursive function on the original bit-sequence b: grab the first 512 bits, hash with H, then do a recursive call after skipping the first 512 bits:

```
Function F (r: list bool) (b: list bool)
      {measure length b} : list bool :=
match msg with
   nil ⇒ r
 | _ ⇒ F (H r (firstn 512 b)) (skipn 512 b)
end.
```

Provided that $|b|$ is a multiple of 512 (which we prove elsewhere), $F(iv, b) = H(H(H(iv, B_0), B_1), \ldots, B_{n-1})$.

We bridge (4) by using the fact that SHA-256 *is* a Merkle-Damgård construction over a compression function. This is a simple matter of matching the definition of SHA-256 to the definition of an MD hash function.

Bridging (3) is a proof that two different views of the SHA padding function are equivalent. Before iterating the compression function on the message, SHA-256 pads it in a standard, one-to-one fashion such that its length is a multiple of the block size. It pads it as such:

$$msg\,|\,[1]\,|\,[0,0,\ldots 0]\,|\,L$$

where | denotes list concatenation and L denotes the 64-bit representation of the length of the message. The number of 0s is calculated such that the length of the entire padded message is a multiple of the block size.

The abstract spec accomplishes this padding in two ways using the functions *fpad* and *splitAndPad*. *fpad* pads a message of known length of the output size c to the block size b, since c is specified to be less than b. *splitAndPad* breaks a variable-length message (of type list bool) into a list of blocks, each size b, padding it along the way. *fpad* is instantiated as a constant, since we know that the length of the message is $c < b$. *splitAndPad* is instantiated as the normal SHA padding function, but tweaked to add one block size to the length appended in $[l_1, l_2]$, since k_{in} (with a length of one block) will be prepended to the padded message later.

To eliminate these two types of ad-hoc padding, we rewrite the abstract spec to incorporate *fpad* and *splitAndPad* into a single padding function split_and_pad included in the hash function, in the style of SHA-256.

$$\mathsf{hash\_words\_padded} := \mathsf{hash\_words} \circ \mathsf{split\_and\_pad}.$$

We then remove *fpad* and *splitAndPad* from subsequent versions of the specification. We can easily prove equality by unfolding definitions.

Bridging bytes and bits. The abstract and concrete HMAC functions have different types, so we cannot prove them *equal*, only *equivalent*. $HMAC_c$ operates on (lists of) bits and $HMAC_a$ operates on (lists of) bytes. ($HMAC_c$ used to operate on vectors, but recall that we replaced them with lists earlier.) To bridge gap (1) we prove, given that the inputs are equivalent, the outputs will be equivalent:

$$k_c \approx k_a \rightarrow$$
$$m_c \approx m_a \rightarrow$$
$$HMAC_c(k_c, m_c) \approx HMAC_a(k_a, m_a).$$

The equivalence relation $\approx$ can be defined either computationally or inductively, and both definitions are useful.

To reason about the behavior of the wrapped functions with which we instantiated the abstract HMAC spec, we use the computational equivalence relation ($\approx_c$) instantiated with a generic conversion function. This allows us to build a framework for reasoning about the asymmetry of converting from bytes to bits versus from bits to bytes, as well as the behavior of repeatedly applied wrapped functions.

Bridging vectors and lists. We bridge (2) by changing all Bvector n to list bool, then proving that all functions preserve the length of the list when needed. This maintains the Bvector n invariant that its length is always n. In general, the use of lists (of bytes, or Z values) is motivated by the desire to reuse Appel [5]'s prior work on SHA literally, whereas the use of Bvector enables a more elegant proof of the proof of cryptographic properties.

Injectivity of splitAndPad. The security proof relies on the fact that splitAndPad is injective, in the sense that $b_1 = b_2$ should hold whenever splitAndPad(b_1) = splitAndPad(b_2). Indeed, this property is violated if we naively instantiate splitAndPad with the bitlists-to-bytelists roundtrip conversion of SHA-256's padding+length function, due to the non-injectivity of bitlists-to-bytelists conversion. On the other hand, as the C programs interpret all length informations as referring to lengths in bytes, attackers that attempt to send messages whose length is not divisible by 8 are effectively ruled out. To verify this property formally, we make the abstract specification (and the proof of **Theorem** HMAC_PRF) parametric in the type of messages. Instantiating the development to the case where messages are bitlists of length $8n$ allows us to establish the desired injectivity condition along the the lines of the following informal argument.

Given a message m, SHA's splitAndPad appends a 1 bit, then k zero bits, then a 64-bit integer representing the length of the message $|m|$; k is the smallest number so that $|\text{splitAndPad}(m_1)|$ is a multiple of the block size. Injective means that if $m_1 \neq m_2$ then $\text{splitAndPad}(m_1) \neq \text{splitAndPad}(m_2)$. The proof has five cases:

- $m_1 = m_2$, then by contradiction.
- $|m_1| = |m_2|$, then $\text{splitAndPad}(m_1)$ must differ from $\text{splitAndPad}(m_2)$ in their first $|m_1|$ bits.
- $|m_1| \neq |m_2|$, $|m_1| \leq 2^{64}$, $|m_2| \leq 2^{64}$, then the last 64 bits (representation of length) will differ.
- $(|m_1| - |m_2|) \bmod 2^{64} \neq 0$, then the last 64 bits (representation of length) will differ.
- $|m_1| \neq |m_2|$, and $(|m_1| - |m_2|) \bmod 2^{64} = 0$; then the lengths $|m_1|, |m_2|$ must differ by at least 2^{64}, so the variation in k_1 and k_2 (which must each be less than twice the block size) cannot make up the difference, so the padded messages will have different lengths.

Our machine-checked proof of injectivity is somewhat more comprehensive than Bellare et al.'s [15], which reads in its entirety, "Notice that a way to pad messages to an exact multiple of b bits needs to be defined, in particular, MD5 and SHA pad inputs to always include an encoding of their length."

Preservation of cryptographic security. Once the equivalence between the two functional programs has been established, and injectivity of the padding function is proved, it is straightforward to prove the applicability of **Theorem** HMAC_PRF (Listing 6) to the API spec.

6 Specifying and verifying the C program

(Items 11, 13 of the architecture.) We use Verifiable C to prove that each function's body satisfies its specification. As in a classic Hoare logic, each kind of C-language statement has one or more proof rules. Appel [6, Ch. 24-26] presents these proof rules, and explains how *tactics*—programmed in the Ltac language of Coq—apply the proof rules to the abstract syntax trees of C programs. The ASTs are obtained by applying the front-end phase of the CompCert compiler to the C program. The HMAC proof (item 13 in §1) is 2832 lines of Coq (including blanks and comments), none of which is in the trusted base because it is all machine-checked.

Just like OpenSSL's implementation of SHA-256, the C code implementing HMAC is *incremental*: the one-shot HMAC function is obtained by composing auxiliary functions hmacInit, hmacUpdate, hmacFinish, and hmacCleanup that are all exposed in the header file. They allow a client to reuse a key for the authentication of multiple messages, and also to provide each individual message in chunks, by repeatedly invoking hmacUpdate. To this end, the auxiliary functions employ the hash function's incremental interface and are formulated over a client-visible struct, HMAC_CTX. Specializing OpenSSL's original header file to the hash function SHA-256 yields the following:[2]

```
typedef struct hmac_ctx_st {
        SHA256_CTX md_ctx; // workspace
        SHA256_CTX i_ctx; // inner SHA structure
        SHA256_CTX o_ctx; // outer SHA structure
        unsigned int key_length;
        unsigned char key[64];
        } HMAC_CTX;

void HMAC_Init(HMAC_CTX *ctx,
                unsigned char *key, int len);

void HMAC_Update(HMAC_CTX *ctx,
                  const void *data, size_t len);

void HMAC_Final(HMAC_CTX *ctx,
                 unsigned char *md);

void HMAC_cleanup(HMAC_CTX *ctx);

unsigned char *HMAC(unsigned char *key,
                    int key_len,
                    unsigned char *d, int n,
                    unsigned char *md);
```

Fields i_ctx and o_ctx store partially constructed SHA data structures that are initialized during HMAC_Init to hold the ⊕ of the normalized key and ipad/opad, respectively, and are copied to the workspace md_ctx where the inner and outer hashing applications are performed.

Omitting the implementations of the other functions, the one-shot HMAC invokes the incremental functions on a freshly stack-allocated HMAC_CTX, where 32 is the digest length of SHA-256:

```
unsigned char *HMAC(unsigned char *key,
                    int key_len, unsigned char *d,
                    int n, unsigned char *md) {
  HMAC_CTX c; static unsigned char m[32];
  if (md == NULL) md=m;
  HMAC_Init(&c, key, key_len);
  HMAC_Update(&c,d,n);
  HMAC_Final(&c,md);
  HMAC_cleanup(&c);
  return(md);
}
```

In order to verify that this code satisfies the specification HMAC256_spec from Section 2, each incremental function is equipped with its individual Verifiable C specification. Each specification is formulated with reference to a suitable Coq function (or alternatively a propositional relation, as extractability is not required) that expresses the function's effect on the HMAC_CTX structure abstractly, without reference to the concrete memory layout.

More precisely, the logical counterpart of an HMAC_CTX structure is given by the Coq type

```
Inductive hmacabs :=
 HMACabs: ∀(ctx iSha oSha: s256abs)
             (keylen: Z) (key: list Z), hmacabs.
```

That is, an *HMAC abstract state* has five components: ctx, iSha, and oSha are *SHA abstract states*, keylen is an integer, and key is a list of (integer) byte values. Appel [5] defines SHA abstract states; if you initialize a SHA module and dump the first n bytes of a message into it, you get a value of type s256abs representing the abstract state of the incremental-mode SHA-256 program.

Appel also defines a relation, update_abs a c_1 c_2, saying that adding another (incremental mode) message fragment s to abstract state c_1 yields state c_2.

We define abstract states for HMAC, and the incremental-mode HMAC update relation, in terms of the SHA s256abs type and update_abs relation.

[2] During the verification, we observed that the fields key_length and key can be eliminated from hmac_ctx_st, for the price of minor alterations to the code, API specification, and proof. A similar modification has recently (and independently) been implemented in boringssl.

```
Definition hmacUpdate (data: list Z)
                        (h1 h2: hmacabs) : Prop :=
  match h1 with HMACabs ctx1 iS oS klen k
  ⇒ ∃ctx2, update_abs data ctx1 ctx2
     ∧ h2 = HMACabs ctx2 iS oS klen k
  end.
```

To connect these definitions to the *upper* parts of our verification architecture, we prove that the composition of these counterparts of the incremental functions (i.e. the counterpart of the one-shot HMAC) coincides with HMAC256 the FIPS functional specification from Section 3.

```
Definition hmacIncremental (k data dig:list Z) :=
∃hInit hUpd, hmacInit k hInit ∧
        hmacUpdate data hInit hUpd ∧
        hmacFinal hUpd dig.

Lemma hmacIncremental_sound k data dig:
       hmacIncremental k data dig →
       dig = HMAC256 data k.
Proof. ... Qed.
```

Downward, we connect hmacabs and HMAC_CTX by a separation logic representation predicate:

```
Definition hmacstate_ (h:hmacabs) (c:val): mpred:=
    EX r:hmacstate,
     !! hmac_relate h r
     && data_at Tsh t_struct_hmac_ctx_st r c.
```

where hmac_relate is a pure proposition specifying that each component of a concrete struct r has precisely the content prescribed by h.

Using these constructions, we obtain API specifications of the incremental functions such as HMAC_Update.

```
Definition HMAC_Update_spec :=
 DECLARE _HMAC_Update
 WITH h1: hmacabs, c : val, d:val, len:Z,
       data:list Z, KV:val
 PRE [ _ctx OF tptr t_struct_hmac_ctx_st,
       _data OF tptr tvoid, _len OF tuint]
   PROP(has_lengthD (s256a_len (absCtxt h1))
                        len data)
   LOCAL(temp _ctx c; temp _data d;
           temp _len (Vint (Int.repr len));
           gvar _K256 KV)
   SEP(`(K_vector KV); `(hmacstate_ h1 c);
        `(data_block Tsh data d))
 POST [ tvoid ]
   EX h2: hmacabs,
     PROP(hmacUpdate data h1 h2)
     LOCAL()
     SEP(`(K_vector KV); `(hmacstate_ h2 c);
          `(data_block Tsh data d)).
```

7 Proof effort

It is difficult to estimate the proof effort, as we used this case study to learn where to make improvements to the usability and automation of our toolset. However, we can give some numbers: size, in commented lines of code, of the specifications and proofs. Where relevant, we give the size of the corresponding C API or function.

8 Related work

We have presented a *foundational, end-to-end* verification. All the relevant aspects of cryptographic proofs or of the C programming language are defined and checked with respect to the foundations of logic. We say a reasoning engine for crypto is *foundational* if it is implemented in, or its implementation is proved correct in, a trustworthy general-purpose mechanized logic. We say a connection to a language implementation is *foundational* if the synthesizer or verifier is connected (with proofs in a trustworthy general-purpose mechanized logic) to the operational semantics compiled by a verified compiler.

Crypto verification. Smith and Dill [40] verify several block-cipher implementations written in Java with respect to a functional spec written either in Java or in ACL2. They compile to bytecode, then use a subset model of the JVM to generate straight-line code. This work is not end-to-end, as the JVM is unverified—and it wouldn't suffice to simply plug in a "verified" JVM, if one existed, without also knowing that the *same* specification of the JVM was used in both proofs. Their method applies only where the number of input bits is fixed and the loops can be completely unrolled. Their verifier would likely be applicable to the SHA-256 block shuffle function, but certainly not to the management code (padding, adding the length, key management, HMAC).

Cryptol [25] generates C or VHDL directly from a functional specification, where the number of input bits is fixed and the loops can be completely unrolled, i.e. the SHA-256 block shuffle, but not the SHA-256 management code or HMAC. The Cryptol synthesizer is not foundational because its semantics is not formally specified, let alone proved.

CAO is a domain specific language for crypto applications, which is compiled into C [11], and equipped with verification technology based on the FRAMA-C tool suite [4].

Libraries of arbitrary-precision arithmetic functions have been verified by Fischer [39] and Berghofer [17] using Isabelle/HOL. Bertot et al. [20] verify GMP's computation of square roots in Coq, based on Filliatre's CORRECTNESS tool for ML-style programs with imperative features [26]. Neither of these formalizations is foundatationally connected to a verified compiler.

Verified assembly implementations of arithmetic functions have been developed by Myreen and Curello [36] and Affeldt [1], who use, respectively, proof-producing (de)compilation and simulation to link assembly code and memory layout to functional specifications at (roughly) the level of our FIPS specifications. Chen et al. [24] verify the Montgomery step in Bernstein's high-speed implementation of elliptic curve 25519 [18], using a combination of SMT solving and Coq to implement a Hoare logic for Bernstein's portable assembly representation qhasm.

The abstraction techniques and representation predicates in these works are compatible with our memory layout predicates. One important future step is to condense commonalities of these libraries into an ontology for crypto-related reasoning principles, reusable across multiple language levels and realised in multiple proof assistants. Doing this is crucial for scaling our work to larger fragments of cryptographic libraries.

Formal verification of protocols is an established research area, and efforts to link abstract protocol verifications to implementations are emerging using automated techniques like model extraction or code generation [8], or interactive proof [2].

Toma and Borrione [41] use ACL2 to prove correctness of a VHDL implementation of the SHA-1 block-shuffle algorithm. There is no connection to (for example) a verified compiler for VHDL.

Backes *et al.* [10] verify mechanically (in EasyCrypt) that Merkle-Damgård constructions have certain security properties.

EasyCrypt. Almeida *et al.* [3] describe the use of their EasyCrypt tool to verify the security of an implementation of the RSA-OAEP encryption scheme. A functional specification of RSA-OAEP is written in EasyCrypt, which then verifies its security properties. An unverified Python script translates the EasyCrypt specification to (an extension of) C, then an extension of CompCert compiles it to assembly language. Finally, a leakage tool verifies that the assembly language program has no more program counter leakage than the source code, i.e. that the compiled program's trace of conditional branches is no more informative to the adversary than the source code's.

The EasyCrypt verifier is not foundational; it is an OCaml program whose correctness is not proved. The translation from C to assembly language is foundational, using CompCert. However, EasyCrypt's C code relies on bignum library functions, but provides no mechanism by which these functions can be proved correct.

CertiCrypt [13] is a system for reasoning about cryptographic algorithms in Coq; it is foundational, but (like EasyCrypt) has no foundational connection to a C semantics. **ZKCrypt**[9] is a synthesizer that generates C code for zero-knowledge proofs, implemented in CertiCrypt, also with no foundational connection to a C semantics.

Bhargavan *et al.* [21] "implement TLS with verified cryptographic security" in F# using the **F7** typechecker. F7 is not capable of reasoning about all of the required cryptographic/probabilistic relationships required to complete the proof. So parts of the proof are completed using EasyCrypt, and there is no formal relationship between the EasyCrypt proofs and the F7 proof; one must inspect the code to ensure that the things admitted in F7 are the same things that are proved in Easy-

Crypt. F7 is also not foundational, because the type checker has a large amount of trusted code and because it depends on the Z3 SMT solver. Another difference between this work and ours is that the code provides a reference implementation in F#, not an efficient implementation in C.

CryptoVerif [22] is a prover (implemented in OCaml) for security protocols in which one can, for example, extract a OCaml program from a CryptoVerif model [23]. CryptoVerif is not foundational, the extraction is not foundational, and the compiler for OCaml is not foundationally verified.

C program verification. There are many program analysis tools for C. Most of them do not address functional specification or functional correctness, and most are unsound and incomplete. They are useful in practice, but cannot be used for an end-to-end verification of the kind we have done.

Foundational formal verification of C programs has only recently been possible. The most significant such works are both operating-system kernels: seL4 [32] and CertiKOS [29]. Both proofs are refinement proofs between functional specifications and operational semantics. Both proofs are done in higher-order logics: seL4 in Isabelle/HOL and CertiKOS in Coq.

Neither of those proof frameworks uses separation logic, and neither can accommodate the use of addressable local variables in C. This means that OpenSSL's HMAC/SHA could not be proved in these frameworks, because it uses addressable local variables.

Additionally, neither of those proof frameworks can handle function pointers. OpenSSL uses function pointers in its "engines" mechanism, an object-oriented style of programming that dynamically connects components together, such as HMAC and SHA. The *Verifiable C* program logic is capable of reasoning about such object-oriented patterns in C [6, Chapter 29], although we have not done so in the work described in this paper.

9 Conclusion

Widely used open-source cryptographic libraries such as OpenSSL, operating systems kernels, and the C compilers that build them, form the backbone of the public's communication security. Since 2013 or so, it has become clear that hackers and nation-states (is there a difference anymore?) are willing to invest enormous resources in searching for vulnerabilities and exploiting them. Other authors have demonstrated that compilers [34] and OS kernels [32, 29] can be built to a *provable zero-functional-correctness-defect standard*. Here we have demonstrated the same, in a modular way, for key components of our common cryptographic infrastructure.

Functional correctness implies zero buffer-overrun defects as well. But there are side channels we have not addressed here, such as timing, fault-injection, and leaks through dead memory. Our approach does not solve these problems; but it makes them no worse. Because we can reason about standard C code, other authors' techniques for side channel analysis are applicable without obstruction.

Functional correctness (with respect to a specification) does not always guarantee that a program has abstract security properties. Here, by linking a proof of cryptographic security to a proof of program correctness, we provide that guarantee.

Not-quite-so-broken TLS: lessons in re-engineering a security protocol specification and implementation

Abstract

Transport Layer Security (TLS) implementations have a history of security flaws. The immediate causes of these are often programming errors, e.g. in memory management, but the root causes are more fundamental: the challenges of interpreting the ambiguous prose specification, the complexities inherent in large APIs and code bases, inherently unsafe programming choices, and the impossibility of directly testing conformance between implementations and the specification.

We present *nqsb-TLS*, the result of our re-engineered approach to security protocol specification and implementation that addresses these root causes. The same code serves two roles: it is both a specification of TLS, executable as a test oracle to check conformance of traces from arbitrary implementations, and a usable implementation of TLS; a modular and declarative programming style provides clean separation between its components. Many security flaws are thus excluded by construction.

nqsb-TLS can be used in standalone Unix applications, which we demonstrate with a messaging client, and can also be compiled into Xen unikernels (specialised virtual machine image) with a trusted computing base (TCB) that is 4% of a standalone system running a standard Linux/OpenSSL stack, with all network traffic being handled in a memory-safe language; this supports applications including HTTPS, IMAP, Git, and Websocket clients and servers. Despite the dual-role design, the high-level implementation style, and the functional programming language we still achieve reasonable performance, with the same handshake performance as OpenSSL and 73% – 84% for bulk throughput.

1 Introduction

Current mainstream engineering practices for specifying and implementing security protocols are not fit for purpose: as one can see from many recent compromises of sensitive services, they are not providing the security we need. Transport Layer Security (TLS) is the most widely deployed security protocol on the Internet, used for authentication and confidentiality, but a long history of exploits shows that its implementations have failed to guarantee either property. Analysis of these exploits typically focusses on their immediate causes, e.g. errors in memory management or control flow, but we believe their root causes are more fundamental:

Error-prone languages: historical choices of programming language and programming style that tend to lead to such errors rather than protecting against them.

Lack of separation: the complexities inherent in working with large code bases, exacerbated by lack of emphasis on clean separation of concerns and modularity, and by poor language support for those.

Ambiguous and untestable specifications: the challenges of writing and interpreting the large and ambiguous prose specifications, and the impossibility of directly testing conformance between implementations and a prose specification.

In this paper we report on an experiment in developing a practical and usable TLS stack, *nqsb-TLS*, using a new approach designed to address each of these root-cause problems. This re-engineering, of the development process and of our concrete stack, aims to build in improved security from the ground up.

We demonstrate the practicality of the result in several ways: we show on-the-wire interoperability with existing stacks; we show reasonable performance, in both bulk transfer and handshakes; we use it in a test oracle, validating recorded packet traces which contain TLS sessions between other implementations; and we use it as part of a standalone instant-messaging client. In addition to use in such traditional executables, nqsb-TLS is usable in applications compiled into unikernels – type-safe, single-address-space VMs with TCBs that run directly on a hypervisor [32]. This integration into a unikernel stack lets us demonstrate a wide range of working systems, including HTTPS, IMAP, Git, and Websocket clients and servers, while sidestepping a further difficulty with radical solutions in this area: the large body of legacy code (in applications, operating systems, and libraries) that existing TLS stacks are intertwined with.

We assess the security of nqsb-TLS also in several ways: for each of the root causes above, we discuss why our approach rules out certain classes of associated flaws, with reference to an analysis of flaws found in previous TLS implementations; and we test our authentication logic with a large corpus of certificate chains generated by using the Frankencert fuzzer [8], which found flaws in several previous implementations. We have also made the system publically available for penetration testing, as a *Bitcoin Piñata*, an example unikernel using nqsb-TLS. This has a TCB size roughly 4% of that of a similar system using OpenSSL on Linux.

We describe our overall approach in the remainder of the introduction. We then briefly describe the TLS protocol (§2), analyse flaws previously found in TLS implementations (§3), and the result of applying our approach, dubbed nqsb-TLS (§4). We demonstrate the duality of nqsb-TLS next by using its specification to validate recorded sessions (§5) and executing its implementation to provide concrete services (§6). We evaluate the interoperability, performance, and security (§7) of nqsb-TLS, describe related work (§8), and conclude (§9).

nqsb-TLS is freely available under a BSD license (`https://nqsb.io`), and the data used in this paper is openly accessible [27].

1.1 Approach

A precise and testable specification for TLS In principle, a protocol specification should unambiguously define the set of all implementation behaviour that it allows, and hence also what it does not allow: it should be *precise*. This should not be confused with the question of whether a specification is loose or tight: a precise specification might well allow a wide range of implementation behaviour. It is also highly desirable for specifications to be *executable as test oracles*: given an implementation behaviour (perhaps a trace captured from a particular execution), the specification should let one compute whether it is in the allowed set or not.

In practice, the TLS specification is neither, but rather a series of RFCs written in prose [13, 14, 15]. An explicit and precise description of the TLS state machine is lacking, as are some security-critical preconditions of its transitions, and there are ambiguities in various semi-formal grammars. There is no way such prose documents can be executed as a test oracle to directly test whether implementation behaviour conforms to the specification. TLS is not unique in this, of course, and many other specifications are expressed in the same traditional prose style, but its disadvantages are especially serious for security protocols.

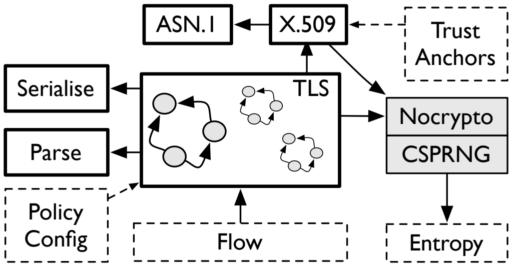

Figure 1: nqsb-TLS is broken down into strongly separated modules. The main part, in bold boxes, has pure value-passing interfaces and internals. The PRNG maintains internal state, while Nocrypto includes C code but has a pure effect-free interface. Arrows indicate depends-on relationships.

For nqsb-TLS, we specify TLS as a collection of pure functions over abstract datatypes. By avoiding I/O and shared mutable state, these functions can be considered in isolation and each is deterministic, with errors returned as explicit values. The top-level function takes an abstract protocol state and an incoming message, and calculates the next state and any response messages. To do so, it invokes subsidiary functions to parse the message, drive the state machine, perform cryptographic operations, and construct the response. This top-level function can be executed as a trace-checker, on traces both from our implementation and from others, such as OpenSSL, to decide whether they are allowed by our specification or not. In building our specification, to resolve the RFC ambiguities, we read other implementations and tested interoperability with them; we thereby capture the practical de facto standard.

Reuse between specification and implementation The same functions form the main part of our implementation, coupled with code for I/O and to provide entropy. Note that this is not an "executable specification" in the conventional sense: our specification is necessarily somewhat loose, as the server must have the freedom to choose a protocol version and cipher suite, and the trace checker must admit that, while our implementation makes particular choices.

Each version of the implementation (Unix, unikernel) has a top-level `Flow` module that repeatedly performs I/O and invokes the pure functional core; the trace-checker has a top-level module of the same type that reads in a trace to be checked offline.

Separation and modular structure This focus on pure functional descriptions also enables a decomposition of the system (both implementation and specification) into strongly separated modules, with typed interfaces, that interact only by exchanging pure values, as shown in Fig. 1. These modules and their interfaces are arranged to ensure that localised concerns such as binary protocol formats, ASN.1 grammars and certificate validation are not spread throughout the stack, with no implicit dependencies via shared memory.

External resources are explicitly represented as modules, instead of being implicitly accessed, and each satisfies a module type that describes collections of operations over an abstract type, and that can be instantiated with any of several implementations. These include the `Nocrypto` cryptography layer and our PRNG, which depends on an external `Entropy` module type.

Communication with the outside world is factored out into an I/O component, `Flow`, that passes a byte sequence to the pure core, then transmits responses and handles timeouts, and is used by the top-level but not by the TLS engine itself. The pure TLS engine depends on some external data, such as the policy config and trust anchors.

Choice of language and style The structure we describe above could be implemented in many different programming languages, but guarantees of memory and type safety are desirable to exclude many common security flaws (lack of memory safety was the largest single source of vulnerabilities in various TLS stacks throughout 2014, as shown in our §3 vulnerability analysis), and expressive statically checked type and module systems help maintain the strongly separated structure that we outlined. Our implementation of nqsb-TLS uses OCaml, a memory-safe, statically typed programming language that compiles to fast native code with a lightweight, embeddable runtime. OCaml supports (but does not mandate) a pure programming style, and has a module system which supports large-scale abstraction via ML functors – modules that can depend on other modules' types. In OCaml, we can encode complex state machines (§4), with lightweight invariants statically enforced by the type checker (state machine problems were the second largest source of vulnerabilities). Merely using OCaml does not guarantee all the properties we need, of course (one can write imperative and convoluted code in any language); our specification and programming styles are equally important.

This is a significant departure from normal practice, in which systems software is typically written in C, but we believe our evaluation shows that it is viable in at least some compelling scenarios (§7).

Non-goals For nqsb-TLS we are focussed on the engineering of TLS specifications and implementations, not on the security protocol itself (as we recall in §3, some vulnerabilities have been found there). We are also not attempting to advance the state of the art in side-channel defence, though we do follow current best practice. We are focussed on making a stack that is usable in practice and on security improvements achievable with better engineering processes, rather than trying to prove that a specification or implementation is correct or secure (see §8 for related work in that direction).

Current state The entire set of TLS RFCs [13, 14, 15] are implemented in nqsb-TLS, apart from minor rarely used features, such as DSS certificates and *anon* and pre-shared keys ciphersuites. As we demonstrate in §7.1, nqsb-TLS can interoperate with many contemporary TLS implementations, but we are not attempting to support legacy options or those of doubtful utility. We neither support SSLv3 [1], nor use RC4 in the default configuration [39]. The crypto wars are over: we have not implemented ciphersuites to adhere to export restrictions, which gave rise to the FREAK and Logjam attacks.

nqsb-TLS is strict (see §7.2), which results in roughly 10% failing connections from legacy clients. But since our main goal is to provide security, we are not willing to make compromises for insecure implementations. In addition to TLS itself, we also implemented ASN.1, X.509 and crypto primitives. From a practical point of view, the largest missing part is elliptic curve cryptography.

2 TLS Background

TLS provides the twin features of authentication and confidentiality. Clients typically verify the server's identity, the server can optionally verify the client's identity, while the two endpoints establish an encrypted communication channel. This channel should be immune from eavesdropping, tampering and message forgery.

There have been three standardised versions of TLS, 1.0, 1.1 and 1.2, while the last SSL (version 3) is still in wide usage. A key feature of TLS is algorithmic agility: it allows the two endpoints to negotiate the key exchange method, symmetric cipher and the message authentication mode upon connecting. This triple is called a cipher suite, and there are around 160 cipher suites standardised and widely supported. Together with a number of standardised extensions to the protocol that can be negotiated, this creates a large possible space of session parameters. This large variation in configuration options is a marked characteristic of TLS, significantly contributing to the complexity of its state machine.

Only a handful implementations of TLS are in wide use. The three major free or open-source implementations are OpenSSL, GnuTLS and Mozilla's NSS. Microsoft supplies SChannel with their operating systems, while Apple supplies Secure Transport with theirs, and Oracle Java runtime comes bundled with JSSE.

Structurally, TLS is a two-layered protocol. The outer layer preserves message boundaries and provides framing. It encapsulates one of five sub-protocols: handshake, change cipher spec, alert, application data or heartbeat. Both layers can contain fragmentation.

A TLS session is initiated by the client, which uses the handshake protocol to signal the highest protocol version, possible extensions, and a set of ciphersuites it supports. The server picks the highest protocol version it shares with the client and a mutually supported ciphersuite, or fails the handshake. The ciphersuite determines whether the server authenticates itself, and depending on the server configuration it requests the client to authenticate itself. After the security parameters for the authenticated encryption scheme are negotiated, the Change Cipher Spec message activates these, and the last handshake message authenticates the handshake. Either party can renegotiate the session over the established channel by initiating another handshake.

The handshake sub-protocol contains a complex state machine, which must be successfully traversed at least once. Handshake messages are independent of other sub-protocols, but some other sub-protocols are dependent of a successful handshake. For instance, it is not possible to exchange application data before a session is established, and it is impossible to affect the use of negotiated session parameters while the negotiation is still in progress.

Server and client authentication is performed by means of X.509 certificates. Usually path validation is used: after one party presents a sequence of certificates called the certificate chain, the other party needs to verify that a) each certificate in the chain is signed by the next certificate; b) the last certificate is signed by one of the trust anchors independent of connection; and c) that the first party owns the private key associated with the first certificate in the chain by transferring a signed message containing session-specific data. For correct authentication, the authenticating party also needs to verify general semantic well-formedness of the involved certificates, and be able to deal with three version of X.509 and a number of extensions.

X.509 certificates are described through ASN.1, a notation for describing the abstract syntax of data, and encoded using Distinguished Encoding Rules (DER), one of the several standard encodings ASN.1 defines. A particular description in the ASN.1 language coupled with a choice of encoding defines both the shape the the data-structures and their wire-level encoding. ASN.1 provides a rich language for describing structure, with a number of primitive elements, like `INTEGER` and `BIT STRING`, and combining constructs, like `SEQUENCE` (a record of sub-grammars) and `CHOICE` (a node joining alternative grammars). The ASN.1 formalism can be used with a compiler that derives parsing and serialisation code for the target language, but TLS implementations more typically contain custom parsing code for dealing with X.509 certificates. As X.509 exercises much of ASN.1, this parsing layer is non-trivial and significantly adds to the implementation complexity.

3 Vulnerability Analysis

In the past 13 months (January 2014 to January 2015), 54 CVE security advisories have been published for 6 widely used TLS implementations (see Table 1): 22 for OpenSSL, 6 for GnuTLS, 7 for NSS, 2 for SChannel, 2 for Secure Transport, 5 for JSSE, and 10 related to errors in their usage in the client software (excluding vulnerabilities related to DTLS – TLS over UDP).

These vulnerabilities have a wide range of causes. We classify them into broad families below, identifying root causes for each and discussing how nqsb-TLS avoids flaws of each kind.

General memory safety violations Most of these bugs, 15 in total, are memory safety issues: out-of-bounds reads, out-of-bounds writes and `NULL` pointer dereferences. A large group has only been demonstrated to crash the hosting process, ending in denial-of-service, but some lead to disclosure of sensitive information.

A now-notorious example of this class of bugs is Heartbleed in OpenSSL (CVE-2014-0160). Upon receiving a heartbeat record, a TLS endpoint should respond by sending back the payload of the record. The record contains the payload and its length. In Heartbleed, the TLS implementation did not check if the length of the received heartbeat matched the length encoded in the record, and responded by sending back as many bytes as were requested on the record level. This resulted in an out-of-bounds read, which lets a malicious client discover parts of server's memory. In April 2014, Cloudflare posed a challenge of exploiting this bug to compromise the private RSA key, which has been accomplished by at least four independent researchers.

nqsb-TLS avoids this class of issues entirely by the choice of a programming language with automated memory management and memory safety guarantees: in OCaml, array bounds are always checked and it is not possible to access raw memory; and our pure functional programming style rules out reuse of mutable buffers.

Certificate parsing TLS implementations need to parse ASN.1, primarily for decoding X.509 certificates. While ASN.1 is a large and fairly complex standard, for the purposes of TLS, it is sufficient to implement one of its encodings (DER), and only some of the primitives. Some TLS implementations contain an ad-hoc ASN.1 parser,

Product	CVE ID	Issue source
OpenSSL	2013-4353, 2015-0206, 2014-[3567, 3512, 3569, 3508, 3470, 0198, 0160]	Memory management
	2015-0205, 2015-0204, 2014-3572, 2014-0224, 2014-3568, 2014-3511	State machine

Table 1: Vulnerabilities in TLS implementations in 2014.

combining the core ASN.1 parsing task with the definitions of ASN.1 grammars, and this code operates as a part of certificate validation.

Unsurprisingly, ASN.1 parsing is a recurrent source of vulnerabilities in TLS and related software, dating back at least to 2004 (MS04-007, a remote code execution vulnerability), and 3 vulnerabilities in 2014 (CVEs 2014-8275, 2014-1568 and 2014-1569). Two examples are CVE-2015-1182, the use of uninitialised memory during parsing in PolarSSL, which could lead to remote code execution, and CVE-2014-1568, a case of insufficiently selective parsing in NSS, which allowed the attacker to construct a fake signed certificate from a large space of byte sequences interpreted as the same certificate.

This class of errors is due to ambiguity in the specification, and ad-hoc parsers in most TLS implementations. nqsb-TLS avoids this class of issues entirely by separating parsing from the grammar description (§4.4).

Certificate validation Closely related to ASN.1 parsing is certificate validation. X.509 certificates are nested data structures standardised in three versions and with various optional extensions, so validation involves parsing, traversing, and extracting information from complex compound data. This opens up the potential for errors both in the control-flow logic of this task and in the interpretation of certificates (multiple GnuTLS vulnerabilities are related to lax interpretation of the structures).

In 2014, there were 5 issues related to certificate validation. A prominent example in the control-flow logic is GnuTLS (CVE-2014-0092), where a misplaced `goto` statement lead to certificate validation being skipped if any intermediate certificate was of X.509 version 1.

Many implementations interleave the complicated X.509 certificate validation with parsing the ASN.1 grammar, leading to a complex control flow with subtle call chains. This illustrates another way in which the choice of programming language and style can lead to errors: the normal C idiom for error handling uses `goto` and negative return values, while in nqsb-TLS we return errors explicitly as values and have to handle all possible variants. OCaml's typechecker and pattern-match exhaustiveness checker ensures this at compile time (§4.3).

State machine errors TLS consists of several subprotocols that are multiplexed at the record level: *(i)* the handshake that initially establishes the secure connection and subsequently renegotiates it; *(ii)* alerts that signal out-of-band conditions; *(iii)* cipher spec activation notifications; *(iv)* heartbeats; and *(v)* application data. The majority of the TLS protocol specification covers the handshake state machine. The path to a successful negotiation is determined during the handshake and depends on the ciphersuite, protocol version, negotiated options, and configuration, such as client authentication. Errors in the handshake logic often lead to a security breach, allowing attackers to perform active man-in-the-middle (MITM) insertion, or to passively gain knowledge over the negotiated security parameters.

There were 10 vulnerabilities in this class. Some led to denial-of-service conditions caused (for example) by `NULL`-pointer dereferences on receipt of an unexpected message, while others lead to a breakdown of the TLS security guarantees. An extensive study of problems in TLS state machine implementations has been done in the literature [2, 11].

A prominent example is Apple's "goto fail" (CVE-2014-1266), caused by a repetition of a `goto` statement targeting the cleanup block of the procedure responsible for verifying the digital signature of the `ServerKeyExchange` message. This caused the procedure to skip the subsequent logic and return the value registered in the output variable. As this variable was initialised to "success", the signature was never verified.

Another typical example is the CCS Injection in OpenSSL (CVE-2014-0224). `ChangeCipherSpec` is the message signalling that the just negotiated security parameters are activated. In the TLS state machine, it is legal only as the penultimate message in the handshake sequence. However, both OpenSSL (CVE-2014-0224) and JSSE (CVE-2014-6593) allowed a CCS message before the actual key exchange took place, which activated predictable initial security parameters. A MITM attacker can exploit this by sending a CCS during handshake, causing two parties to establish a deterministic session key and defeating encryption.

Some of these errors are due to missing preconditions of state machine transitions in the specification. In nqsb-TLS, our code structure (§4.1) makes the need to consider each of these clear. We encode the state machine explicitly, while state transitions default to failure.

Protocol bugs In 2014, two separate issues in the protocol itself were described: POODLE and triple handshakes. POODLE is an attack on SSL version 3, which does not specify the value of padding bytes in CBC mode. Triple handshake [3] is a MITM attack where one negotiates sessions with the same security parameters and resumes. We do not claim to prevent nor solve those protocol bugs in nqsb-TLS, we mitigate triple handshake by resuming sessions only if the extended master secret [4] was used. Furthermore, we focus on a modern subset of the protocol, not including SSL version 3, so neither attack is applicable.

Timing side-channel leaks Two vulnerabilities were related to timing side-channel leaks, where the observable duration of cryptographic operations depended on cryptographic secrets. These were implementation issues, related to the use of variable-duration arithmetic operations. The PKCS1.5 padding of the premaster secret is transmitted during an RSA key exchange. If the unpadding fails, there is computationally no need to decrypt the received secret material. But omitting this step leaks the information on whether the padding was correct through the time signature, and this can be used to obtain the secret. A similar issue was discovered in 2014 in various TLS implementations [34].

nqsb-TLS mitigates this attack by always computing the RSA operation, on padding failure with a fake value. To mitigate timing side-channels, which a memory managed programming language might further expose, we use C implementations of the low level primitives (§4.2).

Usage of the libraries Of the examined bugs, 10 were not in TLS implementations themselves, but in the way the client software used them. These included the high-profile anonymisation software Tor [16], the instant messenger Pidgin and the widely used multi-protocol data transfer tool cURL.

TLS libraries typically have complicated APIs due to implementing a protocol with a large parameter space. For example, OpenSSL 1.0.2 documents 243 symbols in its protocol alone, not counting the cryptographic parts of the API. Parts of its API are used by registering callbacks with the library that get invoked upon certain events. A well-documented example of the difficulty in correctly using these APIs is the OpenSSL certificate validation callback. The library does not implement the full logic that is commonly needed (it omits name validation), so the client needs to construct a function to perform certificate validation using a mix of custom code and calls to OpenSSL, and supply it to the library. This step is a common pitfall: a recent survey [23] showed that it is common for OpenSSL clients in the wild to do this incorrectly. We counted 6 individual advisories stemming from improper usage of certificate validation API, which is a large number given that improper certificate validation undermines the authentication property of TLS and completely undermines its security.

The root cause of this error class is the large and complex legacy APIs of contemporary TLS stacks. nqsb-TLS does not mirror those APIs, but provides a minimal API with strict validation by default. This small API is sufficient for various applications we developed. OpenBSD uses a similar approach with their `libtls` API.

4 The *nqsb-TLS* stack

We now describe how we structure and develop the nqsb-TLS stack, following the approach outlined in the introduction to avoid a range of security pitfalls.

4.1 TLS Core

The heart of our TLS stack is the core protocol implementation. By using pure, composable functions to express the protocol handling, we deal with TLS as a data-transformation pipeline, independent of how the data is obtained or transmitted.

Accordingly, our core revolves around two functions. One (handle_tls) takes the sequence of bytes seen on the wire and a value denoting the previous state, and produces, as new values, the bytes to reply with or to transfer to the application, and the subsequent state. Our state type encapsulates all the information about a TLS session in progress, including the state of the handshake, the cryptographic state for both directions of communication, and the incomplete frames previously received, as an immutable value. The other one (send_application_data) takes a sequence of bytes that the application wishes to send and the previous state, and produces the sequence ready to be sent and the subsequent state. Coupled with a few operations to extract session information from the state, these form the entire interface to the core protocol implementation.

Below the entry points, we segment the records, decrypt and authenticate them, and dispatch to the appropriate protocol handler. One of the places where OCaml helps most prominently is in handling of the combined state machine of handshake and its interdependent subprotocols. We use algebraic data types to encode each possible handshake state as a distinct type variant, that symbolically denotes the state it represents and contains all of the data accumulated so far. The overall state type is simply the discriminated union of these variants. Every operation that extracts information from state needs to scrutinise its value through a form of multi-way branching known as pattern match. This syntactic construct combines branching on the particular variant of the state present with extraction of components. The resulting dispatch leads to equation-like code: branches that deal with distinct states follow directly from the values representing them, process the state data locally, and remain fully independent in the sense of control flow and access to values they operate on. Finally, each separately materialises the output and subsequent state.

This construction and the explicit encoding of state-machine is central to maintaining the state-machine invariants and preserving the coherence of state representation. It is impossible to enter a branch dedicated to a particular transition without the pair of values representing the appropriate state and appropriate input message, and, as intermediate data is directly obtained from the state value, it is impossible to process it without at the same time requiring that the state-machine is in the appropriate state. It is also impossible to manufacture a state-representation ahead of time, as it needs to contain all of the relevant data.

The benefit of this encoding is most clearly seen in CCS-injection-like vulnerabilities. They depend on session parameters being stored in locations visible throughout the handshake code, which are activated on receipt of the appropriate message. In the OpenSSL case (CVE-2014-0224), the dispatch code failed to verify whether all of these locations were populated, which implies that the handshake progressed to the appropriate phase. In our case, the only way to refer to the session parameters is to deconstruct a state-value containing them, and it is impossible to create this value without having collected the appropriate session parameters.

All of core's inner workings adhere to a predictable, restricted coding style. Information is always communicated through parameters and result values. Error propagation is achieved exclusively through results, without the use of exceptions. We explicitly encode errors distinct from successful results, instead of overloading the result's domain to mean error in some parts of its range. The type checker verifies both that each code path is dealing with exactly one possibility, and – through the exhaustiveness checker – that both forms have been accounted for. The repetitive logic of testing for error results and deciding whether to propagate the error or proceed is then abstracted away in a few higher-order functions and does not re-appear throughout the code.

This approach has also proven convenient when maintaining a growing code-base: when we had to add significant new capabilities, e.g. extending the TLS version support to versions 1.1 and 1.2 or implementing client authentication, the scope of changes was localised and the effects they had on other modules were flagged by the type checker.

4.2 Nocrypto

TLS cryptography is provided by *Nocrypto*, a separate library we developed for that purpose. It supports basic modular public-key primitives like RSA, DSA and DH; the two most commonly used symmetric block ciphers, AES and 3DES; the most important hash functions, MD5, SHA and the SHA2 family; and an implementation of the cryptographically strong pseudorandom number generator, Fortuna [20].

One of the fundamental design decisions was to use block-level symmetric encryption and hash cores written in C. For hashing, DES, and the portable version of AES, we use widely available public domain code. In addition, we wrote our own AES core using the Intel AES-NI instructions.

There are two reasons for using C at this level. Firstly, symmetric encryption and hashing are the most CPU-intensive operations in TLS. Therefore, performance concerns motivate the use of C. Secondly, the security impact of writing cryptography in a garbage-collected environment is unclear. Performing computations over secret material in this context is a potential attack vector. The garbage collector pauses might act as an amplifier to any existing timing side-channel leaks, revealing information about the allocation rate. We side-step this issue by leaving the secret material used by symmetric encryption opaque to the OCaml runtime.

Such treatment creates a potential safety problem in turn: even if we manage to prevent certain classes of bugs in OCaml, they could occur in our C code. Our strategy to contain this is to restrict the scope of C code: we employ simple control flow and never manage memory in the C layer. C functions receive pre-allocated buffers, tracked by the runtime, and write their results there. The most complex control flow in these are driving loops that call the compression function (in the case of hashes), or the block transform (in the case of ciphers), over the contents of the input buffer. AES-NI instructions are particularly simplifying in this respect, as the code consists of a sequence of calls to compiler intrinsics.

Presently, only the AES-NI implementation of AES is protected from timing side-channel leaks, since the bulk of the cipher is implemented via constant-time dedicated instructions. The generic code path is yet to be augmented with code to pre-load substitution tables in a non-data-dependent manner.

More complex cryptographic constructions, like cipher modes (CBC, CTR, GCM and CCM) and HMAC are implemented in OCaml on top of C-level primitives. We benefit from OCaml's safety and expressive power in these more complex parts of the code, but at the same time preserve the property that secret material is not directly exposed to the managed runtime.

Public key cryptography is treated differently. It is not block-oriented and is not easily expressed in straight-line code, while the numeric operations it relies on are less amenable to C-level optimisation. At the same time, there are known techniques for mitigating timing leaks at the algorithmic level [28], unlike in the symmetric case. We therefore implement these directly in OCaml using GMP as our bignum backend and employ the standard blinding countermeasures to compensate for potential sources of timing side-channels.

Our Fortuna CSPRNG uses AES-CTR with a self-rekeying regime and a system of entropy accumulators. Instead of entropy estimation, it employs exponential lagging of accumulators, a scheme that has been shown to asymptotically optimally recover from state compromise under a constant input of entropy of unknown quality [17]. To retain purity of the system and facilitate deterministic runs, entropy itself is required from the system as an external service, as shown later in §6.

For the sake of reducing complexity in the upper layers, the API of *Nocrypto* is concise and retains the applicative style, mapping inputs to outputs. We did make two concessions to further simplify it: first, we use OCaml exceptions to signal programming errors of applying cyptographic operations to malformed input (such as buffers which are not a multiple of the block size in CBC mode, or the use of RSA keys unsuitably small for a message). Secondly, we employ a global and changing RNG state, because operations involving it are pervasive throughout interactions with the library and the style of explicit passing would complicate the dependent code.

4.3 X.509

X.509 certificates are rich tree-like data structures whose semantics changes with the presence of several optional extensions. Although the core of the path-validation process is checking of the signature, a cryptographic operation, the correct validation required by the standard includes extensive checking of the entire data structure.

For example, each extension must be present at most once, the key usage extension can further constrain which exact operations a certificate is authorised for, and a certificate can specify the maximal chain length which is allowed to follow. There are several ways in which a certificate can express its own identity and the identity of its signing certificate. After parsing, a correct validation procedure must take all these possibilities into account.

The ground encoding of certificates again benefits from algebraic data types, as the control flow of functions that navigate this structure is directed by the type-checker. On a level above, we separate the validation process into a series of functions computing individual predicates, such as the certificate being self-signed, its validity period matching the provided time or conformance of the present extensions to the certificate version. The conjunction of these is clearly grouped into single top-level functions validating certificates in different roles, which describe the high-level constraints we impose upon the certificates. The entire validation logic amounts to 314 lines of easily reviewable code.

This is in contrast to 7 000 lines of text in the RFC [9], which go into detail to explain extensions – such as policies and name constraints – that are rarely seen in the wild. For the typical HTTPS setting, the RFC fails to clarify how to search for a trust anchor, and assumes instead the presence of exactly one. Due to cross signing there can be multiple chains with different properties which are not covered by the RFC.

nqsb-TLS initially strictly followed the RFC, but was not able to validate many HTTPS endpoints on the Internet. It currently follows the RFC augmented with

Mozilla's guidelines and provides a self-contained condensation of these which can be used to clarify, or even supplant, the specification. We created an extensive test suite with full code coverage, the code has been evaluated (see §7.2) with the Frankencert tool, and it successfully parses most of ZMap's certificate repositories. In addition, we also support signing and serialising to PEM.

The interface to this logic is deterministic (it is made so by requiring the current time as an input). Our X.509 library provides operations to construct a full *authenticator*, by combining the validation logic with the current time at the moment of construction, which the TLS core can be parametrised with. We do not leave validation to the user of the library, unlike other TLS libraries [23]. Instead, we have full implementations of path validation with name checking [42] and fingerprint-based validation, and we use the type system to force the user to instantiate one of them and provide it to the TLS layer.

4.4 ASN.1

ASN.1 parsing creates a tension in TLS implementations: TLS critically relies on ASN.1, but it requires only a subset of DER encoding, and, since certificates are usually pre-generated, needs very little in the way of writing. For the purposes of TLS, it is therefore sufficient to implement just a partial parser.

When implementing ASN.1, a decision has to be made on how to encode the actual abstract grammar that will drive the parsing process, given by various TLS and X.509-related standards. OpenSSL, PolarSSL, JSSE and others, with the notable exception of GnuTLS, do not make any attempts to separate the grammar definition from the parsing process. The leaf rules of ASN.1 are implemented as subroutines, which are exercised in the order required by the grammar in every routine that acts as parser. In other words, they implement the parsers as ad-hoc procedures that interleave the code that performs the actual parsing with the encoding of the grammar to be parsed. Therefore the code that describes the high-level structure of data also contains details of invocation of low-lever parsers and, in the case of C, memory management. Unsurprisingly, ASN.1 parsers provide a steady stream of exploits in popular TLS implementations.

We retain the full separation of the abstract syntax representation from the parsing code, avoiding the complexity of the code that fuses the two. At the same time, we avoid parser generators which output source code that is hard to understand.

Instead, we created a library for declaratively describing ASN.1 grammars in OCaml, using a functional technique known as combinatory parsing [21]. It exposes an opaque data type that describes ASN.1 grammar instances and provides a set of constants (corresponding to terminals) and functions over them (corresponding to productions). Nested applications of these functions to create data that describes ASN.1 grammars follow the shape of the actual ASN.1 grammar definitions. Internally, this tree-like type is traversed at initialisation-time to construct the parsing and serialisation functions.

This approach allows us to create "grammar expressions" which encode ASN.1 grammars, and derive parsers and serialisers. As the ASN.1-language we create is a fragment of OCaml, we retain all the benefits of its static type checking. Types of functions over grammar representations correspond to restrictions in the production rules, so type-checking grammar expressions amounts to checking their well-formedness without writing a separate parser for the grammar formalism. Moreover, type inference automatically derives the OCaml representation of the types defined by ASN.1 grammars.

Such an approach also makes testing much easier. The grammar type is traversed to generate random inhabitants of the particular grammar, which can be serialised and parsed back to check that the two directions match in their interpretation of the underlying ASN.1 encoding and to exercise all of the code paths in both.

A derived parsing function does not interpret the grammar data, but as its connections to component parsing functions are known only when synthesis takes place at run-time, we do not retain the benefit of inlining and inter-function optimisation a truly compiled parser would have. Nonetheless, given that it parses roughly 50 000 certificates per second, this approach does not create a major performance bottleneck. The result is a significant reduction in code complexity: the ASN.1 parsing logic amounts to 620 lines of OCaml, and the ASN.1 grammar code for X.509 certificates and signatures is around 1 000 lines. For comparison, PolarSSL 1.3.7 needs around 7 500 lines to parse ASN.1, while OpenSSL 1.0.1h has around 25 000 in its ASN.1 parser.

5 Using nqsb-TLS as a test oracle

One use of nqsb-TLS is as an *executable test oracle*, an application which reads a recorded TLS session trace and checks whether it (together with some configuration information) adheres to the specification that nqsb-TLS embodies. This recorded session can be a packet capture (using tcpdump) of a TLS session between various implementations (e.g. OpenSSL, PolarSSL, nqsb-TLS), or, for basic testing, a trace generated by nqsb-TLS itself.

To do this we must deal with the looseness of the TLS specification: a TLS client chooses its random nonce, set of ciphersuites, protocol version, and handshake extensions, while a TLS server picks its random nonce, the protocol version, the ciphersuite, possibly the DH group, and possibly extensions. Our test oracle does not make

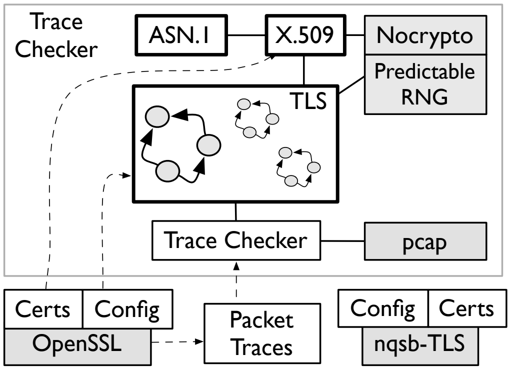

Figure 2: nqsb-TLS acts as a trace checker: the RNG is predictable, configuration and certificates are inputs, driven by packet traces from OpenSSL (or other stacks).

those decisions, but rather takes the parameters recorded in the given session. To make this possible, given the on-the-wire encryption, some configuration information has to be provided to the trace checker, including private key material. In addition, both records and sub-protocols can be fragmented; our test oracle normalises the records to not contain any fragmentation for comparison.

Figure 2 shows how nqsb-TLS can be used to build such a test oracle (note that it does not instantiate the entropy source for this usage). The test oracle produces its initial protocol state from the given session. It calculates `handle_tls` with its state and the record input of the given session, together with the particular selection of protocol version, etc., resulting in an output state, potentially an output record, and potentially decrypted application data. It then compares equality of the output record and the given session. If successful, it uses the output state and next recorded input of the given session to evaluate `handle_tls` again, and repeats to the end of the trace. It thus terminates either when the entire trace has been accepted, which means success; or with a discrepancy between the nqsb-TLS specification and the recorded session, which means failure and needs further investigation. Such a discrepancy might indicate an error in the TLS stack being tested, an error in the nqsb-TLS specification, or an ambiguity in what TLS actually is.

A first test of this infrastructure was to use a recorded session of the change cipher spec injection (CVE-2014-0224): our test oracle correctly denied this session, identifying an unexpected message. We ran our test oracle and validated our 30 000 interoperability traces (see §7.1) and our Piñata traces (see §7.2), and also validated recorded TLS sessions between various implementations (OpenSSL, PolarSSL, nqsb-TLS) using tcpdump.

While running the test oracle we discovered interestingly varied choices in fragmentation of messages among existing stacks, which may be useful in fingerprinting.

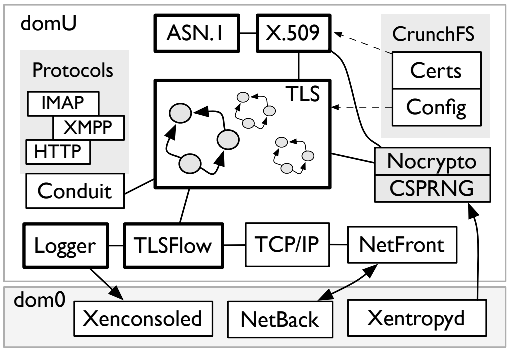

Figure 3: nqsb-TLS as a unikernel domU VM on Xen: a dom0 Xentropyd proxies host entropy, config and certificates are compiled in, various protocols run over TLS.

The test oracle opens up the prospect of extensive testing of the behaviour of different TLS implementations, especially if combined with automated test generation.

6 Using nqsb-TLS in applications

Another use of nqsb-TLS is as a TLS implementation in applications. We ported nqsb-TLS to two distinct environments and developed a series of applications, some for demonstration purposes, others for regular use.

6.1 Porting nqsb-TLS

To use nqsb-TLS as an executable implementation, we have to provide it with implementations of entropy and flow (see Figure 1), and an effectful piece of code that communicates via the network and drives the core.

We pay special attention to prevent common client bugs which arise from complexity of configuring TLS stacks and correspondingly large APIs. In each instance, there is only one function to construct a TLS configuration which can be turned into an I/O interface, the function does extensive validation of the requested parameters, and the resulting configuration object is immutable. This restricts potentially error-prone interactions that configure TLS to a single API point.

Unix Porting nqsb-TLS to Unix was straightforward; we use the POSIX sockets API to build a flow and `/dev/urandom` as the entropy source. The exposed interface provides convenience functions to read certificates and private keys from files, and analogues of `listen`, `connect`, `accept`, `read`, `write`, and `close` for communication.

MirageOS The MirageOS variant allows nqsb-TLS to be compiled into a unikernel VM (see Figure 3). It uses the MirageOS OCaml TCP/IP library [31] to provide the

I/O flow, which is in turn coupled to Xen device drivers that communicate with the backend physical network device via shared memory rings [44]. The logger outputs directly to the VM console, and the certificates and the secret keys are compiled into OCaml data structures at build time and become part of the VM image. A key challenge when running in a virtualised environment is providing a suitable entropy source [18], especially in the common case of a VM having no access to physical hardware. Since specialised unikernels have very deterministic boot-sequences that make sources of entropy even scarcer, we had to extend MirageOS and Xen to avoid cryptographic weaknesses [25].

One way in which we solve this is by relying on dom0 to provide cross-domain entropy injection. We developed *Xentropyd*, a dom0 daemon which reads bytes from `/dev/urandom` and makes them available to VMs via an inter-VM shared memory channel. The entropy device is plugged in as a standard Xen device driver via Xenstore [22], and MirageOS has a frontend library that periodically injects entropy into the nqsb-TLS CSPRNG.

To avoid being fully reliant on dom0, we implement additional entropy harvesting within the unikernel itself. We do this by trapping the MirageOS event loop and using `RDTSCP` instruction to read the Time Stamp Counter (TSC) register on each external event. This provides us with the unpredictability inherent in the ambient events. This source is augmented with readings from the CPU RNG where available: we feed the results of `RDSEED` (or `RDRAND`) instruction into the entropy pool on each event.

To make the RNG more resilient, we do extra entropy harvesting at boot time. Following Whirlwind RNG [18], we employ a timing loop early in the boot phase, designed to take advantage of nondeterminism inherent in the CPU by way of internal races in the CPU state. This provides an initial entropy boost in the absence of *Xentropyd* and helps mitigate resumption-based attacks [18].

In an ideal scenario the entropy would be provided through both mechanisms, but we expect the usage to rely on one or the other, depending on deployment: on an ARM board lacking high-resolution timing and CPU RNG, the user is likely to have control over the hypervisor and be able to install *Xentropyd*. Conversely, in commercial hosting scenarios where the assistance of dom0 might not be available but the extra CPU features are, we expect the user to rely on the internal entropy harvesting.

6.2 Applications

An example application using the Unix interface is the terminal-based instant messaging client *jackline* using XMPP. The XMPP protocol negotiates features, such as TLS, over a plaintext TCP connection. Jackline performs an upgrade to TLS via the `STARTTLS` mechanism before authentication credentials are exchanged. The Unix port of nqsb-TLS contains an API that supports upgrading an already established TCP connection to TLS. Jackline can use either of the authentication APIs (path and fingerprint validation) depending on user configuration.

tlstunnel also runs on Unix and accepts a TLS connection, forwards the application data to another service via TCP, similar to stud and stunnel. This has been deployed since months on some websites.

The Unix application *certify* generates RSA private keys, self-signed certificates, and certificate signing requests in PEM format. It uses nocrypto and X.509.

The OCaml Conduit library (also illustrated in Fig. 3) supports communication transports that include TCP, inter-VM shared memory rings. It provides a high-level API that maps URIs into specific transport mechanisms. We added nqsb-TLS support to Conduit so that any application that links to it can choose between the use of nqsb-TLS or OpenSSL, depending on an environment variable. As of February 2015, 42 different libraries (both client and server) use Conduit and its provided API and can thus indirectly use nqsb-TLS for secure connections. The OPAM package manager uses nqsb-TLS as part of its mirror infrastructure to fetch 2 500 distribution files, with no HTTPS-related regressions encountered.

7 Evaluation

We now assess the interoperability, security, and performance of nqsb-TLS.

7.1 Interoperability

We assess the interoperability of nqsb-TLS in several ways: testing against OpenSSL and PolarSSL on every commit; successfully connecting to most of the Fortune 500 web sites; testing X.509 certificates from ZMap; and by running a web server.

This web server, running since mid 2014, displays the live sequence diagram of a successful TLS session established via HTTPS. A user can press a button on the website which let the server initiate a renegotiation. The server configuration includes all three TLS protocol versions and eight different ciphersuites, picking a protocol version and ciphersuite at random. Roughly 30 000 traces were recorded from roughly 350 different client stacks (6230 unique user agent identifiers).

Of these, around 27% resulted in a connection establishment failure. Our implementation is strict, and does not allow e.g. duplicated advertised ciphersuites. Also, several accesses came from automated tools which evaluate the quality of a TLS server by trying each defined ciphersuite separately.

Roughly 50% of the failed connections did not share a ciphersuite with nqsb-TLS. Another 20% started with bytes which were not interpretable by nqsb-TLS. 12% of the failed connections did not contain the secure renegotiation extension, which our server requires. 5% of the failed traces were attempts to send an early change cipher spec. Another 4% tried to negotiate SSL version 3. 2.5% contained a ciphersuite with null (iOS6).

We parse more than 99% of ZMap's HTTPS (20150615) and IMAP (20150604) certificate repository. The remaining failures are RSASSA-PSS signatures, requiring an explicit NULL as parameter, and unknown and outdated algorithm identifiers.

This four-fold evaluation shows that our TLS implementation is broadly interoperable with a large number of other TLS implementations, which also indicates that we are capturing the de facto standard reasonably well.

Specification mismatches While evaluating nqsb-TLS we discovered several inconsistencies between the RFC and other TLS implementations:

- Apple's SecureTransport and Microsoft's SChannel deny application data records while a renegotiation is in process, while the RFC allows interleaving.
- OpenSSL (1.0.1i) accepts any X.509v3 certificate which contains either digitalSignature or keyEncipherment in keyUsage. RFC [15] mandates digitalSignature for DHE, keyEncipherment for RSA.
- Some unknown TLS implementation starts the padding data [29] (must be 0) with 16 bit length.
- A TLS 1.1 stack sends the unregistered alert 0x80.

7.2 Security

We assess the security of nqsb-TLS in several ways: the discussion of the root causes of many classic vulnerabilities and how we avoid them; mitigation of other specific issues; our state machine was tested [11]; random testing with the Frankencert [8] fuzzing tool; a public integrated system protecting a bitcoin reward; and analysis of the TCB size of that compared with a similar system built using a conventional stack.

Avoidance of classic vulnerability root causes In Sections 3 and 4 we described how the nqsb-TLS structure and development process exclude the root causes of many vulnerabilities that have been found in previous TLS implementations.

Additional mitigations The TLS RFC [15] includes a section on implementation pitfalls, which contains a list of known protocol issues and common failures when implementing cryptographic operations. nqsb-TLS mitigates all of these.

Further issues that nqsb-TLS addresses include:

- Interleaving of sub-protocols, except between change of cipher spec and finished.
- Each TLS 1.0 application data is prepended by an empty fragment to randomise the IV (BEAST).
- Secure renegotiation [40] is required.
- SCSV extension [35] is supported.
- Best practices against attacks arising from mac-then-encrypt in CBC mode are followed (no mitigation of Lucky13 [19])
- No support for export restricted ciphersuites, thus no downgrade to weak RSA keys and small DH groups (FREAK and Logjam).
- Requiring extended master secret [4] to resume a session.

State machine fuzzing Researchers fuzzed [11] nqsb-TLS and found a minor issue: alerts we send are not encrypted. This issue was fixed within a day after discovery, and it is unlikely that it was security-relevant.

Frankencert Frankencert is a fuzzing tool which generates syntactically valid X.509 certificate chains by randomly mixing valid certificates and random data. We generated 10 000 X.509 certificate chains, and compared the verification result of OpenSSL (1.0.1i) and nqsb-TLS The result is that nqsb-TLS accepted 120 certificates, a strict subset of the 192 OpenSSL accepted.

Of these 72 accepted by OpenSSL but not by nqsb-TLS, 57 certificate chains contain arbitrary data in X.509v3 extensions where our implementation allows only restricted values. An example is the key usage extension, which specifies a sequence of OIDs. In the RFC, 9 different OIDs are defined. Our X.509v3 grammar restricts the value of the key usage extension to those 9 OIDs. 12 certificate chains included an X.509v3 extension marked critical but not supported by nqsb-TLS.

Two server certificates are certificate authority certificates. While not required by the path validation, best practices from Mozilla recommend to not accept a server certificate which can act as certificate authority. The last certificate is valid for a Diffie-Hellman key exchange, but not for RSA. Our experimental setup used RSA, thus nqsb-TLS denied the certificate appropriately.

Exposure to new vulnerabilities Building nqsb-TLS in a managed language potentially opens us up to vulnerabilities that would not affect stacks written in C. Algorithmic complexity attacks are a low-bandwidth class of denial-of-service attacks that exploit deficiencies in many common default data structure implementations [10]. The modular structure of nqsb-TLS makes it easy to audit the implementations used within each component. The French computer security governmental office [37] assessed the security of the OCaml runtime in

2013, which lead to several changes (such as distinction between immutable strings and mutable byte arrays).

The Bitcoin Piñata To demonstrate the use of nqsb-TLS in an integrated system based on MirageOS, and to encourage external code-review and penetration testing, we set up a public bounty, the *Bitcoin Piñata*. This is a standalone MirageOS unikernel containing the secret key to a bitcoin address, which it transmits upon establishing a successfully authenticated TLS connection. The service exposes both TLS client and server on different ports, and it is possible to bridge the traffic between the two and observe a successful handshake and the encrypted exchange of the secret.

The attack surface encompasses the entire system, from the the underlying operating system and its TCP/IP stack, to TLS and the cryptographic level. The system will only accept connections authenticated by the custom certificate authority that we set up for this purpose. Reward is public and automated, because if an attacker manages to access the private bitcoin key, they can transfer the bitcoins to an address of their choosing, which is attestable through the blockchain.

While this setup cannot prove the absence of security issues in our stack, it motivated several people to read through our code and experiment with the service.

At the end of June 2015, there were 230 000 accesses to the website from more than 50 000 unique IP addresses. More than 9 600 failed and 12 000 successful TLS connections from 1000 unique IPs were present. Although we cannot directly verify that all successful connection resulted from the service being short-circuited to connect to itself, there have been no outgoing transactions registered in the blockchain. The breakdown of failed connections is similar to §7.1. We collected 42 certificates which were tried for authentication, but failed (not well formatted, not signed, not signed by our trust anchor, private key not present). A detailed analysis of the captured traces showed that most of the flaws in other stacks have been attempted against the Piñata.

Trusted computing base The TCB size is a rough quantification of the attack surface of a system. We assess the TCB of our Piñata, compared to a similar traditional system using Linux and OpenSSL. Both systems are executed on the same hardware and the Xen hypervisor, which we do not consider here. The TCB sizes of the two systems are shown in Table 2 (using `cloc`).

The traditional system contains the Linux kernel (excluding device drivers and assembly code), glibc, and OpenSSL. In comparison, our Piñata uses a minimal operating system, the OCaml runtime, and several OCaml libraries (including GMP). While the traditional system uses a C compiler, our Piñata additionally uses the OCaml compiler (roughly 40 000 lines of code).

	Linux/OpenSSL	Unikernel/nqsb-TLS	
Kernel	1600	48	(36)
Runtime	689	25	(6)
Crypto	230	23	(14)
TLS	41	6	(0)
Total	2560	102	(56)

Table 2: TCB (in kloc); portion of C code in parens

	nqsb-TLS	OpenSSL	PolarSSL
RSA	698 hs/s	723 hs/s	672 hs/s
DHE-RSA	601 hs/s	515 hs/s	367 hs/s

Table 3: Handshake performance of nqsb-TLS, OpenSSL and PolarSSL, using 1024-bit RSA certificate and 1024-bit DH group.

The trusted computing base of the traditional system is 25 times larger than ours. Both systems provide the same service to the outside world and are hardly distinguishable for an external observer.

7.3 Performance

We evaluate the performance of nqsb-TLS, comparing it to OpenSSL 1.0.2c and PolarSSL 1.3.11. We use a single machine to avoid network effects. In the case of nqsb-TLS, we compile the test application as a Unix binary to limit the comparison to TLS itself.

The test machine has an Intel i7-5600 Broadwell CPU and runs Linux 4.0.5 and glibc 2.21. Throughput is measured by connecting the command line tool *socat*, linked against OpenSSL, to a server running the tested implementation, and transferring 100 MB of data from the client to the server. This test is repeated for various transmission block sizes. Handshakes are measured by running 20 parallel processes in a continuous connecting loop and measuring the maximum number of successful connection within 1 second; the purpose of parallelism is to negate the network latency.

Throughput rates are summarized in Figure 4. With 16 byte blocks, processing is dominated by the protocol overhead. This helps us gauge the performance impact of using OCaml relative to C, as nqsb-TLS implements protocol logic entirely in OCaml. At this size, we run at about 78% of OpenSSL's speed.

At 8196 bytes, performance becomes almost entirely dominated by cryptographic processing. All three implementations use AES-NI, giving them roughly comparable speed. OpenSSL's performance lead is likely due to its extensive use of assembly, and in particular the technique of stitching, combining parts the of the cipher mode of operation and hashing function to saturate the CPU pipeline. PolarSSL's performance drop compared

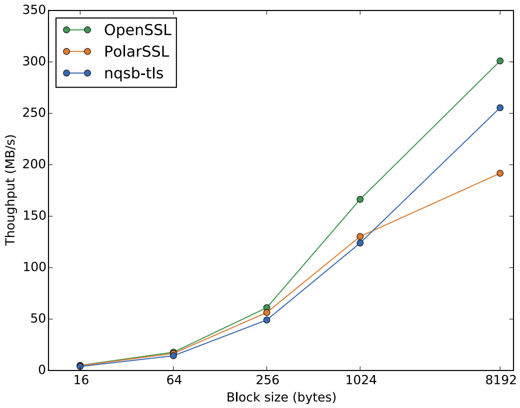

Figure 4: Scaling of throughput with application data size for nqsb-TLS, OpenSSL and PolarSSL, using AES_256_CBC_SHA.

to nqsb-TLS is likely a consequence of our usage of simple software pipelining in the AES-NI code. nqsb-TLS reaches about 84% of OpenSSL's speed in this scenario.

Handshake performance, summarized in Table 3, is roughly similar. We attribute OpenSSL's advantage to their use of C in the protocol handling, and PolarSSL's disadvantage to our use of faster bignum routines provided by GMP. The comparatively smaller cost nqsb-TLS pays for DH is a result of picking shorter exponents, matched to the security strength of the group modulus.

We ran miTLS 0.8.1 through Mono 4.0.1.44 on the same test machine. Using the bundled HTTP server, we achieve a peak throughput of 19 MB/s for a file transfer using the same cipher suite. As the Mono cryptography provider only contains C# AES implementations, we exclude this implementation from further analysis. We do note, however, that the throughput ratio between miTLS and OpenSSL is similar to the one its authors report [5].

The exact numbers are likely to vary with the choice of cipher suite, which places different weights on hashing and cipher performance, the CPU generation, which is utilised to a fuller extent by OpenSSL, and the testing scenario. The broad picture is that our usage of OCaml for all but the lowest-level cryptographic primitives is, in itself, not taking a prohibitive toll on performance.

8 Related Work

Security proofs Several research groups [36, 26, 24, 12, 38] have modelled and formally verified security properties of TLS. Because TLS is a complex protocol, most models use a simplified core, and formalising even these subsets is challenging work which is not very accessible to an implementer audience. Additionally, these models need to be validated with actual implementations, to relate to the de facto standard, but this is rarely done (to do so, some kind of trace checker or executable needs to be developed). Some of these models formalised the handshake protocol, but omitted renegotiation, in which a security flaw was present until discovered in 2009.

miTLS The miTLS [5] stack is developed in F7 with the possibility to extract executable F# code. It is both a formalisation of the TLS protocol and a runnable implementation. This formalisation allowed its developers to discover two protocol-level issues: alert fragmentation and triple handshake. As an implementation, it depends on the Common Language Runtime for execution, and uses its services for cryptographic operations and X.509 treatment (including ASN.1 parsing). In contrast, nqsb-TLS cannot be used for verifying security properties of TLS, but provides a test oracle and a fast runnable implementation which is easily deployable. It compiles to native code and implements the entire stack from scratch, making it self-contained. It can be used e.g. in MirageOS, which only provides the bare TCP/IP interfaces and has no POSIX layer or cryptographic services.

Language-oriented approach to security Mettler et al. propose Joe-E [33], a subset of Java designed to support the development of secure software systems. They strongly argue in favour of a particular programming style to facilitate ease of security reviews.

Our approach shares some of the ideas in Joe-E. By disallowing mutable static fields of Java classes, they effectively prohibit globally visible mutable state and enforce explicit propagation of references to objects, which serve as object capabilities. They also emphasise immutability to restrict the flows of data and achieve better modularity and separation of concerns.

The difference in our approach is that we use immutability and explicit data-passing not only on the module (or class) boundaries but pervasively throughout the code, aiming to facilitate code-review and reasoning on all levels. A further difference is that Joe-E focusses the proposed changes in style on security reviews only, aiming to help the reader of the code ascertain that the code does not contain unforeseen interactions and faithfully implements the desired logic. In contrast, we employ a fully declarative style. Our goals go beyond code review, as large portions of our implementation are accessible as a clarification to the specification, and we have an executable test oracle.

Finally, there is the difference between host languages. Java lacks some of the features we found to be most significant in simplifying the implementation, chiefly the ability to encode deeply nested data structures and traverse them via pattern-matching, and to express local operations in a pure fashion.

Brittle implementations of cryptography systems Schneier et al.'s work [43] discovered several root causes for software implementing cryptographic systems, which explicitly mentions incorrect error handling and flawed API usage. We agree with their principles for software engineering for cryptography, and extend this further by proposing our approach: immutable data, value-passing interfaces, explicit error handling, small API footprint.

TLS implementations in high-level languages Several high-level languages contain their own TLS stack. Oracle Java ships with JSEE, a memory-safe implementation. However its overall structure closely resembles the C implementations. For example, the state machine is built around accumulating state by mutations of shared memory locations, the parsing and validation of certificates are not clearly separated, and the certificate validation logic includes non-trivial control flow. This resulted in high-level vulnerabilities similar in nature to the ones found in C implementations, such as CCS Injection (CVE-2014-0626), and its unmanaged exception system led to several further vulnerabilities [34].

There are at least two more TLS implementations in functional languages, one in Isabelle [30] and one in Haskell. Interestingly, both implementations experiment with their respective languages' expressivity to give the implementations an essentially imperative formulation. The Isabelle development uses a coroutine-like monad to directly interleave I/O operations with the TLS processing, while the Haskell development uses a monad stack to both interleave I/O and to implicitly propagate the session state through the code. In this way both implementations lose the clear description of data-dependencies and strong separation of layers nqsb-TLS has.

Protocol specification and testing There is an extensive literature on protocol specification and testing in general (not tied to a security context). We build in particular on ideas from Bishop et al.'s work on TCP [6, 41], in which they developed a precise specification for TCP and the Sockets API in a form that could be used as a trace-checker, characterising the de facto standard. TCP has a great deal of internal nondeterminism, and so Bishop et al. resorted to a general-purpose higher-order logic for their specification and symbolic evaluation over that for their trace-checker. In contrast, the internal nondeterminism needed for TLS can be bounded as we describe in §5, and so we have been able to use simple pure functional programming, and to arrange the specification so that it is simultaneously usable as an implementation. We differ also in focussing on an on-the-wire specification rather than the endpoint-behaviour or end-to-end API behaviour specifications of that work. In contrast to the Sockets API specified in POSIX, there is no API for TLS. Every implementation defines its custom API, and many have a compatibility layer for the OpenSSL API.

9 Conclusion

We have described an experiment in engineering critical security-protocol software using what may be perceived as a radical approach. We focus throughout on structuring the system into modules and pure functions that can each be understood in isolation, serving dual roles as test-oracle specification and as implementation, rather than traditional prose specifications and code driven entirely by implementation concerns.

Our evaluation suggests that it is a successful experiment: nqsb-TLS is usable in multiple contexts, as test oracle and in Unix and unikernel applications, it has reasonable performance, and it is a very concise body of code. Our security assessment suggests that, while it is by no means guaranteed secure, it does not suffer from several classes of flaws that have been important in previous TLS implementations. In this sense, it is at least not quite so broken as some secure software has been.

In turn, this indicates that our *approach* has value. As further evidence of that, we applied the same approach to the *off-the-record* [7] security protocol, used for end-to-end encryption in instant messaging protocols. We engineered a usable implementation and reported several inconsistencies in the prose specification. The XMPP client mentioned earlier uses nqsb-TLS for transport layer encryption, and our OTR implementation for end-to-end encryption.

The approach cannot be applied everywhere. The two obvious limitations are (1) that we rely on a language runtime to remove the need for manual memory management, and (2) that our specification and implementation style, while precise and concise, is relatively unusual in the wider engineering community. But the benefits suggest that, where it can be applied, it will be well worth doing so.

Abstract

For increased security during TLS certificate validation, a common recommendation is to use a variation of pinning. Especially non-browser software developers are encouraged to limit the number of trusted certificates to a minimum, since the default CA-based approach is known to be vulnerable to serious security threats.

The decision for or against pinning is always a trade-off between increasing security and keeping maintenance efforts at an acceptable level. In this paper, we present an extensive study on the applicability of pinning for non-browser software by analyzing 639,283 Android apps. Conservatively, we propose pinning as an appropriate strategy for 11,547 (1.8%) apps or for 45,247 TLS connections (4.25%) in our sample set. With a more optimistic classification of borderline cases, we propose pinning for consideration for 58,817 (9.1%) apps or for 140,020 (3.8%[1]) TLS connections. This weakens the assumption that pinning is a widely usable strategy for TLS security in non-browser software. However, in a nominal-actual comparison, we find that only 45 apps actually implement pinning. We collected developer feedback from 45 respondents and learned that only a quarter of them grasp the concept of pinning, but still find pinning too complex to use. Based on their feedback, we built an easy-to-use web-application that supports developers in the decision process and guides them through the correct deployment of a pinning-protected TLS implementation.

1 Introduction

Android is the major platform for mobile users and mobile app developers. Many apps handle sensitive information and deploy the transport layer security protocol (TLS) to protect data in transit. Previous research uncovered security issues with TLS in mobile apps [7, 8, 9, 2, 22] that highlight that developers have problems with implementing correct certificate validation while users are challenged by TLS interstitials. Furthermore, the default TLS implementation on Android receives criticism [24, 18]: Adopted from web-browsers, default TLS certificate validation relies on a huge number of root CAs pre-installed on all Android devices [24]. Hence, all Android apps suffer from the same issues as web-browsers: A single malicious CA is able to conduct Man-In-The-Middle attacks (MITMAs) against all apps trusting the respective certificate. To make things even worse, Fahl et al. [8] uncovered that in 97% of all cases where developers implemented their own certificate validation strategy, they turned off validation entirely and left their apps vulnerable to MITMAs with arbitrary certificates, i.e. every active network attacker was able to attack successfully.

Pinning is often recommended as a general countermeasure to tackle the weakest link in the CA-based infrastructure [1, 14, 17, 8]. We use the term *pinning* in this paper to include both pinning the complete X.509 certificate or only the certificate's public key. Instead of trusting a large set of root CAs that come pre-installed with the operating system, software limits the set of certificates it trusts to *pins*, which can be single leaf certificates, single root CA certificates or a set of certificates. Pinning is a straightforward mechanism and its deployment does not require changes to the current CA infrastructure. However, pinning has not found widespread adoption yet. While limiting the number of trusted certificates drastically increases security, pinning doesn't come for free: Embedding trusted certificates into an app requires app updates whenever the pins change. Hence, the decision whether

[1] This smaller percentage in the optimistic case is caused by a different prevalence of third party library use.

pinning is applicable for a TLS connection is always a trade-off between increased security and maintenance effort that is not entirely under the control of an app developer: Whenever users do not update their app although the pins have changed, the app stops working and users might uninstall the broken app. Therefore, to pin or not to pin is a critical decision for app developers, which requires in-depth understanding of the mechanisms behind pinning and its implications on their apps. This is where our work comes in: To the best of our knowledge, we are the first to explore the applicability of pinning as an appropriate alternative certificate validation strategy for non-browser software. In this paper, we make the following contributions:

Status Quo We evaluate the status quo and analyze 639,283 Android apps to find that only 45 apps implement pinning.

Formalization Instead of intuitively recommending pinning, we formalize criteria that must be considered when the decision is made whether to pin or not to pin.

Implementation We apply static code analysis and program slicing to automatically assess those criteria and obtain an overview of the situation for single apps.

Evaluation We evaluate our criteria against a set of 639,283 Android apps for an overview of the applicability of pinning in the Android universe. We find that 223,655 apps establish TLS-secured connections to remote origins; 11,481 (5.13%) of these 223,655 apps are eligible candidates to implement pinning for one or more of their TLS connections.

App Updates Since new certificate pins need to be updated on the users' devices, the update speed is crucial. Therefore, we instrument telemetry data from a popular anti-virus software provider. We evaluate the update behaviour of 871,911 unique users from January 2014 to December 2014 and find that only 50% of the users update to a new app version within the first week after release.

Developer View Although pinning is only applicable in relatively few cases, the nominal-actual comparison leaves room for improvement. We therefore collected feedback from 45 developers of apps for which we would recommend pinning. We identified the developers' major issues with pinning and used their feedback as the foundation to build an easy-to-use web application that assists developers with securing their apps' TLS connections. We offer help on the decision whether to pin or not to pin and support the implementation of pinning with concrete suggestions and code examples.

Take-aways We formulate lessons learned during our evaluation to share them with the research community.

2 Background and Motivation

To establish secure TLS connections, *certificate validation* is important in order for communication partners to authenticate remote endpoints. Therefore, Android and most other non-browser software adopted the in-browser certificate validation strategy, i.e. applications trust a predefined set of *root certificate authorities* (root CAs). When attempting to establish a secure connection, the server provides the client with a *certificate chain*.

2.1 Default Certificate Validation

Certificate chain validation works as follows:

Chain of Trust Based on the certificate chain sent by the server, the client tries to build the *chain of trust* beginning at the server's leaf certificate up to one of the root CA certificates. Every certificate in the chain is checked for validity – i.e. it is not expired and it is signed by its immediate successor in the chain. The second last certificate in the chain must be signed by one of the root CAs installed on the user's device [3]; the last certificate in the chain belongs to the signing root CA.

Hostname Verification A certificate is bound to a certain identity – in this case a particular hostname or a set of hostnames. During *hostname verification*, a client verifies this identity by checking whether the hostname can be matched to one of the identities (i.e. CommonName, SubjectAltName [20]) for which the certificate was issued.

Further checks Complete certificate validation may include further checks, e. g. certificates have to be checked for *revocation* which is done via a certificate revocation list (CRL)[3] or Online Certificate Status Protocol (OCSP)[21].

2.2 MITM Attack

In a Man-In-The-Middle attack (MITMA), the attacker is in a position to intercept network communication. A passive MITMA can only eavesdrop on the communication, while an active MITMA can also tamper with the communication. Correctly configured TLS together with proper certificate validation is fundamentally capable of preventing both passive and active attackers from executing their attacks.

2.3 Alternative Validation Strategies

Over the years, alternative certificate validation strategies have come up [12, 26, 16, 15, 10, 17]. While they all provide approaches to check a certificate chain's validity, our paper focuses on *pinning* [17] as one of the most recommended alternative strategies for non-browser software.

2.3.1 Pinning

Pinning is a notion of certificate validation that uses existing knowledge about the network origin or the certification data presented to protect the TLS connection [17]. Required parameters to be pinned need to be available in an application before the TLS handshake happens. Pinning can be achieved based on different parameters (e.g. public key, whole certificate).
Pinning can also be applied to different subjects:
Leaf Pinning Leaf pinning includes pinning a single leaf certificate or its public key or a set of leaf certificates or their public keys and is the most rigorous way of pinning.
CA Pinning Certificate authority pinning effectively limits the number of trusted certificate authorities and allows for more flexible reconfiguration of deployed TLS certificates. This includes both intermediate and root CAs.

2.3.2 Trust on First Use (TOFU)

Another notion of pinning is *trust on first use* (TOFU). Instead of knowing the information to be pinned in advance, the first certificate (leaf or CA) seen for a TLS connection is stored locally on the client side and used to validate certificates for further connections. Hence, TOFU can be seen as a mix of conventional pinning (cf. Section 2.3.1) and the default validation strategy. TOFU is used to secure SSH connections and is an opt-in feature for HTTPS webservers for which it is called HTTP Public Key Pinning (HPKP [5]). As of today, HPKP has not found widespread adoption on the web [11].

2.4 Flaws in client implementations

The Android platform provides built-in functionalities for handling TLS and certificate validation based on the PKI without further configuration. It comes pre-loaded with an extensive truststore featuring 140+ root CAs [18]. Additionally, the Android framework enables developers to provide custom implementations for handling certificate validation. There are several reasons for developers to use custom implementations:

- Application developers might want to use a self-signed certificate either for testing, effort- or economical reasons;
- When a root CA is not in the system-wide list of trusted root CAs, a company might have an internal CA that issues certificates for use in intranet applications;
- Security can be enhanced by restricting reliance on the PKI to mitigate the exposure to weaknesses in the PKI
- and custom implementations are required to implement leaf or CA pinning.

2.5 Related Work

Recently, TLS has been subject to urgent flaws. Studies by Fahl et al. [7] and Georgiev et al. [9] uncovered a disastrous state of TLS-Code. Georgiev et al. [9] show numerous flaws in non-browser TLS-Code. Fahl et al. [7] identify numerous applications featuring erroneous custom TLS-code that potentially renders applications vulnerable to MITMAs. This is caused by incorrect implementations of custom certificate handling. Investigations on the reasons illustrate that especially developers without a security focus are unaware of the correct use of the APIs that Android provides: They carelessly incorporate code snippets from platforms such as `stackoverflow.com` [8]. In particular, self-signed certificates used during development lead to erroneous code that makes applications vulnerable by deactivating certificate validation completely.

Both of the above investigations [7, 9] focused on the difficulties experienced by developers with the implementation of correct certificate validation. However, they discuss possible countermeasures rather sketchily and do not evaluate the applicability of pinning for non-browser software.

To improve the state of erroneous certificate handling and to mitigate the threats, Fahl et al. [8] suggest to completely disallow custom code. Instead, they propose a framework that allows to realize common use-cases (e.g. self-signed certificates for testing, pinning, default warning messages, etc.) by configuration without the developer writing any TLS-related code. Tendulkar and Enck [23] suggest a similar approach. However, although both approaches try to improve the usability of certificate handling for software developers, they do not support developers in the decision process of whether pinning is a recommendable certificate validation strategy.

3 An Exit Strategy

Previous work shows that TLS is complex and error-prone. Studies imply that the implementation of client code for correct certificate validation is hard for software developers. The general trust model received a lot of criticism over the last years and alternative solutions have not found widespread adoption.

As a general solution for both problems, pinning is often advocated as a secure and reliable alternative to the default trust model for non-browser software [17, 14, 1, 8]. Pinning can serve two purposes. First, it can mitigate the risk of MITMAs as it strengthens the validation process. Secondly, pinning allows to overcome limitations of the current CA infrastructure, e.g. by allowing self-signed certificates.

We challenge the recommendation to use pinning for non-browser software and conduct a deep analysis on the root causes that hinder its widespread adoption in non-browser software.

3.1 Pinning in Android Apps

Before evaluating the status quo, we give a brief overview of how TLS pinning can be implemented in Android apps. In general, Android apps can establish low-level TLS connections via an `SSLSocket` or an `HTTPSUrlConnection` object. Using pinning in these cases requires the developer to implement a custom version of Android's `TrustManager` interface with an appropriate `checkServerTrusted` method. This method has to check whether the certificate sent by the remote server matches one of the given pins. Another option is to use a custom `KeyStore` in which developers can store their own certificates. Many Android applications do not make use of such lower level APIs but use a `WebView` to display HTML directly. Sadly Android does not provide an API to implement pinning for `WebViews`[2]. As a workaround, developers can download all HTML/-JavaScript via the low-level `HTTPSUrlConnection`, store it locally and only use the `WebView` for rendering. However, this is a clear shortcoming of Android's API and makes the implementation of pinning unnecessarily hard.

3.2 Status Quo

For a better understanding of the current adoption of TLS pinning in Android apps, we evaluated custom certificate verification strategies for 639,283 Android apps. Therefore we used `MalloDroid` [7] and extended the classification feature of custom verification implementations. We focused on both customized implementations of the `TrustManager` interface and the usage of a custom `KeyStore` for TLS certificates.

Whenever we found that a `KeyStore` object was created, we conducted a reachability analysis [13] for this object. For objects that were reachable from an app's entry point, we assume that this app uses pinning. Next, we extracted the keystore file that was loaded to check whether leaf or CA certificates were pinned. We found 21 apps that implement pinning using the keystore method. 13 of these apps pin a leaf certificate, while 8 of them pin a custom root CA certificate.

Whenever we found a `TrustManager` implementation, we checked whether the `chain` parameter of the `checkServerTrusted` method was accessed by the implementation. Implementations that do not use this parameter do not verify the remote origin's certificate chain and hence were removed from further analyses. In a second step we conducted a reachability analysis for implemented `TrustManager` objects and removed all implementations that were not reachable from an app's entry point. We found custom `TrustManager` implementations in 42,902 apps and could remove 42,042 apps from the list since they either implemented bypassing `TrustManagers` or were not reachable. The remaining 858 apps implemented 189 different `TrustManagers`. We compared these implementations with the list provided by Fahl et al. [8] and could filter out 124 implementations that basically add logging for certificate validation. We manually reviewed the remaining 65 implementations and found that 13 implemented pinning. Overall, these implementations were used by 24 apps.

Altogether, of the 639,283 apps in our data-set, 45 implement pinning. These numbers confirm findings already reported by Fahl et al. [8].

4 Classification Strategy

The decision whether or not a TLS connection should be secured by pinning depends on multiple factors and is not trivial in many cases.

Furthermore, whenever we cannot reliably identify the origin string for a TLS connection endpoint, we cannot assess whether pinning would be a reasonable validation strategy. Therefore, we report our results for two different scenarios:

[2] `https://code.google.com/p/android/issues/detail?id=76501`

Conservative We report numbers for a conservative scenario. Whenever we cannot identify the origin string for a TLS connection endpoint, we assume that pinning is unfeasible. This covers most of our results.

Optimistic For some of the cases where we could not successfully identify origin strings, pinning could be applied under certain circumstances. These cases are treated differently for the optimistic scenario as detailed in Section 6.

For our classification, we consider the following properties as high level indicators:

Prior Knowledge of the Target Origin Prior knowledge about the target origin is vital: Pinning is only feasible if the developer of an app is able to hard-code target origins into their app. This includes adding target origins at compile time as well as via configuration files before or at run-time. Whenever target origins depend on user- or external app input – e.g. via an `Intent` – at run-time, we consider pinning as not feasible, since web-browsers do not automatically pin certificates for websites for the same reasons.[3]. Automatically pinning previously unknown origins would increase the danger of failed TLS handshakes due to substituted certificates and would decrease acceptance of pinning for both developers and app users.

In the *conservative* scenario, we recommend the default validation strategy for all connections where the origin depends on external input. However, some of these connections can be pinned in the *optimistic* scenario (cf. Section 6).

Ownership of Relevant API Calls App development consists of writing one's own code and embedding external libraries. All source code that was written by the developer or the developer's company is considered owned by the developer. API calls required for certificate validation during the establishment of TLS-secured network connections are *relevant* for this. Relevant API calls might be a `HTTPSUrlConnection` or an `SSLSocket`. Whenever ownership of relevant API calls is given, pinning might be feasible. Library developers do not own their code when it is included in other apps. Therefore, we do not recommend pinning for library code. Library developers cannot control when app developers update their libraries, while app developers can hardly influence whether library developers keep their certificate pins up to date.

For both the *conservative* and the *optimistic* scenario pinning is not recommended in case API ownership is not given.

TLS Certificate Configuration Responsibility Being responsible for the TLS certificate configuration as well as being the owner of relevant API calls eases the coordinated deployment of pinning in apps. In case developers or their companies have control over the TLS certificate configuration of origins used in apps, both the certificate pins in apps and the corresponding server configurations can be coordinated. In these cases, pinning is feasible. Whenever apps communicate with public origins, such as public API interfaces or websites, pinning cannot be recommended. Certificate configurations can change frequently and the responsible administrators only rarely announce them in advance. Unplanned certificate changes can lead to failing TLS handshakes and are therefore unacceptable.

For both the *conservative* and the *optimistic* scenario pinning is not recommended in case the developer is not responsible for TLS certificate configuration.

4.1 Possible Recommendations

The above criteria build the foundation for the decision whether pinning is applicable for a TLS connection in a given app. The classification algorithm recommends one of the following strategies:

Leaf Pinning Leaf pinning limits the number of trusted certificates to the server's leaf certificate/public key (cf. Section 2.3.1).

CA Pinning CA pinning effectively limits the number of trusted CAs (cf. Section 2.3.1). We treat conventional pinning (cf. Section 2.3.1) and TOFU (cf. Section 2.3.2) equally, since both provide a similar level of security (cf. Section 2.3.1) and require the same maintenance overhead from an app developer's point of view.

Default Whenever none of the above criteria applies, pinning is not a recommended strategy and should not be implemented. This also accounts for cases where external input – e.g. user input in an address bar or `Intent` input – influences a TLS connection.

[3] Administrators can configure HTTP Public Key Pinning (HPKP) to pin TLS certificates in modern web-browsers. However, this involves heavy manual configuration work on the server side and does not happen automatically (cf. Section 2).

4.2 Classification Details

Algorithm 1 illustrates the classification process we apply to decide whether pinning is an advisable verification strategy. In the initial state, the default strategy is assumed to be the right choice for a TLS connection, since we do not know yet if pinning is recommendable. First, we check whether the TLS connection is established within a third party library. In this case classification ends with the recommendation to use the default strategy, since ownership of the relevant API is not guaranteed.

Second, we check whether the remote origin depends on user input, other external sources such as `Intents`, or may be configured via a configuration file. In these cases we recommend the default strategy, since control over the remote origin is not guaranteed.

Third, we check whether the TLS connection's remote endpoint is a popular origin; in this case, classification ends with recommending the default strategy, since the TLS configuration of the remote origin is probably not under the developer's control. If we assume that a remote origin is probably under control of the developer, as no other app accesses it, the classification continues: We check whether the origin's certificate was issued by a valid CA or is self-signed. For self-signed certificates and certificates that were issued by a valid CA, we recommend leaf certificate pinning. For certificates issued by an untrusted CA, we recommend CA pinning, since the custom CA is probably under control of the developer.

4.3 Challenges

For our strategy classification, we apply static code analysis on a large set of Android apps. To work as efficiently as possible, we identified multiple challenges:

4.3.1 Relevant API Calls

First, we identify relevant API calls, which means taking remote origins as parameters and establishing a TLS-secured connection between the app and the origin. The official Android API documentation identifies relevant API calls in the packages presented in Table 1.

These API calls are the most low-level calls in the API and they implicitly include higher level APIs such as the `HTTPSUrlConnection`.

Package name
org.apache.http.client.methods.*
org.apache.http.HttpHost
android.webkit.WebView.loadUrl
android.webkit.WebView.loadDataWithBaseURL
android.webkit.WebView.loadData
android.webkit.WebView.postUrl
android.net.http.AndroidHttpClient
java.net.Url

Table 1: Relevant API Calls.

4.3.2 Embedded Static TLS Origins

As described above, knowing remote origins in advance is crucial for pinning. At this point, we focus on extracting whether a remote origin is embedded in an app or depends on user input or is injected via an external interface such as an `Intent`. This information is supplied via parameters to relevant API calls. Although these mainly refer to `String` values, the object-oriented and Java-based nature of the Android platform introduces complexity:

- `Strings` may not be constant values but can be composed of numerous substrings. We identify concatenation of Strings, formatting of `Strings` and platform-specific APIs for building URIs as relevant. Therefore, we statically backtrack these and reproduce `String` values.
- Values can stem from variables or may be return values of method calls. Therefore, we account for intra-application method calls as well.
- Values that stem from `Resources`, `Properties` or `Preferences` hint at configuration parameters.
- Origins can be input parameters for application entrypoints. Entrypoints are parts of an application that allow either other app components, external apps or users to interact with an app. Android application entrypoints are `Activities`, `Services`, `Receivers`, `Intents` and `Bundles`. UI-Components in `Activities` hint at user input.

4.3.3 API Call Ownership

API call ownership is a requirement for pinning. To identify whether an app developer holds ownership of relevant API calls, we must distinguish relevant API calls that are accessed by third party libraries and relevant API calls accessed by code that was

Algorithm 1: The Classification Process.

```
for $r \in results$ do
    $dependencies \leftarrow dependencies(r)$;
    set strategy as default;
    if $dependencies \neq \emptyset$ then
        if $\exists d \in dependencies | d \in \{exposed\,intent, UI-Component\}$ then
            continue;
        else if $\exists d \in dependencies | d \in \{unexposed\,intent, variable, configuration\}$ then
            continue;
    if not callInLibrary(r) and not isPublicHost(r) then
        $host \leftarrow host(r)$;
        $schema \leftarrow schema(r)$;
        $cert \leftarrow cert(r)$;
        $dependencies \leftarrow dependencies(r)$;
        if $isUnderControl(host)$ then
            if $signedByUntrustedCA(cert)$ then
                mark for CA pinning;
            else if $validCertChain(cert)$ or $isSelfSigned(cert)$ then
                mark for leaf pinning;
```

written by the app developer (we call this *custom code*). Whenever we find relevant API calls in code that is shared between multiple apps by different authors, we assume a library that is not under control of an app's developer.

4.3.4 Origin Exclusivity

Whenever the TLS configuration of a remote origin is not in the range of influence of the developer, pinning is not advisable. We classify origins that are shared between multiple apps' authors and connections that access public origins as not under control of the developer.

5 Implementation Details

To decide whether pinning for a TLS connection is advisable and to address the above challenges (cf. Section 4.3), we implement our classification strategy in a multi-step process. We extend[4] the MalloDroid tool [7] and execute the following steps:

1. Disassemble a given Android application to gain access to the application's code and call graph (cf. Section 5.1).
2. Identify relevant API calls – i.e. API calls that implement TLS connections in apps (cf. Sections 5.2 and 4.3.1).
3. Extract information for remote origins applying program slicing (cf. Sections 5.3 and 5.3.1).
4. Determine whether API and/or origin ownership for relevant API calls is given and decide which certificate validation strategy suits best (cf. Sections 4.2 and 5.4).

5.1 Disassembly

In Step 1, we use androguard [4] to disassemble apps and construct call graphs for further processing.

5.2 Relevant API Calls

In Step 2, the call graphs were used to identify apps that make use of API calls in which origin information for establishing TLS-enabled connections is specified (cf. Section 4.3).

We consider API calls as *relevant* if they are used during the process of TLS connection establishment (cf. Table 1).

5.3 Program Slicing

In Step 3, we apply backwards program slicing [25] to collect method parameters which we subsequently call *slicing criteria*. We focus on slicing criteria that

[4] Our MalloDroid extension is available at `https://github.com/sfahl/mallodroid`.

represent remote origins which are used as input for relevant API calls, i. e. we are backtracking parameters that are URLs or hostnames for TLS connections.

Our approach is similar to the one applied by Poeplau et al. [19], who apply a backward slicing algorithm to identify security issues with dynamic code loading in Android apps.

In contrast to backwards slicing single and fixed method parameters, our targets are network origins. A network origin `String` can be a composition of multiple substrings. We take this fact into account by applying backwards slicing for multiple parameters. After backtracking, we join these (multiple) substrings to one origin string whenever possible. To break cycles, we stop the slicer after 80 iterations, which guarantees that the algorithm terminates and also makes sure we do not lose data.

5.3.1 Extracting Origin Strings

Origin strings can be compositions of multiple substrings (e.g. `https://` and `www.example.com` and `:443`). Thus, reconstructing an origin string might require combining multiple sliced substrings. Therefore, after program slicing, we apply a combination of backward and forward analysis. Backwards analysis is used for backtracking constant register values while forward analysis determines calls of a `String` instance. Both, back- and forward analyses are applied multiple times successively as long as we find new substrings that are part of a final origin string.

Algorithm 2 outlines pseudocode for handling `StringBuilder` objects. The algorithm makes use of the following functions:

methodsOnInstance returns a list of all method invocations on an instance (e.g. calls to `toString`, `append` or the constructor for `StringBuilder` objects).

backtrack applies the actual backtracking techniques to gather all substrings for the origin string composition.

add adds one `originSubstring` to the array of `originSubstrings` that make the origin string we are looking for.

join merges all `originSubstrings` to get the final origin string that is represented by the given `StringBuilder` object.

1. Identify instructions indicating the instantiation of a `StringBuilder` object (i.e. a `new-instance` instruction referring to the `StringBuilder` constructor) and store them in `sbos`.

Algorithm 2: StringBuilder Analysis

```
Data: stringBuilderObjects sbos
Result: new originSubstring O
begin
    for $sb \in sbos$ do
        methodInvocations ← methodsOnInstance(sb);
        originSubstrings ← ∅;
        origin ← null;
        for mi in methodInvocations do
            if isAppend(mi) then
                originSubstring ← backtrack(mi.regs[1]);
                if $originSubstring \neq null$ then
                    add(originSubstrings, originSubstring);
            else if isToString(mi) then
                break;
        join(O, originSubstrings);
```

2. Find all method invocations for each `StringBuilder` object `sb`;

3. For calls of the constructor or the `append()` method, backtrack the register value for the `String` parameter `originSubstring` and add it to all `originSubstrings`.

4. Stop on calls of the `toString` method and join all collected `originSubstrings` to a new `originSubstring`.

Similarly, we support `String` concatenation, formatting `Strings`, `UriBuilder` instances, Android `UI-Components`, `Intents`, `Bundles`, `Properties`, `Preferences` and `Resources`. For `Intents` and `Bundles` we identify the source in order to determine whether the corresponding component is exposed externally, e.g. via a `Service`.

5.4 Decide on Validation Strategy

In the final Step 4, we assess whether API and/or origin ownership is given (cf. Section 4). For pinning candidates, X.509 certificate information is collected and a decision for or against pinning is made (cf. Section 4.2).

5.5 Limitations

The described approach is limited in multiple ways. We decided to reverse engineer a large sample of free Android apps and analyze the resulting code. This limits the analysis compared to the analysis of original source code, e.g. we lose variable names and cannot preclude obfuscation. This is however the state of the art for large scale app analyses, since reaching out to developers and asking for source code does not scale well. We apply static code analysis and program slicing to determine the best certificate validation strategy to secure a TLS connection. Our approach does not consider native code in Android apps. We cannot track potential TLS connections in code that was dynamically loaded or when obfuscation was applied.

Since we apply static code analysis techniques, we might report some false positives: Some of the TLS connections we found and identified as being reachable code might not be used during real application usage. However, this is not a specific limitation of our work, but a general limitation of static code analysis.

We might also report some false negatives: Due to the strategy to classify origins to which apps developed by different developers connect as "not under control of the developer", we might miss the scenario that one company has several distinct developers write apps for them that all access the same domain. However, there exist no criteria to distinguish these cases from the common scenario that multiple apps by different developers accessing the same domain means that the domain is not under control of the developers. Therefore, these cases are included in the group of public origins for which we do not recommend pinning.

6 Evaluation

We applied the classification algorithm (cf. Section 4) to a set of 639,283 Android applications we downloaded from Google Play in October 2014. Our data extraction showed that of these apps, 573,258 implemented network connections.

In the following, we report details of our automated large-scale analysis. We report our results on a per-connection base (see Figure 2) as well as on a per-app base (see Figure 1), where an app is counted as eligible for pinning if at least one of its connections can be pinned. We distinguish between a conservative and an optimistic strategy rating (cf. Section 4). Altogether we found 20,020,535 calls to network related API calls (cf. Table 1). For these calls we tried to identify the origin strings. We could identify 1,062,810 calls as TLS connections due to the fact that the corresponding origin string's scheme was HTTPS. 2,420,104 connections were identified as plain HTTP, while 16,537,621 connections did not have a hard-coded origin string in the app's code. Hence, for 81% of all connections, it was not directly possible to determine whether TLS was used. However, a deeper analysis based on our classification criteria (cf. Section 4.2) gives detailed insights into the applicability of pinning. Table 2 gives an overview of the results.

Overall	**Con.**	**Apps**
Hard-coded HTTPS Origin	1,062,810	229,317
Hard-coded HTTP Origin	2,420,104	414,194
Non-hard-coded Origin	16,537,621	553,399
	20,020,535	573,258

Third Party Libraries	**Con.**	**Apps**
Hard-coded HTTPS Origin	917,567	203,159
Hard-coded HTTP Origin	1,659,933	310,331
Non-hard-coded Origin	14,564,581	512,055
	17,142,081	517,790

Custom Code	**Con.**	**Apps**
Hard-coded HTTPS Origin	145,243	48,755
Hard-coded HTTP Origin	760,171	184,184
Non-hard-coded Origin	1,973,040	246,636
	2,878,454	299,863

Table 2: Distribution of Network API Calls.

6.1 Library Code

The majority of network connections we identified were made in third party library code, i.e. users include third party libraries to make use of external functionality. Such connections can include both plain and TLS-protected connections. As described in Section 4.2, we recommend not to use pinning for those TLS connections, as API ownership is not given. Of the 20,021,137 TLS connections we could identify, we found that 17,142,081 (85.6%) connections are embedded in third party libraries.

Table 3 gives an overview of the top 10 third party libraries we found in our data-set.

Most of the identified libraries belong to ad networks (e.g. `com.google.ads.*`), crash reporting tools or app building kits (e.g. `org.apache.cordova.*`) that establish network

Library	Connections
com.google.ads.*	2,535,020
org.apache.cordova.*	1,145,108

(b) Dynamic Origins in Custom Code.

Table 4: Origins in Custom Code – Connections marked with 📌 can be pinned.

connections without any interaction with an app's custom code.

We found the `AndroidPinning` library[5] to be the only library that supports pinning as a security feature out of the box. However, in our data-set we found only 14 apps that made use of this library (cf. Section 3.2).

6.2 Custom Code

Next, we identified network connections that were established in code that was actually written by apps' developers, i.e. network-related API objects were not instantiated within third party libraries.

We found 2,878,454 connections in custom code of which we identified 145,243 as TLS connections. 48,755 apps implemented hard-coded TLS origins as parts of their custom code. Based on the type of the deployed certificate and depending on whether the origin is shared, we evaluated which of these TLS connections are candidates for pinning.

For 1,973,040 of the connections that were implemented as part of apps' custom code, we could not identify hard-coded origins in apps. Those connections could be either HTTP or HTTPS and depend on further input available only at run-time, e.g. user input or Intents. For these connections, we consider a conservative as well as an optimistic scenario. Based on different assumptions, these scenarios allow us to estimate the applicability of pinning in Android apps.

6.2.1 Hard-coded Origins

Overall, we found 145,243 hard-coded HTTPS connections and 760,171 hard-coded HTTP connections in our data-set. For the HTTPS connections, we collected further information such as the number of connections that connect to the same origin and the origin's X.509 certificate whenever possible.

The 145,243 TLS connections we found included connections to 11,203 different TLS-enabled remote origins.

To investigate whether pinning is the recommendable validation strategy, it is important to know if an origin is shared between multiple apps authored by multiple developers or used by apps of a single developer only (cf. Section 4).

Shared Origins 1,301 of the extracted 11,203 hosts were present in multiple apps that were authored by multiple developers. We assume these hosts not to be under the control of an app's developer and hence recommend the default certificate validation strategy, since host-ownership is not given (cf. Section 4). This affects 99,996 of the TLS connections we identified in our data-set (cf. Table 4a).

Table 5 lists the top 10 shared origins in custom code we found in our data-set.

Unique Origins 6,012 origins were unique to one single app while 3,890 origins were included in no more than five apps owned by a single developer. Hence, we assume 9,902 origins to be under the con-

[5] `https://github.com/moxie0/AndroidPinning`

Table 5: Top 10 Remote Origins.

trol of a single developer each. We recommend pinning for these apps and their connections, since both host- and code-ownership are given (cf. Section 4). This affects 45,247 TLS connections in our data-set (cf. Table 4a).

To determine whether leaf pinning or CA pinning is the right choice, we analyzed the deployed certificates for the respective origins. Overall, we gathered 7,941 unique certificate chains. We used Androids pre-installed root CA certificates and Androids certificate validation strategy to verify the validity of the origins' certificates and found that 7,177 of all chains could be verified successfully, while verification failed for 764 chains. Of these non-validating certificate chains, 182 certificates were self-signed; 170 certificates were issued by an unknown CA; 335 certificates were already expired and for 160 certificates hostname verification failed. Table 6 gives an overview of the chains and the affected connections and apps in our data-set.

Verification Result	Con.	Apps
Chain Ok	40,433	10,176
Self-Signed	1,966	486
Custom CA	269	81
Expired	1,709	546
Hostname Mismatch	870	258
	45,247	11,547

Table 6: X.509 Certificates Statistics.

We recommend pinning for all of these connections (cf. Section 4). We recommend leaf pinning for the connections that use a self-signed certificate and CA pinning for all other connections (cf. Table 7).

Type	Connections	Apps
Leaf Pinning	44,978	11,247
CA Pinning	269	81

Table 7: Pinning Statistics (Conservative).

6.2.2 Dynamic Origins

While the unique origins in custom code are good candidates for pinning, the majority of origins for connections in custom code were not hard-coded into the apps at compile time (cf. Table 4). These connections' origins can depend on different external factors such as Intents, UI components etc.

For these connections, we distinguish two scenarios:

Conservative In the conservative scenario, we assume that connections that use dynamic origins cannot be pinned. This assumption prevents us from over-reporting the applicability of pinning, but probably underestimates its applicability as well. Assuming this scenario, 45,247 of the 1,062,810 TLS connections we found in our data-set would be good pinning candidates, which makes up 4.25%.

Optimistic In this scenario, we assume some of the 1,973,040 dynamic origins connections eligible for pinning. We still assume that connections that get their input from Public Intents, Parcels and UI Components are no good pinning candidates, since the app developer probably does not have control over the actual origin strings values. That leaves some of the remaining 1,921,446 connections that depend on dynamic origin strings eligible for pinning. We assume that – as for the custom code with hard-coded origins – 16% of all connections are HTTPS connections (cf. Table 4), which leaves us with 307,431 HTTPS connections. If we again assume that, like for the hard-coded custom code origins, 31.1% of the HTTPS connections can be pinned (cf. Table 4), we can recommend 95,611 connections for pinning. In combination with the 45,247 connections from the conservative scenario, we recommend to pin 140,858 connections in the optimistic scenario. However, while only 86.33% of all known HTTPS connections are implemented in third party library code, but 88.07% of our *assumed* HTTPS connections happen via third library code, the connections we optimistically recommend for pinning make up only 3.8% of all (assumed and definite) HTTPS connections (as opposed to 4.25% for definite HTTPS connections). We can optimistically pin 140,858 connections as opposed to only 45,247 connections in the conservative case. Naturally, we are unable to specify which pinning strategy we would suggest, but extrapolating from the conservative scenario i.e. applying the percentages of which pinning strategy is applicable in the small conservative data-set to the larger data-set, 140,020 cases would be eligible for leaf pinning, while we would recommend CA pinning for 838 connections.

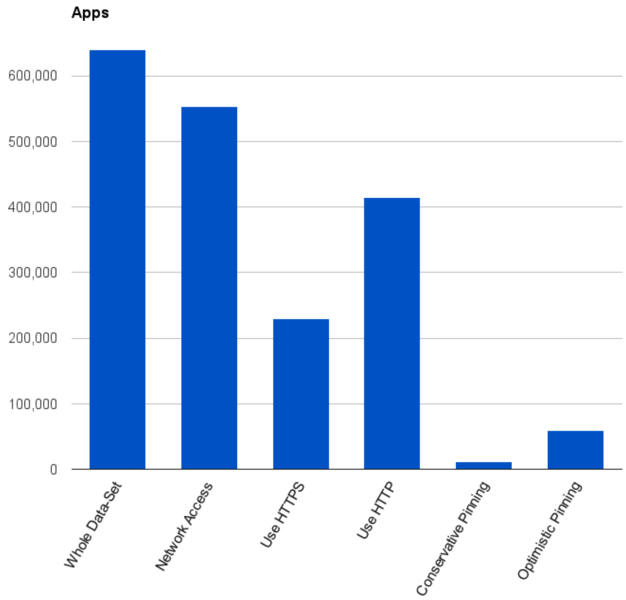

Figure 1: Statistics and Classification Results for Apps; *Network Access* includes apps with custom-coded, library- and dynamic HTTPS and HTTP connections.

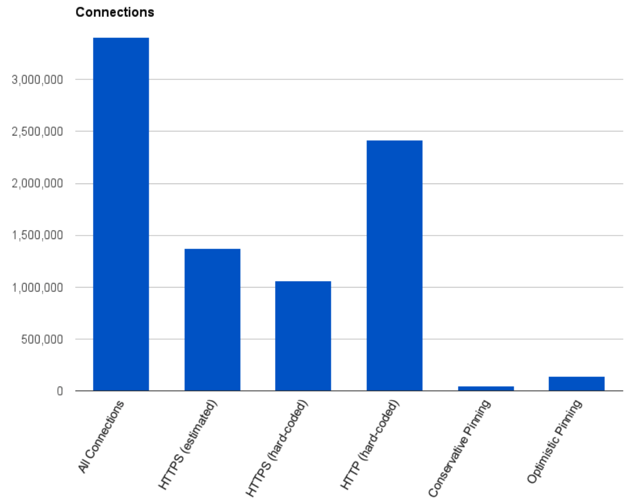

Figure 2: Statistics and Classification Results for Connections.

6.3 Update Frequencies

In addition to the strategy classification, a crucial requirement for pinning to work properly is the possibility to deploy quick updates for apps to distribute new pins. The applicability of pinning for Android apps in general depends on how quickly developers can push new certificate pins to their users' devices. Hence, we were interested in assessing the frequency for app updates.

Although newer Android versions have an auto update feature for apps, this feature is opt-in. Furthermore, the default is that app updates are only downloaded in case a device is connected to a WiFi. Hence, even auto-updates are not guaranteed to happen instantly.

Information about update frequencies is not easily accessible via Google Play. To gain insights into users' update behaviour, we cooperated with a popular anti-virus software vendor for Android with an install base of 5 million devices. Our cooperation partner runs a telemetry program and gathers user data for all users that participate in that program. From January 2014 to December 2014, we collected data for 784,721 unique apps and 871,911 unique users. The 871,911 users that participated in the telemetry program and gave their consent to anonymously analyze the data for our research yield the following meta information:

Pseudonym We assigned a 256-bit random pseudonym to each device to protect the users' privacy. The pseudonym did not reveal any private information.

DeviceInfo We collected manufacturer- and device model information as well as the installed Android version.

DeviceFlags We gathered three different flags for every device: (1) Whether developer options were enabled, (2) whether app installs from untrusted sources were allowed and (3) whether USB debugging was enabled.

PackageInfo For every (pre-)installed app we gathered the package name and version code.

PackageHashes For every (pre-)installed app we gathered SHA256 checksums of the packages and their corresponding signing keys.

Timestamps We gathered timestamps for when we saw an app version installed on a device.

Our interest focused on third party apps such as facebook or games, as these apps get updates pushed via Android's default update mechanism. We excluded Google apps and device vendor specific apps from our analysis, since these can be updated through special update channels provided by Google or the device vendor. We identified Google apps and device vendor apps based on the keys they have been signed with [6].

For third party apps, we found that on average 40% of all users update to a new version on the release day. Around half of all app users update within the first week after release and 70% update within 30 days after release. However, to update all devices, on average 200 days elapse. Figure 3 illustrates the average apps update periods.

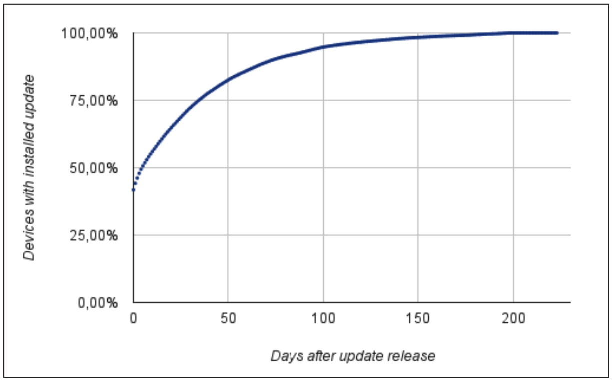

Figure 3: Average days between the release of a new app version and its installation.

These numbers illustrate that app updates are unsuitable for security-critical app components. In case of pinning, half of all users of an app would be unable to use the app during the first week after the update is released, since the pinning-secured TLS handshakes would fail [6].

6.4 Discussion

Our results have multiple major implications: The majority of TLS connections happen in third party libraries (86.33%) and another 68.85% of connections are established with shared hosts. However, although only 4.25% of all TLS connections seem to be good candidates for pinning, the current situation of only 45 apps that actually implement pinning leaves much room for improvement. An additional hurdle for deploying pinning are the lazy update frequencies of many users; losing half of the users for a total of one week after a certificate (pin) update is unacceptable for both app developers and their users. To facilitate the use of pinning for eligible developers, we cannot recommend to hard-code certificate pins into app binaries. Instead, pins should be included via configuration files that can easily be updated via a secure remote connection. Such an update mechanism could be enforced immediately and developers would not depend on the (lazy) update behaviour of their users. An alternative pinning deployment strategy would be to use multiple origins for a TLS connection, e. g. having `pin1.example.com` for one pin version and `pin2.example.com` for a second version. Both mechanisms allow for out-of-band pin updates but come with some extra effort on the developers' side.

7 Developer Support

After conducting a large scale analysis for real world Android apps and the applicability of pinning, we were also interested in the developers' point of view as the actors who actually implement pinning. First, we collected informative feedback from developers to learn more about their view on pinning. Second, based on their valuable and constructive feedback, we built a tool that supports developers in the process of deciding whether to implement pinning and eases the implementation.

7.1 Feedback

We analyzed all apps in our sample set and extracted possible candidates for pinning [7]. For those, we extracted the email addresses of the developers from Google Play, taking care not to create multiple emails for the same recipient, which left us with roughly 3,200 addresses. We emailed a random sample of 500 developers with an introductory email and the plea to provide us feedback on their experience with pinning, or, if they were not the developer, to please forward the email to their app's developer. Our outreach to developers was intended for a qualitative analysis of their feedback and comments to be used as the foundation to build our tool. A quantitative analysis was not our primary focus. We were able to gather 49[8] responses, of which we manually removed 4 who had answered in a nonsensical way or who clearly did not understand English. After we analyzed the 45 responses, we had gained insight into the major problem areas, a saturation of new input was reached and more responses would probably not have provided more valuable insights.

[6] We assume that apps use TLS-secured connections for critical components and do not work properly without Internet access.

[7] Here we made conservative choices to prevent unnecessarily bothering developers.

[8] Given the lack of a platform comparable to Amazon Mechanical Turk for software developer studies, which also means that they donate their time to our research for free, a response rate of 10% seems quite reasonable.

To build our tool with the best possible feature set and usability in mind, we were mainly interested in the following aspects:

Knowledge About Pinning 15 (a third) of our participants stated they knew what pinning was. We asked them to explain this knowledge, and their replies varied from correct mentions of "custom, self-signed certificates", "reduction of the reliance on intermediate/root certificates, if a intermediate/root gets compromised you don't." and "mobile apps that talk to the same well known server all the time" over "securing the communication between the app and the server without needing to pay to issuers out there" to "i don't know" and confused and/or wrong answers like "when you change the servers and/or certificates more often". We rated 80% of the answers as sensible.

Key Result: Only a quarter of the developers who gave us feedback have a basic understanding of pinning.

Desired Change: More detailed and critical explanation of what pinning is and how it works as part of the official Android documentation.

Obstacles Six participants had considered implementing pinning and decided against it. The reasons ranged from "laziness" over confusion to complaints about the complexity and the lack of an "out-of-the-box solution". To the two thirds of our participants who didn't know what pinning was, we showed a short explanatory text [9] and asked them to rate what they imagined could hypothetically keep them from using pinning or convince them to stay with the standard solution. We showed the same set of possible reasons to the developers who were informed about pinning and asked how much these reasons contributed to their not implementing pinning. They ranked "fear of losing users with old app versions / due to hard TLS fails" the highest, followed by "updates required when a certificate changes" and "complexity of the implementation". They said the standard solution was preferable, because "it is easier", they "trust in the existing CA-ecosystem" and "already own CA-signed certificates", but rather not because of "employing several different certificates".

Key Result: Of those who had heard of pinning, 40% had considered implementing it, but discounted it for being unusable or hard to implement.

Desired Change: Provide concrete sample code for the specific use case or app.

Wishlist We received wishes for "good tutorials and programming examples", "example code", "libraries across platforms", a "native Android API", a "test period and simple implementations" and the possibility to "do the same for the web front-end".

Key Result: Developers want better tool support and support in the decision process.

Desired Change: Easy-to-use tool support.

7.2 Tool Support

The developer feedback confirmed that more tool support is required and requested. When offering security solutions, we have to keep in mind that developers usually do not have a strong security focus and are not TLS experts, therefore, choosing and implementing secure solutions must be made as easy as possible. To this end, we built a tool that supports developers with implementing secure certificate validation in general; it additionally helps to decide whether pinning is the appropriate strategy. We made a web application publicly accessible at `https://pinning.android-ssl.org/`, which we base on our classification framework, the evaluation results and the developer study's results. We chose to implement our tool as a web application, since it is easily accessible and allows to keep the data backend up-to-date.

Developers and app users can upload APK files and have results presented to them in a clear web interface. First of all, the developers need to upload their app's APK file, whereupon the web application conducts all required information extraction steps (cf. Section 4) and presents the developer with an overview of relevant API calls and the corresponding remote origins that could be extracted. To increase accuracy, in the next step the developers are asked (1) whether they hold ownership for the relevant API calls and (2) whether they control the TLS configuration for the extracted remote origins (to keep the workflow as simple as possible and not overcharge the developer with unnecessary information, we filter out well known libraries and popular origins). Involving developers into the decision process is especially important in cases where automatic classification might not reveal accurate results, such as for configured origins (cf. Section 4).

Finally, the strategy classification is conducted and we present the developer with our recommendation for making their connections as secure as pos-

[9] taken and adapted from www.owasp.org

sible. In case the default strategy was selected, we do not recommend the developer to take further action. In case leaf or CA pinning is recommended, the developers are encouraged to increase their app's security by implementing pinning. However, we also inform the developers about the downsides of pinning in terms of updatability of certificate pins (cf. Section 6.3). In a last step, the developer is offered support for implementing pinning.

For any given relevant API call and the corresponding remote origin, concrete example code for pinning is generated over the following steps:

1. The remote origin's certificate is fetched and the corresponding pin is computed.
2. A `PinningTrustManager` that uses the pin for certificate validation is generated.
3. Surrounding code that includes the `PinningTrustManager` into the relevant API calls is generated, e.g. for an `HTTPSUrlConnection`, an `SSLContext` is generated that is initialized with the given `PinningTrustManager`.

The developer can then simply include this scaffold into the app and profit from a higher level of security. We asked the interested developers who left their contact information in our developer study to test our web application; 7 participated and gave positive feedback on its usability.

8 Limitations

In addition to the limitations described in Section 5.5, our work has three more limiations.

First, the update behaviour analysis we conducted for the users that participated in the AV's telemetry program might not necessarily represent the global update behaviour. However, we think that security affine users who install anti-virus software on their devices have a tendency to update their software more quickly than average users. Therefore, update frequencies for the global Android user population might be even worse.

Second, the feedback we got from app developers was based on self-reporting and might be influenced by a self-selection bias. Since we emailed developers who our classification framework had identified as good candidates for pinning, but offered them no incentive for taking part in our survey, we could only work with the developers who responded, leaving us with an opt-in bias. However, this is best practice for getting feedback from developers.

Third, our tool is currently implemented as a web service and a standalone command line tool. In the future, it would be reasonable to include the classification and recommendation process into the publication process in Google Play: An uploaded APK file could be run through the tool and unpinned but pinnable connections could be pointed out to the respective developer or pinned automatically via a library.

9 Conclusions

We conducted an extensive analysis on the applicability of pinning as an alternative and more secure certificate validation mechanism for non-browser software. Therefore, we analyzed 639,283 Android apps of which 229,317 (35.9%) use TLS to secure network connections and conservatively recommend pinning for 11,547 (1.8%) of all apps, or 5.0% of the apps that use TLS. This corresponds to 20,020,535 connections, of which 1,062,810 (5.3%) use TLS, of which 45,247 (4.25%) are conservatively recommendable for pinning. Optimistically, including estimates for unclassified connections as well as connections depending on dynamic code loading, we are able to suggest 140,858 connections or 58,817 (9.1%) apps to take pinning into consideration.

This contradicts the common assumption that pinning is a widely applicable solution for making TLS certificate validation in non-browser software more secure. Of the 229,317 apps we analyzed that make use of TLS to secure (some of) their network connections, 203,159 (88.6%) establish TLS connections via third-party libraries.

While we find that pinning is applicable only for relatively few apps and their TLS connections, a nominal-actual comparison illustrates that there is room for improving the current situation, as only 45 of the 11,481 apps that could benefit from pinning actually implement it. To help us understand affected developers and design a solution, we conducted a qualitative study with 45 developers, where we learned that pinning is relatively unknown and often neglected due to usability problems. These results incentivized us to build an easy-to-use web-application to support developers in the decision making process and guide them through the implementation of pinning for appropriate connections.

Our work concludes with the following take-aways:

Poor Support for Pinning The Android API lacks sufficient support for pinning: For low-level APIs, developers have to implement their own certificate validation and need detailed knowledge regarding pinning. For higher level APIs, support for pinning is missing entirely.

Limited Applicability The application of pinning in non-browser software such as apps is very limited: We recommend pinning for only 5.0% of the 229,317 TLS-enabled Android apps we analyzed.

Developer Education Developer feedback showed that only a third of the developers who could have implemented pinning had heard of it before. Pinning seems to be confusing and developers misinformed. In the future, better developer education is required as well as better developer support.

Security Updates Our analysis of update periods for Android apps suggests that Android requires mechanisms to quickly deploy security updates in the future (cf. Section 6.3).

Pinning Implementation The current Android documentation recommends to include pinning information at compile time, i. e. the recommendation is to add pins to the source code of an app. However, our analysis of the update behaviour of Android users suggests that developers should not implement certificate pins into an app's binary. Instead, we recommend to set pins via configuration files that are only accessible by the respective app.

Abstract

Source code authorship attribution is a significant privacy threat to anonymous code contributors. However, it may also enable attribution of successful attacks from code left behind on an infected system, or aid in resolving copyright, copyleft, and plagiarism issues in the programming fields. In this work, we investigate machine learning methods to de-anonymize source code authors of C/C++ using coding style. Our Code Stylometry Feature Set is a novel representation of coding style found in source code that reflects coding style from properties derived from abstract syntax trees.

Our random forest and abstract syntax tree-based approach attributes more authors (1,600 and 250) with significantly higher accuracy (94% and 98%) on a larger data set (Google Code Jam) than has been previously achieved. Furthermore, these novel features are robust, difficult to obfuscate, and can be used in other programming languages, such as Python. We also find that (i) the code resulting from difficult programming tasks is easier to attribute than easier tasks and (ii) skilled programmers (who can complete the more difficult tasks) are easier to attribute than less skilled programmers.

1 Introduction

Do programmers leave fingerprints in their source code? That is, does each programmer have a distinctive “coding style”? Perhaps a programmer has a preference for spaces over tabs, or `while` loops over `for` loops, or, more subtly, modular rather than monolithic code.

These questions have strong privacy and security implications. Contributors to open-source projects may hide their identity whether they are Bitcoin’s creator or just a programmer who does not want her employer to know about her side activities. They may live in a regime that prohibits certain types of software, such as censorship circumvention tools. For example, an Iranian programmer was sentenced to death in 2012 for developing photo sharing software that was used on pornographic websites [31].

The flip side of this scenario is that code attribution may be helpful in a forensic context, such as detection of ghostwriting, a form of plagiarism, and investigation of copyright disputes. It might also give us clues about the identity of malware authors. A careful adversary may only leave binaries, but others may leave behind code written in a scripting language or source code downloaded into the breached system for compilation.

While this problem has been studied previously, our work represents a qualitative advance over the state of the art by showing that Abstract Syntax Trees (ASTs) carry authorial ‘fingerprints.’ The highest accuracy achieved in the literature is 97%, but this is achieved on a set of only 30 programmers and furthermore relies on using programmer comments and larger amounts of training data [12, 14]. We match this accuracy on small programmer sets without this limitation. The largest scale experiments in the literature use 46 programmers and achieve 67.2% accuracy [10]. We are able to handle orders of magnitude more programmers (1,600) while using less training data with 92.83% accuracy. Furthermore, the features we are using are not trivial to obfuscate. We are able to maintain high accuracy while using commercial obfuscators. While abstract syntax trees can be obfuscated to an extent, doing so incurs significant overhead and maintenance costs.

Contributions. First, we use *syntactic features* for code stylometry. Extracting such features requires parsing of incomplete source code using a *fuzzy parser* to generate an *abstract syntax tree*. These features add a component to code stylometry that has so far remained almost completely unexplored. We provide evidence that these features are more fundamental and harder to obfuscate. Our complete feature set consists of a comprehensive set of around 120,000 layout-based, lexical, and syntactic features. With this complete feature set we are able to achieve a significant increase in accuracy compared to previous work. Second, we show that we can scale our method to 1,600 programmers without losing much accuracy. Third, this method is not specific to C or C++, and can be applied to any programming language.

We collected C++ source of thousands of contestants from the annual international competition "Google Code Jam". A bagging (portmanteau of "bootstrap aggregating") classifier - random forest was used to attribute programmers to source code. Our classifiers reach 98% accuracy in a 250-class closed world task, 93% accuracy in a 1,600-class closed world task, 100% accuracy on average in a two-class task. Finally, we analyze various attributes of programmers, types of programming tasks, and types of features that appear to influence the success of attribution. We identified the most important 928 features out of 120,000; 44% of them are syntactic, 1% are layout-based and the rest of the features are lexical. 8 training files with an average of 70 lines of code is sufficient for training when using the lexical, layout and syntactic features. We also observe that programmers with a greater skill set are more easily identifiable compared to less advanced programmers and that a programmer's coding style is more distinctive in implementations of difficult tasks as opposed to easier tasks.

The remainder of this paper is structured as follows. We begin by introducing applications of source code authorship attribution considered throughout this paper in Section 2, and present our AST-based approach in Section 3. We proceed to give a detailed overview of the experiments conducted to evaluate our method in Section 4 and discuss the insights they provide in Section 5. Section 6 presents related work, and Section 7 concludes.

2 Motivation

Throughout this work, we consider an analyst interested in determining the programmer of an anonymous fragment of source code purely based on its style. To do so, the analyst only has access to labeled samples from a set of candidate programmers, as well as from zero or more unrelated programmers.

The analyst addresses this problem by converting each labeled sample into a numerical feature vector, in order to train a machine learning classifier, that can subsequently be used to determine the code's programmer. In particular, this abstract problem formulation captures the following five settings and corresponding applications (see Table 1). The experimental formulations are presented in Section 4.2.

We emphasize that while these applications motivate our work, we have not directly studied them. Rather, we formulate them as variants of a machine-learning (classification) problem. Our data comes from the Google Code Jam competition, as we discuss in Section 4.1. Doubtless there will be additional challenges in using our techniques for digital forensics or any of the other real-world applications. We describe some known limitations in Section 5.

Programmer De-anonymization. In this scenario, the analyst is interested in determining the identity of an anonymous programmer. For example, if she has a set of programmers who she suspects might be Bitcoin's creator, Satoshi, and samples of source code from each of these programmers, she could use the initial versions of Bitcoin's source code to try to determine Satoshi's identity. Of course, this assumes that Satoshi did not make any attempts to obfuscate his or her coding style. Given a set of probable programmers, this is considered a closed-world machine learning task with multiple classes where anonymous source code is attributed to a programmer. This is a threat to privacy for open source contributors who wish to remain anonymous.

Ghostwriting Detection. Ghostwriting detection is related to but different from traditional plagiarism detection. We are given a suspicious piece of code and one or more candidate pieces of code that the suspicious code may have been plagiarized from. This is a well-studied problem, typically solved using code similarity metrics, as implemented by widely used tools such as MOSS [6], JPlag [25], and Sherlock [24].

For example, a professor may want to determine whether a student's programming assignment has been written by a student who has previously taken the class. Unfortunately, even though submissions of the previous year are available, the assignments may have changed considerably, rendering code-similarity based methods ineffective. Luckily, stylometry can be applied in this setting—we find the most stylistically similar piece of code from the previous year's corpus and bring both students in for gentle questioning. Given the limited set of students, this can be considered a closed-world machine learning problem.

Software Forensics. In software forensics, the analyst assembles a set of candidate programmers based on previously collected malware samples or online code repositories. Unfortunately, she cannot be sure that the anonymous programmer is one of the candidates, making this an *open world* classification problem as the test sample might not belong to any known category.

Copyright Investigation. Theft of code often leads to copyright disputes. Informal arrangements of hired programming labor are very common, and in the absence of a written contract, someone might claim a piece of code was her own after it was developed for hire and delivered. A dispute between two parties is thus a two-class classification problem; we assume that labeled code from both programmers is available to the forensic expert.

Authorship Verification. Finally, we may suspect that a piece of code was not written by the claimed programmer, but have no leads on who the actual programmer might be. This is the authorship verification problem. In this work, we take the textbook approach and model it as a two-class problem where positive examples come from previous works of the claimed programmer and negative examples come from randomly selected unrelated programmers. Alternatively, anomaly detection could be employed in this setting, e.g., using a one-class support vector machine [see 30].

As an example, a recent investigation conducted by Verizon [17] on a US company's anomalous virtual private network traffic, revealed an employee who was outsourcing her work to programmers in China. In such cases, training a classifier on employee's original code and that of random programmers, and subsequently testing pieces of recent code, could demonstrate if the employee was the actual programmer.

In each of these applications, the adversary may try to actively modify the program's coding style. In the software forensics application, the adversary tries to modify code written by her to hide her style. In the copyright and authorship verification applications, the adversary modifies code written by another programmer to match his own style. Finally, in the ghostwriting application, two of the parties may collaborate to modify the style of code written by one to match the other's style.

Application	Learner	Comments	Evaluation
De-anonymization	Multiclass	Closed world	Section 4.2.1
Ghostwriting detection	Multiclass	Closed world	Section 4.2.1
Software forensics	Multiclass	Open world	Section 4.2.2
Copyright investigation	Two-class	Closed world	Section 4.2.3
Authorship verification	Two/One-class	Open world	Section 4.2.4

Table 1: Overview of Applications for Code Stylometry

We emphasize that code stylometry that is robust to adversarial manipulation is largely left to future work. However, we hope that our demonstration of the power of features based on the abstract syntax tree will serve as the starting point for such research.

3 De-anonymizing Programmers

One of the goals of our research is to create a classifier that automatically determines the most likely author of a source file. Machine learning methods are an obvious choice to tackle this problem, however, their success crucially depends on the choice of a feature set that clearly represents programming style. To this end, we begin by parsing source code, thereby obtaining access to a wide range of possible features that reflect programming language use (Section 3.1). We then define a number of different features to represent both syntax and structure of program code (Section 3.2) and finally, we train a random forest classifier for classification of previously unseen source files (Section 3.3). In the following sections, we will discuss each of these steps in detail and outline design decisions along the way. The code for our approach is made available as open-source to allow other researchers to reproduce our results[1].

3.1 Fuzzy Abstract Syntax Trees

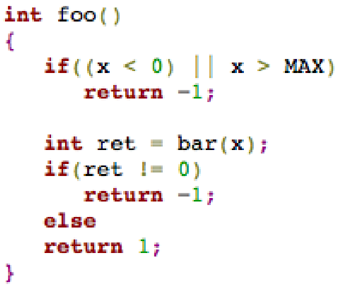
To date, methods for source code authorship attribution focus mostly on sequential feature representations of code such as byte-level and feature level n-grams [8, 13]. While these models are well suited to capture naming conventions and preference of keywords, they are entirely language agnostic and thus cannot model author characteristics that become apparent only in the composition of language constructs. For example, an author's tendency to create deeply nested code, unusually long functions or long chains of assignments cannot be modeled using n-grams alone.

Addressing these limitations requires source code to be parsed. Unfortunately, parsing C/C++ code using traditional compiler front-ends is only possible for *complete code*, i.e., source code where all identifiers can be resolved. This severely limits their applicability in the setting of authorship attribution as it prohibits analysis of lone functions or code fragments, as is possible with simple n-gram models.

As a compromise, we employ the fuzzy parser *Joern* that has been designed specifically with incomplete code in mind [32]. Where possible, the parser produces *abstract syntax trees* for code fragments while ignoring fragments that cannot be parsed without further information. The produced syntax trees form the basis for our feature extraction procedure. While they largely preserve the information required to create n-grams or bag-of-words representations, in addition, they allow a wealth of features to be extracted that encode programmer habits visible in the code's structure.

As an example, consider the function `foo` as shown in Figure 1, and a simplified version of its corresponding abstract syntax tree in Figure 2. The function contains a number of common language constructs found in many programming languages, such as if-statements (line 3 and 7), return-statements (line 4, 8 and 10), and function call expressions (line 6). For each of these constructs, the abstract syntax tree contains a corresponding node. While the leaves of the tree make classical syntactic features such as keywords, identifiers and operators accessible, inner nodes represent operations showing

[1] https://github.com/calaylin/CodeStylometry



```
int foo()
{
   if((x < 0) || x > MAX)
      return -1;

   int ret = bar(x);
   if(ret != 0)
      return -1;
   else
   return 1;
}
```

Figure 1: Sample Code Listing

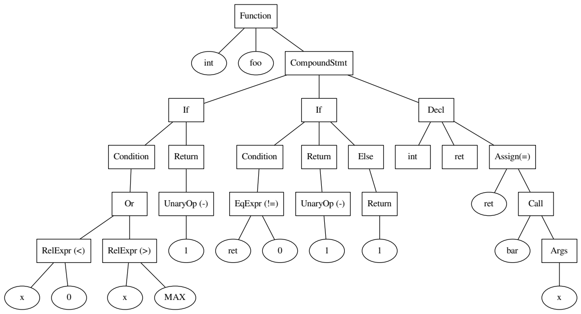


Figure 2: Corresponding Abstract Syntax Tree

how these basic elements are combined to form expressions and statements. In effect, the nesting of language constructs can also be analyzed to obtain a feature set representing the code's structure.

3.2 Feature Extraction

Analyzing coding style using machine learning approaches is not possible without a suitable representation of source code that clearly expresses program style. To address this problem, we present the *Code Stylometry Feature Set* (CSFS), a novel representation of source code developed specifically for code stylometry. Our feature set combines three types of features, namely *lexical features*, *layout features* and *syntactic features*. Lexical and layout features are obtained from source code while the syntactic features can only be obtained from ASTs. We now describe each of these feature types in detail.

3.2.1 Lexical and Layout Features

We begin by extracting numerical features from the source code that express preferences for certain identifiers and keywords, as well as some statistics on the use of functions or the nesting depth. Lexical and layout features can be calculated from the source code, without having access to a parser, with basic knowledge of the programming language in use. For example, we measure the number of functions per source line to determine the programmer's preference of longer over shorter functions. Furthermore, we tokenize the source file to obtain the number of occurrences of each token, so called *word unigrams*. Table 2 gives an overview of lexical features.

In addition, we consider *layout features* that represent code-indentation. For example, we determine whether the majority of indented lines begin with whitespace or tabulator characters, and we determine the ratio of whitespace to the file size. Table 3 gives a detailed description of these features.

Feature	**Definition**	**Count**
WordUnigramTF	Term frequency of word unigrams in source code	dynamic*
ln(num*keyword*/ length)	Log of the number of occurrences of *keyword* divided by file length in characters, where *keyword* is one of *do*, *else-if*, *if*, *else*, *switch*, *for* or *while*	7
ln(numTernary/ length)	Log of the number of ternary operators divided by file length in characters	1
ln(numTokens/ length)	Log of the number of word tokens divided by file length in characters	1
ln(numComments/ length)	Log of the number of comments divided by file length in characters	1
ln(numLiterals/ length)	Log of the number of string, character, and numeric literals divided by file length in characters	1
ln(numKeywords/ length)	Log of the number of unique keywords used divided by file length in characters	1
ln(numFunctions/ length)	Log of the number of functions divided by file length in characters	1
ln(numMacros/ length)	Log of the number of preprocessor directives divided by file length in characters	1
nestingDepth	Highest degree to which control statements and loops are nested within each other	1
branchingFactor	Branching factor of the tree formed by converting code blocks of files into nodes	1
avgParams	The average number of parameters among all functions	1
stdDevNumParams	The standard deviation of the number of parameters among all functions	1
avgLineLength	The average length of each line	1
stdDevLineLength	The standard deviation of the character lengths of each line	1
***About 55,000 for 250 authors with 9 files.**		

Table 2: Lexical Features

3.2.2 Syntactic Features

The syntactic feature set describes the properties of the language dependent abstract syntax tree, and keywords. Calculating these features requires access to an abstract syntax tree. All of these features are invariant to changes in source-code layout, as well as comments.

Table 4 gives an overview of our syntactic features. We obtain these features by preprocessing all C++ source files in the dataset to produce their abstract syntax trees.

Feature	Definition	Count
ln(numTabs/length)	Log of the number of tab characters divided by file length in characters	1
ln(numSpaces/length)	Log of the number of space characters divided by file length in characters	1
ln(numEmptyLines/length)	Log of the number of empty lines divided by file length in characters, excluding leading and trailing lines between lines of text	1
whiteSpaceRatio	The ratio between the number of whitespace characters (spaces, tabs, and newlines) and non-whitespace characters	1
newLineBefore OpenBrace	A boolean representing whether the majority of code-block braces are preceded by a newline character	1
tabsLeadLines	A boolean representing whether the majority of indented lines begin with spaces or tabs	1

Table 3: Layout Features

An abstract syntax tree is created for each function in the code. There are 58 node types in the abstract syntax tree (see Appendix A) produced by *Joern* [33].

Feature	Definition	Count
MaxDepthASTNode	Maximum depth of an AST node	1
ASTNodeBigramsTF	Term frequency AST node bigrams	dynamic*
ASTNodeTypesTF	Term frequency of 58 possible AST node type excluding leaves	58
ASTNodeTypesTFIDF	Term frequency inverse document frequency of 58 possible AST node type excluding leaves	58
ASTNodeTypeAvgDep	Average depth of 58 possible AST node types excluding leaves	58
cppKeywords	Term frequency of 84 C++ keywords	84
CodeInASTLeavesTF	Term frequency of code unigrams in AST leaves	dynamic**
CodeInASTLeaves TFIDF	Term frequency inverse document frequency of code unigrams in AST leaves	dynamic**
CodeInASTLeaves AvgDep	Average depth of code unigrams in AST leaves	dynamic**
***About 45,000 for 250 authors with 9 files.**		
****About 7,000 for 250 authors with 9 files.**		
****About 4,000 for 150 authors with 6 files.**		
****About 2,000 for 25 authors with 9 files.**		

Table 4: Syntactic Features

The AST node bigrams are the most discriminating features of all. AST node bigrams are two AST nodes that are connected to each other. In most cases, when used alone, they provide similar classification results to using the entire feature set.

The term frequency (TF) is the raw frequency of a node found in the abstract syntax trees for each file. The term frequency inverse document frequency (TFIDF) of nodes is calculated by multiplying the term frequency of a node by inverse document frequency. The goal in using the inverse document frequency is normalizing the term frequency by the number of authors actually using that particular type of node. The inverse document frequency is calculated by dividing the number of authors in the dataset by the number of authors that use that particular node. Consequently, we are able to capture how rare of a node it is and weight it more according to its rarity.

The maximum depth of an abstract syntax tree reflects the deepest level a programmer nests a node in the solution. The average depth of the AST nodes shows how nested or deep a programmer tends to use particular structural pieces. And lastly, term frequency of each C++ keyword is calculated. Each of these features is written to a feature vector to represent the solution file of a specific author and these vectors are later used in training and testing by machine learning classifiers.

3.3 Classification

Using the feature set presented in the previous section, we can now express fragments of source code as numerical vectors, making them accessible to machine learning algorithms. We proceed to perform feature selection and train a random forest classifier capable of identifying the most likely author of a code fragment.

3.3.1 Feature Selection

Due to our heavy use of unigram term frequency and TF/IDF measures, and the diversity of individual terms in the code, our resulting feature vectors are extremely large and sparse, consisting of tens of thousands of features for hundreds of classes. The dynamic *Code stylometry feature set*, for example, produced close to 120,000 features for 250 authors with 9 solution files each.

In many cases, such feature vectors can lead to overfitting (where a rare term, by chance, uniquely identifies a particular author). Extremely sparse feature vectors can also damage the accuracy of random forest classifiers, as the sparsity may result in large numbers of zero-valued features being selected during the random subsampling of the features to select a best split. This reduces the number of 'useful' splits that can be obtained at any given node, leading to poorer fits and larger trees. Large, sparse feature vectors can also lead to slowdowns in model fitting and evaluation, and are often more difficult to interpret. By selecting a smaller number of more informative features, the sparsity in the feature vector can be greatly reduced, thus allowing the classifier to both produce more accurate results and fit the data faster.

We therefore employed a feature selection step using WEKA's information gain [26] criterion, which evaluates the difference between the entropy of the distribution of classes and the entropy of the conditional distribution of classes given a particular feature:

$$IG(A, M_i) = H(A) - H(A|M_i) \qquad (1)$$

where A is the class corresponding to an author, H is Shannon entropy, and M_i is the i^{th} feature of the dataset. Intuitively, the information gain can be thought of as measuring the amount of information that the observation of the value of feature i gives about the class label associated with the example.

To reduce the total size and sparsity of the feature vector, we retained only those features that individually had non-zero information gain. (These features can be referred to as IG-CSFS throughout the rest of the paper.) Note that, as $H(A|M_i) \leq H(A)$, information gain is always non-negative. While the use of information gain on a variable-per-variable basis implicitly assumes independence between the features with respect to their impact on the class label, this conservative approach to feature selection means that we only use features that have demonstrable value in classification.

To validate this approach to feature selection, we applied this method to two distinct sets of source code files, and observed that sets of features with non-zero information gain were nearly identical between the two sets, and the ranking of features was substantially similar between the two. This suggests that the application of information gain to feature selection is producing a robust and consistent set of features (see Section 4 for further discussion). All the results are calculated by using CSFS and IG-CSFS. Using IG-CSFS on all experiments demonstrates how these features generalize to different datasets that are larger in magnitude. One other advantage of IG-CSFS is that it consists of a few hundred features that result in non-sparse feature vectors. Such a compact representation of coding style makes de-anonymizing thousands of programmers possible in minutes.

3.3.2 Random Forest Classification

We used the random forest ensemble classifier [7] as our classifier for authorship attribution. Random forests are ensemble learners built from collections of decision trees, each of which is grown by randomly sampling N training samples with replacement, where N is the number of instances in the dataset. To reduce correlation between trees, features are also subsampled; commonly $(logM)+1$ features are selected at random (without replacement) out of M, and the best split on these $(logM)+1$ features is used to split the tree nodes. The number of selected features represents one of the few tuning parameters in random forests: increasing the number of features increases the correlation between trees in the forest which can harm the accuracy of the overall ensemble, however increasing the number of features that can be chosen at each split increases the classification accuracy of each individual tree making them stronger classifiers with low error rates. The optimal range of number of features can be found using the out of bag (oob) error estimate, or the error estimate derived from those samples not selected for training on a given tree.

During classification, each test example is classified via each of the trained decision trees by following the binary decisions made at each node until a leaf is reached, and the results are then aggregated. The most populous class can be selected as the output of the forest for simple classification, or classifications can be ranked according to the number of trees that 'voted' for a label when performing relaxed attribution (see Section 4.3.4).

We employed random forests with 300 trees, which empirically provided the best trade-off between accuracy and processing time. Examination of numerous oob values across multiple fits suggested that $(logM)+1$ random features (where M denotes the total number of features) at each split of the decision trees was in fact optimal in all of the experiments (listed in Section 4), and was used throughout. Node splits were selected based on the information gain criteria, and all trees were grown to the largest extent possible, without pruning.

The data was analyzed via k-fold cross-validation, where the data was split into training and test sets stratified by author (ensuring that the number of code samples per author in the training and test sets was identical across authors). k varies according to datasets and is equal to the number of instances present from each author. The cross-validation procedure was repeated 10 times, each with a different random seed. We report the average results across all iterations in the results, ensuring that they are not biased by improbably easy or difficult to classify subsets.

4 Evaluation

In the evaluation section, we present the results to the possible scenarios formulated in the problem statement and evaluate our method. The corpus section gives an overview of the data we collected. Then, we present the main results to programmer de-anonymization and how it scales to 1,600 programmers, which is an immediate privacy concern for open source contributors that prefer to remain anonymous. We then present the training data requirements and efficacy of types of features. The obfuscation section discusses a possible countermeasure to programmer de-anonymization. We then present possible machine learning formulations along with the verification section that extends the approach to an open world problem. We conclude the evaluation with generalizing the method to other programming languages and providing software engineering insights.

4.1 Corpus

One concern in source code authorship attribution is that we are actually identifying differences in coding style, rather than merely differences in functionality. Consider the case where Alice and Bob collaborate on an open source project. Bob writes user interface code whereas Alice works on the network interface and backend analytics. If we used a dataset derived from their project, we might differentiate differences between frontend and backend code rather than differences in style.

In order to minimize these effects, we evaluate our method on the source code of solutions to programming tasks from the international programming competition *Google Code Jam (GCJ)*, made public in 2008 [2]. The competition consists of algorithmic problems that need to be solved in a programming language of choice. In particular, this means that all programmers solve the same problems, and hence implement similar functionality, a property of the dataset crucial for code stylometry analysis.

The dataset contains solutions by professional programmers, students, academics, and hobbyists from 166 countries. Participation statistics are similar over the years. Moreover, it contains problems of different difficulty, as the contest takes place in several rounds. This allows us to assess whether coding style is related to programmer experience and problem difficulty.

The most commonly used programming language was C++, followed by Java, and Python. We chose to investigate source code stylometry on C++ and C because of their popularity in the competition and having a parser for C/C++ readily available [32]. We also conducted some preliminary experimentation on Python.

A validation dataset was created from 2012's GCJ competition. Some problems had two stages, where the second stage involved answering the same problem in a limited amount of time and for a larger input. The solution to the large input is essentially a solution for the small input but not vice versa. Therefore, collecting both of these solutions could result in duplicate and identical source code. In order to avoid multiple entries, we only collected the small input versions' solutions to be used in our dataset.

The programmers had up to 19 solution files in these datasets. Solution files have an average of 70 lines of code per programmer.

To create our experimental datasets that are discussed in further detail in the results section;
(i) We first partitioned the corpus of files by year of competition. The "main" dataset includes files drawn from 2014 (250 programmers). The "validation" dataset files come from 2012, and the "multi-year" dataset files come from years 2008 through 2014 (1,600 programmers).
(ii) Within each year, we ordered the corpus files by the round in which they were written, and by the problem within a round, as all competitors proceed through the same sequence of rounds in that year. As a result, we performed stratified cross validation on each program file by the year it was written, by the round in which the program was written, by the problems solved in the round, and by the author's highest round completed in that year.

Some limitations of this dataset are that it does not allow us to assess the effect of style guidelines that may be imposed on a project or attributing code with multiple/mixed programmers. We leave these interesting questions for future work, but posit that our improved results with basic stylometry make them worthy of study.

4.2 Applications

In this section, we will go over machine learning task formulations representing five possible real-world applications presented in Section 2.

4.2.1 Multiclass Closed World Task

This section presents our main experiment—de-anonymizing 250 programmers in the difficult scenario where all programmers solved the same set of problems. The machine learning task formulation for de-anonymizing programmers also applies to ghostwriting detection. The biggest dataset formed from 2014's Google Code Jam Competition with 9 solution files to the same problem had 250 programmers. These were the easiest set of 9 problems, making the classification more challenging (see Section 4.3.6). We reached 91.78% accuracy in classifying 250 programmers with the *Code Stylometry Feature Set*. After applying information gain and using the features that had information gain, the accuracy was 95.08%.

We also took 250 programmers from different years and randomly selected 9 solution files for each one of them. We used the information gain features obtained from 2014's dataset to see how well they generalize. We reached 98.04% accuracy in classifying 250 programmers. This is 3% higher than the controlled large dataset's results. The accuracy might be increasing because of using a mixed set of Google Code Jam problems, which potentially contains the possible solutions' properties along with programmers' coding style and makes the code more distinct.

We wanted to evaluate our approach and validate our method and important features. We created a dataset from 2012's Google Code Jam Competition with 250 programmers who had the solutions to the same set of 9 problems. We extracted only the features that had positive information gain in 2014's dataset that was used as the main dataset to implement the approach. The classification accuracy was 96.83%, which is higher than the 95.07% accuracy obtained in 2014's dataset.

The high accuracy of validation results in Table 5 show that we identified the important features of code stylometry and found a stable feature set. This feature set does not necessarily represent the exact features for all possible datasets. For a given dataset that has ground truth information on authorship, following the same approach should generate the most important features that represent coding style in that particular dataset.

A = #programmers, F = max #problems completed		
N = #problems included in dataset (N ≤ F)		
A = 250 from 2014	**A = 250 from 2012**	**A = 250 all years**
F = 9 from 2014	**F = 9 from 2014**	**F ≥ 9 all years**
N = 9	**N = 9**	**N = 9**
Average accuracy after 10 iterations with IG-CSFS features		
95.07%	**96.83%**	**98.04%**

Table 5: Validation Experiments

4.2.2 Mutliclass Open World Task

The experiments in this section can be used in software forensics to find out the programmer of a piece of malware. In software forensics, the analyst does not know if source code belongs to one of the programmers in the candidate set of programmers. In such cases, we can classify the anonymous source code, and if the majority number of votes of trees in the random forest is below a certain threshold, we can reject the classification considering the possibility that it might not belong to any of the classes in the training data. By doing so, we can scale our approach to an open world scenario, where we might not have encountered the suspect before. As long as we determine a confidence threshold based on training data [30], we can calculate the probability that an instance belongs to one of the programmers in the set and accordingly accept or reject the classification.

We performed 270 classifications in a 30-class problem using all the features to determine the confidence threshold based on the training data. The accuracy was 96.67%. There were 9 misclassifications and all of them were classified with less than 15% confidence by the classifier. The class probability or classification confidence that source code fragment C is of class i is calculated by taking the percentage of trees in the random forest that voted for that particular class, as follows2:

$$P(C_i) = \frac{\sum_j V_j(i)}{|T|_f} \tag{2}$$

Where $V_j(i) = 1$ if the j^{th} tree voted for class i and 0 otherwise, and $|T|_f$ denotes the total number of trees in forest f. Note that by construction, $\sum_i P(C_i) = 1$ and $P(C_i) \geq 0 \; \forall \; i$, allowing us to treat $P(C_i)$ as a probability measure.

There was one correct classification made with 13.7% confidence. This suggests that we can use a threshold between 13.7% and 15% confidence level for verification, and manually analyze the classifications that did not pass the confidence threshold or exclude them from results.

We picked an aggressive threshold of 15% and to validate it, we trained a random forest classifier on the same set of 30 programmers 270 code samples. We tested on 150 different files from the programmers in the training set. There were 6 classifications below the 15% threshold and two of them were misclassified. We took another set of 420 test files from 30 programmers that were not in the training set. All the files from the 30 programmers were attributed to one of the 30 programmers in the training set since this is a closed world classification task, however, the highest confidence level in these classifications was 14.7%. The 15% threshold catches all the instances that do not belong to the programmers in the suspect set, gets rid of 2 misclassifications and 4 correct classifications. Consequently, when we see a classification with less than a threshold value, we can reject the classification and attribute the test instance to an unknown suspect.

4.2.3 Two-class Closed World Task

Source code author identification could automatically deal with source code copyright disputes without requiring manual analysis by an objective code investigator. A copyright dispute on code ownership can be resolved by comparing the styles of both parties claiming to have generated the code. The style of the disputed code can be compared to both parties' other source code to aid in the investigation. To imitate such a scenario, we took 60 different pairs of programmers, each with 9 solution files. We used a random forest and 9-fold cross validation to classify two programmers' source code. The average classification accuracy using CSFS set is 100.00% and 100.00% with the information gain features.

4.2.4 Two-class/One-class Open World Task

Another two-class machine learning task can be formulated for authorship verification. We suspect Mallory of plagiarizing, so we mix in some code of hers with a large sample of other people, test, and see if the disputed code gets classified as hers or someone else's. If it gets classified as hers, then it was with high probability really written by her. If it is classified as someone else's, it really was someone else's code. This could be an open world problem and the person that originally wrote the code could be a previously unknown programmer.

This is a two-class problem with classes Mallory and others. We train on Mallory's solutions to problems a, b, c, d, e, f, g, h. We also train on programmer A's solution to problem a, programmer B's solution to problem b, programmer C's solution to problem c, programmer D's solution to problem d, programmer E's solution to problem e, programmer F's solution to problem f, programmer G's solution to problem g, programmer H's solution to problem h and put them in one class called ABCDEFGH. We train a random forest classifier with 300 trees on classes Mallory and ABCDEFGH. We have 6 test instances from Mallory and 6 test instances from another programmer ZZZZZZ, who is not in the training set.

These experiments have been repeated in the exact same setting with 80 different sets of programmers ABCDEFGH, ZZZZZZ and Mallorys. The average classification accuracy for Mallory using the CSFS set is 100.00%. ZZZZZZ's test instances are classified as programmer ABCDEFGH 82.04% of the time, and classified as Mallory for the rest of the time while using the CSFS. Depending on the amount of false positives we are willing to accept, we can change the operating point on the ROC curve.

These results are also promising for use in cases where a piece of code is suspected to be plagiarized. Following the same approach, if the classification result of the piece of code is someone other than Mallory, that piece of code was with very high probability not written by Mallory.

4.3 Additional Insights

4.3.1 Scaling

We collected a larger dataset of 1,600 programmers from various years. Each of the programmers had 9 source code samples. We created 7 subsets of this large dataset in differing sizes, with 250, 500, 750, 1,000, 1,250, 1,500, and 1,600 programmers. These subsets are useful to understand how well our approach scales. We extracted the specific features that had information gain in the main 250 programmer dataset from this large dataset. In theory, we need to use more trees in the random forest as the number of classes increase to decrease variance, but we used fewer trees compared to smaller experiments. We used 300 trees in the random forest to run the experiments in a reasonable amount of time with a reasonable amount of memory. The accuracy did not decrease too much when increasing the number of programmers. This result shows that information gain features are robust against changes in class and are important properties of programmers' coding styles. The following Figure 3 demonstrates how well our method scales. We are able to de-anonymize 1,600 programmers using 32GB memory within one hour. Alternately, we can use 40 trees and get nearly the same accuracy (within 0.5%) in a few minutes.

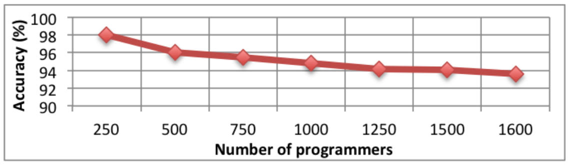

Figure 3: Large Scale De-anonymization

4.3.2 Training Data and Features

We selected different sets of 62 programmers that had F solution files, from 2 up to 14. Each dataset has the solutions to the same set of F problems by different sets of programmers. Each dataset consisted of programmers that were able to solve exactly F problems. Such an experimental setup makes it possible to investigate the effect of programmer skill set on coding style. The size of the datasets were limited to 62, because there were only 62 contestants with 14 files. There were a few contestants with up to 19 files but we had to exclude them since there were not enough programmers to compare them.

The same set of F problems were used to ensure that the coding style of the programmer is being classified and not the properties of possible solutions of the problem itself. We were able to capture personal programming style since all the programmers are coding the same functionality in their own ways.

Stratified F-fold cross validation was used by training on everyone's $(F-1)$ solutions and testing on the F^{th} problem that did not appear in the training set. As a result, the problems in the test files were encountered for the first time by the classifier.

We used a random forest with 300 trees and *(logM)+1* features with F-fold stratified cross validation, first with the *Code Stylometry Feature Set* (CSFS) and then with the CSFS's features that had information gain.

Figure 4 shows the accuracy from 13 different sets of 62 programmers with 2 to 14 solution files, and consequently 1 to 13 training files. The *CSFS* reaches an optimal training set size at 9 solution files, where the classifier trains on 8 $(F-1)$ solutions.

In the datasets we constructed, as the number of files increase and problems from more advanced rounds are included, the average line of code (LOC) per file also increases. The average lines of code per source code in the dataset is 70. Increased number of lines of code might have a positive effect on the accuracy but at the same time it reveals programmer's choice of program

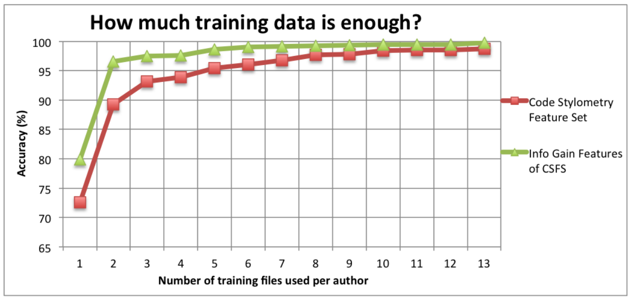

Figure 4: Training Data

length in implementing the same functionality. On the other hand, the average line of code of the 7 easier (76 LOC) or difficult problems (83 LOC) taken from contestants that were able to complete 14 problems, is higher than the average line of code (68) of contestants that were able to solve only 7 problems. This shows that programmers with better skills tend to write longer code to solve Google Code Jam problems. The mainstream idea is that better programmers write shorter and cleaner code which contradicts with line of code statistics in our datasets. Google Code Jam contestants are supposed to optimize their code to process large inputs with faster performance. This implementation strategy might be leading to advanced programmers implementing longer solutions for the sake of optimization.

We took the dataset with 62 programmers each with 9 solutions. We get 97.67% accuracy with all the features and 99.28% accuracy with the information gain features. We excluded all the syntactic features and the accuracy dropped to 88.89% with all the non-syntactic features and 88.35% with the information gain features of the non-syntactic feature set. We ran another experiment using only the syntactic features and obtained 96.06% with all the syntactic features and 96.96% with the information gain features of the syntactic feature set. Most of the classification power is preserved with the syntactic features, and using non-syntactic features leads to a significant decline in accuracy.

4.3.3 Obfuscation

We took a dataset with 9 solution files and 20 programmers and obfuscated the code using an off-the-shelf C++ obfuscator called stunnix [3]. The accuracy with the information gain code stylometry feature set on the obfuscated dataset is 98.89%. The accuracy on the same dataset when the code is not obfuscated is 100.00%. The obfuscator refactored function and variable names, as well as comments, and stripped all the spaces, preserving the functionality of code without changing the structure of the program. Obfuscating the data produced little detectable change in the performance of the classifier for this sample. The results are summarized in Table 6.

We took the maximum number of programmers, 20, that had solutions to 9 problems in C and obfuscated the code (see example in Appendix B) using a much more sophisticated open source obfuscator called Tigress [1]. In particular, Tigress implements *function virtualization*, an obfuscation technique that turns functions into interpreters and converts the original program into corresponding bytecode. After applying function virtualization, we were less able to effectively de-anonymize programmers, so it has potential as a countermeasure to programmer de-anonymization. However, this obfuscation comes at a cost. First of all, the obfuscated code is neither readable nor maintainable, and is thus unsuitable for an open source project. Second, the obfuscation adds significant overhead (9 times slower) to the runtime of the program, which is another disadvantage.

The accuracy with the information gain feature set on the obfuscated dataset is reduced to 67.22%. When we limit the feature set to AST node bigrams, we get 18.89% accuracy, which demonstrates the need for all feature types in certain scenarios. The accuracy on the same dataset when the code is not obfuscated is 95.91%.

Obfuscator	Programmers	Lang	Results w/o Obfuscation	Results w/ Obfuscation
Stunnix	20	C++	98.89%	100.00%
Stunnix	20	C++	98.89*%	98.89*%
Tigress	20	C	93.65%	58.33%
Tigress	20	C	95.91*%	67.22*%
*Information gain features				

Table 6: Effect of Obfuscation on De-anonymization

4.3.4 Relaxed Classification

The goal here is to determine whether it is possible to reduce the number of suspects using code stylometry. Reducing the set of suspects in challenging cases, such as having too many suspects, would reduce the effort required to manually find the actual programmer of the code.

In this section, we performed classification on the main 250 programmer dataset from 2014 using the information gain features. The classification was relaxed to a set of top *R* suspects instead of exact classification of the programmer. The relaxed factor *R* varied from 1 to 10. Instead of taking the highest majority vote of the decisions trees in the random forest, the highest *R* majority vote decisions were taken and the classification result was considered correct if the programmer was in the set of top *R* highest voted classes. The accuracy does not improve much after the relaxed factor is larger than 5.

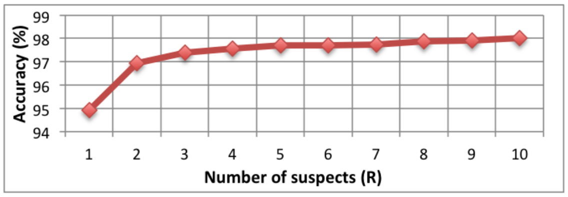

Figure 5: Relaxed Classification with 250 Programmers

4.3.5 Generalizing the Method

Features derived from ASTs can represent coding styles in various languages. These features are applicable in cases when lexical and layout features may be less discriminating due to formatting standards and reliance on whitespace and other 'lexical' features as syntax, such as Python's PEP8 formatting. To show that our method generalizes, we collected source code of 229 Python programmers from GCJ's 2014 competition. 229 programmers had exactly 9 solutions. **Using only the Python equivalents of syntactic features** listed in Table 4 and 9-fold cross-validation, the average accuracy is 53.91% for top-1 classification, 75.69% for top-5 relaxed attribution. The largest set of programmers to all work on the same set of 9 problems was 23 programmers. The average accuracy in identifying these 23 programmers is 87.93% for top-1 and 99.52% for top-5 relaxed attribution. The same classification tasks using the information gain features are also listed in Table 7. The overall accuracy in datasets composed of Python code are lower than C++ datasets. In Python datasets, we only used syntactic features from ASTs that were generated by a parser that was not fuzzy. The lack of quantity and specificity of features accounts for the decreased accuracy. The Python dataset's information gain features are significantly fewer in quantity, compared to C++ dataset's information gain features. Information gain only keeps features that have discriminative value all on their own. If two features only provide discriminative value when used together, then information gain will discard them. So if a lot of the features for the Python set are only jointly discriminative (and not individually discriminative), then the information gain criteria may be removing features that in combination could effectively discriminate between authors. This might account for the decrease when using information gain features. While in the context of other results in this paper the results in Table 7 appear lackluster, it is worth noting that even this preliminary test using only syntactic features has comparable performance to other prior work at a similar scale (see Section 6 and Table 9), demonstrating the utility of syntactic features and the relative ease of generating them for novel programming languages. Nevertheless, a CSFS equivalent feature set can be generated for other programming languages by implementing the layout and lexical features as well as using a fuzzy parser.

Lang.	Programmers	Classification	IG	Top-5	Top-5 IG
Python	23	87.93%	79.71%	99.52%	96.62
Python	229	53.91%	39.16%	75.69%	55.46

Table 7: Generalizing to Other Programming Languages

4.3.6 Software Engineering Insights

We wanted to investigate if programming style is consistent throughout years. We found the contestants that had the same username and country information both in 2012 and 2014. We assumed that these are the same people but there is a chance that they might be different people. In 2014, someone else might have picked up the same username from the same country and started using it. We are going to ignore such a ground truth problem for now and assume that they are the same people.

We took a set of 25 programmers from 2012 that were also contestants in 2014's competition. We took 8 files from their submissions in 2012 and trained a random forest classifier with 300 trees using CSFS. We had one instance from each one of the contestants from 2014. The correct classification of these test instances from 2014 is 96.00%. The accuracy dropped to 92.00% when using only information gain features, which might be due to the aggressive elimination of pairs of features that are jointly discriminative. These 25 programmers' 9 files from 2014 had a correct classification accuracy of 98.04%. These results indicate that coding style is preserved up to some degree throughout years.

To investigate problem difficulty's effect on coding style, we created two datasets from 62 programmers that had exactly 14 solution files. Table 8 summarizes the following results. A dataset with 7 of the easier problems out of 14 resulted in 95.62% accuracy. A dataset with 7 of the more difficult problems out of 14 resulted in 99.31% accuracy. This might imply that more difficult coding tasks have a more prevalent reflection of coding style. On the other hand, the dataset that had 62 programmers with exactly 7 of the easier problems resulted in 91.24% accuracy, which is a lot lower than the accuracy obtained from the dataset whose programmers were able to advance to solve 14 problems. This might indicate that, programmers who are advanced enough to answer 14 problems likely have more unique coding styles compared to contestants that were only able to solve the first 7 problems.

To investigate the possibility that contestants who are able to advance further in the rounds have more unique coding styles, we performed a second round of experiments on comparable datasets. We took the dataset with

12 solution files and 62 programmers. A dataset with 6 of the easier problems out of 12 resulted in 91.39% accuracy. A dataset with 6 of the more difficult problems out of 12 resulted in 94.35% accuracy. These results are higher than the dataset whose programmers were only able to solve the easier 6 problems. The dataset that had 62 programmers with exactly 6 of the easier problems resulted in 90.05% accuracy.

5 Discussion

In this section, we discuss the conclusions we draw from the experiments outlined in the previous section, limitations, as well as questions raised by our results. In particular, we discuss the difficulty of the different settings considered, the effects of obfuscation, and limitations of our current approach.

Problem Difficulty. The experiment with random problems from random authors among seven years most closely resembles a real world scenario. In such an experimental setting, there is a chance that instead of only identifying authors we are also identifying the properties of a specific problem's solution, which results in a boost in accuracy.

In contrast, our main experimental setting where all authors have only answered the nine easiest problems is possibly the hardest scenario, since we are training on the same set of eight problems that all the authors have algorithmically solved and try to identify the authors from the test instances that are all solutions of the 9th problem. On the upside, these test instances help us precisely capture the differences between individual coding style that represent the same functionality. We also see that such a scenario is harder since the randomized dataset has higher accuracy.

Classifying authors that have implemented the solution to a set of difficult problems is easier than identifying authors with a set of easier problems. This shows that coding style is reflected more through difficult programming tasks. This might indicate that programmers come up with unique solutions and preserve their coding style more when problems get harder. On the other hand, programmers with a better skill set have a prevalent coding style which can be identified more easily compared to contestants who were not able to advance as far in the competition. This might indicate that as programmers become more advanced, they build a stronger coding style compared to novices. There is another possibility that maybe better programmers start out with a more unique coding style.

Effects of Obfuscation. A malware author or plagiarizing programmer might deliberately try to hide his source code by obfuscation. Our experiments indicate that our method is resistant to simple off-the-shelf obfuscators such as stunnix, that make code look cryptic while preserving functionality. The reason for this success is that the changes stunnix makes to the code have no effect on syntactic features, e.g., removal of comments, changing of names, and stripping of whitespace.

In contrast, sophisticated obfuscation techniques such as function virtualization hinder de-anonymization to some degree, however, at the cost of making code unreadable and introducing a significant performance penalty. Unfortunately, unreadability of code is not acceptable for open-source projects, while it is no problem for attackers interested in covering their tracks. Developing methods to automatically remove stylometric information from source code without sacrificing readability is therefore a promising direction for future research.

Limitations. We have not considered the case where a source file might be written by a different author than the stated contestant, which is a ground truth problem that we cannot control. Moreover, it is often the case that code fragments are the work of multiple authors. We plan to extend this work to study such datasets. To shed light on the feasibility of classifying such code, we are currently working with a dataset of git commits to open source projects. Our parser works on code fragments rather than complete code, consequently we believe this analysis will be possible.

Another fundamental problem for machine learning classifiers are mimicry attacks. For example, our classifier may be evaded by an adversary by adding extra dummy code to a file that closely resembles that of another programmer, albeit without affecting the program's behavior. This evasion is possible, but trivial to resolve when an analysts verifies the decision.

Finally, we cannot be sure whether the original author is actually a Google Code Jam contestant. In this case, we can detect those by a classify and then verify approach as explained in Stolerman et al.'s work [30]. Each classification could go through a verification step to eliminate instances where the classifier's confidence is below a threshold. After the verification step, instances that do not belong to the set of known authors can be separated from the dataset to be excluded or for further manual analysis.

6 Related Work

Our work is inspired by the research done on authorship attribution of unstructured or semi-structured text [5, 22]. In this section, we discuss prior work on source code authorship attribution. In general, such work (Table 9) looks at smaller scale problems, does not use structural features, and achieves lower accuracies than our work.

The highest accuracies in the related work are achieved by Frantzeskou et al. [12, 14]. They used 1,500 7-grams to reach 97% accuracy with 30 programmers. They investigated the high-level features that contribute to source code authorship attribution in Java and Common Lisp. They determined the importance of each feature by iteratively excluding one of the features from the feature set. They showed that comments, layout features and naming patterns have a strong influence on the author classification accuracy. They used more training data (172 line of code on average) than us (70 lines of code). We replicated their experiments on a 30 programmer subset of our C++ data set, with eleven files containing 70 lines of code on average and no comments. We reach 76.67% accuracy with 6-grams, and 76.06% accuracy with 7-grams. When we used a 6 and 7-gram feature set on 250 programmers with 9 files, we got 63.42% accuracy. With our original feature set, we get 98% accuracy on 250 programmers.

The largest number of programmers studied in the related work was 46 programmers with 67.2% accuracy. Ding and Samadzadeh [10] use statistical methods for authorship attribution in Java. They show that among lexical, keyword and layout properties, layout metrics have a more important role than others which is not the case in our analysis.

There are also a number of smaller scale, lower accuracy approaches in the literature [9, 11, 18–21, 28], shown in Table 9, all of which we significantly outperform. These approaches use a combination of layout and lexical features.

The only other work to explore structural features is by Pellin [23], who used manually parsed abstract syntax trees with an SVM that has a tree based kernel to classify functions of two programmers. He obtains an average of 73% accuracy in a two class classification task. His approach explained in the white paper can be extended to our approach, so it is the closest to our work in the literature. This work demonstrates that it is non-trivial to use ASTs effectively. Our work is the first to use structural features to achieve higher accuracies at larger scales and the first to study how code obfuscation affects code stylometry.

There has also been some code stylometry work that focused on manual analysis and case studies. Spafford and Weeber [29] suggest that use of lexical features such as variable names, formatting and comments, as well as some syntactic features such as usage of keywords, scoping and presence of bugs could aid in source code attribution but they do not present results or a case study experiment with a formal approach. Gray et al. [15] identify three categories in code stylometry: the layout of the code, variable and function naming conventions, types of data structures being used and also the cyclomatic complexity of the code obtained from the control flow graph. They do not mention anything about the syntactic characteristics of code, which could potentially be a great marker of coding style that reveals the usage of programming language's grammar. Their case study is based on a manual analysis of three worms, rather than a statistical learning approach. Hayes and Offutt [16] examine coding style in source code by their consistent programmer hypothesis. They focused on lexical and layout features, such as the occurrence of semicolons, operators and constants. Their dataset consisted of 20 programmers and the analysis was not automated. They concluded that coding style exists through some of their features and professional programmers have a stronger programming style compared to students. In our results in Section 4.3.6, we also show that more advanced programmers have a more identifying coding style.

There is also a great deal of research on plagiarism detection which is carried out by identifying the similarities between different programs. For example, there is a widely used tool called Moss that originated from Stanford University for detecting software plagiarism. Moss [6] is able to analyze the similarities of code written by different programmers. Rosenblum et al. [27] present a novel program representation and techniques that automatically detect the stylistic features of binary code.

7 Conclusion and Future Work

Source code stylometry has direct applications for privacy, security, software forensics, plagiarism, copyright infringement disputes, and authorship verification. Source code stylometry is an immediate concern for programmers who want to contribute code anonymously because de-anonymization is quite possible. We introduce the first principled use of syntactic features along with lexical and layout features to investigate style in source code. We can reach 94% accuracy in classifying 1,600 authors and 98% accuracy in classifying 250 authors with eight training files per class. This is a significant increase in accuracy and scale in source code authorship attribution. In particular, it shows that source code authorship attribution with the *Code Stylometry Feature Set* scales even better than regular stylometric authorship attribution, as these methods can only identify individuals in sets of 50 authors with slightly over 90% accuracy [see 4]. Furthermore, this performance is achieved by training on only 550 lines of code or eight solution files, whereas classical stylometric analysis requires 5,000 words.

Additionally, our results raise a number of questions that motivate future research. First, as malicious code is often only available in binary format, it would be interesting to investigate whether syntactic features can be partially preserved in binaries. This may require our feature set to be improved in order to incorporate information obtained from control flow graphs.

Second, we would also like to see if classification accuracy can be further increased. For example, we would like to explore whether using features that have joint information gain alongside features that have information gain by themselves improve performance. Moreover, designing features that capture larger fragments of the abstract syntax tree could provide improvements. These changes (along with adding lexical and layout features) may provide significant improvements to the Python results and help generalize the approach further.

Finally, we would like to investigate whether code can be automatically normalized to remove stylistic information while preserving functionality and readability.

Abstract

The Tor network is a widely used system for anonymous communication. However, Tor is known to be vulnerable to attackers who can observe traffic at both ends of the communication path. In this paper, we show that prior attacks are just the tip of the iceberg. We present a suite of new attacks, called Raptor, that can be launched by Autonomous Systems (ASes) to compromise user anonymity. First, AS-level adversaries can exploit the asymmetric nature of Internet routing to increase the chance of observing at least one direction of user traffic at both ends of the communication. Second, AS-level adversaries can exploit natural churn in Internet routing to lie on the BGP paths for more users over time. Third, strategic adversaries can manipulate Internet routing via BGP hijacks (to discover the users using specific Tor guard nodes) and interceptions (to perform traffic analysis). We demonstrate the feasibility of Raptor attacks by analyzing historical BGP data and Traceroute data as well as performing real-world attacks on the live Tor network, while ensuring that we do not harm real users. In addition, we outline the design of two monitoring frameworks to counter these attacks: BGP monitoring to detect control-plane attacks, and Traceroute monitoring to detect data-plane anomalies. Overall, our work motivates the design of anonymity systems that are aware of the dynamics of Internet routing.

1 Introduction

Anonymity systems aim to protect user identities from untrusted destinations and third parties on the Internet. Among all of them, the Tor network [25] is the most widely used. As of February 2015, the Tor network comprises of 7,000 relays or proxies which together carry terabytes of traffic every day [8]. Tor serves millions of users and is often publicized by political dissidents, whistle-blowers, law-enforcement, intelligence agencies, journalists, businesses and ordinary citizens concerned about the privacy of their online communications [9].

Along with anonymity, Tor aims to provide low latency and, as such, does not obfuscate packet timings or sizes. Consequently, an adversary who is able to observe traffic on both segments of the Tor communication channel (*i.e.*, between the server and the Tor network, and between the Tor network and the client) can correlate packet sizes and packet timings to deanonymize Tor clients [45, 46].

There are essentially two ways for an adversary to gain visibility into Tor traffic, either by compromising (or owning enough) Tor relays or by manipulating the underlying network communications so as to put herself on the forwarding path for Tor traffic. Regarding network threats, large Autonomous Systems (ASes) such as Internet Service Providers (ISPs) can easily eavesdrop on a portion of all links, and observe any unencrypted information, packet headers, packet timing, and packet size. Recent declarations by Edward Snowden have confirmed that ASes poses a real threat. Among others, the NSA has a program called Marina which stores meta information about user communications for up to a year [15], while the GCHQ has a program called Tempora that stores meta-information for 30 days and buffers data for three days [36]. Also, and maybe more importantly, it has been shown that Tor was targeted by such adversaries in collusion with ASes [10, 12, 11].

In this paper, we present Raptor, a suite of novel traffic analysis attacks that deanonymize Tor users more effectively than previously thought possible. To do so, and unlike previous studies on AS-level adversaries [28, 26, 40], Raptor leverages the *dynamic aspects* of the Internet routing protocol, *i.e.* the Border Gateway Protocol (BGP).

Raptor attacks are composed of three individual attacks whose effects are compounded (§2). First, Raptor exploits the asymmetric nature of Internet routing: the BGP path from a sender to a receiver can be different

	Traffic Analysis	BGP Churn	BGP Hijack	BGP Interception
Symmetric	Known [45, 46]	*Novel* (§4)	*Novel* (§5)	*Novel* (§5)
Asymmetric	*Novel* (§3)			

Table 1: This paper describes Raptor, a suite of previously unknown attacks on the Tor Network

than the BGP path from the receiver to the sender. Internet routing asymmetry increases the chance of an AS-level adversary observing at least one direction of both communication endpoints, enabling a novel asymmetric traffic analysis attack. Second, Raptor exploits natural churn in Internet routing: BGP paths change over time due to link or router failures, setup of new Internet links or peering relationships, or changes in AS routing policies. Changes in BGP paths allow ASes to observe additional Tor traffic, enabling them to deanonymize an increasing number of Tor clients over time. Third, Raptor exploits the inherent insecurity of Internet routing: strategic adversaries can manipulate Internet routing via BGP hijack and BGP interception attacks against the Tor network. These attacks enable the adversary to observe user communications, and to deanonymize clients via traffic analysis.

Raptor attacks were briefly discussed in a preliminary and short workshop paper [48]. In this paper, we go further by measuring the importance of the attacks using real-world Internet control- and data-plane data. We also demonstrate the attacks feasibility by performing them on the live Tor network—*with success*. No real Tor users were harmed in our experiments (§7). Finally, we also describe efficient countermeasures to restore a good level of anonymity. To summarize, we make the following key contributions:

Asymmetric Traffic Analysis and BGP Churn: Using live experiments on the Tor network, we showed that Raptor's asymmetric traffic analysis attacks can deanonymize a user with a 95% accuracy, without any false positives (§3). Using historical BGP and Traceroute data, we showed that by considering routing asymmetry and routing churn, the threat of AS-level attacks increases by 50% and 100%, respectively (§4).

BGP Hijacks and Interceptions: We analyzed known BGP hijacks and interception attacks on the Internet and show multiple instances where Tor relays were among the target prefixes (§5). As an illustration, the recent Bitcoin Hijack attack [1] in 2014, as well as Indosat Hijack attacks [3, 2] in 2014 and 2011 involved multiple Tor relays. To demonstrate the feasibility of such attacks for the purpose of deanonymizing Tor clients, we successfully performed an interception attack against a live Tor relay. Overall, we found that more than 90% of Tor relays are vulnerable to our attacks.

Countermeasures: We present a comprehensive taxonomy of countermeasures against Raptor attacks (§6). In particular, we outline the design of a monitoring framework for the Tor network that aims to detect suspicious AS-level path changes towards Tor prefixes using both BGP and Traceroute monitoring.

2 Raptor Attacks

To communicate with a destination, Tor clients establish layered circuits through three subsequent Tor relays. The three relays are referred to as: *entry* (or *guard*) for the first one, *middle* for the second one, and *exit* relay for the last one. To load balance its traffic, Tor clients select relays with a probability that is proportional to their network capacity. Encryption is used to ensure that each relay learns the identity of only the previous hop and the next hop in the communications, and no single relay can link the client to the destination server.

It is well known that if an attacker can observe the traffic from the destination server to the exit relay as well as from the entry relay to the client (or traffic from the client to the entry relay and from the exit relay to the destination server), then it can leverage correlation between packet timing and sizes to infer the network identities of clients and servers (end-to-end timing analysis). This timing analysis works even if the communication is encrypted.

In the rest of the section, we present the three Raptor attacks and how they contrast to conventional symmetric traffic analysis. We start by discussing how seeing just one direction of the traffic for each segment (between the sender and the guard, and between the last relay and the destination) is sufficient for the adversary (§2.1). We then explain how ASes can exploit natural BGP dynamics (§2.2), or even launch active attacks (§2.3), to compromise the anonymity of Tor users.

2.1 Asymmetric Traffic Analysis

We propose asymmetric traffic analysis, a novel form of end-to-end timing analysis that allows AS-level adversaries to compromise the anonymity of Tor users. Let us suppose that a Tor client is uploading a large file to a Web server. Conventional traffic analysis considers only one scenario where adversaries observe traffic from the

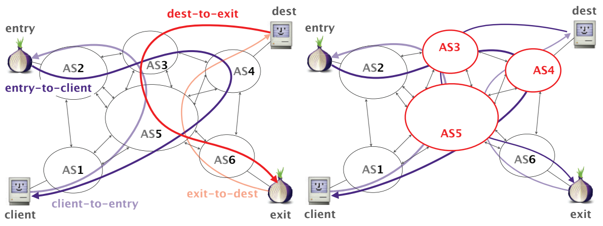

Figure 1: Asymmetric routing increases the power of AS-level adversaries. When considering forward traffic, i.e., client-to-entry and exit-to-destination flows, only AS5 can compromise anonymity. When considering both forward and backward traffic though, AS3, AS4 and AS5 can compromise anonymity. Our measurements confirm that asymmetric traffic analysis is feasible.

client to the entry relay, and from the exit relay to the Web server (same direction as the flow of traffic)[1].

However, Internet paths are often asymmetric: the path from the exit relay to the Web server may be different than the path from the Web server to the exit relay. Thus it is possible that an adversary may not be able to observe the data traffic on the path from the exit relay to the server, but it observes the TCP acknowledgment traffic on the path from the server to the exit relay.

We introduce an asymmetric traffic analysis attack that allows an adversary to deanonymize users as long as the adversary is able to observe *any direction of the traffic*, at both ends of the communication. Note that we can view the conventional end-to-end timing analysis as a special case of our attack, in which the adversary is able to observe traffic at both ends of the anonymous path, and in the same direction as the flow of traffic. Routing asymmetry increases the number of ASes who can observe at least one direction of traffic at both communication endpoints. We illustrate this scenario in Figure 1.

More concretely, our attack is applicable to four scenarios where an adversary observes (a) data traffic from the client to entry relay, and data traffic from exit relay to the server, or (b) data traffic from the client to entry relay, and TCP acknowledgment traffic from the server to exit relay, or (c) TCP acknowledgment traffic from guard relay to the client, and data traffic from exit relay to the server, or (d) TCP acknowledgment traffic from guard relay to the client, and TCP acknowledgment traffic from the server to the exit relay.

A key hurdle in asymmetric traffic correlation is that TCP acknowledgments are cumulative, and there is not a one-to-one correspondence between data packets and the TCP acknowledgment packets. We overcome this hurdle by observing that Tor (and other anonymity systems) use SSL/TLS for encryption, which leaves the TCP header unencrypted. Our attack inspects TCP headers in the observed traffic to retrieve the TCP sequence number field and TCP acknowledgment number field, and analyzes the correlation between these fields of both ends over time. Our experimental results in Section 3 show the feasibility of asymmetric traffic analysis, with a detection accuracy of 95%. Furthermore, asymmetric traffic analysis can be combined with other Raptor attacks, such as exploiting natural churn and BGP interception attack, which we discuss next.

2.2 Natural Churn

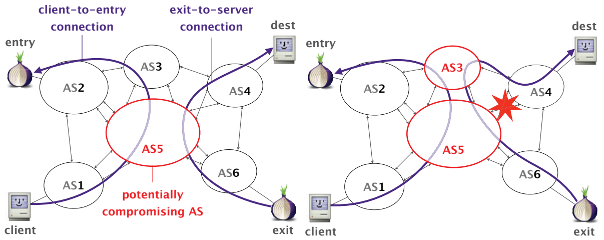

Figure 2: BGP churn increases the number of ASes that can deanonymize Tor traffic. Initially, only AS5 can deanonymize the client, seeing both direction of the traffic (left). After the failure of link (AS4, AS5), both AS5 and AS3 can deanonymize Tor traffic (right).

When users communicate with recipients over multiple time instances, then there is a potential for compromise of anonymity at every communication instance [49, 42]. Thus anonymity can degrade over time. Tor considers this threat from the perspective of adversarial relays (but not adversarial ASes).Tor clients use a fixed entry relay (guard relay) for a period of time (Dingledine et al. recommend 9 months [24]) to mitigate this threat with respect to adversarial relays. We note that the threat of AS-level adversaries still persists, because even though the entry relay is fixed, the set of ASes on the path between the client and the guard relay may change over time. Next, we discuss such attacks that rely on natural churn in BGP paths.

The underlying Internet paths between a client and guard relay vary over time due to changes in the physical topology (*e.g.*, failures, recoveries, and the rollout of new routers and links) and AS-level routing policies (*e.g.*, traffic engineering and new business relationships). These changes give a malicious AS surveillance power that increases over time. For example, AS 3 in Figure 2 does not lie on the original path from the exit to the des-

[1] If the traffic is flowing from the server to the client, then end-to-end timing analysis considers a scenario where the adversary observes traffic from the Web server to the exit relay and from the entry relay to the client.

tination, but a BGP routing change can put AS 3 on the path, allowing it to perform traffic analysis.

In Section 4, we show that the surveillance capability of an AS-level adversary can increase up to 50% when considering BGP churn over a period of one month.

2.3 BGP Hijack

So far, we discussed Raptor attacks that were *passive*. Strategic AS-level adversaries are also capable of launching *active* attacks, that deviate from honest routing behavior. Internet routing is vulnerable to attacks which enable an AS to manipulate inter-domain routing by advertising incorrect BGP control messages. While these attacks are well known in the networking community, we are the first to apply these attacks to anonymity systems such as Tor.

AS-level adversaries can hijack an IP prefix [51] by advertising the prefix as its own. The attack causes a fraction of Internet traffic destined to the prefix to be captured by the adversary. Tor relay nodes can observe a large amount of client traffic. For example, a Tor guard relay observes information about client IP addresses. Thus, the IP prefixes corresponding to Tor guard relays presents an attractive target for BGP hijack.

As a concrete attack example, we consider a scenario where an AS-level adversary aims to deanonymize the user associated with a connection to a sensitive Web server (say a whistleblowing website). The adversary can first use existing attacks on the Tor network to uncover the identity of the client's guard relay [39, 37, 31, 42]. Next, the adversary can launch a BGP hijack attack against the Tor relay. This allows the adversary to see traffic destined to the guard relay. BGP hijack thus enables an adversary to learn the set of all client IP addresses (anonymity set) associated with a guard relay (and the target connection to the sensitive Web server).

We note that in a prefix-hijack attack, the captured traffic is blackholed, and the client's connection to the guard is eventually dropped. Thus, it may not be possible to perform fine-grained traffic analysis to infer the true client identity from this anonymity set. However, the identification of a reduced anonymity set (as opposed to the entire set of Tor users) is already a significant amount of information leakage, and can be combined with other contextual information to break user anonymity [18]. In Section 5, we uncover several real-world BGP hijack attacks in which Tor relays were among the target prefixes.

2.4 BGP Interception

Our BGP hijack attack discussed above allows adversaries to capture traffic destined towards a target Tor prefix, but the captured traffic is blackholed, resulting in the connecting being dropped. Next, we discuss a more sophisticated routing attack called BGP interception attack [16], that allows adversaries to perform exact deanonymization of Tor users.

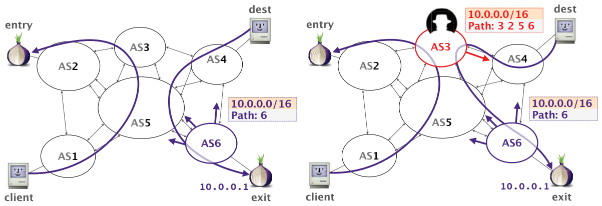

Figure 3: BGP interception attack enables ASes to selectively put themselves on some path. Here, AS3 only sees traffic between the client and the entry relay (left). By intercepting the prefix containing the exit relay (right), AS3 also sees traffic towards the exit relay, enabling it to deanonymize the Tor communication.

A prefix interception attack allows the malicious AS to become an intermediate AS in the path towards the guard relay, *i.e.*, after interception, the traffic is routed back to the actual guard relay. Such an interception attack allows the connection to be kept alive, enabling the malicious AS to exactly deanonymize the client via asymmetric traffic analysis.

Similar to the previous discussion, let us consider an adversary trying to deanonymize the user connecting to a sensitive website (the adversary already sees the traffic towards the website). The adversary can first uncover the identity of the guard relay using existing attacks [39] (as before), and then launch a prefix interception attack against the guard relay. Since the adversary routes the traffic back to the guard relay, the client's connection is kept alive, allowing the adversary to launch asymmetric traffic correlation attacks. Note that in contrast to BGP hijack attacks, BGP interception attacks can perform exact deanonymization of Tor clients.

These attacks enable malicious ASes to deanonymize user identity corresponding to a monitored target connection. Similarly, ASes that already see the client's traffic to its guard can position themselves to observe the traffic between the server and the exit relay by launching interception attacks against exit relays. Figure 3 illustrates this attack scenario.

Finally, we note that a remote adversary can launch interception attacks against both guard relays and exit relays simultaneously, to perform general surveillance of the Tor network. In Section 5, we demonstrate a real-world BGP interception attack against a live Tor relay by collaborating with autonomous system operators.

3 Asymmetric Traffic Analysis

In this section, we experimentally show that asymmetric traffic analysis attacks are feasible. We use the live Tor network for our experiments. To protect the safety of real Tor users, we generate our own traffic through the Tor network. Our goal is to investigate the accuracy of asymmetric traffic analysis in deanonymizing our generated traffic.

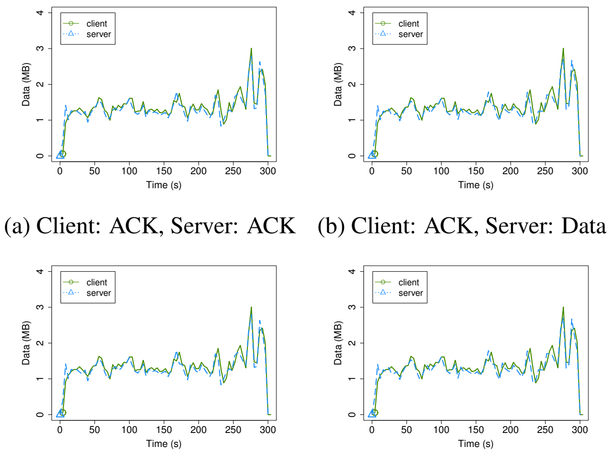
Experimental Setup: In order to generate our own traffic through the live Tor network, we use PlanetLab nodes as clients and Web servers. PlanetLab is an open platform for networking research, that provides access to hundreds of geographically distributed machines. We randomly pick 100 machines on PlanetLab, located across United States, Europe, and Asia. We installed Tor clients on 50 of those machines, and used the Privoxy tool (`www.privoxy.org`) to configure wget requests to tunnel over Tor. The remaining 50 machines were setup to be Web servers, each containing a 100*MB* image file.

We use the default Tor configuration on the 50 client machines. We launch wget requests on the 50 clients at the same time, each requesting a 100MB image file from one of the 50 web servers, respectively. We use tcpdump to capture data for 300 seconds at the clients and the servers during this process.

Asymmetric correlation analysis: In each packet trace, we first extract the TCP sequence number and TCP acknowledgment number fields in the TCP header. Using the TCP sequence and acknowledgment numbers, we next compute the number of transmitted data bytes per unit time. For each pair of observed traces, we compute the correlation between the vector of transmitted data bytes over time. For our analysis, we use the Spearman's rank correlation coefficient (other correlation metrics could also be applicable). For each client, our asymmetric traffic analysis attack selects the server trace with the highest correlation as the best match.

Results: Figure 4 illustrates our asymmetric analysis computed between a client server pair that is communicating. We can see high correlation in all four observation scenarios discussed in Section 2. Figure 5 illustrates our asymmetric analysis computed between a client server pair that is not communicating with each other. We can see that incorrectly matched pairs have poor correlation in all four observation scenarios. Figure 6 illustrates the detection accuracy rate grows as the duration of attack increases, especially in the first 30 seconds.

We computed the detection accuracy of our asymmetric traffic analysis attacks in all four scenarios after 300 seconds (by selecting the highest correlated pair), and obtained an average accuracy of 95% (Table 2). The error matches are all false negatives, for which the client has insignificant correlation coefficients with all servers, so it fails to be matched to any servers. We did not observe any false positives in our results.



(a) Client: ACK, Server: ACK (b) Client: ACK, Server: Data

(c) Client: Data, Server: ACK (d) Client: Data, Server: Data

Figure 4: Asymmetric traffic analysis shows high correlation between a matched client/server pair

	Client ACK/ Server ACK	Client ACK/ Server Data	Client Data/ Server ACK	Client Data/ Server Data
Overall	96%	94%	96%	94%
False negative	4%	6%	4%	6%
False positive	0%	0%	0%	0%

Table 2: Asymmetric traffic analysis accuracy rate

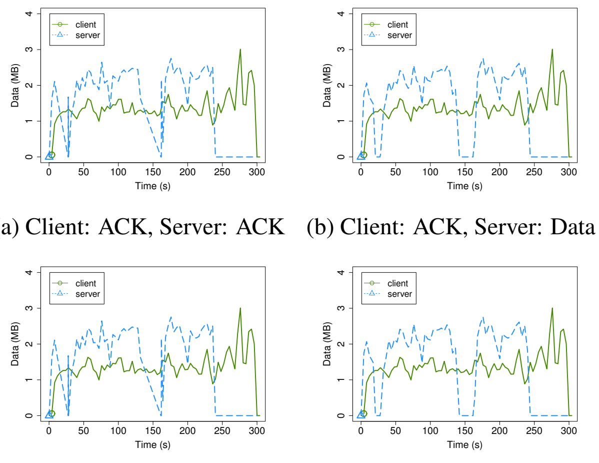
In addition to the actual observed error rate above, we also performed a statistical tests to compute the 95% confidence interval on our error rate, given our sample size of 50 client machines and 50 server machines. Table 3 illustrates the confidence intervals on our error rates.

	Client ACK/ Server ACK	Client ACK/ Server Data	Client Data/ Server ACK	Client Data/ Server Data
False negative	0.48% – 13.71%	1.25% – 16.54%	0.48% – 13.71%	1.25% – 16.54%
False positive	0% – 0.15%	0% – 0.15%	0% – 0.15%	0% – 0.15%

Table 3: Asymmetric traffic analysis error rate confidence interval

4 Natural Churn

In this section, we study and evaluate how routing dynamics, or churn, increase the power of AS-level adversaries in anonymity systems such as Tor. We start with an exhaustive control-plane analysis using collected BGP



(a) Client: ACK, Server: ACK (b) Client: ACK, Server: Data

(c) Client: Data, Server: ACK (d) Client: Data, Server: Data

Figure 5: Asymmetric traffic analysis shows low correlation between an unmatched client/server pair

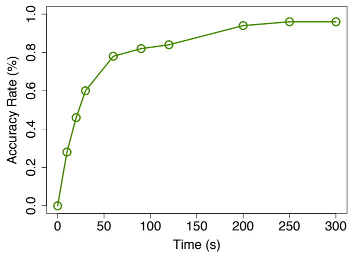


Figure 6: The accuracy of the attack quickly increases with time, reaching 80% within a minute, 95% after five minutes.

data (§4.1). Our results show that churn can increase the amount of compromised Tor circuits by up to 50% over a period of one month. We then confirmed our results by performing targeted data-plane measurements on the Tor network (§4.2). Again, churn significantly increased the percentage of vulnerable Tor circuits, nearly tripling it.

4.1 Control-plane Evaluation

We quantified the impact of churn by measuring how it increased the probability of a single AS (say AS X) to end up simultaneously on the path between a client and a guard relay and on the path between a destination and an exit relay. When this happens, we considered AS X as (potentially) compromising for the pair (client, destination) using the corresponding Tor circuit. Observe that our analysis leverages asymmetric traffic analysis (§3) as it only requires X to be on-path for two publicly-known prefixes, covering the guard and the exit relay.

Datasets We collected 612+ *million* BGP updates pertaining to 550,000 IP prefixes collected by six RIPE-maintained BGP Looking Glass (*rrc*00, *rrc*01, *rrc*03, *rrc*04, *rrc*11, *rrc*14) [6] in January 2015 over 250+ BGP sessions. We processed the dataset to remove any artifacts caused by session resets [20]. In parallel, we also collected Tor-related data (IP address, flags and bandwidth) of about 6755 Tor relays active during the same period of time [4]. Among all Tor relays, 1459 (resp. 1182) of them were listed as guards (resp. exits) and 338 relays were listed as both guard and exit.

We considered each BGP session as a proxy for Tor clients and destinations. Note that analysis implicitly accounts for *any* Internet host reachable directly or indirectly through these BGP sessions. Our dataset contains sessions belonging to major Internet transit providers such as Level-3, ATT, NTT, etc. that provide transit to millions of hosts.

Static baseline. We computed a static baseline by considering the amount of compromising ASes at the beginning of our dataset, *without considering any updates*. On each BGP session s_i, we computed and maintained the routing table used to forward Tor traffic by considering all the BGP announcements and withdrawals received over s_i. More precisely, we kept track of the most-specific routing table entry that was used to forward traffic to any Tor guard or exit relays. We refer to those as *Tor prefixes*. In this context, a routing table entry for a relay r is a five-tuple (t_i, t_f, p, e, L) composed of: *i)* the initial time t_i at which the entry started to be used by the router for forwarding traffic to r; *ii)* the final time t_f at which the entry stopped to be used by the router; *iii)* the corresponding IP prefix p; *iv)* a boolean e denoting whether the r is an entry or an exit relay; and *v)* the list of all the ASes L that will see the traffic en-route to reach r (*i.e.*, the `AS-PATH`).

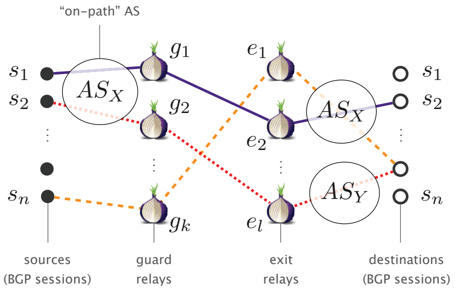

Figure 7: Control-plane evaluation setup

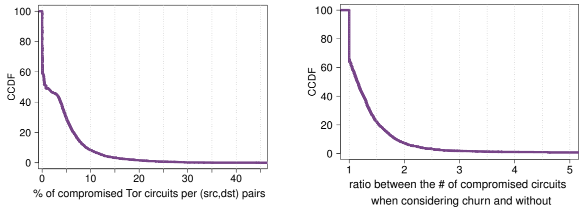
Using the routing-table data, we accounted, for each AS X, the number of pairs ((s_i, g_i), (s_j, e_j)) for which it appeared simultaneously in the `AS-PATH`. Here, s_i (resp. s_j) refers to a client (resp. destination) session, while g_i (resp. e_j) refers to a Tor guard (resp. exit) relay. To ensure meaningful results, we only considered cases in which s_i and s_j are in different ASes to ensure enough diversity in the paths seen. As illustration, in Fig. 7, AS_X is a compromising AS for the pair ((s_1, g_1), (s_2, e_2)), meaning it can deanonymize any clients connected beyond s_1 and exchanging data with a destination connected beyond s_2 which uses g_1 (resp. e_2) as a guard (resp. exit) relay.



(a) Static baseline (b) Churn-induced increase

Figure 8: Without considering churn, more than 5% of all the possible Tor circuits are compromised by at least one AS in 20% of the cases (left). The amount of compromised circuits increase for the majority of the (src, dest) pairs (60%) when considering churn, by up to 50% in 20% of the cases (right).

Fig. 8a depicts the percentage of compromised Tor circuits for each source and destination as a Complementary Cumulative Distribution Function (CCDF). A point (x,y) on the curve means that x% of all Tor circuits, *i.e.* `(guard,exit)` pairs, are compromised for at least y% of all the `(src,dst)` pairs. We see that, for 50% of all the `(src,dst)` pairs, *at least* 0.75% of the Tor circuits are compromised by at least one AS. This number grows to 6% and 13% of the Tor circuits considering the 75th- and 95th-percentile, respectively.

Measuring the effect of churn. We computed the number of extra Tor circuits that got compromised by at least one AS over one month. To be fair, we only considered a Tor circuit as compromised if it crossed the same AS for at least 30 seconds as it is unlikely that a time-correlation attack can be performed in shorter timescale. Fig. 8b plots the ratio between the amount of compromised Tor circuits for each `(src,dst)` pair at the end of the month with respect to the static baseline amount. We see that churn significantly increases the probability of compromise. Indeed, the amount of compromised circuits increase for 60% of the `(src,dst)`. The increase reaches 50% (ratio of 1.5) in 20% of the cases.

In addition to increasing the number of compromised Tor circuits, churn also increases the number of compromisable `(src,dst)` pairs. Indeed, while 5593 `(src,dst)` pairs could be compromised without updates, that number increased to 5754 pairs when considering updates (an augmentation of nearly 3%).

Few powerful ASes see some traffic for a large majority of the Tor circuits. Due to their central position in the Internet, a few ASes naturally tend to see a lot of Tor traffic crossing them. To account for this effect, we compute how many Tor circuits crossed each AS from at least one `(src,dst)` pair. The top 10 ASes in terms of compromised circuits are listed in Table 4. Large networks such as NTT or Level3 are able to see Tor traffic for up to 90% of Tor circuits.

Name	ASN	Tor circuits (%) seen	Country
NTT	2914	91	US
IIJ	2497	91	Japan
BroadbandONE	19151	91	US
Inet7	13030	91	CH
Level3	3356	88	US
Tinet	3257	86	DE
Cogent	174	63	US
Level3/GBLX	3549	58	US
TATA AMERICA	6453	53	US
TeliaSonera	1299	50	SWE

Table 4: A few well-established ASes simultaneously see some traffic for up to 90% of all (entry, exit) relays pairs.

4.2 Data-plane Evaluation

Next, we aim to quantify the impact of churn using data-plane information collected via `traceroute`.

Datasets We ran `traceroute` between 70 RIPE Atlas probes [5] to measure the actual forwarding path taken by packets entering and exiting the Tor network. We selected one probe in 70 different ASes, split in the following four sets:

- S_1 : 10 ASes that contain the most Tor clients [35];
- S_2 : 25 ASes that cumulatively contained ~50% of all guard relay bandwidth;
- S_3 : 25 ASes that cumulatively contained ~50% of all exit relay bandwidth;
- S_4 : 10 ASes that contain the most Tor destinations [35].

We then ran daily traceroutes over a 3 weeks period between all probes in S_1 towards all probes in S_2 (and vice-versa), measuring the forwarding paths P_1 between Tor clients and guard relays, and the paths P_2 between guard relays and Tor clients. Similarly, we measured the forwarding paths P_3 between exit relays and Tor destinations, and the paths P_4 between Tor destinations and exit relays. Overall, we measured $10 \times 25 \times 25 \times 10 = 62500$ possible Tor circuits.

Churn nearly tripled the amount of vulnerable Tor circuits. If we use conventional methodology and only look for common ASes between P_1 and P_3, we found 12.8% of Tor circuits to be vulnerable on the first day of the experiment (red line in Fig. 9). In comparison,

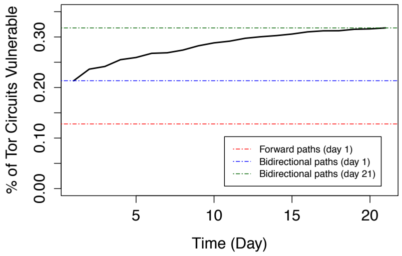


Figure 9: Percentage of Tor circuits vulnerable to an AS level adversary

if we also consider asymmetric paths (*i.e.*, also look for common ASes between P_1 and P_4, P_2 and P_3, and P_2 and P_4), the percentage of vulnerable Tor circuits nearly doubled to 21.3% on the first day (blue line in Fig. 9), and nearly tripled to 31.8% at the end of the three week period (green line in Fig. 9).

5 BGP Attacks: Hijack and Interception

In this section, we study and evaluate the feasibility of BGP hijack and interception attacks on the Tor network. First, we show that Tor relays tend to be concentrated within few ASes and IP prefixes—making those highly attractive targets for hijack and interception attacks (§5.1). Second, we show that, in several real-world BGP hijack attacks, Tor relays were among the target prefixes (§5.2). Third, we perform a real-world BGP interception attack against a live Tor guard relay, *with success*, to demonstrate the ability to accurately deanonymize Tor clients (§5.3).

5.1 Tor relays concentration

The amount of Tor traffic attracted by a hijack or an interception attack depends on the number of relays that lie within the corresponding prefix. As such, prefixes and ASes that host many relays of high bandwidth are an interesting targets for attackers. To evaluate how vulnerable the Tor network was to hijack and interceptions attacks, we computed the number of relays present in each AS and in each BGP prefix. Surprisingly, close to 30% of all relays are hosted in only 6 ASes and 70 prefixes. Together, these relays represent almost 40% of the bandwidth in the entire Tor network (see Table 5). As such, these few prefixes constitute *extremely* attractive targets.

	% relays	% bw	# pfx	Name	ASN
	10.5	23	11.80	OVH	16276
	6.30	13	6.68	Hetzner	24940
	4.78	7	10.52	Online.net	12876
	3.04	4	2.58	Wedos	197019
	2.04	14	4.27	Leaseweb	16265
	1.69	9	3.86	PlusServer	8972
Total	28.35	70	39.71		

Table 5: 6 ASes and 70 prefixes host ~30% of all Tor guard and exit relays as well as ~40% of the entire Tor network bandwidth. As such, these constitute extremely attractive targets for hijacks and interceptions attacks.

5.2 Known Prefix Hijacking Attacks

While there have been numerous well-documented BGP prefix hijacks and interceptions, it was unknown whether Tor traffic was intercepted or not. To this extent, we studied occurrences of well-known prefix hijacks and looked for leaked prefixes covering at least a Tor relay. To do so, we gathered BGP updates from Routeviews [7] around the time of each attack and filtered out the ones unrelated to Tor prefixes. Overall, we found that three well-known hijacks affected Tor relays: two separate incidents involving one of Indonesia's largest telecommunication networks, Indosat, as well as one malicious hijack attack whose goal was to steal Bitcoins.

Event	# hijacked relays	# hijacked guards	# hijacked exits
Indosat 2011	5 (0.24%)	1 (0.15%)	4 (0.44%)
Indosat 2014	44 (0.80%)	38 (1.80%)	17 (1.65%)

Table 6: Summary statistics for known Indosat prefix hijacking events.

Indosat 2011. On January 14th, 2011, Indosat (AS4761) originated 2,800 new prefixes, which covered 824 different ASes [2]. 7 of these prefixes affected the Tor network by covering 5 of the Tor relays. As discussed in Section 2, Indosat *could* potentially have learned information about the client IP addresses associated with each of the guard relays (reduced anonymity set).

Indosat 2014. On April 3, 2014, Indosat originated 417,038 new prefixes; it usually originates 300 prefixes [3]. This compromised 44 Tor relays, 38 of which were guard relays and 17 of which were exit relays (11 hijacked relays were both guards and exits). Table 6 shows the summary statistics of both Indosat hijacking incidents.

Canadian Bitcoin 2014. From February 2014 to May 2014, an attacker compromised 51 networks at

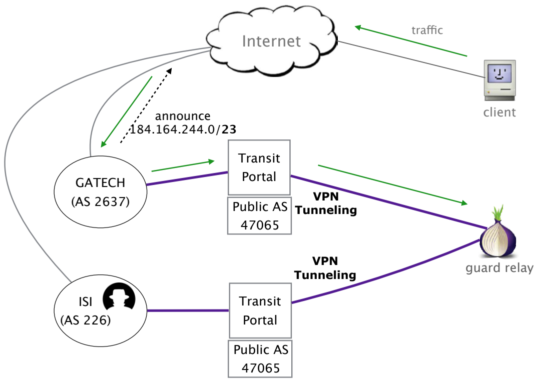

Figure 10: Transit Portal setup

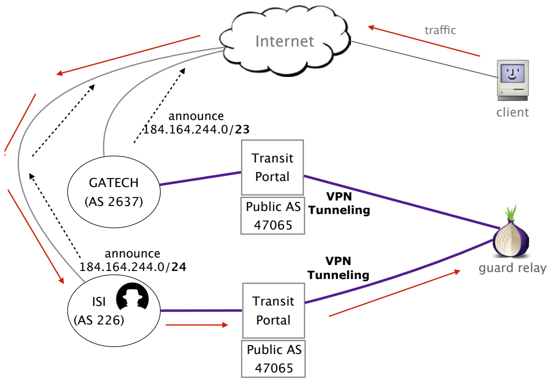

Figure 11: ISI performing interception attack

19 different ISPs, and resulted in the theft of approximately $83,000 in Bitcoin [1]. We found that 198.245.63.0/24 and 162.243.142.0/24 were hijacked, and contained a Tor relay, 198.245.63.228. AS16276 (OVH) owns 198.245.63.0/24, but this prefix was hijacked by AS21548 (MTO Telecom). The Tor relay that consequently was hijacked, 198.245.63.228, was a guard relay located in Montreal, Quebec.

While we do not make any claims about the intent of the above hijacking ASes, our analysis shows the existential threat of real-world routing attacks on the Tor network. Furthermore, the fact that the Tor and the research community missed noticing the presence of Tor relays among the hijacked prefixes is surprising.

5.3 BGP Prefix Interception Attack Experiment

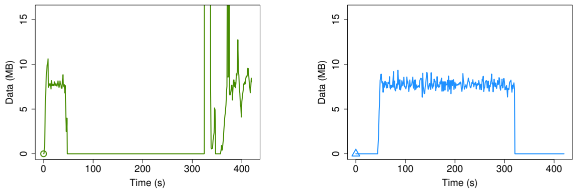
Methodology and setup. We now demonstrate the feasibility of the interception attack by performing one, with success, on the live Tor network. For that, we set up a machine to run as a Tor guard relay and made it reachable to the Internet by announcing a /23 prefix in BGP using Transit Portal (TP) [43]. TP enables virtual ASes to establish full BGP connectivity with the rest of the Internet by proxying their announcements via dozens of worldwide deployments. Next, we configure the 50 Tor clients in PlanetLab to use our Tor guard relay as the entry relay to reach 50 web servers, also hosted in PlanetLab.

In order to perform the BGP prefix interception attack, we used two TP deployments (`GATECH` and `ISI`), located in different ASes. GATECH TP served the purpose of the "good" AS through which Tor traffic is normally routed, while ISI TP served as the "malicious" AS which performed the interception attack. We connected the two TPs to our Tor relay machine via VPN tunnels. First, in order for our Tor guard relay (running on `184.164.244.1`) to be reachable, we advertised 184.164.244.0/23 (run by us in its entirety for the duration of our research) via the GATECH TP, so that traffic destined for IP addresses within that range will be routed, first to the GATECH TP, and then sent to our machine via the corresponding tunnel. We illustrate our setup in Fig. 10.

Next, We advertise BGP prefix `184.164.244.0/24` via the ISI TP, which constitutes a more-specific prefix attack against the original announcement announced by the GATECH TP. Thus, after the new BGP prefix announcement gets propagated through the internet, Tor client traffic that is destined for our guard will be sent to ISI instead. Since we configured the ISI TP to forward traffic to our guard machine, the Tor relay can still receive the traffic and keep the Tor connection alive after the attack. We illustrate the interception attack model in Fig. 11.

Our setup constitutes a BGP interception attack. Initially, traffic is routed via GATECH and arrives at our Tor relay machine via GATECH tunnel. After the attack happens, traffic drains from GATECH tunnel and gets routed via ISI, and thus comes to our Tor relay machine via ISI tunnel instead. Since the traffic still arrives at the relay machine, it is an interception attack and the connection does not get interrupted. We use `tcpdump` on our relay machine, listening to ISI tunnel, to capture client TCP acknowledgment traffic coming from that tunnel, which is exactly the data that an adversary would get from launching such an interception attack.

In the experiment, we first launch simultaneous HTTP requests using `wget` at the 50 Tor clients for the 100MB file at the 50 web servers. Then, 20 seconds after launching the `wget` requests, we start announcing the more-specific prefix via ISI. We use `tcpdump` listening to ISI tunnel to capture TCP acknowledgment traffic sent from the Tor clients during the interception attack. We also use `tcpdump` to capture traffic at the web servers during the whole process. Finally, 300 seconds after launching the



(a) Traffic Flow via GATECH (b) Traffic Flow via ISI

Figure 12: Traffic Flow During the Experiment

attack, we send a withdrawal message via the ISI TP, so the traffic will be routed via GATECH again as normal.

Our interception attack successfully deanonymized Tor sources with a 90% accuracy rate. In Fig. 12, we plot the Tor traffic flow captured on our relay machine from both GATECH tunnel and ISI tunnel. We can see that all traffic is routed via GATECH at the beginning. At $t = 20s$, ISI starts advertising a more specific /24 prefix, which takes approximately 35 seconds for it to be propagated through the internet and drain the traffic from GATECH. At $t = 55s$, traffic starts showing up via ISI, and GATECH does not receive traffic any more. Then, at $t = 300s$, ISI withdraws the IP prefix announcement, which takes approximately 22 seconds for the traffic to appear back on GATECH again. During this interception process, the connection stays alive.

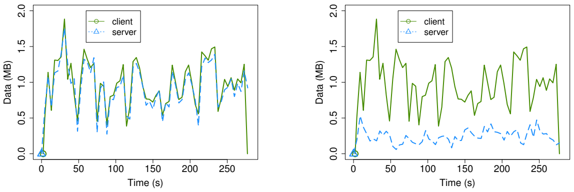
The captured data from ISI tunnel is client TCP acknowledgment traffic. Thus, we will employ our Asymmetric Traffic Analysis approach, described in Section 3, with sample size of 50 client machines and 50 server machines to do the correlation analysis to deanonymize users' identity. We achieve 90% accuracy rate (see Table 7).

	Accuracy Rate	False Negative	False Positive
Client ACK/Server ACK	90%	8%	2%

Table 7: Asymmetric Traffic Analysis accuracy rate

Fig. 13 shows an example of a client with its correlated server and an uncorrelated server, respectively. Note that the time shown on the graph has been adjusted according to the time that traffic starts showing via ISI.

The detection accuracy rate in the interception attack case decreases from the average 95% in static asymmetric traffic analysis to 90%. One main reason is that we configure all 50 Tor clients to connect to the same Tor guard relay, which leads to significantly higher probability that many of them will share the same Tor exit relay (especially those clients which are in the same AS) as well, and as a result, their bandwidths are highly likely to be similar. And also, all the clients start requesting files from the web servers at the same time, so the bandwidth they could achieve will be limited by the guard and the exit relay, which leads to similar bandwidths due to the guard/exit bottleneck. However, this scenario is an extreme and very unlikely case in real Tor connections. With fewer clients connecting to the same Tor guard relay at the same time, the accuracy of the asymmetric traffic analysis should be higher.



(a) Client & Correlated Server (b) Client & Uncorrelated Server

Figure 13: Client ACK versus Server ACK analysis

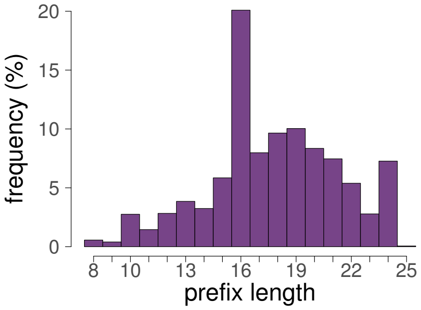


Figure 14: >90% of BGP prefixes hosting relays are shorter than /24, making them vulnerable to our attack.

The vast majority of Tor relays are vulnerable to our attacks. Technically, only prefixes shorter than /24 can be hijacked globally with a more-specific prefix attack as longer prefixes tend to be filtered by default by many ISPs. To make sure of the feasibility of our attack, we computed the prefix length distribution of Tor prefixes (see Fig.14). We can see that *more than* 90% of BGP prefixes hosting relays have prefix length shorter than /24, making them directly vulnerable to a more-specific prefix attack such as ours.

6 Countermeasures Sketch

In this section, we first describe a taxonomy of countermeasures against Raptor attacks. Second, we describe a general approach for AS-aware anonymous communication in which Tor clients are aware of the dynamics of Internet routing. Finally, we describe exploratory approaches for detecting and preventing BGP hijack and interception attacks against Tor.

6.1 Countermeasure Taxonomy

There are two main categories of countermeasures: (a) approaches that reduce the chance of an AS-level adversary observing both ends of the anonymous communication, and (b) approaches that aim to mitigate correlation attacks even when an adversary observes both ends of the anonymous communication. Figure 15 illustrates the design space of potential countermeasures against Raptor attacks. In this work, we advocate the former line of defense – namely, to monitor both routing control-plane and data-plane, and to strategically select Tor relays that minimize the chance of compromise (§6.2). We also advocate defenses that aim to detect and prevent routing attacks (§6.3). We do not focus on the class of approaches that aim to mitigate correlation analysis by obfuscating packet sizes and timings, as they are generally considered too costly to deploy (Appendix A).

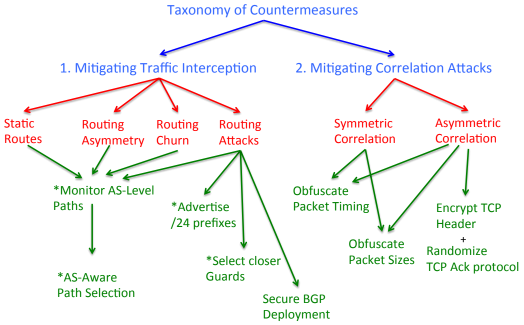

Figure 15: Taxonomy of Countermeasures

6.2 AS-Aware Path Selection

To minimize opportunities for AS-level traffic analysis, the Tor network can monitor the path dynamics between the clients and the guard relays, and between the exit relays and the destinations. Information about path dynamics can be obtained using data-plane (*e.g.*, `traceroute`) or control-plane (*e.g.*, BGP feed) tools. For instance, each relay could publish the list of any ASes it used to reach each destination prefix in the last month. This information can be distributed to all Tor clients as part of the Tor network consensus data. Tor clients can use this data in relay selection, perhaps in combination with their own traceroute measurements of the forward path to each guard relay. For example, Tor clients should select relays such that the same AS does not appear in both the first and the last segments, after *taking path dynamics into account*.

6.3 Mitigating Routing Attacks in Tor

Next, we consider two approaches for mitigating Raptor's routing attacks: detection and prevention.

6.3.1 Monitoring Framework for Detection Routing Attacks

We propose that the Tor network monitor the routing control-plane and data-plane for robust detection of routing attacks. Detecting routing attacks serves two purposes: (1) First, this serves to raise awareness about the problem and hold attackers accountable. (2) Second, Tor directory authorities can notify clients. Such notifications allow the end-user to respond by either suspending its use of Tor (since most hijacks and interceptions are short lived), or choose another Tor relay . Next, we discuss two proof-of-concept monitoring frameworks, based on BGP data and traceroute data respectively.

BGP Monitoring Framework. Our BGP monitoring framework gathers BGP data from the Routeviews project. The framework filters BGP updates to consider data about prefixes that involve a Tor relay. Building upon prior work in routing attack detection [16], we implement the following heuristics. (1) *Frequency heuristic:* routing attacks can be characterized by an AS announcing a path once (or extremely rarely) to a prefix that it does not own. The frequency heuristic detects attacks that exhibit this behavior. It measures the frequency of each AS that originates a given prefix; if the frequency is lower than a specified threshold, then it could be a potential hijack attack. (2) *Time Heuristic.* Most known attacks, including those discussed in § 5, last a relatively short amount of time. The time heuristic measures the amount of time each path to a prefix is announced for; if the amount of time is extremely small (below a specified threshold), then there is the possibility of it being a routing attack.

Detection Capability: We tested our BGP monitoring framework based on BGP data during known prefix hijack attacks, that were discussed in § 5. As a preliminary validation, the frequency and time heuristics were able to detect all of the known attacks; the threshold used for the frequency heuristic was .00001 (the fraction {# of announcements for prefix p originated by AS A}/{total # of announcements for prefix p}), and the threshold used for the time heuristic was .01 (the fraction {length of time that prefix p is originated by AS A}/{total length of time prefix p is announced by any AS}).

Traceroute Monitoring Framework. The BGP monitoring framework provides measurements of actual AS-level paths from BGP collector nodes. However, the input data to the monitoring framework is limited to peers who chose to participate in frameworks such as Routeviews, and BGP data is only a noisy indicator of the routing control-plane. For robust detection of attacks, it is also necessary to monitor the data-plane, which we do via a Traceroute monitoring framework.

Traceroute is a network diagnostic tool that infers the routers traversed by internet packets. To analyze both attacks and changes in AS-level paths to the Tor network, we have built a traceroute monitoring framework that runs traceroutes from 450 PlanetLab machines to all Tor entry and exit relays and stores the resulting traceroute data. The set of all Tor entry and exit relays is updated daily to accommodate new relays that have received the guard and exit flags. BGP hijack and interception attacks typically affect a variety of users from different vantage points. Thus, traceroute measurements from 450 geographically diverse PlanetLab have the ability to detect data-plane anomalies arising out of routing attacks. The PlanetLab machines are distributed across 140 ASes. Meanwhile, the Tor entry relays are distributed across 982 ASes and the exit relays are distributed across 882 ASes. We use Team-Cymru (`http://www.team-cymru.org/`) to compute the mapping between an IP address and its autonomous system. We will make the data collected by our Traceroute monitoring framework available to the research community.

Detection Capability: As a preliminary validation, our Traceroute monitoring framework was able to detect the the BGP interception attack discussed in § 5. From the traceroute data, we observed AS-level path changes from *every* PlanetLab node to our Tor guard relay, indicating an anomaly.

6.3.2 Preventing Routing Attacks in Tor

In addition to monitoring the routing control-plane and data-plane with respect to the Tor network, the following approaches can help *prevent* the threat of Raptor's routing attacks.

Advertising /24 Tor prefixes: Our experimental measurements indicate that over 90% of Tor relays have a prefix length shorter than /24. This allows an AS-level adversary to launch a BGP hijack or interception attack against these Tor relays by advertising a more specific prefix for them (globally). We advocate that the Tor relay operators should be running Tor relays with a prefix length of /24. Autonomous systems typically filter route advertisements of prefix longer than /24, so AS-level adversaries will not be able to launch a more specific hijack or interception attack.

Favoring closer guard relays: Even if a Tor relay advertises a /24 prefix, an AS-level adversary can launch an equally specific prefix hijack or interception attack (by advertising another /24). In this case, the impact of the attack is localized around the attacker's autonomous system, since the route is not globally propagated. We advocate that Tor clients select their guard relays by favoring Tor relays with a shorter AS-level path between them. Tor clients could either obtain AS-level path information via the Tor network consensus download mechanism, or they can perform traceroutes themselves. This further mitigates the risk to Tor clients due to an equally specific prefix attack. We note that by selecting guard relays that are closer to the client in the AS topology, the risk of asymmetric traffic analysis and BGP churn is also mitigated. [2]

Securing inter-domain routing: The research community has proposed multiple protocols for securing inter-domain routing [41, 32, 19, 29, 17]. Real-world deployment of these protocols would mitigate the BGP hijack and interception attacks on Tor. However, this approach requires buy-in from multiple stakeholders in the complex ecosystem of the Internet, and progress on this front has been slow. We hope that the concerns we raise about the compromise of user anonymity in Tor can help accelerate the momentum for improving BGP security.

7 Discussion and Ethical Considerations

Colluding adversaries. In this paper, we quantified the threat of Raptor attacks from the perspective of individual autonomous systems. In practice, autonomous systems can collude with each other to increase their capability of monitoring Tor traffic. For example, autonomous systems within the same legal jurisdiction may be forced to monitor Tor traffic and share it with a single entity that may launch Raptor attacks.

Applicability to other anonymity systems. It is important to note that our attacks merely consider Tor as an example of a low-latency anonymity system. Raptor attacks are broadly applicable to other deployed anonymity systems such as I2P, Freenet and Tribler [47, 21, 50].

Ethical considerations. We introduce and evaluate several novel attacks against the Tor network. The Tor network has a userbase of several million users [9], and these users are especially concerned about the privacy of their communications. Thus, it is of utmost importance that our real-world experiments on the Tor network do not compromise the privacy and safety of Tor users. In this paper, we take multiple precautions to safeguard the privacy of Tor users:

- *Attack our own traffic.* All of our attacks only experiment with traffic that we created ourselves, i.e., we deanonymize our own traffic. In fact, we do not store or analyze traffic of any real Tor user.

[2] We note that if clients select closer guards, then knowledge of the guards reveals probabilistic information about the clients. We will investigate this trade-off in future work.

- *Attack our own relay*. Similarly, to demonstrate the threat of prefix interception attacks on the live Tor network, we launch interception attacks against relays that we already control, i.e., we hijack/intercept our own prefix.

- *Firewall our Tor relay*. We also used network-level firewalls to ensure that real Tor users will never use relays that we control: traffic from real users is dropped by the firewall. Only authorized traffic that we create ourselves can bypass the firewall and use our Tor relay.

8 Related Work

AS-level adversaries: It is well known that an adversary who can observe users' communications at both ends of the segment can deanonymize Tor clients [45, 54]. Feamster and Dingledine were the first to consider the attack from the perspective of an AS-level adversary [28]. Later, Edman and Syverson explored the impact of Tor path selection strategies on the security of the network [26]. Recently, Johnson et al. analyzed the security of the Tor network against AS-level adversaries in terms of user understandable metrics for anonymity [34], and Akhoondi *et al.* [13] considered path selection algorithms that minimize opportunities for AS-level end-to-end traffic analysis. Finally, Murdoch *et al.* [40] considered the analogous analysis with respect to Internet exchange level adversaries, which are also in a position to observe a significant fraction of Internet traffic.

We build upon these works and introduce Raptor attacks, that leverage routing asymmetry, routing churn, and routing attacks to compromise user anonymity more effectively than previously thought possible.

The attack observations in Raptor were briefly discussed in a preliminary and short workshop paper [48]. In this paper, we go further by measuring the importance of the attacks using real-world Internet control- and data-plane data. We also demonstrate the attacks feasibility by performing them on the live Tor network—*with success*. Finally, we also describe efficient countermeasures to restore a good level of anonymity.

Traffic analysis of Tor: An important thread of research aims to perform traffic analysis of Tor communications via side-channel information about Tor relays. Murdoch et al. [39], Evans et al. [27], and Jansen et al. [33] have demonstrated attacks that use node congestion and protocol-level details as a side channel to uncover Tor relays involved in anonymous paths. Furthermore, Mittal et al. [37] and Hopper et al. [30, 31] proposed the use of network throughput and network latency as a side channel to fingerprint Tor relays involved in anonymous paths. We note that most of these attacks provide probabilistic information about Tor relays, and may not deanonymize the Tor clients. In contrast, Raptor attacks can completely deanonymize Tor clients.

BGP insecurity: The networking research community has extensively studied attacks on inter-domain routing protocols including BGP hijack [51, 52, 53, 44] and interception attacks [16]. Similarly, there has been much work on proposing secure routing protocols that resist the above attacks [41, 32, 17, 19, 29]. However, we are the first to study the implications of these attacks on privacy technologies such as the Tor network. Arnbak et al. [14] discuss surveillance capabilities of autonomous systems from a legal perspective, but do not discuss anonymity systems.

9 Conclusion

Raptor attacks exploit the dynamics of Internet routing (such as routing asymmetry, routing churn, and routing attacks) to enable an AS-level adversary to effectively compromise user anonymity.

Our experimental results show that Raptor attacks present a serious threat to the security of anonymity systems. Our key results include (1) demonstration of asymmetric traffic correlation on the live Tor network, which achieves 95% accuracy with no observed false positives, (2) quantifying the impact of routing asymmetry and routing churn on AS-level attacks – an increase of 50% to 100% respectively compared to conventional attacks, (3) uncovering historical BGP hijacks involving Tor relays, and (4) successful demonstration of a traffic analysis attack via BGP interception on the live Tor network. We also outlined a taxonomy of countermeasures against our attacks.

Our work highlights the dangers of abstracting network routing from the analysis of anonymity systems such as Tor, and motivates the design of next generation anonymity systems that resist Raptor.

A Appendix: Rejected Countermeasures

Obfuscating packet timings and sizes: While the use of high latency mix networks [38, 23] and constant rate cover traffic [22] can mitigate timing analysis even against an adversary that observes all communications, these defenses are considered too costly to be deployed in the Tor network.

Mitigating asymmetric attacks: Recall that our asymmetric correlation attack leverages information in the TCP header, namely the sequence number field that indicates the number of acknowledged bytes. One potential countermeasure would be to encrypt the TCP header, by leveraging IP-layer encryption techniques such as IPSec. However, this approach introduces several challenges. First, it would require a substantial engineering effort to migrate Tor towards IPSEC. Second, since IPSEC is not widely used, this would make Tor traffic easy to distinguish from other encrypted traffic, thwarting its use for applications such as censorship resistance. Finally, encrypting the TCP header may not complete solve the attack. For example, an adversary could attempt to correlate TCP data packets with simply the number of TCP ACK packets, disregarding the sequence number field.

Circuit Fingerprinting Attacks:
Passive Deanonymization of Tor Hidden Services

This paper sheds light on crucial weaknesses in the design of hidden services that allow us to break the anonymity of hidden service clients and operators passively. In particular, we show that the *circuits*, paths established through the Tor network, used to communicate with hidden services exhibit a very different behavior compared to a general circuit. We propose two attacks, under two slightly different threat models, that could identify a hidden service client or operator using these weaknesses. We found that we can identify the users' involvement with hidden services with more than 98% true positive rate and less than 0.1% false positive rate with the first attack, and 99% true positive rate and 0.07% false positive rate with the second. We then revisit the threat model of previous website fingerprinting attacks, and show that previous results are directly applicable, with greater efficiency, in the realm of hidden services. Indeed, we show that we can correctly determine which of the 50 monitored pages the client is visiting with 88% true positive rate and false positive rate as low as 2.9%, and correctly deanonymize 50 monitored hidden service servers with true positive rate of 88% and false positive rate of 7.8% in an open world setting.

1 Introduction

In today's online world where gathering users' personal data has become a business trend, Tor [14] has emerged as an important privacy-enhancing technology allowing Internet users to maintain their anonymity online. Today, Tor is considered to be the most popular anonymous communication network, serving millions of clients using approximately 6000 volunteer-operated relays, which are run from all around the world [3].

In addition to sender anonymity, Tor's hidden services allow for receiver anonymity. This provides people with a free haven to host and serve content without the fear of being targeted, arrested or forced to shut down [11]. As a result, many sensitive services are only accessible through Tor. Prominent examples include human rights and whistleblowing organizations such as Wikileaks and Globalleaks, tools for anonymous messaging such as TorChat and Bitmessage, and black markets like Silkroad and Black Market Reloaded. Even many non-hidden services, like Facebook and DuckDuckGo, recently have started providing hidden versions of their websites to provide stronger anonymity guarantees.

That said, over the past few years, hidden services have witnessed various active attacks in the wild [12, 28], resulting in several takedowns [28]. To examine the security of the design of hidden services, a handful of attacks have been proposed against them. While they have shown their effectiveness, they all assume an active attacker model. The attacker sends crafted signals [6] to speed up discovery of *entry guards*, which are first-hop routers on circuits, or use congestion attacks to bias entry guard selection towards colluding entry guards [22]. Furthermore, all previous attacks require a malicious client to continuously attempt to connect to the hidden service.

In this paper, we present the first practical *passive* attack against hidden services and their users called *circuit fingerprinting* attack. Using our attack, an attacker can identify the presence of (client or server) hidden service activity in the network with high accuracy. This detection reduces the anonymity set of a user from millions of Tor users to just the users of hidden services. Once the activity is detected, we show that the attacker can perform website fingerprinting (WF) attacks to deanonymize the hidden service clients and servers. While the threat of WF attacks has been recently criticized by Juarez *et al.* [24], we revisit their findings and demonstrate that the world of hidden services is the ideal setting to wage WF attacks. Finally, since the attack is passive, it is undetectable until the nodes have been deanonymized, and can target thousands of hosts retroactively just by having access to clients' old network traffic.

[*] Joint first author.

Approach. We start by studying the behavior of Tor circuits on the live Tor network (for our own Tor clients and hidden services) when a client connects to a Tor hidden service. Our key insight is that during the circuit construction and communication phase between a client and a hidden service, Tor exhibits fingerprintable traffic patterns that allow an adversary to efficiently and accurately identify, and correlate circuits involved in the communication with hidden services. Therefore, instead of monitoring every circuit, which may be costly, the first step in the attacker's strategy is to identify suspicious circuits with high confidence to reduce the problem space to just hidden services. Next, the attacker applies the WF attack [10, 36, 35] to identify the clients' hidden service activity or deanonymize the hidden service server.

Contributions. This paper offers the following contributions:

1. We present key observations regarding the communication and interaction pattern in the hidden services design in Tor.

2. We identify distinguishing features that allow a passive adversary to easily detect the presence of hidden service clients or servers in the local network. We evaluate our detection approach and show that we can classify hidden service circuits (from the client- and the hidden service-side) with more than 98% accuracy.

3. For a stronger attacker who sees a majority of the clients' Tor circuits, we propose a novel circuit correlation attack that is able to quickly and efficiently detect the presence of hidden service activity using a sequence of only the first 20 cells with accuracy of 99%.

4. Based on our observations and results, we argue that the WF attacker model is *significantly more realistic and less costly* in the domain of hidden services as opposed to the general web. We evaluate WF attacks on the identified circuits (from client and hidden service side), and we are able to classify hidden services in both open and closed world settings.

5. We propose defenses that aim to reduce the detection rate of the presence of hidden service communication in the network.

Roadmap. We first provide the reader with a background on Tor, its hidden service design, and WF attacks in Section 2. We next present, in Section 3, our observations regarding different characteristics of hidden services. In Section 4, we discuss our model and assumptions, and in Sections 5 and 6, we present our attacks and evaluation. In Section 7, we demonstrate the effectiveness of WF attacks on hidden services. We then discuss possible future countermeasures in Section 8. Finally, we overview related works in Section 9, and conclude in Section 10.

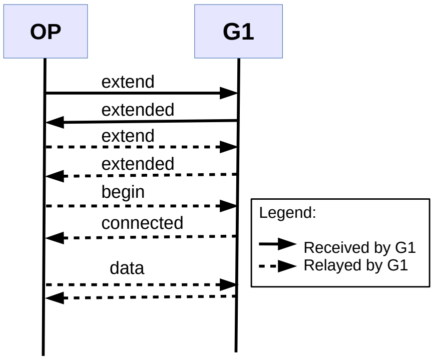

Figure 1: Cells exchanged between the client and the entry guard to build a general circuit for non-hidden streams after the circuit to G1 has been created.

2 Background

We will now provide the necessary background on Tor and its hidden services. Next, we provide an overview of WF attacks.

2.1 Tor and Hidden Services

Alice uses the Tor network simply by installing the Tor browser bundle, which includes a modified Firefox browser and the *Onion Proxy* (OP). The OP acts as an interface between Alice's applications and the Tor network. The OP learns about Tor's relays, *Onion Routers* (ORs), by downloading the network *consensus* document from *directory servers*. Before Alice can send her traffic through the network, the OP builds *circuits* interactively and incrementally using 3 ORs: an entry guard, middle, and exit node. Tor uses 512-byte fixed-sized *cells* as its communication data unit for exchanging control information between ORs and for relaying users' data.

The details of the circuit construction process in Tor proceeds as follows. The OP sends a `create_fast` cell to establish the circuit with the entry guard, which responds with a `created_fast`. Next, the OP sends an `extend` command cell to the entry guard, which causes it to send a `create` cell to the middle OR to establish the circuit on behalf of the user. Finally, the OP sends another `extend` to the middle OR to cause it to create the circuit at exit. Once done, the OP will receive an `extended` message from the middle OR, relayed by the entry guard. By the end of this operation, the OP will have shared keys used for layered encryption, with every hop on the circuit.[1] The exit node peels the last layer of the encryption and establishes the TCP connection to Alice's destination. Figure 1 shows the cells exchanged between OP and the entry guard for regular Tor connections, after the exchange of the `create_fast` and `created_fast` messages.

Tor uses TCP secured with TLS to maintain the OP-to-OR and the OR-to-OR connections, and multiplexes circuits within a single TCP connection. An OR-to-OR connection multiplexes circuits from various users, whereas an OP-to-OR connection multiplexes circuits from the same user. An observer watching the OP-to-OR TCP connection should not be able to tell apart which TCP segment belongs to which circuit (unless only one circuit is active). However, an entry guard is able to differentiate the traffic of different circuits (though the contents of the cells are encrypted).

Tor also allows receiver anonymity through hidden services. Bob can run a server behind his OP to serve content without revealing his identity or location. The overview of creation and usage of hidden services is depicted in Figure 2. In order to be reachable by clients, Bob's OP will generate a hidden service *descriptor*, and execute the following steps. First, Bob's OP chooses a random OR to serve as his *Introduction Point* (IP), and creates a circuit to it as described above. Bob then sends an `establish_intro` message that contains Bob's public key (the client can select more than one IP). If the OR accepts, it sends back an `intro_established` to Bob's OP. Bob now creates a signed descriptor (containing a timestamp, information about the IP, and its public key), and computes a descriptor-id based on the public key hash and validity duration. The descriptor is then published to the hash ring formed by the hidden service directories, which are the ORs that have been flagged by the network as "HSDir". Finally, Bob advertises his hidden service URL `z.onion` out of band, which is derived from the public key. This sequence of exchanged cells to create a hidden service is shown in Figure 3.

In Figure 4, we show how Alice can connect to Bob. Using the descriptor from the hidden service directories, The exchange of cells goes as follows. First, Alice's OP selects a random OR to serve as a *Rendezvous Point* (RP) for its connection to Bob's service, and sends an `establish_rendezvous` cell (through a Tor circuit). If the OR accepts, it responds with a `rendezvous_established` cell. In the meantime, Alice's OP builds another circuit to one of Bob's IPs, and sends an `introduce1` cell along with the address of RP and a cookie (one-time secret) encrypted under Bob's public key. The IP then relays that information to Bob and an `introduce2` cell, and sends an `introduce_ack` towards Alice. At this point, Bob's OP builds a circuit towards Alice's RP and sends it a `rendezvous1`, which causes the RP to send a `rendezvous2` towards Alice. By the end of this operation, Alice and Bob will have shared keys established through the cookie, and can exchange data through the 6 hops between them.

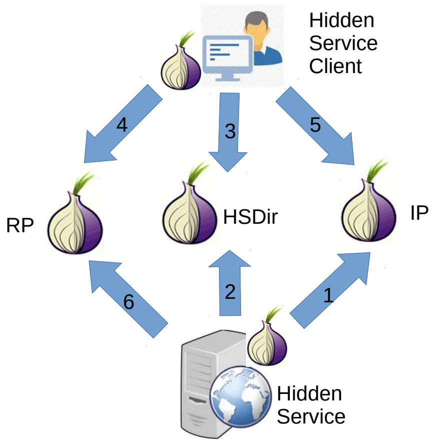

Figure 2: Circuit construction for Hidden Services.

2.2 Website Fingerprinting

One class of traffic analysis attacks that has gained research popularity over the past few years is the website fingerprinting (WF) attack [10, 36, 35, 9]. This attack demonstrates that a *local passive* adversary observing the (SSH, IPsec, or Tor) encrypted traffic is able, under certain conditions, to identify the website being visited by the user.

In the context of Tor, the strategy of the attacker is as follows. The attacker tries to emulate the network conditions of the monitored clients by deploying his own client who visits websites that he is interested in classifying through the live network. During this process, the attacker collects the network traces of the clients. Then, he trains a supervised classifier with many identifying features of a network traffic of a website, such as the sequences of packets, size of the packets, and inter-packet timings. Using the model built from the samples, the attacker then attempts to classify the network traces of users on the live network.

WF attacks come in two settings: open- or closed-world. In the closed-world setting, the attacker assumes that the websites visited are among a list of *k* known websites, and the goal of the attacker is to identify which one. The open-world setting is more realistic in that it assumes that the client will visit a larger set of websites

[1] We have omitted the details of the Diffie-Hellman handshakes (and the Tor Authentication Protocol (TAP) in general), as our goal is to demonstrate the data flow only during the circuit construction process.

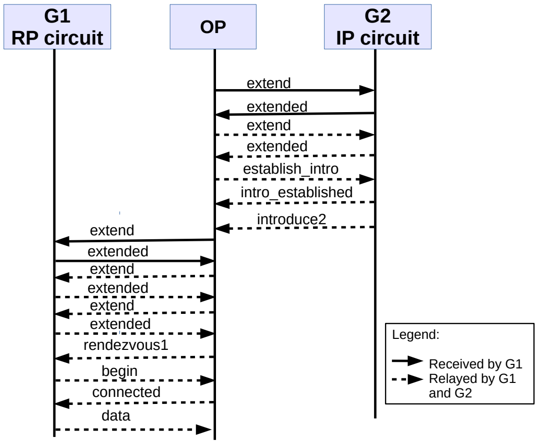

Figure 3: Cells exchanged in the circuit between the entry guards and the hidden service operator after the circuits to G1 and G2 have been created. Note that both G1 and G2 might be the same OR, and that entry guards can only view the first `extend` cell they receive.

n, and the goal of the attacker is to identify if the client is visiting a monitored website from a list of *k* websites, where $k \ll n$.

Hermann *et al.* [20] were the first to test this attack against Tor using a multinomial Naive Bayes classifier, which only achieved 3% success rate since it relied on packet sizes which are fixed in Tor. Panchenko *et al.* [33] improved the results by using a Support Vector Machine (SVM) classifier, using features that are mainly based on the volume, time, and direction of the traffic, and achieved more than 50% accuracy in a *closed-world* experiment of 775 URLs. Several subsequent papers have worked on WF in open-world settings, improved on the classification accuracy, and proposed defenses [10, 36, 35, 9].

3 Observations on Hidden Service Circuits

To better understand different circuit behaviors, we carried out a series of experiments, which were designed to show different properties of the circuits used in the communication between a client and a Hidden Service (HS), such as the Duration of Activity (DoA), incoming and outgoing cells, presence of multiplexing, and other potentially distinguishing features. DoA is the period of time during which a circuit sends or receives cells. The expected lifetime of a circuit is around 10 minutes, but circuits may be alive for more or less time depending on their activities.

For the remainder of this paper, we use the following terminology to denote circuits:

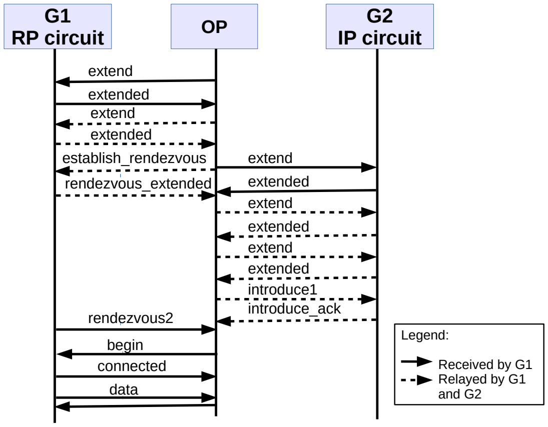

Figure 4: Cells exchanged in the circuit between the entry guards and the client attempting to access a hidden service after the circuits to G1 and G2 have been created.

- HS-IP: This is the circuit established between the Hidden Service (HS) and its Introduction Point (IP). The purpose of this circuit is to listen for incoming client connections. This circuit corresponds to arrow 1 in Figure 2.
- Client-RP: This is the circuit that a client builds to a randomly chosen Rendezvous Point (RP) to eventually receive a connection from the HS after he has expressed interest in establishing a communication through the creation of a Client-IP circuit. This circuit corresponds to arrow 4 in Figure 2.
- Client-IP: This is the circuit that a client interested in connecting to a HS builds to one of the IPs of the HS to inform the service of its interest in waiting for a connection on its RP circuit. This circuit corresponds to arrow 5 in Figure 2.
- HS-RP: This is the circuit that the HS builds to the RP OR chosen by the client to establish the communication with the interested client. Both this circuit and the Client-RP connect the HS and the client together over Tor. This circuit corresponds to arrow 6 in Figure 2.

For our hidden service experiments, we used more than 1000 hidden services that are compiled in `ahmia.fi` [2], an open source search engine for Tor hidden service websites. We base our observations on the logs we obtained after running all experiments for a three month period from January to March, 2015. This is important in order to realistically model steady-state Tor processes, since Tor's circuit building decisions are influenced by the circuit build time distributions. Furthermore, we configured our Tor clients so that they do not use fixed entry guards (by setting UseEntryGuards to 0). By doing so, we increase variety in our data collection, and do not limit ourselves to observations that are only obtained by using a handful of entry guards.

3.1 Multiplexing Experiment

To understand how stream multiplexing works for Client-RP and Client-IP circuits, we deployed a single Tor process on a local machine which is used by two applications: `firefox` and `wget`. Both automate hidden services browsing by picking a random `.onion` domain from our list of hidden services described above. While the `firefox` application paused between fetches to model user think times [19], the `wget` application accessed pages sequentially without pausing to model a more aggressive use. Note that the distribution of user think times we used has a median of 13 seconds, and a long tail that ranges between 152 to 3656 seconds for 10% of user think times. Since both applications are using the same Tor process, our intention is to understand how Tor multiplexes streams trying to access different `.onion` domains. We logged for every `.onion` incoming stream, the circuit on which it is attached. We next describe our observations.

Streams for different `.onion` domains are not multiplexed in the same circuit. When the Tor process receives a stream to connect to a `.onion` domain, it checks if it already has an existing RP circuit connected to it. If it does, it attaches the stream to the same circuit. If not, it will build a new RP circuit. We verified this by examining a 7-hour log from the experiment described above. We found that around 560 RP circuits were created, and each was used to connect to a different `.onion` domain.

Tor does not use IP or RP circuits for general streams. Tor assigns different purposes to circuits when they are established. For streams accessing non-hidden servers, they use general purpose circuits. These circuits can carry multiple logical connections; i.e., Tor multiplexes multiple non-hidden service streams into one circuit. On the other hand, streams accessing a `.onion` domain are assigned to circuits that have a rendezvous-related purpose, which differ from general circuits. We verified the behavior through our experiments, and also by reviewing Tor's specification and the source code.

3.2 Hidden Service Traffic Experiment

The goal of this experiment is to understand the usage of IP and RP circuits from the hidden server and from the client points of view. We deployed a hidden service on the live Tor network through which a client could visit a cached version of any hidden service from our list above, which we had previously crawled and downloaded. Our hidden service was simultaneously accessed by our five separate Tor instances, four of which use `wget`, while one uses `firefox`. Every client chooses a random page from our list of previously crawled hidden pages and requests it from our HS. Again, all clients pause between fetches for a duration that is drawn from a distribution of user think times. During the whole hour, we logged the usage of the IP and RP circuits observed from our hidden server, and we logged the RP and IP circuits from our 5 clients. We ran this experiment more than 20 times over two months before analyzing the results.

In addition, to get client-side traffic from live hidden services, we also deployed our five clients described above to access our list of real Tor HSs, rather than our deployed HS.

Similarly, to understand the usage of general circuits, and to compare their usage to IP, and RP circuits, we also ran clients as described above, with the exception that the clients accessed general (non-hidden) websites using Alexa's top 1000 URL [1]. From our experiments, we generated the cumulative distribution function (CDF) of the DoA, the number of outgoing and incoming cells, which are shown in Figure 5a, 5b, and 5c. We present our observations below.

IP circuits are unique. Figure 5a shows the CDF of the DoA for different circuit types. Interestingly, we observe that IP circuits from the hidden service side (i.e., HS-IP) are long lived compared to other circuit types. We observe that the DoA of IP circuits showed an age of around 3600 seconds (i.e., an hour), which happens to be the duration of each experiment. This seems quite logical as these have to be long living connections to ensure a continuous reachability of the HS through its IP. Another unique aspect of the hidden services' IP circuits, shown in Figure 5b, was that they had exactly 3 outgoing cells (coming from the HS): 2 `extend` cells and one `establish_intro` cell. The number of incoming cells (from the IP to the HS) differ however, depending on how many clients connect to them. Intuitively, one understands that any entry guard could, possibly, identify an OP acting on behalf of an HS by seeing that this OP establishes with him long-lived connections in which it only sends 3 cells at the very beginning. Furthermore, from the number of incoming client cells, an entry guard can also evaluate the popularity of that HS.

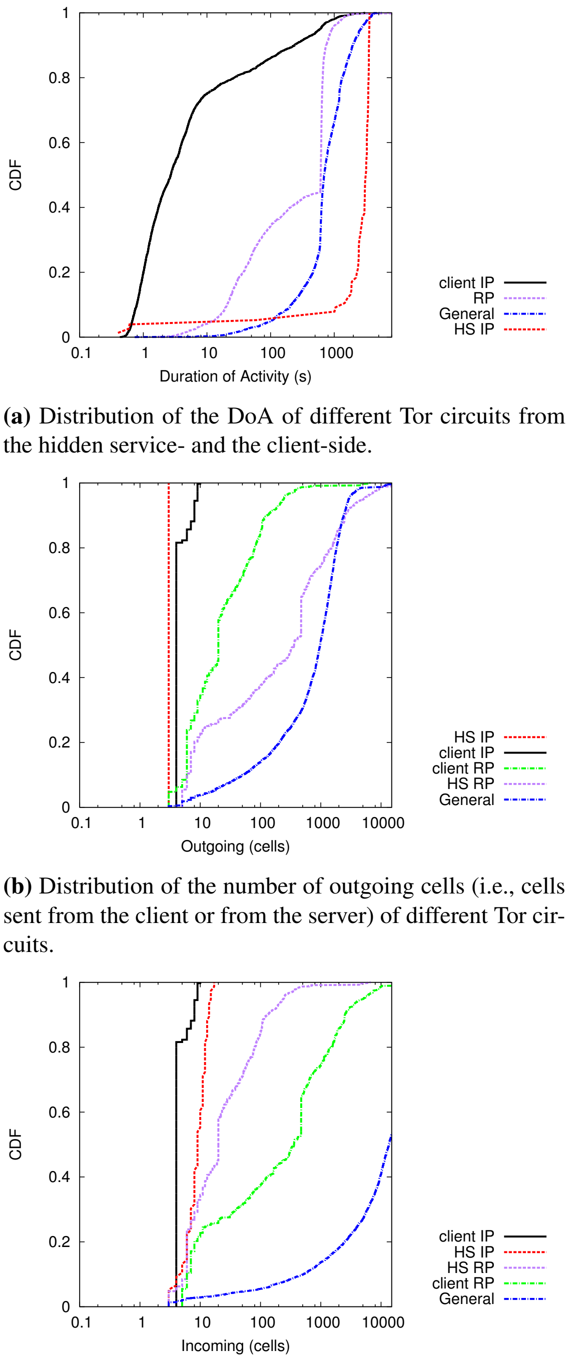
Client-IP circuits are also unique because they have the same number of incoming and outgoing cells. This is evidenced by the identical distributions of the number of incoming and outgoing cells shown in Figures 5b and 5c. For most cases, they had 4 outgoing and 4 incoming cells. The OP sends 3 `extend` and 1 `introduce1` cells, and receives 3 `extended` and 1 `introduce_ack` cells. Some conditions, such as RP failure, occasionally resulted in more exchanged cells, but IP circuits still had the same number of incoming and outgoing cells. Another unique feature was that, contrary to the HS-IP circuits, the Client-IP circuits are very short lived – their median DoA is around a second, as shown in Figure 5a, and around 80% of Client-IP circuits have a DoA that is less than or equal to 10 seconds. We expect this behavior as Client-IP circuits are not used at all once the connection to the service is established.

Active RP circuits, like general circuits, had a median DoA of 600 seconds, which is the expected lifetime of a Tor circuit. This was in particular observed with the clients which accessed our HS (the same RP circuit is reused to fetch different previously crawled pages). On the other hand, when the clients access live Tor hidden services, they have significantly lower DoA. Indeed, we observe (Figure 5a) that general circuits tend to have a larger DoA than RP circuits. The reason for this is that the same RP circuit is not used to access more than one hidden domain. Once the access is over, the circuit is not used again. On the other hand, general circuits can be used to access multiple general domains as long as they have not been used for more than 600 seconds.

HS-RP circuits have more outgoing cells than incoming cells. This is quite normal and expected since that circuit corresponds to the fetching of web pages on a server by a client. Typically, the client sends a few requests for each object to be retrieved in the page whereas the server sends the objects themselves which are normally much larger than the requests. There can be exceptions to this observation when, for instance, the client is uploading documents on the server or writing a blog, among other reasons.

Similarly, because RP circuits do not multiplex streams for different hidden domains, they are also expected to have a smaller number of outgoing and incoming cells throughout their DoA compared to active general circuits. As can be seen in Figures 5b, and 5c, one may distinguish between Client-RP and HS-RP circuits by observing the total number of incoming and outgoing cells. (Note that, as expected, the incoming distributions for the client and for the hidden service RP circuits from Figure 5c are the same as the outgoing distribution for hidden service and client RP, respectively, from Figure 5b.)

The incoming and outgoing distributions of RP circuits are based on fetching a hidden page, so the distributions we see in the figures might represent baseline distributions, and in the real network, they may have more incoming and outgoing cells based on users' activity. Although the exact distributions of the total number of incoming and outgoing cells for RP circuits is based on our models and may not reflect the models of users on the live network, we believe that the general trends are realistic. It is expected that clients mostly send small requests, while hidden services send larger pages.



(a) Distribution of the DoA of different Tor circuits from the hidden service- and the client-side.

(b) Distribution of the number of outgoing cells (i.e., cells sent from the client or from the server) of different Tor circuits.

(c) Distribution of the number of incoming cells (i.e., cells sent to the client or from the server) of different Tor circuits.

Figure 5: Cumulative distribution functions showing our observations from the experiments. Note that the X-axis scales exponentially.

Table 1: Edit distances of hidden pages across several weeks.

Edit distance	1 week	2 weeks	3 weeks	8 weeks
Q1	1	0.997	0.994	0.980
Median	1	1	1	1
Q3	1	1	1	1
Mean	0.96	0.97	0.96	0.927

Table 2: Edit distances of Alexa pages across several weeks.

Edit distance	1 week	2 weeks	3 weeks	8 weeks
Q1	0.864	0.846	0.81	0.71
Median	0.95	0.94	0.92	0.88
Q3	0.995	0.990	0.98	0.96
Mean	0.90	0.88	0.86	0.8

3.3 Variability in Hidden Pages

Over a period of four weeks, we downloaded the pages of more than 1000 hidden services once per week. We then computed the edit distance, which is the number of insertions, deletions, and substitutions of characters needed to transform the page retrieved at time T with the ones retrieved at time $T+k$ weeks (with $k \in [1..8]$). Table 1 shows the three quartiles and the mean for the distribution of edit distances computed, which demonstrates that the pages remained almost identical. For comparison, we also downloaded the pages of Alexa's top 1000 URLs, and computed the edit distances in Table 2. This is not surprising since the sources of variations in the pages are mostly due to dynamism, personalized advertisements, or different locations. None of these sources is applicable to hidden services since clients are anonymous when they initiate the connections. Note that hidden services may implement personalized pages for a user after he or she logs into his or her account; however in the context of this paper, we are mainly concerned with the retrieval of the very first page.

4 Threat Model

Alice's anonymity is maintained in Tor as long as no single entity can link her to her destination. If an attacker controls the entry and the exit of Alice's circuit, her anonymity can be compromised, as the attacker is able to perform traffic or timing analysis to link Alice's traffic to the destination [5, 23, 25, 32]. For hidden services, this implies that the attacker needs to control the two entry guards used for the communication between the client and the hidden service. This significantly limits the attacker, as the probability that both the client and the hidden service select a malicious entry guard is much lower than the probability that only one of them makes a bad choice.

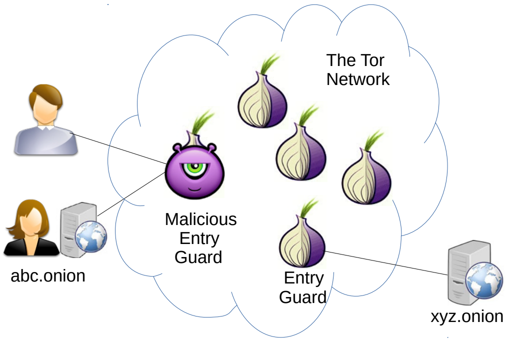


Figure 6: Our adversary can be a malicious entry guard that is able to watch all circuits

Our goal is to show that it is possible for a local passive adversary to deanonymize users with hidden service activities without the need to perform end-to-end traffic analysis. We assume that the attacker is able to monitor the traffic between the user and the Tor network. The attacker's goal is to identify that a user is either operating or connected to a hidden service. In addition, the attacker then aims to identify the hidden service associated with the user.

In order for our attack to work effectively, the attacker needs to be able to extract circuit-level details such as the lifetime, number of incoming and outgoing cells, sequences of packets, and timing information. We note that similar assumptions have been made in previous works [10, 35, 36]. We discuss the conditions under which our assumptions are true for the case of a network admin/ISP and an entry guard.

Network administrator or ISP. A network administrator (or ISP) may be interested in finding out who is accessing a specific hidden service, or if a hidden service is being run from the network. Under some conditions, such an attacker can extract circuit-level knowledge from the TCP traces by monitoring all the TCP connections between Alice and her entry guards. For example, if only a single active circuit is used in every TCP connection to the guards, the TCP segments will be easily mapped to the corresponding Tor cells. While it is hard to estimate how often this condition happens in the live network, as users have different usage models, we argue that the probability of observing this condition increases over time.

Malicious entry guard. Controlling entry guards allows the adversary to perform the attack more realistically and effectively. Entry guards are in a perfect position to perform our traffic analysis attacks since they have full visibility to Tor circuits. In today's Tor network, each OP chooses 3 entry guards and uses them for

45 days on average [16], after which it switches to other guards. For circuit establishment, those entry guards are chosen with equal probability. Every entry guard thus relays on average 33.3% of a user's traffic, and relays 50% of a user's traffic if one entry guard is down. Note that Tor is currently considering using a single fast entry guard for each user [13]. This will provide the attacker with even better circuit visibility which will exacerbate the effectiveness of our attack. This adversary is shown in Figure 6.

5 Circuit Fingerprinting Attack

In this section, we present our circuit fingerprinting attacks. Our attack allows an adversary to accurately and efficiently identify the presence of hidden service activity of a client or a server, and the circuit used to communicate with or by the hidden service (i.e., RP circuit). We first present an attack feasible for a more traditional attacker. Then, we describe a stronger attack for a more powerful adversary who can see more of the circuits from a user.

5.1 Classifying Special Circuits

Since the attacker is monitoring thousands of users, who produce hundreds of thousands of circuits, it is important to find an easy and straightforward approach to flag potentially "interesting" circuits for further examination. The attacker can exploit the simple and surprisingly distinctive features exhibited by IP and RP circuits (both client and hidden service side) to identify those circuits. In particular, we use the following features which are based on our observations in Section 3:

- **Incoming and outgoing cells**: This category of features will be useful in identifying IP circuits. For example, if a circuit sends precisely 3 cells, but has slightly more incoming cells (within a 1-hour duration), then this circuit is HS-IP with a high probability. Furthermore, if a circuit sends more than 3 cells, but has the exact same number of incoming and outgoing cells, then it is a client-IP with a high probability. This feature is also useful in distinguishing Client-RP from HS-RP circuits since we expect that HS-RP circuits to have more outgoing than incoming cells, and vice-versa for Client-RP circuits.

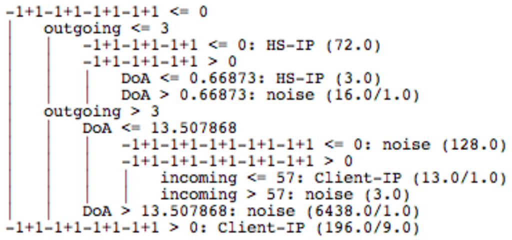
- **Duration of activity**: This feature is useful in distinguishing three groups of circuits: Client-IP circuits, HS-IP circuits, and all other circuits consisting of general, Client-, and HS-RP circuits. Recall that HS-IP circuits are long lived by design in order to be contacted by all interested clients, whereas client-IP circuits are inactive after performing the introduction process between the client and the hidden service, and have a median DoA of 1 second. Active general, Client-RP and HS-RP circuits can be alive and have a median of 600 seconds, which is the default lifetime of a circuit in Tor.

- **Circuit construction sequences**: We represent each of the first 10 cells (enough cells to capture the sequence of circuit establishment) either by the string -1 or +1. Each string encodes the direction of the corresponding cell. For example, the sequence "-1-1+1" corresponds to two outgoing cells followed by one incoming cell. This feature is useful in distinguishing Client-RP circuits from general and HS-RP circuits. The reason is that the circuit construction cell sequences in the case of Client-RP circuits differs from HS-RP and general circuits. This can be observed in Figures 1, 2, and 3. For example, we noticed that the sequence -1+1-1+1-1+1+1-1+1-1 is very common in Client-RP circuits, which corresponds to the sequence between the OP and G1 in Figure 3. However, HS-RP and general circuits have similar sequences so this feature alone cannot differentiate between those two circuit types.

Strategy. Different features are more indicative of certain circuit types. To best exploit those features, we perform our classification in two steps. First, the adversary looks for Client-IP and HS-IP circuits since those are the easiest ones to classify. This also allows the adversary to figure out if he is monitoring a HS or client of a HS. In the second step, the adversary examines the non-IP circuits to find RP circuits among them.

We use decision-tree classification algorithms, since identifying IP and RP circuits is dependent on an if-then-else conditional model as we discussed above. Tree-based algorithms build decision trees whose internal nodes correspond to the tests of features, and the branches correspond to the different outcomes of the tests. The leaves of the tree correspond to the classes, and the classification of a test instance corresponds to selecting the path in the tree whose branch values best reflect the new testing instance. Decisional trees have been used previously in the traffic classification literature [27, 4, 26] and are ideal for our problem.

Figures 7 and 8 depict decision trees which we use in the first step of this attack to identify the IP circuits. Note that general and RP circuits are treated as "noise". The tree in Figure 7 uses all features described above, and has a size of 15 nodes and 8 leaves, whereas the tree in Figure 8 omits the sequences, and only relies on incoming/outgoing packets and the DoA, which results in 10 leaves and a total size of 19 nodes. Both trees are very



```
-1+1-1+1-1+1-1+1 <= 0
|   outgoing <= 3

```

Figure 9: Decisional Tree (C4.5 algorithm) used in identifying RP circuits out of web browsing circuits.

small, which allows for efficient classification. We discuss their performance in Section 6.1.

Once the adversary succeeds in identifying IP circuits, he is able to mark suspicious clients, and he can proceed to identifying their RP circuits. This can reduce his classification costs, and false positives. One challenge in distinguishing RP circuits from general circuits is that we cannot rely on DoA or the total number of incoming and outgoing cells as we did for IP circuits: in the case of general and RP circuits, those values are based on the user activity and can be biased by our models. To avoid such biases, we rely again on features that are protocol-dependent rather than user-dependent. Using our observation about sequences of Client-RP described previously, we can classify the circuit. Finally, to distinguish between HS-RP and general circuits, we use the first 50 cells of each circuit, and count the number of its incoming and outgoing cells. HS-RP circuits will generally have more outgoing than incoming, and the opposite should be true for general browsing circuits.

Figure 9 depicts a decision tree for classifying Client-RP, HS-RP and general circuits. It can be seen from the tree that Client-RP circuits are completely distinguished by their packet sequence fingerprint. Recall that those sequences represent the first 10 cells from the circuit, which is important as we want our sequences to be application independent. Also, HS-RP and general circuits are distinguished from each other by the fraction of incoming and outgoing cells of the first 50 cells. The tree contains a total of 17 nodes and only 9 leaves. We present the performance of this tree in Section 6.1.

5.2 Correlating Two Circuits

As mentioned in Section 4, Tor is considering using only a single entry guard per user. This changes the adversarial model: a malicious entry guard can now see *all* of the circuits used by a connected user. In this scenario, the attacker can see both IP and RP circuits. Even for a traditional entry guard, it has at least 11-25% chance of seeing both circuits. Such an attacker can leverage the fact that *the process of establishing the connection with the hidden service is fingerprintable*.

A client accessing a hidden service will exhibit a different circuit construction and data flow pattern from that of a client accessing a non-hidden service. For a client accessing a hidden service, the OP first builds the RP circuit, and simultaneously starts building a circuit to the IP. In contrast, a client visiting a regular website only establishes one circuit. (Figures 1 and 4 in Section 2 illustrate the exact flow of cells.) Using this fact, the attacker can classify behavior of *pairwise circuits*, and learn the RP of a user. In particular, we show that the first 20 cells of a circuit pair, which include all the cells used to establish connections with IP and RP, are enough to identify IP-RP pairs.

6 Evaluation

To evaluate our features with different machine learning algorithms, we used Weka [18], a free and open-source suite which provides out-of-the-box implementation of various machine learning algorithms. We experimented with the following algorithms: CART [8], which builds binary regression trees based on the Gini impurity, C4.5 [34], which uses information gain to rank possible outcomes, and *k*-nearest neighbors (*k*-NN for short), which considers the neighbors that lie close to each other

Table 3: Number of instances of different circuit types

Dataset	HS-IP	HS-RP	Client-IP	Client-RP	general
IP-Noise	76	954	200	4514	3862
RP-Noise	N/A	954	N/A	4514	3862

in the feature space. When the k-NN classifier is used, we set $k = 2$ with a weight that is inversely proportional to the distance. For each algorithm, we study the true positive rate ($TPR = \frac{TP}{TP+FN}$) and the false positive rate ($FPR = \frac{FP}{TN+FP}$). Specifically, TPR is the rate of correctly identified sensitive class, and FPR is the rate of incorrectly identified non-sensitive class. We collected network traces over the live Tor networks for our clients and server, and we did not touch or log the traffic of other users. We used the latest stable release of the Tor source code (tor-0.2.5.10) in all our experiments.

6.1 Accuracy of Circuit Classification

Datasets. From our long-term experiments described in Section 3, we extracted 5 types of circuits: Client-IP, Client-RP, HS-IP, HS-RP and general circuits. From every circuit, we created an instance consisting of its sequences (first 10 cell), DoA, total incoming and outgoing number of cells within the first 50 cells in the circuit, and a class label corresponding to the circuit type. Furthermore, since Tor is mainly used for web browsing [29], we designed our datasets so that most of the instances are "general" circuits to reflect realistically what an adversary would face when attempting to classify circuits of real users on the live network.

Recall that our general circuits are generated by browsing a random page from the top 1000 websites published by Alexa [1]. This list contains very small webpages (such as localized versions of google.com), and large websites (such as cnn.com). While it is not clear if this set of websites represents what real Tor users visit, we believe that this would not affect our approach since our features are protocol-dependent rather than website- or user-dependent. This is also true about our RP circuits. Therefore, we believe that the specific models and websites should not have an impact on our classification approach. Table 3 shows the number of instances of every class for both datasets.

Since we perform the classification in two steps, we created the following datasets:

- IP-Noise dataset: This dataset consists of 76 HS-IP circuits, 200 Client-IP circuits, and 6593 "noise" circuits. The 200 Client-IP circuits were selected uniformly at random from a large collection of 4514 Client-IP circuits.[2] The circuits labeled with the class "noise" consist of 954 HS-RP, 4514 Client-RP, and 3862 general browsing circuits.

- RP-Noise dataset: This dataset contains 200 Client-RP, 200 HS-RP circuit, and 3862 "noise" circuits (general browsing). The Client-RP and HS-RP circuits were selected uniformly at random from our collection of 954 and 4514 HS-RP and Client-RP circuits, respectively. Again, our goal is to imitate the conditions that the adversary would most likely face on the live network, where the majority of circuits to be classified are general browsing circuits.

Results. We used n-fold cross-validation for the three classification algorithms. This is a validation technique where the dataset is divided into n subsets and $n-1$ subsets are used for training and 1 subset is used for testing, and the process is repeated n times, where each subset is used for validation exactly once. Finally, the results from all n folds are averaged. We set n to 10 for our experiments.

We found that both C4.5 and CART perform equally well in classifying both datasets. We also found that k-NN performs well when cell sequences are used as features but otherwise performs poorly. For the IP-Noise dataset, when cell sequences are not used as a feature, as shown in Figure 10, the per-class TPR for CART ranges between 91.5% (Client-IP class) and 99% (for noise class), whereas the per-class accuracy for C4.5 ranges between 95.5% (Client-IP), and 99.8% (for noise class). k-NN performs worse with a TPR ranging from 55% (for HS-IP class) and 99% (for noise class). k-NN also has a high FPR for the noise class that exceeds 20%. Both C4.5 and Cart have 0% FPR for HS-IP, and have 0.2% and 0.1% FPR for Client-IP, respectively. However, we found that Cart has 7% FPR for the noise class because 17 out of 200 Client-IP instances got misclassified as noise. Therefore, based on the TPR and FPR rates, we conclude that C4.5 outperforms k-NN and Cart for the IP-Noise dataset when no sequences are used as features.

Figure 11 shows that when sequences are used as classification features, all three classifiers perform very well, but C4.5 still outperforms both Cart and k-NN with a nearly perfect per-class TPR. Interestingly, all classifiers provide 0% FPR for HS-IP and very low FPR for Client-IP and noise. We note that C4.5 also provides the best performance since it provides the highest TPR and lowest FPR among other classifiers.

[2] Recall that Client-IP are short-lived and one of these circuits is created every time a client attempts to connect to a HS, whereas HS-IP circuit samples are the most difficult to obtain since we observe each of them for an hour before we repeat experiments.

Table 4: Impact of different features on the TPR and FPR for the RP-Noise dataset. The table shows the accuracy results (TPR / FPR) if individual categories of features are used.

TPR/FPR	Sequences	Cells	Sequences and Cells
HS-RP	0% / 0%	95% / 0.1%	95.5% / 0.1%
Client-RP	98% / 0%	15% / 0.3%	99% / 0%
Noise	100% / 46%	99.5% / 44.8%	99.9% / 2.5%

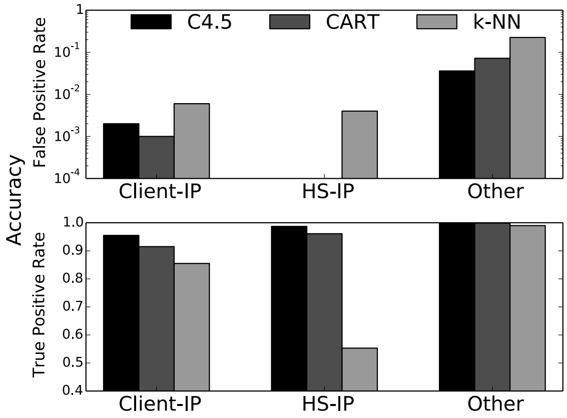

Figure 10: TPR and FPR of circuit classification with 3 classes when no cell sequences are used. FPR is shown in log scale.

For the RP-Noise dataset, we observe that both C4.5 and Cart provide identical performances in terms of TPR and FPR as shown in Figure 12. Both provide very high TPR for all classes, and 0% FPR for HS-RP and Client-RP classes. The FPR achieved by C4.5 and CART for the noise class is also low at 3%. *k*-NN provides slightly higher TPR for the HS-RP class than CART and C4.5, but the TPR is very similar to that achieved by CART and C4.5. We thus conclude that all classifiers perform equally well for the RP-noise dataset. Table 4 shows the impact on the overall accuracy based on different features.

6.2 Accuracy of Circuit Correlation

Datasets. We collected data of both the clients' and the servers' IP and RP circuit pairs for different hidden services. To collect client side circuit pairs, we used both `firefox` and `wget` (with flags set to mimic a browser as much as possible) to connect to hidden and non-hidden services from many different machines, each with one Tor instance. Each client visited 1000 different hidden services and 1000 most popular websites [1] several times. To collect server side circuit pairs, we spawned our own hidden service, and had multiple clients connect and view a page. The number of simultaneously connecting clients ranged from 1 to 10 randomly.

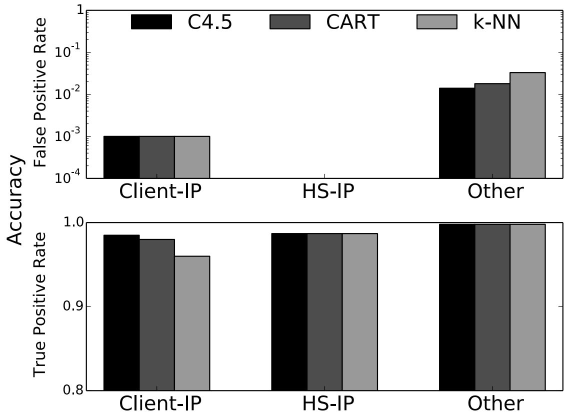

Figure 11: TPR and FPR of circuit classification with 3 classes when cell sequences are used. FPR is shown in log scale.

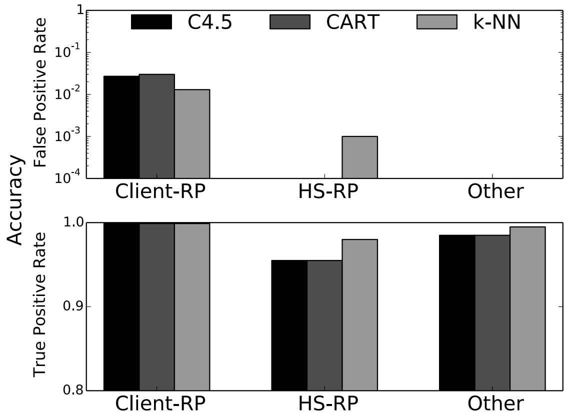

Figure 12: TPR and FPR of circuit classification with 3 classes. FPR is shown in log scale.

We then extracted traces of the first 20 cells of 6000 IP-RP circuit pairs (3000 client and 3000 server pairs) and 80000 of non-special circuit pairs. The non-special circuit pairs included any combination that is not IP-RP (i.e., IP-general, RP-general, general-general).

Result. The accuracy of IP-RP classification is shown in Table 5. We again used 10-fold cross validation to evaluate our attack. We can see that IP-RP circuit pairs are very identifiable: all three algorithms have 99.9% true positive rate, and less than 0.05% false positive rate. This accuracy is likely due to the uniqueness of the exact sequence of cells for IP-RP circuits. From the 6000 sequences of IP-RP pairs and 80000 non-special pairs, there were 923 and 31000 unique sequences respectively. We found that only 14 sequences were shared between the two classes. Furthermore, of those 14 sequences, only 3 of them had more than 50 instances.

This result implies that an adversary who can see a user's IP and RP (e.g., entry guard) can classify IP and RP circuits with almost 100% certainty by observing a

Table 5: IP/RP Pair Classification

Algorithm	True Positive Rate	False Positive Rate
CART	0.999	$2.07 \cdot 10^{-4}$
C4.5	0.999	$3.45 \cdot 10^{-4}$
k-NN	0.999	$6.90 \cdot 10^{-5}$

few cells. Moreover, the attack can be carried out in near real-time speed since we only need the first 20 cells. The attacker can thus effectively rule out most non-sensitive circuits, making data collection much easier.

7 Website Fingerprinting Revisited

In this section, we discuss the impact of our observations and attacks on WF, and show the result of applying modern WF techniques to hidden services. We show that the adversary can classify both the clients' and the operators' hidden service activities with high probability.

7.1 Adversaries Targeting Hidden Services

Juarez *et al.* [24] recently criticized various WF attacks because they made assumptions which were too advantageous for the adversary, and exacerbated the effectiveness of their attacks. In this section, we discuss some of the points that were raised by Juarez *et al.* [24] and show how our attacks address the concerns in the case of attacking hidden services.

Noisy streams. Previous WF attacks assumed that the adversary is able to eliminate noisy background traffic [10, 35, 36]. For example, if the victim's file download stream (noise) is multiplexed in the same circuit with the browsing stream (target), the attacker is able to eliminate the noisy download stream from the traces. With a lack of experimental evidence, such an assumption might indeed overestimate the power of the attack.

In the world of hidden services, we observed that Tor uses separate circuits for different `.onion` domains (Section 3). Furthermore, Tor does not multiplex general streams accessing general non-hidden services with streams accessing hidden services in the same circuit. From the attacker's perspective, this is a huge advantage since it simplifies traffic analysis; the attacker does not have to worry about noisy streams in the background of target streams. Furthermore, the previous assumption that the attacker can distinguish different pages loads is still valid [35]. User "think times" still likely dominate the browsing session, and create noticeable time gaps between cells.

Size of the world. All previous WF attacks have a problem space that is potentially significantly smaller than a realistic setting. Even in Wang *et al.*'s "large" open-world setting, the number of all websites are limited to 10,000 [35]. Moreover, different combinations of websites sharing one circuit could make it impossible to bound the number of untrainable streams. This implies that the false positive rate of WF techniques in practice is significantly higher, since the ratio of trained non-monitored pages to all non-monitored pages go down.

However, in the case of hidden services, the size of the world is significantly smaller than that of the world wide web. Also, while it is true that not all existing hidden services are publicly available, it has been shown that enumerating hidden services is possible [6][3]. In some cases, the attacker could be mainly interested in identifying a censored list of services that make their onion address public. Furthermore, we do not need to consider the blow up of the number of untrainable streams. Since RP always produces clean data, the number of untrained streams is bounded by the number of available hidden services.

Rapidly changing pages. The contents of the general web changes very rapidly as shown by Juarez *et al.* [24]. However, hidden pages show minimal changes over time (Section 3), contrary to non-hidden pages. The slowly changing nature of hidden services reduces the attacker's false positives and false negatives, and minimizes the cost of training. Furthermore, hidden services do not serve localized versions of their pages.

Replicability. Another assumption pointed out by Juarez *et al.* [24], which we share and retain from previous WF attacks, is the replicability of the results. That is, we are assuming that we are able to train our classifier under the same conditions as the victim. Indeed, we acknowledge that since it is difficult to get network traces of users from the live Tor network, we are faced with the challenge of having to design experiments that realistically model the behavior of users, hidden services, and the conditions of the network. That said, our attacks described above use features that are based on circuit interactions and are independent of the users' browsing habits or locations, which can reduce the false positive rate for the WF attacker.

Based on the above discussion, we claim that our attacker model is significantly more realistic than that of previous WF attacks [10, 35, 36]. While the conclusions made by Juarez *et al.* [24] regarding the assumptions of previous WF attacks are indeed insightful, we argue that many of these conclusions do not apply to the realm of hidden services.

[3] As pointed out by a reviewer, it is worth noting that the specific technique used in [6] has since been adressed by a change in the HS directory protocol.

7.2 Methodology

We first note here that hidden services have significantly lower uptime than a normal website on average. We found that only about 1000 hidden services were consistently up of the 2000 hidden services we tried to connect to. This makes collecting significant amounts of traces of hidden services very difficult. Furthermore, we found that hundreds of the available services were just a front page showing that it had been compromised by the FBI. This introduces significant noise to WF printing techniques: we now have hundreds of "different" pages that look exactly the same. We thus tried to group all of these hidden services as one website. This unfortunately limited our open world experiments to just 1000 websites. We also note that there may be other similar cases in our data, where a hidden service is not actually servicing any real content.

7.2.1 Data Collection

We gathered data to test OP servicing a normal user and a hidden service for both closed and open world settings. For the normal user case, we spawned an OP behind which a client connects to any website. We then used both `firefox` and `wget` to visit 50 sensitive hidden services that the attacker monitors (similar to experiments in Section 3). Our sensitive hidden service list contained a variety of websites for whistleblowing, adult content, anonymous messaging, and black markets. We collected 50 instances of the 50 pages, and 1 instance of 950 the other hidden services.

For the hidden service case, we first downloaded the contents of 1000 hidden services using a recursive `wget`. We then started our own hidden service which contains all the downloaded hidden service contents in a subdirectory. Finally, we created 5 clients who connect to our service to simulate users connecting to one server, and visiting a cached page. We then reset all the circuits, and visited a different cached page to simulate a different hidden service. We repeated this experiment 50 times for the 50 monitored hidden services, and once for the other 950 hidden services.

We argue that this setup generates realistic data for the following reasons. First, as shown in Section 3, the actual contents of hidden services changes minimally. Thus servicing older content from a different hidden service within our hidden service should not result in a significantly different trace than the real one. Second, the exact number of clients connected to the service is irrelevant once you consider the results in Section 6. An RP circuit correlates to one client, and thus allows us to consider one client trace at a time. Note that this is how a real-life adversary could generate training data to deanonymize the servers: it could run its own servers of the cached hidden services, and collect large samples of the servers' traffic patterns.

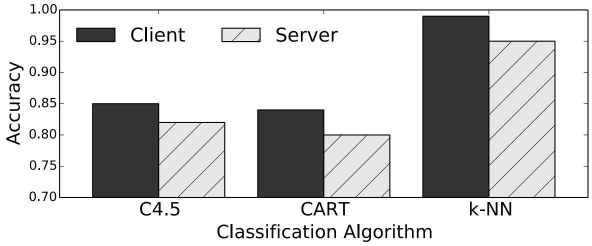

Figure 13: Accuracy of website fingerprinting attacks in closed world setting.

7.2.2 Website Fingerprinting Hidden Services

We extracted features similar to the ones presented in Wang *et al.* [35] from the data we collected.

- **General Features:** We use the total transmission size and time, and the number of incoming and outgoing packets.
- **Packer Ordering:** We record the location of each outgoing cell.
- **Bursts:** We use the number of consecutive cells of the same type. That is, we record both the incoming bursts and outgoing bursts, and use them as features.

We performed WF in closed and open world settings. In the closed world setting, the user visits/hosts a hidden service selected randomly from the list of 50 pages known to the attacker. In the open world setting, the user visits/hosts any of the 1000 pages, only 50 of which are monitored by the attacker. In either case, the attacker collects network traces of the Tor user, and tries to identify which service is associated with which network trace. We can consider the clients and the servers separately since we can identify HS-IP and Client-IP using the attack from Section 5.1 with high probability.

7.3 WF Accuracy on Hidden Services

We ran the same classifiers as the ones used in Section 6: CART, C4.5, and *k*-NN.[4] The accuracy of the classifiers in the closed world setting of both client and server is shown in Figure 13. For the open world setting, we varied the number of non-monitored training pages from 100 to 900 in 100 page increments (i.e., included exactly

[4] For *k*-NN, we tested with both Wang *et al.* [35] and the implementation in Weka, and we got inconsistent results. For consistency in our evaluation, we used the Weka version as with the other two classifiers.

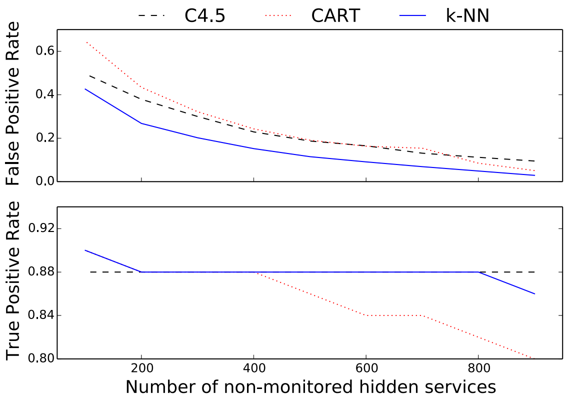

Figure 14: TPR and FPR of the client side classification for different classifiers.

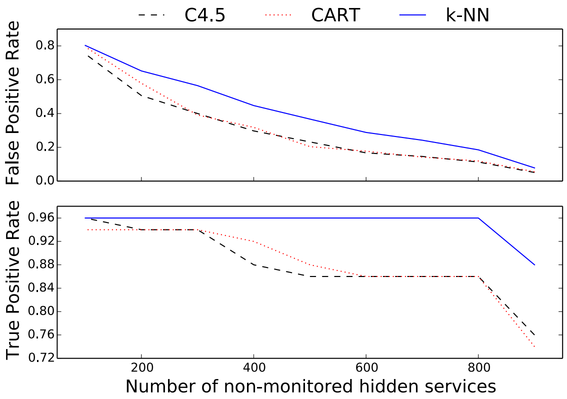

Figure 15: TPR and FPR of the server side classification for different classifiers.

one instance of the websites in the training set), and measured the TPR and FPR. The results of the open world experiment on the clients and the servers are shown in Figure 14 and Figure 15 respectively.

In all settings, we found that *k*-NN classifier works the best for classifying hidden services. We believe this is because *k*-NN considers multiple features simultaneously while the tree-based classifiers consider each feature one after another. In the closed world, the accuracy of *k*-NN was 97% for classifying the clients and 94.7% for the servers. In the open world, the *k*-NN classifier again performed the best. The TPR of *k*-NN reduced slightly as we increased the number of trained non-monitored websites. The TPR ranged from 90% to 88% and 96% to 88% for classifying clients and servers respectively. The FPR steadily decreased as we trained on more non-monitored websites: for classifying clients, it varied from 40% to 2.9% depending on the number of trained pages. Similarly, FPR of classifying servers varied from 80.3% to 7.8% for attacking servers.[5] Though the FPR is too a large for accurate classification when trained only on small number of non-monitored websites, we found that it quickly decreased as we increased the number of websites in the training set.

In general, the classifiers performed better in identifying clients' connections better than the hidden services servers; the TPR was comparable, but the FPR was significantly lower for classifying clients. We believe that this is, at least partially, due to the fact that we are using one real hidden service to emulate multiple hidden services; our data does not capture the differences in the differences in hardware, software, locations, and other characteristics real hidden service servers would have.

8 Future Possible Defenses

Our attacks rely on the special properties of the circuits used for hidden service activities. For the first attack (Section 5.1), we used three very identifiable features of the circuits: (1) DoA, (2) number of outgoing cells, and (3) number of incoming cells. To defend against this attack, Tor should address the three features. First, *all* circuits should have similar lifetime. Client IP and hidden service IP lasts either a very short or very long time, and this is very identifying. We recommend that circuits with less than 400 seconds of activity should be padded to have a lifetime of 400-800 seconds. Furthermore, we suggest that hidden services re-establish their connection to their IPs every 400-800 seconds to avoid any circuits from lasting too long. Second, hidden service and client IP should have a larger and varying number of outgoing and incoming cells. IPs are only used to establish the connection which limits the possible number of exchanged cells. We believe they should send and receive a random number of `PADDING` cells, such that their median value of incoming and outgoing cells is similar to that of a general circuit. We evaluated the effectiveness of this defense on the same dataset used in Section 6.1, and found that the true positive rate for the IPs and RPs fell below 15%. Once the features look the same, the classifiers cannot do much better than simply guessing.

To prevent the second attack (Section 5.2), we recommend that every circuit be established in a pair with the same sequence for the first few cells. If an `extend` fails for either circuit (which should be a rare occurrence), then we should restart the whole process to ensure no information is leaked. To do this efficiently, Tor could use its preemptive circuits. Tor already has the practice of building circuits preemptively for performance reasons. We can leverage this, and build the preemptive circuit

[5] The results are not directly comparable to previous WF attacks due to the differences in the settings, such as the size of the open world.

with another general circuit with the same sequence as the IP-RP pairs. This would eliminate the second attack.

For WF attacks (Section 7), defenses proposed by previous works [35, 9] will be effective here as well. Furthermore, for the clients, the results of Juarez *et al.* [24] suggest that WF attacks on hidden service would have significantly lower accuracy if an RP circuit is shared across multiple hidden service accesses.

9 Related Work

Several attacks challenging the security of Tor have been proposed. Most of the proposed attacks are based on side-channel leaks such as congestion [31, 17], throughput [30], and latency [21]. Other attacks exploit Tor's bandwidth-weighted router selection algorithm [5] or its router reliability and availability [7]. Most of these attacks are active in that they require the adversary to perform periodic measurements, induce congestion, influence routing, or kill circuits.

Our attacks on the other hand, like the various WF attacks, are passive. Other passive attacks against Tor include Autonomous Systems (AS) observers [15], where the attacker is an AS that appears anywhere between the client and his entry guard, and between the exit and the destination.

In addition, several attacks have been proposed to deanonymize hidden services. Øverlier and Syverson [32] presented attacks aiming to deanonymize hidden services as follows: the adversary starts by deploying a router in the network, and uses a client which repeatedly attempts to connect to the target hidden service. The goal is that, over time, the hidden service will choose the malicious router as part of its circuit and even as its entry guard to the client allowing the attacker to deanonymize him using traffic confirmation.

A similar traffic confirmation attack was described by Biryukov *et al.* [6]. The malicious RP sends a message towards the hidden service consisting of 50 padding cells when it receives the `rendezvous1` sent by the hidden service. This signal allows another malicious OR along the circuit from the hidden service to the RP, to identify the hidden service or its entry guard on the circuit. Biryukov *et al.* also show how it is possible for the attacker to enumerate all hidden services and to deny service to a particular target hidden service.

10 Conclusion

Tor's hidden services allow users to provide content and run servers, while maintaining their anonymity. In this paper, we present the first passive attacks on hidden services, which allow an entry guard to detect the presence of hidden service activity from the client- or the server-side. The weaker attacker, who does not have perfect circuit visibility, can exploit the distinctive features of the IP and RP circuit communication and lifetime patterns to classify the monitored circuits to five different classes.

For the stronger attacker, who has perfect circuit visibility (in the case where the client uses only one entry guard), the attacker runs a novel pairwise circuit correlation attack to identify distinctive cell sequences that can accurately indicate IP and RP circuits.

We evaluated our attacks using network traces obtained by running our own clients and hidden service on the live Tor network. We showed that our attacks can be carried out easily and yield very high TPR and very low FPR. As an application of our attack, we studied the applicability of WF attacks on hidden services, and we made several observations as to why WF is more realistic and serious in the domain of hidden services. We applied state-of-the-art WF attacks, and showed their effectiveness in compromising the anonymity of users accessing hidden services, and in deanonymizing hidden services. Finally, we propose defenses that would mitigate our traffic analysis attacks.

11 Code and Data Availability

Our data and scripts are available at `http://people.csail.mit.edu/kwonal/hswf.tar.gz`.

Abstract

In this paper, we analyze and systematize the state-of-the-art graph data privacy and utility techniques. Specifically, we propose and develop *SecGraph* (available at [1]), a uniform and open-source Secure Graph data sharing/publishing system. In SecGraph, we systematically study, implement, and evaluate 11 graph data anonymization algorithms, 19 data utility metrics, and 15 modern Structure-based De-Anonymization (SDA) attacks. To the best of our knowledge, SecGraph is the first such system that enables data owners to anonymize data by state-of-the-art anonymization techniques, measure the data's utility, and evaluate the data's vulnerability against modern De-Anonymization (DA) attacks. In addition, SecGraph enables researchers to conduct fair analysis and evaluation of existing and newly developed anonymization/DA techniques. Leveraging SecGraph, we conduct extensive experiments to systematically evaluate the existing graph data anonymization and DA techniques. The results demonstrate that (*i*) most anonymization schemes can partially or conditionally preserve most graph utilities while losing some application utility; (*ii*) no DA attack is optimum in all scenarios. The DA performance depends on several factors, e.g., similarity between anonymized and auxiliary data, graph density, and DA heuristics; and (*iii*) all the state-of-the-art anonymization schemes are vulnerable to several or all of the modern SDA attacks. The degree of vulnerability of each anonymization scheme depends on how much and which data utility it preserves.

1 Introduction

Many computing systems generate data with graph structure, e.g., social networks, collaboration networks, and email networks [2–4]. Even mobility traces, e.g., WiFi traces, Bluetooth traces, instant message traces, and check-ins, can be modeled by graphs via applying sophisticated techniques [3–5]. Generally, those data are called *graph data*. For research purposes, data and network mining tasks, and commercial applications, these graph data are often transferred, shared, and/or provided to the public, research community, and/or commercial partners. Since graph data carry a lot of sensitive private information of users/systems who generated them [2, 3], it is critical to protect users' privacy during the data transferring, sharing, and/or publishing.

To protect users' privacy, several anonymization techniques have been proposed to anonymize graph data, which can be classified into six categorizes: Naive ID Removal, Edge Editing (EE) based techniques [6], *k*-anonymity based techniques [7–11], Aggregation/Class/Cluster based techniques [12–14], Differential Privacy (DP) based techniques [15–19], and Random Walk (RW) based techniques [20]. Fundamentally, these techniques try to protect users' privacy by perturbing the original graph's structure while preserving as much data utility as possible.

Following Narayanan and Shmatikov's work [2], many new Structure-based De-Anonymization (SDA, we use DA and SDA interchangeably in this paper) attacks on graph data have been proposed, which can be categorized into two classes: *seed-based attacks*, e.g., Narayanan-Shmatikov's attack [2], and *seed-free attacks*, e.g., Ji et al.'s attack [3]. For both types of attacks, the goal is to de-anonymize anonymized users using their uniquely distinguishable structural characteristics.

Surprisingly, although we already have many sophisticated anonymization techniques (e.g., [6, 7, 12, 15, 20]) and powerful SDA attacks (e.g., [2,3,5,21–24]), whether state-of-the-art anonymization techniques can defend against modern SDA attacks is still an open problem. This is because of the incomplete evaluation of existing anonymization and DA techniques. For anonymization works, they usually only evaluate the data utility performance of their proposed techniques (although some works provide a theoretical security guarantee, these guarantees usually do not hold due to improper assumptions or incomplete considerations as analyzed in Section 4). For DA works, they usually evaluate their attacks' performance without applying state-of-the-art anonymization techniques (e.g., k-anonymity based schemes, DP based schemes) to their test data.

Contributions. To address the above open problem, we systematically study, implement, and evaluate existing graph data anonymization techniques and DA attacks. Specifically, our main contributions are as follows.

(a) We design and implement a Secure Graph data publishing/sharing (SecGraph) system (available at [1]). SecGraph enables data owners to anonymize their data using state-of-the-art anonymization techniques, measure the anonymized data's graph and application utilities, and comprehensively evaluate their data's actual vulnerability against modern DA attacks. To the best of our knowledge, SecGraph is the first such system publicly available to both academia and industry. More importantly, SecGraph provides the first *uniform platform* that enables researchers to conduct accurate comparative studies of anonymization/DA techniques, and to comprehensively understand the resistance/vulnerability of existing or newly developed anonymization techniques, the effectiveness of existing or newly developed DA attacks, and graph and application utilities of anonymized data.

(b) In SecGraph, we systematically analyze, implement, and evaluate 11 state-of-the-art graph data anonymization schemes and 19 graph and application utility metrics. We also analyze the 11 anonymization schemes with respect to the 19 utility metrics, both analytically and experimentally. The evaluation results demonstrate that most existing anonymization algorithms can partially or conditionally preserve most graph utilities. However, all the anonymization schemes lose one or more application utility.

(c) We summarize and analyze the fundamental properties of existing SDA attacks. Then, we systematically implement and evaluate 15 modern SDA attacks on real-world graph datasets. Our results show that modern SDA attacks are powerful and robust to seed mapping errors. Furthermore, no attack is optimum in all scenarios. The DA performance of an attack depends on the similarity between the anonymized and auxiliary data, graph density, DA heuristics, etc.

(d) We analytically and experimentally evaluate the performance of existing graph data anonymization schemes on defending against modern SDA attacks. We find that existing anonymization techniques are vulnerable to modern SDA attacks. Their degree of vulnerability depends on how much data utility is preserved in the anonymized data.

Abbreviations. For convenient reference, we summarize the used abbreviations in Table 1.

Roadmap. In Section 2, we study existing graph data anonymization schemes and their utility performance. In Section 3, we study modern SDA attacks. In Section 4, the effectiveness of existing anonymization schemes against modern DA attacks is analyzed. We systematically implement and evaluate SecGraph in Section 5. The future research directions are discussed in Section 6. We conclude this paper in Section 7.

Table 1: Abbreviations and acronyms.

Terms	SDA	Structure-based De-anonymization
	DA	De-anonymization
	SF	Seed-Free
Anonymizatoin	EE	Edge Editing
	DP	Differential Privacy
	RW	Random Walk
	k-NA	k-Neighborhood Anonymity
	k-DA	k-Degree Anonymity
	k-auto	k-automorphism
	k-iso	k-isomorphism
Utility metrics	Deg.	Degree
	JD	Joint Degree
	ED	Effective Diameter
	PL	Path Length
	LCC	Local Clustering Coefficient
	GCC	Global Clustering Coefficient
	CC	Closeness Centrality
	BC	Betweenness Centrality
	EV	Eigenvector
	NC	Network Constraint
	NR	Network Resilience
	Infe.	Infectiousness
	RX	Role extraction
	RE	Reliable Email
	IM	Influence Maximization
	MINS	Minimum-sized Influential Node Set
	CD	Community Detection
	SR	Secure Routing
	SD	Sybil Detection
De-anonymization	DV	Distance Vector [5]
	RST	Randomized Spanning Tress [5]
	RSM	Recursive Subgraph Matching [5]
	DeA	De-Anonymization [25]
	ADA	Adaptive De-Anonymization [25]
	BDK	Backstrom et al.'s attacks [26]
	NS	Narayanan-Shmatikov's attack [2]
	NSR	Narayanan et al.'s attack [21]
	NKA	Nilizadeh et al.'s attack [22]
	PFG	Pedarsani et al.'s attack [23]
	YG	Yartseva-Grossglauser's attack [27]
	KL	Korula-Lattanzi's attack [24]
	JLSB	Ji et al.'s attack [3]

2 Graph Anonymization

2.1 Status Quo

Generally, existing graph data anonymization techniques can be classified into six categories. We discuss each category as follows.

Naive ID Removal. To anonymize graph data, a straightforward method is *naive ID removal*. Although this method has been demonstrated to be extremely vulnerable to SDA attacks, it is still widely used because of its simplicity, ease of applicability, and scalability [2, 3, 5, 26, 28].

Edge Editing based Anonymization. To protect graph data's privacy, Ying and Wu proposed spectrum preserved Edge Editing (EE) based schemes *Add/Del* and *Switch* [6]. Under *Add/Del*, k randomly chosen edges will be added followed by the deletion of another k randomly chosen edges. Under *Switch*, k random *edge switches* are conducted.

***k*-anonymity.** k-anonymity has been widely used to anonymize relational data [29, 30]. Similarly, much effort has been spent to extend k-anonymity to graph data [7–11]. To defend against neighborhood attacks, Zhou and Pei proposed *k-Neighborhood Anonymity* (k-NA) for graph data [7]. In another work, Liu and Terzi considered *degree attacks* and proposed *k-Degree Anonymity* (k-DA) for graph data, under which for each user, there exists at least $k-1$ other users with the same degree [8]. In [9], Zou et al. simultaneously considered four types of structural attacks on graph data and proposed *k-automorphism* (k-auto), where each user always has $k-1$ other symmetric users with respect to $k-1$ automorphic functions. Another similar work is [10], where Cheng et al. proposed *k-isomorphism* (k-iso) to defend against structural attacks. Under k-iso, a graph is partitioned and anonymized into k disjoint isomorphic subgraphs. In [11], Yuan et al. considered personalized privacy protection for anonymizing graph data in terms of both semantic and structural information.

Aggregation/Class/Cluster based Anonymization. Another popular idea to protect graph data is to group users into *clusters* (equivalently, *groups, classes*). In [12], Hay et al. proposed an *aggregation based graph anonymization* algorithm, which first partitions users and then describes the graph at the level of partitions. Another work, at the semantics level, is [13], where Bhagat et al. designed a class-based anonymization algorithm. In [14], Thompson and Yao presented two *cluster-based anonymization* schemes for graph data.

Differential Privacy. Differential Privacy (DP) is an emerging anonymization technique with a strong privacy guarantee [31, 32]. Initially, DP was proposed for statistical databases [31]. Recently, there have been works that seek to enable differentially private graph data release. Aiming at protecting *edge/link privacy*, defined as the privacy of users' relationship in graph data, in [15], Sala et al. introduced *Pygmalion*, a differentially-private graph model. To bypass many difficulties encountered when working with the worst-case sensitivity [15], Proserpio recently presented a general platform, named *wPING*, for differentially private data analysis and publishing [16, 17]. Similar to [15], Wang and Wu also employed the dK-graph generation model for enforcing edge DP in graph anonymization [18]. Another recent work for edge DP is [19], where Xiao et al. proposed a Hierarchical Random Graph (HRG) model based scheme to meet edge DP.

Random Walk based Anonymization. In [20], Mittal et al. proposed a *Random Walk (RW) based anonymization* technique for preserving link (edge) privacy. In this technique, an edge in the original graph is replaced by a RW path.

2.2 Anonymization and Utility

Generally, an anonymization scheme can be evaluated from two perspectives: *data utility preservation* and *resistance to DA attacks*. However, most, if not all, existing graph anonymization works have not been significantly evaluated with respect to their utility or resistance to DA attacks. On one hand, most existing graph anonymization works only conducted limited evaluations on their utility preservation, e.g., degree distribution, path length distribution, which are insufficient to understand their value for high-level data mining tasks and applications, e.g., sense-making, search for similar users, user classification, reliable email, influence maximization. On the other hand and more seriously, to the best of our knowledge, no work (including existing DA works) actually evaluated the resistance of state-of-the-art anonymization techniques against modern SDA attacks.

To address these concerns, we comprehensively analyze the utility of existing graph data anonymization algorithms in this subsection and defer the detailed resistance analysis to Section 4. Before performing the analysis, we first present the used utility metrics, which can be classified as *graph utility metrics* or *application utility metrics*.

2.2.1 Graph Utility Metrics

Graph utility captures how the anonymized data preserves fundamental structural properties of the original graph after applying an anonymization technique. Particularly, we examine 12 graph utility metrics of existing anonymization schemes as follows[1].

Degree (Deg.), which refers to the degree distribution; *Joint Degree (JD)*, which refers to the joint degree distribution of a graph; *Effective Diameter (ED)*, which is defined as the minimum number of hops in which 90% of all connected pairs of nodes can reach each other; *Path Length (PL)*, which refers to the distribution of the

[1] Without of causing confusion, we interchangeably use node and user in this paper.

shortest path lengths between all pairs of users; *Local Clustering Coefficient (LCC) and Global Clustering Coefficient (GCC). Clustering coefficient* measures the degree to which users in graph data tend to cluster together. *Closeness Centrality (CC)*, which is defined as the *inverse of the farness* of a user within a graph and measures how long it takes to spread information from a user to all other users sequentially; *Betweenness Centrality (BC)*, which quantifies the number of times a user acts as a bridge along the shortest path between two other users; *EigenVector (EV)*. The EV of the adjacency matrix A of a graph G is a non-zero vector $\mathbf{v}$ such that $A\mathbf{v} = \lambda\mathbf{v}$, where λ is some scalar multiplier; *Network Constraint (NC)*, which measures the extent to which a user links to others that are already linked to each other; *Network Resilience (NR)* [33], which measures how robust a graph is and is defined as the number of users in the *largest connected component* when users are removed from the graph in the degree decreasing order; and *Infectiousness (Infe.)* [34], which measures the number of users infected by a disease, given that a randomly chosen user is infected and each infected user transmits this disease to its neighbors with some infection rate.

2.2.2 Application Utility Metrics

In reality, most data is published/shared for data/network mining tasks, high-level applications, etc. Therefore, besides examining data's fundamental structural utility, it is also crucial to ensure that the anonymized data is useful for practical applications. Toward this objective, we evaluate 7 popular application utility metrics for anonymization schemes as follows.

(a) *Role eXtraction (RX) [35].* Based on users' structural behavior, users in a graph can be labeled as having different roles, e.g., *clique members*, *periphery-nodes*. RX is an important operation for graph data that is useful for many network mining tasks such as sense-making. We measure the RX utility of an anonymization scheme using the method in [35].

(b) *Reliable Email (RE) [36].* RE is a whitelisting system leveraging users' neighborhoods to filter and block spam emails. To evaluate the structural utility of an anonymization scheme with respect to RE, we take a similar method as in [15] to compute the number of users who can be spammed by a fixed number of compromised neighbors in a graph.

(c) *Influence Maximization (IM) [37].* The IM problem seeks to find a set of θ users such that these θ users have the maximum influence to the network under some influence propagation model. IM is important for many real world applications, e.g., advertisements.

(d) *Minimum-sized Influential Node Set (MINS) [38].* MINS is another popular and important application utility metric that leverages a graph's structure to identify the minimum-sized set of influential nodes, such that all other nodes in the network could be influenced with a probability above a threshold. MINS can be used in many meaningful applications, e.g., social problems alleviation, new products promotion.

(e) *Community Detection (CD) [39].* CD is a popular application on graph data which enables comprehensive analysis of a network structure and supports other applications, e.g., classification, routing (information propagation). To measure the CD utility of an anonymization scheme, we employ the hierarchical agglomeration algorithm proposed in [39].

(f) *Secure Routing (SR) [40].* The structure of graph data can also be used to improve the performance of secure routing for systems such as P2P systems. For our purpose, we evaluate the SR application utility of an anonymization scheme using the method designed in [40].

(g) *Sybil Detection (SD) [41].* Sybil attacks are a serious threat to both centralized and distributed systems, e.g., recommendation systems, anonymity systems. For our purpose, we evaluate the SD application utility of an anonymization scheme using the method in [41].

2.2.3 Anonymization vs Utility

We are ready to analyze the utility performance of existing graph data anonymization techniques. We summarize the graph and application utilities, and Resistance to SDA attacks (R2SDA) (e.g., [2, 3, 25, 27]) of existing graph anonymization schemes in Table 2. We analyze the results in Table 2 as follows.

For the Naive ID removal scheme, it is straightforward that it preserves all the data utility. However, it is also the most vulnerable scheme to SDA attacks.

Since *Add/Del* randomly adds and deletes edges, which is an global edge edition operation and thus it may change many fundamental structural properties of a graph. It follows that it can conditionally or partially preserve both graph and application utilities. However, utilities like JD, GCC, NC, CD, and MINS would be destroyed if too many existing edges are deleted while new edges are added. For *Switch*, it switches two randomly selected qualified edges, which preserves the degree of each user. Consequently, *Switch* can preserve Deg. and partially preserve most other utilities. Furthermore, compared to *Add/Del*, *Switch* can conditionally preserve the RX and CD utilities which are destroyed in *Add/Del*. This is because that *Add/Del* randomly changes users' degree in the global edge edition process and thus some global structure-sensitive application utility is lost or significantly affected. Furthermore, *Add/Del* and *Switch* cannot defend against modern SDA attacks as shown in [2, 3, 5].

Table 2: Analysis of existing graph anonymization techniques. ✓ = preserving the utility, ◐= partially preserving the utility, ♦ = conditionally preserving the utility depending on parameters and considered data (based on our analysis, it is necessary to distinguish *partially* and *conditionally* preserving a data utility. For instance, k-DA conditionally preserves the Deg. utility depending on k while *Add/Del* can partially preserve the Deg. utility for an arbitrary k), ✗ = not preserving the utility, and **n/a** = evaluation not available in existing works.

The k-anonymity based anonymization schemes k-NA [7], k-DA [8], and k-auto [9] can partially/conditionally preserve the graph and most application utilities except for the RX utility. This is because the fundamental idea of k-anonymity based schemes is to make k users/subgraphs structurally similar. Therefore, there is a tradeoff between anonymity and utility. If k is large, more users will be structurally similar while more utility will be lost. On the other hand, if k is chosen to be small, more utility will be preserved at the cost of lower anonymity guarantee. Furthermore, since every user is guaranteed to be structurally similar to at least $k-1$ other users while the RX utility tries to distinguish users based on their structural differences, it turns out k-anonymity based schemes cannot preserve the RX utility. As we discussed before, k-iso achieves structure anonymization by partitioning the original graph into k isomorphic subgraphs. Therefore, several fundamental properties of a graph will be destroyed, e.g., connectivity. It follows that several important graph and application utilities are lost in k-iso, e.g., PL, GCC, NR, Infe., RX, RE, IM, and SR. Finally, compared with other schemes, k-NA, k-auto, and k-iso have higher computational complexities.

Similar to k-anonymity based schemes, the cluster based schemes [12, 14] can conditionally/partially preserve graph and application utilities except for RX. This is because the fundamental idea of cluster based schemes is to make the users within a cluster structurally indistinguishable. Therefore, to what extent these schemes can preserve data utility depends on the cluster size setting. Again, since RX is achieved based on users' structural difference, this utility is not preserved in cluster based schemes.

For DP based schemes (e.g., [15, 19]), their main objective is to protect link privacy by perturbing the edges of a graph. The fundamental idea of these schemes is to make an anonymized graph structurally similar to its neighboring graphs and thus an adversary cannot infer the existence of an edge. Therefore, they can conditionally/partially preserve most graph and application utilities. However, if a high level of privacy is guaranteed, many edges in the graph are changed. Furthermore, similar to *Add/Del*, the edge perturbation in DP also belongs to global edge edition. Therefore, the global structure-sensitive high-level application utilities, e.g., RX, MINS, and CD, are destroyed or significantly reduced in DP based schemes.

In the RW based scheme [20], link privacy is achieved by replacing a random walk path with an edge, and thus this scheme, theoretically, will not change the degree distribution of the original data. It follows that several utilities, e.g., Deg., RX, SD, NR, Infe., can be preserved or partially preserved. However, some other global utilities, e.g. JD, GCC, are lost in the RW based scheme due to the significant change of the overall graph structure.

From Table 2, no existing work evaluates the resistance of state-of-the-art anonymization schemes against modern SDA attacks. Although most of the schemes have nice theoretical privacy guarantees, unfortunately, that privacy analysis cannot guarantee that they can defend against modern SDA attacks due to the improper model of the adversary's auxiliary information, problematic assumptions, etc. Therefore, aiming to address this open problem, we evaluate the effectiveness of existing graph data anonymization schemes against modern SDA attacks in Sections 4 and 5.

3 Graph De-anonymization

3.1 Graph Data DA

3.1.1 Seed-based DA

When de-anonymizing graph data, it is intuitive to identify some users first as seeds. Then, the large scale DA is bootstrapped from these seeds. In [26], Backstrom et al. presented both active attacks and passive attacks to graph data. However, the attacks in [26] have several limitations, e.g., they are not scalable and they leverage sybil users that can be detected by modern sybil defense techniques [41]. To improve the attacks in [26], Narayanan and Shmatikov presented a scalable two-phase DA attack to social networks [2]. In the first phase, some seed users are identified between the anonymized graph and the auxiliary graph. In the second phase, starting from the identified seeds, a self-reinforcing DA propagation process is iteratively conducted based on both graphs' structural characteristics, e.g., node degrees, nodes' eccentricity, edge directionality. Later, Narayanan et al. employed a simplified version of the attack in [2] (using less DA heuristics) for link prediction [21]. In [22], Nilizadeh et al. extended Narayanan and Shmatikov's attack by proposing a community-enhanced DA scheme of social networks. Actually, the community-level DA in [22] can also be applied to enhance other seed-based DA attacks (e.g., [5, 25]).

In [5], Srivatsa and Hicks presented three attacks to de-anonymize mobility traces, which can be modeled as contact graphs by applying multiple preprocessing techniques (e.g., [5]). Similar to Narayanan et al.'s attacks [2, 21], Srivatsa-Hicks' attacks also consist of two phases, where the first phase is for seed identification and the second phase is for mapping (DA) propagation. To achieve mapping propagation, Srivatsa and Hicks proposed three heuristics based on Distance Vector (DV), Randomized Spanning Trees (RST), and Recursive Subgraph Matching (RSM). In [25], Ji et al. proposed two two-phase DA attack frameworks, namely De-Anonymization (DeA) and Adaptive De-Anonymization (ADA), which are workable when the auxiliary data only has partial overlap with the anonymized data.

In [24,27], besides quantifying the de-anonymizability of graph data, the authors also proposed DA attacks. In [27], Yartseva and Grossglauser proposed a simple percolation-based DA algorithm to graph data. Given a seed mapping set, the algorithm incrementally maps every pair of users (from the anonymized and auxiliary graphs respectively) with at least *r* neighboring mapped pairs, where *r* is a predefined mapping threshold. Another similar attack was presented by Korula and Lattanzi [24], which also starts from a seed set and iteratively maps a pair of users with the most number of neighboring mapped pairs.

Table 3: Analysis of existing graph DA techniques. SF = seed-free, AGF = auxiliary graph-free, SemF = semantics-free, A/P = active/passive attack, Scal. = scalable, Prac. = practical, Rob. = robust to noise, ✓ = true, ◐= partially true, ♦ = conditionally true, and ✗ = false.

3.1.2 Seed-free DA

Taking another approach, some powerful seed-free DA attacks on graph data have been proposed. Using degrees and distances to other nodes as each node's fingerprints, Pedarsani et al. proposed a Bayesian model based seed-free algorithm for graph data DA [23]. Another seed-free DA attack to graph data was presented by Ji et al. [3]. Unlike previous attacks, Ji et al.'s attack is an optimization based single-phase cold start algorithm.

3.2 Graph DA Analysis

In this subsection, we analyze the performance of existing graph data DA algorithms. For convenience, in the rest of this paper, we denote Backstrom et al.'s attacks [26] by BDK (the initials of the authors), Narayanan-Shmatikov's attack [2] by NS, Narayanan et al.'s attack [21] by NSR, Nilizadeh et al.'s attack [22] by NKA, Srivatsa-Hicks' three attacks [5] by DV, RST, and RSM, respectively, Pedarsani et al.'s attack [23] by PFG, Yartseva-Grossglauser's attack [27] by YG, Ji et al.'s two attacks [25] by DeA and ADA, respectively, Korula-Lattanzi's attack [24] by KL, and Ji et al.'s attack [3] by JLSB. We show our analytical results in Table 3 and discuss the result as follows.

Except for BDK, all the existing SDA attacks are passive attacks and require auxiliary graphs to perform the attack, i.e., they employ the structural similarity between the the anonymized graph and the auxiliary graph to break the anonymity. However, when we examine the anonymization schemes in Table 2, we find that none properly consider such auxiliary information in their threat models.

To perform BDK attacks [26], an adversary either has to insert some Sybil users in the dataset before the actual anonymized data release, or has to be an internal user that knows its neighborhoods. In either case, such attacks can only de-anonymize some users but cannot de-anonymize users in large scale. Furthermore, the attacks cannot tolerate any topological change of the original data. Therefore, BDK attacks are not scalable or robust. These attacks require that an adversary successfully launches Sybil users or be an internal user that obtains his neighborhoods.

All the examined DA attacks are semantics-free. This is because the structural information itself is sufficient to perfectly or partially de-anonymize graph users. Furthermore, compared to semantics information, structural information is widely available in large scale, resilient to noise, and easily computable [2, 3, 5]. Following this fact, all the attacks except for BDK are (conditionally) scalable, practical, and robust.

Specifically, DV, RST, and RSM [5] are conditionally scalable and practical. This is because they are not computationally feasible when the number of seeds is large. PFG [23] is conditionally practical and robust. This is because it is very sensitive to the graph density of the anonymized data. Generally, this attack is suitable for sparse graphs however it has a significant performance degradation as the graph density increases. YG [27] is conditionally practical because it is designed to de-anonymize users of degree no less than 4 in the anonymized data. In many real world graph datasets, the users with degree less than 4 could dominate or take a significant portion of graph data based on the statistics in [3]. The conditional practicability of KL [24] comes from its improper assumption that $\Theta(\iota \cdot n)$ ($\iota \in (0,1]$ is a constant and n is the number of nodes in a graph) seeds are available, which is too strong to hold for real world DA attacks. Note that, the community-level DA of NKA [22] is scalable (with complexity of $O(n^2)$). However, the NKA [22] is conditionally scalable, practical, and robust. This is because, if the community-level DA of NKA [22] is employed to enhance DV, RST, RSM, YG, and/or KL, it is conditionally scalable, practical, and/or robust. NS [2], NSR [21], DeA, ADA, and JLSB [3, 25] adaptively perform DA employing several heuristics based on a graph's local and global structural characteristics. It follows that they are scalable, practical, and robust as long as similarity exists between anonymized graphs and auxiliary graphs.

Both seed-based attacks (e.g., NS, DV) and seed-free attacks (e.g., PFG, JLSB) have advantages depending on the application scenarios. On one hand, seed-based attacks are more stable with respect to de-anonymizing arbitrary anonymized graphs. The reason is straightforward since seed knowledge provides more auxiliary information to an adversary. On the other hand, it is possible that in some scenarios seeds are not available, and thus seed-free attacks are more general. Furthermore, if there is some error in the seed seeking phase (which is possible in real world attacks), seed-based attacks will suffer performance de-gradation or will possibly fail.

Table 4: DA attacks vs anonymization techniques. Naive = naive ID removal, EE = EE based schemes [6], *k*-anony. = *k*-anonymity based schemes [7]- [10], Cluster = cluster based schemes [12, 14], DP = DP based schemes [15]- [19], RW = the random walk based scheme [20], and ✓, ♦, and ✗ = the anonymization scheme is vulnerable, conditionally vulnerable, and invulnerable (i.e., resistant) to the DA attack, respectively.

4 Anonymization vs DA Analysis

As we analyzed in Tables 2 and 3, understanding the vulnerability/resistance of state-of-the-art graph data anonymization schemes against modern SDA attacks is still an open problem. After carefully analyzing existing anonymization and DA techniques, we summarize the ***vulnerability*** of existing anonymization schemes in Table 4. We further experimentally validate our analysis in Section 5. Below, we analyze and discuss the results in Table 4.

It has been shown in both academia and in practice that the naive ID removal anonymization cannot protect graph data's privacy. Therefore, naive anonymization is vulnerable to all the existing SDA attacks.

As we analyzed before, all other state-of-the-art anonymization schemes (e.g., EE, *k*-anony., Cluster, DP, and RW) are resistant to BDK attacks. Again, this is because an assumption of BDK attacks is that data is anonymized by the naive ID removal technique.

For EE based anonymization schemes ([6]), they are conditionally vulnerable to NKA [22] and vulnerable to all the other modern SDA attacks [2,3,25,27]. This is because although EE can partially modify the structure of a graph, to preserve data utility, many structural properties, e.g., neighborhood, degree distribution, closeness/betweenness centrality distribution, and path length distribution, are generally preserved. Therefore, given an auxiliary graph consisting of the same or overlapping group of users with the anonymized graph, powerful DA heuristics can be designed based on these structural properties to break the privacy of EE based anonymization schemes. Furthermore, the availability of seed users make such heuristics more robust to the noise introduced by EE. For instance, NS breaks EE by employing degree and neighborhood similarity [2], DV, RST, and RSM break EE by employing path length and neighborhood similarity [5], DeA and ADA break EE by employing centrality similarity [25], etc. As we analyzed in Table 2, EE based anonymization schemes (e.g., *Add/Del*) may destroy graphs' community utility, and thus they are conditionally vulnerable to NKA [22].

k-anonymity based anonymization schemes ([7]-[10]) are conditionally vulnerable to modern SDA attacks [2, 3, 25, 27]. The reasons are as follows: *k*-anonymity is initially designed for traditional relational data, which makes a user semantically indistinguishable with $k-1$ other users. Unlike relational data, which are structurally independent of each other, users in graph data have strong structural correlation in addition to semantic similarity. When researchers extended *k*-anonymity to graph data, they extended the concept of traditional semantics to graph data as different structural properties (e.g., degree, neighborhood, and subgraph), and designed schemes to make *k* users structurally indistinguishable with respect to some structural semantics, i.e., degree, neighborhood, subgraph, etc. However, even if users in graph data cannot be distinguished with respect to some structural semantics, e.g., degree, neighborhood, subgraph, they can be de-anonymized by other structural semantics, e.g., path length distribution, closeness centrality, betweenness centrality, or the combinations of several structural semantics. Theoretically, the only way to make users indistinguishable with respect to all structural semantics is to make a graph *completely connected* or *disconnected*, which also implies that all the data utility is destroyed. Therefore, as long as some data utility is preserved in the anonymized data, *k*-anonymity based schemes are vulnerable to modern SDA attacks. The degree of vulnerability depends on how much data utility is preserved.

Cluster based schemes ([12, 14]) are also conditionally vulnerable to modern SDA attacks [2,3,25,27]. The analysis is similar to that of *k*-anonymity. The fundamental idea of cluster based schemes is to cluster users first and then to make the users within a cluster indistinguishable with respect to neighborhoods. Again, even if users are indistinguishable by neighborhoods, they can be de-anonymized by other structural semantics or the combinations of other semantics, e.g., centralities scores, path length distribution. Consequently, cluster based schemes are vulnerable as long as some data utility, especially graph utilities, are preserved in the anonymized data, and the vulnerability depends on the amount of data utility preserved.

DP and RW based schemes ([15]- [20]) are vulnerable to modern SDA attacks except NKA [22]. The reasons are as follows: First, they are designed with the objective of protecting the link privacy of graph data and no dedicated node privacy protection techniques are considered. Second, to protect link privacy, the edges are perturbed in DP based schemes and random walk paths are replaced by edges in the RW based scheme, both with a nice theoretical privacy guarantee. However, after the edge anonymization process, many data utilities, e.g., degree, path length distribution, are still preserved. This implies that, given an auxiliary graph, users are still de-anonymizable based on several structural semantics under DP and RW based schemes. Furthermore, as shown by Narayanan et al. in [21], link privacy can be breached after de-anonymizing the users in an anonymized graph (we also employ the same approach to break users' link privacy [1]). Again, as we analyzed in Table 2, since DP and RW based schemes cannot preserve data's community utility, they are resistant to NKA.

In summary, based on our analysis, state-of-the-art anonymization schemes are still vulnerable to modern DA attacks. The fundamental reasons are: first, existing anonymization schemes only ensure that graph data users are indistinguishable with respect to some structural semantics (properties). However, other structural semantics, especially global ones, and the combinations of multiple structural semantics can still enable effective DA of users; and second, as one of the main objectives, all the anonymization schemes try to preserve as much data utility as possible. However, data utility from the adversary's perspective is equivalent to structural information, which can be used along with an auxiliary graph for conducting powerful DA attacks.

5 SecGraph

As we found when discussing existing anonymization and DA techniques, they all have limitations when evaluating the techniques' performance. For instance, it is still an open problem to understand the resistance/vulnerability of state-of-the-art anonymization schemes against modern DA attacks. To address this open problem, we implement a Secure Graph data publishing/sharing (SecGraph) system.

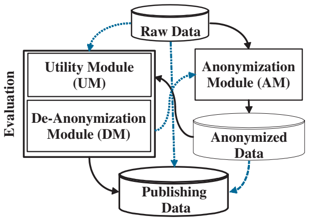

Figure 1: SecGraph: system overview.

5.1 System Overview

The overview of SecGraph is shown in Fig.1. SecGraph consists of three main modules: Anonymization Module (AM), Utility evaluation Module (UM), and DA evaluation Module (DM). The main functions of each module are briefly summarized as follows.

AM: the main function of this module is to anonymize raw graph data and generate anonymized data. In this module, we implement 11 state-of-the-art graph data anonymization schemes, including EE based algorithms [6], *k*-anonymity based algorithms and its variants [7–11], aggregation/class/cluster based algorithms [12–14], differential privacy based algorithms [15–17,19], and the random walk based algorithm [20].

UM: in this module, we evaluate raw/anonymized data's utility with respect to the 12 graph utility metrics and 7 application utility metrics as defined in Section 2.2. With the UM, we can determine whether the data to be published/shared (e.g., the anonymized data) satisfies required utility requirements. We can also evaluate how an anonymization algorithm preserves data utility.

DM: in this module, we implement 15 SDA algorithms (all the existing SDA algorithms, to the best of our knowledge). By this module, the security of data to be published/shared can be evaluated with real-world SDA attacks. More importantly, the effectiveness of an anonymization algorithm can be examined by this module, i.e., whether the anonymized data of an anonymization algorithm is resistant to modern SDA attacks.

We make further remarks on SecGraph and its modules and functions as follows.

(a) From Fig.1, raw data can be published/shared in multiple forms depending on the data owners' requirements on the security/privacy and utility of the data to be published. Each path in Fig.1 represents a data publishing scenario. For instance, the path *raw data* → *publishing data* means to publish the raw data directly. The path *raw data* → *AM* → *anonymized data* → *evaluation* → *publishing data* means that the raw data is anonymized first. Then, the anonymized data will be evaluated with respect to utility and/or practical de-anonymizability before actual publishing. The anonymization and evaluation process may be repeated several times until certain security and utility requirements are met.

(b) To the best of our knowledge, SecGraph is the first implemented uniform secure graph data publishing system, which systematically and comprehensively integrates state-of-the-art anonymization schemes, DA schemes, and graph/application utility measurements. The significance of SecGraph to the graph data anonymization and DA area lies in the following aspects. First, SecGraph enables data owners to conveniently and freely choose any modern anonymization algorithm to anonymize their data. They can also employ different evaluation modules to examine whether the anonymized data meets their security/privacy and utility requirements. Second, SecGraph is a uniform platform for testing and comparing different anonymization and DA algorithms. Previously, due to the lack of a uniform system, existing anonymization/DA algorithms are often proposed and implemented on separate platforms and different environments/settings. Consequently, a number of implementation and evaluation differences (e.g., particular assumptions, models, evaluation datasets, programming, testing environments, parameter settings) limit researchers' understanding of the performance of existing anonymization and DA algorithms in different scenarios. However, as a uniform platform, SecGraph can reduce the evaluation bias caused by implementation and testing differences as much as possible. Therefore, SecGraph allows data owners to choose and compare the actual performance of different data anonymization algorithms on their data and thus to make the best decision. Additionally, SecGraph allows data anonymization researchers to compare their anonymization schemes to existing solutions as well as to examine their schemes' resistance against modern DA attacks. SecGraph also allows data DA researchers to evaluate the performance of new DA attacks by de-anonymizing the anonymized data of state-of-the-art anonymization schemes. Therefore, SecGraph is helpful to both data owners and researchers in conveniently applying existing schemes, comprehensively understanding existing algorithms, and effectively developing new anonymization/DA techniques.

(c) Besides providing a uniform platform, SecGraph is an easily portable and extendable system. First, the algorithms in SecGraph are implemented in Java and thus it is system independent. Second, all the modules of SecGraph are independent of each other, which means that each module can work individually. Additionally, as shown in Fig.1, multiple modules can also work together to perform data anonymization, utility evaluation, and de-anonymizability evaluation. Third, all the schemes/measurements within each module are independent, which means that they can be implemented, evaluated, and employed independently. Furthermore, newly developed anonymization/DA schemes and utility metrics can be easily integrated into SecGraph.

5.2 System Implementation

The implementation of SecGraph is as follows.

In the AM, we implement 11 algorithms, which cover all the categories of state-of-the-art anonymization techniques. Specifically, the implemented anonyzation algorithms are naive ID removal, two EE based algorithms *Add/Del* [6] and *Switch* [6], two *k*-anonymity based algorithms *k*-DA [8] and *k*-iso [10], two cluster based algorithms bounded *t*-means clustering [14] and union-split clustering [14], three DP based algorithms Sala et al.'s scheme [15], Proserpio et al.'s scheme [16, 17], and Xiao et al.'s scheme [19], and one RW based algorithm [20]. Note that, we do not implement all the algorithms discussed in Section 2.1 even though we cover all the categories. The implementation criteria includes representativeness, scalability, and practicality, which led us to implement the latest, scalable, and practical schemes.

In the UM, we implemented the 12 graph utility metrics and 7 application utility metrics as discussed in Section 2.2.

In the DM, we implement all the 15 SDA attacks discussed in Section 3.1. To the best of our knowledge, these are all of the existing SDA attacks.

5.3 SecGraph-based Analysis

5.3.1 Primary Datasets

The employed datasets for evaluation are *Enron*, an email network consisting of 36.7K users and .2M edges, and *Facebook*, a Facebook friendship network in the New Orleans area consisting of 63.7K users and .82M edges [3, 4].

5.3.2 Anonymization vs Utility

In this subsection, we evaluate the utility performance of anonymization algorithms. Due to the space limitation, we do not show the evaluation results of all the implemented algorithms. Particularly, we demonstrate the results of *Switch* [6], *k*-DA [8], *union-split clustering* [14], the improved version of Sala et al.'s DP scheme [15–17], and RW [20] which represent all the categories of anonymization algorithms. The evaluation methodology is that we first anonymize the original graph by an algorithm, and then measure how each data utility is preserved in the anonymized graph compared to the original graph. Specifically, when measuring utilities Deg., JD, PL, LCC, CC, BC, NC, NR, Infe., RX, and RE, we measure the *cosine similarity* between their distributions in the anonymized and original graphs; when measuring ED, GCC, and EV, we measure their *ratios* between the anonymized and original graphs; and when measuring MINS and CD, we measure their *Jaccard similarity* in the anonymized and original graphs.

We demonstrate the results in Table 5. (more results are available in [1]). The criteria for anonymization parameters settings are: (*i*) we follow the same/similar settings as in the original works of these anonymization schemes; and (*ii*) many data utilities can be preserved after anonymization. For the three graph utilities IM, SR, and SD, we only test them on small graphs, and put the results in [1]. We analyze the results in Table 5 as follows.

Generally, the evaluation results in Table 5 are consistent with our analysis in Table 2. Most anonymization algorithms can partially or conditionally preserve most graph and application utilities. Therefore, most of the anonymized data can be employed for graph analytics, data mining tasks, and graph applications.

Among all the graph utilities, JD and GCC are the most sensitive utilities to a graph's structure change, and thus they are the easiest ones to be destroyed by the anonymization algorithms. This is because these two utilities are very sensitive to edge changes. Even if the degree distribution of the anonymized data remains the same as the original data, the JD distribution and GCC may change significantly.

Compared to application utility, existing anonymization algorithms are better at preserving graph utility. For instance, most algorithms lost the RX utility and CD utility. This is because most application utilities depend on several graph utilities, e.g., the role of a user in RX depends on that user's degree, CC, BC, community attributes, and other structural characteristics. Therefore, application utilities are more easily affected than graph utilities, i.e., application utilities are more sensitive to graph's structural changes.

No anonymization scheme is optimal in preserving every data utility. For instance, *Switch* is better than *k*-DA on preserving Deg. and JD while it is worse than *k*-DA on preserving GCC and MINS, and DP is better than RW on preserving LCC and GCC while it is worse than RW on preserving Deg. Therefore, when choosing an anonymization algorithm, it is better to take into account the specific application. Furthermore, RW has the most utility loss, e.g., GCC, RX, MINS, and CD, which is also consistent with our analysis in Table 2. This is because that the graph's global structure is significantly changed in RW by replacing random walk paths with edges.

5.3.3 DA Evaluation

In this subsection, we evaluate the performance of modern DA attacks. As we analyzed before, BDK [26],

Table 5: Utility analysis of anonymization techniques. k is the number of modified edges for *Switch*, and the anonymization parameter for k-DA and Cluster, ε is the anonymization parameter for DP, t is the random walk step for RW, m is the number of edges in the original graph, and $\mathbb{D}$ is the diameter of the original graph ($\mathbb{D} = 11$ for Enron and $\mathbb{D} = 6$ for Facebook).

	Enron										**Facebook**									
Utility	*Switch* (vs. k)		k-DA (vs. k)		Cluster (vs. k)		DP (vs. ε)		RW (vs. t)		*Switch* (vs. k)		k-DA (vs. k)		Cluster (vs. k)		DP (vs. ε)		RW (vs. t)	
	.05m	.1m	5	50	5	50	300	50	2	$\mathbb{D}$	.05m	.1m	5	50	5	50	300	50	2	$\mathbb{D}$

RST [5], and RSM [5] are not scalable/practical; NSR [21] and DeA [25] are simplified versions of NS [2] and ADA [25], respectively; and NKA [22] actually depends on other attacks, e.g., NS. Therefore, here, we focus on evaluating the seven general, practical, and scalable DA attacks: NS [2], DV (we replace its seed identification phase with a scalable one) [5], PFG [23], YG [27], ADA [25], KL [24], and JLSB [3]. Furthermore, PFG and JLSB are seed-free and the other five attacks are seed-based.

First, employing the same Enron and Facebook datasets as before, we evaluate the DA performance of the seven DA attacks. The evaluation methodology is generally the same as in previous works [2, 3, 5, 22, 23, 25, 27]: we first randomly sample two graphs with probability s from the original data as the anonymized graph and auxiliary graph respectively, and then employ the auxiliary graph to de-anonymize the anonymized graph. Furthermore, for seed-based attacks, e.g., NS, DV, YG, ADA, and KL, we feed them 50 pre-identified seed mappings. The DA performance of the evaluated attacks with respect to different s is shown in Table 6. From Table 6, we have the following observations.

With the increase of s, more users can be successfully de-anonymized under each algorithm. The reason is evident. Since a large s implies that the anonymized graph and the auxiliary graph are more structurally similar, more accurate structural information can be employed by all the SDA algorithms. Hence, better DA performance can be achieved.

Generally, all the algorithms have their advantages in some specific scenarios, and no algorithm is the best in all the cases. For instance, to de-anonymize Enron, KL has the best performance when $s = .6$ while ADA has the best performance when $s = .95$. Multiple reasons are responsible for the results such as the similarity between the anonymized and auxiliary graphs, the density of the anonymized/auxiliary graph, the heuristics employed by an algorithm, etc.

According to the results, NS is more suitable for the scenarios where the anonymized and auxiliary graphs are highly similar while unsuitable when they are not sufficiently similar, e.g., it can successfully de-anonymize 95.27% Facebook users when $s = .95$ while only 0.18% users when $s = .6$. The reason is because NS mainly employs local graph structural properties to adaptively conduct user DA, and thus is sensitive to users' local structural characteristics. When s is small, most users are indistinguishable with respect to their local structures, e.g., degree, followed by poor DA performance.

Compared to NS, the other attacks, especially DV, PFG, ADA, and JLSB, are more stable even with a small s. For instance, when $s = .6$, DV, PFG, ADA, and JLSB can successfully de-anonymize 15.63%, 10.87%, 15.68%, and 14.73% Facebook users, respectively. This is because these attacks mainly employ global graph characteristics (e.g., clossness centrality, the distance vector to seeds) to perform the DA, which are more resilient to noise.

Table 6: Performance of DA attacks. s is the probability of generating the auxiliary and anonyized graphs from the original graph. Each value, e.g., 0.1277, in the table indicates the ratio of successfully de-anonymized users.

s	**De-anonymize Enron**							**De-anonymize Facebook**						
	NS	DV	PFG	YG	ADA	KL	JLSB	NS	DV	PFG	YG	ADA	KL	JLSB
.60	.0037	.1277	.0739	.0310	.1305	.1596	.1191	.0018	.1563	.1087	.2832	.1568	.0599	.1473

.75	.0055	.2244	.1349	.1004	.2307	.2152	.1958	.8712	.3068	.2041	.4554	.3078	.1196	.2574
.80	.0061	.2841	.1837	.1014	.2896	.2519	.2474	.9056	.3802	.2586	.4970	.3805	.1508	.3042
.85	.3420	.3481	.2180	.1531	.3522	.3123	.2971	.9231	.4561	.3073	.5402	.4576	.1817	.3559
.90	.3660	.4004	.2736	.1885	.4043	.3389	.3443	.9414	.5659	.3977	.5737	.5670	.2552	.4289
.95	.3937	.5814	.4370	.2277	.5898	.5209	.5438	.9527	.7407	.5584	.6071	.7422	.3989	.5542

For the seed-free attacks, PFG and JLSB, they can achieve comparable performance as seed-based attacks in most scenarios even without any seed information. For instance, when $s = .95$, PFG and JLSB can de-anonymize 43.7% and 54.38% Enron users, respectively, which are better than several seed-based algorithms and further demonstrate the power of structure-based attacks. The reason for the effectiveness of seed-free attacks is that in most cases, the combination of a user's local and global structural characteristics, e.g., degree, neighborhood degree distribution, closeness/betweenness centrality, is sufficient to distinguish him/her from other users.

5.3.4 Robustness of Modern SDA Attacks

The robustness of modern DA attacks with respect to graph noise (e.g., adding fake edges and deleting true edges) has been extensively evaluated in existing works [2,3,5,25]. However, to the best our knowledge, no existing work has evaluated the robustness of any seed-based de-anonymizaton attack to incorrect seed mappings. Employing Enron and Facebook, we address this open issue by conducting such an evaluation and the results are shown in Table 7. We analyze the results in Table 7 as follows.

Generally, all the DA algorithms are robust with respect to incorrect seed mappings in most scenarios. This is because during the DA process, most algorithms also employ other seed-independent structural properties, e.g., degree, closeness/betweenness centrality, in addition to relying on seed-dependent structural properties. Even for the pure seed-based DA attacks, e.g., YG and KL, they perform DA in the decreasing order of user degrees. Therefore, the negative impacts of incorrect seed mappings can be partially offset, i.e., even with some incorrect seed mappings, many users are still distinguishable with respect to their structural characteristics.

For all algorithms, when incorrect seed mappings increase, fewer users can be correctly de-anonymized. The reason is evident: more incorrect seed mappings imply more incorrect seed-dependent structural information is provided to each algorithm, followed by the degradation of the DA performance of each algorithm.

When de-anonymizing Enron, the performance of NS has a significant drop when the percentage of incorrect seed mappings is increased from 8% to 10%. This is because of the seed transitional phenomena as observed in [2], i.e., when the correct effective seed-dependent structural information is below/above some crucial threshold, NS's performance has a significant transition.

DV is much more stable than other algorithms. This is because it is a pure global structure-based attack and thus incorrect seed mappings have minimum impact on it.

5.3.5 Anonymization vs DA

Now, we evaluate the effectiveness of state-of-the-art anonymization techniques against modern DA attacks employing Enron and Facebook. The methodology is that we first employ different anonymization techniques to anonymize Enron/Facebook. Then, we sample an auxiliary graph from Enron/Facebook with probability s. Finally, we employ different DA algorithms to de-anonymize the anonymized data using the auxiliary graph. We show the results in Table 8 and analyze the results as follows.

All the state-of-the-art graph anonymization algorithms are vulnerable to some or all of the modern SDA attacks, which confirmed our analytical results in Table 4. For instance, when $s = .85$, NS can still successfully de-anonymize more than 80% Facebook users anonymized by *Switch*, k-DA, Cluster, or DP, and DV can successfully de-anonymize 15.3% Facebook users anonymized by RW ($t = 2$). Similarly, when $s = .85$, NS can successfully de-anonymize more than 35% Enron users anonymized by k-DA ($k = 5$), Cluster ($k = 5, 50$), YG can successfully de-anonymize 13.73% and 15.49% Enron users anonymized by *Switch* ($k = .05m$) and DP ($\varepsilon = 300$) respectively, and DV can successfully de-anonymize 19.23%/24.12% Enron users anonymized by RW with $t = 2/11$. Based on the results, we conclude that modern SDA attacks are very powerful. As

Table 7: DA robustness with respect to seed errors. Each algorithm is provided with 50 seed mappings, and Λ_e/Λ indicates the percentages of incorrect seed mappings. Each value in the table indicates the ratio of successfully de-anonymized users.

we analyzed in Table 4, two fundamental reasons make state-of-the-art graph anonymization algorithms vulnerable. First, in existing graph anonymization schemes, graph users are only indistinguishable with respect to some structural properties/semantics. However, several other structural properties or the combinations of them can still enable effective graph user DA. Furthermore, the design philosophy of existing anonymization schemes is to preserve as much data utility as possible. However, data utility can be used to conduct powerful SDA attacks. Therefore, it is still an open problem to design effective graph data anonymization algorithms which can defend against modern SDA attacks.

Generally, when *s* is large and the anonymization level (e.g., *k* for *Switch* and *k*-DA) is low, more users can be correctly de-anonymized. The reason is straightforward. A large *s* implies more structural information of the original graph can be preserved in the auxiliary graph and thus more accurate structural characteristics can be employed for DA. Meanwhile, a low anonymization level implies less perturbation applied to the original graph's structure followed by the anonymized graph is more structurally similar to the original graph and thus is easier to be de-anonymized.

Among all the DA attacks, NS, YG, and ADA perform better than other attacks in most scenarios. This is because they mainly employ the combinations of several local structural characteristics to conduct the DA. According to our utility analysis in Table 2 and evaluation results in Table 5, most existing anonymization algorithms can preserve most graph utilities, especially the local graph utilities, e.g., Deg., LCC. It turns out that the graph utility preserved by anonymization algorithms can be used by DA attacks to conduct effective DA. Therefore, in the scenarios where an anonymization algorithm preserves more data utility, the corresponding dataset is more vulnerable to modern SDA attacks.

Among all the anonymization techniques, RW has better performance than others in most of the cases. The reason is that, a random walk path of length *t* is replaced by an edge in RW. It follows that the original graph structure is significantly changed. Therefore, a RW-anonymized graph is more resistant to DA attacks. However, RW achieves such DA resistance at the cost of sacrificing more data utility compared with other anonymization techniques, which is consistent with our utility analysis and evaluation results in Tables 2 and 5. Furthermore, we can also find that in most scenarios, existing anonymization techniques can degrade the performance of SDA attacks. Again, as shown in Tables 2 and 5, some data utilities are also degraded/lost.

6 Future Research and Challenges

In this section, we discuss the future research directions and challenges of graph data anonymization and DA.

Graph Data Anonymization. According to our analytical results in Table 4 and evaluation results in Table 8, all the state-of-the-art anonymization techniques, e.g., *k*-anonymity based schemes, DP based schemes, are vulnerable to modern SDA attacks. Their vulnerability depends on how much data utility is preserved in the anonymized data. Therefore, it is very difficult, if not impossible, to develop effective and universal graph data anonymization techniques to defend against modern SDA attacks. The main challenges are two-folds. First, guaranteeing data utility is one of the primary objectives when publishing/sharing graph data. However, as we explained before, the preserved graph and application utilities enable adversaries to conduct large-scale DA attacks. Therefore, it is a big challenge to effectively anonymize graph data with desired data utility preservation and without enabling adversaries to utilize these data utilities. Second, many local and global structural characteristics (or, structural scemantics), e.g., Deg., LCC, CC, BC, are embedded in graph data's structure. Existing anonymization techniques can only make graph users structurally indistinguishable with respect to one or several semantics, e.g., degree and neighborhood. However, as we explained before, in many scenarios, several other structural semantics and their combinations are sufficient to enable a SDA attack to de-anonymize graph users. Therefore, it is also a key challenge to make graph users structurally indistinguishable with respect to most, if not all, structural semantics.

Considering that it is difficult to seek a tradeoff between generic utility and anonymity, a promising research direction could be developing *application-oriented* anonymization techniques. Instead of preserving as much data utility as possible, one only considers some specific application-aware utility when designing the anonymization techniques. For instance, although RW loses more data utility than most existing graph anonymization techniques, it achieves better anonymity and meanwhile supports some application utility, e.g., sybil detection [20].

Graph Data DA. Based on our DA evaluation results, future DA research may follow two directions.

First, it is interesting to study how to combine the advantages of different algorithms and develop new stable and improved DA schemes. To achieve this, the challenge is to decide which structural characteristics should be employed and how to use these characteristics during the DA process. This is because some structural characteristics are local (e.g., Deg.) while others are global (e.g., CC and BC). It is better to seek a balance between the employed local and global structural semantics. Additionally, some structural characteristics may carry similar structural semantics, and thus simultaneously employing such characteristics will not lead to too much improvement. Furthermore, according to our evaluation experience, the sequence and weights of applying different structural characteristics may induce very different DA performance.

Second, instead of trying to design a uniformly optimal DA algorithm, it is better to develop some anonymization technique-oriented and application-aware DA schemes. This is because, for some anonymization algorithms, e.g., most *k*-anonymity based schemes, they mainly achieve anonymity by local graph perturbation. In this scenario, the global graph characteristics based DA algorithms will be more effective. On the other hand, for some anonymization algorithms, e.g., *Add/Del* and RW, they mainly achieve anonymity through global graph perturbation. Therefore, the local graph characteristics based DA schemes will be better at de-anonymizing the data anonymized by these techniques. Furthermore, according to our DA evaluation experience, some DA attacks are more effective to de-anonymize dense graphs, e.g., NS and JLSB, while some other attacks are more effective to de-anonymize sparse graphs, e.g., DV, PFG. Therefore, when developing new DA algorithms, it is helpful to take into account both the attacked anonymization technique and the attacked application.

More Future Work. In this paper, we focus on implementing and evaluating graph data anonymization and DA techniques. It is also interesting to integrate the anonymization and DA techniques for other data types, e.g., relational data. In the future, we propose to develop a uniform and open-source evaluation system supporting multi-type data anonymization and DA.

7 Conclusion

In this paper, we propose, implement, and evaluate SecGraph (available at [1]), an *open-source* secure graph data publishing/sharing system. Within SecGraph, we systematically analyze, implement, and evaluate 11 graph data anonymization algorithms, 19 data utility metrics, and 15 modern SDA attacks. To the best of our knowledge, SecGraph is the first such system that provides a *uniform platform* enabling data owners to anonymize and evaluate the security of their data, and simultaneously enabling researchers to conduct fair studies of existing or newly developed anonymization/DA techniques. Leveraging SecGraph, we conduct extensive experimental evaluations. The results demonstrate that (*i*) most anonymization schemes can partially or conditionally preserve most graph utility but lose some application utility; (*ii*) no DA attack is optimum in all scenarios. The actual DA performance depends on several factors; and (*iii*) all the state-of-the-art anonymization schemes are vulnerable to modern SDA attacks. Based on our findings and analysis, we discuss the future research directions and challenges of graph data anonymization and DA.

8 Acknowledgments

The authors are very grateful to the anonymous reviewers for their time and valuable comments. The authors are also grateful to the following researchers in developing SecGraph: Ada Fu, Michael Hay, Davide Proserpio, Qian Xiao, Shirin Nilizadeh, Jing S. He, Wei Chen, and Stanford SNAP developers.

This work was partly supported by NSF-CAREER-CNS-0545667. Prateek Mittal was supported in part by the NSF under the grant CNS-1409415.

Abstract

In a provenance-aware system, mechanisms gather and report metadata that describes the history of each object being processed on the system, allowing users to understand how data objects came to exist in their present state. However, while past work has demonstrated the usefulness of provenance, less attention has been given to *securing* provenance-aware systems. Provenance itself is a ripe attack vector, and its authenticity and integrity must be guaranteed before it can be put to use.

We present Linux Provenance Modules (LPM), the first general framework for the development of provenance-aware systems. We demonstrate that LPM creates a trusted provenance-aware execution environment, collecting complete whole-system provenance while imposing as little as 2.7% performance overhead on normal system operation. LPM introduces new mechanisms for secure provenance layering and authenticated communication between provenance-aware hosts, and also interoperates with existing mechanisms to provide strong security assurances. To demonstrate the potential uses of LPM, we design a Provenance-Based Data Loss Prevention (PB-DLP) system. We implement PB-DLP as a file transfer application that blocks the transmission of files derived from sensitive ancestors while imposing just tens of milliseconds overhead. LPM is the first step towards widespread deployment of trustworthy provenance-aware applications.

1 Introduction

A provenance-aware system automatically gathers and reports metadata that describes the history of each object being processed on the system. This allows users to track, and understand, how a piece of data came to exist in its current state. The application of provenance is presently of enormous interest in a variety of disparate communities including scientific data processing, databases, software development, and storage [43, 53]. Provenance has also been demonstrated to be of great value to security by identifying malicious activity in data centers [5, 27, 56, 65, 66], improving Mandatory Access Control (MAC) labels [45, 46, 47], and assuring regulatory compliance [3].

Unfortunately, most provenance collection mechanisms in the literature exist as fully-trusted user space applications [28, 27, 41, 56]. Even kernel-based provenance mechanisms [43, 48] and sketches for trusted provenance architectures [40, 42] fall short of providing a provenance-aware system for malicious environments. The problem of whether or not to trust provenance is further exacerbated in distributed environments, or in layered provenance systems, due to the lack of a mechanism to verify the authenticity and integrity of provenance collected from different sources.

In this work, we present **Linux Provenance Modules (LPM)**, the first generalized framework for secure provenance collection on the Linux operating system. Modules capture *whole-system provenance*, a detailed record of processes, IPC mechanisms, network activity, and even the kernel itself; this capture is invisible to the applications for which provenance is being collected. LPM introduces a gateway that permits the upgrading of low integrity workflow provenance from user space. LPM also facilitates secure distributed provenance through an authenticated, tamper-evident channel for the transmission of provenance metadata between hosts. LPM interoperates with existing security mechanisms to establish a hardware-based root of trust to protect system integrity.

Achieving the goal of trustworthy whole-system provenance, we demonstrate the power of our approach by presenting a scheme for *Provenance-Based Data Loss Prevention (PB-DLP)*. PB-DLP allows administrators to reason about the propagation of sensitive data and control its further dissemination through an expressive policy system, offering dramatically stronger assurances than existing enterprise solutions, while imposing just mil-

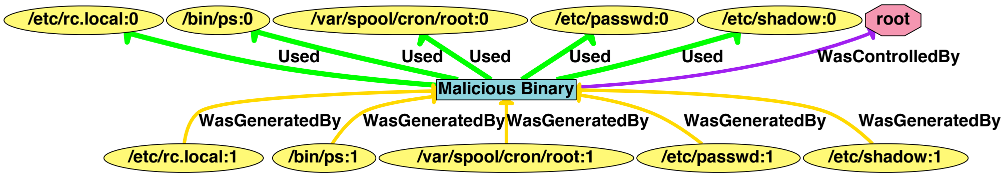

Figure 1: A provenance graph showing the attack footprint of a malicious binary. Edges encode relationships that flow backwards into the history of system execution, and writing to an object creates a second node with an incremented version number. Here, we see that the binary has rewritten `/etc/rc.local`, likely in an attempt to gain persistence after a system reboot.

liseconds of overhead on file transmission. To our knowledge, this work is the first to apply provenance to DLP.

Our contributions can thus be summarized as follows:

- **Introduce Linux Provenance Modules (LPM).** LPM facilitates secure provenance collection at the kernel layer, supports *attested disclosure* at the application layer, provides an *authenticated channel* for network transmission, and is compatible with the W3C Provenance (PROV) Model [59]. In evaluation, we demonstrate that provenance collection imposes as little as 2.7% performance overhead.

- **Demonstrate secure deployment.** Leveraging LPM and existing security mechanisms, we create a trusted provenance-aware execution environment for Linux. Through porting Hi-Fi [48] and providing support for SPADE [29], we demonstrate the relative ease with which LPM can be used to secure existing provenance collection mechanisms. We show that, in realistic malicious environments, ours is the first proposed system to offer secure provenance collection.

- **Introduce Provenance-Based Data Loss Prevention (PB-DLP).** We present a new paradigm for the prevention of data leakage that searches object provenance to identify and prevent the spread of sensitive data. PB-DLP is impervious to attempts to launder data through intermediary files and IPC. We implement PB-DLP as a file transfer application, and demonstrate its ability to query object ancestries in just tens of milliseconds.

2 Background

Data provenance, sometimes called *lineage*, describes the actions taken on a data object from its creation up to the present. Provenance can be used to answer a variety of historical questions about the data it describes. Such questions include, but are not limited to, "*What processes and datasets were used to generate this data?*" and "*In what environment was the data produced?*" Conversely, provenance can also answer questions about the successors of a piece of data, such as "*What objects on the system were derived from this object?*" Although potential applications for such information are nearly limitless, past proposals have conceptualized provenance in different ways, indicating that a one-size-fits-all solution to provenance collection is unlikely to meet the needs of all of these audiences. We review these past proposals for provenance-aware systems in Section 8.

The commonly accepted representation for data provenance is a directed acyclic graph (DAG). In this work, we use the W3C PROV-DM specification [59] because it is pervasive and facilitates the exchange of provenance between deployments. An example PROV-DM graph of a malicious binary is shown in Figure 1. This graph describes an attack in which a binary running with root privilege reads several sensitive system files, then edits those files in an attempt to gain persistent access to the host. Edges encode relationships between nodes, pointing backwards into the history of system execution. Writing to an object triggers the creation of a second object node with an incremented version number. This particular provenance graph could serve as a valuable forensics tool, allowing system administrators to better understand the nature of a network intrusion.

2.1 Data Loss Prevention

Data Loss Prevention (DLP) is enterprise software that seeks to minimize the leakage of sensitive data by monitoring and controlling information flow in large, complex organizations [1].[1] In addition to the desire to control intellectual property, another motivator for DLP systems is demonstrating regulatory compliance for personally-identifiable information (PII),[2] as well as directives such

[1] Our overview of data loss prevention is based on review of publicly available product descriptions for software developed by Bit9, CDW, Cisco, McAfee, Symantec, and Titus.

[2] See NIST SP 800-122

as PCI,[3] HIPAA,[4] SOX.[5] or E.U. Data Protection.[6] As encryption can be used to protect data at rest from unauthorized access, the true DLP challenge involves preventing leakage at the hands of authorized users, both malicious and well-meaning agents. This latter group is a surprisingly big problem in the fight to control an organization's intellectual property; a 2013 study conducted by the Ponemon Institute found that over half of companies' employees admitted to emailing intellectual property to their personal email accounts, with 41 percent admitting to doing so on a weekly basis [2]. It is therefore important for a DLP system to be able to exhaustively explain which pieces of data are sensitive, where that data has propagated to within the organization, and where it is (and is not) permitted to flow.

As DLP systems are proprietary and are marketed so as to abstract away the complex details of their internal workings, we cannot offer a complete explanation of their core features. However, some of the mechanisms in such systems are known. Many DLP products use a *regular expression-based* approach to identify sensitive data, operating similarly to a general-purpose version of Cornell's Spider[7]. For example, in PCI compliance,[3] DLP might attempt to identify credit card numbers in outbound emails by searching for 16 digit numbers that pass a Mod-10 validation check [39]. Other DLP systems use a *label-based* approach to identify sensitive data, tagging document metadata with security labels. The Titus system accomplishes this by having company employees manually annotate the documents that they create;[8] plugins for applications (e.g., Microsoft Office) then prevent the document from being transmitted to or opened by other employees that lack the necessary clearance. In either approach, DLP software is difficult to configure and prone to failure, offering marginal utility at great price.

3 Linux Provenance Modules

To serve as the foundation for secure provenance-aware systems, we present *Linux Provenance Modules (LPM)*. We provide a working definition for the provenance our system will collect in §3.1. In §3.2 we consider the capabilities and aims of a provenance-aware adversary, and identify security and design goals in §3.3. The LPM design is presented in §3.4, and in §3.5 we demonstrate its secure deployment. An expanded description of our system is available in our technical report [8].

3.1 Defining Whole-System Provenance

In the design of LPM, we adopt a model for *whole-system provenance*[9] that is broad enough to accommodate the needs of a variety of existing provenance projects. To arrive at a definition, we inspect four past proposals that collect broadly scoped provenance: SPADE [29], LineageFS [53], PASS [43], and Hi-Fi [48]. **SPADE** provenance is structured around primitive operations of system activities with data inputs and outputs. It instruments file and process system calls, and associates each call to a process ID (PID), user identifier, and network address. **LineageFS** uses a similar definition, associating process IDs with the file descriptors that the process reads and writes. **PASS** associates a process's output with references to all input files and the command line and process environment of the process; it also appends out-of-band knowledge such as OS and hardware descriptions, and random number generator seeds, if provided. In each of these systems, networking and IPC activity is primarily reflected in the provenance record through manipulation of the underlying file descriptors. **Hi-Fi** takes an even broader approach to provenance, treating non-persistent objects such as memory, IPC, and network packets as principal objects.

We observe that, in all instances, provenance-aware systems are exclusively concerned with operations on *controlled data types*, which are identified by Zhang et al. as files, inodes, superblocks, socket buffers, IPC messages, IPC message queue, semaphores, and shared memory [64]. Because controlled data types represent a super set of the objects tracked by system layer provenance mechanisms, we define whole-system provenance as *a complete description of agents (users, groups) controlling activities (processes) interacting with controlled data types during system execution.*

3.2 Threat Model & Assumptions

We consider an adversary that has gained remote access to a provenance-aware host or network. Once inside the system, the attacker may attempt to remove provenance records, insert spurious information into those records, or find gaps in the provenance monitor's ability to record information flows. A network attacker may also attempt to forge or strip provenance from data in transit. Because captured provenance can be put to use in other applications, the adversary's goal may even be to target the provenance monitor itself. The implications and methods of such an attack are domain-specific. For example:

[4] See http://www.hhs.gov/ocr/privacy

[5] Short for the Sarbanes-Oxley Act, U.S. Public Law No. 107-20

[6] See EU Directive 95/46/EC

[7] See http://www2.cit.cornell.edu/security/tools

[8] See http://www.titus.com

[9] This term is coined in [48], but not explicitly defined. We demonstrate the concrete requirements of a collection mechanism for whole-system provenance in this work.

- **Scientific Computing**: An adversary may wish to manipulate provenance in order to commit fraud, or to inject uncertainty into records to trigger a "Climategate"-like controversy [50].

- **Access Control**: When used to mediate access decisions [7, 45, 46, 47], an attacker could tamper with provenance in order to gain unauthorized access, or to perform a denial-of-service attack on other users by artificially escalating the security level of data objects.

- **Networks**: Provenance metadata can also be associated with packets in order to better understand network events in distributed systems [5, 65, 66]. Coordinating multiple compromised hosts, an attacker may attempt to send *unauthenticated* messages to avoid provenance generation and to perform data exfiltration.

We define a provenance trusted computing base (TCB) to be the kernel mechanisms, provenance recorder, and storage back-ends responsible for the collection and management of provenance. *Provenance-aware applications are not considered part of the TCB.*

We make the following assumption with regards to the TCB. In Linux, kernel modules have unrestricted access to kernel memory, meaning that there is no mechanism for protecting LPM from the rest of the kernel. The kernel code is therefore trusted; we assume that the stock kernel will not seek to tamper with the TCB. However, we do consider the possibility that the kernel could be compromised after installation through its interactions with user space applications. To facilitate host attestation in distributed environments, we also assume access to a Public Key Infrastructure (PKI) for provenance-aware hosts to publish their public signing keys.

3.3 System Goals

We set out to provide the following security assurances in the design of of our system-layer provenance collection mechanism. McDaniel et al. liken the needs of a secure provenance monitor [42] to the reference monitor guarantees laid out by Anderson [4]: complete mediation, tamperproofness, and verifiability. We define these guarantees as follows:

G1 **Complete**. Complete mediation for provenance has been discussed elsewhere in the literature in terms of assuring *completeness* [32]: that the provenance record be gapless in its description of system activity. To facilitate this, LPM must be able to observe all information flows that pass through controlled data types.

G2 **Tamperproof.** As many provenance use cases involve enhancing system security, LPM will be an adversarial target. The TCB must therefore be impervious to disabling or manipulation by processes in user space.

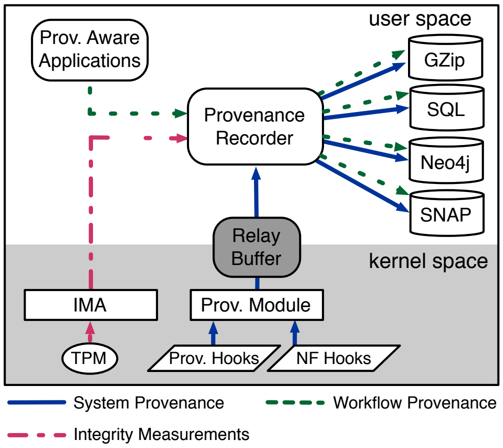

Figure 2: Diagram of the LPM Framework. Kernel hooks report provenance to a recorder in userspace, which uses one of several storage back-ends. The recorder is also responsible for evaluating the integrity of workflow provenance prior to storing it.

G3 **Verifiable**. The functionality of LPM must be verifiably correct. Additionally, local and remote users should be able to attest whether the host with which they are communicating is running the secured provenance-aware kernel.

Through surveying past work in provenance-aware systems, we identify the following additional goals to support whole-system provenance:

G4 **Authenticated Channel**. In distributed environments, provenance-aware systems must provide a means of assuring authenticity and integrity of provenance as it is communicated over open networks [7, 42, 48, 65]. *While we do not seek to provide a complete distributed provenance solution in LPM*, we do wish to provide the required building blocks within the host for such a system to exist. LPM must therefore be able to monitor every network message that is sent or received by the host, and reliably explain these messages to other provenance-aware hosts in the network.

G5 **Attested Disclosure**. Layered provenance, where additional metadata is disclosed from higher operational layers, is a desirable feature in provenance-aware systems, as applications are able to report workflow semantics that are invisible to the operating system [44]. LPM must provide a gateway for upgrading low integrity user space disclosures before logging them in the high integrity provenance record. This is consistent with the Clark-Wilson Integrity model for upgrading or discarding low integrity inputs [17].

In order to bootstrap trust in our system, we have implemented LPM as a parallel framework to Linux Security Modules (LSM) [60, 61]. Building on these results, we show in Section 4 that this approach allows LPM to inherit the formal assurances that have been verified for the LSM architecture.

3.4 Design & Implementation

An overview of the LPM architecture is shown in Figure 2. The LPM patch places a set of *provenance hooks* around the kernel; a *provenance module* then registers to control these hooks, and also registers several Netfilter hooks; the module then observes system events and transmits information via a relay buffer to a *provenance recorder* in user space that interfaces with a datastore. The recorder also accepts disclosed provenance from applications after verifying their correctness using the Integrity Measurements Architecture (IMA) [52].

In designing LPM, we first considered using an experimental patch to the LSM framework that allows “stacking” of LSM modules [10]. However, at this time, no standard exists for handling when modules make conflicting decisions, creating the potential unpredicted behavior. We also felt that dedicated provenance hooks were necessary; by collecting provenance *after* LSM authorization routines, we ensure that the provenance history is an accurate description of authorized system events. If provenance collection occurred *during* authorization, as would be the case with stacked LSMs, it would not be possible to provide this property.

3.4.1 Provenance Hooks

The LPM patch introduces a set of hook functions in the Linux kernel. These hooks behave similarly to the LSM framework’s security hooks in that they facilitate modularity, and default to taking no action unless a module is enabled. Each provenance hook is placed directly beneath a corresponding security hook. The return value of the security hook is checked prior to calling the provenance hook, thus assuring that the requested activity has been authorized prior to provenance capture; we consider the implications of this design in Section 4. A workflow for the hook architecture is depicted in Figure 3. The LPM patch places over 170 provenance hooks, one for each of the LSM authorization hooks. In addition to the hooks that correspond to existing security hooks, we also support Pohly et al.’s Hi-Fi [48] hook that is necessary to preserve Lamport timestamps on network messages [38].

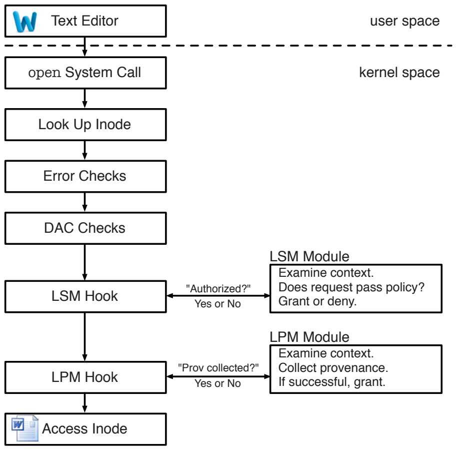

Figure 3: Hook Architecture for the `open` system call. Provenance is collected *after* DAC and LSM checks, ensuring that it accurately reflects system activity. LPM will only deny the operation if it fails to generate provenance for the event.

3.4.2 Netfilter Hooks

LPM uses Netfilter hooks to implement a cryptographic message commitment protocol. In Hi-Fi, provenance-aware hosts communicated by embedding a provenance sequence number in the IP options field [49] of each outbound packet [48]. This approach allowed Hi-Fi to communicate as normal with hosts that were not provenance-aware, but unfortunately was not secure against a network adversary. In LPM, provenance sequence numbers are replaced with Digital Signature Algorithm (DSA) signatures, which are space-efficient enough to embed in the IP Options field. We have implemented full DSA support in the Linux kernel by creating signing routines to use with the existing DSA verification function. DSA signing and verification occurs in the NetFilter `inet_local_out` and `inet_local_in` hooks. In `inet_local_out`, LPM signs over the immutable fields of the IP header, as well as the IP payload. In `inet_local_in`, LPM checks for the presence of a signature, then verifies the signature against a configurable list of public keys. If the signature fails, the packet is dropped before it reaches the recipient application, thus ensuring that there are no breaks in the continuity of the provenance log. The key store for provenance-aware hosts is obtained by a PKI and transmitted to the kernel during the boot process by writing to `securityfs`. LPM registers the Netfilter hooks with the highest prior-

[10] See https://lwn.net/Articles/518345/

ity levels, such that signing occurs just before transmission (i.e., after all other IPTables operations), and signature verification occurs just after the packet enters the interface (i.e., before all other IPTables operations).

3.4.3 Provenance Modules

Here, we introduce two of our own provenance modules (Provmon, SPADE), as well as briefly mention the work of our peers (UPTEMPO):

- **Provmon**. Provmon is an extended port of the Hi-Fi security module [48]. The original Hi-Fi code base was 1,566 lines of code, requiring 723 lines to be modified in the transition. Our extensions introduced 728 additional lines of code. The process of porting did not affect the module's functionality, although we have subsequently extended the Hi-Fi protocol to capture additional lineage information:

  File Versioning. The original Hi-Fi protocol did not track version information for files, leading to uncertainty as to the exact contents of a file at the time it was read. Accurately recovering this information in user space was not possible due to race conditions between kernel events. Because versioning is necessary to break cycles in provenance graphs [43], we have added a version field to the provenance context for inodes, which is incremented on each write.

  Network Context. Hi-Fi omitted remote host address information for network events, reasoning that source information could be forged by a dishonest agent in the network. These human-interpretable data points were replaced with an assigned random identifier for each packet. We found, however, that these identifiers could not be interpreted without remote address information, and incorporated the recording of remote IP addresses and ports into Provmon.

- **SPADE**. The SPADE system is an increasingly popular option for provenance auditing, but collecting provenance in user space limits SPADE's expressiveness and creates the potential for incomplete provenance. To address this limitation, we have created a mechanism that reports LPM provenance into SPADE's Domain-Specific Language pipe [29]. This permits the collection of whole-system provenance while simultaneously leveraging SPADE's existing storage, remote query, and visualization utilities.

- **Using Provenance to Expedite MAC Policies (UPTEMPO)**. Using LPM as a collection mechanism, Moyer et al. investigate provenance analysis as a means of administrating Mandatory Access Control (MAC) policies [54]. UPTEMPO first observes system execution in a sterile environment, aggregating LPM provenance in a centralized data store. It then recovers the implicit information flow policy through mining the provenance store to generate a MAC policy for the distributed system, decreasing both administrator effort and the potential for misconfiguration.

3.4.4 Provenance Recorders

LPM provides modular support for different storage through *provenance recorders*. To prevent an infinite provenance loop, recorders are flagged as provenance-opaque [48] using the `security.provenance` extended attribute, which is checked by LPM before creating a new event. Each recorder was designed to be as agnostic to the active LPM as possible, making them easy to adapt to new modules.

We currently provide provenance recorders that offer backend storage for *Gzip*, *PostGreSQL*, *Neo4j*, and *SNAP*. Commentary on our PostGreSQL and Neo4j reporters can be found in our technical report [8]. We make use of the Gzip and SNAP recorders during our evaluation in Section 6.

The Gzip recorder incurs low storage overheads and fast insertion speeds. On our test bed, we observed this recorder processing up to 400,000 events per second from the Provmon provenance stream. However, because the provenance is not stored in an easily queried form, this back-end is best suited for environments where queries are an offline process.

To create graph storage that was efficient enough for LPM, we used the SNAP graphing library[11] to design a recorder that maintains an in-memory graph database that is fully compliant with the W3C PROV-DM Model [59]. We have observed insertion speeds of over 150,000 events per second using the SNAP recorder, and highly efficient querying as well. This recorder is further evaluated in Section 6.

3.4.5 Workflow Provenance

To support layered provenance while preserving our security goals, we require a means of evaluating the integrity of user space provenance disclosures. To accomplish this, we extend the LPM Provenance Recorder to use the Linux Integrity Measurement Architecture (IMA) [35, 52]. IMA computes a cryptographic hash of each binary before execution, extends the measurement into a TPM Platform Control Register (PCR), and stores the measurement in kernel memory. This set of measurements can be used by the Recorder to make a decision about the integrity of the a Provenance-Aware Application (PAA) prior to accepting the disclosed provenance. When a PAA wishes to disclose provenance, it opens a

[11] See http://snap.stanford.edu

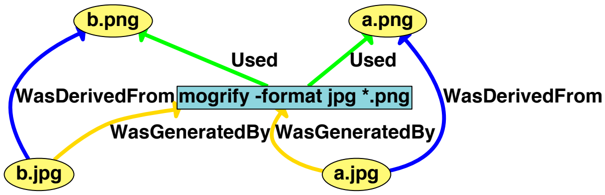

Figure 4: A provenance graph of image conversion. Here, workflow provenance (*WasDerivedFrom*) encodes a relationship that more accurately identifies the output files' dependencies compared to only using kernel layer observations (*Used*, *WasGeneratedBy*).

new UNIX domain socket to send the provenance data to the Provenance Recorder. The Recorder uses its own UNIX domain socket to recover the process's pid, then uses the `/proc` filesystem to find the full path of the binary, then uses this information to look up the PAA in the IMA measurement list. The disclosed provenance is recorded only if the signature of PAA matches a known-good cryptographic hash.

As a demonstration of this functionality, we created a provenance-aware version of the popular ImageMagick utility [12]. ImageMagick contains a batch conversion tool for image reformatting, `mogrify`. Shown in Figure 4, `mogrify` reads and writes multiple files during execution, leading to an *overtainting* problem – at the kernel layer, LPM is forced to conservatively assume that all outputs were derived from all inputs, creating false dependencies in the provenance record. To address this, we extended the Provmon protocol to support a new message, `provmsg_imagemagick_convert`, which links an input file directly to its output file. When the recorder receives this message, it first checks the list of IMA measurements to confirm that ImageMagick is in a good state. If successful, it then annotates the existing provenance graph, connecting the appropriate input and output objects with *WasDerivedFrom* relationships. Our instrumentation of ImageMagick demonstrates that LPM supports layered provenance at no additional cost over other provenance-aware systems [29, 43], and does so in a manner that provides assurance of the integrity of the provenance log.

3.5 Deployment

We now demonstrate how we used LPM in the deployment of a secure provenance-aware system. Additional background on the security technologies use in our deployment can be found in our technical report [8].

3.5.1 Platform Integrity

We configured LPM to run on a physical machine with a Trusted Platform Module (TPM). The TPM provides a root of trust that allows for a measured boot of the system. The TPM also provides the basis for remote attestations to prove that LPM was in a known hardware and software configuration. The BIOS's core root of trust for measurement (CRTM) bootstraps a series of code measurements prior to the execution of each platform component. Once booted, the kernel then measures the code for user space components (e.g., provenance recorder) before launching them, through the use of the Linux Integrity Measurement Architecture (IMA)[52]. The result is then extended into TPM PCRs, which forms a verifiable chain of trust that shows the integrity of the system via a digital signature over the measurements. A remote verifier can use this chain to determine the current state of the system using TPM attestation.

We configured the system with Intel's Trusted Boot (tboot),[13] which provides a secure boot mechanism, preventing system from booting into the environment where critical components (e.g., the BIOS, boot loader and the kernel) are modified. Intel tboot relies on the Intel TXT[14] to provide a secure execution environment. [15] Additionally, we compiled support for IMA into the provenance-aware kernel, which is necessary in order for the LPM Recorder to be able to measure the integrity of provenance-aware applications.

3.5.2 Runtime Integrity

After booting into the provenance-aware kernel, the runtime integrity of the TCB (defined in §3.2) must also be assured. To protect the runtime integrity of the kernel, we deploy a Mandatory Access Control (MAC) policy, as implemented by Linux Security Modules. On our prototype deployments, we enabled SELinux's MLS policy, the security of which was formally modeled by Hicks et al. [33]. Refining the SELinux policy to prevent Access Vector Cache (AVC) denials on LPM components required minimal effort; the only denial we encountered was when using the PostgreSQL recorder, which was quickly remedied with the `audit2allow` tool. Preserving the integrity of LPM's user space components, such as the provenance recorder, was as simple as creating a new policy module. We created a policy module to protect the LPM recorder and storage back-end using the `sepolicy` utility. Uncompiled, the policy module was only 135 lines.

[12] See http://www.imagemagick.org

[13] See http://sf.net/projects/tboot

[14] See https: //www.kernel.org/doc/Documentation/intel_txt.txt

[15] For virtual environments, similar functionality can be provided on Xen via TPM *sealing* and the virtual TPM (vTPM), which is bound to the physical TPM of the host system.

4 Security

In this section, we demonstrate that our system meets all of the required security goals for trustworthy whole-system provenance. In this analysis, we consider an LPM deployment on a physical machine that was enabled with the Provmon module and has been configured to the conditions described in Section 3.5.

Complete (G1). We defined whole-system provenance as a complete description of agents (users, groups) controlling activities (processes) interacting with controlled data types during system execution (§ 3.1). LPM attempts to track these system objects through the placement of provenance hooks (§3.4.1), which directly follow each LSM authorization hook. The LSM's complete mediation property has been formally verified [20, 64]; in other words, there is an authorization hook prior to every security-sensitive operation. Because every interaction with a controlled data type is considered security-sensitive, we know that a provenance hook resides on all control paths to the provenance-sensitive operations. LPM is therefore capable of collecting complete provenance on the host.

It is important to note that, as a consequence of placing provenance hooks beneath authorization hooks, LPM is unable to record failed access attempts. However, inserting the provenance layer beneath the security layer ensures accuracy of the provenance record. Moreover, failed authorizations are a different kind of metadata than provenance because they do not describe processed data; this information is better handled at the security layer, e.g., by the SELinux Access Vector Cache (AVC) Log.

Tamperproof (G2). The runtime integrity of the LPM trusted computing base is assured via the SELinux MLS policy, and we have written a policy module that protects the LPM user space components (§3.5.2). Therefore, the only way to disable LPM would be to reboot the system into a different kernel; this action can be disallowed through secure boot techniques,[13] and is detectable by remote hosts via TPM attestation (§3.5.1).

Verifiable (G3). While we have not conducted an independent formal verification of LPM, our argument for its correctness is as follows. A provenance hook follows each LSM authorization hook in the kernel. The correctness of LSM hook placement has been verified through both static and dynamic analysis techniques [20, 25, 34]. Because an authorization hook exists on the path of every sensitive operation to controlled data types, and LPM introduces a provenance hook behind each authorization hook, LPM inherits LSM's formal assurance of complete mediation over controlled data types. This is sufficient to ensure that LPM can collect the provenance of every sensitive operation on controlled data types in the kernel (i.e., whole-system provenance).

Authenticated Channel (G4). Through use of Netfilter hooks [57], LPM embeds a DSA signature in every outbound network packet. Signing occurs immediately prior to transmission, and verification occurs immediately after reception, making it impossible for an adversary-controlled application running in user space to interfere. For both transmission and reception, the signature is invisible to user space. Signatures are removed from the packets before delivery, and LPM feigns ignorance that the options field has been set if `get_options` is called. Hence, LPM can enforce that all applications participate in the commitment protocol.

Prior to implementing our own message commitment protocol in the kernel, we investigated a variety of existing secure protocols. The integrity and authenticity of provenance identifiers could also be protected via IPsec [36], SSL tunneling,[16] or other forms of encapsulation [5, 65]. We elected to move forward with our approach because 1) it ensures the monitoring of all *all* processes and network events, including non-IP packets, 2) it does not change the number of packets sent or received, ensuring that our provenance mechanism is minimally invasive to the rest of the Linux network stack, and 3) it preserves compatibility with non-LPM hosts. An alternative to DSA signing would be HMAC [9], which offers better performance but requires pairwise keying and sacrifices the non-repudiation policy; BLS, which approaches the theoretical maximum security parameter per byte of signature [12]; or online/offline signature schemes [15, 23, 26, 55].

Authenticated Disclosures (G5). We make use of IMA to protect the channel between LPM and provenance-aware applications wishing to disclose provenance. IMA is able to prove to the provenance recorder that the application was unmodified at the time it was loaded into memory, at which point the recorder can accept the provenance disclosure into the official record. If the application is known to be correct (e.g., through formal verification), this is sufficient to establish the runtime integrity of the application. However, if the application is compromised after execution, this approach is unable to protect against provenance forgery.

A separate consideration for all of the above security properties are Denial of Service (DoS) attacks. *DoS attacks on LPM do not break its security properties.* If an attacker launches a resource exhaustion attack in order to prevent provenance from being collected, all kernel operations will be disallowed and the host will cease to function. If a network attacker tampers with a packet's provenance identifier, the packet will not be delivered to the recipient application. In all cases, the provenance record remains an accurate reflection of system events.

Algorithm 1 Summarizes a's propagation through the system.

```
Require: $a$ is an entity
procedure REPORT($a$)
    $Locations = [\,]$                                ▷ Assigns an empty list.
    for each $s$ in $a, FindSuccessors(a)$ do
        if $s.type$ is File then
            $Locations.Add(< s.disk, s.directory >)$
        else if $s.type$ is Network Packet then
            $Locations.Add(< s.remote\_ip, s.port >)$
        end if
    end for
    return $Locations$
end procedure
```

5 LPM Application: Provenance-Based Data Loss Prevention

To further demonstrate the power of LPM, we now introduce a set of mechanisms for Provenance-Based Data Loss Prevention (PB-DLP) that offer dramatically simplified administration and improved enforcement over existing DLP systems. A provenance-based approach is a novel and effective means of handling data loss prevention; to our knowledge, we are the first in the literature to do so. The advantage of our approach when compared to existing systems is that LPM-based provenance-aware systems already perform system-wide capture of information flows between kernel objects. Data loss prevention in such a system therefore becomes a matter of preventing all derivations of a sensitive source entity, e.g., a Payment Card Industry (PCI) database, from being written to a monitored destination entity (e.g., a network interface).

We begin by defining a policy format for PB-DLP. Individual rules take the form

$$< Srcs = [src_1, src_2, \ldots, src_n], dst >$$

where *Srcs* is a list of entities representing persistent data objects, and *dst* is a single entity representing either a persistent data object such as a file or interface or an abstract entity such as a remote host. The goal for PB-DLP is as follows – an entity e_1 with ancestors A is written to entity e_2 if and only if $A \not\supseteq Srcs$ for *all* rules in the rule set where $e_2 = dst$. The reason that sources are expressed as sets is that, at times, the union of information is more sensitive than its individual components. For example, sharing a person's last name *or* birthdate may be permissible, while sharing the last name *and* birthdate is restricted as PII.[2]

Below, we define the functions that realize this goal. First, we define two provenance-based functions as the basis for a DLP *monitoring phase*, which allows administrators to learn more about the propagation of sensitive data on their systems. Then, we define mechanisms for a DLP *enforcement phase*.

Algorithm 2 Mediates request to write e to d given $Rules$.

```
Require: $e, d$ are entities
Require: $Rules$ is a PB-DLP policy
procedure PROVWRITE($e, d, Rules$)
    for each $rule$ in $Rules$ do
        if $d = rule.dst$ then
            $A = FindAncestors(e)$
            $NumSrcs = length(rule.Srcs)$
            for each $src$ in $rule.Srcs$ do
                if $src$ in $A$ then
                    $NumSrcs--$
                end if
            end for
            if $NumSrcs = 0$ then                     ▷ $A \supseteq Srcs$, deny.
                return PB-DLP_DENY
            end if
        end if
    end for
    return PB-DLP_PERMIT                              ▷ $A \not\supseteq Srcs$, permit.
end procedure
```

5.1 Monitoring Phase

The goal of monitoring is to allow administrators to reason about how sensitive data is stored and put to use on their systems. The end product of the monitor phase is a set of rules (a policy) that restrict the permissible flows for sensitive data sources. Monitoring is an ongoing process in DLP, where administrators attempt to iteratively improve protection against data leakage. The first step is to identify the data that needs protection. Identifying the source of such information is often quite simple; for example, a database of PCI or PII data. However, reliably finding data objects that were derived from this source is extraordinarily complicated using existing solutions, but is simple now with LPM. To begin, we define a helper function for system monitoring:

1. *FindSuccessors(Entity)*: This function performs a provenance graph traversal to obtain the list of data objects derived from *Entity*.

FindSuccessors can then be used as the basis for a function that summarizes the spread of sensitive data:

2. *Report(Entity)*: List the locations that a target object and its successors have propagated. This function is defined in Algorithm 1.

The information provided by *Report* is similar to the data found in the Symantec DLP Dashboard [1], and could be used as the backbone of a PB-DLP user interface. Administrators can use this information to write a PB-DLP policy or revise an existing one.

5.2 Enforcement Phase

Possessing a PB-DLP policy, the goal of the enforcement phase is to prevent entities that were derived from sensitive sources from being written to restricted locations. To do so, we need to inspect the object's provenance to discover the entities from which it was derived. We define the following helper function:

3. *FindAncestors(Entity)*: This function performs a provenance graph traversal to obtain the list of data objects used in the creation of *Entity*.

FindAncestors can be then used as the basis for a function that prevents the spread of sensitive data:

4. *ProvWrite(Entity, Destination, Rules)*: Write the target entity to the destination if and only if it is valid to the provided rule set, as defined in Algorithm 2.

5.3 File Transfer Application

In many enterprise networks that are isolated from the Internet via firewalls and proxies, it is desirable to share files with external users. File transfer services are one way to achieve this, and provide a single entry/exit point to the enterprise network where files being transferred can be examined before being released.[17] In the case of incoming files, scans can check for known malware, and in some cases, check for other types of malicious behavior from unknown malware.

We implemented PB-DLP as a file transfer application for provenance-aware systems using LPM's Provmon module. The application interfaced with LPM's SNAP recorder using a custom API. Before permitting a file to be transmitted to a remote host, the application ran a query that traversed *WasDerivedFrom* edges to return a list of the file's ancestors, permitting the transfer only if the file was not derived from a restricted source. PB-DLP allows internal users to share data, while ensuring that sensitive data is not exfiltrated in the process.

Because provenance graphs continue to grow indefinitely over time, in practice the bottleneck of this application is the speed of provenance querying. We evaluate the performance of PB-DLP queries in Section 6.3.

5.4 PB-DLP Analysis

Below, we select two open source systems that approximate *label based* and *regular expression (regex) based* DLP solutions, and compare their benefits to PB-DLP.

5.4.1 Label-Based DLP

The SELinux MLS policy [31] provides information flow security through a label-based approach, and could be used to approximate a DLP solution without relying on commercial products. Proprietary label-based DLP systems rely on manual annotations provided by users, requiring them to provide correct labeling based on their knowledge of data content. Using SELinux as an exemplar labeling system is therefore an *extremely conservative* approach to analysis.

Within an MLS system, each subject, and object, is assigned a classification level, and categories, or compartments. Consider an example system, with classification levels, $\{A,B\}$ with A dominating B, and compartments $\{\alpha,\beta\}$. We can model our policy as a lattice, where each node in the lattice is a tuple of the form $\{< level >, \{compartments\}\}$. Once the policy is defined, it is possible to enforce the simple and *-properties. If a user has access to data with classification level A, and compartment α, he cannot read anything in compartment $\{\beta\}$ (*no read-up*). Furthermore, when data is accessed in A,$\{\alpha\}$, the user cannot write anything to B,$\{\alpha\}$ (*no write-down*).

In order to use SELinux's MLS enforcement as a DLP solution, the administrator configures the policy to enforce the constraint that no data of specified types can be sent over the network. However, this is difficult in practice. Consider an example system that processes PII. The users of the system may need to access information, such as last names, and send these to the payroll department to ensure that each employee receives a paycheck. Separately, the user may need to send a list of birthdays to another user in the department to coordinate birthday celebrations for each month. Either of these activities are acceptable (Figure 5, Decision Condition 2). However, it is common practice for organizations to have stricter sharing policies for data that contains multiple forms of PII, so while either of these identifiers could be transmitted in isolation, the two pieces of information combined could not be shared (Figure 5, Decision Condition 3).

The MLS policy cannot easily handle this type of data fusion. In order to provide support for correctly labeling fused data, an administrator would need to define the power set of all compartments within the MLS policy. In the example above, the administrator would define the following compartments: $\{\}$, $\{\alpha\}$, $\{\beta\}$, $\{\alpha,\beta\}$. In the default configuration SELinux supports 256 unique categories, meaning an SELinux DLP policy could only support eight types of data. Furthermore, the MLS policy does not support defining multiple categories within a single sensitivity level[18]. This implies that the MLS policy cannot support having a security level for A,$\{\alpha\}$ and for A,$\{\alpha,\beta\}$. Instead, the most restrictive labeling must be defined to protect the data on the system. In contrast, PB-DLP can support an arbitrary number of data fusions.

[17] Two examples of vendors that provide this capability are FireEye (http://www.fireeye.com) and Accellion (http://www.accellion.com/)

[18] See the definition of level statements at `http://selinuxproject.org/page/MLSStatements`

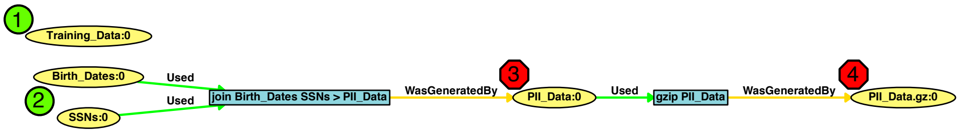

Figure 5: A provenance graph of PII data objects that are first fused and then transformed. The numbers mark DLP decision conditions. Objects marked by green circles *should not* be restricted, while red octagons *should* be restricted. Label-Based DLP correctly handles data resembling PII (1,2) and data transformations (4), but struggles with data fusions (3). Regex-Based DLP correctly identifies data fusions (3), but is prone to incorrect handling of data resembling PII (1) and fails to identify data transformations (4). PB-DLP correctly handles all conditions.

5.4.2 Regex-Based DLP

The majority of DLP software relies on pattern matching techniques to identify sensitive data. While enterprise solutions offer greater sophistication and customizability, their fundamental approach resembles that of Cornell's Spider [7], a forensics tools for identifying sensitive personal data (e.g., credit card or social security numbers). Because it is open source, we make use of Spider as an exemplar application for regex-based DLP.

Regex approaches are prone to *false positives*. Spider is pre-configured with a set of regular expressions for identifying potential PII, e.g., `(\d{3}-\d{2}-\d{4})` identifies a social security number. However, it is common practice for developers to generate and distribute training datasets to aid in software testing (Figure 5, Decision Condition 1). Spider is oblivious to information flows, instead searching for content that bears structural similarity to PII, and therefore would be unable to distinguish between true PII and training data. PB-DLP tracks the propagation of data from its source onwards, and could trivially differentiate between true PII and training sets.

Regex approaches are also prone to *false negatives*. Even after the most trivial data transformations, PII and PCI data is no longer identifiable to the Spider system (Figure 5, Decision Condition 4), permitting its exfiltration. To demonstrate, we generated a file full of random valid social security numbers that Spider was able to identify. We then ran `gzip` on the file and stored it in a second file. Spider was unable to identify the second file, but PB-DLP correctly identified both files as PII since the `gzip` output was derived from a sensitive input.

6 Evaluation

We now evaluate the performance of LPM. Our benchmarks were run on a bare metal server machine with 12 GB memory and 2 Intel Xeon quad core CPUs. The Red Hat 2.6.32 kernel was compiled and installed under 3 different configurations: all provenance disabled (*Vanilla*), LPM scaffolding installed but without an enabled module (*LPM*), and LPM installed with the Provmon module enabled (*Provmon*).

Test Type	Vanilla	LPM	Provmon
Process tests, times in μseconds (smaller is better)			
null call	0.14	0.14 (0%)	0.14 (0%)
null I/O	0.21	0.21 (0%)	0.32 (52%)
stat	1.57	1.6 (2%)	2.8 (78%)
open/close file	2.75	2.42 (-12%)	3.91 (42%)
signal install	0.25	0.25 (0%)	0.25 (0%)
signal handle	1.37	1.29 (-6%)	1.39 (1%)
fork process	380	396 (4%)	401 (6%)
exec process	873	879 (1%)	911 (4%)
shell process	2990	3000 (0%)	3113 (4%)
File and memory latencies in μseconds (smaller is better)			
file create (0k)	11.5	11.2 (-3%)	15.8 (37%)
file delete (0k)	8.51	8.12 (-5%)	11.8 (39%)
file create (10k)	23.4	21.6 (-8%)	28.8 (23%)
file delete (10k)	12.5	12 (-4%)	14.7 (18%)
mmap latency	1062	1053 (-1%)	1120 (5%)
protect fault	0.32	0.3 (-6%)	0.346 (8%)
page fault	0.016	0.016 (0%)	0.016 (0%)
100 fd select	1.53	1.53 (0%)	1.53 (0%)

Table 1: LMBench measurements for LPM kernels. All times are in microseconds. Percent overhead for modified configurations are shown in parenthesis.

6.1 Collection Performance

We used LMBench to microbenchmark LPM's impact on system calls as well as file and memory latencies. Table 1 shows the averaged results over 10 trials for each kernel, with a percent overhead calculation against Vanilla. For most measures, the performance differences between LPM and Vanilla are negligible. Comparing Vanilla to Provmon, there are several measures in which overhead is noteworthy: *stat, open/close, file creation and deletion*. Each of these benchmarks involve LMBench manipulating a temporary file that resides in `/usr/tmp/lat_fs/`. Because an absolute path is provided, before each system call occurs LMBench first traverses the path to the file, resulting in the creation of 3 different provenance events in Provmon's `inode_permission` hook, each of which is transmitted to user space via the kernel relay. While

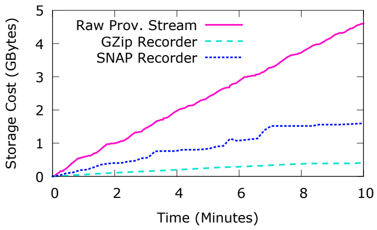

Figure 6: Growth of provenance storage overheads during kernel compilation.

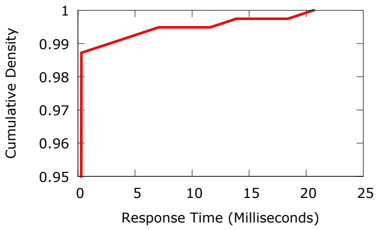

Figure 7: Performance of ancestry queries for objects created during kernel compilation.

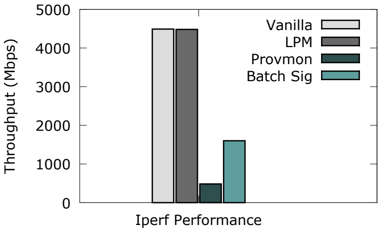

Figure 8: LPM network overhead can be reduced with batch signature schemes.

the overheads seem large for these operations, the logging of these three events only imposes approximately 1.5 microseconds per traversal. Moreover, the overhead for opening and closing is significantly higher than the overhead than reads and writes (*Null I/O*); thus, the higher open/close costs are likely to be amortized over the course of regular system use. A provenance module could further reduce this overhead by maintaining state about past events within the kernel, then blocking the creation of redundant provenance records.

Test	Vanilla	Provmon	Overhead
Kernel Compile	598 sec	614 sec	2.7%
Postmark	25 sec	27 sec	7.5%
Blast	376 sec	390 sec	4.8%

Table 2: Benchmarking Results. Our provenance module imposed just 2.7% overhead on kernel compilation.

To gain a more practical sense of the costs of LPM, we also performed multiple benchmark tests that represented realistic system workloads. Each trial was repeated 5 times to ensure consistency. The results are summarized in Table 2. For the kernel compile test, we recompiled the kernel source (in a fixed configuration) while booted into each of the kernels. Each compilation occurred on 16 threads. The LPM scaffolding (without an enabled module) is not included, because in both tests it imposed less than 1% overhead. In spite of seemingly high overheads for file I/O, Provmon imposes just 2.7% overhead on kernel compilation, or 16 seconds. The Postmark test simulates the operation of an email server. It was configured to run 15,000 transactions with file sizes ranging from 4 KB to 1 MB in 10 subdirectories, with up to 1,500 simultaneous transactions. The Provmon module imposed just 7.5% overhead on this task. To estimate LPM's overhead for scientific applications, we ran the BLAST benchmarks [19], which simulates biological sequence workloads obtained from analysis of hundreds of thousands of jobs from the National Institutes of Health.

For kernel compile and postmark, Provmon outperforms the PASS system, which exacted 15.6% and 11.5% overheads on kernel compilation and postmark, respectively [43]. Provmon introduces comparable kernel compilation overhead to Hi-Fi (2.8%) [48]. It is difficult to compare our Blast results to SPADE and PASS, as both used a custom workload instead of a publicly available benchmark. SPADE reports an 11.5% overhead on a large workload [29], while PASS reports just an 0.7% overhead. Taken as a whole, though, LPM collection either meets or exceeds the performance of past systems, while providing additional security assurances.

6.2 Storage Overhead

A major challenge to automated provenance collection is the storage overhead incurred. We plotted the growth of provenance storage using different recorders during the kernel compilation benchmark, shown in Figure 6. LPM generated 3.7 GB of raw provenance. This required only 450 MB of storage with the Gzip recorder, but provenance cannot be efficiently queried in this format. The SNAP recorder builds an in-memory provenance graph. We approximated the storage overhead through polling the virtual memory consumed by the recorder process in the `/proc` filesystem. The SNAP graph required 1.6 GB storage; the reduction from the raw provenance stream is due to the fact that redundant events did not lead to the creation of new graph components. In contrast, the PASS system generates 1.3 GB of storage overhead during kernel compilation while collecting less information (e.g., shared memory). LPM's storage overheads are thus comparable to other provenance-aware systems.

6.3 Query Performance (PB-DLP)

We evaluated query performance using our exemplar PB-DLP application and LPM's SNAP recorder. The provenance graph that was populated using the routine from the kernel compile benchmark. This yielded a raw provenance stream of 3.7 GB, which was translated by the recorder into a graph of 6,513,398 nodes and 6,754,059

[19] See http://fiehnlab.ucdavis.edu/staff/kind/Collector/Benchmark/Blast_Benchmark

edges. We were then able to use the graph to issue *ancestry queries*, in which the subgraphs were traversed to find the data object ancestors of a given file. Because we did not want ephemeral objects with limited ancestries to skew our results, we only considered the results of objects with more than 50 ancestors.

In the *worst case*, which was a node that had 17,696 ancestors, the query returned in just 21 milliseconds. Effectively, we were able to query object ancestries at line speed for network activity. We are confident that this approach can scale to large databases through precomputation of expensive operations at data ingest, making it a promising strategy for provenance-aware distributed systems; however, we note that these results are highly dependent on the size of the graph. Our test graph, while large, would inevitably be dwarfed by the size of the provenance on long-lived systems. Fortunately, there are also a variety of techniques for reducing these costs. Bates et al. show that the results from provenance graph traversals can be extensively cached when using a fixed security policy, which would allow querying to amortize to a small constant cost [7]. LPM could also be extended to support deduplication [63, 62] and policy-based pruning [6, 13], both of which could further improve performance by reducing the size of provenance graphs.

6.4 Message Commitment Protocol

Under each kernel configuration, we performed *iperf* benchmarking to discover LPM's impact on TCP throughput. iperf was launched in both client and server mode over `localhost`. The client was launched with 16 threads, two per each CPU. Our results can be found in Figure 8. The Vanilla kernel reached 4490 Mbps. While the LPM framework imposed negligible cost compared to the vanilla kernel (4480 Mbps), Provmon's DSA-based message commitment protocol reduced throughput by an order of magnitude (482 Mbps). Through use of `printk` instrumentation, we found that the average overhead per packet signature was 1.2 ms.

This result is not surprising when compared to IPsec performance. IPsec's Authentication Header (AH) mode uses an HMAC-based approach to provide similar guarantees as our protocol. AH has been shown to reduce throughput by as much as half [16]. An HMAC approach is a viable alternative to establish integrity and data origin authenticity and would also fit into the options field, but would require the negotiation of IPsec security associations. Our message commitment protocol has the benefit of being fully interoperable with other hosts, and does not require a negotiation phase before communication occurs. Another option for increasing throughput would be to employ CPU instruction extensions [30] and security co-processor [19] to accelerate the speed of DSA. Yet another approach to reducing our impact on network performance would be to employ a batch signature scheme [11]. We tested this by transmitting a signature over every 10 packets during TCP sessions, and found that throughput increased by 3.3 times to approximately 1600 Mbps. Due to the fact that this overhead may not be suitable for some environments, Provmon can be configured to use Hi-Fi identifiers [48], which are vulnerable to network attack but impose negligible overhead. LPM's impact on network performance is specific to the particular module, and can be tailored to meet the needs of the system.

7 Discussion

Without the aid of provenance-aware applications, LPM will struggle to accurately track dependencies through workflow layer abstractions. The most obvious example of such an abstraction is the copy/paste buffer in windowing applications like Xorg. This is a known side channel for kernel layer security mechanisms, one that has been addressed by the Trusted Solaris project [10], Trusted X [21, 22], the SELinux-aware X window system [37], SecureView [20], and General Dynamics' TVE [21]. Without provenance-aware windowing, LPM will conservatively assume that all files opened for reading are dependencies of the paste buffer, leading to false dependencies. LPM is also unable to observe system side channels, such as timing channels or L2 cache measurements [51], a limitation shared by many other security solutions [18].

Although we have not presented a secure distributed provenance-aware system in this work, LPM provides the foundation for the creation of such a system. In the presented modules, provenance is stored locally by the host and retrieved on an as-needed basis from other hosts. This raises availability concerns as hosts inevitably begin to fail. Availability could be improved with minimal performance and storage overheads through Gehani et al.'s approach of duplicating provenance at k neighbors with a limited graph depth d [27, 28].

Finally, LPM does not address the matter of provenance confidentiality; this is an important challenge that is explored elsewhere in the literature [14, 46]. LPM's Recorders provide interfaces that can be used to introduce an access control layer onto the provenance store.

8 Related Work

While myriad provenance-aware systems have been proposed in the literature, the majority *disclose* provenance within an application [32, 41, 65] or workflow [24, 58]. It

[20] See http://www.ainfosec.com/secureview

[21] See http://gdc4s.com/tve.html

is difficult or impossible to obtain *complete* provenance in this manner. This is because systems events that occur outside of the application, but still effect its execution, will not appear in the provenance record.

The alternative to disclosed systems are *automatic* provenance-aware systems, which collect provenance transparently within the operating system. Gehani et al.'s SPADE is a multi-platform system for eScience and grid computing audiences, with an emphasis on low latency and availability in distributed environments [29]. SPADE's *provenance reporters* make use of familiar application layer utilities to generate provenance, such as polling `ps` for process information and `lsof` for network information. This gives rise to the possibility of *incomplete* provenance due to race conditions. The PASS project collects the provenance of system calls at the virtual filesystem (VFS) layer. PASSv1 provides base functions for provenance collection that observe processes' file I/O activity [43]. Because these basic functions are manually placed around the kernel, there is no clear way to extend PASSv1 to support additional collection hooks; we address this limitation in the modular design of LPM. PASSv2 introduces a Disclosed Provenance API for tighter integration between provenance collected at different layers of abstraction, e.g., at the application layer [44]. PASSv2 assumes that disclosing processes are benign, while LPM provides a secure disclosure mechanism for attesting the correctness of provenance-aware applications. Both SPADE and PASS are designed for benign environments, making no attempt to protect their collection mechanisms from an adversary.

Previous work has considered the security of provenance under relaxed threat models relative to LPM's. In SProv, Hasan et al. introduce *provenance chains*, cryptographic constructs that prevent the insertion or deletion of provenance inside of a series of events [32]. SProv effectively demonstrates the authentication properties of this primitive, but is not intended to serve as a secure provenance-aware system; attackers can still append false records to the end of the chain, delete the whole chain, or disable the library altogether. Zhou et al. consider provenance corruption an inevitability, and show that provenance can detect *some* malicious hosts in distributed environments provided that a critical mass of correct hosts still exist [65]. They later strengthen these assurances through use of provenance-aware software-defined networking [5]. These systems consider only network events, and are unable to speak to the internal state of hosts. Lyle and Martin sketch the design for a secure provenance monitor based on trusted computing [40]. However, they conceptualize provenance as a TPM-aided proof of code execution, overlooking interprocess communication and other system activity that could inform execution results, and therefore offer information that is too coarse-grained to meet the needs of some applications. Moreover, to the best of our knowledge their system is unimplemented.

The most promising model to date for secure provenance collection is Pohly et al.'s Hi-Fi system [48]. Hi-Fi is a Linux Security Module (LSM) that collects *whole-system provenance* that details the actions of processes, IPC mechanisms, and even the kernel itself (which does not exclusively use system calls). Hi-Fi attempts to provide a provenance reference monitor [42], but remains vulnerable to the provenance-aware adversary that we describe in Section 3.2. Enabling Hi-Fi blocks the installation of other LSM's, such as SELinux or Tomoyo, or requires a third party patch to permit module stacking. This blocks the installation of MAC policy on the host, preventing runtime integrity assurances. Hi-Fi is also vulnerable to adversaries in the network, who can strip the provenance identifiers from packets in transit, resulting in irrecoverable provenance. Unlike LPM, Hi-Fi does not attempt to provide layered provenance services, and therefore does not consider the integrity and authenticity of provenance-aware applications.

Provenance collection is a form of information flow monitoring that is related, but fundamentally distinct, from past areas of study. Due to space constraints, our discussion of Information Flow Control (IFC) systems has been relegated to our technical report [8].

9 Conclusion

In this work, we have presented LPM, a platform for the creation of trusted provenance-aware execution environments. Our system imposes as little as 2.7% performance overhead on normal system operation, and can respond to queries about data object ancestry in tens of milliseconds. We have used LPM as the foundation of a provenance-based data loss prevention system that can scan file transmissions to detect the presence of sensitive ancestors in just tenths of a second. The Linux Provenance Module Framework is an exciting step forward for both provenance- and security-conscious communities.

Securing Self-Virtualizing Ethernet Devices

Igor Smolyar Muli Ben-Yehuda Dan Tsafrir
Technion – Israel Institute of Technology
{igors,muli,dan}@cs.technion.ac.il

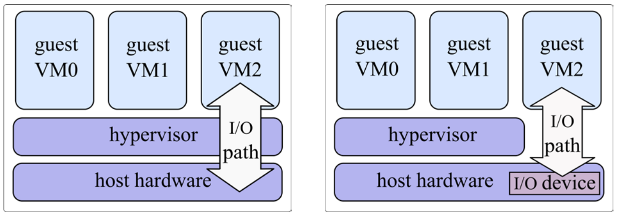
Abstract

Single root I/O virtualization (SRIOV) is a hardware/software interface that allows devices to “self virtualize” and thereby remove the host from the critical I/O path. SRIOV thus brings near bare-metal performance to untrusted guest virtual machines (VMs) in public clouds, enterprise data centers, and high-performance computing setups. We identify a design flaw in current Ethernet SRIOV NIC deployments that enables untrusted VMs to completely control the throughput and latency of other, unrelated VMs. The attack exploits Ethernet ”pause” frames, which enable network flow control functionality. We experimentally launch the attack across several NIC models and find that it is effective and highly accurate, with substantial consequences if left unmitigated: (1) to be safe, NIC vendors will have to modify their NICs so as to filter pause frames originating from SRIOV instances; (2) in the meantime, administrators will have to either trust their VMs, or configure their switches to ignore pause frames, thus relinquishing flow control, which might severely degrade networking performance. We present the Virtualization-Aware Network Flow Controller (VANFC), a software-based SRIOV NIC prototype that overcomes the attack. VANFC filters pause frames from malicious virtual machines without any loss of performance, while keeping SRIOV and Ethernet flow control hardware/software interfaces intact.

1 Introduction

A key challenge when running untrusted virtual machines is providing them with efficient and secure I/O. Environments running potentially untrusted virtual machines include enterprise data centers, public cloud computing providers, and high-performance computing sites.

There are three common approaches to providing I/O services to guest virtual machines: (1) the hypervisor *emulates* a known device and the guest uses an unmodified driver to interact with it [71]; (2) a *paravirtual driver* is installed in the guest [20, 69]; (3) the host assigns a real device to the guest, which then controls the device directly [22, 52, 64, 74, 76]. When emulating a device or using a paravirtual driver, the hypervisor intercepts all interactions between the guest and the I/O device, as shown in Figure 1a, leading to increased overhead and significant performance penalty.



(a) Traditional Virtualization (b) Direct I/O Device Assignment

Figure 1: Types of I/O Virtualization

The hypervisor can reduce the overhead of device emulation or paravirtualization by assigning I/O devices directly to virtual machines, as shown in Figure 1b. Device assignment provides the best performance [38,53,65,76], since it minimizes the number of I/O-related world switches between the virtual machine and its hypervisor. However, assignment of standard devices is not scalable: a single host can generally run an order of magnitude more virtual machines than it has physical I/O device slots available.

One way to reduce I/O virtualization overhead further and improve virtual machine performance is to offload I/O processing to scalable self-virtualizing I/O devices. The PCI Special Interest Group (PCI-SIG) on I/O Virtualization proposed the Single Root I/O Virtualization (SRIOV) standard for scalable device assignment [60]. PCI devices supporting the SRIOV standard present themselves to host software as multiple virtual interfaces. The host can assign each such partition directly to a different virtual machine. With SRIOV devices, virtual machines can achieve bare-metal performance even for the most demanding I/O-intensive workloads [38, 39]. We describe how SRIOV works and why it improves performance in Section 2.

New technology such as SRIOV often provides new capabilities but also poses new security challenges. Because SRIOV provides untrusted virtual machines with unfettered access to the physical network, such machines can inject malicious or harmful traffic into the network. We analyze the security risks posed by using SRIOV in environments with untrusted virtual machines in Section 3. We find that SRIOV NIC, as currently deployed, suffers from a major design flaw and cannot be used securely together with network flow control.

We make two contributions in this paper. The **first contribution** is to show how a malicious virtual machine with access to an SRIOV device can use the Ethernet flow control functionality to attack and completely control the bandwidth and latency of other unrelated VMs using the same SRIOV device, without their knowledge or cooperation. The malicious virtual machine does this by transmitting a small number of Ethernet pause or Priority Flow Control (PFC) frames on its host's link to the edge switch. If Ethernet flow control is enabled, the switch will then shut down traffic on the link for a specified amount of time. Since the link is shared between multiple untrusted guests and the host, none of them will receive traffic. The details of this attack are discussed in Section 4. We highlight and experimentally evaluate the most notable ramifications of this attack in Section 5.

Our **second contribution** is to provide an understanding of the fundamental cause of the design flaw leading to this attack and to show how to overcome it. We present and evaluate (in Section 6 and Section 7) the Virtualization-Aware Network Flow Controller (VANFC), a software-based prototype of an SRIOV NIC that successfully overcomes the described attack without any loss in performance.

With SRIOV, a single physical endpoint includes both the host (usually trusted) and multiple untrusted guests, all of which share the same link to the edge switch. The edge switch must either trust all the guests and the host or trust none of them. The former leads to the flow control attack we show; the latter means doing without flow control and, consequently, giving up on the performance and efficient resource utilization flow control provides.

With SRIOV NICs modeled after VANFC, cloud users could take full advantage of lossless Ethernet in SRIOV device assignment setups without compromising their security. By filtering pause frames generated by the malicious virtual machine, VANFC keeps these frames from reaching the edge switch. The traffic of virtual machines and host that share the same link remains unaffected; thus VANFC is 100% effective in eliminating the attack. VANFC has no impact on throughput or latency compared to the baseline system not under attack.

VANFC is fully backward compatible with the current hardware/software SRIOV interface and with the Ethernet flow control protocol, with all of its pros and cons. Controlling Ethernet flow by pausing physical links has its fundamental problems, such as link congestion propagation, also known as the ”congestion spreading” phenomenon [13]. The attack might also be prevented by completely redesigning the Ethernet flow control mechanism, making it end-to-end credit-based, as in InfiniBand [18], for example. But such a pervasive approach is not practical to deploy and remains outside the scope of this work. Instead, VANFC specifically targets the design flaw in SRIOV NICs that enables the attack. VANFC prevents the attack without any loss of performance and without requiring any changes to either Ethernet flow control or to the SRIOV hardware/software interfaces.

One could argue that flow control at the Ethernet level is not necessary, since protocols at a higher level (e.g., TCP) have their own flow control. We show why flow control is required for high performance setups, such as those using Converged Enhanced Ethernet, in Section 8.

In Section 9 we provide some notes on the VANFC implementation and on several aspects of VM-to-VM traffic security. We present related work in Section 10. We offer concluding remarks on SRIOV security as well as remaining future work in Section 11.

2 SRIOV Primer

Hardware emulation and paravirtualized devices impose a significant performance penalty on guest virtual machines [15, 16, 21, 22, 23]. Seeking to improve virtual I/O performance and scalability, PCI-SIG proposed the SRIOV specification for PCIe devices with self-virtualization capabilities. The SRIOV spec defines how host software can partition a single SRIOV PCIe device into multiple PCIe “virtual” devices.

Each SRIOV-capable physical device has at least one Physical Function (PF) and multiple virtual partitions called Virtual Functions (VFs). Each PF is a standard PCIe function: host software can access it as it would any other PCIe device. A PF also has a full configuration space. Through the PF, host software can control the entire PCIe device as well as perform I/O operations. Each PCIe device can have up to eight independent PFs.

VFs, on the other hand, are “lightweight” (virtual)

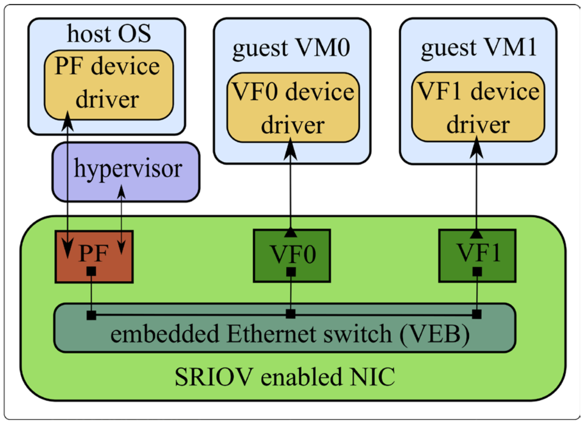


Figure 2: SRIOV NIC in a virtualized environment

PCIe functions that implement a subset of standard PCIe device functionalities. Virtual machines driving VFs perform only I/O operations through them. For a virtual machine to use a VF, the host software must configure that VF and assign it to the virtual machine. Host software often configures a VF through its PF. VFs have a partial configuration space and are usually presented to virtual machines as PCIe devices with limited capabilities. In theory, each PF can have up to 64K VFs. Current Intel implementations of SRIOV enable up to 63 VFs per PF [42] and Mellanox ConnectX adapters usually have 126 VFs per PF [57].

While PFs provide both control plane functionality and data plane functionality, VFs provide only data plane functionality. PFs are usually controlled by device drivers that reside in the trusted, privileged, host operating system or hypervisor. As shown in Figure 2, in virtualized environments each VF can be directly assigned to a VM using device assignment, which allows each VM to directly access its corresponding VF, without hypervisor involvement on the I/O path.

Studies show that direct assignment of VFs provides virtual machines with nearly the same performance as direct assignment of physical devices (without SRIOV) while allowing the same level of scalability as software-based virtualization solutions such as device emulation or paravirtualization [33, 38, 41, 77]. Furthermore, two VMs that share the same network device PF can communicate efficiently since their VM-to-VM traffic can be switched in the network adapter. Generally, SRIOV devices include embedded Ethernet switch functionality capable of efficiently routing traffic between VFs, reducing the burden on the external switch. The embedded switch in SRIOV capable devices is known as a Virtual Ethernet Bridge (VEB) [51].

SRIOV provides virtual machines with I/O performance and scalability that is nearly the same as bare metal. Without SRIOV, many use cases in cloud computing, high-performance computing (HPC) and enterprise data centers would be infeasible. With SRIOV it is possible to virtualize HPC setups [24, 37]. In fact, SRIOV is considered the key enabling technology for fully virtualized HPC clusters [54]. Cloud service providers such as Amazon Elastic Compute Cloud (EC2) use SRIOV as the underlying technology in EC2 HPC services. Their Cluster Compute-optimized virtual machines with high performance enhanced networking rely on SRIOV [2]. SRIOV is important in traditional data centers as well. Oracle, for example, created the Oracle Exalogic Elastic Cloud, an integrated hardware and software system for data centers. Oracle Exalogic uses SRIOV technology to share the internal network [40].

3 Analyzing SRIOV Security

Until recently, organizations designed and deployed Local Area Networks (LANs) with the assumption that each end-station in the LAN is connected to a dedicated port of an access switch, also known as an edge switch.

The edge switch applies the organization's security policy to this dedicated port according to the level of trust of the end-station connected to the port: some machines and the ports they connect to are trusted and some are not. But given a port and the machine connected to it, the switch enforcing security policy must know how trusted that port is.

With the introduction of virtualization technology, this assumption of a single level of trust per port no longer holds. In virtualized environments, the host, which is often a trusted entity, shares the same physical link with untrusted guest VMs. When using hardware emulation or paravirtualized devices, the trusted host can intercept and control all guest I/O requests to enforce the relevant security policy. Thus, from the point of view of the network, the host makes the port trusted again.

Hardware vendors such as Intel or Mellanox implement strict VF management or configuration access to SRIOV devices. Often they allow VFs driven by untrusted entities to perform only a limited set of management or configuration operations. In some implementations, the VF performs no such operations; instead, it sends requests to perform them to the PF, which does so after first validating them.

On the data path, the situation is markedly different. SRIOV's raison d'être is to avoid host involvement on the data path. Untrusted guests with directly assigned VFs perform data path operations—sending and receiving network frames—directly against the device. Since the device usually has a single link to the edge switch, the device aggregates all traffic, both from the trusted host and from the untrusted guests, and sends it on the single shared link. As a result, untrusted guests can send any network frames to the edge switch.

Giving untrusted guests uncontrolled access to the edge switch has two implications. First, since the edge switch uses its physical resources (CAM tables, queues, processing power) to process untrusted guests' traffic, the switch becomes vulnerable to various denial of service attacks. Second, sharing the same physical link between trusted and untrusted entities exposes the network to many Ethernet data-link layer network attacks such as Address Resolution Protocol (ARP) poisoning, Media Access Control (MAC) flooding, ARP spoofing, MAC address spoofing, and Spanning Tree Protocol (STP) attacks [14, 17, 47, 56, 73, 75]. Therefore, the edge switch must never trust ports connected to virtualized hosts with an SRIOV device.

Although the problem of uncontrolled access of untrusted end-points is general to Ethernet networks, using SRIOV devices imposes additional limitations. As we will see in the next few subsections, not trusting the port sometimes means giving up the required functionality.

3.1 Traditional Lossy Ethernet

Traditional Ethernet is a lossy protocol; it does not guarantee that data injected into the network will reach its destination. Data frames can be dropped for different reasons: because a frame arrived with errors or because a received frame was addressed to a different end-station. But most data frame drops happen when the receiver's buffers are full and the receiving end-station has no memory available to store incoming data frames. In the original design of the IEEE 802.3 Ethernet standard, reliability was to be provided by upper-layer protocols, usually TCP [63], with traditional Ethernet networks providing best effort service and dropping frames whenever congestion occurs.

3.2 Flow Control in Traditional Ethernet

Ethernet Flow Control (FC) was proposed to control congestion and create a lossless data link medium. FC enables a receiving node to signal a sending node to temporarily stop data transmission. According to the IEEE 802.3x standard [6], this can be accomplished by sending a special Ethernet pause frame. The IEEE 802.3x pause frame is defined in Annex 31B of the spec [9] and uses the MAC frame format to carry pause commands.

link speed, Gbps	single frame pause time, ms	frame rate required to stop transmission, frames/second
1	33.6	30
10	3.36	299
40	0.85	1193

Table 1: Pause frame rate for stopping traffic completely

When a sender transmits data faster than the receiver can process it and the receiver runs out of space, the receiver sends the sender a MAC control frame with a pause request. Upon receiving the pause frame, the sender stops transmitting data.

The pause frame includes information on how long to halt the transmission. The `pause_time` is a two byte MAC Control parameter in the pause frame that is measured in units of `pause_quanta`. It can be between 0 to 65535 `pause_quanta`. The receiver can also tell the sender to resume transmission by sending a special pause frame with the `pause_time` value set to 0.

Each `pause_quanta` equals 512 "bit times," defined as the time required to eject one bit from the NIC (i.e., 1 divided by the NIC speed). The maximal pause frame `pause_time` value can be 65535 `pause_quanta`, which is $65535 \times 512 = 33.6$ million bit times.

For 1Gbps networks, one pause frame with `pause_time` value of 65535 `pause_quanta` will tell the sender to stop transmitting for 33.6 million bit times, i.e., 33.6 ms. A sender operating at 10 Gbps speed will pause for 3.36 ms. A sender operating at 40 Gbps speed will pause for 0.85 ms.

Table 1 shows the rate at which a network device should receive pause frames to stop transmission completely. The `pause_time` value of each frame is 0xFFFF. Sending 30 pause frames per second will tell the sender to completely stop transmission on a 1Gbps link. For a sender operating at 10 Gbps speed to stop transmission requires sending 299 frames/second. For a sender operating at 40 Gbps speed to stop transmission requires sending 1193 frames/second.

3.3 Priority Flow Control in Ethernet

To improve the performance and reliability of Ethernet and make it more suitable for data centers, the IEEE 802.1 working group proposed a new set of standards, known as Data Center Bridging (DCB) or Converged Enhanced Ethernet (CEE).

In addition to the IEEE 802.3x Ethernet pause, the new IEEE 802.1Qbb standard proposed to make Ethernet truly “lossless” in data center environments by adding Priority-based Flow Control (PFC) [8].

Similar to the 802.3x FC, PFC is a link-level flow control mechanism, but it is implemented on a per traffic-class basis. While 802.3x FC pauses all traffic on the link, PFC makes it possible to pause a specific class of traffic using the same pause frame structure. PFC operates on individual traffic classes, as defined by Annex I of the IEEE 802.1Q standard [7]. Up to 8 traffic classes can be defined for PFC per link.

3.4 Attacking VMs via Flow Control

Direct device assignment enables malicious guests to attack the Ethernet network via well-known Layer 2 attacks [14, 17, 47, 56, 73, 75]. Even when using virtualization-aware switching extensions such as the Virtual Edge Port Aggregator (VEPA) [30, 31], all guests with direct access to the VFs of the same PF still share the same physical link to the edge switch, and the edge switch still allocates processing resources per link.

Since both 802.3x and 802.1Qbb perform flow control on a link-level basis, and the link is shared between VMs, any flow control manipulation by a single VM will affect the PF and all VFs associated with this PF. This means that a malicious VM is capable of controlling the bandwidth and latency of all VMs that share the same adapter.

The malicious VM can pause all traffic on the link by sending 802.3x pause frames and can stop a specific traffic class by sending 802.1Qbb pause frames. To stop all traffic on a 10 Gbps Ethernet link, an attacker needs to transmit pause frames at a rate of 300 frames/second, which is about 155 Kbps of bandwidth. The attacker can fully control the bandwidth and latency of all tenant VMs with minimal required resources and without any cooperation from the host or from other guest VMs.

4 Attack Evaluation

4.1 Experimental Setup

We constructed a lab setup in which we perform and evaluate the flow-control attack described in the previous section. We use a Dell PowerEdge R420 server, which is a dual socket with six cores per socket, with Intel Xeon E5-2420 CPUs running at 1.90GHz. The chipset is the Intel C600 series. The server includes 16GBs of memory and an SRIOV-capable Intel NIC (10GbE 82599 or 1GbE I350) installed in PCIe generation 3 slots with two VFs enabled.

We use the KVM Hypervisor [50] and Ubuntu server 13.10 with 3.11.0 x86_64 kernel for the host, guest VMs, and the client. Each guest is created with 2GBs of memory, two virtual CPUs, and one VF directly assigned to it. Client and host machines are identical servers connected to the same dedicated switch, as shown in Figure 3.

To achieve consistent results, the server’s BIOS profile is performance optimized, all power optimizations are tuned off, and Non-Uniform Memory Access (NUMA) is enabled. The guest virtual CPUs are pinned to the cores on the same NUMA node to which the Intel PF is connected. The host allocates to the guest memory from the same NUMA node as well.

For our 1GbE environment, we use an Intel Ethernet I350-T2 network interface connected to a Dell PowerConnect 6224P 1Gb Ethernet switch. For our 10GbE environment, we use an Intel 82599 10 Gigabit TN network interface connected to an HP 5900AF 10Gb Ethernet switch.

Host and client use their distribution’s default drivers with default configuration settings. Guest VMs use version 2.14.2 of the `ixgbevf` driver for the Intel 10G 82599 Ethernet controller virtual function and the default `igbvf` version 2.0.2-k for the Intel 1G I350 Ethernet controller virtual function. Ethernet flow control IEEE 802.3x is enabled on switch ports. We set the Ethernet Maximal Transfer Unit (MTU) to 1500 bytes on all Ethernet switches and network interfaces in our tests.

4.2 Benchmark Methodology

We conduct a performance evaluation according to the methodology in RFC 2544 [25]. For throughput tests, we use an Ethernet frame size of 1518 bytes and measure maximal throughput without packet loss. Each throughput test runs for at least 60 seconds and we take the average of 5 test cycles. To measure latency, we use 64 and 1024 byte messages. Each latency test runs at least 120 seconds and we measure the average of at least 15 test cycles. (While RFC 2544 dictates running 20 cycles, we obtained plausible results after 15 cycles; thus, we decided to reduce test runtime by running each test only 15 cycles.)

Benchmark Tools: We measure throughput and latency with two well-known network benchmark utilities: `iperf` [3] and `netperf` [45]. We use the `iperf` TCP stream test to measure throughput and the `netperf` TCP_RR test to measure latency. The `iperf` and `netperf` clients are run on the client machine, while

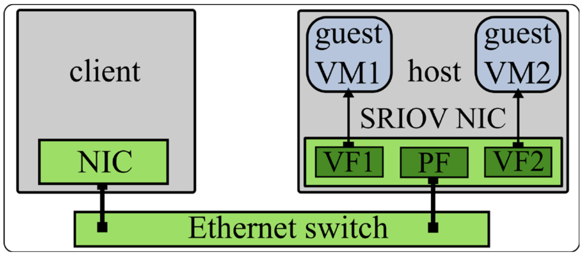

Figure 3: Setup scheme

the iperf and netperf servers are run on VM1. We measure on the client the bandwidth and latency from the client to VM1.

Traffic Generators: In addition to the traffic generated by the benchmark tools, we use tcpdump [44] to capture traffic and tcpreplay [5] to send previously captured and modified frames at the desired rate.

Testbed Scheme: The testbed scheme is shown in Figure 3. Our testbed consists of two identical servers, one acting as client and the other as the host with SRIOV capable NIC. We configure two VFs on the host's SRIOV PF. We assign VF1 to guest VM1 and VF2 to guest VM2. Client and host are connected to the same Ethernet switch. We generate traffic between VM1 and the client using iperf and netperf. VM2 is the attacking VM.

4.3 Flow-Control Attack Implementation

We use tcpreplay [5] to send specially crafted 802.3x pause frames at the desired rate from the malicious VM2.[1] When the switch receives a pause frame from VM2, it inhibits transmission of any traffic on the link between the switch and the PF, including the traffic between the client and VM1, for a certain number of pause_time quanta. Sending pause frames from VM2, we can manipulate the bandwidth and latency of the traffic between VM1 and the client. The value of pause_time of each pause frame is 0xFFFF pause_quanta units. Knowing the link speed, we can calculate the pause frame rate, as described in Section 3, and impose precise bandwidth limits and latency delays on VM1. The results of the attack in both 1GbE and 10GbE environments are presented in Section 4.4.

4.4 Attack Results

Figures 4 and 5 show the results of the pause frame attack on victim throughput in the 1GbE and 10GbE environments respectively. Figures 4a and 5a show victim (VM1) throughput under periodic attack of VM2. Every 10 seconds, VM2 transmits pause frames for 10 seconds at 30 frames/second (as shown in Figure 4a) and at 300 frames/second (as shown in Figure 5a). In this test we measure the throughput of the victim system, VM1. The figures clearly show that VM2 can gain complete control over VM1 throughput: starting from the tenth second, the attacker completely stops traffic on the link for ten seconds.

Figure 6 shows the results of the pause frame attack on victim latency in the 10GbE environment. Figure 6a shows victim latency under the same periodic attack described above. In this test we use 64B and 1024B messages. For better result visualization, we lowered the attack rate to 150 pause frames/second. Figure 6a shows that the attacker can increase victim latency to 250% by running the attack at a rate of only 150 frames/second.

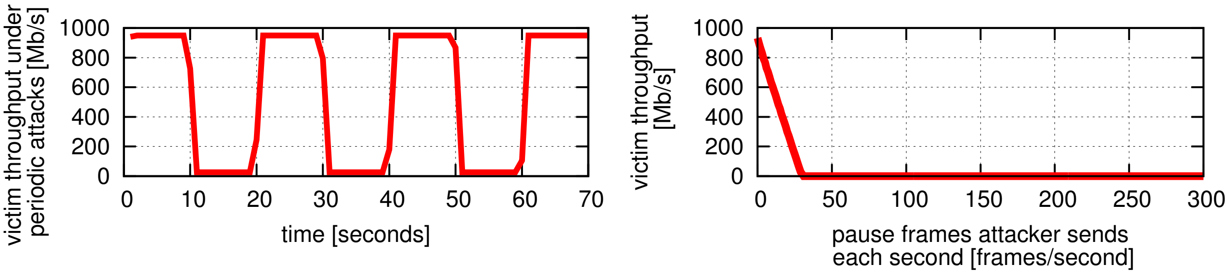
Victim throughput Figures 4b and 5b display throughput of VM1 as a function of the rate of pause frames VM2 sends. From Figure 4b we can see that VM2 can pause all traffic on the 1GbE link with almost no effort, by sending pause frames at a rate of 30 frames/second. For the 10GbE link, VM2 needs to work a little bit harder and raise its rate to 300 frames/second. This test's results confirm the calculations shown in Table 1. Figures 7a and 7b confirm that the measured victim throughput is exactly as predicted. In other words, it is easily and completely controlled by the attacker.

These tests show that a malicious VM can use the pause frame attack to control the throughput of other VMs with precision. Furthermore, we see that the pause frame attack requires minimal effort from the attacker and will be hard to detect amid all the other network traffic. To halt all transmissions on the 10GbE link, the attacker only needs to send 64B pause frames at 300 frames/second. 300 frames/second is approximately 0.002% of the 14.88 million frames/second maximum frame rate for 10GbE.[2] Discovering such an attack can be quite challenging, due to the low frame rate involved, especially on a busy high-speed link such as 10GbE or 40GbE.

Victim latency Figure 6b shows the victim's latency as a function of the attacker's pause frame rate. In this test we measure the latency of 64 byte messages and 1024 byte messages. We see that the figures for both 64B

[1] We use 802.3x pause frames for the sake of simplicity, but we could have used PFC frames instead. PFC uses exactly the same flow control mechanism and has the same MAC control frame format. The only difference between PFC frames and pause frames is the addition of seven pause_time fields in PFC that are padded in 802.3x frames.

[2] The maximum frame rate equals the link speed divided by the sum of sizes of the preamble, frame length and inter-frame gap.



(a) (b)

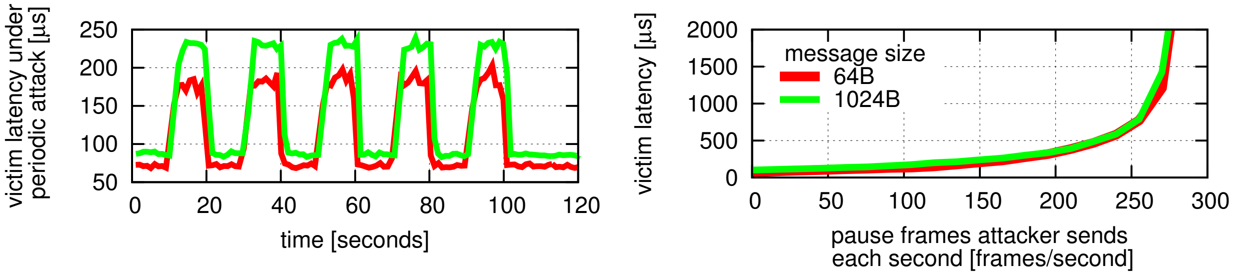
(a) (b)

Figure 5: Pause frame attack: victim throughput in 10GbE environment



(a) (b)

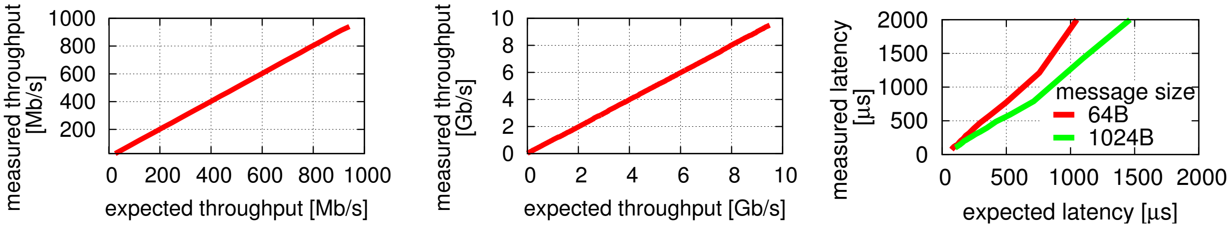
Figure 6: Pause frame attack: victim latency in 10GbE environment

and 1024B are barely distinguishable and almost converge; the latency is the same for small and large size messages under attack.

In Figure 7c we see that measured latency and expected latency differ somewhat. In practice, this difference means that an attacker can control the victim's latency with slightly less precision than it can control its throughput, but it can still control both with high precision and relatively little effort.

In back-to-back configuration, without a switch, latency behaves as expected. We believe this difference is caused by the switch's internal buffering methods—in addition to storing frames internally, the Ethernet switch prevents the possible side effects of such buffering e.g., head-of-line blocking [70] and congestion spreading [13]. To accurately explain this phenomenon, we need access to the switch internals; unfortunately, the Ethernet switch uses proprietary closed software and hardware.

Experiments with Non-Intel Devices We performed an identical experiment on same setup with an SRIOV Broadcom NetXtreme II BCM57810 10GbE NIC [26] and got the same results. Our attack is valid for this NIC as well.



(a)

(b)

(c)

Figure 7: Pause frame attack: expected vs. measured throughput and latency

We also tried the attack described above on another vendor's 40GbE SRIOV adapter. Whenever the attacking VM transmitted MAC control frames (pause frames) through its VF, the adapter completely locked up and became unresponsive. It stopped generating both transmit and receive interrupts, and required manual intervention to reset it, by reloading the PF driver on the host. This lockup appears to be a firmware issue and has been communicated to the adapter vendor.

Clearly, with this adapter and this firmware issue, a malicious VM could trivially perform a straightforward denial of service attack against its peer VMs that use this adapter's VFs and against the host. But since this attack is trivial to discover, we focus instead on the stealthier pause frame attack, which is much harder to discover and protect against.

5 Attack Ramifications

The consequences of the attack are substantial. If Ethernet flow control is enabled on the SRIOV device, the host's VMs' security is compromised and the VM's are susceptible to the attack.

The attack cannot be prevented using the filtering capabilities of currently available SRIOV Ethernet devices due to their minimal filtering capability. At best, modern SRIOV NICs are capable of enforcing anti-spoofing checks based on the source MAC address or VLAN tag of the VM, to prevent one VM from pretending to be another. In the attack we describe, the adversary generates flow control frames with the malicious VM's source MAC and VLAN tag, so anti-spoofing features cannot block the attack.

Since the attack cannot be prevented with current NICs and switches, cloud providers must either be content with flawed security and fully trust the guest VMs or disable the Ethernet flow control in their networks. Neither option is palatable. The former is unrealistic for the public cloud and unlikely be acceptable to private cloud providers. The latter means giving up the performance benefits of lossless Ethernet, increasing overall resource utilization, and reducing performance. We discuss in greater detail the performance advantages that Ethernet flow control provides in Section 8.

6 Improving SRIOV Security

The attack described in the previous sections is the result of a fundamental limitation of SRIOV: from the network point of view, VFs and their associated untrusted VMs are all lumped together into a single end-station. To secure SRIOV and eliminate the attack while keeping flow control functionality, we propose to extend SRIOV Ethernet NIC filtering capability to filter traffic transmitted by VFs, not only on the basis of source MAC and VLAN tags—the method currently employed by anti-spoofing features—but also on the basis of the MAC destination and Ethernet type fields of the frame. This filtering cannot be done by the host without some loss of performance [39] and has to be done before traffic hits the edge switch. Hence it must be done internally in the SRIOV NIC. We built a software-based prototype of an SRIOV Ethernet NIC with pause frame filtering. Before presenting the prototype, we begin by describing the internals of an SRIOV NIC.

6.1 SRIOV NIC Internals

Figure 8a shows a detailed schema of an SRIOV Ethernet NIC. The SRIOV device is connected to the external adjacent Ethernet switch on the bottom side and to the host's PCIe bus, internal to the host, on the top side.

Switching The NIC stores frames it receives from the external switch in its internal buffer. The size of this buffer is on the order of hundreds of KBytes, depending on the NIC model: 144KB in Intel I350 [43] and 512KB in Intel 82599 [42]. After receiving a packet, the SRIOV NIC looks up the frame's MAC in its MAC address table, finds the destination VF according to the frame's destination MAC address, and copies the frame (using DMA) over the PCIe bus to the VF's buffer ring, which is allocated in the host's RAM. This is analogous to a standard Ethernet switch that receives a packet on an ingress port, looks up its MAC address, and chooses the right egress port to send it to. The data path of the frame is marked with a red dashed line in Figure 8a. In addition, SRIOV NIC is able to perform VM-to-VM switching internally, without sending the frames to the external switch.

Internal Buffer When Ethernet flow control is enabled, the SRIOV NIC starts monitoring its internal buffer. If the NIC cannot process received frames fast enough, for example due to an overloaded or slow PCIe link, the buffer fills up. Once it reaches a predefined threshold, the SRIOV NIC generates and sends pause frames to the external Ethernet switch. The switch then holds transmissions to the NIC for the requested time, storing these frames in its own internal buffers. While the switch is buffering frames, the NIC should continue copying the frames it buffered into the each VF's ring buffer, clearing up space in its internal buffer.

Ring Buffer The final destination for a received frame is in its VF's ring buffer, located in host RAM. The network stack in the VM driving the VF removes frames from its ring buffers at a rate that is limited by the CPU. If the VM does not get enough CPU cycles or is not efficient enough, the NIC may queue frames to the ring buffer faster than the VM can process them. When the ring buffer fills up, most Ethernet NICs (e.g., those of Intel's and Mellanox's) will simply drop incoming frames. Less commonly, a few NICs, such as Broadcom's NetXtreme II BCM57810 10GbE, can monitor each VF's ring buffer. When the ring buffer is exhausted, the NIC can send pause frames to the external switch to give the host CPU a chance to catch up with the sender. When available, this functionality is usually disabled by default.

Outbound Security Some SRIOV Ethernet NICs (e.g., Intel 82599 10GbE [42] or I350 1GbE [43] NICs) include anti-spoofing functionality. They can verify that the source MAC address and/or VLAN tag of each frame transmitted by the VF belongs to the transmitting VF. To this end, these NICs have an internal component that can inspect and even change frames transmitted from the VF. In addition, Intel SRIOV NICs have advanced inbound filtering capabilities, storm control, rate limiting, and port mirroring features, very much like any standard Ethernet switch.

As we can see, Ethernet SRIOV devices implement on-board a limited form of Ethernet switching. That is why such devices are also known as virtual Ethernet bridges (VEBs).

6.2 The VANFC design

The key requirement from VANFC is to filter outbound traffic transmitted by a VF. Ideally, VANFC would be implemented in a production SRIOV NIC. Unfortunately, all tested SRIOV NICs are proprietary with closed firmware. Furthermore, most frame processing logic is implemented in high speed ASIC hardware.

We opted instead to build VANFC as a software-based prototype of an SRIOV NIC that filters outbound traffic. VANFC takes advantage of the following two observations: `(1)` VEB embedded into the SRIOV NIC device replicates standard Ethernet switching behavior and can be considered as a virtual Ethernet switch; `(2)` all valid pause frames are generated by the NIC's hardware and have the PF's source MAC address, whereas invalid—malicious—pause frames are sent with source address of a VF. Should the adversary VM attempt to generate pause frames with the PF's source MAC address, the NIC's anti-spoofing will find and drop these frames.

In order to filter transmitted malicious pause frames, we first need to identify pause frames. In such frames the Ethernet type field is `0x8808` (MAC control type), the MAC opcode field is `0x0001` (pause opcode), and the destination MAC address is multicast `01-80-C2-00-00-01`. For any such packet, the VANFC filter should drop the frame if the source MAC is different than the PF's MAC address.

As mentioned previously, most SRIOV NICs already have a component that can filter outbound traffic; this component is a part of the SRIOV device's internal Ethernet switch and cannot be modified. Our prototype extends this switch in software by running the extension on the wire between the SRIOV NIC and the external switch.

Filtering Component For our Ethernet filtering device we use the standard Linux bridge configured on an x86-based commodity server running Ubuntu server 13.10 and equipped with two Intel 82599 10 Gigabit TN Network controllers installed in PCIe gen 2 slots. One NIC is connected to the host PF and the other is connected to the external Ethernet switch, as displayed in Figure 8b. Ethernet switching is performed by the Linux bridge [4] and filtering is done by the `ebtables` [32].

Performance model Bridge hardware is fast enough not to be a bottleneck for 10Gb Ethernet speed. However, by adding to the setup an Ethernet device implemented in software, we increased latency by a constant delay of approximately 55µs. An eventual implementa-

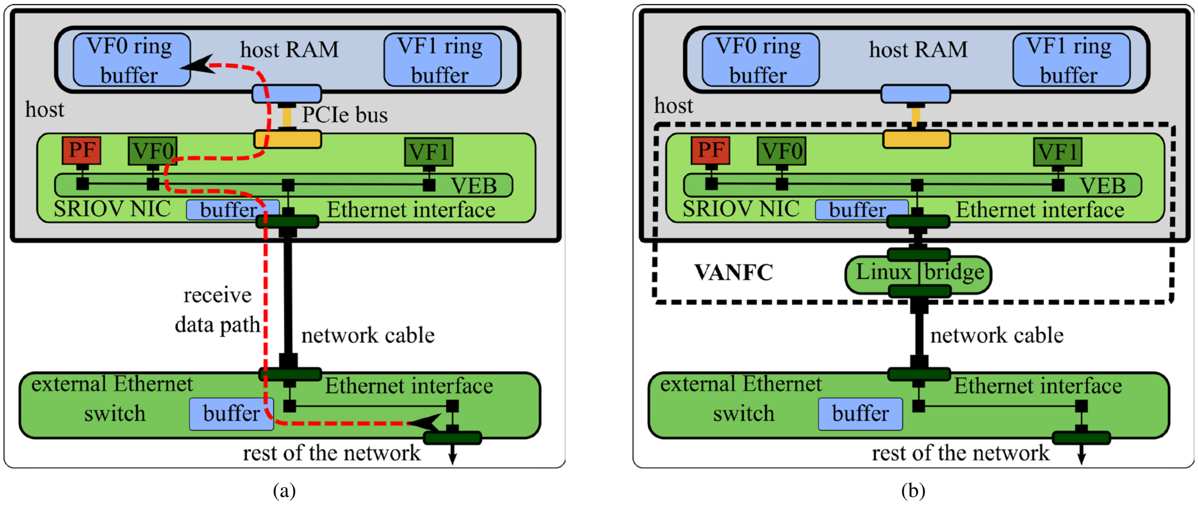


Figure 8: Fig. (a) shows schema of current SRIOV NIC internals; Fig. (b) shows VANFC schema.

tion of VANFC in hardware will eliminate this overhead; we therefore discount it in latency oriented performance tests.

We wanted to make this bridge completely transparent and not to interfere with passing traffic: the host should keep communicating with the external switch and the switch should keep communicating with the host as in the original setup without VANFC. VANFC should change neither the SRIOV software/hardware interface nor the Ethernet flow control protocol. To ensure this, we made a few modifications in Linux bridge code and in the Intel 82599 device driver used by the bridge device.

Bridge Modification The standard Ethernet bridge should not forward MAC control frames that are used to carry pause commands since MAC control frames are designed to be processed by Ethernet devices. Since we want the bridge to deliver all of the traffic between the SRIOV device and the external switch, including the pause frames sent by the PF, we modify the Linux bridging code to forward MAC control frames and use `ebtables` to filter pause frames not sent from the PF. Our experiments use a static configuration for `ebtables` and for the Linux bridge.

Device Driver Modification We use a modified `ixgbe` driver version 3.21.2 for Intel 10G 82599 network controllers on the bridge machine. According to the Intel 82599 controller data-sheet [42], the flow control mechanism of the device receives pause frames when flow control is enabled; otherwise the device silently drops pause frames. In our setup, we disable the flow control feature of Intel NICs installed in the bridge machine and we configure them to forward pause frames up to the OS, where they should be processed by the bridge and `ebtables`. We do this by enabling the Pass MAC Control Frames (PMCF) bit of the MAC Flow Control (MFLCN) register, as described in section 3.7.7.2 of the Intel 82599 data-sheet [42].

Ring Buffer Exhaustion As mentioned, some SRIOV devices are capable of monitoring a VF's ring buffer and automatically generating pause frames when it is exhausted. In such a scenario, pause frames will be generated with the source MAC address of the PF and will not be recognized by the VANFC. We argue that such pause frame generation should be disabled in **any** SRIOV based setup, regardless of whether the VMs are trusted. Since the VM fully controls the VF's ring buffer, a malicious VM can modify its software stack (e.g., the VF device driver) to manipulate the ring buffer so that the SRIOV device monitoring the ring buffer will generate pause frames on the VM's behalf. Such pause frames will reach the external switch, which will stop its transmissions to the host and other VMs, leaving us with the same attack vector.

Automatic generation of pause frames on VF ring buffer exhaustion is problematic even if all VMs are trusted. Consider, for example, a VM that does not have enough CPU resources to process all incoming traffic and exhausts the VF's ring buffer. Sending pause frames to the switch may help this VM process the buffer but will halt the traffic to other VMs. Thus, to keep the SRIOV device secure, an SRIOV NIC should not automatically send pause frames when the VF's ring buffer is exhausted regardless of whether the VM is trusted.

Nevertheless, monitoring VF ring buffers can be useful for keeping the Ethernet network lossless and avoiding dropped frames. We propose that the SRIOV device monitor ring buffers, but instead of automatically generating pause frames on ring buffer exhaustion, it should notify the hypervisor. The hypervisor, unlike the device, could then carefully consider whether the VM is malicious or simply slow. If the VM is simply slow, the hypervisor could give it a scheduling boost or assign more CPU resources to it, thereby giving it a chance to process its ring buffer before it fills up. We plan to explore this avenue in future work.

7 Evaluating VANFC

We evaluate VANFC in several scenarios. The **baseline** scenario includes an unprotected system, as shown in Figure 3, and no attack is performed during the test. In this scenario we measure the system's baseline throughput and latency. The **baseline system under attack** includes the same unprotected system but here VM2 runs the attack during the test, sending pause frames at a constant rate of 150 frames/sec. In this scenario we measure the effectiveness of the attack on an unprotected system.

In the **protected system** scenario, VANFC, shown in Figure 8b, replaces the unprotected system. In this scenario VM2 does not perform any attack during the test. We use this scenario to measure the performance overhead introduced by VANFC compared to the baseline. In the **protected system under attack** scenario, we also use VANFC, but here the attacker VM2 sends pause frames at a constant rate of 150 frames/sec. In this scenario we verify that VANFC indeed overcomes the attack.

We perform all tests on the 10GbE network with the same environment, equipment, and methodology as described in Section 4.1.

As explained in Section 6.2, to filter malicious pause frames, our solution uses a software-based filtering device, which adds constant latency of 55µs. A production solution would filter these frames in hardware, obviating this constant latency overhead of software-based model. Thus, in latency-oriented performance tests of the VANFC, we reduced 55µs from the results.

Evaluation Tests To evaluate the performance of the described scenarios, we test throughput and latency using `iperf` and `netperf`, as previously described.

In addition, we configure the `apache2` [34] web server on VM1 to serve two files, one sized 1KB and one sized 1MB. We use `apache2` version 2.4.6 installed from the Ubuntu repository with the default configuration. We run the `ab` [1] benchmark tool from the client to test the performance of the web server on VM1.

VM1 also runs `memcached` [35] server version 1.4.14, installed from the Ubuntu repository with the default configuration file. On the client we run the `memslap` [78] benchmark tool, part of the `libmemcached` client library, to measure the performance of the `memcached` server on VM1.

Figure 9 displays normalized results of the performed tests. We group test results into two categories: throughput oriented and latency oriented. Throughput oriented tests are `iperf` running pure TCP stream and `apache2` serving a 1MB file. These tests are limited by the 10GbE link bandwidth. During the tests, the client and server CPUs are almost idle.

From Figure 9 we conclude that VANFC completely blocks VM2's attack and introduces no performance penalty.

8 Necessity of Flow Control

One can argue that flow control is not required for proper functionality of high level protocols such as TCP. It then follows from this argument that SRIOV can be made "secure" simply by disabling flow control.

The TCP protocol does provide its own flow control mechanism. However, many studies have shown that TCP's main disadvantage is high CPU utilization [28, 36, 46, 55, 66]. Relying on TCP alone for flow control leads to increased resource utilization.

In public cloud environments, users pay for computational resources. Higher CPU utilization results in higher charges. In enterprise data centers and high-performance computing setups, resource consumption matters as well. Ultimately, someone pays for it. In clouds, especially, effective resource utilization will become increasingly more important [12].

Certain traffic patterns that use the TCP protocol in high-bandwidth low-latency data center environments may suffer from catastrophic TCP throughput collapse, a phenomenon also known as the *incast* problem [58]. This problem occurs when many senders simultaneously transmit data to a single receiver, overflowing the network buffers of the Ethernet switches and the receiver, thus causing significant packet loss. Studies show that Ethernet flow control functionality, together with congestion control protocol, can mitigate the *incast* problem, thus improving the TCP performance [27, 62].

As part of a recent effort to converge current network infrastructures, many existing protocols were implemented over Ethernet, e.g., Remote DMA over Converged Ethernet (RoCE) [19]. RoCE significantly reduces CPU utilization when compared with TCP.

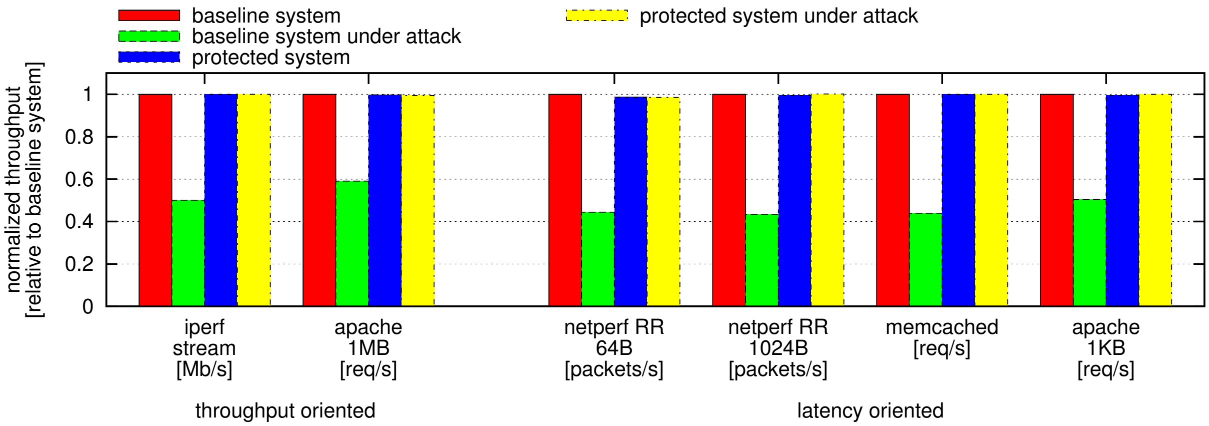

Figure 9: VANFC performance evaluation results

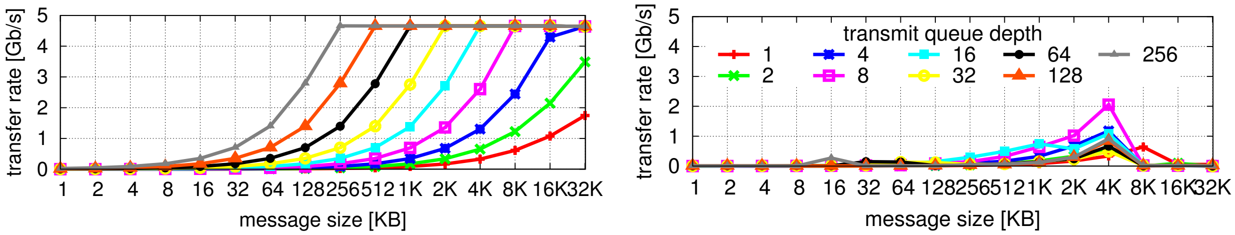

(a)

(b)

Figure 10: Performance of a single RoCE flow in the system with two competing RoCE flows. Graph (a) shows performance with enabled flow control; graph (b) shows performance with disabled flow control.

A few recent studies that evaluate performance of different data transfer protocols over high speed links have been published [48, 49, 67, 72]. Kissel et al. [49] compare TCP and RoCE transfers over 40GbE links using the same application they developed for benchmarking. Using TCP, they managed to reach a speed of 22Gbps while the sender's CPU load was 100% and the receiver's CPU load was 91%. With OS-level optimizations, they managed to reach a speed of 39.5 Gbps and reduce the sender's CPU load to 43%. Using the RoCE protocol, they managed to reach 39.2 Gbps while the CPU load of the receiver and sender was less than 2%! These results clearly show that RoCE significantly reduces CPU utilization and thus the overall cost of carrying out computations. It is especially important when a large amount of data is being moved between computational nodes in HPC or data center environments, where virtualization is becoming prevalent and increasing in popularity [24, 37, 54].

Studies show that RoCE cannot function properly without flow control [48, 49, 67, 72]. Figure 10, taken from Kissel et al. [49], with the authors' explicit permission, shows the performance effect of flow control on two competing data transfers using the RoCE protocol. Figure 10a shows the performance of a single RoCE data transfer while another RoCE data transfer is competing with it for bandwidth and flow control is enabled. Both transfers effectively share link bandwidth. Figure 10b shows the performance of the same RoCE data transfer when flow control is disabled. As can be seen in the figure, without flow control the RoCE data transfer suffers, achieving a fraction of the performance shown in Figure 10a. We have also independently reproduced and verified these results.

Kissel et al. also show [49] that the same problem is relevant not only to RoCE but can be generalized to TCP as well. Thus we conclude that disabling flow control would cause less effective resource utilization and lead to higher cost for cloud customers and for any organization deploying SRIOV. Conversely, securing SRIOV against flow control attacks would make it possible for SRIOV and flow control to coexist, providing the performance benefits of both without relinquishing security.

9 Discussion

Notes on Implementation VANFC can be implemented as part of an SRIOV device already equipped with an embedded Ethernet switch or it can be implemented in the edge Ethernet switch, by programming the edge switch to filter flow control frames from VFs' MAC addresses. Adding VANFC functionality to the NIC requires less manufacturing effort; it is also more convenient and cheaper to replace a single NIC on a host than to replace an edge switch. Nevertheless, in large-scale virtualization deployments, such as those of cloud providers or corporate virtual server farms, a single 10GbE Ethernet switch with high port density (for example, the 48 port HP 5900AF 10Gb Ethernet switch in our testbed) serves many host servers with SRIOV capable devices. In such scenarios, upgrading 48 SRIOV devices connected to the 48 port switch requires considerably more resources than single switch upgrade.

Having said that, we argue that proper implementation of the solution to the described problem is in the SRIOV NIC and not in the edge Ethernet switch. The problem we discuss is strictly related to the virtualization platform and caused by a design flaw in the SRIOV NIC's internal switching implementation. Mitigating the problem in the edge switch, an external device whose purpose is not handle virtualization problems of the host, would force the edge switch to learn about each VF's MAC address and to distinguish PFs from VFs, coupling the edge switch too closely with the NICs.

VEB and VEPA Another important security aspect of SRIOV is VM-to-VM traffic. In SRIOV devices with an embedded VEB switch, VM-to-VM traffic does not leave the host network device and is not visible to the external edge switch, which enforces the security policy on the edge of the network. To make all VM traffic visible to the external switch, the VEB switch should act as a VEPA and send all VM traffic to the adjacent switch.

A properly configured Ethernet switch and the use of a VEPA device can enforce a security policy (ACL, port security) on malicious VM traffic and prevent most L2 attacks. However, while VEPA solves many manageability and security issues that pertain to switching in virtualized environments [29], it does not address the flow control attack we presented earlier. This is because VEPA still shares the same single link between multiple untrusted guests and the host and does not manage flow control per VF. Besides not solving the flow control attack, it uses, again, the edge Ethernet switch, which is external to the source of the problem–SRIOV NIC. Thus, a VEPA extension should not be considered for the solution and the problem should be solved in the SRIOV NIC.

10 Related Work

Several recent works discussed the security of self-virtualizing devices. Pék et al. [61] described a wide range of attacks on host and tenant VMs using directly assigned devices. They performed successful attacks on PCI/PCIe configuration space, on memory mapped I/O, and by injecting interrupts. They also described an NMI injection attack. Most of the attacks they discussed can be blocked by a fix in the hypervisor or by proper hardware configuration.

Richter et al. [68] showed how a malicious VM with a directly attached VF can perform DoS attacks on other VMs that share the same PCIe link by overloading its own Memory Mapped I/O (MMIO) resources and flooding the PCIe link with write request packets. As the authors mention, this attack can be mitigated by using the QoS mechanisms defined by the PCIe standard [59].

All of the attacks discussed in the aforementioned papers are based on weak security implementations of software (e.g., a hypervisor) or hardware (a chipset system error reporting mechanism) that are internal to the host. Our attack exploits different design aspects of SRIOV devices: it targets the interoperability of SRIOV devices with software and hardware external to the host.

There are ongoing efforts of the Data Center Bridging Task Group, which is a part of the IEEE 802.1 Working Group, to standardize configuration, management and communication of virtual stations connected to the adjacent bridge. The working group proposed the 802.1Qbg Edge Virtual Bridging [10] and 802.1BR Bridge Port Extension [11] standards. Both standards concentrate on configuration and management of the bridge services for virtual stations, leaving the flow control of virtual stations out of their scope. To the best of our knowledge, our work is the first to present the problem of self-virtualizing devices in converged enhanced Ethernet environments with flow control, and the first to suggest a solution for it.

11 Conclusions and Future Work

Self-virtualizing devices with SRIOV lie at the foundation of modern enterprise data centers, cloud computing, and high-performance computing setups. We have shown that SRIOV, as currently deployed on current Ethernet networks, is incompatible with required functionality such as flow control. This is because flow control relies on the assumption that each endpoint is trusted, whereas with SRIOV, each network endpoint is comprised of multiple, possibly untrusted, virtual machines. We show how to overcome this flaw by teaching the NIC about virtual functions. We present the prototype of such a system, VANFC, and its evaluation. Our prototype is 100% effective in securing SRIOV against this flaw while imposing no overhead on throughput or latency-oriented workloads.

Future work includes continuing to investigate the security of SRIOV devices; extending our work from Ethernet to other networking technologies such as InfiniBand and Fiber Channel; looking at the security of direct-assigned self-virtualizing devices other than NICs, such as high-end NVMe SSDs and GPGPUs; developing VF co-residency detection techniques; and using the hypervisor to solve the problem of VM ring buffer exhaustion. Handling this with software without losing performance will be challenging. On VANFC specifically, we plan to continue our evaluation and to explore what an eventual hardware-based implementation would look like.

Abstract

Mandatory protection systems such as SELinux and SEAndroid harden operating system integrity. Unfortunately, policy development is error prone and requires lengthy refinement using audit logs from deployed systems. While prior work has studied SELinux policy in detail, SEAndroid is relatively new and has received little attention. SEAndroid policy engineering differs significantly from SELinux: Android fundamentally differs from traditional Linux; the same policy is used on millions of devices for which new audit logs are continually available; and audit logs contain a mix of benign and malicious accesses. In this paper, we propose *EASEAndroid*, the first SEAndroid analytic platform for automatic policy analysis and refinement. Our key insight is that the policy refinement process can be modeled and automated using semi-supervised learning. Given an existing policy and a small set of known access patterns, EASEAndroid continually expands the knowledge base as new audit logs become available, producing suggestions for policy refinement. We evaluate EASEAndroid on 1.3 million audit logs from real-world devices. EASEAndroid successfully learns 2,518 new access patterns and generates 331 new policy rules. During this process, EASEAndroid discovers eight categories of attack access patterns in real devices, two of which are new attacks directly against the SEAndroid MAC mechanism.

1 Introduction

Operating system integrity relies on the correctness of 1) trusted computing base (TCB) code and 2) access control policy protecting the TCB code and OS resources. It is generally impractical to verify the correctness of OS code in commodity systems. Therefore, mandatory access control (MAC) policy is often used as a fallback when the security of the software inevitably fails [29].

SELinux [6] is the most notable MAC policy framework widely used in practice. Security Enhanced Android [38] (known simply as SEAndroid) is a recent port of SELinux to the Android platform. However, while Android is based on a Linux kernel, the runtime environment is vastly different than existing Linux distributions for commodity PCs. This difference resulted in a complete redesign of the MAC policy rules, with several new object classes (e.g., for Android's binder IPC).

As with SELinux, SEAndroid policy development is a challenging task, requiring many iterations of refinement to be ready for commercial deployment. For example, Google introduced a very permissive SEAndroid policy into Android version 4.3 and did not enable enforcement. Version 4.4 enabled enforcement, but the policy was still very permissive, containing only a few system daemons. Finally, Android version 5.0 provides a much more robust (but not perfect) version of the policy. Additionally, major smartphone vendors need to customize Google's base SEAndroid policy for their devices to add additional protections against known attacks.

SEAndroid policy refinement is currently a very manual process that typically involves analyzing audit logs to identify proposed changes. There are two general approaches to SEAndroid policy refinement. The first approach is to develop a least privilege [35] policy (also known as a "strict" policy in SELinux terminology) and monitor audit logs for access patterns that should be allowed. The second approach is to begin with a more permissive policy, refine the policy to prevent (or contain) privilege escalation attacks and use audit logs to verify the refinement. Each approach has disadvantages. If the policy is too strict, it will hurt the usability of deployed real-world devices. If the policy is too permissive, it will allow attacks. As a result, smartphone vendors use a combination of these two approaches.

The goal of our research is to significantly reduce the manual effort required to refine SEAndroid policy using audit logs. Audit log analysis is challenging for several reasons. First, audit logs are collected from millions of real-world devices, and purely manual analysis is impractical. Second, the audit logs contain both benign access patterns and malicious access patterns. Existing SELinux tools such as `audit2allow` that blindly create rules to allow all access patterns in audit logs are error prone. Third, the functionality of both benign applications and malicious exploits is continually changing/upgrading, requiring frequent reassessment of the deny/allow boundary to refine the policy.

In this paper, we present Elastic Analytics for SEAndroid (EASEAndroid) as the first large-scale audit log and policy analytic platform for automatic policy analysis and refinement of SEAndroid-style MAC policy. Our key insight is that the policy refinement process can be modeled and automated using semi-supervised learning [18], a popular knowledge-base construction technique [16, 21]. We apply EASEAndroid to a database of 1.3 million audit logs from real-world Samsung devices running Android 4.3 over the entire year of 2014.[1] EASEAndroid correctly discovers 336 new benign access patterns and 2,182 new malicious access patterns, and automatically translates them into 331 policy rules. The generated rules are consistent with rules manually added by policy analysts. Among the malicious access patterns, EASEAndroid further discovers two new types of attacks in the wild directly targeting SEAndroid MAC mechanism itself.

This paper makes the following contributions:

- *We propose EASEAndroid, a semi-supervised learning approach for refining MAC policy at large scale.* Our approach scales to millions of audit logs that contain a mix of benign and malicious access patterns. While we focus on SEAndroid, the approach is more broadly applicable to type enforcement (TE) MAC policy.

- *We implement a prototype of EASEAndroid to help policy analysts analyze SEAndroid audit logs.* The implementation generates policy refinements, and discovers new Android attacks, providing new knowledge of both benign and malicious access patterns learned from audit logs for policy analysts.

- *We evaluate EASEAndroid on 1.3 million audit logs from real-world Samsung devices.* Using this dataset, EASEAndroid successfully learns 2,518 benign and malicious access patterns and generates 331 policy rules as a refinement. EASEAndroid also discovers two new types of attacks directly targeting SEAndroid. With the help of EASEAndroid, this is the first large-scale study on real-world malicious access patterns in Android devices.

The remainder of this paper proceeds as follows. Section 2 provides background on SEAndroid and semi-supervised learning. Section 3 defines the problem addressed in this paper. Section 4 describes the EASEAndroid design. Section 5 evaluates EASEAndroid against a large database of real-world audit logs. Section 6 discusses limitations. Section 7 overviews related work. Section 8 concludes.

2 Background

2.1 SELinux and SEAndroid

SEAndroid is a port of SELinux's type enforcement (TE) MAC policy to the Android platform [4]. As such, SEAndroid enforces mandatory policy on system-level operations between subjects and objects (e.g., system calls) [6]. In general, processes are regarded as subjects, whereas files, sockets, etc. are objects in different classes. A security context label is assigned to subjects (or objects) that share the same semantics. Traditionally, the subject label is called a *domain*, and the object label is called a *type* (nomenclature from DTE [12]). A policy rule defines which domain of subjects can operate which class and type of objects with a set of permissions, such as open, read, write [28]. For example,

```
allow app app_data_file:file {open read}
```

allows processes with the `app` domain to `open` and `read` `file` class objects assigned the `app_data_file` type. In addition to `allow` rules, SELinux provides `neverallow` rules to define policy invariants for malicious accesses that should never be allowed. These rules are enforced at policy compile-time and are necessary due to the complexity of the SELinux policy language.

SEAndroid extends SELinux's policy semantics to support Android-specific functionality, including mediation of Binder IPC and assigning security contexts based on application digital signatures. The goal of SEAndroid is to reduce the attack surface and limit the damage if any flaw or vulnerability is exploited causing privilege escalation [38]. This goal is accomplished by confining the capabilities of different privileged Android applications and system daemons.

The Android platform is vastly different than traditional Linux distributions, therefore the SEAndroid policy rules were created from scratch. While the regularity of Android's UNIX-level interactions results in a policy that is less complex than the example SELinux policy for PCs, the SEAndroid policy is still nontrivial and error prone. It requires careful understanding of subtle interactions between different privileged processes. In practice, policy development requires continual manual refinement based on audit logs.

[1] See Appendix A for more details about audit log collection.

```
type=1400 msg=audit(1399587808.122:14):
avc: denied { entrypoint } pid=285 comm="init"
scontext=u:r:init:s0
tcontext=u:object_r:system_file:s0 tclass=file

type=1300 msg=audit(1399587808.122:14):
syscall=11(execve) success=no exit=-13
items=1 ppid=1 pid=285 uid=0 gid=0
comm="init" exe="/init" subj=u:r:init:s0

type=1302 msg=audit(1399587808.122:14):
item=0 name="/system/etc/install-recovery.sh"
inode=3799 dev=b3:10 mode=0100755
ouid=0 ogid=0 obj=u:object_r:system_file:s0
```

Listing 1: A denied access event example recorded at the epoch time 1399587808.122 in an audit log. It consists of three entries: labels & permission (1400), syscall & process info (1300), object info (1302).

An audit log captures security labels and system calls of the operations that are not explicitly allowed by a rule. As shown in Listing 1, a denied operation generally has three entries with epoch timestamps. Log entries with `type=1400` record the denied permission (e.g., `entrypoint`), the security labels of the subject (source), called `scontext`, and the object (target), called `tcontext`, as well as the object's class, called `tclass` (e.g., `file`). Log entries with `type=1300` record the system call and the subject's process information, including the executable file path. Log entries with `type=1302` record the object information (e.g., the file name).

Traditionally, policy analysts develop and refine a policy by manually analyzing audit logs. Existing SELinux tools such as Tresys's setools [8] are used to analyze SEAndroid policies based on interactive user interface. Analysts also develop simple shell and Python scripts to parse audit logs. Unfortunately, such tools are not scalable to a large number of audit logs, and cannot distinguish benign or malicious access patterns in real-world audit logs. In addition, analysts often use a tool called `audit2allow` [9] that can create new `allow` rules by directly using the security labels captured in `type=1400` entries in audit logs. However, blindly using this tool may increase attack surface, because in some cases, existing labels are too coarse-grained or semantically inappropriate. Therefore, policy refinement usually consists of the creation and modification of both security labels and policy rules. Once the policy is refined by analysts, it is pushed to users' devices through a secure over-the-air (OTA) channel, similar to antivirus signature updates.

2.2 Semi-Supervised Learning

Semi-supervised learning is a type of machine learning that trains on both labeled[2] data (used by supervised learning) and unlabeled data (used by unsupervised learning) [18]. It is typically used when labeled data is insufficient and expensive to collect, and a large set of unlabeled data is available. By correlating the features in unlabeled data with labeled data, a semi-supervised learner infers the labels of the unlabeled instances with strong correlation. This labeling increases the size of labeled data set, which can be used to further re-train and improve the learning accuracy [44]. This iterative training process is commonly referred to as bootstrapping. Semi-supervised learning is popular for information extraction and knowledge base construction. Examples include NELL [16, 17], Google Knowledge Vault [21].

We hypothesize that the process of developing and refining SEAndroid policy is analogous to semi-supervised learning. Human analysts encode their knowledge about various access patterns into a policy. When analyzing audit logs, analysts find semantic correlations between known and unknown access patterns to infer whether the unknown ones are benign or malicious, such as a known malicious subject performing an unseen behavior (likely malicious), or a system daemon performing a new but similar functional operation (likely benign). These new patterns expand analysts' knowledge and help them refine the policy. However, when more and more logs are collected containing access patterns about new Android systems and new attacks, manual learning is time-consuming and likely to miss important knowledge. Our insight is that semi-supervised learning can automate this process to achieve scalability in policy refinement.

3 Problem

Refining SEAndroid policy is more challenging than refining SELinux policy. Existing SELinux tools such as `audit2allow` are severely limited in their ability to help policy analysts. This task has the following challenges.

C-1: *Consumer devices produce millions of audit logs.* Policy analysts cannot practically analyze audit log entries manually. A solution must automate or semi-automate the audit log analysis.

C-2: *Real-world audit logs contain a mixture of benign and malicious accesses.* Classifying log entries as benign or malicious is a central design challenge. It is often difficult to classify an access in isolation. Instead, the analysis must look at the broad context of the access, as well as the contexts of related known accesses.

C-3: *Target functionality is not static.* The set of benign and malicious applications continues to evolve as new software and malware is developed, requiring continuous audit log analysis and policy refinement.

[2] Here, labeled and unlabeled are machine learning terms, not related to security labels.

For example, benign software may access new resources, while malware may exploit new vulnerabilities to achieve privilege escalation.

We now define two terms to clarify the discussion in the remainder of this paper.

Definition 1 (Access Event)**.** *An access event is the access control event that causes the three audit log entries described in Section 2. These log entries may result from a policy denial, or an* `auditallow` *policy rule, which allows but logs the access.*

Note that this definition does not include allowed accesses that are not contained in the audit log.

Since audit logs are collected for millions of devices, the logs contain many duplicate access events. For the purposes of audit log analysis, it is useful to abstract the salient details of access events into an access pattern.

Definition 2 (Access Pattern)**.** *An access pattern is a 6-tuple (sbj, sbj_label, perm, tclass, obj, obj_label). Many access events may map to the same access pattern.*

Here *sbj* refers to a concrete subject such as an Android application or system binary. Binaries carried inside an application are generalized as the application. *obj* refers to concrete objects such as file paths and socket names. In some cases, we group over-specific files that share the same filesystem semantics as one *obj* (e.g., `/sdcard`). The values of *sbj* and *obj* are derived from the `comm`, `exe`, `pid`, and `name` values in the `type=1300,1302` log entries. *perm* and *tclass* are the same as the permission and the object's class in the `type=1400` log entries and policy rules. *sbj_label* and *obj_label* are derived from the `scontext` and `tcontext` values in `type=1400` log entries. For example, the access pattern for the access event in Listing 1 is ("`/init`", "`init`", "`entrypoint`", "`file`", "`/system/etc/install-recovery.sh`", "`system_file`").

Problem Statement: Given 1) a large dataset of new access patterns from audit logs, 2) a small set of known access patterns (e.g., known attacks), and 3) an SEAndroid policy, we seek to a) separate new benign access patterns from new malicious access patterns in the dataset, and b) suggest new rules and refined labels for the policy.

Threat Model and Assumptions: We assume that an audit log is collected from an Android device with a policy loaded in either enforcing or permissive mode. We assume the integrity of audit log contents. We therefore assume that the Linux kernel and its audit subsystem are not compromised. However, even if the SEAndroid policy properly confines Android applications and system daemons, they may be compromised by the adversary.

4 EASEAndroid

Elastic Analytics for SEAndroid (EASEAndroid) is a large-scale audit log and policy analytic platform for automated policy refinement. The novelty of EASEAndroid is that it models the policy refining process as a semi-supervised learning of new access patterns. At a high level, EASEAndroid starts with an initial knowledge base containing existing policy rules and a small set of (potentially manually) identified access patterns. It expands the knowledge base by correlating, classifying, and incorporating new access patterns captured by audit logs. Based on the new knowledge, EASEAndroid suggests policy changes (new rules and new domain and type labels in the context of SEAndroid). As more audit logs become available, EASEAndroid continuously expands the knowledge base and refines the policy.

Figure 1 shows the architecture of EASEAndroid. The architecture uses three machine learning algorithms that consider different perspectives of the knowledge base and audit logs. The output of these algorithms is fed into a combiner that combines and appends the new knowledge into the knowledge base. This learning process is iterated multiple times until no more new knowledge can be learned from the current audit log input. Finally, the policy generator suggests refinements.

Each machine learning algorithm analyzes a different perspective of the data. The goal of each algorithm is to find semantic correlations between unknown new access patterns and existing knowledge base, in order to classify each new access pattern as benign or malicious.

1. The *nearest-neighbors-based (NN) classifier* classifies new access patterns based on their relations to known access patterns in the knowledge base. It finds new access patterns that are related to known subjects/objects (e.g., known subjects are updated and perform new access patterns). By treating these known subjects/objects as neighbors of the new access patterns, it classifies the new access patterns based on the majority of their known neighbors.
2. The *pattern-to-rule distance measurer* calculates the distance between new access patterns and existing policy rules. If a new access pattern is closest to an `allow` rule, it is classified as benign. If it is closest to a `neverallow` rule, it is classified as malicious. If the access pattern is not close to either type of rule, it remains unclassified. The pattern-to-rule distance measurer also exposes potentially incomplete rules in existing policy for refinement.
3. The *co-occurrence learner* considers correlations across access patterns using statistical relations between new and known access patterns that frequently occur together in audit logs. Our intuition is

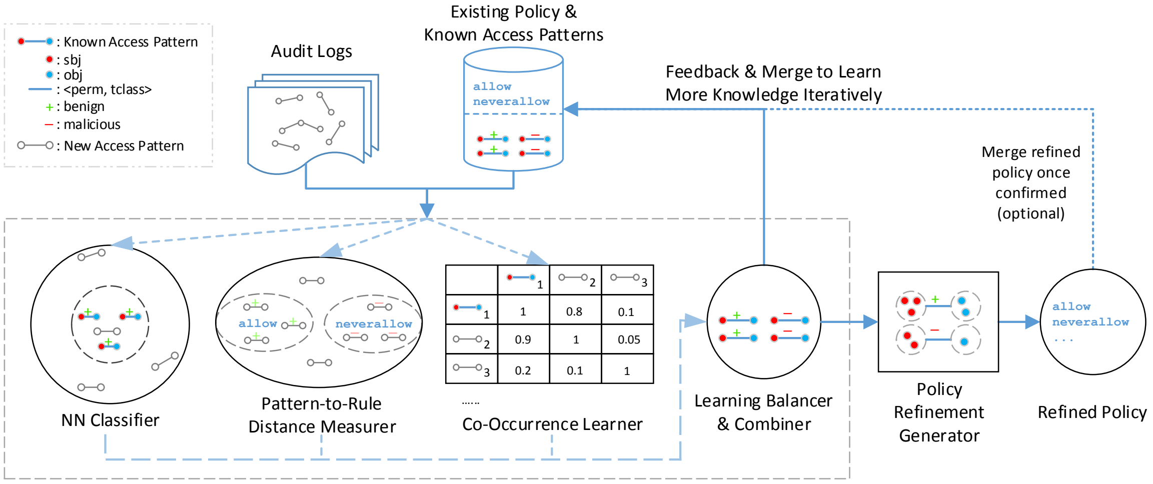

Figure 1: EASEAndroid consists of four learning components and a policy generator to iteratively learn new patterns and refine policy

that a benign functionality or a malicious attack often involves a series of access patterns that are captured together in an audit log. If known and new access patterns occur together, we can use the known ones to infer the classification of the new ones.

Each learner is configured with its own threshold to classify new access patterns independently. However, it is non-trivial to define proper thresholds because too relaxed thresholds could cause false classification, lowering the learning precision, while too strict thresholds could leave potential access pattern candidates unclassified, lowering the learning coverage.

The *learning balancer & combiner* manages the threshold of each learner, balances the precision and coverage, and combines the classification results from the three learners. It has two modes: (1) an *automated mode* that uses strict threshold in each learner to achieve high precision with the cost of less coverage; and (2) a *semi-automated mode* that relaxes each learner's threshold to achieve high coverage and relies on a majority vote from the three learners to increase the precision. In practice, the result of semi-automated mode requires policy analysts' verification to control error rate.

Finally, the *policy generator* takes newly classified access patterns as input from the combiner, to suggest policy refinements in the form of new rules and new security labels. It uses a clustering algorithm to group similar subjects and objects together. The clustering algorithm follows the principle of least privilege by inferring fine-grained labels that can cover and only cover the clustered concrete subjects and objects. In practice, the resulting refined policy can be confirmed by policy analysts and merge into the knowledge base to analyze new audit logs after the refined policy is deployed.

The remainder of this section describes each stage of the EASEAndroid architecture in detail.

4.1 Nearest-Neighbors-based Classifier

Nearest-neighbors-based (NN) learning is a common technique for classifying an unlabeled instance based on its nearest labeled neighbors within a defined distance [41]. Our intuition of using NN for access pattern classification is two-fold. First, known subjects often perform previously unseen access patterns in audit logs. This scenario often occurs when Android applications and system binaries are updated with new capabilities. Second, some known access patterns are also performed by new subjects. This scenario occurs when certain operations become popular and are copied by other new applications. In practice, some exploit kits and repackaged applications [43] have been found to share the same set of known malicious access patterns.

These two scenarios cause known subjects and patterns to be semantically connected with new subjects and patterns. EASEAndroid leverages this connectivity as the distance metric to design the NN classifier. When multiple known subjects (or patterns) connect to the same new pattern (or subject), the NN classifier can infer whether the new pattern (or subject) is benign or malicious, based on the majority of the connected known neighbors. Note that here the observation is with respect to concrete subjects and objects in access patterns. Hence, only a 4-tuple $(sbj, perm, tclass, obj)$ out of the original 6-tuple is required. For completeness, our implementation still includes sbj_label and obj_label in the dataset, but they are not used in this learner.

Algorithm 1 shows the procedure of the NN classifier. AP_k collects known 4-tuple access patterns, either benign or malicious. In practice, our AP_k is a small set contain-

Algorithm 1 NN-based Classification of Access Patterns

```
$AP_k \leftarrow \{(s_k, p_k, t_k, o_k) | s_k \in S_k, (p_k, t_k, o_k) \in P_k\}$
$AP_u \leftarrow \{(s_u, p_u, t_u, o_u) | s_u \in S_u, (p_u, t_u, o_u) \in P_u\}$
$AP_c \leftarrow \emptyset$
procedure NN_CLASSIFIER($AP_k$, $AP_u$, $AP_c$)
    for each $(s, p, t, o) \in AP_u$ do
        if $s \in S_k \cap S_u$ and $(p, t, o) \in P_u - P_k$ then
            $S_{tmp} \leftarrow findAllSbjs((p, t, o), AP_u)$
            if $IsMajorityKnown(S_{tmp}, S_k)$ then
                $AP_c \leftarrow AP_c \cup Classify((s, p, t, o))$
            end if
        else if $s \in S_u - S_k$ and $(p, t, o) \in P_k \cap P_u$ then
            $P_{tmp} \leftarrow findAllPatterns(s, AP_u)$
            if $IsMajorityKnown(P_{tmp}, P_k)$ then
                $AP_c \leftarrow AP_c \cup Classify((s, p, t, o))$
            end if
        end if
    end for
end procedure
return $AP_c$
```

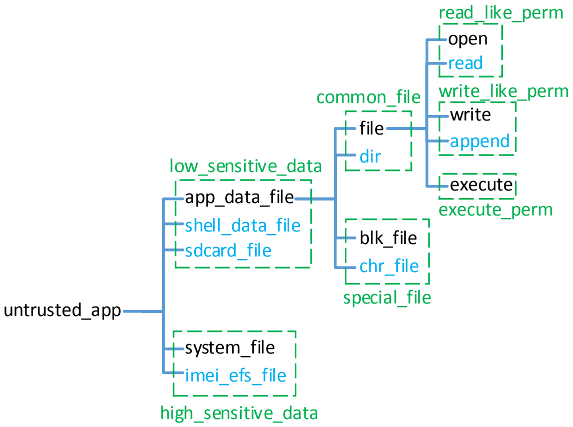

Figure 2: A decision tree example based on rules related to subject domain as `untrusted_app`. The black nodes are from existing rules and the blue nodes are semantic siblings.

ing a few well-confirmed subjects and patterns, used as the initial seed. AP_u collects all unknown new access patterns from audit logs. To clearly describe the above two cases, we further divide the 4-tuple into S for all subjects, and P for the triples *(perm, tclass, obj)* as partial patterns shared by multiple subjects. AP_c is the result set of newly classified access patterns.

For each 4-tuple in AP_u, we check if it is a known subject with a new triple (partial pattern), or a new subject with a known triple. In the first case, besides the subject in this 4-tuple, $findAllSbjs$ collects all subjects S_{tmp} that perform (connect) the same new triple in AP_u, including both known and new subjects. Then $IsMajorityKnown$ checks if the majority of S_{tmp} is a set of known subjects from S_k with the same benign or malicious flag. If so, the new access pattern is classified as benign or malicious accordingly. The second case is done in the same way but using known triples to classify new subjects.

The function $IsMajorityKnown$ uses two empirically defined thresholds (m, σ). m determines the minimum required neighbors and σ is a percentage for how many known neighbors in S_{tmp} or P_{tmp} are required as a majority. Table 1 in the evaluation studies the effects of different threshold values.

From the perspective of machine learning, our NN-based classifier is a type of *radius-based near neighbors learning* [13], a variant of the common k-nearest-neighbors (kNN). The difference is that kNN is based on the top k neighbors while we find all neighbors within a radius as nearest neighbors (connectivity is the radius in our case).

Note that, it is possible that some access patterns are rarely connected with known ones. Besides, an access pattern could be evenly connected to both known benign and malicious ones. Both cases cause $IsMajorityKnown$ to return false. In this case, the NN classifier leaves the access patterns as unclassified and relies on the following learners to complement the learning process.

4.2 Pattern-to-Rule Distance Measurer

EASEAndroid's second data perspective is the closeness of access patterns to policy rules. Since audit logs record denied accesses that cannot match with an `allow` rule, it is useful to know how far/close the denied access pattern is from an existing rule. In particular, because policy rules are developed incrementally, they may only cover a subset of permissions or access patterns and miss similar access patterns belonging to the same operation.

A common case of this is an imprecise list of permissions in an `allow` rule. For example, writing a file not only requires `write` permission, but also `append` and sometimes `create` (in case the file does not exist). Some malicious operations can also be performed using semantically equivalent, but different access patterns.

The pattern-to-rule distance measurer quantifies the difference between access patterns and existing rules. The purpose of this measurer is two-fold. First, pattern-to-rule distance indicates how likely a new access pattern is to be benign or malicious. Second, if an access pattern is very close to a policy rule, the policy refinement generator (Section 4.5) can update the rule rather than creating a new rule from scratch.

The distance measurer uses a metric based on the 1) subject label, i.e., *domain*, 2) object label, i.e., *type*, 3) tclass, e.g., `file`, and 4) permission, e.g., `write`. Note that all four of these elements are in both the SE-

Android policy allow rules, as well as the 6-tuple representing an access pattern in the audit log. Intuitively, an access pattern is very close to a rule if it shares the same labels and tclasses only with slightly different permissions (e.g., write vs append). The distance increases a little, but is still close, if a pattern and a rule operate on different but similar tclasses (e.g., file vs dir).

EASEAndroid systematically measures distance using decision trees based on existing policy rules. The distance is defined by the matching depth for a specific access pattern. Decision trees are built as follows.

Step 1: For every subject label, find all related rules and follow their semantic order to build a tree skeleton starting from the subject as the root, followed by object labels, tclasses and permissions as nodes in each layer.

Step 2: Extend each node with its semantically similar siblings.

Figure 2 shows an example decision tree. The black nodes indicate the tree skeleton, which uses rules such as allow untrusted_app app_data_file:file {open}, where app_data_file is the object node in the second layer and file is the tclass node in the third layer and so on. Then each node is extended with its semantic siblings, such as sdcard_file in the same group of low sensitive data as app data.

Given an access pattern and a decision tree, the distance measurer walks the decision tree and tries to match the access pattern's subject label, object label, tclass, and permission with each layer. The matching depth indicates how close a pattern is to existing rules. For the example in Figure 2, access pattern $ap_i =$ (untrusted_app, sdcard_file, dir, read) matches the fourth layer. The distance is computed as follows:

$$Dist(ap_i) = TotalLayerDepth - MatchedDepth(ap_i)$$

If we define $TotalLayerDepth = 4$, then $Dist(ap_i) = 0$, indicating the access pattern is very close to the rule. We create trees for both allow and neverallow rules to compute the distances from both sides.

In practice, the effectiveness of the distance metric depends on the correctness of semantic siblings. Fortunately, the SEAndroid policy development frequently uses semantic groups. A list of permissions, tclasses, and object types are already grouped together in policy source code using macros and attribute [7]. These groups form a ground truth for semantic siblings.

Additionally, recall that some existing subject and object labels are coarse-grained (e.g., labels assigned to various objects using wildcard in policy source code). If a pattern matches with a rule with a coarse-grained label, the distance measurer marks the distance as low confidence and relies on the learning balancer & combiner for additional verification (Section 4.4).

Finally, note that this technique can be further extended to measure access pattern to access pattern distance. Since the pattern-to-rule distance helps to infer both new patterns as well as identify incomplete rules for refinement, our design considers policy rules and leaves the distance between access patterns for future work.

4.3 Co-Occurrence Learner

When analyzing a large number of audit logs, some access patterns frequently occur together in many logs. This is because some high-level benign functionality or some popular multi-step attacks consist of a series of access patterns within a time period (typically minutes). The statistics of co-occurrence is a valuable means of correlating access patterns that have different subjects or objects, but share the same group semantics. When a group contains both known and new access patterns, the known access patterns can be used to infer the semantics of the new access patterns. In fact, co-occurrence is popular in natural language processing and knowledge extraction. For example, it is used for finding words that are frequently used together in a specialized domain [15].

The co-occurrence of access pattern can be represented using a $n \times n$ matrix for all n unique access patterns from the audit logs, as shown below. Each row stores one access pattern ap_i's co-occurrence percentage with every other access pattern, denoted in each column. The value c_{ij} is the percentage of the number of times that ap_i co-occurs with ap_j out of the total number of ap_i's occurrences throughout the logs.

$$CO_{AP} = \begin{array}{c} \\ ap_i \\ ap_j \\ \ldots \end{array} \begin{array}{c} \begin{array}{ccc} ap_i & ap_j & \ldots \end{array} \\ \begin{bmatrix} 1 & c_{ij} & \ldots \\ c_{ji} & 1 & \ldots \\ \ldots & \ldots & 1 \end{bmatrix} \end{array},$$

$$\text{where } c_{ij} = \frac{CoOccurNum(ap_i, ap_j)}{TotalOccurNum(ap_i)}$$

When counting the number of co-occurrences, it is important to avoid noise and duplicates. In practice, we use a time frame of 10 minutes to determine whether two access patterns are part of a co-occurrence set. Recall from Section 2 that each access pattern has an epoch timestamp. Additionally, when counting the occurrence at the granularity of logs, repeated pairs of co-occurred access patterns in one log are counted only once.

To use this co-occurrence matrix, the learner focuses on the rows with new access patterns. For each ap_i row, the learner sorts columns and selects the set of known access patterns in columns whose percentage is above a threshold. A majority vote of this known access pattern set determines the classification of the new ap_i (benign or malicious). On the other hand, the known access pattern rows may also have some highly co-occurred new access pattern columns. However, one known access pattern is usually not enough to classify a new access pattern.

Note that the matrix is not symmetric. c_{ij} can be different from c_{ji} due to different total occurrence counts. For instance, some popular known malicious access patterns (e.g., `remount /system`) can co-occur with multiple less popular new access patterns, because multi-step attacks often use different steppingstones to achieve the final privilege escalation goal.

4.4 Learning Balancer & Combiner

Each learner is configured with its own threshold to classify new access patterns independently. However, it is non-trivial to define proper thresholds due to two reasons. On the one hand, if a threshold is too relaxed, it could cause false classification, lowering the learning precision and might further propagate the error to the next iteration of semi-supervised learning. On the other hand, if a threshold is too strict, it could miss potential access pattern candidates and leaves them as unclassified, lowering the learning coverage.

We design the learning balancer & combiner to manage the threshold setting of each learner, balance the precision and coverage, and combine the classification results from the three learners (also called ensemble or multi-view learning [17]). The final combined classification result is added to the knowledge base and sent to the policy refinement generator. Specifically, we propose two quantifiable methods to achieve the balancing:

Automated Mode: Since each learner specializes in one dimension, each learner with a strict threshold can directly contribute its classified access patterns with high precision. For example, we can set a minimum of 10 required known neighbors with a 90% bar for $IsMajorityKnown$ in NN classifier; $Dist(ap_i) = 0$ with fine-grained rules in pattern-to-rule distance measurer; and $c_{ij} > 0.9$ with known access pattern set ≥ 10 in co-occurrence learner. The high precision of strict thresholds enables EASEAndroid to be used in an automated mode over multiple iterations of semi-supervised learning. However, with such strict thresholds, some access pattern candidates can be left as unclassified.

Semi-Automated Mode: This mode relaxes the thresholds to get more access pattern candidates. It uses a majority vote to choose the candidates shared by at least two learners with the same classification result, and the third learner must not have conflicting result.

Note that relaxed thresholds can increase the possibility of error propagation. However, if the analysis can tolerate a semi-automated configuration, relaxed thresholds can be used. Here a human analyst can investigate low-confident candidates and input external knowledge into EASEAndroid for better learning in future.

4.5 Policy Refinement Generator

Finally, the policy refinement generator translates newly classified access patterns[3] into the final policy form. A key part of the generator is to assign the concrete subjects (*sbjs*) and objects (*objs*) in the access pattern with appropriate security labels before generating policy rules.

According to the Android Open Source Project, Google provides a baseline definition of security labels for common subjects (e.g., system apps and binaries) and basic objects (e.g., basic files/dirs in Android file system structure). However, Google recommends that manufacturers replace the generic default labels with fine-grained labels to decrease the attack surface [4].

Recall that both the access pattern 6-tuple and the incomplete rules identified by the distance measurer include subject labels and object labels from the existing policy. While some of the labels are coarse-grained, they serve as a baseline to derive fine-grained labels. Specifically, the policy refinement generator takes all access patterns as input and clusters them into groups where each group shares the same 4-tuple *(sbj_label, perm, tclass, obj_label)*. Each group is further clustered by *sbjs* and *objs* to create subgroups that share the detailed semantics to derive fine-grained labels.

Our current generator prototype groups *sbjs* and derives fine-grained subject labels for built-in, vendor, and untrusted applications and binaries separately. The generator also groups file-like objects (e.g., `file`, `dir`, `blk_file`), which comprise the majority of tclasses. Group is performed using a *longest common prefix* search on file paths. This optimization helps to derive more fine-grained labels than provided by the general Android filesystem structure. Finally, the generator produces rules in the form of *(new_sbj_label, perm, tclass, new_obj_label)* as a policy refinement. If access patterns are matched with incomplete rules by the distance measurer, new rules merge with existing rules' permissions.

The generator handles benign and malicious patterns separately and generates `allow` and `neverallow` rules, respectively. Note that, it is possible that newly generated rules may conflict with existing rules due to incomplete or tightened access control. In such cases, policy analysts manually resolve conflicts (e.g., using `auditallow` to verify). Nevertheless, EASEAndroid exposes these conflicts with evidence collected through learning, therefore easing the policy refining process.

[3] In practice, the learning process can iterate multiple times with current audit logs. The generator caches all classified access patterns.

5 Evaluation

We implement a prototype of EASEAndroid and evaluate the learning capability and the security effectiveness of EASEAndroid from three perspectives:

1. We evaluate the coverage and precision of the classification result of EASEAndroid, and how they are affected by different threshold settings (Section 5.3).
2. We conduct a case study of the policy refinement generated by EASEAndroid, also comparing the generated rules with human-written rules (Section 5.4).
3. We further conduct a study on the new malicious access patterns classified by EASEAndroid and discuss several interesting new findings of attacks in the wild (Section 5.5).

5.1 Environment Setup

We build a prototype of EASEAndroid on an 8-node Hadoop cluster with each node having 8-core Xeon 2GHz, 32 GB memory. We use open source Cloudera Impala as the distributed SQL layer, with 10K SLOC Java as the learning layer. Parallelism is heavily employed for fast analytics. A data set of 1.3 million audit logs used in the following experiments are analyzed by EASEAndroid within 3 hours in a cold start.

5.2 Audit Log & Existing Knowledge

Audit Logs & Existing Policy We make use of 1.3 million audit logs over the entire 2014 from real-world devices running Android 4.3 (See Appendix A about audit log collection). All devices are loaded with an early version of Samsung SEAndroid policy (the policy remained unchanged) in enforcing mode[4]. The policy contains 5,094 `allow` rules and 59 `neverallow` rules developed by policy analysts. This policy is loaded as existing knowledge into EASEAndroid's knowledge base, used by the pattern-to-rule distance measurer.

The audit logs contain a total of over 14 million denied access events. After eliminating duplicate entries, we identify approximately 145K unique access events and further generalize them into 3,530 access patterns. For example, third-party app process ids under `/proc/` are generalized as `/proc/app_pid` in access patterns.

The subjects in the audit logs consist of 113 system (built-in) binaries, 1,182 external binaries (e.g., installed by `adb`), and 626 Android apps, which are captured because they perform system-level operations that do not go through Android framework/Dalvik VM (normal app operations are already allowed by the policy).

Initial Known Malicious Access Patterns In the initial knowledge base, we prepare a small set of known malicious access patterns as the initial seed to kick off learning. The set contains 9 confirmed exploit kits with their 17 malicious access patterns (e.g., psneuter CVE-2011-1149, Motochopper CVE-2013-2596, vroot CVE-2013-6282 and several exploit apps). Note that we do not have known benign access patterns initially as we rely on the `allow` rules in the existing policy.

Ground Truth To analyze the classification result of benign and malicious access patterns, we use a later version of human-written policy (6,337 `allow` rules, 94 `neverallow` rules) as the ground truth. We also consult with experienced policy analysts about the result.

5.3 Coverage & Precision of the Classification by EASEAndroid

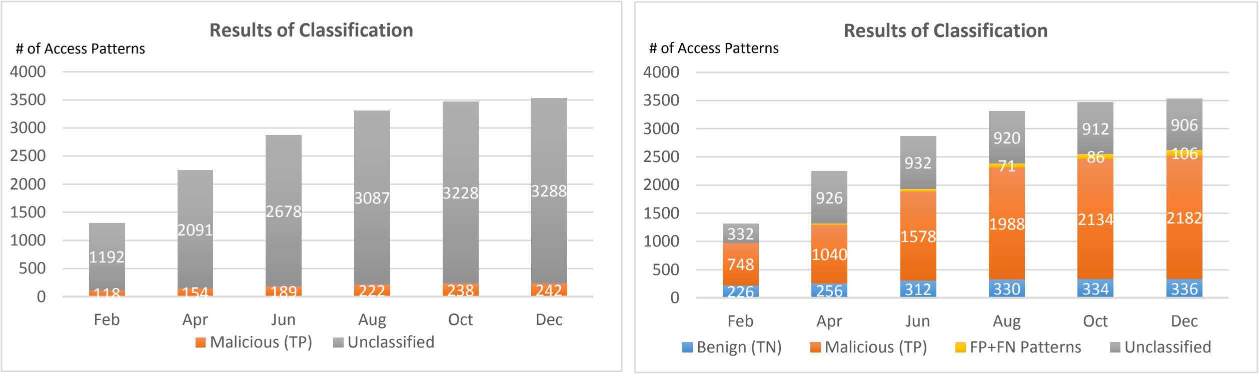
5.3.1 Coverage compared with naive matching

To illustrate the effect of EASEAndroid's learning coverage, we design a *naive matching* tool as a baseline to compare with EASEAndroid learning when both analyzing the same set of new access patterns from the audit logs, as shown in Figure 3. The naive matching tool is a dumb access pattern matching tool with no learning capability. It only uses the known subjects and access patterns in the initial knowledge base and can only match new access patterns directly related to them, based on the subjects and objects in the syscall entries in audit logs. In contrast, EASEAndroid starts from the initial knowledge base and keeps expanding the knowledge base.

As the audit logs are continuously collected over the year, we setup 6 analyses at a rate of every two months. Each analysis takes as input the accumulated audit logs from Jan 2014 to the current month (e.g., "Feb" is 2-month logs, "Apr" is 4-month logs, "Dec" is the entire year's logs). It is a typical scenario of semi-supervised learning with incremental input data. It also follows the nature that new benign/malicious patterns are gradually accumulated in audit logs over time.

As shown in Figure 3, EASEAndroid dramatically outperforms the naive matching in each analysis. As the total number of access pattern keeps increasing, EASEAndroid's coverage reaches about 74% in the final December analysis. EASEAndroid also discovers that the majority of denied access patterns in real world are malicious and they keep emerging while benign access patterns gradually stabilize. In contrast, the coverage of naive matching remains around 7%, because it can only match access patterns related to the initial known ones, the 9 exploit kits, which are updated with a small set of

[4] Some devices are found being rooted and may switch to permissive mode. See Section 5.5



(a) Access patterns matched by naive matching with no learning capability as the baseline. A small set of new malicious patterns are matched related to the 9 exploits since they are updated and keep trying some new malicious patterns over time. But the majority is still unclassified.

(b) Access patterns classified by EASEAndroid starting from the initial knowledge. New patterns classified in each analysis become the incremental knowledge to classify more patterns in the next analysis. Benign patterns get stable over time, while new malicious patterns keep emerging.

Figure 3: The comparison between naive matching and EASEAndroid on analyzing the same set of access patterns

Threshold Setting	Classified Malicious (TP+FP)	Classified Benign (TN+FN)	Remain Unclassified	True Malicious (TP)	False Malicious (FP)	True Benign (TN)	False Benign (FN)
$\sigma = 55\%, Dist \leq 2, c_{ij} > 0.55$	77.2%	14.0%	8.8%	62.96%	37.04%	58.65%	41.35%
$\sigma = 65\%, Dist \leq 1, c_{ij} > 0.65$	70.0%	11.8%	18.2%	88.73%	11.27%	71.35%	28.65%
$\sigma = 75\%, Dist \leq 1, c_{ij} > 0.75$	65.7%	10.9%	23.4%	91.35%	8.65%	88.92%	11.08%

Table 1: The coverage and precision of EASEAndroid with different threshold settings after comparison with ground truth. The first three columns summarize the overall classification coverage over the 3,530 patterns. The following four columns give more details about the percentages of each set of true/false-classified benign and malicious patterns. Row 4 is the threshold setting used in Figure 3(b).

new access patterns over time. But it still leaves the majority unclassified.

Specifically, all three learners of EASEAndroid contribute to the high classification coverage. In the first February analysis, EASEAndroid first matches 118 malicious access patterns, same as naive matching. Then it performs multiple learning iterations with the current audit logs in both automated and semi-automated mode. In summary, in automated mode, the NN classifier finds 282 patterns using threshold $(m,\sigma) = (10,85\%)$ in $IsMajorityKnown$. The pattern-to-rule distance measurer finds 95 patterns using $Dist(ap_i) = 0$ with existing `neverallow` rules. The co-occurrence learner finds 110 patterns with $c_{ij} > 0.85$. In semi-automated mode, we relax the thresholds to (10,75%), $Dist(ap_i) \leq 1$, $c_{ij} > 0.75$, respectively and further find 143 patterns based on the majority vote of the three learners.

As for benign access patterns in the February analysis, since the initial knowledge lacks benign patterns, the pattern-to-rule distance measurer classifies the first 23 benign patterns using $Dist(ap_i) = 0$ with existing `allow` rules and adds them to the knowledge base. Then the three learners contribute the remaining 203 using the same threshold settings.

Due to the strict thresholds, the automated mode classifies access patterns with no false positives or negatives. However, in the semi-automated mode, we do find 34 false-benign (False-Negative[5]) access patterns and the 72 false-malicious (False-Positive) ones in the final December analysis, mainly due to two reasons. First, a small set of access patterns are shared by both privileged benign system binaries and malicious apps with similar occurrences (e.g., both access `/proc/stat`), which make EASEAndroid hard to distinguish with relaxed thresholds. Second, some mis-classified patterns in early analyses affect the learning precision in later ones. In fact, there are only 4 false-malicious patterns in the February analysis. But then the NN classifier uses them to mistakenly find more false-malicious ones in the following analyses. Nevertheless, this limitation of the semi-automated mode is expected. Therefore in practice, the semi-automated mode requires policy analysts to verify the result to avoid error propagation. Analysts can also input extra constraints and knowledge about the access patterns of privileged system binaries to help EASEAndroid increase the precision.

There are still 906 access patterns unclassified in the

[5] We treat malicious as positive, benign as negative.

final analysis due to their low occurrence (less than five days throughout the year). After manual analysis, we find that some access patterns are likely malicious and might be isolated attack attempts in the wild. However, the statistics is too low to reach the threshold. In such cases, we have to wait for more similar access patterns coming in future audit logs. In Section 6, we discuss the limitation that isolated/targeted attacks may evade EASEAndroid's detection if they are not widely spread.

5.3.2 Coverage & precision with different threshold settings

The thresholds for the three learners play an important role on the coverage and the precision of EASEAndroid. In practice, it is important to find a balance between the coverage and the precision. In this section, we further investigate the detailed coverage and precision difference by choosing 5 different threshold settings from very relaxed to very strict as shown in Table 1. The listed threshold settings are for the automated mode. The semi-automated mode is relaxed by reducing 10% on both *IsMajorityKnown* (minimum neighbors unchanged) and c_{ij}, and increasing 1 in $Dist(ap_i)$. The first three columns show the overall percentage (adds to 100%) summarizing the classified malicious and benign and unclassified over the total 3,530 access patterns. The following four columns provide the more detailed TP/FP and TN/FN percentage of classified malicious and benign access patterns.

We can see that the thresholds in Row 1 is largely relaxed. Although it has the highest coverage, both FP (37.04%) and FN (41.35%) are too high, making it practically useless. In contrast, Row 5's thresholds achieve 100% correctness on classifying benign patterns. But it also leaves 37.7% patterns unclassified. The middle 3 rows are more balanced. Row 3 and 4 are candidates for practical use. In practice, analysts can also use multiple thresholds respectively, such as with Row 4 and 5 together, and only need to investigate the diff of their learning results since we have high confidence with the result of Row 5.

Admittedly, each individual threshold for each learner may have a different effect on the final classification result. To analyze more detailed threshold difference, or find an optimal vector of thresholds, a cross-validation [27] can be performed with multiple real-world audit log sets.

5.4 Case Study of Refinement Generation & Comparison with Human Policy

In the last December analysis in Figure 3, the policy refinement generator finally generates 51 new `allow` rules from the 336 benign access patterns, and 280 new `neverallow` rules from the 2,182 malicious access patterns, by extending identified incomplete rules and creating new fine-grained security labels to replace existing coarse-grained ones. In this section, we use the following example as a case study to illustrate the generated refinement.

EASEAndroid classified as benign 9 access patterns that read some time-zone data files under `/data/misc/zoneinfo`. These access patterns are found in multiple Android framework-related binaries (subjects) in `/system/bin`, including `surfaceflinger`,`dhcpcd`,`pppd` and a vendor-specific daemon. In the 6-tuples, the time-zone data files carry `system_data_file`, which is the default label for all files under `/data`. Naively generating a rule with this label (using `audit2allow`) would over-grant the subjects with permissions to access all files under `/data`.

EASEAndroid instead finds that these files all share the same `/data/misc/zoneinfo` file path prefix, and thus derives a new label `zoneinfo_file` specifically for them, adding to the labeling definition `file_contexts`:

```
/data/misc/zoneinfo/.* \
u:object_r:zoneinfo_file:s0
```

In practice, the full path prefix can be transformed into an underscore-joined label to keep the semantics and prevent conflict (though abbreviation may be required). EASEAndroid also creates a new attribute `access_zoneinfo_domain` to group the above subject domains, as the following:

```
attribute access_zoneinfo_domain;
typeattribute surfaceflinger \
access_zoneinfo_domain;...
```

Finally, EASEAndroid generates a new rule based on the new labels defined above:

```
allow access_zoneinfo_domain
zoneinfo_file:file {open read}
```

This rule only covers the 9 patterns observed by EASEAndroid, thus preventing unnecessary accesses being granted, following the least privilege principle.

The rules generated by EASEAndroid for the 336 benign access patterns are compared with human-written rules in the later policy version. Semantically, all access patterns allowed by EASEAndroid rules are also permitted by human-written rules. However, syntactically, EASEAndroid in general creates a larger set of more-specific rules, while human-written rules are more concise with the frequent use of policy `macros`, which ease the policy writing and are expanded during compile time [7]. It may be desirable to aggregate EASEAndroid's more specific rules for better human-readability; this remains for future work.

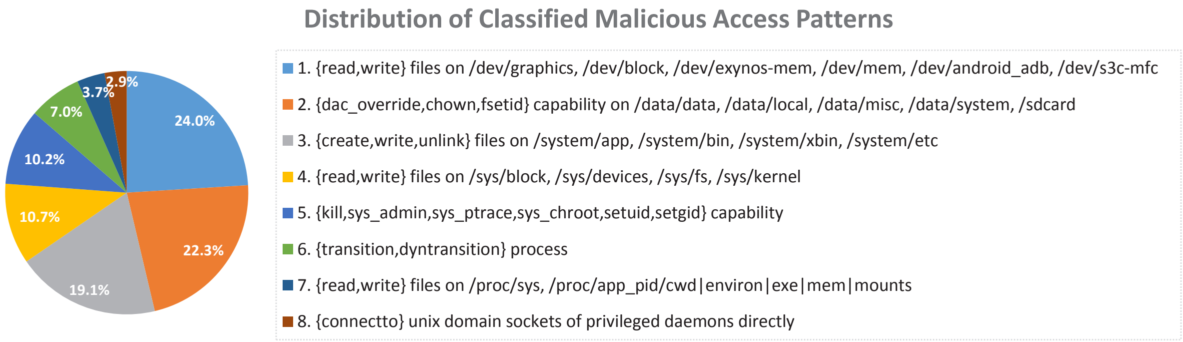

Figure 4: The distribution of malicious access patterns classified by EASEAndroid.

5.5 Case Study of Classified Malicious Access Patterns

For the one-year dataset of audit logs processed by EASEAndroid, 2,182 access patterns are classified as malicious. The reader is reminded that the starting point of analysis is 17 access patterns derived (manually) from 9 confirmed exploit kits. The access patterns newly classified as malicious by EASEAndroid capture malicious behavior much more precisely than has previously been possible. To the best of our knowledge, this is the first large-scale study of system-level malicious access patterns from real-world Android devices.

The subjects in these malicious access patterns are mostly untrusted third-party shell binaries and apps. For the purpose of understanding and discussion, they are categorized based on the permissions [5] (shown in braces) and the objects they accessed, which were mainly privileged files. Figure 4 shows the resulting 8 categories of malicious access patterns, each discussed below. Two of them (modify `/sys/fs/selinux` and `transition` to privileged domains) are new attacks in Android which directly target the SEAndroid MAC mechanism itself.

1. Exploit `/dev` nodes
The most common malicious access patterns are the ones that exploit various vulnerabilities in device nodes under `/dev`. For instance, EASEAndroid found 62 different shell binaries and exploit apps trying to directly read and write `/dev/graphics/*` (exploiting a previously-known framebuffer vulnerability). After identifying these subjects, EASEAndroid further discovered that they bundled various exploits targeting several other device nodes as well (including vendor-specific nodes). Some of these subjects were found to successfully gain root privileges. However, note that a good SEAndroid policy is still able to provide protection even on a rooted device (e.g., even `init` has limited permissions), as long as the Linux kernel is not compromised.[6]

2. Request file-related privileged capabilities
The second most frequent category of malicious access patterns are that subjects try to use privileged capabilities to modify the file mode bits and ownership of various files. This is a classic privilege escalation attack step; external binary files pushed to the device (e.g., in `/data/local/tmp`) may be given unintended capabilities, and important data files (e.g., in `/data/system`) can be made writable for attacks to proceed.

3. Modify `/system` partition
This is also a common step in exploits that the `/system` partition is modified with new binaries added such as `su,busybox`. Normally, the `/system` partition is mounted as read-only. But some subjects were able to remount the partition as writable. However, they were still captured by the audit logs because their domain labels were not allowed to write `system_file` under `/system`.

4. Access `/sys` filesystem
`/sys` is a virtual filesystem that exports kernel-level information to userspace, normally used by privileged system daemons. EASEAndroid found that untrusted subjects also try to directly access `/sys`, particularly `/sys/fs/selinux`, which contains the policy content and runtime state. Untrusted subjects may try to modify the policy content, either to switch to the permissive mode, or to get more permissions. We believe this is a new type of attack directly against SEAndroid MAC mechanism. Although this new attack is expected to emerge, it is still surprising to discover that the new attack has already become popular in the wild.

5. Request process-related privileged capabilities
EASEAndroid also found that some untrusted subjects ask for privileged process capabilities, such as `kill`'ing other processes, or `sys_admin` managing a list of functionalities [5]. The most common example is to use `sys_ptrace` to ptrace another process. This capability is attempted by several third-party management/moni-

[6] Since certain subjects gain root, they may be able to rollback to the permissive mode. The audit logs might just record the malicious access patterns but not actually block them.

tor apps, and game hacking apps (to modify other game apps' score/rewards).

6. Transition to privileged domains
Another new type of attack directly targeting SEAndroid is that untrusted apps try (some succeed) to gain more privileges by transforming their subject domains from `untrusted_app` to domains with higher privileges, including `init,init_shell,system_app`, and vendor daemon domains.[7] Interestingly, this case is found due to the conflict reported by the majority-vote in the semi-automated mode. An access pattern classified as malicious by both the NN classifier and the co-occurrence learner, is classified as benign by the pattern-to-rule distance measurer, because it is close to an `allow` rule. The conflict indicates that the subject carries a wrong domain.

7. Access `/proc` filesystem
Like `/sys`, `/proc` is also frequently accessed, especially by third-party management/monitor apps. Although reading `/proc/app_pid/*` might not be directly damaging, the information can be leveraged as a side-channel to compose attacks [20]. Besides, EASEAndroid also showed that certain apps try to write `/proc/sys/kernel/kptr_restrict` to gain access to the kernel symbol table, a common step in kernel exploits.

8. Connect to Unix sockets of privileged daemons
Unix domain socket is a more complicated case in SEAndroid. By design, some Unix sockets in system daemons such as `adbd,debuggerd` can be connected by apps, while others are reserved only for privileged daemons. EASEAndroid is able to distinguish these two cases, mainly by the co-occurrence learner. It found one new benign access pattern between two vendor daemons and several malicious ones that untrusted apps try to directly connect to Unix sockets of highly privileged daemons, such as `init`.

In summary, with EASEAndroid's learning, we find a group of interesting malicious access patterns and new attacks in Android. EASEAndroid also generates 280 fine-grained `neverallow` rules. 52 rules are found in the later policy. But others still require deeper investigation, since the knowledge learned by current EASEAndroid prototype may not be sufficient to understand the attack mechanisms behind these malicious access patterns.

6 Discussion

Blurred line between benign and malicious In practice, the line between benign and malicious might be blurred and subjective. It depends on specific security requirements and use cases to determine whether an access pattern is really benign or malicious. For example, individual users may like rooting their own devices and using the game hacking apps mentioned above, while game developers treat them as malicious because they bypass the in-app purchase. Nevertheless, EASEAndroid's learning provides more detailed evidence of access patterns' semantics for policy analysts to make the final decision.

Information missed by audit logs EASEAndroid relies on audit logs to learn new access patterns and derive policy refinements. However, two types of information could be missed or not available in audit logs, which can cause EASEAndroid to miss important knowledge. First, by default, audit logs only capture system-level operations that are denied by the policy currently loaded in a device. If the policy is too permissive or has too coarse-grained allow rules, malicious access patterns could be mistakenly allowed and missed by audit logs. To mitigate this issue, policy analysts should use `auditallow` to mark coarse-grained or uncertain rules so that audit logs can capture the operations allowed by these rules for EASEAndroid's analysis.

Second, framework-level operations are not available in audit logs, because they are controlled by Android permission model. But these upper-level operations contain valuable semantics (e.g., attack mechanisms). Without them, it is difficult to explain and distinguish certain benign/malicious access patterns in audit logs. Since Android 5.0, `logcat` is involved in SEAndroid auditing. In future, EASEAndroid can integrate logs from `logcat` to have more semantics in the knowledge base.

Countermeasure against EASEAndroid Similar to tampering virus sampling in AntiVirus programs, attackers can disable or compromise the audit log mechanism (logging and uploading) to avoid malicious access patterns being learned. Currently, we rely on Linux kernel protection [11] to ensure the integrity of audit log mechanism. And we argue that enabling audit log with policy refinement updates is a recommended security service for the majority users to have the latest security protection (or mandatory for enterprise users).

By design, if a malicious access pattern is widely spread and affects a large number of normal users, audit logs can catch the pattern for EASEAndroid to analyze. However, it is possible that isolated or targeted attacks may evade the detection of EASEAndroid if they are not popular enough to reach the thresholds, or deliberately avoid having semantic correlation with known malicious access patterns. In such cases, although EASEAndroid may leave them as unclassified, it still helps narrow down the scope for policy analysts to investigate. And policy analysts can input extra knowledge into EASEAndroid to help increase the coverage and precision.

It is also potentially possible that attackers manipulate the co-occurrence rate by intentionally forcing the be-

[7] Policy analysts suggest that it is also possible that some daemons may have zero-day vulnerabilities that are exploited to run attacks.

nign and malicious patterns to co-occur in one log, such as triggering the benign pattern first and then launching the attack. Such data poisoning attack may fool EASEAndroid's learning, which requires extra constraints or more logs from different devices to dilute the poisoned logs [14].

7 Related Work

Though SEAndroid is fairly new, SELinux has been developed and researched for years, including SELinux policy analysis and verification [10, 23, 36, 42], policy visualization [40], policy conflict resolving [26], policy simplifying [33, 34], policy comparison [19], policy information-flow integrity measurement [22, 24, 25, 37], etc. Also, the above research work usually assumes a relatively complete SELinux policy that has already been well developed. And the analysis usually focuses on stable desktop Linux system or only a few specific application programs (e.g., `sshd,httpd`). Due to the architecture difference, SEAndroid faces different challenges from SELinux, because current SEAndroid policy is still incomplete and under active development and continuous refinement.

In terms of SELinux policy generation, Polgen proposed by MITRE is a tool that guides policy analysts to develop policies based on system call traces [39]. However, it does not have machine learning capability and only focuses on system call traces from a single application program, which is not scalable. Madison proposed by Redhat is an extension of `audit2allow` that can generate policy similar to the reference policy style, such as using `macros` [30]. However, like `audit2allow`, it cannot create new security labels to cover new access patterns.

There is very little SELinux research related to machine learning. Marouf et al. proposed a similar approach to Polgen that analyzes system call traces to simplify SELinux policy [32]. Markowsky et al. proposed an IDS system that uses SELinux denials as input to an SVM classifier to detect attacks [31]. But there is no policy analysis or refinement.

Android SafetyNet [1] is a new security service provided by Google, which includes analyzing SELinux logs collected from Android devices, though no specific technical details about the SELinux log analysis have been disclosed.

8 Conclusion

Developing SEAndroid policies is a non-trivial task. In this paper, we have proposed EASEAndroid, the first SEAndroid audit log analytic platform for automatic policy analysis and refinement. EASEAndroid innovatively applies semi-supervised learning to MAC policy development. It has been evaluated with 1.3 million audit logs from real-world devices. It successfully discovered over 2,500 new benign and malicious access patterns, generated 331 policy rules, and found 2 new attacks in the wild directly targeting SEAndroid MAC mechanism.

A Data Collection Policies

Collection of audit logs used in this research strictly followed the Privacy Policy of Samsung [3], and conformed to the conditions described in Samsung's End User License Agreement [2]. Audit logs were collected anonymously from users who consented to provide diagnostic and usage data to help Samsung improve the quality and the performance of its products and services. Only Samsung authorized employees, using Samsung's internal computer systems, had access to the audit logs. No individual audit log information was released outside of Samsung while conducting the experiments described in this paper.

Marionette: A Programmable Network-Traffic Obfuscation System

Abstract

Recently, a number of obfuscation systems have been developed to aid in censorship circumvention scenarios where encrypted network traffic is filtered. In this paper, we present *Marionette*, the first programmable network traffic obfuscation system capable of simultaneously controlling encrypted traffic features at a variety of levels, including ciphertext formats, stateful protocol semantics, and statistical properties. The behavior of the system is directed by a powerful type of probabilistic automata and specified in a user-friendly domain-specific language, which allows the user to easily adjust their obfuscation strategy to meet the unique needs of their network environment. In fact, the Marionette system is capable of emulating many existing obfuscation systems, and enables developers to explore a breadth of protocols and depth of traffic features that have, so far, been unattainable. We evaluate Marionette through a series of case studies inspired by censor capabilities demonstrated in the real-world and research literature, including passive network monitors, stateful proxies, and active probing. The results of our experiments not only show that Marionette provides outstanding flexibility and control over traffic features, but it is also capable of achieving throughput of up to 6.7Mbps when generating RFC-compliant cover traffic.

1 Introduction

Many countries have begun to view encrypted network services as a threat to the enforcement of information control and security policies. China [41] and Iran [7] are well-known for their efforts to block encrypted services like Tor [14], while other countries, such as the United Kingdom [18], have begun to express interest in blocking VPNs and anonymity systems. These discriminatory routing policies are empowered by analyzing traffic at both the network layer (e.g. TCP/IP headers) and, more recently, the application layer. The latter looks for specific features of packet payloads that act as a signature for the application-layer protocol being transported.

To combat application-layer filtering, several systems have been proposed to obfuscate packet payloads, and generally hide the true protocol being transported. Broadly speaking, these methods fall into one of three categories: those that use encryption to fully randomize the messages sent (e.g., obfs4 [34], ScrambleSuit [42], Dust [40]); those that tunnel traffic using existing software artifacts (e.g., FreeWave [21], Facet [24]); and those that use encryption in combination with some lightweight ciphertext formatting to make the traffic mimic an allowed protocol (e.g., FTE [15], StegoTorus [38]). A few of these systems have been deployed and are currently used by more comprehensive circumvention systems, such as Lantern [1], uProxy [5], and Tor [14].

Despite the progress these obfuscation systems represent, each of them suffers from one or more shortcomings that severely limit their ability to adapt to new network environments or censorship strategies. Lightweight obfuscation methods based on randomization fail in situations where protocol whitelisting is applied, as in the recent Iranian elections [13]. Tunneling systems are intimately tied to a specific protocol that may not always be permitted within the restrictive network environment, such as the case of Skype in Ethiopia [27]. Protocol-mimicry systems really only aim to mimic *individual* protocol messages, and therefore fail to traverse proxies that enforce stateful protocol semantics (e.g., Squid [39]) . Moreover, these systems can be quite brittle in the face of proxies that alter protocol messages in transit (e.g., altering message headers can render FTE [15] inoperable). In any case, all of the systems are incapable of changing their target protocol or traffic features without heavy system re-engineering and redeployment of code. This is a huge undertaking in censored networks.

	Message	**Stateful**	**Multi-layer**	**Traffic**	**Active**		**Goodput**
Case Study	**Content**	**Behavior**	**Control**	**Statistics**	**Probing**	**Protocol(s)**	**(Down/Up)**
Regex-Based DPI	✓	-	-	-	-	HTTP, SSH, SMB	68.2 / 68.2 Mbps
Proxy Traversal	✓	✓	-	-	-	HTTP	5.8 / 0.41 Mbps
Protocol Compliance	✓	✓	✓	-	-	FTP, POP3	6.6 / 6.7 Mbps
Traffic Analysis	✓	✓	✓	✓	-	HTTP	0.45 / 0.32 Mbps
Active Probing	✓	✓	✓	-	✓	HTTP, FTP, SSH	6.6 / 6.7 Mbps

Figure 1: Summary of Marionette case studies illustrating breadth of protocols and depth of feature control.

The Marionette System. To address these shortcomings, we develop the Marionette system. Marionette is a network-traffic obfuscation system that empowers users to rapidly explore a rich design space, without the need to deploy new code or re-design the underlying system.

The conceptual foundation of Marionette is a powerful kind of probabilistic automaton, loosely inspired by probabilistic input/output automata [45]. We use these to enforce (probabilistic) sequencing of individual ciphertext message types. Each transition between automata states has an associated block of actions to perform, such as encrypting and formatting a message, sampling from a distribution, or spawning other automata to support hierarchical composition. By composing automata, we achieve even more comprehensive control over mimicked protocol behaviors (e.g., multiple dependent channels) and statistical features of traffic. In addition, the automata admit distinguished error states, thereby providing an explicit mechanism for handling active attacks, such as censor-initiated "probing attacks."

At the level of individual ciphertext formats, we introduce another novel abstraction that supports fine-grained control. These *template grammars* are probabilistic context-free grammars (CFG) that compactly describes a language of templates for ciphertexts. Templates are strings that contain placeholder tokens, marking the positions where information (e.g., encrypted data bytes, dates, content-length values) may be embedded by user-specified routines. Adopting a CFG to describe templates has several benefits, including ease of deployment due to their compact representation, ability to directly translate grammars from available RFCs, and use of the grammar in receiver-side parsing tasks.

Everything is specified in a user-friendly domain-specific language (DSL), which enables rapid development and testing of new obfuscation strategies that are robust and responsive to future network monitoring tools. To encourage adoption and use of Marionette it has been made available as free and open source software[1].

Case studies. To display what is possible with Marionette, we provide several case studies that are inspired by recent research literature and real-world censor capabilities. These are summarized in Figure 1. For one example, we show that Marionette can implement passive-mode FTP by spawning multiple models that control interdependent TCP connections. For another, we use Marionette to mimic HTTP with enforced protocol semantics and resilience to message alteration, thereby successfully traversing HTTP proxies.

Our studies show that Marionette is capable of implementing a range of application-layer protocols, from HTTP to POP3, while also providing great depth in the range of traffic features it controls. Most importantly, it maintains this flexibility without unduly sacrificing performance – achieving up to 6.7Mbps while still maintaining fully RFC-compliant protocol semantics. We also show that the system performance is network-bound, and directly related to the constraints of the Marionette format being used.

Security Considerations. While our case studies are motivated by well-known types of adversaries, we avoid a formal security analysis of our framework for two reasons. First, the security of the system is intimately tied to the automata and template grammars specified by the user, as well as how the chosen protocols and features interact with the adversary. Second, any principled security analysis requires a generally accepted adversarial model. At the moment, the capabilities of adversaries in this space are poorly understood, and there are no formalized security goals to target. With that said, we believe our case studies represent a diverse sample of adversaries known to exist in practice, and hope that the flexibility of our system allows it to adapt to new adversaries faced in deployment. More fully understanding the limits of our system, and the adversaries it may face, is left for future work.

2 Related Work

In this section, we discuss previous work in the area of obfuscation and mimicry of application-layer protocols, as well as their common ancestry with network traffic generation research. The majority of systems aiming to avoid application-layer filtering are *non-programmable*, in the sense that they adopt one strategy at design-time

Figure 2: A comparison of features across randomization, mimicry, tunneling, and programmable obfuscation systems. A “✓" in the first four columns mean the system is appropriate for the indicated type of monitoring device; in the last two, it means that the system has the listed property. Multi-layer control is the ability to control features beyond single, independent connections. High-throughput systems are defined as any system capable of > 1Mbps throughput. Both FTE and Marionette can trade throughput for control over ciphertext traffic features.

and it cannot be changed without a major overhaul of the system and subsequent re-deployment. The non-programmable systems can be further subdivided into three categories based on their strategy: randomization, mimicry, or tunneling. A *programmable* system, however, allows for a variety of dynamically applied strategies, both randomization and mimicry-based, without the need for changes to the underlying software. Figure 2 presents a comparison of the available systems in each category, and we discuss each of them below. For those interested in a broader survey of circumvention and obfuscation technologies, we suggest recent work by Khattak et al. that discusses the space in greater detail [23].

Network Traffic Generation. Before beginning our discussion of obfuscation systems, it is important to point out the connection that they share with the broader area of network traffic generation. Most traffic generation systems focus on simple replay of captured network sessions [33, 19], replay with limited levels of message content synthesis [12, 31], generation of traffic mixes with specific statistical properties and static content [10, 37], or heavyweight emulation of user behavior with applications in virtualized environments [43]. As we will see, many mimicry and tunneling systems share similar strategies with the the key difference that they must also transport useful information to circumvent filtering.

Randomization. For systems implementing the randomization approach, the primary goal is to remove all static fingerprints in the content and statistical characteristics of the connection, effectively making the traffic look like “nothing.” The obfs2 and obfs3 [34] protocols were the first to implement this approach by re-encrypting standard Tor traffic with a stream cipher, thereby removing all indications of the underlying protocol from the content. Recently, improvements on this approach were proposed in the ScrambleSuit system [42] and obfs4 protocol [34], which implement similar content randomization, but also randomize the distribution of packet sizes and inter-arrival times to bypass both DPI and traffic analysis strategies implemented by the censor. The Dust system [40] also offers both content and statistical randomization, but does so on a per-packet, rather than per-connection basis. While these approaches provide fast and efficient obfuscation of the traffic, they only work in environments that block specific types of known-bad traffic (i.e., blacklists). In cases where a whitelist strategy is used to allow known-good protocols, these randomization approaches fail to bypass filtering, as was demonstrated during recent elections in Iran [13].

Mimicry. Another popular approach is to mimic certain characteristics of popular protocols, such as HTTP or Skype, so that blocking traffic with those characteristics would result in significant collateral damage. Mimicry-based systems typically perform shallow mimicry of only a protocol’s messages or the statistical properties of a single connection. As an example, StegoTorus [38] embeds data into the headers and payloads of a fixed set of previously collected HTTP messages, using various steganographic techniques. However, this provides no mechanism to control statistical properties, beyond what replaying of the filled-in message templates achieves. SkypeMorph [26], on the other hand, relies on the fact that Skype traffic is encrypted and focuses primarily on replicating the statistical features of packet sizes and timing. Ideally, these mimicked protocols would easily blend into the background traffic of the network, however research has shown that mimicked protocols can be distinguished from real versions of the same protocol using protocol semantics, dependencies among connections, and error conditions [20, 17]. In addition, they incur sometimes significant amounts of overhead due to the constraints of the content or statistical mimicry, which makes them much slower than randomization approaches.

Tunneling. Like mimicry-based systems, tunneling approaches rely on potential collateral damage caused by blocking popular protocols to avoid filtering. However, these systems tunnel their data in the payload of real instances of the target protocols. The Freewave [21] system, for example, uses Skype's voice channel to encode data, while Facet [24] uses the Skype video channel, SWEET [47] uses the body of email messages, and JumpBox [25] uses web browsers and live web servers. CensorSpoofer [36] also tunnels data over existing protocols, but uses a low-capacity email channel for upstream messages and a high-capacity VoIP channel for downstream. CloudTransport [8] uses a slightly different approach by tunneling data over critical (and consequently unblockable) cloud storage services, like Amazon S3, rather than a particular protocol. The tunneling-based systems have the advantage of using real implementations of their target protocols that naturally replicate all protocol semantics and other distinctive behaviors, and so they are much harder to distinguish. Even with this advantage, however, there are still cases where the tunneled data causes tell-tale changes to the protocol's behavior [17] or to the overall traffic mix through skewed bandwidth consumption. In general, tunneling approaches incur even more overhead than shallow mimicry systems since they are limited by the (low) capacity of the tunneling protocols.

Programmable Systems. Finally, programmable obfuscation systems combine the benefits of both randomization and mimicry-based systems by allowing the system to be configured to accommodate either strategy. Currently, the only system to implement programmable obfuscation is Format-Transforming Encryption (FTE) [15], which transforms encrypted data into a format dictated by a regular expression provided by the user. The approach has been demonstrated to have both high throughput and the ability to mimic a broad range of application-layer protocols, including randomized content. Unfortunately, FTE only focuses on altering the content of the application-layer messages, and not statistical properties, protocol semantics, or other potentially distinguishing traffic features.

Comparison with Marionette. Overall, each of these systems suffers from a common set of problems that we address with Marionette. For one, these systems, with the exception of FTE, force the user to choose a single target protocol to mimic without regard to the user's throughput needs, network restrictions, and background traffic mix. Moreover, many of the systems focus on only a fixed set of traffic features to control, usually only content and statical features of a single connection. In those cases where tunneling is used, the overhead and latency incurred often renders the channel virtually unusable for many common use cases, such as video streaming. The primary goal of Marionette, therefore, is not to develop a system that implements a single obfuscation method to defeat all possible censor strategies, but instead to provide the user with the ability to choose the obfuscation method that best fits their use case in terms of breadth of target protocols, depth of controlled traffic features, and overall network throughput.

3 Models and Actions

We aim for a system that enables broad control over several traffic properties, not just those of individual application-layer protocol messages. These properties may require that the system maintain some level of state about the interaction to enforce protocols semantics, or allow for non-deterministic behavior to match distributions of message size and timing. A natural approach to efficiently model this sort of stateful and nondeterministic system is a special type of probabilistic state machine, which we find to be well-suited to our needs and flexible enough to support a wide range of design approaches.

Marionette models. A *Marionette model* (or just model, for short) is a tuple $M = (Q, Q_{\rm nrm}, Q_{\rm err}, C, \Delta)$. The *state* set $Q = Q_{\rm nrm} \cup Q_{\rm err}$, where $Q_{\rm nrm}$ is the set of *normal states*, $Q_{\rm err}$ is the set of *error states*, and $Q_{\rm nrm} \cap Q_{\rm err} = \emptyset$. We assume that $Q_{\rm nrm}$ contains a distinguished start state, and that at least one of $Q_{\rm nrm}, Q_{\rm err}$ contains a distinguished finish state. The set C is the set of *actions*, which are (potentially) randomized algorithms. A string $\mathcal{B} = f_1 f_2 \cdots f_n \in C^*$ is called an *action-block*, and it defines a sequence of actions. Finally, Δ is a transition relation $\Delta \subseteq Q \times C^* \times (\mathsf{dist}(Q_{\rm nrm}) \cup \emptyset) \times \mathbb{P}(Q_{\rm err})$ where $\mathsf{dist}(X)$ the set of distributions over a set X, and $\mathbb{P}(X)$ is the powerset of X. The roles of $Q_{\rm nrm}$ and $Q_{\rm err}$ will be made clear shortly.

A tuple $(s, \mathcal{B}, (\mu_{\rm nrm}, S)) \in \Delta$ is interpreted as follows. When M is in state s, the action-block $\mathcal{B}$ may be executed and, upon completion, one samples a state $s'_{\rm nrm} \in Q_{\rm nrm}$ (according to distribution $\mu_{\rm nrm} \in$

$\mathsf{dist}(Q_{\mathrm{nrm}}))$. If the action-block fails, then an error state is chosen non-deterministically from S. Therefore, $\{s'_{\mathrm{nrm}}\} \cup S$ is the set of valid next states, and in this way our models have both proper probabilistic and non-deterministic choice, as in probabilistic input/output automata [45]. When $(s, \mathcal{B}, (\mu_{\mathrm{nrm}}, \emptyset)) \in \Delta$, then only transitions to states in Q_{nrm} are possible, and similarly for $(s, \mathcal{B}, (\emptyset, S))$ with transitions to states in Q_{err}.

In practice, normal states will be states of the model that are reached under normal, correct operation of the system. Error states are reached with the system detects an operational error, which may or may not be caused by an active adversary. For us, it will typically be the case that the results of the action-block $\mathcal{B}$ determine whether or not the system is operating normally or is in error, thus which of the possible next states is correct.

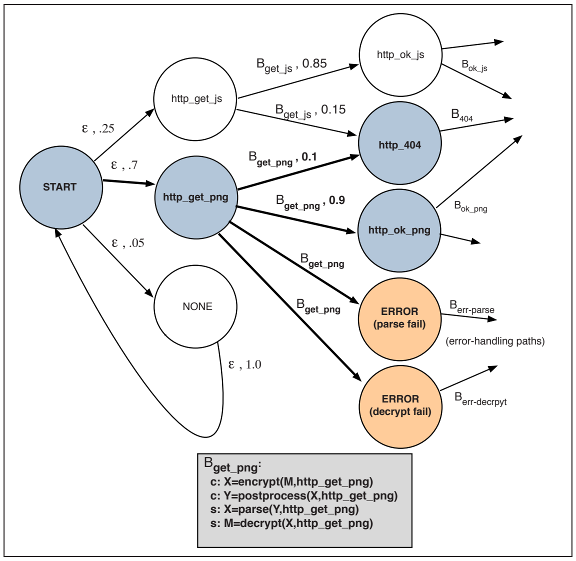

Figure 3: A partial graphical representation of a Marionette model for an HTTP exchange. (Transitions between http_get_js and error states dropped to avoid clutter.) The text discusses paths marked with bold arrows; normal states on these are blue, error states are orange.

Discussion. Marionette models support a broad variety of uses. One is to capture the intended state of a channel between two communicating parties (i.e., what message the channel should be holding at a given point in time). Such a model serves at least two related purposes. First, it serves to drive the implementation of procedures for either side of the channel. Second, it describes what a passive adversary would see (given implementations that realize the model), and gives the communicating parties some defense against active adversaries. The model tells a receiving party exactly what types of messages may be received next; receiving any other type of message (i.e., observing an invalid next channel state) provides a signal to commence error handling, or defensive measures.

Consider the partial model in Figure 3 for an exchange of ciphertexts that mimic various types of HTTP messages. The states of this model represent effective states of the shared channel (i.e., what message type is to appear next on the channel). Let us refer to the first-sender as the client, and the first-receiver as the server. In the beginning, both client and server are in the start state. The client moves to state http_get_js with probability 0.25, state http_get_png with probability 0.7, and state NONE with probability 0.05. In transitioning to any of these states, the empty action-block is executed (denoted by ε), meaning there are no actions on the transition. Note that, at this point, the server knows only the set $\{$http_get_js, http_get_png, NONE$\}$ of valid states and the probabilities with which they are selected.

Say that the client moves to state http_get_png, thus the message that should be placed on the channel is to be of the http_get_png type. The action-block $\mathcal{B}_{\textsf{get\_png}}$ gives the set of actions to be carried out in order to affect this. We have annotated the actions with "c:" and "s:" to make it clear which meant to be executed by the client and which are meant to be executed by the server, respectively. The client is to encrypt a message M using the parameters associated to the handle http_get_png, and then apply any necessary post-processing in order to produce the (ciphertext) message Y for sending. The server, is meant to parse the received Y (e.g. to undo whatever was done by the post-processing), and then to decrypt the result.

If parsing and decrypting succeed at the server, then it knows that the state selected by the client was http_get_png and, hence, that it should enter http_404 with probability 0.1, or http_ok_png with probability 0.9. If parsing fails at the server (i.e. the server action parse(Y,http_get_png) in action block $\mathcal{B}_{\textsf{get\_png}}$ fails) then the server must enter state ERROR (parse fail). If parsing succeeds but decryption fails (i.e., the server action decrypt(X,http_get_png) in action block $\mathcal{B}_{\textsf{get\_png}}$ fails) then the server must enter state ERROR (decrypt fail). At this point, it is the client who must keep alive a front of potential next states, namely the four just mentioned (error states are shaded orange in the figure). Whichever state the server chooses, the associated action-block is executed and progress through the model continues until it reaches the specified finish state.

Models provide a useful design abstraction for specifying allowable sequencings of ciphertext messages, as well as the particular actions that the communicating parties should realize in moving from message to message (e.g., encrypt or decrypt according to a particular ciphertext format). In practice, we do not expect sender and receiver instantiations of a given model will be identical. For example, probabilistic or nondeterministic choices made by the sender-side instantiation of a model (i.e., which transition was just followed) will need to be "determinized" by the receiver-side instantiation. This determinization process may need mechanisms to handle ambiguity. In Section 7 we will consider concrete specifications of models.

4 Templates and Template Grammars

In an effort to allow fined-grained control over the format of individual ciphertexts on the wire, we introduce the ideas of ciphertext-format templates, and grammars for creating them. *Templates* are, essentially, partially specified ciphertext strings. The unspecified portions are marked by special placeholders, and each placeholder will ultimately be replaced by an appropriate string, (e.g., a string representing a date, a hexadecimal value representing a color, a URL of a certain depth). To compactly represent a large set of these templates, we will use a probabilistic context-free grammar. Typically, a grammar will create templates sharing a common motif, such as HTTP request messages or CSS files.

Template Grammars. A template grammar $G = (V, \Sigma, R, S, p)$ is a probabilisitic CFG, and we refer to strings $T \in L(G)$ as templates. The set V is the set of non-terminals, and $S \in V$ is the starting non-terminal. The set $\Sigma = \overline{\Sigma} \cup P$ consists of two disjoint sets of symbols: $\overline{\Sigma}$ are the *base terminals*, and P is a set of *placeholder terminals* (or just placeholders). Collectively, we refer to Σ as template terminals. The set of rules R consists of pairs $(v, \beta) \in V \times (V \cup \Sigma)^*$, and we will sometimes adopt the standard notation $v \to \beta$ for these. Finally, the mapping $p\colon R \to (0, 1]$ associates to each rule a probability. We require that the sum of values $p(v, \cdot)$ for a fixed $v \in V$ and any second component is equal to one. For simplicity, we have assumed all probabilities are non-zero. The mapping p supports a method for sampling templates from $L(G)$. Namely, beginning with S, carry out a leftmost derivation and sample among the possible productions for a given rule according to the specified distribution.

Template grammars produce templates, but it is not templates that we place on the wire. Instead, a template T serves to define a set of strings in Σ^*, all of which share the same template-enforced structure. To produce these strings, each placeholder $\gamma \in P$ has associated to it a *handler*. Formally, a handler is a algorithm that takes as inputs a template $T \in \Sigma^*$ and (optionally) a bit string $c \in \{0, 1\}^*$, and outputs a string in Σ^* or the distinguished symbol $\perp$, which denotes error. A handler for γ scans T and, upon reading γ, computes a string in $s \in \Sigma^*$ and replaces γ with s. The handler halts upon reaching the end of T, and returns the new string T' that is T but will all occurrences of γ replaced. If a placeholder γ is to be replaced with a string from a particular set (say a dictionary of fixed strings, or an element of a regular language described by some regular expression), we assume the restrictions are built into the handler.

As an example, consider the following (overly simple) production rules that could be a subset of a context-free grammar for HTTP requests/responses.

$$\begin{array}{rcl} \langle\text{header}\rangle & \to & \langle\text{date\_prop}\rangle\text{: }\langle\text{date\_val}\rangle\texttt{\textbackslash r\textbackslash n} \\ & & \mid \langle\text{cookie\_prop}\rangle\text{: }\langle\text{cookie\_val}\rangle\texttt{\textbackslash r\textbackslash n} \\ \langle\text{date\_prop}\rangle & \to & \texttt{Date} \\ \langle\text{cookie\_prop}\rangle & \to & \texttt{Cookie} \\ \langle\text{date\_val}\rangle & \to & \gamma_{\text{date}} \\ \langle\text{cookie\_val}\rangle & \to & \gamma_{\text{cookie}} \end{array}$$

To handle our placeholders γ_{date} and γ_{cookie}, we might replace the former with the result of FTE["(Jan|Feb|...")], and the latter with the result of running FTE["([a-zA-Z...)"]. In this example our FTE-based handlers are responsible for replacing the placeholder with a ciphertext that is in the language of its input regular expression. To recover the data we parse the string according to the the template grammar rules, processing terminals in the resultant parse tree that correspond to placeholders.

5 System Architecture

In Section 3 we described how a Marionette model can be used to capture stateful and probabilistic communications between two parties. The notion of abstract actions (and action-blocks) gives us a way to use models generatively, too. In this section, we give a high-level description of an architecture that supports this use, so that we may transport arbitrary datastreams via ciphertexts that adhere to our models. We will discuss certain aspects of our design in detail in subsequent sections. Figure **??** provides a diagram of this client-server proxy architecture. In addition to models, this architecture consists of the following components:

- The client-side *driver* runs the main event loop, instantiates models (from a model specification file, see Section 6.3), and destructs them when they have reached the end of their execution. The complimentary receiver-side *broker* is responsible for listening to incoming connections and constructing and destructing models.

- *Plugins* are the mechanism that allow user-specified actions to be invoked in action-blocks. We discuss plugins in greater detail in Section 6.2.

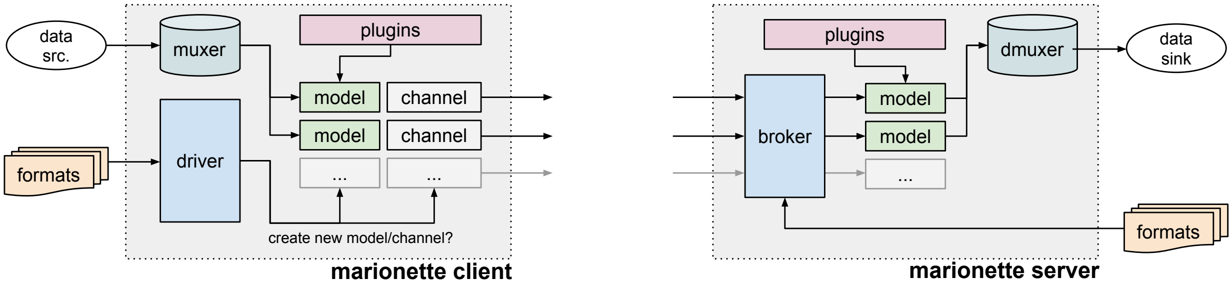

Figure 4: A high-level diagram of the Marionette client-server architecture and its major components for the client-server stream of communications in the Marionette system.

- The client-side *multiplexer* is an interface that allows plugins to serialize incoming datastreams into bitstrings of precise lengths, to be encoded into messages via plugins. The receiver-side *demultiplexer* parses and deserializes streams of cells to recover the underlying datastream. We discuss the implementation details of our (de)multiplexer in Section 6.1.

- A *channel* is a logical construct that connects Marionette models to real-world (e.g., TCP) data connections, and represents the communications between a specific pair of Marionette models. We note that, over the course of a channel's lifetime, it may be associated with multiple real-world connections.

Let's start by discussing how data traverses the components of a Marionette system. A datastream's first point of contact with the system is the incoming multiplexer, where it enters a FIFO buffer. Then a driver invokes a model that, in turn, invokes a plugin that wants to encode n bits of data into a message. Note that if the FIFO buffer is empty, the multiplexer returns a string that contains no payload data and is padded to n bits. The resultant message produced by the plugin is then relayed to the server. Server-side, the broker attempts to dispatch the received message to a model. There are three possible outcomes when the broker dispatches the message: (1) an active model is able to process it, (2) a new model needs to be spawned, or (3) an error has occurred and the message cannot be processed. In case 1 or 2, the cell is forwarded to the demultiplexer, and onward to its ultimate destination. In case 3, the server enters an error state for that message, where it can respond to a non-Marionette connection. We also note that the Marionette system can, in fact, operate with some of its components disabled. As an example, by disabling the multiplexer/demultiplexer we have a traffic generation system that doesn't carry actual data payloads, but generates traffic that abides by our model(s). This shows that there's a clear decoupling of our two main system features: control over cover traffic and relaying datastreams.

6 Implementation

Our implementation of Marionette consists of two command line applications, a client and server, which share a common codebase, and differ only in how they interpret a model. (e.g., initiate connection vs. receive connection) Given a model and its current state, each party determines the set of valid transitions and selects one according to the model's transition probabilities. In cases where normal transitions and error transitions are both valid, the normal transitions are preferred.

Our prototype of Marionette is written in roughly three thousand lines of Python code. All source code and engineering details are available as free and open-source software[2]. In this section, we will provide an overview of some of the major engineering obstacles we overcame to realize Marionette.

6.1 Record Layer

First, we will briefly describe the Marionette record layer and its objectives and design. Our record layer aims to achieve three goals: (1) enable multiplexing and reliability of multiple, simultaneous datastreams, (2) aid Marionette in negotiating and initializing models, and (3) provide privacy and authenticity of payload data. We implement the record layer using variable-length *cells*, as depicted in Figure 5, that are relayed between the client and server. In this section, we will walk through each of our goals and discuss how our record layer achieves them.

Multiplexing of datastreams. Our goal is to enable reliability and in-order delivery of datastreams that we tunnel through the Marionette system. If multiple streams are multiplexed over a single marionette channel, it must be capable of segmenting these streams. We achieve this by including a *datastream ID* and *datastream sequence number* in each cell, as depicted in Figure 5. Sender side, these values are populated at the time of the cell

[2] `https://github.com/kpdyer/marionette`

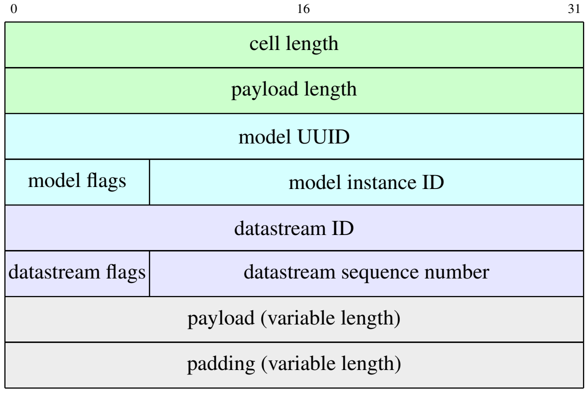

Figure 5: Format of the plaintext Marionette record layer cell.

creation. Receiver side, these values used to reassemble streams and delegate them to the appropriate data sink. The *datastream flags* field may have the value of OPEN, RELAY or CLOSE, to indicate the state of the datastream.

Negotiation and initialization of Marionette models. Upon accepting an incoming message, a Marionette receiver iterates through all transitions from the given model's start state. If one of the action blocks for a transition is successful, the underlying record layer (Figure 5) is recovered and then processed. The *model flags* field, in Figure 5, may have three values: START, RUNNING, or END. A START value is set when this is the first cell transmitted by this model, otherwise the value is set to RELAY until the final transmission of the model where an END is sent. The *model UUID* field is a global identifier that uniquely identifies the model that transmitted the message. The *model instance ID* is used to uniquely identify the instance of the model that relayed the cell from amongst all currently running instances of the model.

For practical purposes, in our proof of concept, we assume that a Marionette instance ID is created by either the client or server, but not both. By convention, the party that sends the first information-carrying message (i.e., first-sender) initiates the instance ID. Once established, the model instance ID has two potential uses. In settings where we have a proxy between the Marionette client and server, the instance ID can be used to determine the model that originated a message despite multiplexing performed by the proxy. In other settings, the instance ID can be used to enhance performance and seed a random number generator for shared randomness between the client and server.

Encryption of the cell. We encrypt each record-layer cell M using a slightly modified encrypt-then-MAC authenticated encryption scheme, namely $C = \mathsf{AES}_{K1}(\mathrm{IV}_1 \| \langle |M| \rangle) \| \mathsf{CTR}[\mathsf{AES}]^{\mathrm{IV}_2}_{K_1}(M) \| T$, where $\mathrm{IV}_1 = 0 \| R$ and $\mathrm{IV}_2 = 1 \| R$ for per-message random R. The first component of the encrypted record is a header. Here we use AES with key $K1$ to encrypt IV_1 along with an encoding of the length of M[3]. The second component is the record body, which is the counter-mode encryption of M under IV_2 and key $K1$, using AES as the underlying blockcipher[4]. Note that CTR can be length-preserving, not sending IV_2 as part of its output, because IV_2 is recoverable from IV_1. The third and component is an authentication tag T resulting from running $\mathsf{HMAC\text{-}SHA256}_{K2}$ over the entire record header and record body. One decrypts in the standard manner for encrypt-then-MAC.

6.2 Plugins

User-specified plugins are used to execute actions described in each model's action blocks. A plugin is called by the Marionette system with four parameters: the current channel, global variables shared across all active models, local variables scoped to our specific model, and the input parameters for this specific plugin (e.g., the FTE regex or the template grammar). It is the job of the plugin to attempt its action given the input parameters. By using global and local dictionaries, plugins can maintain long-term state and even enable message passing between models. We place few restrictions on plugins, however we do require that if a plugin fails (e.g., couldn't receive a message) it must return a failure flag and revert any changes it made when attempting to perform the action. Meanwhile, if it encounters a fatal error (e.g., channel is unexpectedly closed) then it must throw an exception.

To enable multi-level models, we provide a *spawn* plugin that can be used to spawn new model instances. In addition, we provide *puts* and *gets* for the purpose of transmitting static strings. As one example, this can be used to transmit a static, non-information carrying banner to emulate an FTP server. In addition, we implemented FTE and template grammars (Section 4) as our primary message-level plugins. Each plugin has a synchronous (i.e., blocking) and asynchronous (i.e., non-blocking) implementation. The FTE plugin is a wrapper around the FTE[5] and regex2dfa[6] libraries used by the Tor Project for FTE [15].

[3] One could also use the cell-length field in place of $\langle |M| \rangle$.

[4] Since $\mathrm{IV}_1 \neq \mathrm{IV}_2$ we enforce domain separation between the uses of AES_{K1}. Without this we would need an extra key.

6.3 The Marionette DSL

Finally, we present a domain-specific language that can be used to compactly describe Marionette models. We refer to the formats that are created using this language as *Marionette model specifications* or *model specifications* for short. Figure 6 shows the Marionette modeling language syntax.

We have two primary, logical blocks in the model specification. The `connection` block is responsible for establishing model states, actions blocks that are executed upon a transition, and transition probabilities. An `error` transition may be specified for each state and is taken if all other potential transitions encounter a fatal error. The `action` block is responsible for defining a set of actions, which is a line for each party (client or server) and the plugin the party should execute. Let's illustrate the Marionette language by considering the following example.

```
connection([connection_type]):
    start [dst] [block_name] [prob | error]
    [src] [dst] [block_name] [prob | error]
    ...
    [src]  end  [block_name] [prob | error]

action [block_name]:
    [client | server] plugin(arg1, arg2, ...)
    ...
```

```
connection(tcp, 80):
    start         http_get_js   NULL    0.25
    start         http_get_png  NULL    0.7
    http_get_png  http_404      get_png 0.1
    http_get_png  http_ok_png   get_png 0.9
    http_ok_png   ...

action get_png:
    client fte.send("GET /\w+ HTTP/1\.1...")

action ok_png:
    server fte.send("HTTP/1\.1 200 OK...")

...
```

Figure 6: **Top:** The Marionette DSL. The connection block is responsible for establishing the Marionette model, its states and transitions probabilities. Optionally, the `connection_type` parameter specifies the type of channel that will be used for the model. **Bottom:** The partial model specification that implements the model from Figure 3.

Example: Simple HTTP model specification. Recall the model in Figure 3, which (partially) captures an HTTP connection where the first client-server message is an HTTP get for a JS or PNG file. Translating the diagram into our Marionette language is a straightforward process. First, we establish our connection block and specify `tcp` and port `80` — the server listens on this port and the client connects to it. For each transition we create an entry in our connection block. As an example, we added a transition between the `http_get_png` and `http_404` state with probability 0.1. For this transition we execute the `get_png` action block. We repeat this process for all transitions in the model ensuring that we have the appropriate action block for each transition.

For each action block we use synchronous FTE. One party is sending, one is receiving, and neither party can advance to the next state until the action successfully completes. Marionette transparently handles the opening and closing of the underlying TCP connection.

7 Case Studies

We evaluate the Marionette implementation described in Section 6 by building model specifications for a breadth of scenarios: protocol misidentification against regex-based DPI, protocol compliance for complex stateful protocols, traversal of proxy systems that actively manipulate Marionette messages, controlling statistical features of traffic, and responding to network scanners. We then conclude this section with a performance analysis of the formats considered.

For each case study, we analyze the performance of Marionette for the given model specification using our testbed. In our testbed, we deployed our Marionette client and server on Amazon Web Services m3.2xlarge instances, in the us-west (Oregon) and us-east (N. Virginia) zones, respectively. These instances include 8 virtual CPUs based on the Xeon E5-2670 v2 (Ivy Bridge) processor at 2.5GHz and 30GB of memory. The average round-trip latency between the client and server was 75ms. Downstream and upstream *goodput* was measured by transmitting a 1MB file, and averaged across 100 trials. Due to space constraints we omit the full model specifications used in our experiments, but note that each of these specifications is available with the Marionette source code[7].

7.1 Regex-Based DPI

As our first case study, we confirm that Marionette is able to generate traffic that is misclassified by regex-based DPI as a target protocol of our choosing. We are reproducing the tests from [15], using the regular expressions referred to as *manual-http*, *manual-ssh* and *manual-smb* in order to provide a baseline for the performance of the Marionette system under the simplest of specifications. Using these regular expressions, we engineered a Mari-

[7] `https://github.com/kpdyer/marionette`

	Misclassification	
Target Protocol	**bro [28]**	**YAF [22]**
HTTP (manual-http from [15])	100%	100%
SSH (manual-ssh from [15])	100%	100%
SMB (manual-smb from [15])	100%	100%

Figure 7: Summary of misclassification using existing FTE formats for HTTP, SSH, and SMB.

onette model that invokes the non-blocking implementation of our FTE plugins.

For each configuration we generated 100 datastreams in our testbed and classified this traffic using bro [28] (version 2.3.2) and YAF [22] (version 2.7.1.) We considered it a success if the classifier reported the *manual-http* datastreams as HTTP, the *manual-ssh* datastreams as SSH, and so on. In all six cases (two classifiers, three protocols) we achieved 100% success. These results are summarized in Figure 7. All three formats exhibited similar performance characteristics, which is consistent with the results from [15]. On average, we achieved 68.2Mbps goodput for both the upstream and downstream directions, which actually exceeds the goodput reported in [15].

7.2 Protocol-Compliance

As our next test, we aim to achieve protocol compliance for scenarios that require a greater degree of inter-message and inter-connection state. In our testing we created model specifications for HTTP, POP3, and FTP that generate protocol-compliant (i.e., correctly classified by bro) network traffic. The FTP format was the most challenging of the three, so we will use it as our illustrative example.

An FTP session in passive mode uses two data connections: a control channel and a data channel. To enter passive mode a client issues the `PASV` command, and the server responds with an address in the form `(a,b,c,d,x,y)`. As defined by the FTP protocol [30], the client then connects to TCP port `a.b.c.d:(256*x+y)` to retrieve the file requested in the `GET` command.

Building our FTP model specification. In building our FTP model we encounter three unique challenges, compared to other protocols, such as HTTP:

1. FTP has a range of message types, including usernames, passwords, and arbitrary files, that could be used to encode data. In order to maximize potential encoding capacity, we must utilize multiple encoding strategies (e.g., FTE, template grammars, etc.)
2. The FTP protocol is stateful (i.e., message order matters) and has many message types (e.g., `USER`, `PASV`, etc,) which do not have the capacity to encode information.
3. Performing either an active or passive FTP file transfer requires establishing a new connection and maintaining appropriate inter-connection state.

To address the first challenge, we utilize Marionette's plugin architecture, including FTE, template grammars, multi-layer models, and the ability to send/receive static strings. To resolve the second, we rely on Marionette's ability to model stateful transitions and block until, say, a specific static string (e.g., the FTP server banner) has been sent/received. For the third, we rely not only on Marionette's ability to spawn a new model, but we also rely on inter-model communications. In fact, we can generate the listening port server-side on the the fly and communicate it in-band to the client via the `227 Entering Passive Mode (a,b,c,d,x,y)` command, which is processed by a client-side template-grammar handler to populate a client-side global variable. This global variable value is then used to inform the spawned model as to which server-side TCP port it should connect.

Our FTP model specification relies upon the upstream password field, and upstream (PUT) and downstream (GET) file transfers to relay data. In our testbed the FTP model achieved 6.6Mbps downstream and 6.7Mbps upstream goodput.

7.3 Proxy Traversal

As our next case study, we evaluate Marionette in a setting where a protocol-enforcing proxy is positioned between the client and server. Given the prevalence of the HTTP protocol and breadth of proxy systems available, we focus our attention on engineering Marionette model specifications that are able to traverse HTTP proxies.

When considering the presence of an HTTP proxy, there are at least five ways it could interfere with our communications. A proxy could: (1) add HTTP headers, (2) remove HTTP headers, (3) modify header or payload contents, (4) re-order/multiplex messages, or (5) drop messages. Marionette is able to handle each of these cases with only slight enhancements to the plugins we have already described.

We first considered using FTE to generate ciphertexts that are valid HTTP messages. However, FTE is sensitive to modifications to its ciphertexts. As an example, changing the case of a single character of an FTE ciphertext would result in FTE decryption failure. Hence, we need a more robust solution.

Fortunately, template grammars (Section 4) give us fine-grained control over ciphertexts and allows us to tolerate ciphertext modification, and our record layer (Section 6.1) provides mechanisms to deal with stream multiplexing, message re-ordering and data loss. This covers all five types of interference mentioned above.

Building our HTTP template grammar. As a proof of concept we developed four HTTP template grammars. Two languages that are HTTP-GET requests, one with a header field of `Connection: keep-alive` and one with `Connection: close`. We then created analogous HTTP-OK languages that have keep-alive and close headers. Our model oscillates between the keep-alive GET and OK states with probability 0.9, until it transitions from the keep-alive OK state to the GET close state, with probability 0.1

In all upstream messages we encode data into the URL and cookie fields using the FTE template grammar handler. Downstream we encode data in the payload body using the FTE handler and follow this with a separate handler to correctly populate the content-length field.

We provide receiver-side HTTP parsers that validate incoming HTTP messages (e.g., ensure content length is correct) and then extract the URL, cookie and payload fields. Then, we take each of these components and reassemble them into a complete message, independent of the order they appeared. That is, the order of the incoming headers does not matter.

Coping with multiplexing and re-ordering. The template grammar plugin resolves the majority of issues that we could encounter. However, it does not allow us to cope with cases where the proxy might re-order or multiplex messages. By multiplex, we mean that a proxy may interleave two or more Marionette TCP channels into a single TCP stream between the proxy and server. In such a case, we can no longer assume that two messages from the same incoming datastream are, in fact, two sequential messages from the same client model. Therefore, in the non-proxy setting there is a one-to-one mapping between channels and server-side Marionette model instances. In the proxied setting, the channel to model instance mapping may be one-to-many.

We are able to cope with this scenario by relying upon the non-determinism of our Marionette models, and our record layer. The server-side broker attempts to execute all action blocks for available transitions across all active models. If no active model was able to successfully process the incoming message, then the broker (Section 5) attempts to instantiate a new model for that message. In our plugins we must rely upon our record layer to determine success for each of these operations. This allows us to deal with cases where a message may successfully decode and decrypt, but the model instance ID field doesn't match the current model.

Testing with Squid HTTP proxy. We validated our HTTP model specification and broker/plugin enhancements against the Squid [39] caching proxy (version 3.4.9). The Squid caching proxy adds headers, removes header, alters headers and payload contents, and reorders/multiplexes datastreams. We generated 10,000 streams through the Squid proxy and did not encounter any unexpected issues, such as message loss.

In our testbed, our HTTP model specification for use with Squid proxy achieved 5.8Mbps downstream and 0.41Mbps upstream goodput, with the upstream bandwidth limited by the capacity of the HTTP request format.

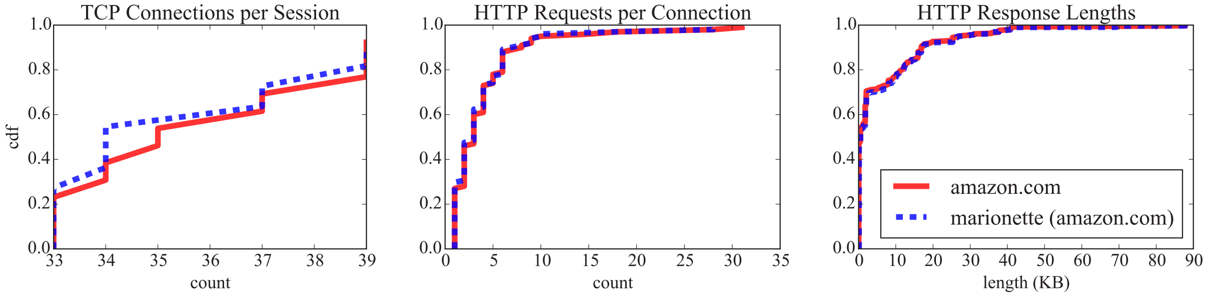
7.4 Traffic Analysis Resistance

In our next case study, we control statistical features of HTTP traffic. As our baseline, we visited `Amazon.com` with Firefox 35 ten times and captured all resultant network traffic[8]. We then post-processed the packet captures and recorded the following values: the lengths of HTTP response payloads, the number of HTTP request-response pairs per TCP connection, and the number of TCP connections generated as a result of each page visit. Our goal in this section is to utilize Marionette to model the traffic characteristics of these observed traffic patterns to make network sessions that "look like" a visit to `Amazon.com`. We will discuss each traffic characteristic individually, then combine them in a single model to mimic all characteristics simultaneously.

Message lengths. To model message lengths, we started with the HTTP response template grammar described in Section 7.3. We adapted the response body handler such that it takes an additional, integer value as input. This integer dictates the output length of the HTTP response body. On input n, the handler must return an HTTP response payload of exactly length n bytes.

From our packet captures of `Amazon.com` we recorded the message length for each observed HTTP response payload. Each time our new HTTP response template grammar was invoked by Marionette, we sampled from our recorded distribution of message lengths and used this value as input to the HTTP response template grammar. With this, we generate HTTP response payloads with lengths that match the distribution of those observed during our downloads of `Amazon.com`.

[8] Retrieval performed on February 21, 2015.



TCP Connections per Session

HTTP Requests per Connection

HTTP Response Lengths

Figure 8: A comparison of the aggregate traffic features for ten downloads of amazon.com using Firefox 35, compared to the traffic generated by ten executions of the Marionette model mimicking amazon.com.

Messages per TCP connection. We model the number of HTTP request-response pairs per TCP connection using the following strategy, which employs hierarchical modeling. Let's start with the case where we want to model a single TCP connection that has n HTTP request-response pairs. We start by creating a set of models which contain exactly n request-response pair with probability 1, for all n values of interest. We can achieve this by creating a model M_n with $n+1$ states, n transitions, and exactly one path. From the start state each transition results in an action block that performs one HTTP request-response. Therefore, M_n models a TCP connection with exactly n HTTP request-response pairs.

Then, we can employ Marionette's hierarchical model structure to have fine-grained control over the number of HTTP request-response pairs per connection. Let's say that we want to have n_1 request-response pairs with probability p_1, n_2 with probability p_2, and so on. For simplicity, we assume that all values n_i are unique, all values p_i are greater than 0, and $\Sigma_{i=0}^{m} p_i = 1$. For each possible value of n_i we create a model M_{n_i}, as described above. Then, we create a single parent model which has a start state with a transition that spawns M_{n_1} with probability p_1, M_{n_2} with probability p_2, and so on. This enables us to create a single, hierarchical model that that controls the number of request-response pairs for arbitrary distributions.

Simultaneously active connections. Finally, we aim to control the total number of connections generated by a model during an HTTP session. That is, we want our model to spawn n_i connections with probability p_i, according to some distribution dictated by our target. We achieve this by using the same hierarchical approach as the request-response pairs model, with the distinction that each child model now spawns n_i connections.

Building the model and its performance. For each statistical traffic feature, we analyzed the distribution of values in the packet captures from our `Amazon.com` visits. We then used the strategies in this section to construct a three-level hierarchical model that controls all of the traffic features simultaneously: message lengths, number of request-response pairs per connection, and the number of simultaneously active TCP connections. With this new model we deployed Marionette in our testbed and captured all network traffic it generated. In Figure 8 we have a comparison of the traffic features of the `Amazon.com` traffic, compared to the traffic generated by our Marionette model.

In our testbed, this model achieved 0.45Mbps downstream and 0.32Mbps upstream goodput. Compared to Section 7.3 this decrease in performance can be explained, in part, by the fact that `Amazon.com` has many connections with only a single HTTP request-response, and very short messages. As one example, the most common payload length in the distribution was 43 bytes. Consequently, the majority of the processing time was spent waiting for setup and teardown of TCP connections.

7.5 Resisting Application Fingerprinting

In our final case study, we evaluate Marionette's ability to resist adversaries that wish to identify Marionette servers using active probing or fingerprinting methods. We assume that an adversary is employing off-the-shelf tools to scan a target host and determine which services it is running. An adversary may have an initial goal to identify that a server is running Marionette and not an industry-standard service (e.g., Apache, etc.). Then, they may use this information to perform a secondary inspection or immediately block the server. This problem has been shown to be of great practical importance for services such as Tor [41] that wish to remain undetected in the presence of such active adversaries.

Our goal is to show that Marionette can coerce fingerprinting tools to incorrectly classify a Marionette server

```
connection(tcp, 8080):
  start    upstream       http_get    1.0
  upstream downstream     http_ok     1.0
  upstream downstream_err http_ok_err error
  ...

action http_ok_err:
  server io.puts("HTTP/1.1 200 OK\r\n" \
             + "Server: Apache/2.4.7\r\n..."
             ...
```

Figure 9: Example HTTP model specification including active probing resistance.

Protocol	Fingerprint Target	Scanner		
		nmap	Nessus	metasploit
HTTP	Apache 2.4.7	✓	✓	✓
FTP	Pure-FTPd 1.0.39	✓	✓	✓
SSH	OpenSSH 6.6.1	✓	✓	✓

Figure 10: A ✓ indicates that Marionette was able to successful coerce the fingerprinting tool into reporting that the Marionette server is the fingerprint target.

as a service of our choosing. As one example, we'll show that with slight embellishments to the formats we describe in Section 7.1 and Section 7.2, we can convince nmap [4] that Marionette is an instance of an Apache server.

7.5.1 Building Fingerprinting-Resistant Formats

In our exploration of fingerprinting attacks we consider three protocols: HTTP [16], SSH [46], and FTP [30]. For HTTP and SSH we started with the formats described in Section 7.1, and for FTP we started the format described in Section 7.2. We augmented these formats by adding an error transition (Section 3) that invokes an action that mimics the behavior of our target service. This error transition is traversed if all other potential transitions encounter fatal errors in their action blocks, which occur if an invalid message is received.

As an example, for our HTTP format we introduce an error transition to the `downstream_err` state. This transition is taken if the `http_ok` action block encounters a fatal error when attempting to invoke an FTE decryption. In this specific format, a fatal error in the `http_ok` action block is identified if an invalid message is detected when attempting to perform FTE decryption (i.e., doesn't match the regex or encounters a MAC failure). In the example found in Figure 9, upon encountering an error, we output the default response produced when requesting the index file from an Apache 2.4.7 server.

7.5.2 Fingerprinting Tools

For our evaluation we used nmap [4], Nessus [3], and metasploit [2], which are three commonly used tools for network reconnaissance and application fingerprinting. Our configuration was as follows.

nmap: We used nmap version 6.4.7 with version detection enabled and all fingerprinting probes enabled. We invoked nmap via the command line to scan our host. Nmap's service and version fields were used to identify its fingerprint of the target.

Nessus: For Nessus we used version 6.3.6 and performed a Basic Network Scan. We invoked Nessus via its REST API to start the scan and then asynchronously retrieved the scan with a second request. The reported fingerprint was determined by the `protocol` and `svc_name` for all plugins that were triggered.

metasploit: We used version 4.11.2 of metasploit. For fingerprinting SSH, FTP, and HTTP we used the `ssh_version` , `ftp_version` and `http_version` modules, respectively. For each module we set the RHOST and RPORT variable to our host and the reported fingerprint was the complete text string returned by the module.

7.5.3 Results

We refer to the *target* or *fingerprint target* as the application that we are attempting to mimic. To establish our fingerprint targets we installed Apache 2.4.7, Pure-FTPd 1.0.39 and OpenSSH 6.6.1 on a virtual machine. We then scanned each of these target applications with each of our three fingerprinting tools and stored the fingerprints.

To create our Marionette formats that mimic these targets, we added error states that respond identically to our target services. As an example, for our Apache 2.4.7, we respond with a success status code (200) if the client requests the `index.html` or `robots.txt` file. Otherwise we respond with a File Not Found (404) error code. Each server response includes a `Server: Apache 2.4.7` header. For our FTP and SSH formats we used a similar strategy. We observed the request initiated by each probe, and ensured that our error transitions triggered actions that are identical to our fingerprinting target.

We then invoked Marionette with our three new formats and scanned each of the listening instances with our fingerprinting tools. In order to claim success, we require two conditions. First, the three fingerprinting tools in our evaluation must report the exact same fingerprint as the target. Second, we require that a Marionette client must be able to connect to the server and relay data, as described in prior sections. We achieved this for all

Section	Protocol	Percent of Time Blocking on Network I/O	
		Client	Server
7.1	HTTP, SSH, etc.	56.9%	50.1%
7.2	FTP, POP3	90.1%	80.5%
7.3	HTTP	84.0%	96.8%
7.4	HTTP	65.5%	98.8%

Figure 11: Summary of case study formats and time spent blocking on network I/O for both client and server.

nine configurations (three protocols, three fingerprinting tools) and we summarize our results in Figure 10.

7.6 Performance

In our experiments, the performance of Marionette was dominated by two variables: (1) the structure of the model specification and (2) the client-server latency in our testbed. To illustrate the issue, consider our FTP format in Section 7.2 where we require nine back-and-forth messages in the FTP command channel before we can invoke a PASV FTP connection. This format requires a total of thirteen round trips (nine for our messages and four to establish the two TCP connections) before we can send our first downstream ciphertext. In our testbed, with a 75ms client-server latency, this means that (at least) 975ms elapse before we send any data. Therefore, a disproportionately large amount of time is spent blocking on network I/O.

In Figure 11 we give the percentage of time that our client and server were blocked due to network I/O, for each of the Marionette formats in our case studies. In the most extreme case, the Marionette server for the HTTP specification in Section 7.4 sits idle 98.8% of the time, waiting for network events. These results suggest that that certain Marionette formats (e.g., HTTP in Section 7.4) that target high-fidelity mimicry of protocol behaviors, network effects can dominate overall system performance. Appropriately balancing efficiency and realism is an important design consideration for Marionette formats.

8 Conclusion

The Marionette system is the first programmable obfuscation system to offer users the ability to control traffic features ranging from the format of individual application-layer messages to statistical features of connections to dependencies among multiple connections. In doing so, the user can choose the strategy that best suits their network environment and usage requirements. More importantly, Marionette achieves this flexibility without sacrificing performance beyond what is required to maintain the constraints of the model. This provides the user with an acceptable trade-off between depth of control over traffic features and network throughput. Our evaluation highlights the power of Marionette through a variety of case studies motivated by censorship techniques found in practice and the research literature. Here, we conclude by putting those experimental results into context by explicitly comparing them to the state of the art in application identification techniques, as well as highlighting the open questions that remain about the limitations of the Marionette system.

DPI. The most widely used method for application identification available to censors is DPI, which can search for content matching specified keywords or regular expressions. DPI technology is now available in a variety of networking products with support for traffic volumes reaching 30Gbps [11], and has been demonstrated in real-world censorship events by China [41] and Iran [7]. The Marionette system uses a novel template grammar system, along with a flexible plugin system, to control the format of the messages produced and how data is embedded into those messages. As such, the system can be programmed to produce messages that meet the requirements for a range of DPI signatures, as demonstrated in Sections 7.1 and 7.2.

Proxies and Application Firewalls. Many large enterprise networks implement more advanced proxy and application-layer firewall devices that are capable of deeper analysis of particular protocols, such as FTP, HTTP, and SMTP [39]. These devices can cache data to improve performance, apply protocol-specific content controls, and examine entire protocol sessions for indications of attacks targeted at the application. In many cases, the proxies and firewalls will rewrite headers to ensure compliance with protocol semantics, multiplex connections for improved efficiency, change protocol versions, and even alter content (e.g., HTTP chunking). Although these devices are not known to be used by nation-states, they are certainly capable of large traffic volumes (e.g., 400TB/day [6]) and could be used to block most current obfuscation and mimicry systems due to the changes they make to communications sessions. Marionette avoids these problems by using template grammars and a resilient record layer to combine several independent data-carrying fields into a message that is robust to reordering, changes to protocol headers, and connection multiplexing. The protocol compliance and proxy traversal capabilities of Marionette were demonstrated in Sections 7.2 and 7.3, respectively.

Advanced Techniques. Recent papers by Houmansadr et al. [20] and Geddes et al. [17] have presented a number of passive and active tests that a censor could use to identify mimicry systems. The passive tests include examination of dependent communication channels that are not present in many mimicry systems, such as a TCP control channel in the Skype protocol. Active tests include dropping packets or preemptively closing connections to elicit an expected action that the mimicked systems do not perform. Additionally, the networking community have been developing methods to tackle the problem of traffic identification for well over a decade [9], and specific methods have even been developed to target encrypted network traffic [44].

To this point, there has been no evidence that these more advanced methods have been applied in practice. This is likely due to two very difficult challenges. First, many of the traffic analysis techniques proposed in the literature require non-trivial amounts of state to be kept on every connection (e.g., packet size bi-gram distributions), as well as the use of machine learning algorithms that do not scale to the multi-gigabit traffic volumes of enterprise and backbone networks. As a point of comparison, the Bro IDS system [28], which uses DPI technology, has been known to have difficulties scaling to enterprise-level networks [35]. The second issue stems from the challenge of identifying rare events in large volumes of traffic, commonly referred to as the base-rate fallacy. That is, even a tiny false positive rate can generate an overwhelming amount of collateral damage when we consider traffic volumes in the 1 Gbps range. Sommer and Paxson [32] present an analysis of the issue in the context of network intrusion detection and Perry [29] for the case of website fingerprinting attacks.

Regardless of the current state of practice, there may be some cases where technological developments or a carefully controlled network environment enables the censor to apply these techniques. As we have shown in Section 7.4, however, the Marionette system is capable of controlling multiple statistical features not just within a single connection, but also across many simultaneous connections. We also demonstrate how our system can be programmed to spawn interdependent models across multiple connections in Section 7.2. Finally, in Section 7.5, we explored the use of error transitions in our models to respond to active probing and fingerprinting.

Future Work. While the case studies described in the previous section cover a range of potential adversaries, we note that there are still many open questions and potential limitations that have yet to be explored. For one, we do not have a complete understanding of the capabilities of the probabilistic I/O automata to model long-term state. These automata naturally exhibit the Markov property, but can also be spawned in a hierarchical manner with shared global and local variables, essentially providing much deeper conditional dependencies. Another area of exploration lies in the ability of template grammars to produce message content outside of simple message headers, potentially extending to context-sensitive languages found in practice. Similarly, there are many questions surrounding the development of the model specifications themselves since, as we saw in Section 7.6, these not only impact the unobservability of the traffic but also its efficiency and throughput.

CONIKS: Bringing Key Transparency to End Users

Marcela S. Melara, Aaron Blankstein, Joseph Bonneau[†], Edward W. Felten, Michael J. Freedman

Princeton University, [†]Stanford University/Electronic Frontier Foundation

Abstract

We present CONIKS, an end-user key verification service capable of integration in end-to-end encrypted communication systems. CONIKS builds on transparency log proposals for web server certificates but solves several new challenges specific to key verification for end users. CONIKS obviates the need for global third-party monitors and enables users to efficiently monitor their own key bindings for consistency, downloading less than 20 kB per day to do so even for a provider with billions of users. CONIKS users and providers can collectively audit providers for non-equivocation, and this requires downloading a constant 2.5 kB per provider per day. Additionally, CONIKS preserves the level of privacy offered by today's major communication services, hiding the list of usernames present and even allowing providers to conceal the total number of users in the system.

1 Introduction

Billions of users now depend on online services for sensitive communication. While much of this traffic is transmitted encrypted via SSL/TLS, the vast majority is not end-to-end encrypted meaning service providers still have access to the plaintext in transit or storage. Not only are users exposed to the well-documented insecurity of certificate authorities managing TLS certificates [10, 11, 64], they also face data collection by communication providers for improved personalization and advertising [25] and government surveillance or censorship [24, 57].

Spurred by these security threats and users' desire for stronger security [43], several large services including Apple iMessage and WhatsApp have recently deployed end-to-end encryption [19, 62]. However, while these services have limited users' exposure to TLS failures and demonstrated that end-to-end encryption can be deployed with an excellent user experience, they still rely on a centralized directory of public keys maintained by the service provider. These key servers remain vulnerable to technical compromise [17, 48], and legal or extralegal pressure for access by surveillance agencies or others.

Despite its critical importance, secure key verification for end users remains an unsolved problem. Over two decades of experience with PGP email encryption [12, 55, 70] suggests that manual key verification is error-prone and irritating [22, 69]. The EFF's recent Secure Messaging Scorecard reported that none of 40 secure messaging apps which were evaluated have a practical and secure system for contact verification [50]. Similar conclusions were reached by a recent academic survey on key verification mechanisms [66].

To address this essential problem, we present CONIKS, a deployable and privacy-preserving system for end-user key verification.

Key directories with consistency. We retain the basic model of service providers issuing authoritative name-to-key bindings within their namespaces, but ensure that users can automatically verify *consistency* of their bindings. That is, given an *authenticated binding* issued by *foo.com* from the name *alice@foo.com* to one or more public keys, anybody can verify that this is the same binding for *alice@foo.com* that every other party observed.

Ensuring a stronger *correctness* property of bindings is impractical to automate as it would require users to verify that keys bound to the name *alice@foo.com* are genuinely controlled by an individual named Alice. Instead, with CONIKS, Bob can confidently use an authenticated binding for the name *alice@foo.com* because he knows Alice's software will monitor this binding and detect if it does not represent the key (or keys) Alice actually controls.

These bindings function somewhat like certificates in that users can present them to other users to set up a secure communication channel. However, unlike certificates, which present only an authoritative signature as a proof of validity, CONIKS bindings contain a cryptographic proof of consistency. To enable consistency checking, CONIKS servers periodically sign and publish an authenticated data structure encapsulating all bindings issued within their namespace, which all clients automatically verify is consistent with their expectations. If a CONIKS server ever tries to *equivocate* by issuing multiple bindings for a single username, this would require publishing distinct data structures which would provide irrefutable proof of the server's equivocation. CONIKS clients will detect the equivocation promptly with high probability.

Transparency solutions for web PKI. Several proposals seek to make the complete set of valid PKIX (SSL/TLS) certificates visible by use of public authenticated data structures often called *transparency logs* [4, 34, 38, 39, 53, 60]. The security model is similar to CONIKS in that publication does not ensure a certificate is correct, but users can accept it knowing the valid domain owner will promptly detect any certificate issued maliciously.

Follow-up proposals have incorporated more advanced features such as revocation [4, 34, 38, 60] and finer-grained limitations on certificate issuance [4, 34], but all have made several basic assumptions which make sense for web PKI but not for end-user key verification. Specifically, all of these systems make the set of names and keys/certificates completely public and rely to varying degrees on third-party monitors interested in ensuring the security of web PKI on the whole. End-user key verification has stricter requirements: there are hundreds of thousands of email providers and communication applications, most of which are too small to be monitored by independent parties and many of which would like to keep their users' names and public keys private.

CONIKS solves these two problems:

1. Efficient monitoring. All previous schemes include third-party monitors since monitoring the certificates/bindings issued for a single domain or user requires tracking the entire log. Webmasters might be willing to pay for this service or have their certificate authority provide it as an add-on benefit. For individual users, it is not clear who might provide this service free of charge or how users would choose such a monitoring service, which must be independent of their service provider itself.

CONIKS obviates this problem by using an efficient data structure, a *Merkle prefix tree*, which allows a single small proof (logarithmic in the total number of users) to guarantee the consistency of a user's entry in the directory. This allows users to monitor only their own entry without needing to rely on third parties to perform expensive monitoring of the entire tree. A user's device can automatically monitor the user's key binding and alert the user if unexpected keys are ever bound to their username.

2. Privacy-preserving key directories. In prior systems, third-party monitors must view the entire system log, which reveals the set of users who have been issued keys [34, 39, 53, 60]. CONIKS, on the contrary, is privacy-preserving. CONIKS clients may only query for individual usernames (which can be rate-limited and/or authenticated) and the response for any individual queries leaks no information about which other users exist or what key data is mapped to their username. CONIKS also naturally supports obfuscating the number of users and updates in a given directory.

CONIKS in Practice. We have built a prototype CONIKS system, which includes both the application-agnostic CONIKS server and an example CONIKS Chat application integrated into the OTR plug-in [8, 26, 65] for Pidgin [1]. Our CONIKS clients automatically monitor their directory entry by regularly downloading consistency proofs from the CONIKS server in the background, avoiding any explicit user action except in the case of notifications that a new key binding has been issued.

In addition to the strong security and privacy features, CONIKS is also efficient in terms of bandwidth, computation, and storage for clients and servers. Clients need to download about 17.6 kB per day from the CONIKS server and verifying key bindings can be done in milliseconds. Our prototype server implementation is able to easily support 10 million users (with 1% changing keys per day) on a commodity machine.

2 System Model and Design Goals

The goal of CONIKS is to provide a key verification system that facilitates practical, seamless, and secure communication for virtually all of today's users.

2.1 Participants and Assumptions

CONIKS's security model includes four main types of principals: identity providers, clients (specifically client software), auditors and users.

Identity Providers. Identity providers run CONIKS servers and manage disjoint namespaces, each of which has its own set of name-to-key bindings.[1] We assume a separate PKI exists for distributing providers' public keys, which they use to sign authenticated bindings and to transform users' names for privacy purposes.

While we assume that CONIKS providers may be malicious, we assume they have a reputation to protect and do not wish to attack their users in a public manner. Because CONIKS primarily provides transparency and enables reactive security in case of provider attacks, CONIKS cannot deter a service provider which is willing to attack its users openly (although it will expose the attacks).

Clients. Users run CONIKS client software on one or more trusted devices; CONIKS does not address the problem of compromised client endpoints. Clients *monitor* the consistency of their user's own bindings. To support monitoring, we assume that at least one of a user's clients has access to a reasonably accurate clock as well as access to secure local storage in which the client can save the results of prior checks.

We also assume clients have network access which cannot be reliably blocked by their communication provider. This is necessary for *whistleblowing* if a client detects

[1] Existing communication service providers can act as identity providers, although CONIKS also enables dedicated "stand-alone" identity providers to become part of the system.

misbehavior by an identity provider (more details in §4.2). CONIKS cannot ensure security if clients have no means of communication that is not under their communication provider's control.[2]

Auditors. To verify that identity providers are not equivocating, *auditors* track the chain of signed "snapshots" of the key directory. Auditors publish and gossip with other auditors to ensure global consistency. Indeed, CONIKS clients all serve as auditors for their own identity provider and providers audit each other. Third-party auditors are also able to participate if they desire.

Users. An important design strategy is to provide good baseline security which is accessible to nearly all users, necessarily requiring some security tradeoffs, with the opportunity for upgraded security for advanced users within the same system to avoid fragmenting the communication network. While there are many gradations possible, we draw a recurring distinction between *default users* and *strict users* to illustrate the differing security properties and usability challenges of the system.

We discuss the security tradeoffs between these two user security policies in §4.3.

2.2 Design Goals

The design goals of CONIKS are divided into security, privacy and deployability goals.

Security goals.

G1: Non-equivocation. An identity provider may attempt to equivocate by presenting diverging views of the name-to-key bindings in its namespace to different users. Because CONIKS providers issue signed, chained "snapshots" of each version of the key directory, any equivocation to two distinct parties must be maintained forever or else it will be detected by auditors who can then broadcast non-repudiable cryptographic evidence, ensuring that equivocation will be detected with high probability (see Appendix B for a detailed analysis).

G2: No spurious keys. If an identity provider inserts a malicious key binding for a given user, her client software will rapidly detect this and alert the user. For default users, this will not produce non-repudiable evidence as key changes are not necessarily cryptographically signed with a key controlled by the user. However, the user will still see evidence of the attack and can report it publicly. For strict users, all key changes must be signed by the user's previous key and therefore malicious bindings will not be accepted by other users.

Privacy goals.

G3: Privacy-preserving consistency proofs. CONIKS servers do not need to make any information about their bindings public in order to allow consistency verification. Specifically, an adversary who has obtained an arbitrary number of consistency proofs at a given time, even for adversarially chosen usernames, cannot learn any information about which other users exist in the namespace or what data is bound to their usernames.

G4: Concealed number of users. Identity providers may not wish to reveal their exact number of users. CONIKS allows providers to insert an arbitrary number of *dummy entries* into their key directory which are indistinguishable from real users (assuming goal G3 is met), exposing only an upper bound on the number of users.

Deployability goals.

G5: Strong security with human-readable names. With CONIKS, users of the system only need to learn their contacts' usernames in order to communicate with end-to-end encryption. They need not explicitly reason about keys. This enables seamless integration in end-to-end encrypted communication systems and requires no effort from users in normal operation.

G6: Efficiency. Computational and communication overhead should be minimized so that CONIKS is feasible to implement for identity providers using commodity servers and for clients on mobile devices. All overhead should scale at most logarithmically in the number of total users.

3 Core Data Structure Design

At a high level, CONIKS identity providers manage a directory of verifiable bindings of usernames to public keys. This directory is constructed as a Merkle prefix tree of all registered bindings in the provider's namespace.

At regular time intervals, or epochs, the identity provider generates a non-repudiable "snapshot" of the directory by digitally signing the root of the Merkle tree. We call this snapshot a *signed tree root* (STR) (see §3.3). Clients can use these STRs to check the consistency of key bindings in an efficient manner, obviating the need for clients to have access to the entire contents of the key directory. Each STR includes the hash of the previous STR, committing to a linear history of the directory.

To make the directory privacy-preserving, CONIKS employs two cryptographic primitives. First, a *private index* is computed for each username via a verifiable unpredictable function (described in §3.4). Each user's keys are stored at the associated private index rather than his or her username (or a hash of it). This prevents the data structure from leaking information about usernames. Second, to ensure that it is not possible to test if a users'

[2] Even given a communication provider who also controls all network access, it may be possible for users to whistleblow manually by reading information from their device and using a channel such as physical mail or sneakernet, but we will not model this in detail.

key data is equal to some known value even given this user's lookup index, a cryptographic *commitment*[3] to each user's key data is stored at the private index, rather than the public keys themselves.

3.1 Merkle Prefix Tree

CONIKS directories are constructed as Merkle binary prefix trees. Each node in the tree represents a unique prefix i. Each branch of the tree adds either a 0 or a 1 to the prefix of the parent node. There are three types of nodes, each of which is hashed slightly differently into a representative value using a collision-resistant hash $H()$:

Interior nodes exist for any prefix which is shared by more than one index present in the tree. An interior node is hashed as follows, committing to its two children:

$$h_{\text{interior}} = \mathrm{H}\left(h_{\text{child.0}}||h_{\text{child.1}}\right)$$

Empty nodes represent a prefix i of length ℓ (depth ℓ in the tree) which is not a prefix of any index included in the tree. Empty nodes are hashed as:

$$\mathrm{h}_{\text{empty}} = \mathrm{H}\left(k_{\text{empty}}||k_n||i||\ell\right)$$

Leaf nodes represent exactly one complete index i present in the tree at depth ℓ (meaning its first ℓ bits form a unique prefix). Leaf nodes are hashed as follows:

$$\mathrm{h}_{\text{leaf}} = \mathrm{H}\left(k_{\text{leaf}}||k_n||i||\ell||\mathrm{commit}(\mathrm{name}_i||\mathrm{keys}_i)\right)$$

where $\mathrm{commit}(\mathrm{name}_i||\mathrm{keys}_i)$ is a cryptographic commitment to the name and the associated key data. Committing to the name, rather than the index i, protects against collisions in the VUF used to generate i (see §3.4).

Collision attacks. While arbitrary collisions in the hash function are not useful, a malicious provider can mount a birthday attack to try to find two nodes with the same hash (for example by varying the randomness used in the key data commitment). Therefore, for t-bit security our hash function must produce at least $2t$ bits of output.

The inclusion of depths ℓ and prefixes i in leaf and empty nodes (as well as constants k_{empty} and k_{leaf} to distinguish the two) ensures that no node's pre-image can be valid at more than one location in the tree (including interior nodes, whose location is implicit given the embedded locations of all of its descendants). The use of a tree-wide nonce k_n ensures that no node's pre-image can be valid at the same location between two distinct trees which have chosen different nonces. Both are countermeasures for the *multi-instance setting* of an attacker attempting to find a collision at more than one location simultaneously.[4]. Uniquely encoding the location requires the attacker to target a specific epoch and location in the tree and ensures full t-bit security.

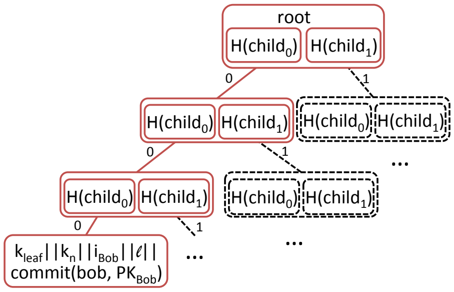

Figure 1: An authentication path from Bob's key entry to the root node of the Merkle prefix tree. Bob's index, i_{Bob}, has the prefix "000". Dotted nodes are not included in the proof's authentication path.

If the tree-wide nonce k_n is re-used between epochs, a parallel birthday attack is possible against each version of the tree. However, choosing a new k_n each epoch means that every node in the tree will change.

3.2 Proofs of Inclusion

Since clients no longer have a direct view on the contents of the key directory, CONIKS needs to be able to prove that a particular index exists in the tree. This is done by providing a proof of inclusion which consists of the complete *authentication path* between the corresponding leaf node and the root. This is a pruned tree containing the prefix path to the requested index, as shown in Figure 1. By itself, this path only reveals that an index exists in the directory, because the commitment hides the key data mapped to an index. To prove inclusion of the full binding, the server provides an opening of the commitment in addition to the authentication path.

Proofs of Absence. To prove that a given index j has no key data mapped to it, an authentication path is provided to the longest prefix match of j currently in the directory. That node will either be a leaf node at depth ℓ with an index $i \neq j$ which matches j in the first ℓ bits, or an empty node whose index i is a prefix of j.

3.3 Signed Tree Roots

At each epoch, the provider signs the root of the directory tree, as well as some metadata, using their directory-signing key SK_d. Specifically, an STR consists of

$$\mathrm{STR} = \mathrm{Sign}_{SK_d}\left(t||t_{prev}||\mathrm{root}_t||\mathrm{H}(\mathrm{STR}_{prev})||P\right)$$

[3] Commitments are a basic cryptographic primitive. A simple implementation computes a collision-resistant hash of the input data and a random nonce.

[4] This is inspired by Katz' analysis [33] of hash-based signature trees

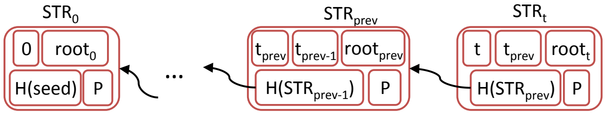

Figure 2: The directory's history is published as a linear hash chain of signed tree roots.

where t is the epoch number and P is a summary of this provider's current security policies. P may include, for example, the key K_{VUF} used to generate private indices, an expected time the next epoch will be published, as well as the cryptographic algorithms in use, protocol version numbers, and so forth. The previous epoch number t_{prev} must be included because epoch numbers need not be sequential (only increasing). In practice, our implementation uses UNIX timestamps.

By including the hash of the previous epoch's STR, the STRs form a *hash chain* committing to the entire history, as shown in Figure 2. This hash chain is used to ensure that if an identity provider ever equivocates by creating a fork in its history, the provider must maintain these forked hash chains for the rest of time (i.e. it must maintain *fork consistency* [41]). Otherwise, clients will immediately detect the equivocation when presented with an STR belonging to a different branch of the hash chain.

3.4 Private Index Calculation

A key design goal is to ensure that each authentication path reveals no information about whether any *other* names are present in the directory. If indices were computed using any publicly computable function of the username (such as a simple hash), each user's authentication path would reveal information about the presence of other users with prefixes "close" to that user.

For example, if a user *alice@foo.com*'s shortest unique prefix in the tree is i and her immediate neighbor in the tree is a non-empty node, this reveals that at least one users exists with the same prefix i. An attacker could hash a large number of potential usernames offline, searching for a potential username whose index shares this prefix i.

Private Indices. To prevent such leakage, we compute private indices using a *verifiable unpredictable function*, which is a function that requires a private key to compute but can then be publicly verified. VUFs are a simpler form of a stronger cryptographic construction called verifiable random functions (VRFs) [47]. In our application, we only need to ensure that a user's location in the tree is not predictable and do not need pseudorandomness (although statistical randomness helps to produce a balanced tree).

Given such a function VUF(), we generate the index i for a user u as:

$$i = \mathrm{H}\left(\mathrm{VUF}_{K_{\mathrm{VUF}}}(u)\right)$$

K_{VUF} is a public key belonging to the provider, and it is specified in the policy field of each STR. A hash function is used because indices are considered public and VUFs are not guaranteed to be one-way. A full proof of inclusion for user u therefore requires the value of VUF(u) in addition to the authentication path and an opening of the commitment to the user's key data.

We can implement a VUF using any deterministic, existentially unforgeable signature scheme [47]. The signature scheme must be deterministic or else the identity provider could insert multiple bindings for a user at different locations each with a valid authentication path. We discuss our choice for this primitive in §5.2.

Note that we might like our VUF to be collision-resistant to ensure that a malicious provider cannot produce two usernames u, u' which map to the same index. However, VUFs are not guaranteed to be collision-resistant given knowledge of the private key (and the ability to pick this key maliciously). To prevent any potential problems we commit to the username u in each leaf node. This ensures that only one of u or u' can be validly included in the tree even if the provider has crafted them to share an index.

4 CONIKS Operation

With the properties of key directories outlined in §3, CONIKS provides four efficient protocols that together allow end users to verify each other's keys to communicate securely: registration, lookup, monitoring and auditing. In these protocols, providers, clients and auditors collaborate to ensure that identity providers do not publish spurious keys, and maintain a single linear history of STRs.

4.1 Protocols

4.1.1 Registration and Temporary Bindings

CONIKS provides a registration protocol, which clients use to register a new name-to-key binding with an identity provider on behalf of its user, or to update the public key of the user's existing binding when revoking her key. An important deployability goal is for users to be able to communicate immediately after enrollment. This means users must be able to use new keys *before* they can be added to the key directory. An alternate approach would be to reduce the epoch time to a very short interval (on the order of seconds). However, we consider this undesirable both on the server end and in terms of client overhead.

CONIKS providers may issue *temporary bindings* without writing any data to the Merkle prefix tree. A temporary binding consists of:

$$\mathrm{TB} = \mathrm{Sign}_{K_d}\left(STR_t, i, k\right)$$

The binding includes the most recent signed tree root STR_t, the index i for the user's binding, and the user's new key information k. The binding is signed by the identity provider, creating a non-repudiable promise to add this data to the next version of the tree.

To register a user's key binding with a CONIKS identity provider, her client now participates in the following protocol. First, the client generates a key pair for the user and stores it in some secure storage on the device. Next, the client sends a registration request to the provider to the bind the public key to the user's online name, and if this name is not already taken in the provider's namespace, it returns a temporary binding for this key. The client then needs to wait for the next epoch and ensure that the provider has kept its promise of inserting Alice's binding into its key directory by the next epoch.

4.1.2 Key Lookups

Since CONIKS clients only regularly check directory roots for consistency, they need to ensure that public keys retrieved from the provider are contained in the most recently validated directory. Thus, whenever a CONIKS client looks up a user's public key to contact her client, the provider also returns a proof of inclusion showing that the retrieved binding is consistent with a specific STR. This way, if a malicious identity provider attempts to distribute a spurious key for a user, it is not able to do so without leaving evidence of the misbehavior. Any client that looks up this user's key and verifies that the binding is included in the presented STR will then promptly detect the attack.

In more detail, CONIKS's lookup protocol achieves this goal in three steps (summarized in Fig. 3). When a user wants to send a secure message to another user, her client first requests the recipient's public key at her provider. To allow the client to check whether the recipient's binding is included in the STR for the current epoch, the identity provider returns the full authentication path for the recipient's binding in the Merkle prefix tree along with the current STR. In the final step, the client recomputes the root of the tree using the authentication path and checks that this root is consistent with the presented STR. Note that, if the recipient has not registered a binding with the identity provider, it returns an authentication path as a proof of absence allowing the client to verify that the binding is indeed absent in the tree and consistent with the current STR.

4.1.3 Monitoring for Spurious Keys

CONIKS depends on the fact that each client monitors its own user's binding every epoch to ensure that her key binding has not changed unexpectedly. This prevents a malicious identity provider from inserting spurious keys

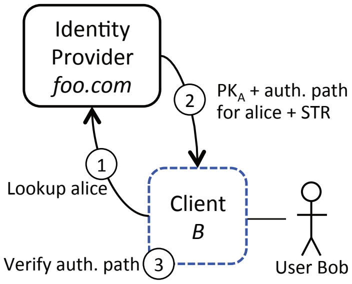

Figure 3: Steps taken when a client looks up a user's public key at her identity provider.

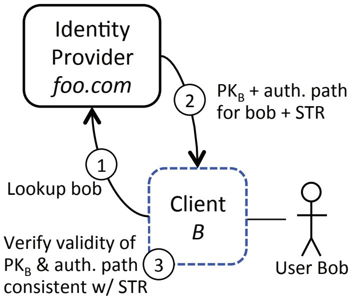

Figure 4: Steps taken when a client monitors its own user's binding for spurious keys every epoch.

that are properly included in the STR. Clients do not monitor other user's bindings as they may not have enough information to determine when another user's binding has changed unexpectedly.

Fig. 4 summarizes the steps taken during the monitoring protocol. The client begins monitoring by performing a key lookup for its own user's name to obtain a proof of inclusion for the user's binding. Next, the client checks the binding to ensure it represents the public key data the user believes is correct. In the simplest case, this is done by checking that a user's key is consistent between epochs. If the keys have not changed, or the client detects an authorized key change, the user need not be notified.

In the case of an unexpected key change, by default the user chooses what course of action to take as this change may reflect, for example, having recently enrolled a new device with a new key. Alternatively, security-conscious users may request a stricter key change policy which can be automatically enforced, and which we discuss further in §4.3. After checking the binding for spurious keys, the client verifies the authentication path as described in §3, including verifying the user's private index.

4.1.4 Auditing for Non-Equivocation

Even if a client monitors its own user's binding, it still needs to ensure that its user's identity provider is presenting consistent versions of its key directory to all participants in the system. Similarly, clients need to check

that the identity provider of any user they contact is not equivocating about its directory. In other words, clients need to verify that any provider of interest is maintaining a linear STR history. Comparing each observed STR with every single other client with which a given client communicates would be a significant performance burden.

Therefore, CONIKS allows identity providers to facilitate auditing for their clients by acting as auditors of all CONIKS providers with which their users have been in communication (although it is also possible for any other entity to act as an auditor). Providers achieve this by distributing their most recent STR to other identity providers in the system at the beginning of every epoch.[5]

The auditing protocol in CONIKS checks whether an identity provider is maintaining a linear STR history. Identity providers perform the history verification whenever they observe a new STR from any other provider, while clients do so whenever they request the most recent STR from a specific identity provider directly. We summarize the steps required for an auditor to verify an STR history in Fig. 5. The auditor first ensures that the provider correctly signed the STR before checking whether the embedded hash of the previous epoch's STR matches what the auditor saw previously. If they do not match, the provider has generated a fork in its STR history.

Because each auditor has independently verified a provider's history, each has its own view of a provider's STR, so clients must perform an STR comparison to check for possible equivocation between these views (summarized in Fig. 6). Once a client has verified the provider's STR history is linear, the client queries one or more CONIKS identity providers at random.[6] The client asks the auditor for the most recent STR it observed from the provider in question. Because the auditor has already verified the provider's history, the client need not verify the STR received from the auditor. The client then compares the auditor's observed STR with the STR which the provider directly presented it. The client may repeat this process with different auditors as desired to increase confidence. For an analysis of the number of checks necessary to detect equivocation with high probability, see App. B.

CONIKS auditors store the current STRs of CONIKS providers; since the STRs are chained, maintaining the current STR commits to the entire history. Because this is a small, constant amount of data (less than 1 kB) it is efficient for a single machine to act as an auditor for thousands of CONIKS providers.

4.2 Secure Communication with CONIKS

When a user Bob wants to communicate with a user Alice via their CONIKS-backed secure messaging service *foo.com*, his client *client B* performs the following steps. We assume both Alice's and Bob's clients have registered their respective name-to-key bindings with *foo.com* as described in §4.1.1.

1. Periodically, *client B* checks the consistency of Bob's binding. To do so, the client first performs the monitoring protocol (per §4.1.3), and then it audits *foo.com* (per §4.1.4).
2. Before sending Bob's message to *client A*, *client B* looks up the public key for the username *alice* at *foo.com* (§4.1.2). It verifies the proof of inclusion for *alice* and performs the auditing protocol (§4.1.4) for *foo.com* if the STR received as part of the lookup is different or newer than the STR it observed for *foo.com* in its latest run of step 1.
3. If *client B* determines that Alice's binding is consistent, it encrypts Bob's message using *alice*'s public key and signs it using Bob's key. It then sends the message.

Performing checks after missed epochs. Because STRs are associated with each other across epochs, clients can "catch up" to the most recent epoch if they have not veri-

[5] CONIKS could support an auditing protocol in which clients directly exchange observed STRs, obviating the need of providers to act as auditors. The design of such a protocol is left as future work.

[6] We assume the client maintains a list of CONIKS providers acting as auditors from which it can choose any provider with equal probability. The larger this list, the harder it is for an adversary to guess which providers a client will query.

fied the consistency of a binding for several epochs. They do so by performing a series of the appropriate checks until they are sure that the proofs of inclusion and STRs they last verified are consistent with the more recent proofs. This is the only way a client can be sure that the security of its communication has not been compromised during the missed epochs.

Liveness. CONIKS servers may attempt to hide malicious behavior by ceasing to respond to queries. We provide flexible defense against this, as servers may also simply go down. Servers may publish an expected next epoch number with each STR in the policy section *P*. Clients must decide whether they will accept STRs published at a later time than previously indicated.

Whistleblowing. If a client ever discovers two inconsistent STRs (for example, two distinct versions signed for the same epoch time), they should notify the user and *whistleblow* by publishing them to all auditors they are able to contact. For example, clients could include them in messages sent to other clients, or they could explicitly send whistleblowing messages to other identity providers. We also envision out-of-band whistleblowing in which users publish inconsistent STRs via social media or other high-traffic sites. We leave the complete specification of a whistleblowing protocol for future work.

4.3 Multiple Security Options

CONIKS gives users the flexibility to choose the level of security they want to enforce with respect to key lookups and key change. For each functionality, we propose two security policies: a default policy and a strict policy, which have different tradeoffs of security and privacy against usability. All security policies are denoted by flags that are set as part of a user's directory entry, and the consistency checks allow users to verify that the flags do not change unexpectedly.

4.3.1 Visibility of Public Keys

Our goal is to enable the same level of privacy SMTP servers employ today,[7] in which usernames can be queried (subject to rate-limiting) but it is difficult to enumerate the entire list of names.

Users need to decide whether their public key(s) in the directory should be publicly visible. The difference between the default and the strict lookup policies is whether the user's public keys are encrypted with a secret symmetric key known only to the binding's owner and any other user of her choosing. For example, if the user Alice follows the default lookup policy, her public keys are not encrypted. Thus, anyone who knows Alice's name *alice@foo.com* can look up and obtain her keys from her *foo.com*'s directory. On the other hand, if Alice follows the strict lookup policy, her public keys are encrypted with a symmetric key only known to Alice and the users of her choosing.

Under both lookup policies, any user can verify the consistency of Alice's binding as described in §4, but if she enforces the strict policy, only those users with the symmetric key learn her public keys. The main advantage of the default policy is that it matches users' intuition about interacting with any user whose username they know without requiring explicit "permission". On the other hand, the strict lookup policy provides stronger privacy, but it requires additional action to distribute the symmetric key which protects her public keys.

4.3.2 Key Change

Dealing with key loss is a difficult quandary for any security system. Automatic key recovery is an indispensable option for the vast majority of users who cannot perpetually maintain a private key. Using password authentication or some other fallback method, users can request that identity providers change a user's public key in the event that the user's previous device was lost or destroyed. If Alice chooses the default key change policy, her identity provider *foo.com* accepts any key change statement in which the new key is signed by the previous key, as well as unsigned key change requests. Thus, *foo.com* should change the public key bound to *alice@foo.com* only upon her request, and it should reflect the update to Alice's binding by including a key change statement in her directory entry. The strict key change policy *requires* that Alice's client sign all of her key change statements with the key that is being changed. Thus, Alice's client only considers a new key to be valid if the key change statement has been authenticated by one of her public keys.

While the default key change policy makes it easy for users to recover from key loss and reclaim their username, it allows an identity provider to maliciously change a user's key and falsely claim that the user requested the operation. Only Alice can determine with certainty that she has not requested the new key (and password-based authentication means the server cannot prove Alice requested it). Still, her client will detect these updates and can notify Alice, making surreptitious key changes risky for identity providers to attempt. Requiring authenticated key changes, on the other hand, does sacrifice the ability for Alice to regain control of her username if her key is

[7] The SMTP protocol defines a *VRFY* command to query the existence of an email address at a given server. To protect user's privacy, however, it has long been recommended to ignore this command (reporting that any usernames exists if asked) [42].

ever lost. We discuss some implications for key loss for strict users in §6.

5 Implementation and Evaluation

CONIKS provides a framework for integrating key verification into communications services that support end-to-end encryption. To demonstrate the practicality of CONIKS and how it interacts with existing secure communications services, we implemented a prototype CONIKS Chat, a secure chat service based on the Off-the-Record Messaging [8] (OTR) plug-in for the Pidgin instant messaging client [1, 26]. We implemented a stand-alone CONIKS server in Java (∼2.5k sloc), and modified the OTR plug-in (∼2.2k sloc diff) to communicate with our server for key management. We have released a basic reference implementation of our prototype on Github.[8]

5.1 Implementation Details

CONIKS Chat consists of an enhanced OTR plug-in for the Pidgin chat client and a stand-alone CONIKS server which runs alongside an unmodified Tigase XMPP server. Clients and servers communicate using Google Protocol Buffers [2], allowing us to define specific message formats. We use our client and server implementations for our performance evaluation of CONIKS.

Our implementation of the CONIKS server provides the basic functionality of an identity provider. Every version of the directory (implemented as a Merkle prefix tree) as well as every generated STR are persisted in a MySQL database. The server supports key registration in the namespace of the XMPP service, and the directory efficiently generates the authentication path for proofs of inclusion and proofs of absence, both of which implicitly prove the proper construction of the directory. Our server implementation additionally supports STR exchanges between identity providers.

The CONIKS-OTR plug-in automatically registers a user's public key with the server upon the generation of a new key pair and automatically stores information about the user's binding locally on the client to facilitate future consistency checks. To facilitate CONIKS integration, we leave the DH-based key exchange protocol in OTR unchanged, but replace the socialist millionaires protocol used for key verification with a public key lookup at the CONIKS server. If two users, Alice and Bob, both having already registered their keys with the *coniks.org* identity provider, want to chat, Alice's client will automatically request a proof of inclusion for Bob's binding in *coniks.org*'s most recent version of the directory. Upon receipt of this proof, Alice's client automatically verifies the authentication path for Bob's name-to-key binding (as described in §4.1.2), and caches the newest information about Bob's binding if the consistency checks pass. If Bob has not registered his key with *coniks.org*, the client falls back to the original key verification mechanism. Additionally, Alice's client and Bob's clients automatically perform all monitoring and auditing checks for their respective bindings upon every login and cache the most recent proofs.

CONIKS Chat currently does not support key changes. Furthermore, our prototype only supports the default lookup policy for name-to-key bindings. Fully implementing these features is planned for the near future.

5.2 Choice of Cryptographic Primitives

To provide a 128-bit security level, we use SHA-256 as our hash function and EC-Schnorr signatures [21, 63].

Unfortunately Schnorr signatures (and related discrete-log based signature schemes like DSA [36]) are not immediately applicable as a VUF as they are not deterministic, requiring a random nonce which the server can choose arbitrarily.[9] In Appendix A we describe a discrete-log based scheme for producing a VUF (and indeed, a VRF) in the random-oracle model. Note that discrete-log based VUFs are longer than basic signatures: at a 128-bit security level using elliptic curves, we expect signatures of size 512 bits and VUF proofs of size 768 bits.

Alternately, we could employ a deterministic signature scheme like classic RSA signature [59] (using a deterministic padding scheme such as PKCS v. 1.5 [31]), although this is not particularly space-efficient at a 128-bit security level. Using RSA-2048 provides approximately 112 bits of security [3] with proofs of size 2048 bits. [10]

Using pairing-based crypto, BLS "short signatures" [7] are also deterministic and provide the best space efficiency with signature sizes of just 256 bits, making them an efficient choice both for signatures and VUF computations. BLS signatures also support *aggregation*, that is, multiple signatures with the same key can be compressed into a single signature, meaning the server can combine the signatures on n consecutive roots. However there is not widespread support for pairing calculations required for BLS, making it more difficult to standardize and deploy.

We evaluate performance in Table 1 in the next section for all three potential choices of signature/VUF scheme.

[8] `https://github.com/coniks-sys/coniks-ref-implementation`

[9] There are deterministic variants of Schnorr or DSA [5, 49] but these are not *verifiably* deterministic as they generate nonces pseudorandomly as a symmetric-key MAC of the data to be signed.

[10] We might tolerate slightly lower security in our VUF than our signature scheme, as this key only ensures privacy and not non-equivocation.

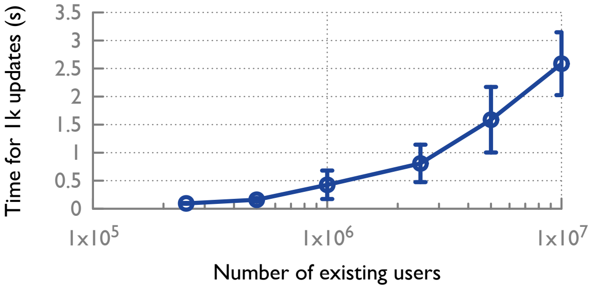

Figure 7: Mean time to re-compute the tree for a new epoch with 1K updated nodes. The x-axis is logarithmic and each data point is the mean of 10 executions. Error bars indicate standard deviation.

5.3 Performance Evaluation

To estimate the performance of CONIKS, we collect both theoretical and real performance characteristics of our prototype implementation. We evaluate client and server overheads with the following parameters:

- A single provider might support $N \approx 2^{32}$ users.
- Epochs occur roughly once per hour.
- Up to 1% of users change or add keys per day, meaning $n \approx 2^{21}$ directory updates in an average epoch.
- Servers use a 128-bit cryptographic security level.

Server Overheads. To measure how long it takes for a server to compute the changes for an epoch, we evaluated our server prototype on a 2.4 GHz Intel Xeon E5620 machine with 64 GB of RAM allotted to the OpenJDK 1.7 JVM. We executed batches of 1000 insertions (roughly 3 times the expected number of directory updates per epoch) into a Merkle prefix with 10 M users, and measured the time it took for the server to compute the next epoch.

Figure 7 shows the time to compute a version of the directory with 1000 new entries as the size of the original namespace varies. For a server with 10 M users, computing a new Merkle tree with 1000 insertions takes on average 2.6 *s*. As epochs only need to be computed every hour, this is not cumbersome for a large service provider. These numbers indicate that even with a relatively unoptimized implementation, a single machine is able to handle the additional overhead imposed by CONIKS for workloads similar in scale to a medium-sized communication providers (e.g., TextSecure) today.

While our prototype server implementation on a commodity machine comfortably supports 10M users, we note that due to the statistically random allocation of users to indices and the recursive nature of the tree structure, the task parallelizes near-perfectly and it would be trivial to scale horizontally with additional identical servers to compute a directory with billions of users.

Lookup Cost. Every time a client looks up a user's binding, it needs to download the current STR, a proof of of inclusion consisting of about $\lg_2(N)+1$ hashes plus one 96-byte VUF proof (proving the validity of the binding's private index). This will require downloading $32 \cdot (\lg_2(N)+1)+96 \approx 1216$ bytes. Verifying the proof will require up to $\lg_2(N)+1$ hash verifications on the authentication path as well as one VUF verification. On a 2 GHz Intel Core i7 laptop, verifying the authentication path returned by a server with 10 million users, required on average 159 μs (sampled over 1000 runs, with $\sigma = 30$). Verifying the signature takes approximately 400 μs, dominating the cost of verifying the authentication path. While mobile-phone clients would require more computation time, we do not believe this overhead presents a significant barrier to adoption.

Monitoring Cost. In order for any client to monitor the consistency of its own binding, it needs fetch proof that this binding is validly included in the epoch's STR. Each epoch's STR signature (64 bytes) must be downloaded and the client must fetch its new authentication path. However, the server can significantly compress the length of this path by only sending the hashes on the user's path which have changed since the last epoch. If n changes are made to the tree, a given authentication path will have $\lg_2(n)$ expected changed nodes. (This is the expected longest prefix match between the n changed indices and the terminating index of the given authentication path.) Therefore each epoch requires downloading an average of $64+\lg_2(n) \cdot 32 \approx 736$ bytes. Verification time will be similar to verifying another user's proof, dominated by the cost of signature verification. While clients need to fetch each STR from the server, they are only required to *store* the most recent STR (see §5.3).

To monitor a binding for a day, the client must download a total of about 19.1 kB. Note that we have assumed users update randomly throughout the day, but for a fixed number of updates this is actually the worst-case scenario for bandwidth consumption; bursty updates will actually lead to a lower amount of bandwidth as each epoch's proof is $\lg_2(n)$ for n changes. These numbers indicate that neither bandwidth nor computational overheads pose a significant burden for CONIKS clients.

Auditing cost. For a client or other auditor tracking all of a provider's STRs, assuming the policy field changes rarely, the only new data in an STR is the new timestamp, the new tree root and signature (the previous STR and epoch number can be inferred and need not be transmitted). The total size of each STR in minimal form is just 104 bytes (64 for the signature, 32 for the root and 8 for a timestamp), or 2.5 kB per day to audit a specific provider.

	#	#	#	approx. download size					
	VUFs	sigs.	hashes	RSA		EC		BLS	
lookup (per binding)	1	1	$\lg N+1$	1568	B	1216	B	1120	B
monitor (epoch)	0	1	$\lg n$	928	B	726	B	704	B
monitor (day)	1	$k^{\dagger}$	$k\lg n$	22.6	kB	17.6	kB	16.1	kB
audit (epoch, per STR)	0	1	1	288	B	96	B	64	B
audit (day, per STR)	0	$k^{\dagger}$	k	6.9	kB	2.3	kB	0.8	kB

Table 1: Client bandwidth requirements, based the number of signatures, VUFs and hashes downloaded for lookups, monitoring, and auditing. Sizes are given assuming a $N \approx 2^{32}$ total users, $n \approx 2^{21}$ changes per epoch, and $k \approx 24$ epochs per day. Signatures that can be aggregated into a single signature to transmit in the BLS signature scheme are denoted by †.

6 Discussion

6.1 Coercion of Identity Providers

Government agencies or other powerful adversaries may attempt to coerce identity providers into malicious behavior. Recent revelations about government surveillance and collection of user communications data world-wide have revealed that governments use mandatory legal process to demand access to information providers' data about users' private communications and Internet activity [9, 23, 24, 51, 52]. A government might demand that an identity provider equivocate about some or all name-to-key bindings. Since the identity provider is the entity actually mounting the attack, a user of CONIKS has no way of technologically differentiating between a malicious insider attack mounted by the provider itself and this coerced attack [18]. Nevertheless, because of the consistency and non-equivocation checks CONIKS provides, users could expose such attacks, and thereby mitigate their effect.

Furthermore, running a CONIKS server may provide some legal protection for service providers under U.S. law for providers attempting to fight legal orders, because complying with such a demand will produce public evidence that may harm the provider's reputation. (Legal experts disagree about whether and when this type of argument shelters a provider[45].)

6.2 Key Loss and Account Protection

CONIKS clients are responsible for managing their private keys. However, CONIKS can provide account protection for users who enforce the paranoid key change policy and have forfeit their username due to key loss. Even if Alice's key is lost, her identity remains secure; she can continue performing consistency checks on her old binding. Unfortunately, if a future attacker manages to obtain her private key, that attacker may be able to assume her "lost identity".

In practice, this could be prevented by allowing the provider to place a "tombstone" on a name with its own signature, regardless of the user's key policy. The provider would use some specific out-of-band authorization steps to authorize such an action. Unlike allowing providers to issue key change operations, though, a permanent account deactivation does not require much additional trust in the provider, because a malicious provider could already render an account unusable through denial of service.

6.3 Protocol Extensions

Limiting the effects of denied service. Sufficiently powerful identity providers may refuse to distribute STRs to providers with which they do not collude. In these cases, clients who query these honest providers will be unable to obtain explicit proof of equivocation. Fortunately, clients may help circumvent this by submitting observed STRs to these honest identity providers. The honest identity providers can verify the other identity provider's signature, and then store and redistribute the STR.

Similarly, any identity provider might ignore requests about individual bindings in order to prevent clients from performing consistency checks or key changes. In these cases, clients may be able to circumvent this attack by using other providers to proxy their requests, with the caveat that a malicious provider may ignore all requests for a name. This renders this binding unusable for as long as the provider denies service. However, this only allows the provider to deny service, any modification to the binding during this attack would become evident as soon as the service is restored.

Obfuscating the social graph. As an additional privacy requirement, users may want to conceal with whom they are in communication, or providers may want to offer anonymized communication. In principle, users could use Tor to anonymize their communications. However, if only few users in CONIKS use Tor, it is possible for providers to distinguish clients connecting through Tor from those connecting to the directly.

CONIKS could leverage the proxying mechanism described in §6.3 for obfuscating the social graph. If Alice would like to conceal with whom she communicates, she could require her client to use other providers to proxy any requests for her contacts' bindings or consistency proofs. Clients could choose these proxying providers uniformly at random to minimize the amount of information any single provider has about a particular user's contacts. This can be further improved the more providers agree to act as proxies. Thus, the only way for providers to gain information about whom a given user is contacting would be to aggregate collected requests. For system-wide Tor-like anonymization, CONIKS providers could form a mixnet [13], which would provide much higher privacy guarantees but would likely hamper the deployability of the system.

Randomizing the order of directory entries. Once a user learns the lookup index of a name, this position in the tree is known for the rest of time because the index is a deterministic value. If a user has an authentication path for two users *bob@foo.com* and *alice@foo.com* which share a common prefix in the tree, the Bob's authentication path will leak any changes to Alice's binding if his key has not changed, and vice-versa. *foo.com* can prevent this information leakage by randomizing the ordering of entries periodically by including additional data when computing their lookup indices. However, such randomized reordering of all directory entries would require a complete reconstruction of the tree. Thus, if done every epoch, the identity provider would be able to provide enhanced privacy guarantees at the expense of efficiency. The shorter the epochs, the greater the tradeoff between efficiency and privacy. An alternative would be to reorder all entries every n epochs to obtain better efficiency.

Key Expiration. To reduce the time frame during which a compromised key can be used by an attacker, users may want to enforce key expiration. This would entail including the epoch in which the public key is to expire as part of the directory entry, and clients would need to ensure that such keys are not expired when checking the consistency of bindings. Furthermore, CONIKS could allow users to choose whether to enforce key expiration on their binding, and provide multiple security options allowing users to set shorter or longer expiration periods. When the key expires, clients can automatically change the expired key and specify the new expiration date according to the user's policies.

Support for Multiple Devices. Any modern communication system must support users communicating from multiple devices. CONIKS easily allows users to bind multiple keys to their username. Unfortunately, device pairing has proved cumbersome and error-prone for users in practice [32, 67]. As a result, most widely-deployed chat applications allow users to simply install software to a new device which will automatically create a new key and add it to the directory via password authentication.

The tradeoffs for supporting multiple devices are the same as for key change. Following this easy enrollment procedure requires that Alice enforce the cautious key change policy, and her client will no longer be able to automatically determine if a newly observed key has been maliciously inserted by the server or represents the addition of a new device. Users can deal with this issue by requiring that any new device key is authenticated with a previously-registered key for a different device. This means that clients can automatically detect if new bindings are inconsistent, but will require users to execute a manual pairing procedure to sign the new keys as part of the paranoid key change policy discussed above.

7 Related Work

Certificate validation systems. Several proposals for validating SSL/TLS certificates seek to detect fraudulent certificates via transparency logs [4, 34, 38, 39, 53], or observatories from different points in the network [4, 34, 54, 58, 68]. Certificate Transparency (CT) [39] publicly logs all certificates as they are issued in a signed append-only log. This log is implemented as a chronologically-ordered Merkle binary search tree. Auditors check that each signed tree head represents an extension of the previous version of the log and gossip to ensure that the log server is not equivocating.

This design only maintains a set of issued certificates, so domain administrators must scan the entire list of issued certificates (or use a third-party monitor) in order to detect any newly-logged, suspicious certificates issued for their domain. We consider this a major limitation for user communication as independent, trustworthy monitors may not exist for small identity providers. CT is also not privacy-preserving; indeed it was designed with the opposite goal of making all certificates publicly visible.

Enhanced Certificate Transparency (ECT) [60], which was developed concurrently [46] extends the basic CT design to support efficient queries of the current set of valid certificates for a domain, enabling built-in revocation. Since ECT adds a second Merkle tree of currently valid certificates organized as a binary search tree sorted lexicographically by domain name, third-party auditors must verify that no certificate appears in only one of the trees by mirroring the entire structure and verifying all insertions and deletions.

Because of this additional consistency check, auditing in ECT requires effort linear in the total number of changes to the logs, unlike in CT or CONIKS, which only require auditors to verify a small number of signed tree roots. ECT also does not provide privacy: the proposal suggests storing users in the lexicographic tree by a hash of their name, but this provides only weak privacy as most usernames are predictable and their hash can easily be determined by a dictionary attack.

Other proposals include public certificate observatories such as Perspectives [54, 58, 68], and more complex designs such as Sovereign Keys [53] and AKI/ARPKI [4, 34] which combine append-only logs with policy specifications to require multiple parties to sign key changes and revocations to provide proactive as well as reactive security.

All of these systems are designed for TLS certificates, which differ from CONIKS in a few important ways. First, TLS has many certificate authorities sharing a single, global namespace. It is not required that the different CAs offer only certificates that are consistent or non-overlapping. Second, there is no notion of certificate or name privacy in the TLS setting,[11] and as a result, they use data structures making the entire name-space public. Finally, stronger assumptions, such as maintaining a private key forever or designating multiple parties to authorize key changes, might be feasible for web administrators but are not practical for end users.

Key pinning. An alternative to auditable certificate systems are schemes which limit the set of certificate authorities capable of signing for a given name, such as certificate pinning [16] or TACK [44]. These approaches are brittle, with the possibility of losing access to a domain if an overly strict pinning policy is set. Deployment of pinning has been limited due to this fear and most web administrators have set very loose policies [35]. This difficulty of managing keys, experienced even by technically savvy administrators, highlights how important it is to require no key management by end users.

Identity and key services. As end users are accustomed to interacting with a multitude of identities at various online services, recent proposals for online identity verification have focused on providing a secure means for consolidating these identities, including encryption keys.

Keybase [37] allows users to consolidate their online account information while also providing semi-automated consistency checking of name-to-key bindings by verifying control of third-party accounts. This system's primary function is to provide an easy means to consolidate online identity information in a publicly auditable log. It is not designed for automated key verification and it does not integrate seamlessly into existing applications.

Nicknym [56] is designed to be purely an end-user key verification service, which allows users to register existing third-party usernames with public keys. These bindings are publicly auditable by allowing clients to query any Nicknym provider for *individual* bindings they observe. While equivocation about bindings can be detected in this manner in principle, Nicknym does not maintain an authenticated history of published bindings which would provide more robust consistency checking as in CONIKS.

Cryptographically accountable authorities. Identity-based encryption inherently requires a trusted private-key generator (PKG). Goyal [28] proposed the accountable-authority model, in which the PKG and a user cooperate to generate the user's private key in such a way that the PKG does not know what private key the user has chosen. If the PKG ever runs this protocol with another party to generate a second private key, the existence of two private keys would be proof of misbehavior. This concept was later extended to the black-box accountable-authority model [29, 61], in which even issuing a black-box decoder algorithm is enough to prove misbehavior. These schemes have somewhat different security goals than CONIKS in that they require discovering two *private* keys to prove misbehavior (and provide no built-in mechanism for such discovery). By contrast, CONIKS is designed to provide a mechanism to discover if two distinct *public* keys have been issued for a single name.

VUFs and dictionary attacks. DNSSEC [15] provides a hierarchical mapping between domains and signing keys via an authenticated linked list. Because each domain references its immediate neighbors lexicographically in this design, it is possible for an adversary to enumerate the entire set of domains in a given zone via *zone walking* (repeatedly querying neighboring domains). In response, the NSEC3 extension [40] was added; while it prevents trivial enumeration, it suffers a similar vulnerability to ECT in that likely domain names can be found via a dictionary attack because records are sorted by the hash of their domain name. Concurrent with our work on CONIKS, [27] proposed NSEC5, effectively using a verifiable unpredictable function (also in the form of a deterministic RSA signature) to prevent zone enumeration.

8 Conclusion

We have presented CONIKS, a key verification system for end users that provides consistency and privacy for users' name-to-key bindings, all without requiring explicit key management by users. CONIKS allows clients to efficiently monitor their own bindings and quickly detect equivocation with high probability. CONIKS is highly scalable and is backward compatible with existing secure communication protocols. We have built a prototype

[11] Some organizations use "private CAs" which members manually install in their browsers. Certificate transparency specifically exempts these certificates and cannot detect if private CAs misbehave.

CONIKS system which is application-agnostic and supports millions of users on a single commodity server.

As of this writing, several major providers are implementing CONIKS-based key servers to bolster their end-to-end encrypted communications tools. While automatic, decentralized key management without least a semi-trusted key directory remains an open challenge, we believe CONIKS provides a reasonable baseline of security that any key directory should support to reduce user's exposure to mass surveillance.

A Discrete-log Based VRF Construction

We propose a simple discrete-log based VRF in the random oracle model. By definition, this scheme is also a VUF as required. This construction was described by Franklin and Zhang [20] although they considered it already well-known. Following Micali et al.'s outline [47], the basic idea is to publish a commitment c to the seed k of a pseudo-random function, compute $y = f_k(x)$ as the VUF, and issue non-interactive zero-knowledge proofs that $y = f_k(x)$ for some k to which c is a commitment of. The public key and private key are c and k.

Parameters. For a group[12] $\mathscr{G}$ with generator g of prime order q, the prover chooses a random $k \overset{R}{\leftarrow} (1,q)$ as their private key and publishes $G = g^k$ as their public key. We require two hash functions: one which maps to curve points [6, 30] $\mathbf{H}_1 : * \to \mathscr{G}$ and one which maps to integers $\mathbf{H}_2 : * \to (1,q)$ which are modeled as random oracles.

VRF computation. The VRF is defined as:

$$\mathrm{VRF}_k(m) = \mathbf{H}_1(m)^k$$

Non-interactive proof The prover must show in zero-knowledge that there is some x for which $G = g^k$ and $H = h^k$ for $h = \mathbf{H}_1(m)$. The proof is a standard Sigma proof of equality for two discrete logarithms made non-interactive using the Fiat-Shamir heuristic [14]. The prover chooses $r \overset{R}{\leftarrow} (1,q)$ and transmits $s = \mathbf{H}_1(m, g^r, h^r)$ and $t = r - sk \mod q$.

To verify that $\mathrm{VRF}_k(m) = \mathbf{H}_1(m)^k$ is a correct VRF computation given a proof (s,t), the verifier checks that

$$s = \mathbf{H}_1\left(m, g^t \cdot G^s, H(m)^t \cdot \mathrm{VRF}_k(m)^s\right)$$

We refer the reader to [14, 20] for proof that this scheme satisfies the properties of a VRF. Note that the pseudorandomness

[12] Note that we use multiplicative group notation here, though this scheme applies equally to elliptic-curve groups.

reduces to the Decisional Diffie-Hellman assumption. The tuple $(\mathbf{H}_1(m), G = g^k, \mathrm{VRF}_k(m) = \mathbf{H}_1(m)^k)$ is a DDH triple, therefore an attacker that could distinguish $\mathrm{VRF}_k(m)$ from random could break the DDH assumption for $\mathscr{G}$.

Efficiency. Proofs consist of a group elements (the VRF result $\mathbf{H}_1(m)^k$) and two integer which is the size of the order of the group $((s,t))$. For 256-bit elliptic curve, this leads to proofs of size 768 bits (96 bytes).

B Analysis of Equivocation Detection

CONIKS participants check for non-equivocation by consulting auditors to ensure that they both see an identical STR for a given provider P. Clients perform this cross-verification by choosing uniformly at random a small set of auditors from the set of known auditors, querying them for the observed STRs from P, and comparing these observed STRs to the signed tree root presented directly to the client by P. If any of the observed STRs differ from the STR presented to the client, the client is sure to have detected an equivocation attack.

B.1 Single Equivocating Provider

Suppose that *foo.com* wants to allow impersonation of a user Alice to hijack all encrypted messages that a user Bob sends her. To mount this attack, *foo.com* equivocates by showing Alice STR A, which is consistent with Alice's *valid* name-to-key binding, and showing Bob STR B, which is consistent with a fraudulent binding for Alice.

If Bob is the only participant in the system to whom *foo.com* presents STR B, while all other users and auditors receive STR A, Alice will not detect the equivocation (unless she compares her STR directly with Bob's). Bob, on the other hand, will detect the equivocation immediately because performing the non-equivocation check with a single randomly chosen auditor is sufficient for him to discover a diverging STR for *foo.com*.

A more effective approach for *foo.com* is to choose a subset of auditors who will be presented STR A, and to present the remaining auditors with STR B. Suppose the first subset contains a fraction f of all auditors, and the second subset contains the fraction $1-f$. If Alice and Bob each contact k randomly chosen providers to check consistency of *foo.com*'s STR, the probability that Alice fails to discover an inconsistency is f^k, and the probability that Bob fails to discover an inconsistency is $(1-f)^k$. The probability that both will fail is $(f-f^2)^k$, which is maximized with $f=\frac{1}{2}$. Alice and Bob therefore *fail* to discover equivocation with probability

$$\varepsilon \leq \left(\frac{1}{4}\right)^k$$

In order to discover the equivocation with probability $1-\varepsilon$, Alice and Bob must perform $-\frac{1}{2}\log\frac{\varepsilon}{2}$ checks. After performing 5 checks each, Alice and Bob would have discovered an equivocation with 99.9% probability.

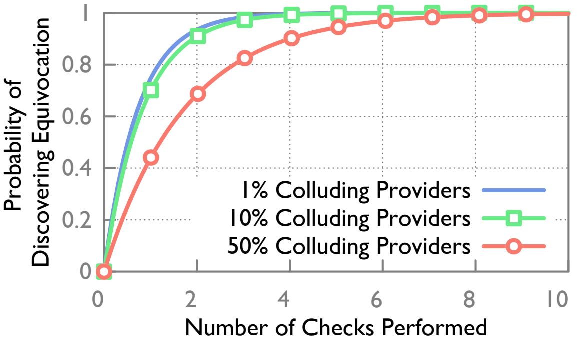

Figure 8: This graph shows the probability that Alice and Bob will detect an equivocation after each performing k checks with randomly chosen auditors.

B.2 Colluding Auditors

Now suppose that *foo.com* colludes with auditors in an attempt to better hide its equivocation about Alice's binding. The colluding auditors agree to tell Alice that *foo.com* is distributing STR A while telling Bob that *foo.com* is distributing STR B. As the size of the collusion increases, Alice and Bob become less likely to detect the equivocation. However, as the number of auditors in the system (and therefore, the number of auditors not participating in the collusion) increases, the difficulty of detecting the attack decreases.

More precisely, we assume that *foo.com* is colluding with a proportion p of all auditors. The colluding auditors behave as described above, and *foo.com* presents STR A to a fraction f of the non-colluding providers. Alice and Bob each contacts k randomly chosen providers. The probability of Alice failing to detect equivocation within k checks is therefore $(p+(1-p)f)^k$ and the probability of Bob failing to detect equivocation within k checks is $(p+(1-p)(1-f))^k$. The probability that neither Alice nor Bob detects equivocation is then

$$\varepsilon = ((p+(1-p)f)(p+(1-p)(1-f)))^k$$

As before, this is maximized when $f=\frac{1}{2}$, so the probability that Alice and Bob *fail* to detect the equivocation is

$$\varepsilon \leq \left(\frac{1+p}{2}\right)^{2k}$$

If $p = 0.1$, then by doing 5 checks each, Alice and Bob will discover equivocation with 99.7% probability.

Figure 8 plots the probability of discovery as p and k vary. If fewer than 50% of auditors are colluding, Alice and Bob will detect an equivocation within 5 checks with over 94% probability. In practice, large-scale collusion is unexpected, as today's secure messaging services have many providers operating with different business models and under many different legal and regulatory regimes. In any case, if Alice and Bob can agree on a single auditor whom they both trust to be honest, then they can detect equivocation with certainty if they both check with that trusted auditor.

Investigating the Computer Security Practices and Needs of Journalists

Abstract

Though journalists are often cited as potential users of computer security technologies, their practices and mental models have not been deeply studied by the academic computer security community. Such an understanding, however, is critical to developing technical solutions that can address the real needs of journalists and integrate into their existing practices. We seek to provide that insight in this paper, by investigating the general and computer security practices of 15 journalists in the U.S. and France via in-depth, semi-structured interviews. Among our findings is evidence that existing security tools fail not only due to usability issues but when they actively interfere with other aspects of the journalistic process; that communication methods are typically driven by sources rather than journalists; and that journalists' organizations play an important role in influencing journalists' behaviors. Based on these and other findings, we make recommendations to the computer security community for improvements to existing tools and future lines of research.

1 Introduction

In recent decades, improved digital communication technologies have reduced barriers to journalism worldwide. Security weaknesses in these same technologies, however, have put journalists and their sources increasingly at risk of identification, prosecution, and persecution by powerful entities, threatening efforts in investigative reporting, transparency, and whistleblowing.

Recent examples of such threats include intensifying U.S. leak prosecutions (e.g. [46, 54]), the secret seizure of journalists' phone records by the U.S. Justice Department [55], the collection of journalists' emails by the British intelligence agency GCHQ [11], politically-motivated malware targeting journalists (among others) [13, 36, 41, 45], and other types of pervasive digital surveillance [34]. In the U.S., these developments have led to a documented "chilling effect", leading sources to reduce communication with journalists even on non-sensitive issues [25, 40]. Elsewhere, risks to journalists and sources cross the line from legal consequences to the potential for physical harm [42, 57, 58].

Responses to these escalating threats have included guides to best computer security practices for journalists (e.g., [17, 43, 47, 62]), which recommend the use of tools like PGP [67], Tor [22], and OTR [14]. More generally, the computer security community has developed many secure or anonymous communication tools (e.g., [4, 10, 14, 21–23, 63, 67]). These tools have seen relatively little adoption within the journalism community, however, even among the investigative journalists that should arguably be their earliest adopters [48].

To design and build tools that will successfully protect journalist-source communications, it is critical that the technical computer security community understand the practices, constraints, and needs of journalists, as well as the successes and failures of existing tools. However, the journalistic process has not been deeply studied by the academic computer security community. We seek to fill that gap in this paper, which is the result of a collaboration between researchers in the journalism and computer security communities, and which is targeted at a technical computer security audience.

To achieve this, we develop a grounded understanding of the journalistic process from a computer security perspective via in-depth, semi-structured interviews. Following accepted frameworks for qualitative research [18, 30, 35], we focus closely on a small number of participants. We interviewed 15 journalists employed in a range of well-respected journalistic institutions in the United States and France, analyzing these interviews using a grounded theory approach [18, 30]. We then synthesize these findings to shed light on the general practices (Section 4.3), security concerns (Section 4.4), defensive strategies (Section 4.5), and needs (Section 4.6) of journalists in their communications with sources.

Our interviews offer a glimpse into journalistic processes that deal with information and sources of a range of sensitivities. Some of our participants report being the direct targets of threats like eavesdropping and data theft: for example, one participant received threatening letters and had his laptop (and nothing else) stolen from his home while working on sensitive government-related stories. Others discuss their perceived or hypothetical security concerns, which we systematize in Section 4.4 — along with threats that participants tended to overlook, such as the trustworthiness of third-party services.

By cataloguing the computer security tools that our participants do and don't use (Section 4.5), we reveal new reasons for their successes or failures. For example, built-in disk encryption is widely used among our participants because it is both easy-to-use and does not require explicit installation. However, we find that many security tools are not used regularly by our participants. Beyond the expected usability issues, we find that the most critical failures arise when security tools interfere with another part of a journalist's process. For example, anonymous communication tools fail when they compromise a journalist's ability to verify the authenticity of a source or information. As one participant put it: *"If I don't know who they are and can't check their background, I'm not going to use the information they give."* This requirement limits the effectiveness even of tools developed specifically for journalists — such as SecureDrop [26], which supports anonymous document drops — and highlights how crucial it is for computer security experts who design tools for journalists to understand and respect the requirements of the journalistic process.

Based on our findings, we make recommendations for technical computer security researchers focusing on journalist-source communications, including:

- *Focus on sources:* Journalists often choose communication methods based on sources' comfort with and access to technology, rather than the sensitivity of information — particularly when sources are on the other side of a "digital divide" (e.g., low-income populations with limited access to technology).
- *Consider journalistic requirements:* Security tools that impede essential aspects of the journalistic process (e.g., source authentication) will struggle to see widespread adoption. Meanwhile, unfulfilled technical needs (e.g., the absence of a standard knowledge management tool for notes) may cause journalists to introduce vulnerabilities into their process (e.g., reliance on third-party cloud tools not supported by their organization). These unfulfilled needs, however, present opportunities to integrate computer security seamlessly into new tools with broader applicability to the field of journalism.
- *Beyond journalist-source communications:* A journalist's organization and colleagues play an important role in the security of his or her practices; security tools must consider this broader ecosystem.

We consider these and other lessons and recommendations in more detail below. Taken together, our findings suggest that further collaboration between the computer security and journalism communities is critical, with our work as an important first step in informing and grounding future research in computer security around journalist-source communications.

2 Related Work

We provide context for our study through a survey of three types of related works: studies of journalists and computer security, computer security guidelines developed specifically for journalists, and secure communication tools.

Studies of journalists and computer security. Several recent studies interviewed or surveyed journalists (among others) in Mexico [58], Pakistan [42], Tibet [15] and Vietnam [57] to shed light on the risks associated with their work, as well as their use and understanding of computer security technologies (such as encryption). Despite the different context, our findings echo some of the findings in these studies: for example, that maintaining communication with sources may take precedence over security [57], that meeting in person may be preferable to digital communication [15], and that the use of more sophisticated computer security tools is typically limited even in the face of real threats, including risk of physical harm [42, 57, 58]. These prior studies primarily recommended increased computer security education and training for journalists; though we concur, our work focuses more on technical recommendations.

Though most journalists in countries like the United States do not face physical harm, recent interviews of U.S. journalists and lawyers [40] revealed a distinct chilling effect in these fields resulting from revelations about widespread government surveillance. For example, journalists reported increased reluctance by sources to discuss even non-sensitive topics. Another recent report [48] provides quantitative survey data about the use of computer security tools by investigative journalists, suggesting (as we also find) that sophisticated computer security tools have seen limited adoption. These studies begin to paint a picture of the computer security mental models and needs of journalists; we expand on that understanding in this work and distill from it concrete technical and research recommendations.

The computer security community has previously studied the usability and social challenges with encryption among other populations (e.g., [27, 65]). Where applicable, we draw comparisons or highlight differences to the findings of these works.

Computer security guidelines for journalists. Recent concerns about government surveillance have prompted journalists in the U.S. and elsewhere to weigh computer security more seriously. For example, several groups have developed computer security guidelines and best practices for journalists [17, 43, 47, 62]. Online guides for journalists and other technology users (e.g., [16]) also abound. These efforts highlight the need for engagement between the journalism and computer security communities, but generally take the approach of educating journalists to use existing available tools, such as GPG and Tor. The goal of our work is to provide the developers of new technologies with a deep, grounded understanding of the needs and security concerns of journalists.

Secure communication. A large body of work exists on secure communication and data storage, both commercially and in the computer security research literature. For example, various smartphone applications aim to provide secure text messaging or calling [6, 60, 64]; a range of desktop applications provide disk encryption and cleaning [1, 5, 8]; Tor [22, 61] aims to provide anonymous web surfing; Tails [4] aims to provide a private and anonymous operating system; and tools like GPG and CryptoCat provide encryption for email and chat messages respectively [2, 31]. Several email providers have also attempted to provide secure and anonymous email [3, 44]. Though valuable, most of these tools and techniques have known weaknesses: anonymous email, for example, lacks essential legal protections [38, 51]. Tor and Tails do not protect against all threats and present usability challenges (e.g., [49]). Finally, many applications that appear to provide certain security properties fail to provide those guarantees in the face of government requests [33, 56].

While the above-mentioned commercial tools are among those frequently recommended to journalists, the computer security research community has also considered anonymous communications in depth. These efforts include developing, analyzing, and attacking systems like trusted relays, mix systems, and onion routing such as that used in Tor. Good summaries of these bodies of work can be found in [21] and [23]. Secure messaging in general is summarized in [63]. There have also been a number of efforts toward creating self-destructing data, including early work by Perlman [52] and more recent work on Vanish [28, 29]. An analysis of different approaches for secure data deletion appears in [53]. There have also been significant efforts toward ephemeral and secure two-way communications, such as the off-the-record (OTR) messaging system [14, 32].

Though the above-mentioned technologies are valuable, our research suggests that many of them require steps or actions at odds with substantive aspects of the journalistic process or technical access issues of journalists and/or their sources. Moreover, these access issues are often most acute among the most vulnerable source populations with whom journalists work (e.g., sources involved in the criminal justice system).

Though some journalism-specific tools have been developed and deployed, notably SecureDrop [20, 26] and similar systems, our findings suggests that such anonymous document drops — while more secure — comprise only a small portion of journalists' source material. In a similar vein, Witness [7] and the Syria Accountability Project [59] focus on collecting and securely storing sensitive eyewitness data, but are not necessarily designed to protect the kind of ongoing communications that our research and other sources [37, 39] suggest commonly drives sensitive reporting.

3 Methodology

To make possible a sufficiently rigorous qualitative, grounded theory based [18, 30] analysis of the general and computer security needs and practices of journalists, we followed the recommendation of Guest et al. [35] to conduct 12-20 interviews, until new themes stopped emerging [18]. Our in-depth, semi-structured interviews were conducted with 15 journalists. Table 1 summarizes our participants and interviews.

Human subjects and ethics. Our study was approved by the human subjects review boards (IRBs) of our institutions before any research activities began. We obtained informed written or verbal consent from all participants, both to participate in the study as well as to have the interviews audio recorded. We transmitted and stored these audio files only in encrypted form. We did not record or store any explicitly identifying metadata (e.g., the name of a journalist or organization), nor do we report those here. Though we asked participants to reflect on recent source communications, including those that touched on sensitive information, we explicitly asked them *not* to reveal identifying information about specific sources or stories. As journalists are normally responsible for protecting source identities, these constraints were not out of the ordinary; indeed, we felt that the resulting interviews did not contain unnecessarily sensitive details.

3.1 Recruitment

We recruited our participants via our existing connections to journalistic institutions, usually via verbal or email contact with a staff member followed by an email containing our recruitment blurb. For better anonymity, participants at each organization were not recruited directly but were selected by our contact person according to individuals' availability at the time of the interviews. In communicating with the main organizational contacts, we stressed a desire for balance in terms of participants' technical skill and the sensitivity of their work. The vast majority of interviews were conducted in-person, though a few were conducted via Skype.

For the purposes of this study, we limited our search for participants to journalists directly employed by well-respected journalistic institutions rather than freelance journalists. This focus allows us to explore the role of a journalist's employer in his or her computer security practices (or lack thereof). Our interviewees came from six different news organizations. Of these, four represent newsrooms and journalists who deal regularly with international (including non-Western) sources and stories of national and/or international profile. So while the organizations themselves are based in the U.S. and/or France, their work involves sources outside of those countries as well. The remaining organizations have a primarily U.S.-focused source base.

Nine interviews were conducted in France with journalists from French and U.S. journalistic institutions. Two of these interviews were conducted in French and were translated to English by another researcher. Both the interviewer and the translator are proficient in French. Due to our qualitative interview method and corresponding small sample size, we do not attempt to draw conclusions about differences between French and U.S. journalists in this work.

We do note that our participants are not necessarily representative of all journalists. It may be that journalists who agreed to speak with us are more (or less) security-conscious than those who declined, or that that the experiences of U.S. and French journalists differ from those of journalists in other countries. We also expect that the practices of freelance journalists differ from those of institutional journalists. Future work should study these questions; nevertheless, our interviews give us a valuable glimpse into the computer security practices and needs of a significant subset of the journalistic community.

3.2 Interview Procedure

One of the researchers conducted all of the interviews in the period from November 2014 through February 2015. Interviews were audio recorded and later transcribed and coded (more details below) by the remaining (non-interviewing) researchers. Each interview took between 15-45 minutes and had two parts:

Part 1: Questions about a specific story
We first prompted participants to tell us about the practices and tools that they use as journalists by asking them to think about a specific recent example. We asked:

> *Please think about a specific story that you have published in approximately the last year for which you spoke with a source. (There is no need to tell us the specific story or source, unless you believe this information is not sensitive and would like to share it.)*

In this context, we then asked about:

- Whether they had a relationship with the source prior to this story;
- How they first contacted the source about the story;
- Primary form(s) of communication with the source;
- Whether they would feel comfortable asking this source to use a specific communication method; and
- How representative this example is of their communication with sources in general.

Part 2: General questions
We then asked participants more general questions about their work as a journalist, including questions about:

- Their note-taking and storage process, and whether they take any steps to protect or share their notes;
- Problems that might arise if their digital notes or communications were revealed;
- Any non-technological strategies they use to protect themselves or their sources;
- Whether someone has ever recommended they use security-related technology in their work;
- How they define "sensitive" information or sources in their work;
- Any specific security-related problems to which they wish they had a solution;
- What kinds of devices they use, and who owns and/or administers them;
- Whether they have anyone, inside or outside of their organization, to whom they can go for help with computer security or other technologies; and
- Their self-described comfort level with technology and security-related technology.

Finally, we gave participants an opportunity to share any additional thoughts with us and to ask us any questions.

Throughout the interviews, we allowed participants to elaborate and ask clarification questions, and we asked follow-up questions where appropriate. As a result, the interviews did not necessarily proceed in the same order nor did they address identical questions.

3.3 Coding

To analyze the interviews, we used a grounded theory [18, 30] approach in which we developed a set of themes, or "codes", via an iterative process. After the interviewing researcher had conducted nearly half of the interviews, three additional researchers each independently listened to and transcribed several interviews. These researchers then met in person to develop, test, and iteratively modify an initial set of codes. Two researchers then independently coded each interview. As additional interviews were performed, the researchers reexamined and modified the codebook as necessary, going back and

		Participant		Interview			Technical Expertise	
Number	*Identifier*	*Gender*	*Organization (Type)*	*Location*	*Language*	*Length*	*General*	*Security*
1	P0	Male	Large, established	France	English	32 min	High	High
2	P1	Female	Large, new	USA	English	31 min	High	Medium
3	P2	Female	Large, established	France	English	39 min	Medium	Low
4	P3	Female	Large, established	France	English	39 min	High	Medium
5	P4	Female	Large, established	France	English	42 min	Medium	Low
6	P5	Male	Large, established	France	French	24 min	Medium	Low
7	P6	Male	Large, established	France	French	23 min	Medium	Medium
8	P7	Female	Large, established	France	English	27 min	High	Low
9	P8	Male	Large, established	France	English	20 min	High	Medium
10	P9	Male	Large, new	USA	English	41 min	High	Medium
11	P10	Female	Large, new	USA	English	31 min	Medium	Medium
12	P11	Female	Large, new	USA	English	19 min	Medium	Low
13	P12	Female	Small, new	USA	English	17 min	Medium	Low
14	P13	Female	Small, new	USA	English	34 min	High	Low
15	P14	Female	Small, established	USA	English	25 min	Medium	Medium

Table 1: **Interviews.** One researcher conducted all interviews between November 2014 and February 2015, at six well-respected journalistic institutions. The two interviews conducted in French were translated to English by another researcher (both researchers are proficient in French). On the right, we report participants' general and security-specific technical expertise; these values are self-reported. Organization size descriptors are based on those used by the Online News Association (`http://journalists.org/awards/online-journalism-awards-rules-eligibility/`). "New" organizations have existed for 10 years or less.

recoding previously coded interviews. This iterative process was repeated until the final codebook was created and all interviews were coded. The researchers then met in person to reach consensus where possible. We report inter-coder agreement inline with our results.

4 Results

We now turn to a discussion of results from our interviews. In designing and analyzing our interviews, we focused on several primary research questions, around which we organize this section:

1. What are the *general practices* of journalists in communicating with their sources?
2. What are the *security concerns* and threat models of journalists with respect to source communication?
3. What, if any, *defensive strategies* (technical or otherwise) do journalists employ to protect themselves or their sources? How and why do some possible defensive strategies succeed and others fail?
4. What are the *needs of journalists* in their communications with sources that are currently hampered or unfulfilled by computer security technologies?

By applying an appropriate qualitative analysis [18, 30, 35], we identify important themes and other observations present in the interviews. Where applicable, we report the raw number of participants who discussed a certain theme in order to give a rough indication of its prevalence amongst journalists. Our results are not quantitative, however: a given participant failing to mention a particular theme does not necessarily mean that it is inapplicable to him or her.

Each interview was coded independently by two researchers: a primary coder who coded all interviews, and two additional coders who coded non-overlapping sets of 9 and 6 interviews respectively. We report raw numbers based on the primary coder, with Cohen's kappa (κ) as a measure of inter-coder agreement [19] (averaging kappas for the two sets of coders). The average kappa for all results in the paper is 0.88. Fleiss rates any value of kappa over 0.75 as excellent agreement and between 0.40 and 0.75 as intermediate to good agreement [24].

4.1 Participants

Our participants are journalists working at major journalistic institutions in both the United States and France. Table 1 summarizes our 15 interviews and participants.

As reflected in Table 1, we spoke with journalists across the spectrum of general technical and computer security expertise. Some of our participants comfortably discussed their use of security tools such as encrypted chat and email, while others did not use or mention any security technologies at all. Regardless of technical and computer security expertise, our participants work with sources and stories of varying sensitivity. Stories considered "sensitive" by our participants include those involving information provided off-the-record by government officials, leaked or stolen documents, vulnerable populations (e.g., abuse victims or homeless people), and personal information that sources did not want published.

4.2 Key Findings

Before diving into our detailed results, we briefly highlight our key findings.

First, we find that journalist-source communications are often *driven by the source*. Participants tended to select communication mechanisms based on the comfort level, capacities, and preferences of sources, deferring to them to specify the use of computer security tools rather than imposing these on sources. In this sense, the existing communication habits of sources are a primary obstacle to adoption of secure communication tools among journalists. In particular, the *digital divide*, in which source populations do not have access to or knowledge about technology, presents a serious challenge.

Additionally, our study reveals both *expected security concerns* (e.g., government surveillance, disciplinary consequences for sources) and *less expected security concerns* (e.g., financial impact on organizations) held by our participants. Participants described many *ad hoc defensive strategies* to address these concerns, including ways to authenticate sources, to obfuscate information in filenames and notes, and to obfuscate communications metadata by contacting sources through intermediaries.

Finally, beyond the expected *usability and adoption challenges* of computer security technologies, we find that a major barrier to adoption of these tools arises when they *interfere with a journalist's other professional needs*. For example, participants described the challenge of authenticating anonymous sources, and more generally, the need to reduce communication barriers with sources. Our study also reveals the need among journalists for a more general knowledge management platform, for which today's journalists use ad hoc methods based on tools like Google Docs and Evernote. This need may represent an opportunity to seamlessly integrate stronger computer security properties into journalistic practices.

4.3 General Practices

We begin by overviewing the general journalistic process described by our participants, in order to provide important context for the computer security community when it designs tools for journalists. We highlight security implications where applicable, and dive into these more deeply in later subsections.

Finding sources. Many participants discussed having long-term sources (10 of 15), particularly for sensitive information (e.g., sources in government). A different subset described finding new sources relevant to new stories (10 of 15), often by following referrals from previously known contacts. The importance of long-term sources poses security challenges: for example, it may be hard to protect metadata about communications over a long period, especially if the journalist's communication with that source is not always sensitive (and thus not always conducted over secure channels).

Communicating with sources. Our participants typically communicate with sources by email, phone, SMS, and/or in person. Security tools, such as encrypted messaging, were used only in exceptional cases where the context was known in advance to be sensitive, and both the journalist and source were sufficiently tech-savvy.

The choice of communication technology is typically determined by what is most convenient for the source, including the platform on which source is most likely to respond. Several participants discussed the importance of reducing communication barriers to sources. In the words of P13, *"taking down barriers is the most important thing to source communication."* Thus, if the source is concerned about security and sufficiently tech-savvy, the journalist may use security technologies to communicate; however, several of our participants expressed hesitation about interfering with a source's decision about what form of communication — even if insecure — is acceptable. For example, P9 said:

> *[The source] probably understand[s] the threat model they're under better than I would. So, it brings up an interesting question: do you go with what they're comfortable with? Or do you say, alright, actually let me assess what's going on and get back to you with what would be appropriate. [...] People's first impression is that they would go by what the source feels comfortable doing. As opposed to stepping in and being paternalistic about it.*

This finding suggests that the computer security community must consider sources as well as journalists when developing secure communication tools for journalism.

Building trust with sources. In order to feel comfortable providing sensitive information, a source must trust the journalist. While some trust with sources is built naturally over time, several participants mentioned explicit strategies for building trust with sources, including: speaking with people informally before they become official sources, being explicit with sources about what is "on the record," respecting sources' later requests not to include something in a story, and using security technologies to protect communications.

Communication tools. Table 2 summarizes the non-security-specific technologies participants mentioned using in their work. Primary communication tools include phone, SMS, and email, with limited use of social media to contact sources (usually as a last resort). In addition to digital communication, in-person meetings with sources are common. While some participants reported meeting in person for security reasons, most cited this as a means to gain higher quality information from sources.

Among storage technologies, we note that Google Docs/Drive is particularly popular, and that many of the tools mentioned involve syncing local data to cloud storage. Though cloud storage may have security implications (e.g., exposing sensitive data to third parties), few participants voiced these concerns explicitly.

Tool or technology	Number of participants (of 15)	Inter-coder agreement (κ)
Phone	15	1.00
Email (unencrypted)	15	1.00
Google Docs/Drive	8	1.00
Microsoft Word	8	1.00
SMS	8	1.00
Social media	7	0.83
Dropbox	4	1.00
Skype	4	1.00
Evernote	3	1.00
Text editor	2	1.00
Chat (unencrypted)	1	1.00
Scrivener	1	1.00

Table 2: **Non-security-specific tools.** This table reports the number of participants who mentioned using various non-security-specific tools or technologies in their work.

Devices and accounts. Though participants typically reported relatively strong "data hygiene" practices for email — i.e., conducting work-related communications only from a work email account — everyone we spoke to used at least one personal device or account for communicating with sources, including personal laptops and (more commonly) personal cell phones. Many participants reported using iPhones or iPads, often to take photos of documents or audio-record interviews. These devices are not necessarily encrypted, and the resulting files may be automatically backed up to cloud storage. Personal/professional distinctions were often blurred for social media accounts, and participants frequently reported using personal Google Drive, Dropbox, or Evernote accounts to sync, store and share data, particularly when the organization did not have its own enterprise Google Apps instance set up. As we discuss later, even participants who exhibited otherwise careful data security practices did not express concern about the security implications of storing data with third parties.

Many participants (7 of 15) reported that their employers have administrative access to their work computer, particularly at larger or older organizations. From a security perspective, this arrangement may allow organizations to ensure that journalists have updated systems and do not accidentally install malware, but it may also prevent journalists from installing security tools. It could also potentially expose sensitive information to the broader organization.

Two participants reported taking actions to circumvent the administrative rights of their employers: one insisted on being granted administrative access officially, while the other silently disabled his employer's remote access due to security and privacy concerns. He also mentioned being required to provide his laptop decryption key to his employer; he complied, but then re-encrypted his laptop and kept the new key to himself.

Note-taking. The journalists we spoke to described a variety of strategies for taking notes, most commonly audio-recording (13 of 15), electronic notes (12 of 15), and handwritten notes (10 of 15). We were somewhat surprised by the prevalence of audio recording, since such recordings may be particularly sensitive. Only two participants explicitly mentioned that they record audio only when intending to publish a full transcription.

We also asked participants about whether they share their notes with others. No one we spoke with ever shares notes outside of their organization, but many (13 of 15) sometimes share portions of notes within their organization. This sharing is typically done when working with another journalist on a story or for fact-checking. Most participants reported using some kind of third-party platform (e.g., Google Docs or Dropbox) for storing and sharing information. Several mentioned explicit strategies for sanitizing or redacting notes before sharing them (e.g., using codenames or omitting information); we discuss such strategies further in Section 4.5.

Knowledge management. We identify a possible opportunity for computer security in the knowledge management practices of journalists. In particular, several participants discussed strategies for organizing their notes and references for different projects and stories over time, including the use of file system folders, Google Drive, Evernote, and Scrivener. These knowledge management techniques were all ad hoc; no two participants described identical techniques. Indeed, several participants explicitly discussed the lack of a good knowledge management tool for journalists as a challenge. As we discuss in Section 4.6, this gap represents an opportunity for integrating computer security into the journalistic process.

4.4 Security Concerns

We now turn specifically to security-related issues, considering first the security concerns voiced in our interviews. Because one researcher's prior experience in the journalism community suggested that the term "threat modeling" is familiar but not widely understood, we elicited these concerns indirectly, by asking: "Of the information that you currently store digitally, would it be problematic if it were to become known to people or organizations outside of you and/or your news organization? If so, who would be at risk?" Because the concept of risk is dependent on a judgment about vulnerability, we also asked participants about their view on what kind of sources or information they considered "sensitive," whether or not they had worked with it personally.

Concrete threats experienced. A small number of participants reported encountering direct tangible threats or harms themselves in the course of their work. For example, one journalist told us that during his time report-

Category	Concern	Number of participants (of 15)	Inter-coder agreement (κ)
Threats to sources	Discovery by government	6	0.88
	Disciplinary action (e.g., lost job)	6	0.88
	Reputation/personal consequences	6	0.88
	Generally vulnerable populations (e.g., abuse victims)	4	0.65
	Discovery by others wishing to reveal identity	3	0.80
	Physical danger	3	0.86
	Prison	2	1.00
Threats to journalist or organization	Reputation consequences (incl. loss of source's trust)	9	0.89
	Being "scooped" (i.e., journalistic competition)	6	1.00
	False or misleading information from a source	4	0.36
	Physical threats (incl. theft)	2	0.50
	Financial consequences	1	1.00
Threats to others	Political / foreign relations consequences	1	0.50
	Other	1	1.00

Table 3: **Security concerns.** We report how many participants mentioned various threats to themselves, to their sources, to their organizations, or to others. These are not necessarily threats that participants have directly encountered or acted on themselves — that is, they discussed threats both in a hypothetical sense (concerns they have) and a concrete sense (real issues they have encountered).

ing on government-related scandals, his work phones had been wiretapped, his laptop (and nothing else) had been stolen from his home, and he had received letters threatening his and his family's lives and safety. Another described communications with contacts in a foreign region, in which phone communications were regularly terminated when the conversation broached what she perceived as sensitive topics. In total, 6 participants mentioned the knowledge or strong suspicion that their or their sources' digital communications had been retroactively collected or actively monitored.

General concerns. In addition to these concrete attacks and threats, participants mentioned a range of risks that they consider in communications with sources. These concerns are organized and summarized in Table 3.

Many of the general security concerns reported by participants were in line with our expectations: governments attempting to identify sources, reputational threats or harms, and legal or disciplinary consequences. The most common concern involved reputational harm and loss of credibility by the journalist and his or her organization, largely characterized as a compromised ability to gain access to and establish trust with future sources.

Participants also mentioned several threats that we had not initially anticipated. For example, one participant discussed the possible financial consequences to his organization when it reported on a scandal involving a major advertiser. Several participants mentioned concern about being "scooped" by other journalists if they lost their competitive advantage in having early access to certain information. One participant worried that her web searches on sensitive work-related topics would make her a surveillance target in her personal life, so she avoided doing those searches on her home computer.

Overlooked concerns. We identify several security concerns that were generally overlooked by our participants, despite being well-known to computer security experts.

Third parties. Only one participant expressed concern about the trustworthiness of major third parties, such as Apple, Google, or Microsoft. While some participants expressed hesitation about how secure a certain practice is, they did not explicitly discuss these major technology providers as being a possible security risk. Unfortunately, this implicit trust assumption may not be warranted — e.g., consider reports of government or other compromises of major companies [34, 66] and the FBI's National Security Letters compelling service providers to release information [50].

Metadata. While a few participants expressed concerns about the metadata connecting them to their sources (discussed further in Section 4.5 below), most did not discuss metadata as a threat even implicitly. Indeed, even those who explicitly took steps to protect their notes or communications (e.g., using encryption) did not generally discuss the need to similarly protect metadata.

Legal concerns. Finally, there was virtually no mention in any of the interviews of the risk of lawsuit resulting from or discovery of digitally stored or communicated information. There are several possible explanations for this, though comments from most of those interviewed suggest that they did not feel their own work was ever likely to be the subject of a government investigation.

4.5 Defensive Strategies

Whether or not they had experienced concrete threats, most participants reported using some defensive strategies, including security technologies as well as non-technical or technology-avoidant strategies. Figure 4 systematizes these strategies, and Table 5 summarizes participants' use of specific security technologies.

Category	Defense	Number of participants (of 15)	Inter-coder agreement (κ)
Technical defenses	Encrypting digital notes	6	1.00
	Keeping files local (not in the cloud)	5	0.89
	Encrypted communication with colleagues	3	0.81
	Circumventing organization's admin rights on computer	2	0.50
	Encrypted communication with sources	2	0.50
	Anonymous communication (e.g., over Tor)	2	1.00
	Air-gapping a computer (keeping it off the internet)	1	1.00
	Using additional, secret devices or temporary burner phones	1	1.00
	Visually obscuring information in photos/videos (e.g., blurring)	1	0.50
Ad hoc non-technical strategies	Using code names in communications or notes	8	1.00
	Claiming bad handwriting as a defense for written notes	3	1.00
	Contacting sources through intermediaries	2	0.81
	Citing multiple sources to create plausible deniability	1	1.00
	Using some method to authenticate source	1	1.00
Explicitly avoiding technology	Communicating in person	7	0.72
	Self-censoring (avoiding saying things in notes/email)	6	0.86
	Communicating only vague information electronically	5	0.83
	Physically mailing digital data (e.g., on USB stick)	2	1.00
Physical defenses	Home alarm system	1	1.00
	Physical safe (e.g., to store notes)	1	1.00
	Shredding paper documents	1	1.00

Table 4: **Defensive techniques.** We report the number of participants who mentioned using various defensive techniques to protect themselves, their notes, and/or their sources.

	Number of participants (of 15)				Inter-coder
Security tool or technology	*Use regularly*	*Tried but don't use*	*Haven't tried*	*Not mentioned*	agreement (κ)
Dispatch	0	0	1	14	1.00
Encrypted chat (e.g., OTR, CryptoCat)	5	0	1	9	0.90
Encrypted email (e.g., GPG, Mailvelope)	4	4	1	6	0.92
Encrypted messaging (e.g., Wickr, Telegram)	0	1	0	14	1.00
Encrypted phone (e.g., SilentCircle)	0	2	0	13	1.00
Other encryption (e.g., hard drive, cloud)	5	1	0	9	1.00
Password manager	1	0	1	13	1.00
SecureDrop	0	0	1	14	1.00
Tor	2	1	0	12	0.89
VPN	2	1	0	12	1.00

Table 5: **Security tools.** This table lists security technologies discussed by participants. We report on the number who regularly use, have tried but don't regularly use, and haven't tried each tool. We consider use to be "regular" even if it depends on the sensitivity of the source or story, i.e., if the journalist regularly employs that tool when appropriate, even if not in every communication.

Non-technical defensive strategies. Since not all of our participants were computer security experts — and certainly most journalists are not — we were particularly interested in non-technical or otherwise ad hoc strategies that they have developed to protect themselves, their notes, or their sources. As reflected in Table 4, a commonly mentioned non-technical strategy is avoiding technology entirely, e.g., meeting sources face-to-face, physically mailing digital data, and/or communicating only vague information electronically. For example, P6 told us (translated from French):

> *I don't use phones, I don't send email. Sometimes I send SMS messages, but these messages are very vague.* [Later in the interview he adds:] *I don't use technical methods [to protect my sources]. I prefer to work in an old fashioned way. A little bit like Bin Laden did.*

The reference to Bin Laden echoes an issue raised in a recent report about U.S. journalists, which describes how concerns about surveillance and increased leak investigations have caused journalists to feel like they must "act like criminals" to communicate with sources [40].

Some of these non-technical strategies, however, were cited specifically for their journalistic rather than their security value. In explaining the choice to meet a source primarily in person, participant P11 noted:

> *I think it's always preferable because of the level of intimacy and information that you gain. You get better results and [...] you can sort of verify in different ways the stories that they're telling you.*

Ad hoc defensive strategies. We also uncovered a number of ad hoc strategies that make incidental use of technology. For example, participant P0 described his strategy for authenticating a source whose email address he found on a public mailing list: he asked that source to post a particular sentence on Twitter, allowing P0 to verify that the email and Twitter accounts indeed belonged to the same individual. In another example, P5 described a strategy for hiding the connection between himself and a sensitive source in the government by contacting the source through an intermediary. In particular, P5 called the source's assistant at previous job and stated a false name; when the assistant passed this message on, the source knew whom to contact.

These strategies of avoiding technology entirely or using ad hoc methods for specific cases suggest that our participants (and/or their sources) are not always comfortable with existing security technologies, and/or that these technologies do not meet their security needs in a straightforward way, as we discuss further in Section 4.6.

Technical defensive strategies. As reflected in Table 4, several participants explicitly mentioned using security technologies to protect themselves, their notes, or their sources. Table 5 summarizes specific security technologies mentioned, broken down by how often participants mentioned using these technologies.

Most commonly, participants mentioned using encryption to protect communications or stored data. Even participants with low computer security expertise often mentioned and even used encryption. For example, P5, who otherwise mentioned no technical security strategies, uses the Mac Disk Utility to encrypt virtual drives on his machine. Indeed, several participants mentioned using built-in file or disk encryption of this sort, suggesting that these tools are reasonably discoverable and usable. The lack of installation overhead may also contribute to their prevalence among our participants.

Participants who reported use of computer security technology for source communication fell roughly into two groups: those whose sources demanded it, and those who had participated in some kind of computer security training either through their workplace or at an external event. Sustained use, however, was seen only in intra-institutional communications (largely chat). Those who used these tools for communication with sources did so only sporadically (as required by a particular source), and reported an extended timeframe to become comfortable using them (particularly GPG and OTR).

We observe several security technologies that were under-represented in our interviews. For example, SecureDrop [26] and Dispatch [12], which were designed specifically for journalists, were mentioned by only one participant who did not report ever having used them.

Reasons for not using security technologies. We asked participants whether anyone (a source, a colleague, or anyone else) had ever recommended that they use any computer security tools or technologies. Of our 15 participants, 10 replied that they had received such a recommendation. Of those, however, only four began regularly using any of the recommended tools.

For participants who had never tried, or tried but did not continue using tools mentioned in the interview (see Table 5), we coded the interviews for reasons for not using security technologies. These reasons are summarized in Table 6, and we highlight a few important issues here.

Usability, reliability, and education. Echoing findings from prior studies (e.g., [65]), many participants discussed challenges related to usability of security tools and the need for education of journalists and sources about security issues. These challenges result in limited adoption of these tools among sources and colleagues, reducing their utility to even the most technically savvy journalist. For example, one participant described a situation where he and his colleagues worked with sensitive data; as the size of the group grew and included less security-versed individuals, it became harder to maintain strict data security practices (echoing prior findings about the social context surrounding such tools [27]).

In addition to the well-known usability challenges with many security tools, participant P10 described the difficulty of knowing which tools to trust:

> *A lot of services out there say they're secure, but having to know which ones are actually audited and approved by security professionals — it takes a lot of work to find that out.*

Digital divide. A challenge frequently mentioned in our interviews (by 4 of 15 participants) is the "digital divide": many sources do not understand or even have access to computer security technology, making it infeasible for journalists to use technical tools to secure their communications with these sources. As our participants described, this challenge applies particularly to vulnerable populations, such as low-income communities, abuse victims, homeless people, etc. To take just one example, P12 discussed the digital divide as follows:

> *Most of the [sensitive sources] I've worked with [are] also people who probably aren't very tech-savvy. Like, entry-level people in prisons, or something like that. So if they were really concerned about communication, I don't quite know what a secure, non-intimidatingly-techy way would be. [...] Some of them don't even necessarily have email addresses.*

Lack of institutional support for computer security. Another important challenge for some journalists attempting to use security technologies is a lack of institutional support. Though some participants described supportive organizations, 9 of 15 mentioned that they did *not* have

Category	Reasons for not using security technology	Number of participants (of 15)	Inter-coder agreement (κ)
Usability and adoption	Not enough people using it	5	0.79
	Digital divide: sources don't have/understand technology	4	0.86
	Security technology is too complicated	3	1.00
	Hard to evaluate credibility/security of a tool	2	0.50
Interference with journalism	Creates barrier to communication with sources	5	0.64
	Doesn't want to impose on sources	5	0.83
	Interferes with some other part of their work	3	1.00
Other	Work isn't sensitive enough / no one is looking	8	0.41
	Uses a non-technical strategy instead	6	0.70
	Insufficient support from organization	2	0.80
	Tool doesn't provide the needed defense	1	1.00

Table 6: **Reasons journalists report not using security technologies.** We report the number of participants who mentioned various reasons for why they haven't tried or don't regularly use computer security technologies. Note that some of these themes may overlap (i.e., a single statement made by a participant may have been coded with more than one of the themes in this table).

anyone to go to for help with computer security issues who was both within their organization and whose role explicitly involved providing technical support of this nature. Instead, 5 participants had no one to ask for help or had to go outside their organizations, while 4 received help from other journalists within their organization who happened to be knowledgable about these issues (e.g., because they cover related stories). Similarly, many participants (6 of 15) explicitly reported not having administrative privileges on their work computers, making it difficult or impossible to install security tools not officially supported by the organizations.

Inconsistencies and vulnerabilities. Finally, we reflect on several inconsistencies or vulnerabilities that we observed in the described behaviors of our participants.

A common inconsistency (observed in 5 of 15 interviews) involved protecting data effectively in one context but insufficiently in another. For example, participant P5 (quoted above) avoids using technology to communicate with sources due to real threats he has encountered (including eavesdropping, laptop theft, and death threats) — but uses his iPad (with no mention of encryption) to photograph sensitive documents provided without permission by sources.

Participants also frequently discussed or acknowledged the potential danger in a particular practice, but did not change their behavior. For example, P10 told us: *"I should have a separate work [Gmail] account but I just use my personal one"* — a sentiment echoed by other participants. As another example, when asked if he takes steps to protect his notes, P5 responded: *"I should. But no."* In another case, though a participant considered herself "comfortable" with computer security technology and worked with sensitive information, she did not use and seemingly could not name any security tools.

We also identified several vulnerabilities present in the behaviors of participants but not explicitly acknowledged by any of them. For example, while some participants explicitly mentioned meeting with sources face-to-face for security reasons (in addition to journalistic reasons), they did not mention taking precautions like leaving behind or turning off electronic devices at these meetings. Indeed, many participants (though not necessarily those using face-to-face meetings for security reasons) mentioned using their iPhones or other devices to audio-record in-person conversations with sources. Participants also frequently use document management services that sync data to a third-party cloud service, such as Google Docs and Evernote.

4.6 Needs of Journalists

A major goal of our study is to inform future efforts by the computer security community to develop tools to protect journalist-source communications. To that end, we identify needs of journalists in their communications with sources that are hampered or unfulfilled by current computer security technologies. Needs that are still unfulfilled present immediate opportunities for future work, while needs that are hampered suggest reasons why existing technologies have failed to find greater adoption.
